
(Sec. 156), changing the frequency of the primary current by changing generator speed (Sec. 157), adjusting the resistance of the secondary circuit (Sec. 158), introducing a foreign voltage into the secondary circuits (Sec. 159), and operating motors in cascade (Sec. 160) have very limited application. In recent years, however, rapid changes in the technology of solid-state electronics have resulted in the availability of electronic drive systems for ac induction motors that make speed control of such motors feasible for an increasing number of applications. Known as *electronic adjustable-speed drives* (ASDs), these systems are available in virtually any horsepower for all kinds of applications from many manufacturers. In all cases, the motor manufacturer should be consulted concerning the use of an ASD and the limits of ASD output characteristics that can be used.

In addition to controlling the speed of a motor at load, ASDs are available to control the motor during starting and stopping periods, providing controlled acceleration and deceleration, thus limiting the starting current and providing gentle startups and gradual shutdowns, to increase equipment life and reduce mechanical breakdowns. By matching motor speed to the requirements of the load, ASDs can save energy that mechanical devices, such as valves and vanes, would waste.

ASDs may change the input power from single-phase to three-phase, for the speed control of small three-phase motors from single-phase power supplies, or may control the pulse width of the single-phase supply, typically used for the speed control of ceiling-mounted paddle fans. Frequency control, within limits, may be combined with voltage control, with the lower frequency at low voltage and increasing frequency with increasing voltage.

Commonly, ASDs also include motor-overload protection, although additional external overload protection may be specified to meet Code requirements. Other functions, such as adjustable-load limitation, phase-failure protection, ASD component-failure protection, etc., may also be included.

For further information on the speed control of induction motors, refer to Secs. 289 and 321.

162. Classification of squirrel-cage induction medium motors. Polyphase squirrel-cage induction medium motors rated more than 1 hp were formerly called “integral horsepower” motors. Polyphase squirrel-cage induction medium motors are classified by NEMA standards into four design types as follows:

A *Design A motor* is a squirrel-cage motor designed to withstand full-voltage starting and developing locked-rotor and pull-up torque as shown in Sec. 164 and breakdown torque as shown in Sec. 165, with locked-rotor current higher than the values shown in Sec. 163 and having a slip at rated load of less than 5 percent.*

A *Design B motor* is a squirrel-cage motor designed to withstand full-voltage starting, developing locked-rotor, breakdown, and pull-up torques adequate for general application as specified in Secs. 164 and 165, drawing locked-rotor current not to exceed the values shown in Sec. 163 and having a slip at rated load of less than 5 percent.*

A *Design C motor* is a squirrel-cage motor designed to withstand full-voltage starting, developing locked-rotor torque for special high-torque application up to the values shown in Sec. 164, pull-up torque as shown in Sec. 164, and breakdown torque up to the values shown in Sec. 165, with locked-rotor current not to exceed the values shown in Sec. 163 and having a slip at rated load of less than 5 percent.

A *Design D motor* is a squirrel-cage motor designed to withstand full-voltage starting, developing high locked-rotor torque as shown in Sec. 164, with locked-rotor current not greater than shown in Sec. 163 and having a slip at rated load of 5 percent or more.

*Motors with 10 and more poles may have slip slightly greater than 5 percent

FIGURE 7.92 Typical speed-torque characteristics for squirrel-cage induction motors.

The former standard for *Design E* motors was rescinded by NEMA in February 2000. Typical speed-torque curves for the four design types are given in Fig. 7.92.

163. Locked-Rotor Current of Three-Phase 60-Hz Medium Squirrel-Cage Induction Motors Rated at 230 V (NEMA standard)*

The locked-rotor current of single-speed, three-phase, constant-speed induction motors, when measured with rated voltage and frequency impressed and with rotor locked, shall not exceed the following values:

hp	Locked rotor current, A [†]	Design letters	hp	Locked rotor current, A [†]	Design letters
1/2	20	B,D	50	725	B,C,D
3/4	25	B,D	60	870	B,C,D
1	30	B,D	75	1085	B,C,D
1 1/2	40	B,D	100	1450	B,C,D
2	50	B,D	125	1815	B,C,D
3	64	B,C,D	150	2170	B,C,D

7 1/2	127	B,C,D	250	3650	B
10	162	B,C,D	300	4400	B
15	232	B,C,D	350	5100	B
20	290	B,C,D	400	5800	B
25	365	B,C,D	450	6500	B
30	435	B,C,D	500	7250	B
40	580	B,C,D			

*This material is reproduced with the permission of the National Electrical Manufacturers Association from NEMA Standards Publication MG 1-2006 copyright © 2006 by NEMA.

[†]Locked-rotor current of motors designed for voltages other than 230 V shall be inversely proportional to the voltages.

164. Locked-Rotor Torque of Single-Speed Polyphase Squirrel-Cage Medium Motors with Continuous Ratings (NEMA standard)*

1. The locked-rotor torque of Designs A and B, 60- and 50-Hz, single-speed, polyphase squirrel-cage medium motors, with rated voltage and frequency applied, shall be not less than the following values, which are expressed in percent of full-load torque requirements. For applications involving higher torque requirements, see the locked-rotor-torque values for Design C and D motors.

hp	Synchronous speeds, rpm							
	60 Hz	3600	1800	1200	900	720	600	514

166. The Design A (normal-torque, normal-starting-current) motor is the old standard type of squirrel-cage induction motor. It is a constant-speed machine with a slip of from 2 to 5 percent at full load. It is not adapted for speed-control service. The starting torques with rated voltage applied are at least as great as given in Sec. 164.

The locked-rotor starting currents with rated voltage applied vary from 500 to 1000 percent of full-load current, the smaller values applying to motors with the larger number of poles.

The full-voltage starting currents of motors of 5 hp and smaller will be within the limitations of most power companies, so they are generally started directly across the line. Motors of larger size than 5 hp will have full-voltage starting currents that will not be within the limitations of some power companies and in such cases are started with reduced voltage.

The breakdown torques are from 175 to 300 percent of full-load torque.

167. The Design B (normal-torque, low-starting-current) squirrel-cage motor is so designed that its rotor has a high reactance and resistance at start but nearly normal reactance and resistance under running conditions. This enables this type of motor to produce approximately the same starting torque for a given voltage as the normal-torque, normal-starting-current motor but with a much smaller value of starting current.

The running performance will be very nearly but not quite so good as that of the normal-torque, normal-starting-current type, the efficiency, power factor, and breakdown torques being slightly less and the speed regulation slightly larger. The breakdown torques will be at least as great as those given in Sec. 165. The locked-rotor starting current with rated voltage applied will be not greater than that given in Sec. 163. The full-voltage starting currents of motors of 30 hp and smaller will be within the limitations of most power companies, so the motors are generally started directly across the line. Motors of larger size than 30 hp will have full-voltage starting currents that will not be within the limitations of many power companies and therefore frequently must be started with reduced voltage.

168. Design C (high-torque, low-starting-current) squirrel-cage induction motors are usually constructed with two squirrel-cage windings on the rotor, located one above the other in the rotor slots. During the starting period most of the current is carried by the top winding, which has a high resistance. This enables the motor to produce a larger starting torque with about the same value of starting current as the normal-torque, low-starting-current type of motor. After the motor has come up to speed, the two windings are equally effective in carrying the rotor current, and its operating characteristics are similar to those of the normal-torque, low-starting-current type of motor.

The locked-rotor starting currents with rated voltage applied will be not greater than those given in Sec. 163. The full-voltage starting current of motors of 30 hp and smaller will be within the limitations of most power companies, so they are generally started directly across the line. Motors of larger size than 30 hp will have full-voltage starting currents that will not be within the limitations of many power companies and therefore frequently must be started with reduced voltage. The starting torques with rated voltage impressed will be at least as great as those given in Sec. 164, Part 2. The breakdown torques will be at least as great as those given in Sec. 165.

169. The Design D (high-resistance-rotor) squirrel-cage motor, owing to the high resistance of its rotor winding, produces a high starting torque with a low value of starting current.

These motors are made in two general types, which may be classified as medium-slip and high-slip. The medium-slip motors have full-load slips from 7 to 11 percent, while the high-slip machines have full-load slips from 12 to 17 percent. The medium-slip motors are suitable for driving punch presses, shears, bulldozers, and other heavy-inertia machinery which operates under heavy, fluctuating-load conditions and which is either provided with flywheels or has a flywheel effect. These motors have full-voltage starting torques of at least 275 percent of full-load torque and full-voltage starting currents which will be not greater than those given in Sec. 163. The maximum torque of the motor occurs at standstill, so there is no noticeable breakdown torque. The full-voltage starting currents are within the limitations of most power companies. Reduced-voltage starting would not as a rule be satisfactory because of the nature of the application of these motors.

The high-slip motors are designed for meeting the requirements of elevator drive and small cranes and hoists. These motors have full-voltage starting torques of at least 275 percent of full-load torque and full-voltage starting currents which will be not greater than those given in Sec. 163. Their full-voltage starting currents meet the limitations of practically all power companies. Like the medium-slip motors, they have no breakdown torque. Owing to the nature of their application, reduced-voltage starting would not be satisfactory.

170. Derating for harmonic content (NEMA MG 1-2006).* Harmonic currents are introduced when the line voltages applied to a polyphase induction motor include voltage components at frequencies other than nominal (fundamental) frequency of the supply. Consequently, the temperature rise of the motor operating at a particular load and per unit voltage harmonic factor will be greater than that for the motor operating under the same conditions with only voltage at the fundamental frequency applied.

When a motor is operated at its rated conditions and the voltage applied to the motor consists of components at frequencies other than the nominal frequency, the rated horsepower of the motor should be multiplied by the factor shown in Fig. 7.92A to reduce the possibility of damage to the motor. This curve is developed under the assumption that only harmonics equal to odd multiples (except those divisible by three) of the fundamental frequency are present. It is assumed that any voltage unbalance or any even harmonics, or both, present in the voltage are negligible. This derating curve is not intended to apply when

FIGURE 7.92A Proposed derating curve for harmonic voltages.

*This material is reproduced with the permission of the National Electrical Manufacturers Association from the NEMA Standards Publication MG 1-2006 copyright © 2006 by NEMA.

the motor is operated at other than its rated frequency nor when operated from a variable voltage or a variable frequency power supply, or both.

The harmonic voltage factor (HVF) is defined as follows:

$$\sqrt{\sum_{n=5}^{n=\infty} \frac{(V_n)^2}{n}}$$

where n = order of odd harmonic, not including those divisible by three

V_n = the per-unit magnitude of the voltage at the n th harmonic frequency

EXAMPLE With per-unit voltages of 0.10, 0.07, 0.045, and 0.036 occurring at the 5, 7, 11, and 13th harmonics, respectively, the value of the HVF is:

$$\sqrt{\frac{0.10^2}{5} + \frac{0.07^2}{7} + \frac{0.045^2}{11} + \frac{0.036^2}{13}} = 0.0546$$

171. Automatic-start induction motors are so arranged that they start with a high-resistance rotor and, after coming up to speed, are automatically changed to have a low-resistance rotor. At start approximately one-third of the rotor copper is in service.

These motors are made in two types. In one type the machine is of generally normal construction but with two rotor windings, one of high resistance and the other of low resistance. At standstill the low-resistance rotor winding is open-circuited so that only the high-resistance winding is in service. As the motor speeds up, a centrifugal device short-circuits the low-resistance winding so that both windings are in service.

In the other type of motor the primary winding is located on the rotor. There are two secondary windings located on the stator, one of high resistance and the other of low resistance. The functioning of the two windings is controlled by magnetic switches so that there is no centrifugal device. The low-resistance winding is of the wound type, and the high-resistance one is a squirrel-cage winding. In starting, a magnetic contactor connects the primary to the line, with the low-resistance winding open-circuited. After a certain lapse of time, a second contactor closes, short-circuiting the low-resistance winding.

These automatic-start motors are started on full voltage and have starting torques from 225 to 250 percent of full-load torque, with starting currents from 350 to 375 percent of full-load current. Their breakdown torques vary from 200 to 250 percent of full-load torque, and they have pull-in torques of from 150 to 200 percent of full-load torque. They are suitable for high-starting-torque duty when starting periods are not too frequent or of too long duration, as in compressors and air-conditioning-equipment service. They can be used in many places where power companies will not allow the starting currents drawn by high-torque, low-starting-current motors when thrown directly across the line.

172. Multispeed induction motors are squirrel-cage induction motors constructed so that the number of poles for which the stator is wound can be altered. Since the speed of an induction motor depends upon the number of poles for which the stator is wound, changing the number will alter the speed of the motor. The change in the number of poles is produced either by means of entirely separate windings or by a change in the interconnections of the different parts of a single winding. In either case the necessary leads are brought out from the stator winding to a drum controller through which the necessary change in connections is made. A gradual speed control is not possible with the multispeed motor. Motors of this type which can

be operated at two, three, or four different speeds can be obtained. Four speeds are the maximum for which it is feasible to construct multispeed induction motors. To design and construct a machine for more than four speeds would require too many complications in the wiring.

Multispeed induction motors have a practically constant speed from no load to full load for each one of their rated speed connections. They are available in all the following types:

1. Normal-torque, normal-starting-current
2. Normal-torque, low-starting-current
3. High-torque, low-starting-current
4. Low-torque, low-starting-current
5. High-resistance, medium- or high-slip

Multispeed induction motors may be designed and rated for constant-torque service, constant-horsepower service, or varying-torque, varying-horsepower service. The allowable rating of constant-torque motors varies directly with the speed. Constant-horsepower motors have the same rated horsepower for all speeds. With varying-torque, varying-horsepower motors the full-load rated torque varies directly with the speed. The horsepower rating of these machines therefore varies as the square of the speed.

173. Efficiency of Squirrel-Cage Induction Motors (see Sec. 152)

1. Efficiency of Polyphase Squirrel-Cage Medium Motors with Continuous Ratings.* The full-load efficiency of Design A and B single-speed polyphase squirrel-cage medium motors in the range of 1 through 400 hp for frames assigned in accordance with NEMA Standards Publication No. MG 13, above 250 hp up to and including 500 hp, and equivalent Design C ratings shall be identified on the nameplate by a nominal efficiency selected from the Nominal Efficiency column in Table 1 which shall not be greater than the average efficiency of a large population of motors of the same design.

TABLE 1 Efficiency Levels

Nominal efficiency	Minimum efficiency based on 20% loss difference
99.0	98.8
98.9	98.7
98.8	98.6
98.7	98.5

The efficiency shall be identified on the nameplate by the caption “NEMA Nominal Efficiency” or “NEMA Nom. Eff.”

The full-load efficiency, when operating at rated voltage and frequency, shall be not less than the minimum value indicated in Column B of Table 1 associated with the nominal value in Column A.

Variations in materials, manufacturing processes, and tests result in motor-to-motor efficiency variations for a given motor design; the full-load efficiency for a large population of motor of a single design is not a unique efficiency but rather a band of efficiency. Therefore, Table 1 has been established to indicate a logical series of nominal motor efficiencies and the minimum associated with each nominal. The nominal efficiency represents a value which should be used to compute the energy consumption of a motor or group of motors.

2. Efficiency Levels of Energy-Efficient Polyphase Squirrel-Cage Induction Motors. The nominal full-load efficiency of polyphase squirrel-cage induction motors rated 600 V or less, identified on the nameplate as “energy efficient” and having a corresponding minimum efficiency in accordance with Column B of Table 1 shall equal or exceed the values listed in Table 2 for the motor to be classified as “energy efficient.”

174. Wound-rotor induction motors, when operated without external resistance in the rotor circuit and with the slip rings short-circuited, have operating characteristics similar to those of normal-torque, normal-starting-current squirrel-cage machine. If external resistance is inserted in the rotor circuit, the speed of the motor can be controlled. With load on the motor the speed can be controlled over a wide range. At no load and with light loads on the motor, it is possible to obtain only slight changes in the speed. When the speed is adjusted for any particular load, the speed does not stay constant as the load varies but decreases considerably as the load increases. The amount that the speed drops off from no load to full load depends upon the amount of external resistance in the rotor circuit; the greater the resistance, the greater the speed change. The characteristics of the wound-rotor motor operating with external resistance in the rotor circuit are similar to those for a dc motor with armature control. Considerable energy is lost in the external resistance, the efficiency of the motor being reduced approximately in proportion to the reduction in speed produced. Wound-rotor motors are started by throwing the stator directly across the line with external resistance in the rotor circuit. The value of the starting torque developed and the corresponding starting current depends upon the amount of external resistance in the rotor circuit (see Secs. 150 and 153). The breakdown torque of a wound-rotor motor will

be at least as large as the figures given in Sec. 176. With the proper amount of external resistance in the rotor to produce a maximum torque at standstill, the starting current will be from 250 to 300 percent of the full-load current. The maximum value of the starting torque will be from 200 to 275 percent of full-load torque.

Wound-rotor motors with speed control are constant-torque machines, the horsepower decreasing in proportion to the decrease in speed.

175. Average Efficiencies and Power Factors for Polyphase Wound-Rotor Induction Motors (with Rotor Short-Circuited)

hp	Efficiency			Power factor

177. In the commutator brush-shifting type of polyphase induction motor,

the relative location of the two windings is reversed from that of the ordinary induction motor. The primary winding, the winding that is connected to the supply, is located on the rotor. The secondary winding is placed in the stator slots. In addition to the primary winding, the rotor carries a second winding which is connected to a commutator in the same manner as in a dc motor. The two ends of each phase of the secondary winding (the stationary winding) are connected to two brushes bearing upon the commutator. The arrangement and connection of the windings are indicated in Fig. 7.93. The position of the two brushes of each phase can be shifted by means of a handwheel.

When the handwheel is adjusted so that the brushes of each phase are on the same commutator segment, the secondary winding is short-circuited and the motor operates like a squirrel-cage machine. As the brushes are moved apart, a section of the adjusting winding is placed in series with the secondary winding. This impresses upon the secondary an additional voltage to the one induced in it by the revolving magnetic field. If the brushes are moved in one direction, the voltage impressed by the adjusting winding will oppose the normal induced voltage. Such a shift of the brushes will therefore reduce the speed of the machine. A shifting of the brushes in the opposite direction causes the voltage from the adjusting winding to aid the normal induced voltage in the secondary and thus increases the speed of the motor. These machines are designed to give a speed range of 3:1. The highest speed is approximately 40 percent above synchronous speed, and the lowest speed is approximately 60 percent below synchronous speed. The decrease in speed from no load to full load is from 5 to 10 percent at the high speeds and from 15 to 25 percent at the low speeds. Very low, creeping speeds can be obtained by inserting resistance in the rotor circuit.

These brush-shifting motors are rated on a constant-torque basis, so that the horsepower rating decreases with the speed. The breakdown torque at low speeds is from 140 to 250 percent of full-load torque. The breakdown torque increases somewhat with the speed, so that at high speed it is from 300 to 400 percent of normal torque.

These motors are started by connecting the primary directly to the line with the brushes in the low-speed position. In this way they will develop a starting torque of from 140 to 150 percent of full-load torque with a starting current of from 125 to 175 percent of full-load current for the maximum horsepower rating. In some special cases, resistance is connected in series with the secondary for starting.

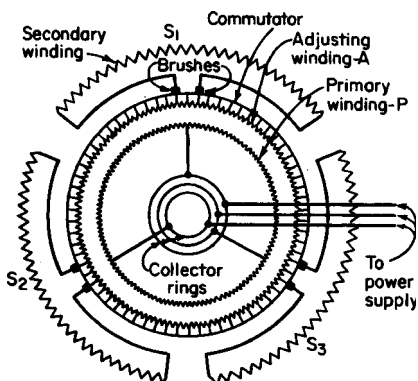

FIGURE 7.93 Commutator type of polyphase induction motor. [General Electric Co.]

178. Synchros are special ac motors employed for:

1. Remote indication of position, such as indicating the position of generator rheostats, waterwheel governors, water-reservoir levels, gates or valves, and turntables
2. Remote signaling systems, such as signaling from switchboard to generator room or from steel-mill furnace to blower room and marine signals between engine room and bridge
3. Automatic or remote position control, such as system frequency, synchronizing of incoming generators, waterwheel governors, gates or valves, color screens on lights in theaters, and motor drives (see Sec. 144)

4. Operation of two machines so as to maintain a definite time-position relation or a definite speed relation, as in lift bridges, hoists, kiln drives, elevators, unit printing presses, and conveyors

Synchros are known by various trade names such as Selsyn, Synchronie, Auto-syn, and Telegon. Units are available in single-phase and three-phase types. The polyphase units conform in appearance and general characteristics to a three-phase wound-rotor induction motor. The single-phase units have a three-phase wound secondary and a single-phase primary. Some single-phase units are constructed with the primary located on the stationary member of the machine, and others with the primary on the movable member. Depending upon the torque developed by the machine, synchros are classified as indicating synchros or power synchros. Power synchros are always of three-phase construction. Most of the indicating synchros are constructed single-phase. Indicating synchros are manufactured in a general-purpose type and a high-accuracy type. The general-purpose type will indicate angular position within an accuracy of plus or minus 5° , and the high-accuracy type provides an accuracy of indication within plus or minus 1° .

A synchro system requires the use of at least two synchro machines. The connections for two single-phase units are shown in Fig. 7.94, and those for two three-phase units in Fig. 7.95. With both the single-phase and the polyphase units, if the rotors of the two machines are in corresponding positions, the voltages of the two secondaries at each instant of time will be equal in magnitude and opposite in direction. Therefore, no current will flow in the rotor circuits, no torque will be developed in either machine, and the machines will be in equilibrium. When the two rotors are not in corresponding positions, the voltages of the two secondaries will not neutralize each other and a current will be produced in the two secondaries. This current will produce torque in the machines, which will act upon the rotors, tending to move them into corresponding positions.

FIGURE 7.94 Circuit for two single-phase synchros.

FIGURE 7.95 Circuit for two three-phase synchros.

In signaling or indicating applications the synchro located at the sending end is called the *transmitter*, and the synchro at the receiving end is called the *receiver*. If desired, a number of receivers can be connected in parallel to a single transmitter. The torque exerted upon each receiver will be reduced from that available when only one receiver is used. The torque can be calculated from the following formula:

$$T_r = T_1 \times \frac{2}{N + 1} \quad (5d)$$

where T_r is the torque available at each receiver
 T_1 is the torque available if only one receiver is used
 N is the number of receivers

When the position taken by the receiver differs from that of the transmitter, a three-phase synchro is introduced between the transmitter and the receiver. This intermediate synchro is called a *differential synchro*. With such a system, the receiver will take up a position that will be either the sum or the difference of the angles applied to the transmitter and the differential. Conversely, if two synchros are connected through a differential synchro and each is turned through an angle, the differential synchro will indicate the difference between the two angles.

The fundamental synchro control circuit generally used for control purposes is shown in Fig. 7.96. When the positions of the rotors coincide, a maximum voltage will be induced in stator S_2 . When the rotors are displaced 90 electrical degrees from each other, no resultant voltage will be produced between the terminals of S_2 .

This is true since the axis of the winding S_2 will be located 90 electrical degrees from the axis of the field produced in machine 2. The system is adjusted so that when the desired condition exists, the rotors will be displaced 90 electrical degrees from each other. This is the equilibrium position. The circuit therefore functions to produce an error voltage in the stator of machine 2 whenever there is a displacement of the shafts from the equilibrium position. The relative polarity of the error voltage depends upon the direction of the displacement. The error voltage can be employed to instigate the functioning of other devices, which will operate to correct the condition causing the displacement. These correction devices will function until the synchros are brought into the equilibrium position, when absence of voltage in S_2 will stop their functioning. Refer to Sec. 144 for the application of synchros in position drive control.

FIGURE 7.96 Fundamental synchro control circuit for the production of an error voltage.

179. Synchronous motors. The general construction of a synchronous motor is the same as that of synchronous ac generators with the addition of an auxiliary winding similar to either the squirrel-cage or the wound-rotor winding of an induction motor embedded in the pole faces. The purpose of the auxiliary winding is to produce starting torque so that the motor will be self-starting. A synchronous motor will not develop starting torque through synchronous-motor action. A synchronous motor is started without dc field excitation by induction-motor action through its auxiliary winding. As the motor comes up to speed and dc excitation voltage is applied to its field winding, a pull-in torque is developed, tending to pull the motor into step. If the inertia of the load is not too great, this pull-in torque will accelerate the motor to synchronous speed, and it will continue to operate as a synchronous motor. As long as the motor runs at synchronous speed, the auxiliary winding will be inactive, since no voltage will be produced in the auxiliary winding under this condition. If the motor should instantaneously tend to run at a speed slightly greater or less than synchronous, a voltage is produced in the auxiliary winding, causing a flow of current. This current will produce a torque which will act to bring the motor back to synchronous speed. The auxiliary winding, in addition to furnishing a means of making the motor self-starting, therefore provides a dampening effect tending to eliminate instantaneous fluctuations of the speed.

A synchronous motor has two very important characteristics. It operates at constant speed, and its power factor is under the control of the operator. If the average speed of a synchronous motor deviates from synchronism, the motor pulls out of step and ceases to function as a synchronous motor. The power factor, unlike that of an induction motor, is not a fixed value dependent upon the design and load. It depends upon the value of the direct field current and can be adjusted by the operator to a leading, unity, or lagging power-factor value. For any particular load a certain field current will make the motor operate at

unity power factor. This value of field current is called *normal excitation*. A field current less than normal excitation will produce a lagging power factor, and a field current more than normal will produce a leading power factor.

180. A synchronous motor can be used to correct low power factor of the system that feeds it in addition to driving a mechanical load provided it has sufficient capacity. This characteristic is often of considerable importance. It is well known that the power factor of the induction motor, even under full-load condition, is seldom greater than 95 percent, and it often falls as low as 50 or 60 percent at light load. The result is that an ac generator driving a considerable number of induction motors ordinarily operates at a comparatively low power factor. If this alternator is loaded to its full kilowatt capacity at such a low power factor, over-heating will result.

If the alternator is not loaded beyond its normal current capacity, it operates at a low energy load but with the same heating losses as at full load on account of the reduced power factor. The advantage of the synchronous motor on such a system is that by proper adjustment of its field current it can be made to draw from the line a current which is leading with respect to the voltage and which will neutralize the lagging current taken by the induction motors. The current in the ac generator can thereby be brought into phase with the voltage, and the generator will operate under its normal conditions. When used in this manner as a compensator for lagging current, the synchronous motor must be of larger size than required by its power output on account of the excess current which it draws from the line.

A *synchronous condenser* is a synchronous motor that operates only to correct the power factor and does not pull any mechanical load.

181. Classification of synchronous motors

1. According to power-factor rating
 - a. 1.0 (unity)-power-factor
 - b. 0.8 (leading)-power-factor
2. According to speed
 - a. High-speed
 - b. Low-speed
3. According to service
 - a. General-purpose
 - b. Special-purpose

The horsepower ratings of synchronous motors are based on unity or 0.8-pf operation. A unity power-factor motor is designed to carry its rated horsepower load when operating at unity power factor. An 0.8-pf motor is designed to carry its rated horsepower load when operating at 0.8 pf leading. Either a unity- or an 0.8-pf-rated motor can be operated at power factors below their rated amount provided the horsepower output is reduced below the rated value by a sufficient amount so that the machine will not be overheated in operation.

Synchronous motors are divided into two groups according to the value of their rated speed. Motors with speeds of 500 rpm or greater are called *high-speed motors*, and those with speeds below 500 rpm are classed as *low-speed motors*.

182. General-purpose synchronous motors are rated on a 40°C temperature-rise basis with a service factor of 1.15 (see Sec. 130). When started with full voltage, these motors will have starting kVA inrushes of from 550 to 700 percent of the motor's normal kVA rating. Normal torque values for these motors are given in Sec. 184. The pull-in torques as given in Sec. 184 are based on the standardized normal Wk^2 of load.

183. Operation at Other Than Rated Power Factors (NEMA standard)*

1. For an 0.8-pf motor which is to operate at 1.0 pf with normal 0.8-pf armature current and with field excitation reduced to correspond to that armature current at 1.0 pf, multiply the rated horsepower and torque values of the motor by the following constants to obtain the horsepower at 1.0 pf and the torques in terms of the 1.0-pf horsepower rating:

Horsepower	1.25
Locked-rotor torques	0.8
Pull-in torque	0.8
Pullout torque (approximate)	0.6

For example, consider a 1000-hp, 0.8-pf motor which has a locked-rotor torque of 100 percent, a pull-in torque of 100 percent, and a pullout torque of 200 percent and which is to be operated at 1.0 pf. In accordance with the foregoing, this motor could be operated at 1250 hp, 1.0 pf, 80 percent locked-rotor torque (based upon 1250 hp), 80 percent pull-in torque (based upon 1250 hp), and a pullout torque of approximately 120 percent (based upon 1250 hp).

2. For a 1.0-pf motor which is to operate at 0.8 pf with normal 1.0-pf field excitation and the armature current reduced to correspond to that excitation, multiply the rated horsepower and torque values of the motor by the following constants to obtain the horsepower at 0.8 pf and the torques in terms of the 0.8-pf horsepower rating:

Horsepower	0.35
Locked-rotor torques	2.85
Pull-in torque	2.85
Pullout torque (approximate)	2.85

For example, consider a 1000-hp, 1.0-pf motor which has a locked-rotor torque of 100 percent, a pull-in torque of 100 percent, and a pullout torque of 200 percent and which is to be operated at 0.8 pf. In accordance with the foregoing, this motor could be operated at 350 hp, 0.8 pf, 285 percent locked-rotor torque (based upon 350 hp), 285 percent pull-in torque (based upon 350 hp), and a pullout torque of approximately 570 percent (based upon 350 hp).

*This material is reproduced with the permission of the National Electrical Manufacturers Association from the NEMA Standards Publication MG 1-2006 copyright © 2006 by NEMA.

184. Minimum-Torque Values for Synchronous Motors

(NEMA standard)*

The locked-rotor, pull-in, and pullout torques (motors shall be capable of delivering pull-out torque for at least 1 min), with rated voltage and frequency applied, shall be not less than the following:

Speed, rpm	hp	Power factor	Torques, percent of rated full-load torque			
			Locked-rotor	Pull-in (based on normal Wk^2 of load) ^{†,‡}	Pullout [‡]	
500-1800	200 and below	1.0	100	100	150	
	150 and below	0.8	100	100	175	
	250-1000	1.0	60	60	150	
	200-1000	0.8	60	60	175	
	1250 and larger		1.0	40	60	150
			0.8	40	60	175
450 and below	All ratings	1.0	40	30	150	
		0.8	40	30	200	

*This material is reproduced with the permission of the National Electrical Manufacturers Association from the NEMA Standards Publication MG 1-2006 copyright © 2006 by NEMA.

[†]Values of normal Wk^2 are given in Sec. 185.

[‡]With rated excitation current applied.

185. Effect of load Wk^2 . The inertia of the load (load Wk^2) is very important in the selection and operation of synchronous motors. The load inertia that a synchronous motor can accelerate is limited by the thermal capacity of its amortisseur winding. Smaller synchronous motors can accelerate relatively higher load Wk^2 than larger motors can. NEMA sets standards for the load Wk^2 which can be accelerated for standard synchronous motors.

186. Special-purpose synchronous motors. For applications in which the characteristics of general-purpose motors do not fit the operating requirements, the manufacturer fits the design of the auxiliary windings and motor proportions to meet specific applications. These custom-made motors are built with the following types of auxiliary windings:

1. Conventional squirrel-cage winding
2. Conventional squirrel-cage winding plus single-phase wound-rotor winding
3. Three-phase wound-rotor winding

The fundamental connections and functioning of the different types of auxiliary windings are illustrated in Fig. 7.97.

By means of proper design of a conventional squirrel-cage winding the torque characteristics can be varied over the limits given in Sec. 184. If higher starting torques with low starting kVA are required, a wound-rotor auxiliary winding is employed (see Fig. 7.97). For applications requiring a fairly high starting torque with a fairly low starting-inrush kVA, a single-phase wound-rotor winding is added to the conventional squirrel cage. For applications requiring exceptionally high starting torques with low starting kVA, a three-phase

Conventional design. Start: Motors start like standard induction motors, by means of squirrel-cage windings embedded in the pole faces. **Run:** The motor comes up to speed and after a predetermined definite time, the dc field excitation is applied. This causes the motor to shift from induction to synchronous operation.

High torque; low starting kVA. Start: Motor gets high torques at start with low-kVA inrush, by a standard squirrel-cage winding plus a separate series winding on the pole faces connected to an external resistor. **Run:** The motor comes up to speed and after a predetermined definite time, the dc field excitation is applied. This causes the motor to shift from induction to synchronous operation.

High torque; starting kVA 50 percent or less of normal. Start: Motor starts like any ordinary three-phase wound-rotor motor. The external resistor makes possible variable high torque together with extremely low starting kVA. **Run:** The motor comes up to speed and after a predetermined definite time, the dc field excitation is applied. This causes the motor to shift from induction to synchronous operation.

FIGURE 7.97 Types of auxiliary windings for synchronous motors. [Westinghouse Electric Corp.]

wound-rotor winding is employed. Motors with a wound-rotor auxiliary winding are started under full voltage with external resistance inserted in the auxiliary winding as in starting wound-rotor induction motors.

187. The repulsion motor (Fig. 7.98) has an armature which is like that of a dc machine. It is provided with two brushes E_1 and E_2 , which are inclined to the axis of the stator winding. These brushes are connected by a low-resistance conductor D , which short-circuits the armature. A machine of this type has a high starting torque with a small starting current and a rapidly decreasing speed with increasing load, being similar in this respect to a dc series motor. The power factor of the repulsion motor increases with the speed, and near synchronous speed it attains a value much higher than is generally obtained in induction motors. These motors are used principally for constant-torque applications such as printing-press drives, fans, and blowers. The direction of rotation of a repulsion motor can be reversed by shifting the brushes to the reverse side of the neutral.

188. The compensated repulsion motor (Fig. 7.99) is similar to the repulsion motor, except that it has a compensating winding and two compensating brushes C_1 and C_2 , which the repulsion motor does not have. The compensating winding is wound on the stator. The compensating brushes are connected in series with the compensating winding. These motors have a starting torque equal to about $2\frac{1}{2}$ to 3 times full-load torque with approximately twice full-load current. Owing to the corrective action of the compensating winding, the power factor is very high at all loads. However, the efficiency of this machine is lower than that of the induction motor. Single-phase motors of this type are well adapted for loads involving heavy starting torque and sudden overloads.

FIGURE 7.98 Repulsion motor.

FIGURE 7.99 Compensated repulsion motor.

189. Brush-shifting type of single-phase motor. The brush-shifting single-phase repulsion motor, as manufactured by the General Electric Co., is a compensated repulsion motor. It is an adjustable varying-speed type of motor. Speed is adjusted by shifting the position of the brushes on the rotor. The speed may be controlled directly at the motor by means of a brush-shifting handle attached to the brush rigging. If the speed is to be controlled from some point remote from the motor, the brush-shifting handle can be

connected to a pedestal or foot controller by means of a rocker-shaft assembly (bracket, rocker shaft, and levers). These motors can be obtained in $\frac{1}{4}$ - to 3-hp sizes for either a reversing or a nonreversing service. The motor is reversed simply by shifting the brushes in the opposite direction from the neutral point. The brush-shifting motor is a constant-torque motor. The rated horsepower is the allowable horsepower for the highest speed. As the speed is reduced, the allowable horsepower is reduced in proportion. A speed reduction of 3:1 is possible when operating against a constant torque of 75 percent of the rated value. If operating against 100 percent normal torque, a speed reduction of 4:1 can be obtained. The no-load speed is approximately 60 percent above synchronous speed. At no load or with light loads very little speed reduction is possible. The starting torque of these motors with full voltage varies from 150 to 300 percent of full-load rated torque for four-pole machines and from 125 to 250 percent for six-pole motors, depending upon the brush position.

The breakdown torque is more than 400 percent of full-load rated torque when the brushes are in the maximum-speed position. As the brushes are shifted for the lower speeds, the breakdown torque decreases. These motors are generally started with full voltage.

190. A single-phase induction motor, when its rotor is not revolving, has no starting torque. After the rotor commences revolving, a continuous turning effort is exerted by a certain interaction of magnetic fields. Single-phase induction motors are provided, therefore, with auxiliary means for making them self-starting. Single-phase induction motors can be divided into the following groups, depending upon the method employed for starting:

1. Shading-coil
2. Inductively split-phase
3. Capacitor split-phase
4. Repulsion-start, induction-run
5. Repulsion-induction

191. Shading-coil single-phase induction motors. Some fractional-horsepower motors, principally those used on small ventilating fans, are made self-starting by the *shading-coil method*. The stator winding of these motors is not distributed around the frame, as in most induction motors, but is wound on projecting pole pieces, as in dc machines. In addition to the main stator winding a short-circuited coil, or shading coil, as it is called, is placed around only a portion of the pole piece (Fig. 7.100). This shading coil makes the flux in the portion of the pole piece surrounded by it lag behind the flux in the other portion of the pole. The shifting of the flux thus produced will develop sufficient torque to start small motors under very light load conditions. These motors are made in sizes of from $\frac{1}{250}$ to $\frac{1}{40}$ hp and are used for driving small fans.

FIGURE 7.100 Construction of a shading-coil motor.

192. The inductively split-phase single-phase induction motor is provided with an auxiliary starting winding in addition to the main stator winding. This winding is located in stator slots so that it is displaced 90 electrical degrees from the main stator

FIGURE 7.101 Single-phase motor.

winding, as shown in Fig. 7.101. If two currents sufficiently out of phase with each other are passed through the main and auxiliary windings, conditions similar to those existing in a two-phase induction motor will be produced. The necessary two currents, which are from 30 to 45 degrees out of phase with each other, are obtained from the single-phase supply by constructing one of the circuits with a relatively high inductance and the other with a relatively high resistance. The main or running winding is normally of high inductance at the time of starting. The auxiliary winding is wound with finer wire, giving it higher resistance than the main winding. The running winding remains in the circuit at all times of operation, while the starting winding remains in the circuit only until the motor has reached 50 to 80 percent of synchronous speed. When the speed at which the starting winding should be cut out is reached, an automatic centrifugal switch operates and opens the starting circuit. This type of single-phase induction motor thus starts as a two-phase machine until the starting winding is cut out, when it continues to operate, by virtue of the running winding only, as a single-phase motor.

These motors are constant-speed machines, not adapted for any speed control. They are made in sizes up to $\frac{1}{3}$ hp and in two types, the general-purpose type and the high-torque type. The general-purpose type has the following characteristics: full-voltage starting torque 75 to 175 percent of full-load torque, full-voltage starting current with NEMA specifications of Sec. 200, breakdown torque 175 to 225 percent of full-load torque, and pull-up torque 75 to 200 percent of full-load torque. They are suitable for full-voltage starting on any power system.

The high-torque type of motor has the following characteristics: full-voltage starting torque 150 to 275 percent of full-load torque, full-voltage starting current approximately 850 percent of full-load current, breakdown torque 225 to 350 percent of full-load torque, and pull-up torque 225 to 325 percent of full-load torque. The full-voltage starting currents exceed NEMA specifications of Sec. 200 and may not be permissible for some installations.

193. Capacitor motors are single-phase induction motors which have two stator windings displaced 90 electrical degrees from each other just as the inductively split-phase motor does. Therefore their starting torque is developed by two-phase action. In the capacitor motor the necessary phase displacement between the currents of the two stator

windings is produced by placing a capacitor in series with the auxiliary winding. By this means the phase displacement can be made more nearly 90 degrees, which results in better starting torque with lower starting current than can be obtained with the inductively split-phase-started motor. Capacitor motors are available in the following types:

1. Capacitor-start, induction-run
2. Capacitor-start, capacitor-run
 - a. Two-value capacitor (high-torque)
 - b. Permanent-split capacitor (low-torque)
3. Multispeed, capacitor-start, capacitor-run

Capacitor motors have the advantages of quiet operation, high power factors, and reduction in radio interference.

194. The capacitor-start, induction-run

motor starts by two-phase action. After the motor has reached approximately 75 percent of full-load speed, a centrifugal switch opens the auxiliary circuit, and the motor continues to run as an ordinary single-phase induction motor. A diagram for a motor of this type is shown in Fig. 7.102. These motors develop starting torques of 275 to 400 percent of rated full-load torque. The breakdown torque is from 200 to 300 percent of rated full-load torque. Starting currents are sufficiently low so that the motors are started with full voltage. Motors of this type are made in sizes of from $\frac{1}{8}$ to $\frac{3}{4}$ hp.

FIGURE 7.102 Connection diagram of a capacitor-start, induction-run motor. [Wagner Electric Corp.]

195. Capacitor-start, capacitor-run single-phase induction motors utilize both stator windings at all times. The motor secures its power from a single-phase supply but really operates when both starting and running as a two-phase motor. For the *two-value capacitor motor* a larger value of capacity is used during the starting period than is employed for running conditions. This larger capacity can be obtained by adding a capacitor (Figs. 7.103 and 7.104) or by changing the connections to an autotransformer which supplies the power to a single capacitor (Fig. 7.105). For small motors the change in the connections between starting and running is performed by a centrifugal switch (Fig. 7.103), while for larger motors a definite time relay is employed (Fig. 7.104). The two-value capacitor motor produces a high starting torque of 275 to 450 percent of rated full-load torque with starting currents that in most cases are sufficiently low so that the motors can be started with full voltage. Breakdown torques will be from 200 to 300 percent of rated full-load torque. These motors are available in sizes of from $\frac{1}{8}$ to 10 hp.

The permanent-split-capacitor motor utilizes a single value of capacity that is the same for both starting and running (Fig. 7.106). There is no change in connections between the starting and running conditions. These motors have low starting torques of a value from 40 to 60 percent of rated full-load torque. The breakdown torques will be from 150 to 200 percent of rated full-load torque. The starting current will generally be sufficiently low for full-voltage starting. These motors are made in sizes of from $\frac{1}{8}$ to 10 hp.

FIGURE 7.103 Connection diagram for a two-value capacitor motor (capacitor-start, capacitor-run) with centrifugal switch. [Wagner Electric Corp.]

FIGURE 7.104 Connection diagram for a two-value capacitor motor (capacitor-start, capacitor-run) with acceleration relay. [General Electric Co.]

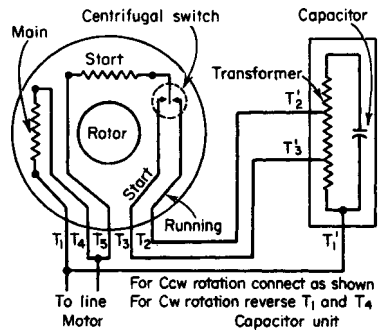

FIGURE 7.105 High-starting-torque capacitor motor. [General Electric Co.]

The principal advantage of capacitor-start, capacitor-run motors over capacitor-start, induction-run motors is that they operate at a higher power factor.

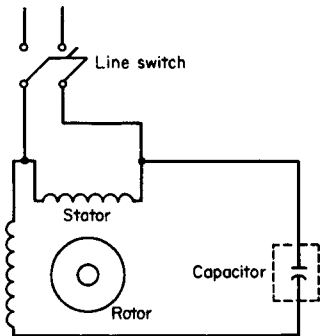

FIGURE 7.106 Permanent-split-capacitor motor. [General Electric Co.]

196. Multispeed capacitor motors are typically permanent-split-capacitor motors used for fan service in appliances. These motors have a tapped main winding operated at full voltage and are not intended for general use. Multispeed capacitor motors may also be single-value capacitor-start, capacitor-run motors equipped with a selector switch and an auto-transformer for supplying different voltages to the main winding. They are suitable only for special classes of services, since the breakdown torque is

reduced in proportion to the square of the voltage impressed on the main winding. It is possible to provide the motor with a centrifugal switch so that when properly connected, the motor can be started only with full voltage impressed upon the main winding.

197. Repulsion-start, induction-run single-phase motors. Single-phase induction motors which are started by repulsion-motor action are constructed similarly to the straight-repulsion motor with the addition of a centrifugal device which shorts the commutator segments after the motor has come up to speed. The motor starts as a repulsion motor, but after it has come up to the required speed so that the commutator segments are short-circuited, it operates as a straight-induction motor. These motors are constant-speed machines not capable of speed control. The starting torques of different motors vary from 300 to 500 percent of full-load torque. The breakdown torque is at least 175 percent of full-load torque. Starting currents of these motors vary from 200 to 350 percent of full-load current, so generally they can be started directly across the line. When it is necessary or desirable to limit the starting current to smaller values, a resistance type of starter is employed. These motors are made in sizes of from $1/8$ to 15 hp.

198. The repulsion-induction motor has two rotor windings. One of these windings is an ordinary induction rotor winding, and the other is a repulsion winding connected to a commutator with short-circuited brushes. There is frequently a compensating winding on the stator connected to brushes bearing on the commutator, as discussed in Sec. 188. This motor starts by repulsion-motor action. Since there is no short-circuiting device, after the machine has come up to speed, both the repulsion and the induction windings are active. Under running conditions the motor functions as a combined induction and repulsion motor. The starting torque with rated voltage impressed for different sizes and speeds varies from 225 to 300 percent of full-load torque. There is no definite breakdown point, maximum torque occurring at standstill. The starting currents of these motors, when thrown directly across the line, are within the requirements of most power companies. When starting currents are to be limited to smaller values, a resistance type of starter is employed. The repulsion-induction motor is a constant-speed machine with a speed variation from no load to full load of about 6 percent. Its speed cannot be adjusted. These motors are made in sizes of from $1/2$ to 10 hp.

199. The single-phase series, or universal, motor (Fig. 7.107) comprises an armature of the dc type connected in series with the field. It will operate successfully on either ac or dc circuits. The single-phase series motor finds its widest application in fractional-horsepower services such as those for fans, appliance motors, and electric tools. These machines have approximately the same speed-torque characteristics as dc series machines. In

the larger capacities, single-phase series motors are equipped with windings which compensate for the armature reaction. The compensating winding is placed in the pole face and must be so connected that at any instant the current will flow in the same direction in all the conductors under any one pole. The winding can be connected in series with the armature. When so connected, it is called a *conductively compensated winding*. The compensating

FIGURE 7.107 Series or universal motor.

winding can be short-circuited on itself. When thus arranged, it receives its current by induction, and the machine is said to be inductively compensated.

200. Small single-phase motors.* Small single-phase motors (1 hp or less) were formerly called *fractional-horsepower* motors. NEMA standardization rules specify that the minimum locked-rotor torque of single-phase, general-purpose small motors, with rated voltage and frequency applied, shall be not less than the following:

hp	Minimum locked-rotor, oz·ft*					
	60-Hz speed, rpm			50-Hz speed, rpm		
	3600	1800	1200	3000	1500	1000
1/8	...	24	32	...	29	39
1/6	15	33	43	18	39	51
1/4	21	46	59	25	55	70
1/3	26	57	73	31	69	88
1/2	37	85	100	44	102	120
3/4	50	119	...	60	143	...
1	61	73

*On the high voltage connection of the dual voltage motors, minimum locked-rotor torques up to 10% less than these values may be expected.

NEMA standards also specify that the locked-rotor current of 60-Hz single-phase, general-purpose small motors shall not exceed the values given in the following table.

Two-, four-, six-, and Eight-pole, 60-Hz motors, single-phase

hp	Locked-rotor currents, A			
	115 V		230 V	
	Design O	Design N	Design O	Design N
1/6 and smaller	50	20	25	12
1/4	50	26	25	15
1/3	50	31	25	18
1/2	50	45	25	25
3/4	...	61	...	35
1	...	80	...	45

*This material is reproduced with the permission of the National Electrical Manufacturers Association from NEMA Standards Publication MG 1-2006, copyright © 2006 by NEMA.

201. Single-phase medium motors.* Single-phase medium motors rated more than 1 hp were formerly called *integral-horsepower* motors. Single-phase medium motors are classified by NEMA into two design types, Design L and Design M. The distinction is made on the basis of the value of the locked-rotor current of the motor. NEMA standards specify that the locked-rotor current of single-phase, 60-Hz Design L and M motors of all types, when measured with rated voltage and frequency impressed and with the rotor locked, shall not exceed the following values:

hp	Locked-rotor currents, A		
	Design L motors		Design M motors, 230 V
	115 V	230 V	
$\frac{1}{2}$	45	25	...
$\frac{3}{4}$	61	35	...
1	80	45	...
$1\frac{1}{2}$...	50	40
2	...	65	50
3	...	90	70
5	...	135	100
$7\frac{1}{2}$...	200	150
10	...	260	200

In accordance with NEMA standards the locked-rotor torque of single-phase, 60-Hz, general-purpose medium motors, with rated voltage and frequency applied, shall be not less than the following:

hp	Minimum locked-rotor torque, lb·ft		
	Synchronous Speed, rpm		
	3600	1800	1200
$\frac{3}{4}$	8.0
1	...	9.0	9.5
$1\frac{1}{2}$	4.5	12.5	13.0
2	5.5	16.0	16.0
3	7.5	22.0	23.0
5	11.0	33.0	...
$7\frac{1}{2}$	16.0	45.0	...
10	21.0	52.0	...

202. Methods of reversing motors. In the following paragraphs instructions are given for reversing the different types of motors.

Direct-Current Shunt or Series Motors. Interchange the connections of either the field or the armature winding. Reversing the line leads will not change the direction of rotation. If the motor is not equipped with commutating poles, the brushes should be shifted to the same position on the opposite side of the neutral axis.

*This material is reproduced with the permission of the National Electrical Manufacturers Association from NEMA Standards Publication MG 1-2006, copyright © 2006 by NEMA.

Direct-Current Compound Motors.

Method 1. Interchange the connections of the two armature leads.

Method 2. Interchange the connections of the two shunt-field leads and also the connections of the two series-field leads. Interchanging the connections of just the two shunt-field leads would change the direction of rotation, but the motor would operate as a differential compound motor instead of cumulatively. If the motor is not equipped with commutating poles, the brushes should be shifted to the same position on the opposite side of the neutral axis.

Any Four-Wire Two-Phase Induction Motor. Interchange the connections to the line of the two leads of either phase.

Any Three-Wire Two-Phase Induction Motor. Interchange the connections to the line of the two outside wires.

Any Three-Phase Induction Motor. Interchange the connections to the line of any two leads. In reversing the commutator type of polyphase induction motor the brush-shifting mechanism must be adjusted to the proper position for the reversed rotation in addition to reversing the connections of two of the line leads.

Synchronous Motors. Ordinary synchronous motors are reversed in the same manner as induction motors.

Single-Phase Induction, Shading-Pole Starting. The direction of rotation cannot be reversed except in special cases. If the pole pieces of the machine can be removed, the direction of rotation can be reversed by revolving the pole pieces 180° on their own axes. This will place the shading coils on the opposite sides of the pole pieces. With these machines, each shading-coil circuit must be provided with a switch. The direction of rotation depends on which shading-coil circuit is closed.

Single-Phase Induction, Inductively Split-Phase Starting. Interchange the connections of either the main or the auxiliary winding.

Single-Phase Capacitor Motor. Interchange the connections of either the main or the auxiliary winding.

Single-Phase Induction, Started by Repulsion Action. Shift the brushes to the same position on the opposite side of the neutral axis.

Single-Phase Repulsion Motor. Shift the brushes to the same position on the opposite side of the neutral axis.

Single-Phase Series Motor. It is reversed in the same manner as a dc series motor.

202A. Electric-motor braking. Braking of electric motors can be performed by friction braking, plugging, dynamic braking, or regenerative braking.

Friction braking of electric motors consists of retarding the motor speed or of completely stopping the motor by a solenoid-operated friction brake of the shoe or disk type.

Plugging is the method of retarding the motor speed and completely stopping the motor or of reversing the motor by applying electric power in the reverse direction so that the motor develops torque in the direction opposite to that of rotation. Plugging will quickly

bring a motor and its driven load to a stop. If the reverse power is not removed when the motor comes to a stop, the motor will reverse and accelerate in the opposite direction.

Dynamic braking is the method of retarding the motor speed or of completely stopping the motor through making the motor act as a generator with a resistance load.

Regenerative braking is the method of retarding the motor speed by making the motor, functioning as a generator, feed its generated power back into the supply line. Regenerative braking will not stop the motor. It is effective only for the braking of overhauling loads. Overhauling loads are those which attain a speed greater than that of the motor speed-load characteristic and under which, therefore, the load tends to drive the motor.

203. Plugging of motors. To employ plugging retardation of an electric motor, a reversing switch or contactor must be provided in the control equipment. To stop or retard the speed of the motor by plugging, the connections to the power supply are simply reversed in the proper manner so that the motor develops torque in the opposite direction to that in which it is rotating. For squirrel-cage induction motors, the braking action can be cushioned to reduce the shock to the machine and power system by the use of resistance connected in series with the reversed connections to the supply. For wound-rotor induction motors, the plugging torque can be controlled by adjusting the resistance in the motor secondary circuit. For synchronous motors, the dc field circuit is deenergized during the plugging operation, and the motor is plugged in the same manner as a squirrel-cage induction motor. For dc motors, additional resistance must be used in series with the reversed power connections. When the motor must come to a stop without reversal, a zero-speed switch or a timing relay must be used to open the motor circuit when the machine comes to a stop.

Advantages

1. Simple arrangement and installation
2. Fast operating performance
3. Freedom to rotate after stopping in contrast to braking with a mechanically set brake
4. No friction parts and freedom from maintenance
5. Suitability for large motors and severe duty

Disadvantages

1. Reversing controller required
2. Zero-speed switch or consistent timing relay required if reversing is to be prevented
3. Availability of power required (plugging impossible if power fails)
4. Power system capable of supplying the peak plugging current required
5. Special bracing possibly required for motor windings

If motor and its load must positively be held stationary when the motor is deenergized, an additional spring-set or other type of mechanical brake is necessary.

204. In dynamic braking, the armature of the motor is disconnected from the power supply, and the load will drive the motor as a generator. The generator action is loaded either through resistance banks or through part of the motor winding. For dc shunt or compound motors, the armature is disconnected from the line and connected to a resistor bank; the shunt field is left connected to the supply line. For dc series motors, the machine is disconnected from the supply, and the armature and series-field circuits are segregated from

each other. The field winding is connected in series with the proper limiting resistance to the supply line. The armature is connected to a resistor bank load.

For dynamic braking of squirrel-cage induction motors, a source of excitation must be provided. This excitation may be provided (1) from a separate source of direct current, (2) from the ac supply through a rectifier, or (3) by means of capacitors. In the first method, dynamic braking is accomplished by disconnecting the motor from the supply and connecting one phase of the motor primary to a separate source of direct current. The motor will then be driven by the load as a generator and will load itself through the induced current in the motor secondary flowing through the squirrel-cage winding. The dc excitation must be removed at the end of the braking period; otherwise the windings will overheat. In the second method, dynamic braking is accomplished in the same manner as in the first method except that the dc supply for the excitation is obtained from the ac supply through a single-phase rectifier. The rectifier is usually of the contact, or barrier-layer, type.

A diagram of the connections required is shown in Fig. 7.108. In the third method, a capacitor is permanently connected across the motor terminals. In braking, the motor is disconnected from the supply. The capacitor will supply the motor with excitation so that it will

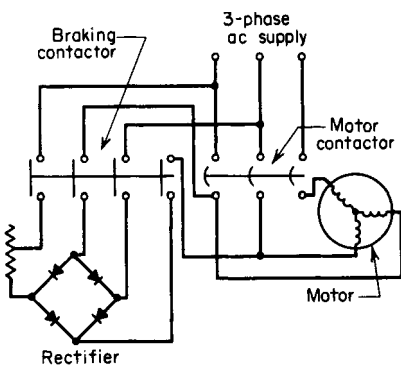

FIGURE 7.108 Dynamic braking of an induction motor with rectified direct current.

function as an induction generator. The braking action is produced by the power losses inside the machine. The braking action can be improved by connecting a loading resistor in parallel with the capacitor. The larger the capacitor, the greater the braking action. All braking action ceases with this method at about one-third of synchronous speed.

For wound-rotor induction motors, dynamic braking could be accomplished by all three of the methods just described for squirrel-cage motors. However, the first method, using a separate source of direct current for excitation, is usually the only feasible one. The amount of the braking action can be controlled by adjusting the secondary resistance. For synchronous motors, dynamic

braking is accomplished by disconnecting the motor armature from the ac supply and connecting the armature to a resistor bank load. The field is left excited from direct current.

Advantages

1. The motor cannot be reversed. No zero-speed switch or other antireversing device is required.
2. There is smooth, positive retardation lacking the shock of a mechanically set brake and less severe than plugging.
3. The braking torque is easily adjustable by varying the dc excitation or, as in wound-rotor induction-motor applications, by varying the motor secondary resistors.
4. In dynamic braking of small ac motors by the use of capacitors, the braking is independent of the power supply; furthermore, the capacitor furnishes a power-factor correction while the motor is operating.

Disadvantages

1. A source of dc excitation is required during the braking period except in capacitor braking.
2. Braking is not available if the exciting source fails.

3. This method is more expensive and more complicated than plugging. If the source of excitation is not already available and additional equipment must be installed, the extra cost may be prohibitive.
4. Control must provide means for disconnecting the excitation at the expiration of the braking period.
5. Dynamic braking is useless as a holding force after motor has come to rest and is deenergized.
6. Capacitor dynamic braking is ineffective and ceases to exist below approximately one-third speed; therefore, it is of little value except on drives involving considerable friction. The cost of capacitor braking is prohibitive with large motors.
7. Rectifier-excited dynamic braking is impracticable and expensive in the case of large motors.

205. Regenerative braking cannot be used for stopping a motor. It will produce braking action only when the load overhauls the motor and drives the motor at a speed above the speed-load characteristic of the motor. When a load overhauls its drive motor (except for series dc motors), the voltage generated in the machine will be greater than the supply-line voltage. Consequently the motor will function as a generator and feed power back into the supply line. This is an inherent characteristic of the motor and does not require any changing of connections or control equipment. If a series dc motor is overhauled by its load, the motor loses its excitation and becomes incapable of regenerative braking unless the connections are changed. Therefore, to use regenerative braking on a series motor the series field and armature must be segregated from each other and connected individually to the supply. Sufficient resistance must be connected in series with the series field so that the current will be held to normal value.

Advantages

No extra equipment is required except for series-wound dc motors. This method can be made effective with dc motors at reduced speeds by strengthening the motor field, i.e., by lowering the speed at which the motor will regenerate.

Disadvantages

This method is effective only at overhauling speeds; it is useless as a means of stopping. If dc motors must be made to regenerate at low speeds, the control becomes involved and expensive. The motor may require special fields.

CONVERSION EQUIPMENT

206. The conversion of alternating current to direct current is usually effected with a motor-generator set, a synchronous converter, an electronic rectifier, a contact (barrier-layer) rectifier, or solid-state semiconductor rectifiers.

207. A motor-generator set consists of a motor mechanically coupled to and driving one or more generators. The motor is usually alternating-current and is mounted on the same bedplate and on the same shaft with the generator or generators which it drives.

A motor-generator set can be employed to convert electrical energy from one voltage or frequency to another voltage or frequency, to convert alternating current to direct current, or to convert direct current to alternating current. When an ac motor is used, it may be of either the induction or the synchronous type. The induction type has the advantages of low first cost and rugged construction. It may also be wound for voltages as high as 13,500 V. This will, in many cases, eliminate the necessity for transformers. This type has, however, poorer speed regulation and a lower power factor. A synchronous-motor drive is probably more frequently used for large-capacity installations than is the induction motor. The synchronous motor is inherently a constant-speed motor. Therefore, a more nearly constant voltage can be maintained at the generator terminals than by the use of an induction motor. The field of the synchronous motor may be overexcited. The motor then acts as a synchronous condenser, thus improving the power factor.

208. A synchronous converter (sometimes called a *rotary converter*) for converting alternating to direct current or vice versa consists (Fig. 7.109) of a dc motor equipped with slip rings. Taps are brought out from equidistant points on the armature winding and connected to these rings. As ordinarily used, the machine is then driven as a synchronous motor, by an alternating emf which is impressed on the armature through the slip rings. As the armature rotates, an alternating emf is induced in the armature winding, as in any dc generator. This alternating induced emf is rectified by the commutator and leaves the brushes as a pulsating or direct current. If a synchronous converter is utilized for converting alternating current to direct current, it is called a *direct converter*, or merely a converter. If it converts direct current to alternating current, it is called an *inverted converter*. If the main-pole flux distribution is such that the induced emf has a sine waveform (see Table 209 for values),

$$\frac{E_{ac}}{E_{dc}} = 0.707 \left(\sin \frac{180}{n} \right) \quad (6)$$

where E_{ac} = the effective alternating-current voltage, in volts between adjacent slip rings
 E_{dc} = the direct-current voltage, in volts
 n = the number of slip rings for a bipolar machine or the number of taps per pair of poles for a multipolar machine

FIGURE 7.109 Two-pole single-phase synchronous converter.

209. Ratio of the Effective AC to DC Voltage with Different Numbers of Taps

Number of taps per pair of poles	Number of phases	$\frac{E_{ac}}{E_{dc}}$ (between adjacent taps)	$\frac{E_{ac}}{E_{dc}}$ (line voltage)
2	1	0.707	0.707
3	3	0.612	0.612
4	4 or 2	0.500	0.707
6	6	0.354	$\left\{ \begin{array}{l} 0.707 \text{ (diametrical)} \\ 0.612 \text{ (double } \Delta) \end{array} \right\}$
12	12	0.183	

NOTE Synchronous converters are subject to hunting. The cause of hunting and the remedy are the same as for a synchronous motor.

210. The methods of starting a synchronous converter are (1) from its dc side as a shunt motor, (2) by means of an auxiliary motor mounted on its shaft, and (3), if polyphase, from its ac side as an induction motor. Whatever method is used, the armature must be brought up almost to synchronous speed before the load is applied to the generator.

211. Usual Relation among Number of Poles, Phases, Taps, and Slip Rings of a Synchronous Converter

Phases	2 pole		4 pole		6 pole		8 pole		12 pole	
	Slip rings	Taps	Slip rings	Taps	Slip rings	Taps	Slip rings	Taps	Slip rings	Taps
1	2	2	2	4	2	6	2	8	2	12
2	4	4	4	8	4	12	4	16	4	24
3	3	3	3	6	3	9	3	12	3	18
6	6	6	6	12	8	18	6	24	6	36

NOTE The tendency of modern practice in large three-phase conversion installations is to use a six-phase converter. It is connected to the three-phase line through a set of transformers.

212. The relation between the values of direct and alternating current of any synchronous converter is

$$I_{dc} = 0.354 \times I_{ac} \times n \times \text{power factor} \times \text{efficiency} \tag{7}$$

where I_{dc} = direct current, in amperes

I_{ac} = effective alternating current, in amperes

n is as given in Eq. (6)

213. A frequency-changer motor generator consists of an ac generator or generators driven by an induction or a synchronous motor or motors. The frequency of the generator is different from that of the motor. Since the speed regulation of the induction motor is inherently poorer, a synchronous driving motor is usually applied. The output frequency

of a set which is driven by a synchronous motor will vary only with the input frequency and not with the load. The synchronous motor can also be utilized for improving the power factor of the energy-supplying system. Since the motor and the generator are mounted on the same shaft and hence rotate at the same speed, the desired frequency change must be obtained by a proper ratio between the number of motor poles and the number of generator poles. The ratio between the frequency applied to the motor and the frequency which the generator will supply is exactly equal to the ratio between the number of poles on the motor and the number of poles on the generator. That is,

$$\frac{\text{Number of poles on motor}}{\text{Number of poles on generator}} = \frac{\text{frequency applied to motor}}{\text{frequency supplied by generator}} \quad (8)$$

For 60- to 25-Hz conversion this practically limits the speed to 300 rpm with 24 poles on the 60-Hz machine and 10 poles on the 25-Hz machine.

TROUBLES OF AC MOTORS AND GENERATORS: THEIR LOCALIZATION AND CORRECTION

214. Troubles of ac machinery. Much of the material under this heading is based on that in the book *Motor Troubles*, by E. B. Raymond.

215. Induction-motor troubles (H. M. Nichols, *Power and the Engineer*). The author asserts that the unsatisfactory operation of an induction motor may be due to either external or internal conditions. The voltage or the frequency may be wrong, or there may be an overload on the machine. Low voltage is the most frequent cause of trouble. The starting current sometimes amounts to twice the running current, with the result that the voltage is particularly low at starting. The best remedy for this disorder is larger transformers and larger motor leads, one or both. The troubles that occur most frequently within the motor itself are caused by faulty insulation and by an uneven air gap due to the springing of the motor shaft or to excessive wear in the bearings. If a wound-rotor machine refuses to start, the trouble may be due to an open circuit in the rotor winding. Most wound-rotor motors designed to employ a starting resistance will not start at all if the resistance is left out of the secondary circuit with the secondary circuit open. A short-circuited coil in the motor will make its existence known by local heating in the latter.

216. Troubles of ac generators (*Westinghouse Instruction Book*). The following causes may prevent ac generators from developing their normal emf:

1. The speed of the generator may be below normal.
2. The switchboard instruments may be incorrect, and the voltage may be higher than that indicated, or the current may be greater than is shown by the readings.
3. The voltage of the exciter may be low because its speed is below normal, its series field is reversed, or part of its shunt field is reversed or short-circuited.
4. The brushes of the exciter may be incorrectly set.
5. A part of the field rheostat or other unnecessary resistance may be in the field circuit.
6. The power factor of the load may be abnormally low.

217. Causes of shutdowns of induction motors. Sometimes there is trouble from blowing fuses. Or possibly, and more serious, the fuses do not blow, and the motor, perhaps humming loudly, comes to a standstill. Under these conditions the current may be 10 times normal, so that the heating effect, being increased as the square of the current or a hundredfold, causes the machine to burn out its insulation.

Since the torque, or turning power, of an induction motor is proportional to the square of the applied voltage (one-half voltage produces only one-quarter torque), it is evident that lowering the voltage has a decided effect upon the ability of the motor to carry load and may be the cause of its stopping. Another cause may be that the load on the motor more than equals its maximum output.

The bearings may have become worn, so that the air gap, which ordinarily is not much over 0.040 in (1 mm) and on small motors may be as small as 0.015 in (0.38 mm), has been gradually reduced at the lower side of the rotor to practically zero. The rotor commences to rub on the stator. The friction soon becomes so great that it is more than the motor can carry, and the motor shuts down.

A shutdown may be due to the bearings' introducing excessive friction. Hot bearings, in turn, may be due to excess of belt tension, dirt in the oil, oil rings not turning, or improper alignment of the motor to the machine that it drives. Under such conditions, ascertain whether the voltage has been normal, whether the air gap is such that the armature is free from the field, and whether the load imposed upon the motor is more than that for which it was designed. In any installation a system whereby an inspector will examine the gap, bearings, etc., periodically should be arranged.

Rarely, shutting down may be due to the working out of the starting switch, which may be located within the armature. Such a switch is operated by a lever engaging a collar that bears on contacts which, as they move inward, cut out the resistance that is in series with the rotor winding and is located within it.

If the short-circuiting brushes work back, introducing resistance into the armature circuit while the machine is trying to carry load, the machine will at once slow down and probably stop, usually burning out the starting resistance. Of course, this can occur only from faulty construction. The remedy is to fit the brushes properly so that they will not work out. It is well to inspect them at the time of air-gap inspection.

218. Low torque while starting induction motors. Even when the circuit to the motor is closed, it sometimes does not start. The same general laws of voltage, etc., apply to the motor at starting as when it is running. Hence, the points mentioned in Sec. 217 should be investigated and, if necessary, corrected. The resistance, which is frequently inserted in the armature, may be short-circuited, thus giving a low starting torque. To obtain a proper starting torque with a reasonable current with a wound-rotor motor, a resistance must be inserted in the rotor circuit. The resistance not only limits the current, which would be large with the motor standing still, but causes the current of the armature to assume a more effective phase relation, so that a far larger torque is obtained with the same current. A partial or complete short circuit of the resistance will reduce the starting torque.

219. Low maximum output of induction motors. The maximum load which a motor can carry may be less than desired or less than the nameplate indicates. This may be due to improper interconnection of the motor windings or to low line voltage. If the line voltage is considerably below the rated voltage of the motor, the maximum torque that the motor can develop may be so reduced that the motor will stall on small overloads. Many motors are designed for operation at two voltages, for example, 115/230 or 230/460. This is accomplished by dividing the stator winding into two parts. For operation on the low-voltage

rating, the two parts of the winding should be connected in parallel, while for operation on the high-voltage rating the two parts should be connected in series. Sometimes, when a motor is put in service on a supply which has a voltage corresponding to the low-voltage rating of the motor, the windings are connected in series. With this connection the motor would be operating at half rated voltage. This wrong connection will be indicated by the motor's starting very slowly or failing to start or by its stalling without overheating and without tripping the overcurrent devices.

220. Winding faults of induction motors. It sometimes happens that when an attempt is made to operate a new induction motor, although it will start, the currents are excessive and unbalanced, undue heating appears, or a peculiar noise is emitted, accompanied possibly by dimming of the lights on the same circuit and the lowering of speed, with perhaps an actual shutdown of other induction motors thereon. If, after examination, no difficulty is found with the air gap, belt tension, starting resistance, or bearings, the probabilities are that the coils of the motor have been wrongly connected or that the winding has been damaged during transportation. Certain indications of these conditions are shown by instrument readings. The winding faults in a three-phase motor may be:

1. One coil of the rotor may be open-circuited. The armature or the rotor may have a defective winding, just as may the stator.
2. Two coils or phases of the armature may be open-circuited.
3. The armature may be connected properly, but the stator coil or phase may be reversed.
4. Part of the stator may be short-circuited.
5. One phase of the stator may be open-circuited.

221. With an open circuit in the field or stator in a three-phase motor, the current would flow only in two legs. There would be no current in the other leg, and the motor would not start from rest with all switches closed. However, a three-phase or two-phase motor will run and do work single-phase if it is assisted in starting. The starting torque is zero, but as the speed increases, the torque increases.

With a small motor, giving a pull on the belt will introduce enough torque so that the motor will pick up its load. Therefore while an open circuit in the field winding should be found and repaired, if there is not time for repairs, the motor can be operated single-phase to about two-thirds of normal load. The power-factor conditions and effects on the rest of the circuit are practically no worse than when the motor is running three-phase. The torque of a 1-hp three-phase induction motor from rest to synchronism, when running single-phase, is indicated in Fig. 7.88.

222. Squirrel-cage armature or rotor troubles. Unusual operation due to reversals of phase, phases being open-circuited, and other causes occur with squirrel-cage armatures as well as with wound armatures. Poor soldering of the armature bars may be the cause. Sometimes a solder flux that will ensure proper operation for a while can be used, but time will develop poor electrical contacts because of chemical action at the joints. If the resistances of all the squirrel-cage joints are uniformly high, the effect is simply like that of an armature having a high resistance, which causes a lowering of the speed and local heating at the joints. If some of the joints are perfect but some bad, the motor may not have the ability to come up to speed, and there will be unbalanced currents.

223. Effects of unbalanced voltages on induction motors. The maximum output of a polyphase induction motor may be materially decreased if the voltages impressed on the different phases are unequal. On a three-phase system the three voltages between the legs 1–2, 2–3, and 1–3 should be approximately equal. Also on a two-phase system the voltage 1–2 should equal the voltage 3–4. If these voltages impressed on the induction motor are not equal, the maximum output of the motor as well as the current in the various legs is proportionately affected.

For example, with a two-phase motor, if the voltages in the two legs differ by 20 percent, a condition sometimes met in normal practice, the output of the motor may be reduced by 25 percent. Then, instead of being able to give its maximum output of, say, 150 percent for a few moments, it will give only 112 percent. The varying loads which the motor may have to carry may shut it down. In cases of low maximum output, the relative voltages on the various legs should always be investigated. If they vary, the trouble may be due to this variation.

In addition to the effect on the maximum output, the unequal distribution of current in a two-phase motor under such conditions may be quite serious. Consider a specific case of a 15-hp, six-pole, 1200-rpm, 230-V motor with the voltage on one leg 230 and the voltage on the other leg 180; current in leg 1 was 60 A and in leg 2 was 35 A at full load. The normal current at full load was 35 A. Thus the fuse might blow in the phase carrying the high current, causing the motor to run single-phase. If an attempt were made to start the motor, the blown fuse not being noticed, there would be no starting torque.

When unbalanced voltages are detected, make a careful check for a blown fuse. Often a service or feeder fuse will open and go undetected except for slight unbalanced line-to-line voltages. This occurs on installations such as sewer treatment plants, where some large pump, vacuum, or blower motors run continuously. If a “main” fuse opens while one of these motors is running, the motor itself generates the “third” phase, and other motors will start and run at reduced efficiency. If three-phase motors are protected by three overload relays, the large line current in one motor lead will cause the circuit to open. Accordingly, check for open fuses in the feeder or service switch if properly sized motor-overload devices trip out frequently.

If only two overload protective devices are provided for three-phase motors, the excessive current could be in the unprotected leg and cause a motor-winding failure.

If no fuses have been detected and unbalanced line-to-line voltages exist, check to see whether single-phase loads connected to the three-phase system are properly balanced.

After checking for open fuses and balanced single-phase loads, call the electric power company if unbalanced voltages appear on the line side of the main service switch.

224. Induction-motor starting-compensator troubles. Sometimes a mistake is made in the connections to the compensator, so that full voltage is used at starting and lesser voltage after throwing over the switch. Then the motor at starting takes excessive current, and since the maximum output is in proportion to the square of the voltage, the motor capacity is much reduced when it is apparently running in the operating position. Such action, therefore, can usually be accounted for by a wrong connection in the compensator. Sometimes a motor connected to a compensator takes more current at starting than it should; under this condition a lower tap should be tried. Compensators are usually supplied with various taps, and the one which produces the least disturbance on the line, giving at the same time the desired starting torque on the motor, should be selected.

When a motor, having been connected to a compensator, will not start, the cause may be entirely in the compensator. The compensator may have become open-circuited owing to a flash within. The switch may have become deranged so that it will not close, or a connection within the compensator may have loosened. Possibly, when a motor will not start when it is connected to a compensator just installed, one secondary coil of the compensator may be improperly interconnected.

225. Induction-motor collector-ring troubles. It is essential that the contact of the brushes on the collector rings be good; otherwise contact resistance will be so great as to slow the motor down and to cause heating of the collector itself. This effect is particularly noticeable when carbon brushes are used. The contact resistance of a carbon brush under normal operation pressure and carrying its usual density of current (40 A/in², or 6.2 A/cm²) is 0.04 Ω/in² (0.258 Ω/cm²). Thus, under normal conditions, the drop is 0.04 × 40, which equals 1.6 V. If the contact is only one-quarter of the surface, this drop would be 6.4 V and might materially affect the speed of the motor. Thus, if the speed is farther below synchronous speed than it should be, an investigation of the fit of the brush upon the collector may show up the trouble.

If copper brushes are used, this trouble is much less liable to occur, since the drop of the voltage due to contact resistance when running at normal density (150 A/in², or 23.25 A/cm²) is only one-tenth that of carbon. The same trouble may occur owing to the pigtail, which is generally used with carbon brushes, making poor contact with the carbon, which gives the same effect as a poor contact with the collector itself.

226. Improper end play in induction motors. Induction motors are so designed that the revolving parts will play endwise in the bearing, $\frac{1}{16}$ in (1.6 mm) or so. If in setting up the machine the bearings so limit this end action that the rotor does not lie exactly in the middle of the stator, a strong magnetic pull tends to center the rotor. If the bearings will not permit this centering, the thrust collars must take the extra thrust, which in an induction motor is considerable. If in addition to the magnetic thrust the belt pull is such as also to draw in the same direction, the trouble is increased. The end force may be such as to heat the bearing excessively and to cause cutting, soon rendering the motor inoperative.

In case of trouble with bearings, the end play should be tested by pushing against the shaft with a small piece of wood, placed on the shaft center. With the machine operating under normal conditions there should be no particular difficulty in pushing the shaft first one way from one side and then the other way from the other side. If it is found that the revolving part is hugging closely against one side, the trouble can be corrected either by pressing the spider along the shaft in a direction toward which the hugging is occurring or by driving the tops of the lamination teeth in the same direction. With a wooden wedge the tops of the teeth can often be driven over $\frac{1}{8}$ to $\frac{3}{16}$ in (3.2 to 4.8 mm) without any difficulty. This movement will usually correct the trouble. Driving the teeth of the stator $\frac{1}{8}$ in or so in the opposite direction to that of the end thrust will usually accomplish the same result. It is best to choose the teeth (stator or rotor) which are most easily driven over. The thin, long ones move more easily than do the short, broad ones.

227. Oil leakage of induction motors. Sometimes a bearing will permit oil to be drawn out, perhaps a very little at a time. Ultimately enough will accumulate to show on the outside or on the windings of the machine. Although a motor will run for a period with its windings wet with ordinary lubricating oil without apparently being injured, insulation soaked with oil will deteriorate and eventually fail.

FIGURE 7.110 Grooves to prevent oil leakage.

One of the principal causes is a suction of the oil due to the drafts of air from the rotor, and one of the best methods of stopping the trouble, under ordinary conditions, is to cut grooves as shown in Fig. 7.110 at B and D. These grooves on a 50-hp motor may be $\frac{1}{8}$ in

(3.2 mm) deep and $\frac{3}{16}$ in (4.8 mm) wide. Each groove has three holes drilled through the bearing shell to convey the oil collected by the grooves into the oil well. These grooves are just as effective with a split as with a solid bearing. It is impossible here to discuss the various causes of oil leakage. The grooves as suggested are a general remedy and cover many cases.

228. General summary of synchronous-motor troubles. Failure of a synchronous motor to start is often due to faulty connections in the auxiliary apparatus. This should be carefully inspected for open circuits or poor connections. An open circuit in one phase of the motor itself or a short circuit will prevent the motor from starting. Most synchronous motors are provided with an ammeter in each phase so that the last two causes can be determined from their indications: no current in one phase in case of an open circuit and excessive current in case of a short circuit. Either condition will usually be accompanied by a decided buzzing noise, and a short-circuited coil will often be quickly burned out. The effect of a short circuit is sometimes caused by two grounds on the machine.

Starting troubles should never be assumed until there has been a trial to start the motor light, i.e., with no load except its own friction. It may be that the starting load is too great for the motor.

If the motor starts but fails to develop sufficient torque to carry its load when the field circuit has been closed, the trouble will usually be found in the field circuit. First, determine whether or not the exciter is giving its normal voltage. If the exciter voltage is assumed to be correct, the trouble will probably be due to one of the following causes: (1) open circuit in the field winding or rheostat or (2) short circuit or reversal of one or more of the field spots. An open circuit can often be located by inspection or by use of a magnet.

Most field troubles are caused by excessive induced voltage at the start or by a break in the field circuit. Excessive voltage may break down the insulation between field winding and frame or between turns on any one field spool, thus short-circuiting one or more turns, or it may even burn the field conductor off, causing an open circuit.

Causes of overheating in synchronous motors are about the same as those in ac generators. Probably the most common cause of overheating is excessive armature current due to an attempt to make the motor carry its rated load and at the same time compensate for a power factor lower than that for which it was designed. If the motor is not correcting a low power factor but doing mechanical work only, the field current should be adjusted so that the armature current is minimum for the average load that the motor carries.

229. Difficulties in starting synchronous motors. A synchronous motor starts as an induction motor. The starting torque, as in an induction motor, is proportional to the square of the applied voltage. For example, if the voltage is halved, the starting effort is quartered. When a synchronous motor will not start, the cause may be that the voltage on the line has been pulled below the value necessary for starting. In general, at least half voltage is required to start a synchronous motor.

Difficulty in starting may also be caused by an open circuit in one of the lines to the motor. Assume the motor to be three-phase. If one of the lines is open, the motor becomes single-phase, and no single-phase synchronous motor, as such, is self-starting. The motor therefore will not start and will soon get hot. The same condition is true of a two-phase motor if one of the phases is open-circuited.

Difficulty in starting may be due to a rather slight increase in static friction. It may be that the bearings are too tight, perhaps from cutting during the previous run. Excessive belt tension, if the synchronous motor is belted to its load, or any cause which increases starting friction will probably give trouble. Difficulty in starting may be due to field excitation

on the motor. After excitation exceeds one-quarter of normal value, the starting torque is influenced. With full field on, most synchronous motors will not start at all. The field should be short-circuited through a proper resistance during the starting period.

Usually compensators are used for starting synchronous motors. If there is a reversed phase in a compensator or if the windings of the armature of the synchronous motor are connected incorrectly, there will be little starting torque. Incorrect connection can be located by noting the unbalanced entering current. Readings to determine this unbalancing should be taken with the armature revolving slowly. The revolving can be effected by any mechanical means. While the motor is standing still, even with correct connections, the armature currents of the three phases usually differ somewhat. This is due to the position of the poles in relation to the armature, but when the armature is revolving slowly, the currents should average up. If the rotor cannot be revolved mechanically, similar points on each phase of the armature must be found. Then when the rotor is set successively at these points, the currents at each setting should be the same. Each phase, when located in a certain specific position as related to a pole, should, with right connections, take a certain specific current. With wrong connections the currents will not be the same.

230. Open circuit in the field of a synchronous motor. If in the operation of a synchronous motor the field current breaks for any reason, the armature current will appreciably increase, causing either a shutdown or excessive heat. It becomes important therefore in synchronous motors to have the field circuit permanently established.

231. Short circuit in an armature coil of a synchronous motor. A short circuit in an armature coil of a synchronous motor burns it out completely, charring it down to the bare copper. When this occurs, the symptoms are so evident that there is no difficulty in identifying the trouble. Under ordinary circumstances such a coil may be cut out and operation continued. In an induction motor, the current in the short-circuited coil rises only to a certain value but heats it many times more than normal. It is not necessarily burned out immediately, and perhaps it may not be burned out at all.

232. Hunting of synchronous motors. Synchronous motors served by certain primary sources of energy tend to hunt. The periodicity of the swinging is determined by properties of the armature and the circuit. It may reach a certain magnitude and there stick, or the swinging may increase until finally the motor breaks down altogether. This trouble usually occurs on long lines having considerable resistance between the source of energy and the synchronous motor. Sometimes it occurs under the most favorable conditions. Irregular rotation of a prime mover, such as a single-cylinder steam engine, is often responsible for the trouble. The usual remedy is to apply to the poles bridges of copper or brass in which currents are induced by the wavering of the armature. These currents tend to stop the motion. Different companies use different forms of bridges. When hunting or pulsating occurs and the motor is not already equipped with bridges, it is best to consult the manufacturer. In general, the weaker the field on a synchronous motor, the less the pulsation. Sometimes pulsations may be so reduced that no trouble results, simply by running with a somewhat weaker field current.

233. Improper armature connections in synchronous motors. This trouble usually manifests itself by unbalanced entering currents and by a negligible or very low starting torque. The circuits should be traced out and the connections remade until the three entering currents for three-phase or the two entering currents for two-phase are approximately

equal. These currents will not be equal even with correct connection when the armature is standing still.

234. Bearing troubles of synchronous motors are similar to those of induction motors. A difference is that with a synchronous motor the air gap between the revolving element and the poles is relatively large, so that the wearing of the bearing, which throws the armature out of center, is not so serious as with an induction motor. End play should be treated in the same way as with an induction motor.

235. Collector rings and brushes. One of the most common sources of trouble with synchronous motors is sparking at the collector rings. Much of this trouble is due to the lack of proper care. The collector rings are one of the most important parts of the machine, and they should be frequently inspected.

Any black spots that appear on the surface of the collector should be removed by rubbing lightly with fine sandpaper the first time that the machine is shut down. It is very important that this be done because although these spots are not serious in themselves, they will lead to pitting of the rings and the necessity of regrinding. However, no harm is done to the rings if the condition is corrected at once.

Sometimes an imprint of the brushes will be found on the surface of the collectors. This may occur on a machine which is subjected to moisture or acid fumes which will act on the surface of the ring. In case the machine is shut down for any length of time, the fumes will act upon the surface of the ring except where it is in contact with the brushes. The surface of the ring will be slightly high at this point. This causes the brush to jump slightly and arc and thus burn its imprint on the ring.

In such an installation it is a good practice for the operator, when shutting down the machine, to apply a little paraffin to the rings as the motor comes to a stop and while they are still warm. In general, rings give better service when the motor is run continuously than when it is shut down part of the time.

Another cause of brush imprint on the rings is a slight imbalance in the rotor, which causes a jerk or movement in the rings once every revolution. This results in jumping of the brush, with a consequent small arc, which in time burns an imprint of the brush on the ring.

Brush imprints due to fumes will occur at any point where the motor happens to stop. Imprints due to a rotor imbalance will always occur at the same place on the ring relative to the rotor.

Since there is always an electrolytic action on the surface of an iron ring, the collector operation is improved by occasionally reversing the polarity of the rings. Sometimes trouble will occur on one ring only, and by reversing the polarity every day or so the trouble will entirely disappear.

Occasionally ring trouble will arise from a ring not being of uniform hardness, so that it wears unevenly. Such a ring should be replaced. Small pinholes in the surface of a cast-iron ring will not cause trouble.

236. Bearing troubles of motors and generators. Modern generators and motors have self-oiling bearings. These should be filled to such a height that the rings will carry sufficient oil upon the shaft. If the bearings are too full, oil will be thrown out along the shaft. Watch the bearings carefully from the time at which the machine is first started until the bearings are warmed up; then note the oil level. The expansion of the oil due to heat and foaming raises the level considerably during that time. The oil should be renewed about once in 6 months or oftener if it becomes dirty or causes the bearings to heat.

The bearings must be kept clean and free from dirt. They should be examined frequently to see that the oil supply is properly maintained and that the oil rings do not stick. Use only the best quality of oil. New oil should be run through a strainer if it appears to contain any foreign substances. If the oil is used a second time, it should first be filtered and, if warm, allowed to cool. If a bearing becomes hot, first feed heavy lubricant copiously, loosen the nuts on the bearing cap, and then, if the machine is belt-connected, slacken the belt. If no relief is afforded by these means, shut down, keeping the machine running slowly until the shaft is cool so that the bearing may not "freeze." Renew the oil supply before starting again. A new machine should always be run at a slow speed for an hour or so to see that it operates properly. The bearings should be inspected at regular intervals to ensure that they always remain in good condition. The higher the speed, the greater the care to be taken in this regard.

A warm bearing, or "hot box," is probably due to one of the following causes: (1) excessive belt tension, (2) failure of the oil rings to revolve with the shaft, (3) rough bearing surface, and (4) improper lining up of bearings or fitting of the journal boxes.

CARE OF MOTORS*

237. Modern methods of design and construction have made the electric motor one of the least complicated and most dependable forms of machinery in existence and have thereby made the matter of its maintenance one of comparative simplicity. This statement should not, however, be taken to mean that proper maintenance is not important; on the contrary, it must be given careful consideration if the best performance and longest life are to be expected from the motor. The two major features, from the standpoint of their effect upon the general performance of the motor, are those of proper lubrication and the care given to insulation, because they concern the most vital, and probably the most vulnerable, parts of the machine.

238. Lubrication. The designs of bearings and bearing housings of motors have been remarkably improved. The bearings of modern motors, whether sleeve, ball, or roller, require infrequent attention. This advance in the art is not yet fully appreciated, for although there may have been some necessity for more frequent attention in the case of older designs with housings less tight than on modern machines, oiling and greasing of new motors are quite often entrusted to uninformed and careless attendants, with the result that oil or grease is copiously and frequently applied to the outside as well as the inside of bearing housings. Some of the excess lubricant is carried into the machine and lodges on the windings, where it catches dirt and thereby hastens the ultimate failure of the insulation.

Modern designs provide for a plentiful supply of oil or grease being held in dusttight and oiltight housings. If the proper amount of a suitable lubricant is applied before starting, there should be no need to refill the housings for several months even in dusty places. Infrequent though periodic and reasonable attention to modern bearings of any type will tend to ensure longer life of both bearings and insulation.

239. Greasing ball bearings. Only a high grade of grease, having the following general characteristics, should be used for ball-bearing lubrication:

*Courtesy of General Electric Co.

1. Consistency a little stiffer than that of Vaseline, maintained over the operating-temperature range
2. Melting point preferably over 150°C
3. Freedom from separation of oil and soap under operating and storage conditions
4. Freedom from abrasive matter, acid, and alkali

In greasing a motor, care must be taken not to add too large a quantity of grease, as this will cause too high an operating temperature with resulting expansion and leaking of the grease, especially with large bearings operated at slow speeds.

1. **Pressure-Relief Systems.** The following procedure is recommended for greasing ball-bearing motors equipped with a pressure-relief greasing system:

Make sure, by wiping clean the pressure-gun fitting, bearing housing, and relief plug, that no dirt gets into the bearing with the grease. Always remove the relief plug from the bottom of the bearing before using the grease gun. This prevents putting excessive pressure inside the bearing housing. Excessive pressure might rupture the bearing seals.

With a clean screwdriver or similar tool, free the relief hole of any hardened grease, so that any excess grease will run freely from the bearing. With the motor running, add grease with a hand-operated pressure gun until it begins to flow from the relief hole. This tends to purge the housing of old grease. If it might prove dangerous to lubricate the motor while it is running, follow the procedure with the motor at a standstill.

Allow the motor to run long enough after adding grease to permit the rotating parts of the bearing to expel all excess grease from the housing. This very important step prevents overgreasing the bearing. Stop the motor and replace the relief plug tightly with a wrench.

2. **Other Types.** A motor that is not equipped with the pressure-gun fitting and relief plug on the bearing housing cannot be greased by the procedures described. Under average operating conditions, the grease with which the bearing housings of these motors were packed before leaving the factory is sufficient to last approximately 1 year. When the first year of service has elapsed and once a year thereafter (or oftener if conditions warrant), the old grease should be removed and the bearings supplied with new grease. To do this, disassemble the bearing housings and clean the inside of the housings and housing plates or caps and the bearings with a suitable solvent. When they have been thoroughly cleansed of old grease, reassemble all parts except the outer plates or caps.

Apply new grease, either by hand or from a tube, over and between the balls. The amount of grease to be used varies with the type and frame size of the particular motor. The instruction sheet that accompanied the motor should be consulted for this information.

The addition of the correct amount of grease fills the bearing housing one-third to one-half full. More than the amount specified must not be used. When the motor is reassembled, any V grooves that are found in the housing lip should be refilled with grease (preferably a fibrous, high-temperature-sealing grease) which will act as an additional protective seal against the entrance of dirt or foreign particles.

240. The technique for greasing motors equipped with roller bearings is very similar to that used for ball bearings. Specific instructions for the individual design should be followed, however, because more frequent greasing or slight changes in technique may sometimes be necessary.

241. Oiling sleeve bearings. The oil level in sleeve-bearing housings should be checked periodically with the motor stopped. If the motor is equipped with an oil-filler gage, the gage should be approximately three-quarters full at all times.

If the oil is dirty, drain it off by removing the drain plug, which is usually located in the bottom or side of the bearing housing. Then flush the bearing with clean oil until the outcoming oil is clean.

In fractional-horsepower motors, there may be no means of checking oil level, as all the oil may be held in the waste packing. In such cases, a good general rule for normal motor service is to add 30 to 70 drops of oil at the end of the first year and to reoil at the end of each subsequent 1000 h of motor operation.

Most fractional-horsepower motors built today require lubrication about once a year. Small fan and agitator motors will often require more frequent lubrication, with 3-month intervals between oilings.

242. Cleaning Bearings

Sleeve Bearings. Sleeve-bearing housings are provided with liberal settling chambers into which dust, dirt, and oil sludge collect. The only cleaning necessary is to remove the drain plug and drain the oil, which will flush out most of the settled material with it.

Whenever the motor is disassembled for general cleaning, the bearing housing should be washed out with a solvent. Before being assembled, the bearing lining should be dried and the shaft covered with a film of oil.

Ball Bearings. The pressure-relief method of greasing motors, described above, tends to purge the bearing housing of used grease. Complete cleaning of bearings, therefore, is required at infrequent intervals only. For a thorough and convenient flushing when the bearings are not disassembled, the following method is recommended.

1. Wipe clean the housing, pressure-gun, and relief fittings, and then remove the fittings. Every care should be taken to keep dirt out of the bearings. Once in a bearing, a bit of abrasive may not be removed even with the most thorough cleaning. Afterward, it may become dislodged and get between the bearing surfaces with subsequent serious results.
2. With a clean screwdriver or a similar tool, free the pressure-fitting hole in the top of the bearing housing of hardened grease. Also free the relief-plug hole in the bottom of the housing of old grease to permit easy expulsion of the old grease during the cleaning process after the solvent has been added.
3. Fill a syringe with any suitable modern grease solvent, and inject some of it into the bearing housing through the pressure-fitting hole while the motor is running. As the grease becomes thinned by the solvent, it will drain out through the relief hole. Continue to add solvent until it drains out quite clear.
4. Replace the relief plug and inject solvent until it can be seen splashing in the filling hole. Allow the solvent to churn for a few minutes, and then remove the relief plug and drain off the solvent. Repeat the churning operation until the solvent runs clean.
5. When using any type of solvent for flushing, replace the relief plug and inject a small amount of light lubricating oil. Allow it to churn for a minute or two before draining off. This will flush out the solvent. To complete the job, grease the bearing, using the method previously described.

This method permits the cleaning of all standard motors operating at an angle not exceeding 15° from the horizontal, except totally enclosed, fan-cooled motors. For these

motors, the bearing at the pulley end can be flushed as described. To clean the fan-end bearing, first remove the fan cover and fan to make the drain plug at the bottom of the housing accessible.

243. Care of insulation. Motors should be stored in a dry, clean place until ready for installation. Heat should be supplied, especially for larger high-voltage machines, to protect them against alternate freezing and thawing. This advice is equally applicable to spare coils.

Motors that have been long in transit in a moist atmosphere or have been idle for an extended period without heat to prevent the accumulation of moisture should be thoroughly dried out before being placed in service. Machines may also become wet by accident, or they may sweat as a result of a difference in their temperature and that of the surrounding air, just as cold water pipes sweat in a warm, humid atmosphere. This condition is, of course, very injurious and should be prevented, particularly in the case of large or important motors, by keeping them slightly warm at all times. Current at a low voltage can be passed through the windings, electric heaters can be used, or even steam pipes can be utilized for protective purposes. During extended idle periods, tarpaulins can be stretched over the motor, and a small heater put inside to maintain the proper temperature.

244. Drying out. If a motor has become wet from any cause whatever, it should be dried out thoroughly before being operated again. The most effective method is to pass current through the windings, using a voltage low enough to be safe for the winding in its moist condition. For 2300-V motors, 230 V is usually satisfactory for circulating this drying-out current. Thermometers should be placed on the windings to see that they are being heated uniformly. Temperatures should not exceed 90°C (Class A insulation). Applying the heat internally in this manner drives out all moisture and is particularly effective on high-voltage motors, in which the insulation is comparatively thick.

Heat can be applied externally by placing heating units around or in the machine, covering the whole with canvas or other covering and leaving a vent at the top to permit the escape of moisture. In doing this it is essential that warm air circulate over all the surfaces to be dried. The air should be allowed to escape as soon as it has absorbed moisture. Therefore, the heaters should be so placed and baffles so arranged as to get a natural draft, or small fans can be used to force circulation. Twelve-inch (0.3-m) fans set to blow air across the fronts of glow heaters and then into the lower part of a machine from opposite sides, and so on up around the windings and out the top, will produce excellent results. The temperature of the winding should not be allowed to exceed 100°C for Class A-insulated motors. Smaller machines can conveniently be placed in ovens, the same temperature limits being observed.

245. Insulation-resistance tests. The time required for complete drying out depends considerably on the size and voltage of the motor. Insulation-resistance measurements should be taken at intervals of 4 or 5 h until a fairly constant value is reached. This value should at least equal the recommended Institute of Electrical and Electronic Engineers standard, which is

$$\text{Megohms} = \frac{\text{voltage}}{\text{kVA}/100 + 1000} \quad (9)$$

The insulation resistance of dry motors in good condition is considerably higher than this value.

The more convenient way to measure this resistance is through the use of a megohmmeter, although if a 500-V dc source is available, readings can be taken with a voltmeter. The ungrounded side of the system should be connected to all the motor terminals through the voltmeter, the opposite or grounded side being connected directly to the motor frame. The insulation resistance is found by the method of Sec. 177 of Div. 1.

When the voltmeter method is used, the connection to the frame should always be made through a fuse of not more than 10 A in size. The circuit should be tested, and the side showing a complete or partial ground then connected to the frame through the fuse.

Obviously, the insulation resistance varies over a wide range, depending upon moisture, temperature, cleanliness, etc., but it is a good indication of the general condition of the insulation and its ability to stand the operating voltage. Such readings should be taken before a high-potential test to determine whether the insulation is ready for such a test and afterward to make sure that the high potential has not injured the insulation.

246. High-voltage tests. High-voltage tests should be made after drying out or after repairs to determine the dielectric strength of the insulation. New windings should successfully stand a high-potential 50–60 Hz test of twice the normal voltage plus 1000. There is some disagreement as to the proper value to use for motors that have been in operation for some time, but it is reasonable to assume that after thorough cleaning and drying the winding of a used motor should stand 150 percent of normal voltage for 1 min. Small high-potential testing sets are available for such work and are of such capacity that very little damage will result from a breakdown during a test.

247. Periodic inspection. A systematic and periodic inspection of motors is necessary to ensure best operation. Of course, some machines are installed where conditions are ideal and dust, dirt, and moisture are not present to an appreciable degree, but most motors are located where some sort of dirt accumulates in the windings, lowering the insulation resistance and cutting down creepage distance. Steel-mill dusts are usually highly conductive, if not abrasive, and lessen creepage distances. Other dusts are highly abrasive and actually cut the insulation while being carried through by the ventilating air. Fine cast-iron dust quickly penetrates most insulating materials. Hence the desirability of cleaning motors periodically. If conditions are extremely severe, open motors might require a certain amount of cleaning each day. For less severe conditions, weekly inspection and partial cleaning are desirable. Most machines require a complete overhauling and thorough cleaning about once a year.

For the weekly cleaning, the motor should be blown out, using moderate-pressure, dry, compressed air of about 25 to 30 psi (172,369 to 206,843 Pa) pressure. If conducting and abrasive dusts are present, even lower pressure may be necessary, and suction is to be preferred, as damage can easily be caused by blowing the dust and metal chips into the insulation. On most dc motors and large ac motors the windings are usually fairly accessible, and the air can be properly directed to prevent such damage. On the larger ac machines the air ducts should be blown out so that the ventilating air can pass through as intended.

On large machines insulation-resistance readings should be taken in the manner indicated above. As long as the readings are consistent, the condition of the insulation would ordinarily be considered good. Low readings would indicate increased current leakage to ground or to other conductors, owing to one of perhaps several causes, such as deteriorated insulation, moisture, dirty or corroded terminals, etc.

Inspection and servicing should be systematic. Frequency of inspection and degree of thoroughness may vary and must be determined by the maintenance engineer. They will be governed by (1) the importance of the motors in the production scheme (If the motor fails,

will production be slowed seriously?), (2) percentage of the day in which the motor operates, (3) the nature of the service, and (4) the environment.

An inspection schedule must therefore be elastic and adapted to the needs of each plant. The following schedule, covering both ac and dc motors, is based on average conditions insofar as dust and dirt are concerned.

Every Week

1. Examine commutator and brushes.
2. Check oil level in bearings.
3. See that oil rings turn with the shaft.
4. See that the shaft is free of oil and grease from bearings.
5. Examine starter, switch, fuses, and other controls.
6. Start motor and see that it is brought up to speed in normal time.

Every Six Months

1. Clean motor thoroughly, blowing out dirt from windings, and wipe commutator and brushes.
2. Inspect commutator clamping ring.
3. Check brushes and renew any that are more than half worn.
4. Examine brush holders and clean them if dirty. Make sure that brushes ride free in the holders.
5. Check brush pressure.
6. Check brush position.
7. Drain, wash out, and renew oil in sleeve bearings.
8. Check grease in ball or roller bearings.
9. Check operating speed or speeds.
10. See that the end play of the shaft is normal.
11. Inspect and tighten connections on the motor and control.
12. Check current input and compare with normal input.
13. Run the motor and examine the drive critically for smooth running, absence of vibration, and worn gears, chains, or belts.
14. Check motor foot bolts, end-shield bolts, pulley, coupling, gear and journal set-screws, and keys.
15. See that all covers, belt, and gear guards are in good order, in place, and securely fastened.

Once a Year

1. Clean out and renew grease in ball- or roller-bearing housings.
2. Test insulation by a megohmmeter.
3. Check the air gap.
4. Clean out magnetic dirt that may be hanging on poles.
5. Check clearance between the shaft and journal boxes of sleeve-bearing motors to prevent operation with worn bearings.

6. Clean out undercut slots in the commutator.
7. Examine connections of the commutator and armature coils.
8. Inspect armature bands.

247A. Records. Maintenance persons should have a record card for every motor in the plant. All repair work, with the cost, and every inspection can be entered on the record. In this way, excessive attention or expense will show up, and the causes can be determined and corrected.

Inspection records will also serve as a guide to tell when motors should be replaced because of the high cost to keep them operating. Misapplications, poor drive engineering, and the like will also be disclosed.

248. Brush inspection. The first essential for satisfactory operation of brushes is free movement of the brushes in their holders. Uniform brush pressure is necessary to assure equal current distribution. Adjustment of brush holders should be set so that the face of the holder is approximately $\frac{1}{8}$ in (3.175 mm) up from the commutator; any distance greater than this will cause brushes to wedge, resulting in chattering and excessive sparking.

Check the brushes to make sure that they will *not* wear down too far before the next inspection. Keep an extra set of brushes available so that replacements can be made when needed. Sand in new brushes, and run the motor without load as long as possible.

It is false economy to use brushes down to the absolute minimum length before replacement. There have been cases in which brushes wore down until the metal where the pigtail connects to the brush touched the commutator. This, of course, caused severe damage to the commutator.

Make sure that each brush surface in contact with the commutator has the polished finish that indicates good contact and that the polish covers all this surface of the brush. Check the freedom of motion of each brush in the brush holder.

When replacing a brush, be sure to put it in the same brush holder and in its original position. It has been found helpful to scratch a mark on one side of the brush when removing it so that it will be replaced properly.

Check the springs that hold the brushes against the commutator. Improper spring pressure may lead to commutator wear and excessive sparking. Excessive heating may have annealed the springs, in which case they should be replaced and the cause of heating corrected. Larger motors have means for adjusting the spring pressure, which should be 2 to $2\frac{1}{2}$ psi (13,790 to 17,237 Pa) of area of brush contact with the commutator.

249. Commutator inspection. Inspect the commutator for color and condition. It should be clean, smooth, and a polished brown color where the brushes ride on it. A bluish color indicates overheating of the commutator.

Roughness of the commutator should be removed by sandpapering or stoning. Never use emery cloth or an emery stone. For this operation, run the motor without load. If sandpaper is used, wrap it partly around a wood block. The stone is essentially a piece of grindstone, known to the trade as a commutator stone. Press the stone or sandpaper against the commutator with moderate pressure with the motor running without load, and move it back and forth across the commutator surface. *Use care not to come in contact with live parts.*

If the armature is very rough, it should be taken out and the commutator turned down in a lathe. When this is done, it is usually necessary to cut back the insulation between the

commutator bars slightly. After the commutator has been turned down, the brushes should be sanded and run in as described previously. This is not necessary after light sandpapering or stoning.

250. Cleaning. About once a year or oftener if conditions warrant, motors should be cleaned thoroughly. Smaller motors, the windings of which are not particularly accessible, should be taken apart.

First, the heavy dirt and grease should be removed with a heavy, stiff brush, wooden or fiber scrapers, and cloths. Rifle-cleaning bristle brushes can be used in the air ducts. Dry dust and dirt may be blown off, using dry compressed air at moderate pressure, for example, 25 to 50 psi (172,369 to 344,738 Pa) pressure at the point of application, taking care to below the dirt out from the winding. As stated before, if the dirt and dust are metallic, conducting, or abrasive, air pressure may drive the material into the insulation and damage it. Hence, for such conditions pressure is not so satisfactory as a suction system. If compressed air at low pressure is used, care must be taken to direct it properly so that the dust will not cause damage and will not be pocketed in the various corners.

Grease, oil, and sticky dirt are easily removed by applying cleaning liquids specifically designed for purpose. Any of these liquids evaporate quickly and, if not applied too generously, will not soak or injure the insulation.

If one of the other liquids must be used, it should be applied outdoors or in a well-ventilated room. It must be remembered that gasoline or naphtha vapor is heavier than air and will flow into pits, basements, etc., and may remain there for hours or even days. The casual smoker or a spark from a hammer or chisel or even from a shoe nail may cause a serious explosion. Therefore, proper ventilation of the room is essential and may require specially piped ventilating fans. The use of carbon tetrachloride obviates the explosion hazard, but some ventilation is required to remove the vapor, which might affect the safety and comfort of the workers.

There are several good methods of applying the cleansing liquid. A cloth, saturated in the liquid, can be used to wipe the coils. A paintbrush, dipped in the liquid container, is handy to get into the corners and crevices and between small coils. Care should be taken not to soak the insulation, as would be the case if coils or small machines were dipped into the liquid.

Probably the best method of applying the liquid is to spray it on. A spray gun, paint-spraying appliance, or an ordinary blowtorch is often used with good results, although the last device is likely to give a heavier spray than desirable. An atomizer will give excellent results using a pressure of about 80 psi (551,581 Pa) if the insulation is in good condition or 40 to 50 psi (275,790 to 344,738 Pa) if the insulation is old. The atomizer should be held not more than 5 or 6 in (127 or 152 mm) away from the coils.

Although the insulation will dry quickly at ordinary room temperature after such cleaning methods, it is highly desirable to heat it to drive off all moisture before applying varnish. This heating or drying-out process has already been discussed and therefore need only be mentioned here.

If the motor can be spared from service long enough, the insulation should be dried out by heating to from 90 to 100°C. While the motor is warm, a high-grade insulating varnish should be applied. For severe acid, alkali, or moisture conditions, a black plastic baking varnish or epoxy resin is best. If oil or dusts are present, a clear or yellow varnish or epoxy resin should be used.

The varnish may be sprayed or brushed on. For small stators or rotors, it is best to dip the windings into the varnish, cleaning off the adjacent metal parts afterward by using a solvent of the varnish. After applying the varnish, the best results are obtained by baking for 6 to 7 h at about 100°C. Experience with particular conditions of operation or the condition

of the insulation may indicate the desirability of applying a second coat of the same varnish, followed again by 6 to 7 h of baking at 100°C.

If the machine must be put back in service quickly or if facilities are not available for baking, fairly good results will be obtained by applying one of the quick-drying black or clear varnishes which dry in a few hours at ordinary room temperature.

Insulation-resistance readings should be taken, as explained previously, to determine whether the winding is in satisfactory condition for applying a high-potential test. After this test, it is a good practice to run the motor without load for a short time to make certain that everything has been connected, assembled, and adjusted properly.

Motors should generally be given an overhauling at intervals of 5 years or so normally or, if the service is more severe, more frequently. This practice is beneficial in avoiding breakdowns and in extending the useful life of the equipment. When periodic overhauling is practiced, the following advice may be helpful:

1. Check the motor air gap, between stator and rotor, with feelers for uniformity. Too little clearance at the bottom may indicate worn bearings.
2. Take the motor apart and inspect it thoroughly. Measurement of the bearings and journals may disclose a need for new bearing linings. Remove the waste from waste-packed bearings and rearrange or replace it so that any glaze on the wool is removed from its point of contact with the shaft. Any gummy deposit on the wool should be replaced. All lubricant should be cleaned out of the bearings, and a fresh supply put in when the motor is reassembled.
3. The rotors should be cleaned with a solvent to remove any accumulated dirt, after which any rust should be removed with fine sandpaper (not emery paper). When clean and dry, the rotors should be coated with a good grade of clear varnish or lacquer to protect them from moisture. To prevent injury to the bearings, they should be completely protected with a clean rag when the motor is disassembled.
4. The rotors of wound-rotor motors should be given the same treatment as the stators. In addition, soldered joints and binding cords should be inspected and any weakness remedied.
5. The stator bore should be cleaned of dirt with a solvent, and any rust should be removed with fine sandpaper (not emery paper). Care should be taken during this operation not to damage the top sticks or end turns of the stator winding. When the stator bore has dried, any remaining dirt in the bore should be wiped out with a cloth or brushed out with a soft brush. A hand bellows or dry compressed air at low pressure may also be employed.

CONTROL EQUIPMENT FOR MOTORS

251. Electric Controller Terminology

Ambient Temperature. The temperature of the medium such as air, water, or earth into which the heat of the equipment is dissipated. For self-ventilated equipment, the ambient temperature is the average* temperature of the air in the immediate neighborhood of the equipment. For air- or gas-cooled equipment with forced ventilation or secondary water cooling, the ambient temperature is taken as that of the ingoing air or cooling gas. For self-ventilated enclosed (including oil-immersed) equipment considered as a complete unit, the ambient temperature is the average* temperature of the air outside the enclosure in the immediate neighborhood of the equipment.

*The average of temperature readings at several locations.

Apparatus. A term said to describe the enclosure, the enclosed equipment, and attached appurtenances.

Auxiliary Contacts of a Switching Device. Those contacts which, in addition to the main-circuit contacts, function with the movement of the latter.

Combination Controller. A full magnetic or semimagnetic controller with additional externally operable disconnecting means contained in a common enclosure. The disconnecting means may be a circuit breaker or a disconnect switch. Combination starters are specific forms of combination controllers.

Contactors. A two-state (on-off) device for repeatedly establishing and interrupting an electric power circuit. Interruption is obtained by introducing a gap or a very large impedance.

Continuous Duty. A duty that demands operation at substantially constant load for an indefinitely long time.

Control Circuit of a Control Apparatus or System. That circuit which carries the electric signals directing the performance of the controller but does not carry the main power circuit.

Drum Controller. An electric controller that utilizes a drum switch as the main switching element.

Drum Switch. A switch in which the electric contacts are made by segments or surfaces on the periphery of a rotating cylinder or sector or by the operation of a rotating cam.

Duty (of a Controller). A requirement of service that defines the degree of regularity of the load. The frequency and length of time of operation and rest must be specified.

Electric Controller. A device or group of devices which serves to govern in some predetermined manner the electric power delivered to the apparatus to which it is connected. The term *controller* does not apply to a simple disconnecting means whose primary purpose in a motor circuit is to disconnect the circuit, together with the motor and its controller, from the source of power.

Full-Magnetic Controller. An electric controller having all its basic functions performed by devices that are operated by electromagnets.

General-Use Switch. A switch which is intended for use in general distribution and branch circuits. It is rated in amperes and is capable of interrupting the rated current at the rated voltage.

Intermittent Duty. A requirement of service that demands operation for alternate periods of (1) load and no load, (2) load and rest, or (3) load, no load, and rest, such alternate intervals being definitely specified.

Isolating Switch. A switch intended for isolating an electric circuit from the source of power. It has no interrupting rating, and it is intended to be operated only after the circuit has been opened by some other means.

Magnetic Contactor. A contactor actuated by electromagnetic means.

Magnetic-Control Relay. A relay which is actuated by electromagnetic means. When not otherwise qualified, the term refers to a relay intended to be operated by the opening and closing of its coil circuit and having contacts designated for energizing and/or deenergizing the coils of magnetic contactors or other magnetically operated device.

Manual Controller. An electric controller having all its basic functions performed by devices that are operated by hand; for example, a toggle switch or a drum-type controller.

Master Switch. A switch dominates the operation of contactors, relays, or other remotely operated devices. A master switch may be automatic, such as a float switch or a pressure regulator, or it may be manually operated, such as a drum, pushbutton, or knife switch.

Motor-Circuit Switch. A switch intended for use in a motor branch circuit. It is rated in horsepower, and it is capable of interrupting the maximum operating overload (see "Operating Overload") current of a motor of the same rating at the rated voltage.

Open-Phase Protection (Phase-Failure Protection). A form of protection that operates to disconnect the protected equipment on the loss of current in one phase conductor of a polyphase circuit or to prevent the application of power to the protected equipment in the absence of one or more phase voltages of a polyphase system.

Open-Phase Relay. A polyphase relay designed to operate when one or more input phases of a polyphase circuit are open.

Operating Overload. The overcurrent to which electric apparatus is subjected in the course of the normal operating conditions that it may encounter. For example, those currents in excess of running current which occur for a short time as a motor is started or jogged are considered normal operating overloads for control apparatus.

Overcurrent Relay. A relay that operates when the current through the relay during its operating period is equal to or greater than its setting.

Overload Protection. The effect of a device operative on excessive current, but not necessarily on short circuit, to cause and maintain the interruption of current to the device governed. When it is a function of a controller for a motor, the device employed provides for interrupting any operating overloads but is not required to interrupt short circuits.

Overload Relay. A relay that responds to electric load and operates at a preset value of overload. Overload relays are usually current relays, but they may be power, temperature, or other relays.

Part-Winding Starter. A starter which applies voltage successively to the partial sections of the primary winding of an alternating-current motor.

Periodic Duty. A type of intermittent duty in which the load conditions are regularly recurrent.

Phase-Sequence-Reversal Protection (Phase-Reversal Protection). A form of protection that prevents energization of the protected equipment on reversal of the phase sequence in a polyphase circuit.

Pilot-Duty Rating. A generic term formerly used to indicate the ability of a control device to control other devices.

Relay. An electric device that is designed to interpret input conditions in a prescribed manner and after specified conditions have been met to respond to cause contact operation or similar abrupt change in associated electric control circuits. Inputs are usually electric but may be mechanical, thermal, or of other quantities. Limit switches and similar simple devices are not relays. A relay may consist of several units, each responsive to specified inputs, the combination providing the desired performance characteristic.

Semimagnetic Controller. An electric controller having only part of its basic function performed by devices that are operated by electromagnets.

Snap Action. A rapid motion of contacts from one position to another position or their return. This action is relatively independent of the rate of travel of the actuator.

Solid-State Contactor. A contactor whose function is performed by a semiconductor device or devices.

Starter. An electric controller for accelerating a motor from rest to normal speed, to protect, and to stop the motor. (A device designed for starting a motor in either direction of rotation includes the additional function of reversing and should be designated a *reversing starter*.)

Three-Wire Control. A control function which utilizes a momentary-contact pilot device and a holding circuit contact to provide undervoltage protection.

Two-Wire Control. A control function which utilizes a maintained-contact type of pilot device to provide undervoltage release.

Undervoltage Protection. The effect of a device, operative on the reduction or failure of voltage, to cause and maintain the interruption of power to the main circuit.

Undervoltage Release. The effect of a device, operative on the reduction or failure of voltage, to cause the interruption of power to the main circuit but not to prevent the reestablishment of the main circuit on return of voltage.

252. Enclosure of controllers. Except when the control equipment is mounted on switchboard panels under the control of experienced operators, the control equipment of motors should be enclosed in a metal or approved nonmetallic case. Different types of enclosures are available to meet the requirements of any surrounding conditions. Most general-purpose controllers are enclosed in a sheet-metal case. If a controller must be placed in a hazardous location in an explosive atmosphere, the advice of the experts of the control manufacturers should be obtained. The standard types of nonventilated enclosures are given in Sec. 253.

253. Classification of standard types of nonventilated enclosures for electric controllers (National Electrical Manufacturers Association) is as follows:*

Type 1. Enclosures constructed for indoor use to provide a degree of protection to personnel against access to hazardous parts and to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt).

*This material is reproduced with the permission of the National Electrical Manufacturers Association from NEMA Standards Publication NEMA 250-2003, copyright © 2003 by NEMA.

Type 2. Enclosures constructed for indoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt); and to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (dripping and light splashing).

Type 3. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and windblown dust); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow); and that will be undamaged by the external formation of ice on the enclosure.

Type 3R. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow); and that will be undamaged by the external formation of ice on the enclosure.

Type 3S. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and windblown dust); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow); and for which the external mechanism(s) remain operable when ice laden.

Type 3X. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and windblown dust); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow); that provides an additional level of protection against corrosion and that will be undamaged by the external formation of ice on the enclosure.

Type 3RX. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow); that will be undamaged by the external formation of ice on the enclosure that provides an additional level of protection against corrosion; and that will be undamaged by the external formation of ice on the enclosure.

Type 3SX. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and windblown dust); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow); that provides an additional level of protection against corrosion; and for which the external mechanism(s) remain operable when ice laden.

Type 4. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of

the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and windblown dust); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow, splashing water, and hose-directed water); and that will be undamaged by the external formation of ice on the enclosure.

Type 4X. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (windblown dust); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (rain, sleet, snow, splashing water, and hose-directed water); that provides an additional level of protection against corrosion; and that will be undamaged by the external formation of ice on the enclosure.

Type 5. Enclosures constructed for indoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and settling airborne dust, lint, fibers, and flyings); and to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (dripping and light splashing).

Type 6. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (hose-directed water and the entry of water during occasional temporary submersion at a limited depth); and that will be undamaged by the external formation of ice on the enclosure.

Type 6P. Enclosures constructed for either indoor or outdoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (hose-directed water and the entry of water during prolonged submersion at a limited depth); that provides an additional level of protection against corrosion and that will be undamaged by the external formation of ice on the enclosure.

Type 7. Type 7 enclosures are intended for use indoors in locations classified as Class I, Group A, B, C, or D, as defined in the National Electrical Code. The letters A, B, C, and D indicate the gas or vapor atmospheres in the hazardous location. The enclosures are marked with the appropriate Class and Group(s) for which they have been qualified.

These enclosures are capable of withstanding the pressures resulting from an internal explosion of the specified gases and containing such an explosion sufficiently that an explosive gas-air mixture existing in the atmosphere surrounding the enclosure will not be ignited. Enclosed heat-generating devices do not cause external surfaces to reach temperatures capable of igniting explosive gas-air mixtures in the surrounding atmosphere.

Type 8. Type 8 enclosures are for indoor or outdoor use in locations classified as Class I, Group A, B, C, or D, as defined in the National Electrical Code. The letters A, B, C, and D indicate the gas or vapor atmospheres in the hazardous location. The enclosures are marked with the appropriate Class and Group(s) for which they have been qualified.

These enclosures and enclosed devices are arranged so that all arcing contacts, connections, and so forth are immersed in oil. Arcing is confined under the oil such that it will not ignite an explosive mixture of the specified gases in internal spaces above the oil or in the

atmosphere surrounding the enclosure. Enclosed heat-generating devices do not cause external surfaces to reach temperatures capable of igniting explosive gas-air mixtures in the surrounding atmosphere.

Type 9. Type 9 enclosures are intended for indoor use in locations classified as Class II, Group E, F, or G, as defined in the National Electrical Code. The letters E and G indicate the dust atmospheres in the hazardous location. The enclosures are marked with the appropriate Class and Group(s) for which they have been qualified.

These enclosures are capable of preventing the entrance of dust. Enclosed heat-generating devices do not cause external surfaces to reach temperatures capable of igniting or discoloring dusts on the enclosure or igniting dust-air mixtures in the surrounding atmosphere.

Type 10. Type 10 enclosures are designed to meet the requirements of the Mine Safety and Health Administration, U.S. Department of the Interior, which may be in effect from time to time. They are for equipment to be used in mines with atmospheres containing methane or natural gas with or without coal dust.

Type 12. Enclosures constructed (without knockouts) for indoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and circulating dust, lint, fibers, and flyings); and to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (dripping and light splashing).

Type 12K. Enclosures constructed (with knockouts) for indoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and circulating dust, lint, fibers, and flyings); and to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (dripping and light splashing).

Type 13. Enclosures constructed for indoor use to provide a degree of protection to personnel against access to hazardous parts; to provide a degree of protection of the equipment inside the enclosure against ingress of solid foreign objects (falling dirt and circulating dust, lint, fibers, and flyings); to provide a degree of protection with respect to harmful effects on the equipment due to the ingress of water (dripping and light splashing); and to provide a degree of protection against the spraying, splashing, and seepage of oil and non-corrosive coolants.

253A. The following tables provide comparisons of specific applications of enclosures for indoor and outdoor nonhazardous locations (NEMA standard).*

Note that because the NEC has relocated this information from the motor article (Article 430) to the general requirements article (Article 110), it now applies to enclosures generally and not just for motor controllers:

*This material is reproduced with the permission of the National Electrical Manufacturers Association from NEMA Standards Publication NEMA 250-2003, copyright © 2003 by NEMA.

Comparison of Specific Applications of Enclosures for Indoor Nonhazardous Locations

Provides a degree of protection against the following environmental conditions	Type of enclosure									
	1*	2*	4	4X	5	6	6P	12	12K	13
Incidental contact with the enclosed equipment	X	X	X	X	X	X	X	X	X	X
Falling dirt	X	X	X	X	X	X	X	X	X	X
Falling liquids and light splashing	...	X	X	X	X	X	X	X	X	X
Circulating dust, lint, fibers, and flyings [†]	X	X	...	X	X	X	X	X
Settling airborne dust, lint, fibers, and flyings [†]	X	X	X	X	X	X	X	X
Hosedown and splashing water	X	X	...	X	X
Oil and coolant seepage	X	X	X
Oil or coolant spraying and splashing	X
Corrosive agents	X	X
Occasional temporary submersion	X	X
Occasional prolonged submersion	X

*These enclosures may be ventilated. However, Type 1 may not provide protection against small particles of falling dirt when ventilation is provided in the enclosure top. Consult the manufacturer.

[†]These fibers and flyings are nonhazardous materials and are not considered the Class III-type ignitable fibers or combustible flyings. For Class III-type ignitable fibers or combustible flyings. For Class III-type ignitable fibers or combustible flyings see the National Electrical Code, Article 500.

Comparison of Specific Applications of Enclosures for Outdoor Nonhazardous Locations

Provides a degree of protection against the following environmental conditions	Type of enclosure									
	3	3R*	3S	3X	3RX*	3SX	4	4X	6	6P

Occasional prolonged submersion	X

*These enclosures may be ventilated.

[†]External operating mechanisms are not required to be operable when the enclosure is ice-covered.

[‡]External operating mechanisms are operable when the enclosure is ice-covered.

254. Motor controllers* are classified according to size and to the method of performing the necessary operations, shown below.

1. Manual
2. Magnetic
 - a. Full magnetic with automatic master switch
 - b. Full magnetic with manual master switch
 - c. Semimagnetic

*This material is reproduced with the permission of the National Electrical Manufacturers Association from NEMA Standards Publication ICS2-2000, copyright © 2000 by NEMA.

The following tables list the NEMA controller sizes for manual and magnetic single- and three-phase motor controllers. There are no NEMA size designations for semimagnetic controllers.

Manual Motor Controllers: Maximum Ratings

NEMA size	Single-phase hp (LRA)		Three-phase hp (LRA)	
	115 V, 60 Hz	230 V, 60 Hz	200 V, 60 Hz	460 V, 60 Hz
M-0	1 (80)	2 (65)	3	5 (42)
M-1	2 (130)	3 (90)	7½	10 (70)
M-1P	3 (140)	5 (135)		

Ratings for Three-Phase Single-Speed Full-Voltage Magnetic Controllers for Limited Plugging and Limited Jogging Duty

Size of controller	Continuous current rating (A)	At 200 V 60 Hz		At 230 V 60 Hz		At 400 V 50 Hz		At 460 V 60 Hz		At 575 V 60 Hz		Service-limit current rating (A)
		HP*	LRA	HP*	LRA	HP*	LRA	HP*	LRA	HP*	LRA	
		00	9	1.5	46	1.5	40	1.5	26	2	25	
0	18	3	73.6	3	64	5	58	5	46	5	36.8	21
1	27	7.5	146	7.5	127	10	102	10	81	10	64.8	32
2	45	10	186.3	15	232	25	231	25	183	25	146	52
3	90	25	420	30	435	50	458	50	363	50	290	104
4	135	40	667	50	725	75	686	100	725	100	580	156
5	270	75	1248	100	1450	150	1369	200	1450	200	1160	311
6	540	150	2496	200	2900	300	2746	400	2900	400	2320	621
7	810			300	4400			600	4350	600	3480	932
8	1215			450	6500			900	6525	900	5220	1400
9	2250			800	11600			1600	11600	1600	9280	2590

*These horsepower ratings are based on the locked-rotor current ratings given in Table 45, Div. 12. For motors having higher locked-rotor currents, a larger controller should be used so that its locked-rotor current rating is not exceeded.

Ratings for Single-Phase Full-Voltage Magnetic Controllers for Limited Plugging and Limited Jogging Duty

Size or controller	Continuous current rating, A	Single-phase horsepower (LRA) at		Service-limit current rating, A
		115 V	230 V	
00	9	⅓ (50)	1 (48)	11
0	18	1 (96)	2 (72)	21
1	27	2 (144)	3 (102)	32
IP	36	3 (204)	5 (168)	42
2	45	3	7½ (240)	52
3	90	7.5 (480)	15 (450)	104

In a manual controller all the basic operations, such as the closing of switches and the movement of rheostat handles, are performed by hand.

In a magnetic controller the basic functions of the closing of switches or the movement of rheostat handles are performed by magnetic contactors (see Sec. 255). A full-magnetic controller is one which automatically performs all its operations in the proper sequence after the closure of a master switch. The master switch for a full-magnetic controller, such as a float switch, a pressure switch or regulator, or a time switch, is frequently automatically operated. In other cases, the master switch, such as a pushbutton, is manually operated. A semimagnetic controller operates with a combination of manual and magnetic performance. In certain cases, some of the basic operations are performed by hand and the rest by means of magnetic contactors. In other types of semimagnetic controllers, all the basic operations are performed with magnetic contactors, but the time and sequence of the operation of the contactors are controlled by hand.

255. A magnetic contactor is a switch operated by an electromagnet. One form of magnetic contactor is shown in Fig. 7.111, which illustrates the basic parts. It consists of a stationary electric magnet, as at *a* in the figure, and a movable iron armature *b*, on which are mounted an electrical contact *c* and a stationary electrical contact *d*. When no current is flowing through the operating coil *e* of the electric magnet *a*, the armature is held away from the magnet by means of gravitational force or a spring. Under this condition the contacts *c* and *d* are open. When the operating coil is energized, the magnet attracts the armature and closes the electrical contacts *c* and *d*.

Magnetic contactors may be of the shunt or the series type, depending upon the connection of the operating coil. In the shunt contactor the operating coil is connected across the terminals of the circuit or portion of the circuit that the contactor is controlling. In some cases the operating coil of a shunt contactor might be connected to a separate course of supply from the circuit controlled by the contactor. A series contactor has its operating coil connected in series with the circuit controlled by the contactor.

FIGURE 7.111 Magnetic contactor. [Square D, Schneider Electric]

256. Series contactors for motor-control application are constructed so that the contactor will not close until the current of the circuit has dropped below a definite value. They are made in two general forms, *single-coil* and *two-coil*. The single-coil type is referred to simply as a series contactor, while the two-coil type is called a *series lockout* contactor. Both types, however, possess the lock-out feature of the contactor; i.e., they are held open until the current has dropped to some definite value.

The general principle of operation of the single-coil type can be understood from a study of Fig. 7.112. The current passing through the operating coil produces an mmf which acts upon two magnetic paths. One path is through the core of the coil, a section of restricted area *A*, the armature, and main air gap back to the core of the coil. The other path is through the core of the coil, adjustable air gap, tail of armature *B*, armature, and main air gap

FIGURE 7.112 A series contactor operating magnet.

back to the core of the coil. When no current is passing through the coil, the armature is in the open position. When a large current is passing through the operating coil, the mmf is so strong that part *A* of restricted area becomes saturated so that the flux through this part cannot exceed a certain amount. The magnetic flux through the adjustable air gap and part *B* will vary with the current through the operating coil, and this path will not become saturated. Any flux passing across the adjustable air gap produces an attracting force on the tail of armature *B* which tends to hold the armature open against the closing force exerted between the core and the main part of the armature. As the current is reduced in value, the

flux across the adjustable air gap is reduced and thus reduces the holding-out force on tail *B*. After the current has been reduced to a certain value, which depends upon the adjustment of the adjustable air gap, the holding-out force on tail *B* is not sufficient to overcome the closing force exerted by the core upon the main part of the armature, and the contactor closes.

In the two-coil type of series contactor (Fig. 7.113), two coils are connected in series with each other and the circuit to be controlled. The armature is pivoted so that one coil, the larger of the two, acts upon one side of the armature, exerting a force tending to close the contactor. The smaller coil acts upon the other side of the armature and exerts a force tending to hold the contactor open. The areas of the magnetic circuits are so designed that the force tending to close the contactor remains practically constant regardless of the value of the current, while the force tending to hold the contactor open varies with the current. Therefore, after the current has decreased to a certain value, the holding-out force is not sufficient to overcome the closing force and the contactor closes. The air gap of the locking-out circuit can be adjusted so that the current above which the contactor holds open can be adjusted over a wide range.

FIGURE 7.113 Magnetic lockout contactor.

257. Overload protective devices. Most motor controllers have incorporated in them as an integral part some device for protecting the motor against overloads harmful to it. These overload protective devices are made in many different types and forms. Those made by reliable manufacturers are listed by the Underwriters Laboratories Inc. Before purchasing control equipment, take care to make sure that the equipment has been listed by them. All the following types of overload protective devices are used in motor-control equipment.

1. Non-time-delay fuses
2. Time-delay fuses
3. Circuit breakers
4. Thermal sensors
5. Thermal overload relays

6. Magnetic overload relays
7. Solid-state overload relays

For a description of these devices see Div. 4. For selection of overload protective devices with respect to both size and type, refer to Secs. 380, 381, and 382.

258. Undervoltage devices. Most motor starters are provided with either an undervoltage protective device or an undervoltage release device.

An *undervoltage protective device* is one which opens the supply circuit to the motor upon failure or reduction of voltage and which maintains the circuit open until it is again closed by the operator.

An *undervoltage release device* is one which operates on a reduction or failure of voltage, thereby opening the main circuit, but it does not prevent the automatic reclosing of the main circuit upon the return of normal voltage. It is applied in conjunction with some automatic starters. In certain applications, such as fans, blowers, and pumps, an automatic starter provided with an undervoltage release may be advantageously used. Its operation on a reduction or failure of voltage will stop the motor. Then the reestablishment of voltage causes the automatic starter to restart the motor, thus minimizing the shutdown period. An undervoltage release should not be employed in applications in which an unexpected return of power would endanger an operator.

259. Methods of controlling the acceleration of motors with the type of power system on which they may be used are given below. The simplest method is one in which the motor is thrown directly across the line by means of a manual or magnetic switch. The speed of acceleration of the motor and the magnitude and duration of the starting current depend solely upon the characteristics of the motor and its connected load.

With manual control of acceleration the speed of acceleration depends upon the judgment of the operator. Manual control can be obtained through the use of manual controllers or semimagnetic controllers. In semimagnetic controllers of this type, the time and sequence of closing of the magnetic contactors are controlled by a manually operated master switch.

With automatic acceleration the only part of the starting operation that may depend upon the operator is the initiation of the sequence of events (such as pushing a START button). When this is done, the resulting sequence of operations is automatically performed and controlled by contactors alone or by contactors controlled by relays.

Acceleration methods	Applicable to
A. No acceleration control (across-the-line starting)	AC and small dc motors
B. Manual	AC and dc
C. Automatic	
1. Time	
a. Solenoid with action retarded by an adjustable dashpot	DC
b. Pneumatic timer	AC and dc
c. Timing relay	AC and dc
d. Inductive time limit	AC and dc
e. Electronic timer	AC
2. Current	AC and dc
3. Counter-emf	DC
4. Time-current (magnetic relay)	DC
5. Time-current (electronic)	AC
6. Frequency	AC

260. In time-limit acceleration the closing of the respective contactor contacts is controlled by a timing device so that the starting resistance is shorted out of the circuit or connections to the autotransformer are changed in a certain definite time. Most modern automatic starters are of the time-limit type. They are used for all general-purpose applications. The other types of automatic acceleration are used for special applications in which they have advantages over the time-limit type. The timing of the closing of the respective contactors for time-limit acceleration can be accomplished in several ways, as listed in Sec. 259.

261. In time-limit acceleration provided by a solenoid with action retarded by an adjustable dashpot, the time of closing the magnetic accelerating contactors is controlled by a fluid dashpot attached to the lower part of the operating rod of a solenoid. In some starters the dashpot-controlled solenoid is a timing relay (Sec. 265) which controls the time of closing the operating coil of a magnetic accelerating contactor (Sec. 262).

262. A fluid-dashpot timing relay is illustrated in Fig. 7.114. The motion of the plunger of the solenoid is retarded by an adjustable fluid dashpot attached to the lower end of the solenoid plunger. The delayed time for closing the relay contacts can be adjusted from 2 to 30 s. The dashpot is filled with a silicone fluid whose viscosity is affected only very slightly by changes in temperature. Such relays will operate satisfactorily in ambient temperatures from +120 to -30°F (+49 to -35°C).

263. Solid-state reduced-voltage starters, as shown in Fig. 7.115, are available from several manufacturers in ratings up to at least 800 hp for standard three-phase, ac induction motors. These include such features as:

FIGURE 7.114 Fluid-dashpot timing relay. [Allen-Bradley Company, Inc.]

FIGURE 7.115 Solid-state reduced-voltage starter. [Eaton Corp., Cutler-Hammer Products]

1. Adjustable starting current, from 100 to 400 percent of motor full-load current, to match breakaway torque to applied load
2. Adjustable current limit, from 100 to 400 percent of motor full-load current, providing stepless acceleration at reduced current and torque
3. Adjustable current ramp, from 2 to 30 s, for very gradual acceleration, such as to take up slack in the drive system even after the fixed turn-on ramp has expired
4. Adjustable pulse start, from 0 to 2 s, providing an initial 400 percent current pulse to the motor to break loose high-friction, high-inertia loads
5. Adjustable current trip, from 50 to 400 percent of motor full-load current, with contacts to initiate audible or visual alarm signaling when the motor reaches the trip setting
6. Power-saving feature which reduces voltage to the motor when it is running at no load or is lightly loaded, to reduce energy consumption

It should be noted that solid-state controllers employ silicon-controlled rectifiers (SCRs) which do not provide an air break when off. When the branch-circuit disconnect is closed, a solid-state controller has potentially lethal voltages at the motor terminals as well as at the line terminals, even in the OFF state. An isolation contactor or magnetic contactor provides the necessary isolation.

264. Contactors equipped with pneumatic timers provide a means for the time control of acceleration. The timer of Fig. 7.116 consists of an air chamber and an adjustable vent which controls the time delay of the operation of the contactors. The timer is actuated by a lever attached to the arm of a contactor.

The principle of controlling acceleration by a mercury timer is shown in Fig. 7.117. All contactors except the last acceleration contactor are equipped with a pneumatic timer. When the START button is pressed, current flows from L1, through STOP and START buttons to 10, through the operating coil ③, through contacts $\overline{No.5}$ and back to L2. This energizes the operating coil ③ of the main-line contactor $\frac{3}{1}$. Contactor $\frac{3}{1}$ closes, connecting the motor across the line in series with all the starting resistance. When contactor $\frac{3}{1}$ closes, it closes

FIGURE 7.116 Pneumatic timer. [Square D, Schneider Electric]

FIGURE 7.117 Principle of time-limit acceleration by means of pneumatic timers.

its auxiliary contacts $\frac{3}{\text{NO}}$, which provides a means of energizing the operating coils of the contactors when the START button is released. The closing of contactor 3 causes the pneumatic timer 3M to start to function. After a certain definite time required for the air to pass through the orifice of the plunger, pneumatic timer 3M closes its contact $\frac{3M}{\text{NO}}$. This energizes the operating coil ④ of accelerating contactor 4, which closes its contacts $\frac{4}{\text{NO}}$. This shorts the resistance R_7-R_8 . The closing of contactor 4 causes the pneumatic timer 4M, attached to it, to start to function. After a certain definite time this timer closes its contacts $\frac{4M}{\text{NO}}$, energizing the operating coil ⑤ of accelerating contactor 5. Contactor 5 operates, closing its contacts $\frac{5}{\text{NO}}$ and shorting out resistance R_6-R_7 . The motor is now connected directly across the line.

265. Timing relays are the most commonly used devices to obtain automatic control of motor acceleration. A timing relay is a device which, when energized, will operate to close or open its contacts after a definite lapse of time from the instant that the relay is energized. Time-limit control of motor acceleration is accomplished with these relays through their time control of the closing or opening of the operating circuits of the motor-accelerating contactors.

The more common types are pneumatic timing relays, fluid-dashpot timing relays, and synchronous-motor timing relays. The fluid-dashpot and pneumatic relays are operated by a magnetic coil which, when energized, exerts a pull upon the central movable member, or plunger. The time taken for the movable member to close or open the contacts of the relay is governed by the retarding action of the dashpot or air bellows.

Dashpot timing relays (Fig. 7.114) are equipped with an adjustable fluid dashpot. The fluid used should be one whose viscosity is not affected by changes in ambient temperature. The timing range of these relays can be adjusted from about 2 to 30 s.

Pneumatic relays (Fig. 7.118) are equipped with an air chamber and adjustable vent which controls the time delay in the operation of the relay. The timing range of these relays can be adjusted from about 0.2 to 200 s.

Synchronous-motor timer relays (Fig. 7.119) consist of a set of contacts driven from the shaft of a very small synchronous motor so that there is a definite time lag between the starting of the motor and the closing of the contacts. A controller utilizing such a relay is described in Sec. 312.

FIGURE 7.118 Pneumatic timing relay. [Square D, Schneider Electric]

FIGURE 7.119 Synchronous-motor timer relay. [General Electric Co.]

266. Acceleration controlled by inductive time-limit contactors or relays makes use of the inductive time-lag effect of the decay of current in a heavily inductive circuit. This method of timing is often called *magnetic timing*. In controllers employing this method, each accelerating contactor may be of the inductive time-limit type or of the ordinary shunt type, each being controlled by an inductive time relay. Inductive time-limit contactors may be of the normally open-contact (holdout) type or of the normally closed type.

267. An inductive time-limit accelerating contactor of the normally open-contact type (Fig. 7.120) consists of a pivoted armature acted upon by two coils located on opposite sides of the pivot point. The main operating coil acts to close the contactor, while the auxiliary coil acts to hold the contactor open. In the diagram of the controller of Fig. 7.121 the coils marked 2R, 3R, 4R, and 5R are the main operating coils of the respective inductive time-limit contactors 2R, 3R, 4R, and 5R. The coils marked HC2, HC3, HC4, and HC5 are the holdout coils of the contactors 2R, 3R, 4R, and 5R, respectively.

FIGURE 7.120 Inductive time-limit contactor of the normally open-contact type.

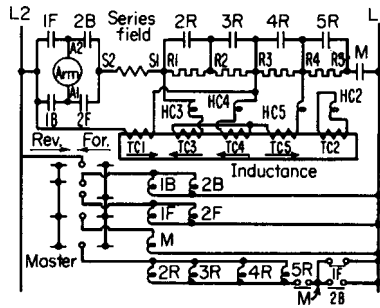

FIGURE 7.121 Connections for inductive time-limit acceleration. [Eaton Corp., Cutler-Hammer Products]

268. The principle of controlling acceleration by inductive time-limit accelerating contactors of the normally open-contact type is illustrated by the typical control diagram of Fig. 7.121. In addition to the contactors, an iron-core inductive unit is required. This inductance consists of a set of coils TC1, TC2, TC3, TC4, and TC5 wound on a common iron core. In starting the motor from rest, if the operator moves the master switch to the running position for forward direction of rotation, the circuits of operating coils 1F, 2F, and M to close. This connects the motor across the line in series with all the starting resistance. Voltage will be impressed upon coils TC1, TC3, TC4, and TC5, causing these coils to be energized and to hold out their respective contactors. But the coils are so connected that the mmf's of the coils just neutralize each other, so that no flux is produced in the core. There is therefore no current in the closed circuit of coils HC2 and TC2, and contactor 2R is free to close when its operating coil is energized. As soon as contactors 1F and M have closed, auxiliary contacts on these contactors close the circuits of the operating coils 2R, 3R, 4R, and 5R. Contactor 2R immediately closes, shorting out the section of resistance R1-R2 and shorting coils HC3 through TC3. This unbalances the mmf's of the inductance, and a definite flux is produced in the core. This change in flux and the inductance of coils HC3 and TC3 oppose the delay of current in HC3 and TC3. After a certain

lapse of time the current in *HC3* will drop to nearly zero. The holdout coil *HC3* of the contactor *3R*, being now deenergized while its main coil *3R*, is energized, causes contactor *3R* to close. The closing of contactor *3R*, shorting coils *HC4* and *TC4*, again unbalances the flux. After a definite time lapse the current in *HC4* will drop to nearly zero, and contactor *4R* will close. Closing of *4R* shorts coils *HC5* and *TC5* and once again unbalances the flux. After another definite time interval the current *HC5* drops to nearly zero, and contactor *5R* is allowed to close. The motor is then connected directly to the line.

When plugging, i.e., throwing from full speed in one direction to full speed in the other, one should have a time delay in the closing of contactor *2R*. Coil *TC1* is connected across the armature and resistance R_1-R_2 . The current through coil *TC* therefore depends upon the sum of the voltage across the armature and the resistor R_1-R_2 . The voltage across the armature when starting from rest is very low, but in plugging, it is normal line voltage. In plugging, therefore, the current through *TC1* is much higher than it is when starting from rest. This larger current through *TC1* unbalances the mmf's of the inductance and produces a flux which induces a current in shorted coils *HC2* and *TC2*. This induced current will hold out contactor *2R* until the current has had time to be reduced to nearly zero.

269. The principle of time-limit acceleration by inductive time-limit contactors of the normally closed-circuit type is illustrated in Fig. 7.123. A contactor of this type is shown in Fig. 7.122. A copper tube encircles the magnetic core of the contactor, over which two operating coils are wound. These two coils act in opposition to each other. When the main winding is open-circuited after having been carrying current, the magnetic flux decreases. This decrease in flux induces a heavy current in the enclosed copper tube. The induced current opposes the decay of the flux, so that there is a considerable lapse of time after the circuit of the main coil is opened before the flux decays sufficiently to allow the armature to be released. The length of time delay will depend upon the original value of the flux, which can be controlled by adjusting the current in the neutralizing winding.

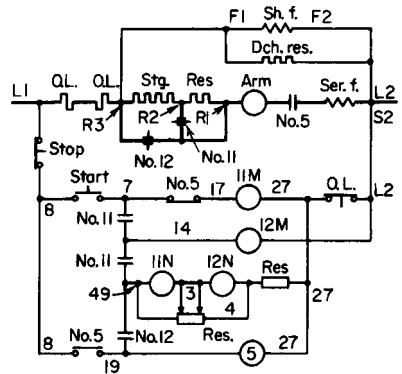

FIGURE 7.122 Inductive time contactor of the normally closed-contact type. [Westinghouse Electric Corp.]

◆ Main contacts of inductive time-limit accelerating contactors (contacts normally closed) ⊕ Auxiliary contacts of inductive time-limit accelerating contactors

FIGURE 7.123 Principle of time-limit acceleration by means of inductive time-limit contactors of the normally closed-contact type.

Acceleration is automatically performed in the following manner. When the START button is pressed, current flows from L1, through STOP and START contacts to 7, through contacts 5, operating coil (H), contacts OL, and back to line L2. The armature of contactor 11 is therefore attracted, opening its main contacts 11 and closing its auxiliary contacts 11. The closing of the two sets of auxiliary contacts 11 energizes the main operating coil (M) and neutralizing coils (H) and (M). The armature of contactor 12 is therefore attracted, opening its main contacts and closing its auxiliary contacts 12. This energizes the operating coil (5), which closes the main-line contactor 5. The motor is then connected to the line in series with all the starting resistance. When contactor 5 closes, it opens its auxiliary contacts 5 and closes its auxiliary contacts 5. The closing of contacts 5 keeps the operating circuits of the contactors energized when the START button is released. The opening of contacts 5 opens the main operating coil circuit (H) so that after a definite time, determined by the adjustment of the resistances controlling (H) and (M), contactor 11 drops out and thereby closes its main contacts, shorting out the resistance R₂-R₂. At the same time, auxiliary contacts 11 are opened, which opens the circuit of the main operating coil (M). After a definite time the flux of contactor 12 decreases a sufficient amount so that contactor 12 drops out, closing its main contacts and shorting out resistance R₃-R₂. The motor is now connected directly across the line. As contactor 12 drops out, its auxiliary contact 12 opens, which disconnects all the operating coils of the accelerating contactors. In case of an overload, the operating coils or bimetallic heater elements open the contacts OL, deenergizing the operating coil (5) of the main-line contactor so that the motor is disconnected from the line and will not start up again until pressing the START button again starts the above sequence of starting operations. To stop the motor, the STOP button is pressed, which opens the circuit of the operating coil of the main-line contactor.

270. Acceleration by means of inductive time relays

requires the use, for each step of resistance, of an ordinary shunt contactor in conjunction with a magnetic time relay. A magnetic time (inductive-time) relay can be constructed in just the same manner as the inductive-time accelerating contactors of the normally closed-contact type described in Sec. 269. The only differences are that it is smaller in size and that its main contacts are not capable of carrying as heavy currents. The principle of operation in obtaining acceleration by this means is shown in Fig. 7.124. The same general system of symbols is used as given in Sec. 269 and Fig. 7.123. The main contacts of the line contactor are 5. The

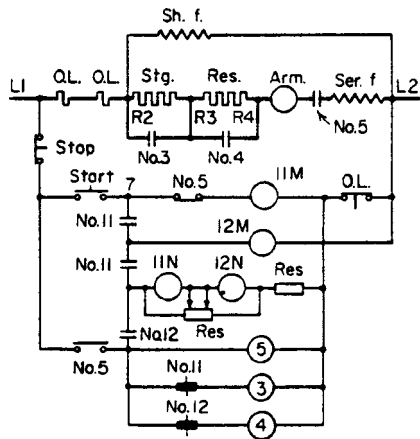

FIGURE 7.124 Principle of operation of time-limit acceleration by means of inductive-time-limit relays.

contacts of the regular shunt-coil accelerating contactors are $\frac{3}{11}$ and $\frac{4}{11}$. The main contacts of the inductive-time-limit relays are $\frac{11}{11}$ and $\frac{12}{12}$. When the START button is pressed, current flows from $L1$ through the STOP and START button to 7, through contacts $\frac{5}{5}$, operating coil $\frac{11}{11}$, contacts $\frac{0}{11}$, and back to line $L2$. The armature of relay 11 is therefore attracted, opening its main contacts $\frac{11}{11}$, which opens the circuit operating coil ③. At the same time auxiliary contacts $\frac{11}{11}$ close, thus energizing operating coil $\frac{12}{12}$ and neutralizing coils $\frac{11}{11}$ and $\frac{12}{12}$. The armature of relay 12 is therefore attracted, opening its main contacts $\frac{12}{12}$, which open the circuit of operating coil ④. At the same time auxiliary contacts $\frac{12}{11}$ close, energizing operating coil ⑤, which closes the main-line contactor 5. The motor is then connected to the line in series with all the starting resistance. When contactor 5 closes, it closes its auxiliary contact $\frac{5}{5}$ and opens its auxiliary contact $\frac{5}{5}$. The closing of $\frac{5}{5}$ makes power available for the operating coils when the START button is released. Opening of contact $\frac{5}{5}$ opens the main operating-coil circuit $\frac{11}{11}$ so that after a definite time determined by the adjustment of the resistance controlling the neutralizing coils $\frac{11}{11}$ and $\frac{12}{12}$ relay 11 drops out and thereby closes its main contacts $\frac{11}{11}$. Closing of contacts $\frac{11}{11}$ energizes the operating coil ③, which operates contactor 3, shorting out the resistance R_2-R_3 . As relay 11 drops out, it opens its auxiliary contacts $\frac{11}{11}$, which open the circuit of the main operating coil $\frac{12}{12}$ of relay 12. After a definite time, the flux of relay 12 decreases a sufficient amount so that relay 12 drops out, closing its main contacts $\frac{12}{12}$ and energizing the operating coil ④. Operating coil ④ closes the contacts of contactor 4, which short out the resistance R_3-R_4 . The motor is now connected directly across the line. As relay 12 drops out, its auxiliary contacts $\frac{12}{11}$ open, which disconnects all the operating coils of the accelerating relays.

271. Time-limit acceleration controlled by pneumatic timing relays attached to contactors (see Fig. 7.125).

When the START button is pressed, current flows from + through the START and STOP buttons, through the overload relay OL contacts, through the main contactor operating coil $\frac{M}{M}$, and back to -. This energizes the operating coil $\frac{M}{M}$ of the mainline contactor, which closes its contact $\frac{A}{11}$ and connects the motor across the line in series with all the starting resistance. When the contactor M closes, it also closes its auxiliary contact $\frac{M}{11}$, which provides a current path around the START pushbutton, which can now be released. A pneumatic timer attached to the M contactor also begins its time delay when the M contactor closes. After the preset delay, the timed contact $\frac{M}{11}$ closes and energizes the operating coil of the first acceleration contactor $\frac{1A}{1A}$. When $\frac{1A}{1A}$ is energized, acceleration contact $\frac{1A}{11}$ closes and bypasses a portion of the resistance in series with the motor. A pneumatic timer attached to the $1A$ contactor also begins its time delay when the $1A$ contactor closes. After the preset delay, the timed contact $\frac{1A}{11}$ closes and energizes the operating coil of the second acceleration contactor $\frac{2A}{2A}$. When $\frac{2A}{2A}$ is energized, acceleration

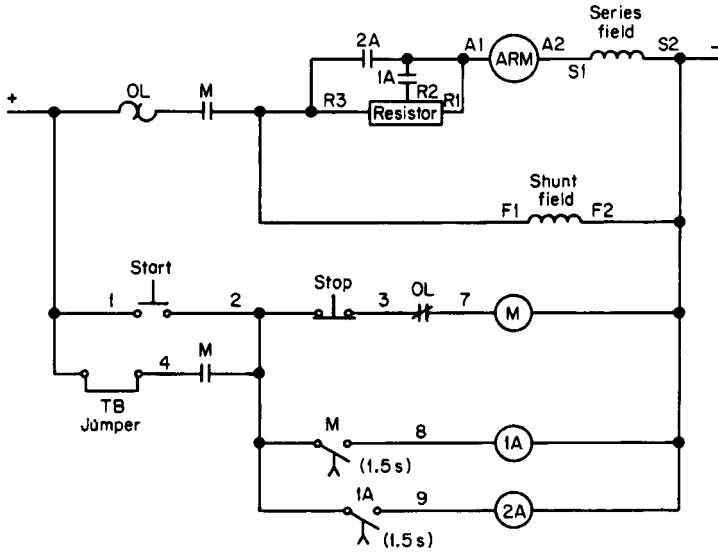

FIGURE 7.125 Principle of time-limit acceleration by means of the pneumatic timing-relay method applied to a dc motor. [Square D, Schneider Electric]

contact $\frac{2A}{\text{---}}$ closes and bypasses the remainder of the resistance in series with the motor. The motor is now running across the line.

Primary-resistor starting of squirrel-cage motors is another effective method (see Fig. 7.126). Operation of the pilot device initiates the timing relay TR and closes its two normally open auxiliary contacts $\frac{TR}{\text{---}}$. This energizes the coil \textcircled{M} of the main-line contactor and closes its contacts $\frac{M}{\text{---}}$. Since the voltage drop in the resistors causes a decreased voltage at the motor terminals, the motor starts and accelerates at reduced voltage, with a consequent reduction in current and torque. After a certain time delay, the timing relay TR times out, and the timed contact closes and energizes the operating coil \textcircled{A} of the accelerating contactor. When coil \textcircled{A} is energized, the contacts $\frac{A}{\text{---}}$ are closed, causing resistors to be shorted out and thereby transferring the motor to line-voltage operation. The motor remains energized during the transfer from the reduced-voltage start to line-voltage operation. Note the elementary wiring diagram for this control in Fig. 7.126.

272. With current-limit acceleration, cutting out the various steps of starting resistance or changing taps on an autotransformer is controlled by the decay of the starting current as the motor accelerates. The rapidity of closing the successive contactors depends upon the load of the motor. With light loads the motor will accelerate on each step more rapidly, so that the current decreases more rapidly and causes the successive contactors to function in a shorter time. Total time for the starting period therefore depends upon the load.

Current-limit acceleration is performed by means of series contactors of the types described in Sec. 256. Acceleration can be accomplished by using series contactors of the

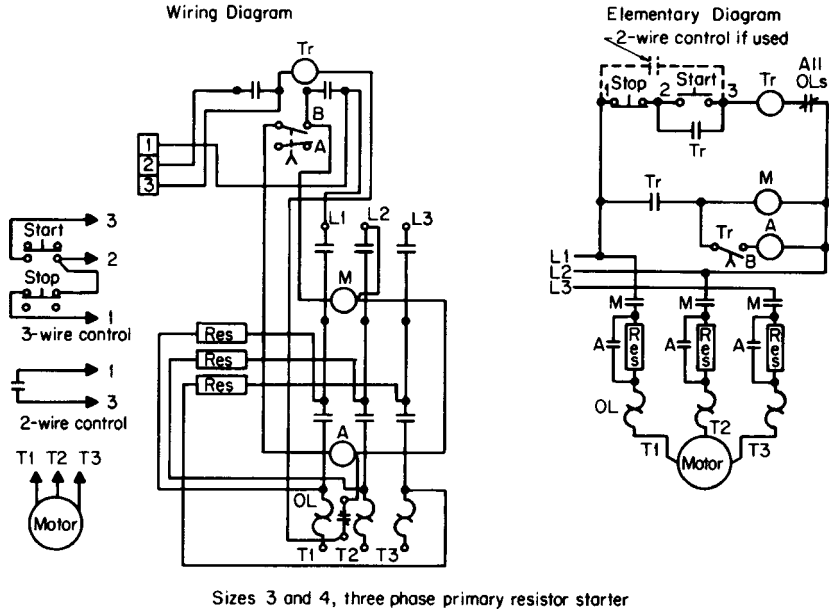

FIGURE 7.126 Principle of primary-resistor starting of squirrel-cage motors. [Square D, Schneider Electric]

FIGURE 7.127 Principle of current-limit acceleration by means of series contactors of the single-coil type.

single-coil type as shown in Fig. 7.127. Pressing the START button energizes the operating coil ③ of the main-line contactor 3 so that line contacts 3 close, connecting the motor to the line in series with the starting resistance. When the starting current has decreased to the value for which the series contactor 4 is adjusted, operating coil ④ closes its contactor 4. The closing of contacts 4 shorts out the section of resistance R_7-R_8 and allows the starting current to pass through operating coil ⑤ of the second series accelerating contactor. When the starting current has decreased to the value for which the series contactor 5 is adjusted, operating coil ⑤ closes its contactor 5. Closing of contact 6 shorts out all the starting resistance and also the main operating coils of contactors 4 and 5, so that there will be no danger of these contactors dropping out under light loads. Contactor 5 has an auxiliary shunt holding coil 5, which holds this contactor closed after it has once been closed by its main operating coil ⑤. When contactor 5 closes, it also closes its auxiliary contacts 5, thus energizing the auxiliary holding-coil circuit for the contactor. The motor is now connected directly to the line.

The method of controlling acceleration by means of two-coil series lockout contactors (Sec. 256) is shown in Fig. 7.128. Pressing the START button energizes the operating coil ③

of the main-line contactor 3 so that line contacts $\frac{3}{1}$ close, connecting the motor to the line in series with the starting resistance. When the starting current has decreased to the value below that for which the lockout coil OL of contactor 4 will hold this contactor open,

contactor 4 closes its contacts $\frac{4}{1}$. This shorts out the section of starting resistance R_7-R_8

and the lockout coil OL of contactor 4 so that the contactor will not drop out under light loads. The current now passes through the operating coil O and lockout coil OL of contactor 5, which locks open until the current has dropped in value to the amount for which the contactor is adjusted to operate. When the current has dropped to this value, contactor 5 closes its contacts $\frac{5}{1}$, which short out the resistance R_6-R_7 and the lockout coil OL . With the lockout coils shorted out, these contactors do not need any auxiliary shunt holding coil, since the series operating coils will hold the contactors closed with only about 5 percent of their normal current. The motor is now connected directly across the line.

FIGURE 7.128 Principle of current-limit acceleration by means of series contactors of the two-coil type.

273. Counter-emf acceleration is really a special method of current-limit acceleration, since the current that flows through the motor depends upon the value of the counter-emf. It is applicable only to dc motors. The time required for the starting period will depend upon the load on the motor in just the same way as for the other current-limit acceleration methods.

When acceleration is controlled by the counter-emf method, the operating coils of the magnetic contactors are connected across the armature winding (Fig. 7.129). At standstill no counter-emf is produced in the armature winding. As soon as the motor starts to revolve, a counter-emf is generated in the armature winding. The counter-emf is directly proportional to the speed so that as the motor speeds up, the counter-emf increases. Since the operating coils of the magnetic contactors are connected across the armature, their operation depends upon the value of the counter-emf. The magnetic contactors are adjusted so that a definite value of counter-emf is required to operate each one, a higher value of counter-emf being required to operate each successive contactor. When the speed has reached a value at which the counter-emf is sufficient to operate one of the contactors, the contactor closes and shorts out a section of the starting resistance.

FIGURE 7.129 Principle of counter-emf acceleration.

274. Time-current control of acceleration, as the name implies, is a combination of time and current control of the accelerating period. With time control the time of acceleration is entirely independent of the load on the motor, while with current control the time of acceleration depends entirely upon the load on the motor. With time-current control the

time of acceleration is modified by the load on the motor but is not entirely dependent upon the load.

One method of obtaining time-current control of acceleration is through the use of the time-current acceleration relay of Fig. 7.130. This relay consists of a series operating coil *A*, a steel core *C*, a core support plate *B*, an air gap *F*, and a movable circular inductor tube *E*, carrying the movable contacts *G* and a set of stationary contacts *H*. When the circuit of the operating coil is closed, the current changes in a very short time from zero to some definite value, depending upon the circuit in series with which the coil is connected. A magnetic flux is built up rapidly in the iron core *C* and air gap *F*. This flux also links with the inductor tube *E*, which forms a closed single-turn conductor. The rapid change of flux linked with the induction tube *E* causes considerable current to be induced in the induction tube. The current through the operating coil and the induced current in the inductor tube are in such directions that they produce a repelling force between the coil and the tube. The tube is therefore rapidly propelled upward upon the closing of the operating-coil circuit. The parts are so designed that considerable force is exerted upon the tube, and it would travel 1 ft (0.3 m) or more if it were not for the fact that as the tube starts to move, it passes through the field *F*, which now causes eddy currents to be set up in the tube. These eddy currents cause a retarding action, just as a wattmeter vane is retarded as it is forced through a magnetic field, and this, combined with the force of gravity, stops the tube, which then starts to fall under the force of gravity. Inasmuch as current still flows through *A*, causing flux in *F*, the inductor tube is likewise retarded by eddy currents in the downward direction just as it is retarded in the upward direction. This retarding action therefore provides a time delay, which may be as much as 1.45 s, in the closing of contacts *G* and *H*. The length of time will depend upon the current *A* and the type of inductor tube used. Since the current in *A* determines the strength of the flux in *F*, *C*, and *E*, a lower current in *A* will cause the inductor tube to jump less distance, and the retarding action in the downward direction will be less, so the time also will be less. In practice, the current in *A* is the same as the motor current, so that when heavy current flows in the motor owing to a heavy load, the time will be longer, and when the motor current is less as on light loads, the time will be less. Hence we have time-current control, i.e., a system of control in which the time is modified by the current or load on the motor.

II. Cross-section view.

FIGURE 7.130 Time-current relay. [Square D, Schneider Electric]

The principle of time-current control of acceleration with these time-current relays is illustrated by the elementary control circuit in Fig. 7.131. When the *START* button is pressed, the operating coil ③ of the main-line contactor 3 is energized. Contacts $\frac{3}{1}$ close and connect the motor to the line in series with the starting resistance. Upon the closing of contactor 3, current passes through the operating coil ⑥ of time-current relay 6, and the auxiliary contacts $\frac{3}{2}$ of contactor 3 close. Current will start to flow through operating coil ④, but before its contactor 4 has time to close its contacts $\frac{4}{1}$, the inductor-tube relay 6 has been raised and opens the contacts $\frac{6}{2}$ of this relay, thereby opening the circuit of operating coil ④. After a time delay, depending upon the setting of relay 6 and the load on the motor, the inductor tube of relay 6 drops and recloses contacts $\frac{6}{2}$. The operating coil ④ of contactor 4 is now energized, and contactor 4 operates, closing its contacts $\frac{4}{1}$. This shorts out the resistance R_9-R_{10} , closes auxiliary contacts $\frac{4}{2}$, and energizes the operating coil ⑦ of time-current relay 7. Current will flow through the operating coil ⑤ of contactor 5, but before the contactor can close, the inductor tube of relay 7 has jumped up and opened the $\frac{7}{2}$ contacts. After a time delay, the inductor tube of relay 7 drops, reclosing the contacts $\frac{7}{2}$ of this relay and energizing the operating coil ⑤ of contactor 5. Contactor 5 now operates and closes its contacts $\frac{5}{1}$. The motor is now connected directly to the line.

FIGURE 7.131 Principle of time-current acceleration by means of a magnetic time-current relay.

275. AC static, stepless crane control for wound-rotor motors is a development of the Square D Co. This type of control is used with a three-phase, ac wound-rotor motor. The control consists of thyristor assemblies on the primary side and fixed secondary resistors. Stepless, regulated hoisting and lowering speeds are obtained by using a thyristor stepless master switch and a permanent-magnet type of tachometer. Indicating lights mounted on control modules help the troubleshooting of modules (Fig. 7.132).

Five pairs of thyristor assemblies are used in the motor primary circuit to provide static, stepless control of the phase sequence and magnitude of motor voltage. The power-limit stop is arranged to disconnect the motor and directly open the brake circuit when the switch trips. Balanced three-phase motor power for lowering out of the tripped limit stop is also provided. A fixed resistor in each phase of the motor secondary is used to alter the basic speed-torque characteristic for speed-regulated operation. The application of this type of control is shown in Fig. 7.132.

Reduced speed is obtained by adjusting the degree of conduction of the power thyristors. The solid-state control modules produce properly synchronized firing pulses to turn on the thyristors in response to a speed-control signal.

The master-switch inductor unit produces an ac output voltage which is proportional to the amount of deflection of the master-switch handle from the off point. The signal converter changes this ac command signal to a dc signal. A permanent-magnet type of tachometer generator, mechanically coupled to a rotating unit of the hoist drive, provides the feedback signal used to obtain speed regulation. The signal comparator module compares these signals. Its output speed-control signal is used to actuate the thyristor control

FIGURE 7.132 AC static, stepless thyristor control for crane ac wound-rotor motors. [Square D, Schneider Electric]

modules, which energize either the hoist or lower thyristors to produce proper motor operation.

The tachometer continuity module is used to apply an ac voltage to the tachometer circuit and its collectors to ensure continuity. This ac voltage operates the undervoltage relay. Overspeed protection is provided by a mechanical centrifugal overspeed switch in the tachometer assembly.

276. Frequency control of acceleration is a development of the Square D Co. for application to wound-rotor induction motors. The operation of the frequency relays employed in this method depends upon the action of resonant circuits. An ac circuit which contains both inductance and capacity will be resonant at some definite frequency, depending upon the value of the inductance and the capacity. At the resonant frequency, such a circuit will pass a very much higher value of current than at any other frequency. The current of such circuits will increase with frequency up to the resonant frequency. The operating coils of the frequency relays, which have a certain value of inductance, will produce a resonant circuit when connected in series with an external condenser. If condensers of different capacities are used with a set of relays, the respective relays will become resonant at different frequencies (Fig. 7.133). The higher the capacity, the lower the resonant frequency.

FIGURE 7.133 Frequency relays for the control of acceleration of a wound-rotor induction motor. [Square D, Schneider Electric]

The application of this method of acceleration to a wound-rotor induction motor is shown in Fig. 7.134. The relays PR , $1AR$, $2AR$, and $3AR$ are frequency relays. Each relay operating coil in series with its capacitor is connected to a potentiometer rheostat so that it can be adjusted to the proper current. The relays are supplied with power from the secondary resistor so as to receive a maximum voltage of 90 V, on 60-Hz circuits, when the motor primary is first connected to the line. The relays have normally closed contacts. After a relay has attracted its armature, the armature will not drop out until the current of the operating coil has decreased to a certain value. The frequency at which the current reaches the dropout value will vary with the resonant frequency of the circuit. The higher the resonant frequency, the higher the frequency at which the dropout current will be reached. The relays are connected in series with progressively larger values of capacity, so that the resonant frequencies of the relays progressively decrease. The dropout currents will occur at progressively lower frequencies. At standstill the frequency of the secondary circuit of an induction motor is the same as that of the primary supply circuit and decreases as the speed of the motor increases. It is approximately zero at full speed. The frequency relays will therefore drop out progressively as the motor accelerates. The operation of the motor illustrated can be controlled manually by moving the master controller to successive positions, or the acceleration can be made fully automatic by throwing the master to the last position. If the master is thrown to the last position forward, when the motor is at rest, the master contacts MF , F , P , $1A$, $2A$, and $3A$ will all be closed. The motor will then be automatically accelerated as follows. Operating coils \textcircled{M} and \textcircled{F} are first energized; they operate contactors F and M and close contacts $\frac{F}{\uparrow\downarrow}$ and $\frac{M}{\uparrow\downarrow}$. Closing contactor F closes its auxiliary

Elementary Diagram for Bridge or Trolley Control

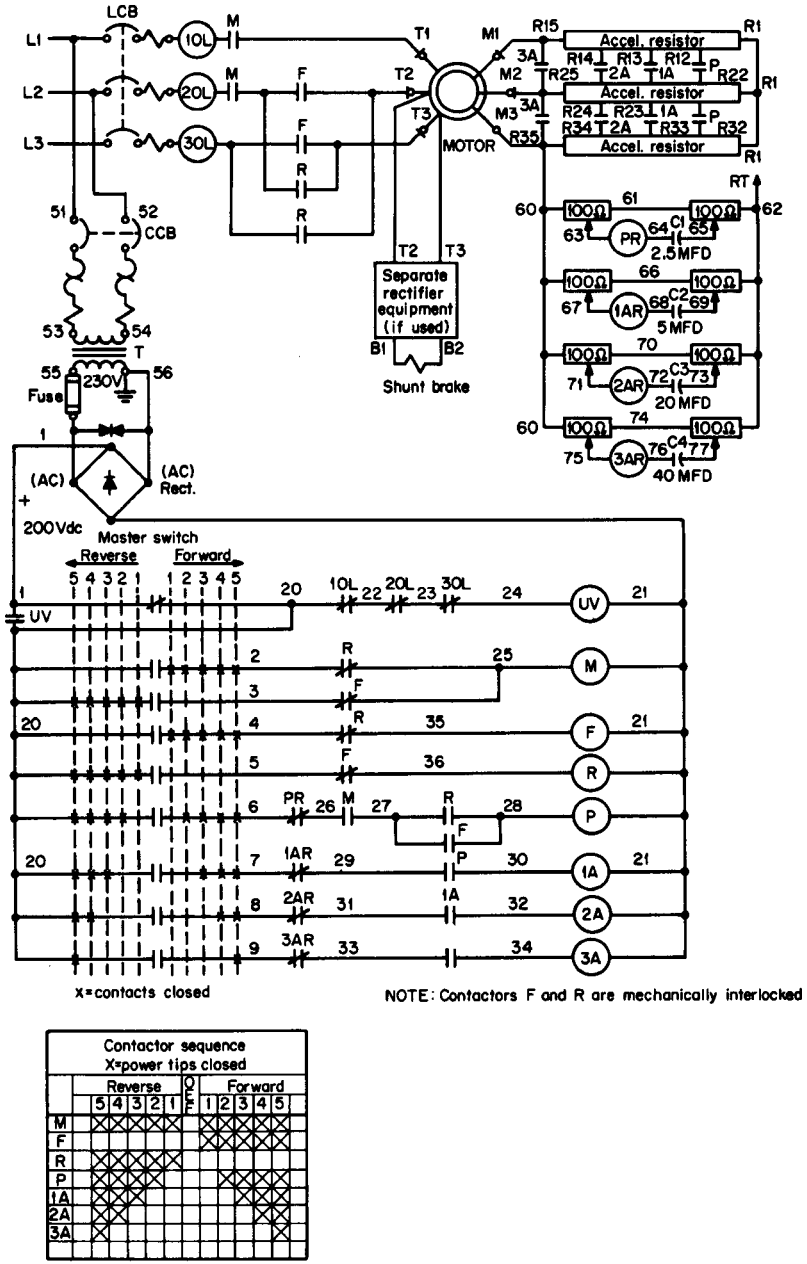

FIGURE 7.134 Principle of frequency acceleration.

contacts $\frac{F}{\text{---}}$. The motor is now connected to the line with resistance in its rotor circuit. The starting current in the rotor circuit energizes the operating coils PR , $1AR$, $2AR$, and $3AR$ of all the frequency relays. The relay PR , which is the plugging relay and has only $2\frac{1}{2} \mu\text{F}$ in series with its coil, will not pass enough current to operate. Since all the frequency relays have normally closed contacts, the contacts $\frac{PR}{\text{---}}$ of relay PR will stay closed, and operating coil \textcircled{P} of contactor P will be energized. Thus contactor P will close its contacts $\frac{P}{\text{---}}$ immediately. The frequency relays $1AR$, $2AR$, and $3AR$ will operate immediately upon passage of current through the motor and therefore will open their contacts $\frac{1AR}{\text{---}}$, $\frac{2AR}{\text{---}}$ and $\frac{3AR}{\text{---}}$. Closure of contactor P closes its auxiliary contacts $\frac{P}{\text{---}}$, but operating coil $\textcircled{1A}$ will not be energized until relay $1AR$ drops out and closes its contacts $\frac{1AR}{\text{---}}$. Relay $1AR$ will drop out after the motor has accelerated to a sufficient speed so that the frequency of the rotor is such as to cause the current of operating coil $\textcircled{1AR}$ to decrease the dropout value. When relay $1AR$ drops out, it closes its contacts $\frac{1AR}{\text{---}}$ and energizes the operating coil $\textcircled{1A}$ of contactor $1A$. Contactor $1A$ then operates and closes its contacts $\frac{1A}{\text{---}}$, shorting out some of the resistance. In a similar manner as the motor accelerates, frequency relays $2AR$ and $3AR$ drop out at progressively higher speeds and cause contactors $2A$ and $3A$ to close.

277. Methods of starting dc motors. As discussed in Sec. 136, dc motors are almost always started with resistance in series with the armature winding. Both manual and automatic starters are used.

278. Types of Controllers for dc Motors

<i>Controller Type</i>	<i>Remarks</i>
1. Manual starters	Available in nonreversing and reversing types
a. Across-the-line	without dynamic braking
b. Starting rheostats (dial-type starters)	Obsolete; suitable only for nonreversing service without dynamic braking
c. Drum	Suitable for nonreversing and reversing service with or without dynamic braking
d. Multiple-switch	Suitable only for nonreversing service without dynamic braking
2. Manual-starting and speed-regulating controllers	Obsolete; suitable only for nonreversing service without dynamic braking
a. Starting and speed-regulating rheostats (dial-type controllers)	Suitable for nonreversing and reversing service with or without dynamic braking
b. Drum	
3. Magnetic starters	Available in nonreversing and reversing types
a. Time-limit acceleration	with or without dynamic braking
b. Current-limit acceleration	
c. Counter-emf-limit acceleration	
d. Time-current acceleration	

279. Across-the-line manual starters for dc motors are made as standard equipment in sizes up to and including 2 hp. They consist of a manually operated switch in a suitable enclosure. They can be obtained with or without thermal overload relays. Those of the smaller types are sometimes called *auxiliary* or *secondary breakers* (see Div. 4). Most of the overload relay devices can be reset by throwing the handle to the extreme off and then to the on position. The release mechanism generally is constructed on the trip-free principle so that the switch cannot be held closed against a dangerous overload. These starters cannot be provided with undervoltage release or protective devices. Typical starters of these types are shown in Figs. 7.135, 7.136A, 7.136B, 7.136C, and 7.137.

I. Flush-plate type for switch-box mounting.

II. Enclosed key-operated toggle-switch type.

III. Enclosed toggle-switch type.

FIGURE 7.137 Manual across-the-line fractional-horsepower starters for ac or dc motors: left, toggle-switch type; right, pushbutton type. [Eaton Corp., Cutler-Hammer, Inc.]

280. Starting rheostats for dc motors,

sometimes called *dial* or *face-plate starters*, are obsolete and no longer available. They will be encountered only on very old installations. They consist of a series of contacts mounted on an insulating panel and connected to different points in a resistance unit (see Fig. 7.138). An arm or a dial bearing a contact is arranged so that it can be moved across the stationary row of contacts. Moving the arm to the first contact closes the armature circuit in series with the starting resistance. As the arm is moved across the buttons, sections of the starting resistance are successively cut out of the circuit until the last contact is reached. Then all the resistance has been cut out of the circuit, and the armature is connected directly across the line. These starting rheostats are not suitable for reversing or dynamic braking service. They can be used for starting series, shunt, or compound-wound motors.

FIGURE 7.138 Low-voltage protection provided by a low-voltage coil and by a no-field coil.

281. Undervoltage protective devices for starting rheostats will also be encountered only on very old installations. Replacements are not available.

These can be operated by either a low-voltage coil or a no-field coil (Fig. 7.138). On a manually operated starter, each device usually consists of an electromagnet M , which under conditions of normal voltage holds the operating arm R in the running position, and a spring (not shown in the diagram) which returns the operating arm to the off position upon failure or decrease of voltage. Starters are sometimes so constructed that instead of the electromagnet being made strong enough to hold the arm in the running position against the force of the spring, a catch is provided to engage and hold the arm after it has been manually moved to the running position. Then, if the voltage drops below a predetermined value, the

electromagnet disengages the catch. This releases the arm, which is returned to the off position by the spring. The magnet coil may be connected directly across the line (Fig. 7.138, I) with a protective resistance in series, in which case it is called a *low-voltage coil*, or it may be connected in series with the shunt field (Fig. 7.138, II), in which case it is called a *no-field coil*. Both arrangements provide low-voltage protection. If the coil is connected across the line, the current carried by the coil, and therefore the coil losses, will be less than if it is connected in series with the shunt field. The difference between the maximum and minimum field currents of wide-speed-range adjustable-speed motors renders it impractical to design a series-connected holding coil which will operate satisfactorily throughout the range.

282. In starting a dc motor using a starting rheostat close the line switch and move the operating arm of the rheostat step by step over the contacts, waiting a few seconds on each contact for the motor to accelerate. If this process is performed too quickly, the motor may be damaged by excessive current; if too slowly, the rheostat may be damaged. If the motor fails to start on the first step, move promptly to the second step and if necessary to the third, but no farther. If the motor doesn't start when the third step is reached, open the line switch at once, allow the starter handle to return to the off position, and look for faulty connections, overload, etc. The time of starting a motor with full-load torque should not, as a general rule, exceed 15 s for rheostats for motors of 5 hp and lesser output and 30 s for those of greater output.

283. To stop a dc motor using a starting rheostat, open the line switch. the arm will return automatically to the off position. Never force the operating arm of any starting rheostat back to the off position.

FIGURE 7.139 Solid state or overload relay. [Siemens Energy & Automation, Inc.]

284. Overload protection is not generally provided in starting rheostats. Overload protection must be provided at some other point in the motor circuit by means of fuses, circuit breakers, or magnetic contactors controlled by overload relays (Fig. 7.139).

285. Drum-switch controllers are made in a variety of types. They can be obtained for both reversing and nonreversing service and with or without contacts for dynamic braking. They are used for series, shunt, and compound motors. The essential features of a drum controller are a central movable drum upon which are mounted a set of contact segments and a set of stationary contact fingers. A typical drum controller is illustrated in Fig. 7.140. The movement of the drum is controlled by means of a handle on top of the case. As this handle is moved from the off position, the arma-

ture circuit is closed in series with the starting resistance by means of the first set of movable segments on the drum, making contact with the first set of stationary fingers. As the handle is moved around, the resistance is short-circuited step by step by the contacts located farther around on the drum. Small controllers of this type are self-contained, the starting resistance being mounted in a ventilated box on the rear of the drum switch. In

FIGURE 7.140 Nonreversing drum controller. [Westinghouse Electric Corp.]

FIGURE 7.141 Connections for a thermal overload protective unit used with a drum starter.

the larger sizes the resistance is mounted separately from the drum switch. Drum controllers do not provide any overload or undervoltage protection. Short-circuit protection may be provided by fuses or a circuit breaker mounted separately from the controller. A magnetic contactor with an overload relay will provide both overload and undervoltage protection. Such a protective unit has the advantage that it may be electrically interlocked with the drum switch so that the line contactor cannot be closed unless the drum switch is in the off position. This provision safeguards against the possibility of the motor being thrown directly across the line. Connections for a typical magnetic-contactor protective panel are shown in Fig. 7.141.

286. The manually operated multiple-switch controller for dc motors (Fig. 7.142) comprises a number of switches S , which are manually closed in sequence. Thereby the resistances R are shunted out of circuit as the armature accelerates. The switches are mechanically interlocked so that they cannot be closed in anything but the proper sequence. When the last switch S_5 is closed, all the resistance is short-circuited. The switches, after being closed, are held in the closed position by a catch. This catch is in turn held by a low-voltage protective magnet M .

FIGURE 7.142 Connections for a multiple-switch dc controller.

Upon the failure of voltage, the catch is released and all the switches are thrown to the off position by gravity or by a spring. A switch of this type is especially adapted for

starting large motors. A sufficient time period will elapse in the ordinary closing of the switches to provide a protection against too rapid acceleration. The arrangement of a number of switches in parallel tends to minimize heating of the contacts, particularly of the contact of the last switch S_5 . One of the contact blocks of each switch is often made of laminated copper strips and the other of carbon. The laminated brushes and the copper-to-carbon arcing contacts render a switch of this type exceptionally adaptable for use with large motors. Overload protection must be provided outside the controller. These controllers are suitable for series, shunt, or compound motors in nonreversing service without dynamic braking.

287. Apparatus for field control of shunt or compound motors. The variable resistance in series with the shunt field, necessary for the speed control of shunt or compound motors by the field-control method, may be provided by means of a field rheostat separate from the starting rheostat, or the starting rheostat and the field rheostat may be combined into a single piece of equipment forming a combined starting and speed-adjusting controller. Such combined starting and speed-adjustment controllers are available in both dial and drum types of construction.

Drum controllers for combined starting and speed adjustment (field control) are provided with two sets of contacts, one for control of the starting resistance and the other for control of the speed of the motor through variation of shunt-field resistance. Although controllers of this type are most frequently applied on machine tools, they are desirable for any service in which the work is severe and the expense of a controller is justified.

288. Motor-generator variable-voltage systems, formerly called Ward-Leonard systems, consist of an adjustable-voltage dc generator driven at a constant speed by an ac motor and a source of direct current to excite the generator separately. The variable-output voltage of the dc generator serves as the input to one or more dc motors whose speed will vary with the voltage supplied. The motor-generator combination acts as an amplifier, since a small current in the generator exciter circuit can control the generator output voltage and the armature current of one or more driven dc motors. These systems are regenerative; e.g., the descending load on a hoist driven by a dc motor supplied by the motor-generator system will return energy to the system.

289. Solid-state variable-voltage systems supply direct current as the output of a bank of thyristors called a converter. A converter can be described as equipment that will change electrical energy from one form to another. This change is accomplished in two different modes of operation. The first mode is *rectification*, in which the converter changes alternating current or voltage to direct current or voltage. The second mode is known as *inversion*, in which the converter changes direct current or voltage to alternating current or voltage. During rectification, power flow is from alternating to direct current. Conversion is accomplished with as few as three or six thyristors, although multiples of these frequently are connected in parallel to increase capacity.

Although the converter and its controls are relatively simple, dc variable-speed drives provide satisfactory performance in the most demanding applications. These applications range from simple, general-purpose nonreversing drives with a fixed shunt field and a 5 percent voltage regulator to sophisticated steel-mill reversing drives with shunt-field controls and high-performance 0.1 percent speed regulators. Generally, the latter also provide inversion capabilities for fast deceleration via power pumpback into the ac line.

Solid-state converters, through proven performance, provide a high degree of reliability. Modern forms of modular construction and packaging techniques allow quick replacement of components or assemblies to minimize downtime if a fault occurs. The compactness and light weight of modern converters eliminate the need for elaborate foundations and require a minimum amount of floor space. In many instances, the converters can be wall-mounted or packaged with other system assemblies to utilize floor space efficiently.

Form Classifications. Standard designations are used to describe converter characteristics. An operating-quadrant diagram (Fig. 7.143) is used for this purpose. The designations are intended to describe the functional characteristics of converters but not necessarily the circuits of components used. Converters are identified by “form” letters to classify their functional capabilities.

Form A. A single converter capable of unidirectional voltage and current flow. It operates as a rectifier in Quadrant I only.

Form B. A double converter capable of providing a positive voltage and current or a negative voltage and current. It has no inversion capability and operates as a rectifier in Quadrants I and III.

Form C. A single converter capable of bipolarity voltage and unidirectional current flow. It operates as a rectifier in Quadrant I and as an inverter in Quadrant IV.

Form D. A double converter capable of bipolarity voltage and bidirectional current flow. It operates as a rectifier in Quadrants I and III and as an inverter in Quadrants II and IV. Its performance is identical to that of a Ward-Leonard drive.

These forms refer to the converter capabilities only and not to the motor. Motor direction and power flow may be reversed by armature switching or field reversal without the use of an elaborate Form D converter. For example, a motor can be reversed with a Form A converter and a reversing switch or a reversing field. Similar combinations may be obtained for regeneration (reverse power flow).

FIGURE 7.143 Operating quadrants of thyristor converter units.

290. Apparatus for armature speed control of dc motors. When armature speed control is employed, the same piece of equipment serves for both starting and speed control. An ordinary starting controller should not be used for armature speed control, however, as it is not designed for continuous duty but only for intermittent service, as in starting. In employing a controller for armature speed control, make sure that it is designed for that type of service and not simply for starting duty. Controllers suitable for armature control are available in both the rheostat and the drum types.

291. Rheostat-type armature-control speed regulators (Fig. 7.144) are used for speed reduction with shunt, compound, or series motors in nonreversing service when the torque required decreases with the speed but remains constant at any given speed, as with fans, blowers, and centrifugal pumps. They can also be used in applications in which the torque is independent of the speed, as in printing presses. However, this method of

FIGURE 7.144 Armature-control speed regulator, removed from enclosure.

speed control is not suitable for such applications if operation continues for long periods at reduced speed, since such operation is not economical. If the torque varies, constant speed cannot be obtained with these controllers.

In the regulator shown, the low-voltage release consists of an electromagnet enclosed in an iron shell, a sector on the pivot end of the operating arm, and a strong spring which tends to return the arm to the off position. The magnet is mounted directly below the pivot of the arm, and its coil is connected in shunt across the line in series with a protecting resistance. When the magnet is energized, its plunger rises and forces a steel ball into one of a series of depressions in the sector on the arm with a sufficient force to hold the arm against the action of the spring; each depression corresponds to a contact. The arm can be easily moved by the operator, however, as the ball rolls when the arm is turned. When the voltage fails, the magnet plunger falls and the spring throws the operating arm to the off position. Standard commercial rheostats of this type are designed to give about 50 percent speed reduction on the first notch.

292. Operation of armature-control speed regulators (Fig. 7.144). Continuous motion of the operating arm starts the motor and brings it gradually to maximum speed. Moving the arm over the first few contact buttons increases the shunt-field strength if the motor is shunt or compound. The movement over the succeeding buttons cuts out armature resistance and permits the motor to speed up.

293. Drum controllers suitable for armature speed control are widely used for crane and hoist motors and in railway applications. Their general appearance and construction are the same as for the drum controller shown in Fig. 7.140. Crane controllers are arranged for reversing service and usually for dynamic braking.

294. Magnetic contactors and starters for dc motors are available in a number of different types for reversing and nonreversing duty, with or without dynamic braking, and for inching and jogging service. They can be used with constant-speed or adjustable-speed shunt or compound motors and with series motors. When they are used with adjustable-speed motors, speed is controlled by a field rheostat mounted separately from the magnetic controller.

When armature speed control is required, it is obtained by controlling the functioning of the contactors by a master controller. The operator adjusts the master controller to the position for the desired speed, and this action initiates the functioning of the contactors, which adjusts the resistance to the corresponding value.

Magnetic starters consist of the necessary magnetic contactors and relays mounted on a panel (open type) or enclosed in a sheet-metal cabinet (enclosed type). Magnetic starters and controllers are equipped with some form of overload relay which opens the circuit of the operating coil of the line contactor upon the occurrence of an overload on the motor. The master switch for initiating the operation of the controller may consist of an automatic float or pressure switch, a pushbutton switch, or a drum or rotary switch. The automatic switches and the pushbutton masters are used for simple control such as starting and stopping or starting, stopping, and reversing, while the drum or rotary switch is employed when full speed control by the operator is required, as for the control of cranes, hoists, etc. Undervoltage protection or release is provided through the operating coil of the main-line contactors, since upon failure or abnormal reduction of the line voltage, the operating coil of the contactor will be deenergized and the contactor will open the motor circuit. The principles of the different methods of automatically controlling the acceleration are discussed in Secs. 259 to 275. The appearance of typical dc magnetic controllers is shown in Figs. 7.145 to 7.149 inclusive.

295. Field relays must be used with magnetic starters when field speed control is employed. This is necessary to ensure that the motor will be started with full field. These relays are called *vibrating* or *fluttering relays*, since during the acceleration or deceleration of the motor their armatures flutter or vibrate between the open and closed positions, alternately shorting and cutting in the field resistance. The operating coil of the relay is connected in series with the armature of the motor, and the contacts are connected across the shunt-field rheostat. During the starting period, whenever the armature current exceeds the value for which the relay is set, the relay will close, short-circuiting the field resistance so that the field strength is maximum. After the starting resistance in series with the armature has been cut out of the circuit, the field relay will hold in until the motor has accelerated sufficiently to reduce the armature current to the value which will allow the field relay to drop out. As it drops out, the field resistance will be cut into the field circuit, thus weakening the field strength. This weakening of the field reduces the counter-emf and therefore will cause the armature current to increase and further accelerate the motor. The increase in armature current causes the field relay to close again, short-circuiting the field resistance. This action is rapidly repeated, the relay vibrating between open and closed positions until the motor has been accelerated to the speed for which the field rheostat is adjusted. The armature current is then at its normal value and is not sufficient to operate the field relay, which remains open with the field resistance cut into the field circuit.

296. DC safety disconnect switches, as shown in Fig. 7.150, are specially designed to provide in a very satisfactory manner for the disconnect switch required by the National Electrical Code for crane installations. The switch in Fig. 7.150 is arranged for lever operation but is not difficult to close, in contrast to most large-size manually operated disconnect switches. Pushing the operating handle up closes the double-pole control-circuit contacts and energizes the magnetic coil to close the switch and connect power to the crane. Pulling the operating handle down breaks both sides of the control circuit.

FIGURE 7.150 Direct-current motor disconnect switch.

297. Methods of starting polyphase squirrel-cage induction motors

1. Full-voltage (across-the-line)
2. Reduced-voltage
 - a. By means of autotransformer (compensator)
 - b. By means of series resistor
 - c. By means of series reactor
 - d. By means of part-winding
 - e. By means of star-delta
 - f. By means of solid-state reduced-voltage

Any polyphase induction motor can be safely started by applying full voltage at starting without harm to the motor, but as discussed in Sec. 132, the heavy starting current drawn from the line by this method may produce too great power and voltage fluctuations in the power supply system. When the starting current must be reduced, one of the methods listed in item 2 above is employed for reducing the voltage impressed on the motor during starting. In Method *a* the motor is connected at the start to the secondary of an autotransformer. After the machine has accelerated sufficiently, the motor is switched over to full line voltage. With this method there are just two steps in the sequence of starting operations: reduced voltage of some definite value and, directly, full line voltage. Starters employing

the transformer method of reducing the voltage are called compensators or auto-transformer starters. In Method *b*, resistance is connected in series with the motor leads from the supply. One or more steps of resistance can be employed. In most cases only one step is used, so that the motor is first connected to the line with some definite value of resistance in series, and then, after the machine has accelerated sufficiently, it is thrown over to full line voltage. When starting conditions are more severe or the starting current must be more closely regulated, additional steps are employed for cutting out resistance. Method *c* is similar to the series-resistance method except that reactance is inserted in series with the motor during starting instead of resistance. With this method only one step of reactance is used.

For the same value of starting torque developed, the autotransformer method of starting will limit the first value of peak starting current to the lowest value. The amount of power consumed during the starting period will be considerably less than with resistance starting. A disadvantage of this method is that the motor is generally entirely disconnected from the supply during the transition period from reduced to full line voltage. This causes a second peak current to be drawn from the line at the instant that full voltage is applied. Some power companies will not allow the use of autotransformer starters for this reason.

With resistance starting, the motor is connected to the supply continuously throughout the starting period, the motor impressed voltage being increased by shorting out the starting resistance. Although the line current will increase whenever some or all of the starting resistance is short-circuited, the magnitude of such peaks will not be nearly so great as the peak current involved at the instant when full voltage is applied with autotransformer starting. The resistance-starting method has the advantage that it produces very smooth starting conditions with respect both to strains imposed upon the motor and load and to the power and voltage fluctuations produced in the supply circuit during the starting period. Resistance starting is used when the strains imposed upon the load with compensator starting would be detrimental or when this method is required by the regulations of power supply companies. The resistance method is not generally satisfactory unless a starting torque of 50 percent or less of full-load torque is sufficient.

With series-reactance starting, just as in resistance starting, the motor connections need not be broken during the starting period. The reactor is short-circuited when the motor attains its maximum speed on reduced voltage. For the same current drawn from the line, reactance starting will develop the same starting torque as resistance starting. Reactance starting has the advantages over resistance starting that less power is consumed during the starting period and that the transition peaks of current will be lower because of the opposing effect of the inductance to sudden changes in the current. For the same number of steps reactance starting will produce the smoothest starting conditions of any of the three starting methods. However, in the smaller sizes control equipment of this type is more expensive than either of the other two types and for all sizes is more expensive than resistance starting. It is not practicable to make reactance starters for more than two steps of starting control, so that, by using a greater number of steps, smoother starting can be obtained with resistance starting. For many large motors, a reactance starter will be cheaper than a transformer starter, since only two sets of switching contacts are required for a one-step starter as compared with three sets for a transformer starter. For these reasons, reactance starting is utilized only with very large motors when one or two steps of starting will be satisfactory.

On account of the lower cost of across-the-line starters the general practice is to employ this type of starting whenever it is possible to use motors whose starting currents are within the allowable limits.

Refer to Fig. 7.152 and Secs. 299, 300, and 301 for further comparison.

In method (d), the motor is provided with two windings, and 12 leads are generally brought out. On initial start-up, only one winding is energized, and the second winding is

energized after a short predetermined time delay. Two contactors, rated for part-winding start, are required, and overload protection must be provided for each winding. Part-winding start motors are often dual-voltage motors, such as 230/460 V, with each winding designed for 230 V. When used on 230-V service, the windings are connected in parallel. When used for 460-V service, they are connected in series. In 230-V service, part-winding start (two-step) or full-winding start is available. In 460-V service the motor must be used with full-winding start. See Sec. 312.

In method (e), the motor has six leads, two for each winding, and is connected in star for the initial start-up, then reconnected in delta for normal running. The transition of connection may be initiated by a timer or a current-sensing device. The transition period from star to delta may be "open," in which case the motor is entirely disconnected from the supply during the transition period, or "closed" transition may be used, which involves additional contactors and resistors to maintain current during the transition period. Mechanical interlocking of contactors, to prevent them from closing a short circuit across the line, is necessary. The overload protection should be connected into only one end of each winding and selected on the basis of 58 percent of the motor full-load current. That is, when selecting the overload protection, enter the manufacturer's overload selection tables using a motor full-load current equal to 58 percent of the nameplate full-load current for the motor in its across-the-line delta connection. Starters for star-delta start motors, with mechanically interlocked contactors, are available. See sec. 313 for complete schematic diagrams.

In method (f), solid-state reduced-voltage starters are used, as described in Sec. 263.

298. Starting with and without compensators. The starting current taken by a squirrel-cage induction motor at the instant of starting is equal to the applied emf divided by the impedance of the motor. Only the duration of this current, and not its value, is affected by the torque against which the motor is required to start. The effect of starting without and with a compensator is illustrated by diagrams I and II in Fig. 7.151. Motor I is thrown directly on a 460-V line. The impedance of the motor is 5Ω per phase; the starting torque, 10 lb at 1-ft radius; and the current taken, 92 A. In diagram II a compensator is inserted, stepping down the line voltage from 460 to 60 percent of 460, or 276 V. This reduces the starting current of the motor to 60 percent of 92, or about 55 A, and the starting torque becomes $0.6^2 \times 10$, or 3.6 lb at 1-ft radius. The current in the line is reduced to 60 percent of 55, or 33 A.

Thus when a compensator is used, the starting torque of the motor can be reduced to approximately the value required by the load, and the current taken from the line is correspondingly decreased.

FIGURE 7.151 Starting with (I) and without (II) compensator.

299. General Comparison of Starting Conditions among Three Types of Reduced-Voltage Starters

(Allis-Chalmers Corporation)

Characteristic	Autotransformer type	Primary resistor type	Reactor type
Starting line current at same motor terminal voltage	Least	More than autotransformer type	
Starting power factor	Low	High	Low
Quantity of power drawn from the line during starting	Less	More than autotransformer type	
Torque	Torque increases slightly with speed	Torque increases greatly with speed	
Torque efficiency	The autotransformer-type starter provides the highest motor starting torque of any reduced-voltage starter for each ampere drawn from the line during the starting period	Low	Low
Smoothness of acceleration	Motor is momentarily disconnected from the line during transfer from start to run	Smoother. As the motor gains speed, the current decreases. Voltage drop across resistor or reactor decreases and motor terminal voltage increases. Transfer is made with little change in motor terminal voltage	
Cost	Equal	Lower in small sizes, otherwise equal	Equal
Ease of control	Equal	Equal	Equal
Maintenance	Equal	Equal	Equal
Safety	Equal	Equal	Equal
Reliability	Equal	Equal	Equal
Line disturbance	Varies with line condition and type of load		

300. Comparison of Current Torque Starting Characteristics for Squirrel-Cage Motors

(Allis-Chalmers Corporation)

Refer to Fig. 7.152.

Method of starting	Starting current drawn from the line as a percentage of full-load current	Starting torque as a percentage of full-load torque
Connecting motor directly to the line—full potential	470	160
Autotransformer 80% tap	335	105
Resistor or reactor starter to give 80% applied voltage	375	105
Autotransformer 65% tap	225	67
Resistor or reactor starter to give 65% applied voltage	305	67
Resistor or reactor starter to give 58% applied voltage	273	54
Autotransformer 50% tap	140	43
Resistor or reactor starter to give 50% applied voltage	233	43

FIGURE 7.152 Accelerating torque characteristics of a squirrel-cage induction motor. [Allis-Chalmers Corporation]

301. Comparison of autotransformer and resistance for decreasing voltage in starting squirrel-cage motors. The motor in Fig. 7.153 is supposed to require 100 A to start it, i.e., to provide the energy needed to produce the necessary starting torque. At I, where an autotransformer is used to lower the voltage to 115, a current of 100 A is produced in the motor primary with a current in the line of 50 A. This condition is due to

FIGURE 7.153 Starting with resistance and with compensator.

the transformer action of the autotransformer. At II are shown the running conditions at which the autotransformer is entirely disconnected from the circuit. At III are illustrated the conditions that would obtain if the voltage were lowered for starting by inserting resistance in series with the line. Obviously 100 A must flow in all portions of the line even though the resistance of 1.15Ω reduces the line voltage of 230 to a voltage of 115, which is impressed on the motor. There is a loss of energy in the resistance. For the same line starting current the starting torque available with the resistance method will be considerably less than that developed when a compensator is employed. As stated in Sec. 297, the resistance-starting method has the advantage that it produces very smooth starting conditions with respect to both the strains imposed upon the motor and load and the voltage fluctuations produced in the supply circuit during the starting period. A comparison of starting torques and currents when reducing the voltage in the two different ways is given in Table 300.

302. Across-the-line ac motor controllers are made in a variety of types. The most common types are:

1. Manual motor-starting switch with no overload protection (toggle and drum switches)
2. Manual motor-starting switch with thermal overload protection
3. Magnetic switch (contactor) without overload protection
4. Magnetic switch with thermal overload protection

303. The manual motor-starting switch is simply a tumbler, rotary, or lever switch without overload protection constructed in an especially rugged manner. Some designs provide undervoltage protection. A single switch is used for nonreversing duty and an interlocked pair for reversing duty up to 2 hp. Drum-switch types are more commonly used for reversing applications. Some representative types are illustrated in Figs. 7.154 and 7.155.

304. Manual across-the-line starting switches with thermal overload protection are shown in Figs. 7.156, 7.157, and 7.158. The overload protection is obtained by means of a thermal overload relay. (For more comprehensive discussion of the principles of thermal overload relays refer to Div. 4.)

305. Magnetic across-the-line motor controllers consist of a magnetically operated contactor controlled from a pushbutton station. Starters are provided with thermal overload and undervoltage protection. For the switch and circuit shown in Fig. 7.159,

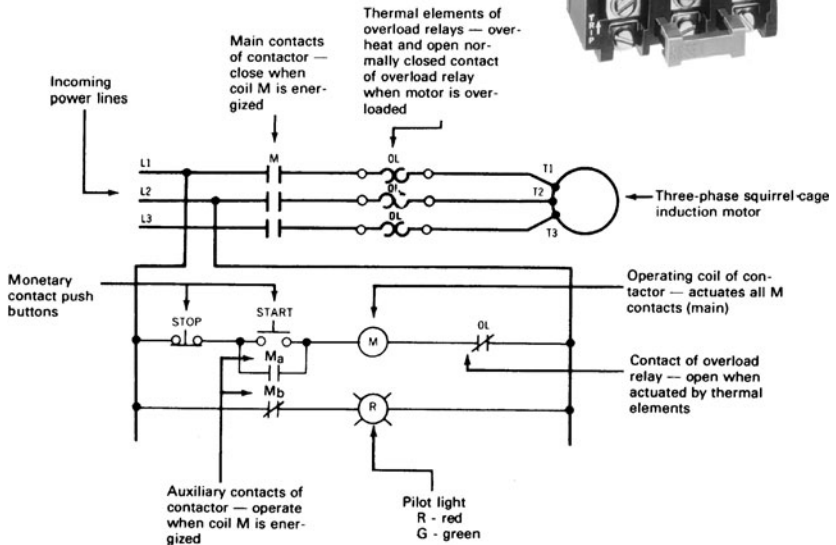

FIGURE 7.159 Magnetic across-the-line starting. [Square D, Schneider Electric]

pressing the **START** button closes the circuit of the operating coil <M> of the magnetic contactor. This allows a current to flow from one side of the line, through the **START** button, through the operating coil, and back to the other side of the line. The operating coil, being energized, closes the magnetic contactor. The closing also closes an auxiliary contact so that when the **START** button is released, the operating coil is still energized. To stop the motor the **STOP** button is pressed. This opens the circuit of the operating coil, allowing the switch to reopen. In case of an overload the thermal overload relays operate and open their contacts. This deenergizes the operating coil and allows the contactor to open. If the voltage of the line fails or falls to a low value, the operating coil will not be energized sufficiently to hold the contacts of the contactor closed. As the contactor drops out, the contacts are opened and the motor will not start upon return of normal voltage until the **START** button is pressed.

FIGURE 7.160 Reversing-type magnetic cross-the-line starter for a squirrel-cage motor. [Westinghouse Electric Corp.]

Magnetic across-the-line starting controllers are made in a variety of types for both nonreversing and reversing duty. The reversing types consist of two magnetic contactors electrically interlocked so as to prevent the closing of both switches at the same time (Fig. 7.160).

306. Combination magnetic across-the-line starters are the magnetic across-the-line starters which include in the same metal enclosure the motor branch-circuit short-circuit protective device. The following different combinations are available as standard equipment:

1. Magnetic starter and motor-circuit protector (Fig. 7.161)
2. Magnetic starter and fused motor-circuit switch (Fig. 7.162)
3. Magnetic starter and inverse-time circuit breaker

National Electrical Code rules require the installation of short-circuit protection and a motor-circuit disconnect means on the line side of each magnetic starter. Combination starters make a very compact and neat installation to meet these requirements. Almost any desired combination for nonreversing or reversing service can be obtained (Fig. 7.163).

307. Motor-circuit protection and isolation. The disconnect means required by the National Electrical Code provides a way to isolate the motor and other portions of the motor branch circuit from the power lines to permit safe servicing and replacement of fuses. This disconnect means there must be a circuit breaker, a motor-circuit switch (rated in either motor horsepower or motor full-load current and motor locked-rotor current), or a properly rated general-use switch. General-use switches are used primarily with small motors. The motor branch circuit must also contain short-circuit protection for the circuit components. This protection may be in the form of either time-delay or non-time-delay fuses selected in accordance with the rules of the National Electrical Code, motor short-circuit protectors (fuse-type devices called MSCPs), or a circuit breaker.

FIGURE 7.161 Combination starter with adjustable-trip-only circuit breaker. [Westinghouse Electric Corp.]

FIGURE 7.162 Combination starter with fusible disconnect, control transformer, and optional features. [Square D, Schneider Electric]

FIGURE 7.163 Across-the-line combination starter and Type 12 horizontal enclosure with optional features. [Allen Bradley Company, Inc.]

For small motors, adjustable magnetic-trip-only circuit breakers, called *motor-circuit protectors*, offer close short-circuit protection because the magnetic-trip element of these devices can be adjusted to the lowest possible value that permits the motor to start. On the other hand, molded-case inverse-time circuit breakers in the smaller frame sizes (up to 150 A) have no provision for adjusting their magnetic-trip setting, and the inverse-time characteristic of these circuit breakers is slower for a given overload than the inverse-time characteristic of the thermal overload relays in the circuit. Hence, the latter operate first and open the circuit when an overload or low-level fault occurs. The magnetic-trip portion of an inverse-time circuit breaker is the only portion that ever causes the circuit breaker to operate in a properly designed motor branch circuit containing overload relays.

308. Reduced-voltage starters. From the viewpoint of controlling current in-rush, the solid-state reduced-voltage starter provides a smoother start for squirrel-cage motors than any other type of starting equipment. Stepless primary resistance starting also provides a smooth start. When the power company severely limits the motor inrush current, these are the ideal automatic motor starters. The primary resistance starter is, however, the most expensive method of reduced-voltage starting and should never be used when an appreciable breakaway torque is required.

FIGURE 7.164 Low-voltage autotransformer reduced-voltage synchronous motor starter. [Allen Bradley Company, Inc.]

The automatic autotransformer starter (Fig. 7.164) is the most effective method of reduced-voltage starting when the application requires a reduction in the current drawn from the line coupled with the greatest possible starting torque. Closed-circuit transition, an option afforded by the autotransformer starter, is particularly advantageous since the high transient currents associated with open-circuit transition starters are eliminated.

Primary-resistance starters are usually employed when the starting current must be reduced and a lower starting torque as compared with that of the autotransformer starter is of little consequence. Primary-reactance starters are similar to the primary-resistance type but are usually applied only to high-voltage starters or on starters for very large motors.

One of the least expensive methods of obtaining reduced-inrush-current starting involves a part-winding starter. It uses two smaller-size contactors as compared with the contactor size employed for across-the-line starting. Voltage-reducing equipment such as transformers, resistors, or reactors is not required. Transition from start to run is inherently closed-circuit transition, and therefore high transient currents during the transition period are nonexistent. Part-winding starting does have some disadvantages. It has a very low and erratic starting torque and can be applied only to induction motors which have been designed for part-winding service. Almost invariably, this type of starting is increment because of the low starting torque. Part-winding starting is not recommended for drives that are frequently started or for high-inertia drives. Its main application is in air-conditioning and ventilating installations.

Star-delta starting is similar to part-winding starting, in that accessory equipment for voltage reduction is not necessary. The stator winding of the motor must be connected in delta with six leads brought out. Starting current and torque are about one-third normal. Star-delta starting is more efficient than part-winding starting and is somewhat more expensive.

309. Primary-resistance starters for squirrel-cage induction motors are made in both manual (semimagnetic) and magnetic types. The magnetic types generally provide time-limit acceleration. They are similar to starters for dc motors, except that they are provided with resistors and switching equipment for each phase, all phases being switched simultaneously. In some types all the resistance is cut out in one step, while in others the starting resistance is cut out in several steps. The manual starters may be of the dial or the drum type. With the manual starters, overload and undervoltage (if desired) protection must be provided separately from the starter. A magnetic starter is shown in Fig. 7.165. Magnetic starters are provided with overload protection and with undervoltage protection or release as desired. Primary-resistance starters of the drum and magnetic types can be obtained for reversing or nonreversing service.

310. Primary-reactance starters. It is possible to reduce the motor terminal voltage as required by using series reactors rather than resistors. However, this method is not generally employed except in high-voltage or high-current installations, or both, in which the heating and physical construction of resistors is a problem. The use of reactors results in an exceptionally low starting power factor and somewhat aggravates the already poor line regulation. Then, too, owing to the relative difficulty of changing the reactance values in the field, reactor starting is more expensive and less flexible than resistor starting on all but the largest machines. The added cost has a very real basis, in that the reactors must be carefully designed and applied, since any saturation would lead to inrushes equal to full-voltage starting current. Such a condition would, of course, make the use of the reactors pointless.

FIGURE 7.165 Primary-resistance-type reduced-voltage motor starter, ac, polyphase. [Allen-Bradley Company, Inc.]

Resistor- and reactor-starting methods have one advantage in common: in both cases, the motor terminal voltage is a function of the current taken from the line. It can therefore be assumed that during acceleration the motor voltage will rise as the line current drops, resulting in greater accelerating energy at the higher speeds and a correspondingly less severe disturbance when the transition to full voltage occurs. This advantage is generally overestimated, first, because the line current does not decrease significantly from locked value until rather late in the accelerating period, and, second, because the difference between the line voltage and the motor terminal voltage is a vector and not a scalar difference.

311. Autotransformer starting. One of the most effective methods of reduced-voltage starting uses the autotransformer. It is preferred to the primary-resistance type when the starting current drawn from the line must be held to a minimum value and maximum starting torque per line ampere is needed.

The autotransformer starter has distinctive characteristics which are often overlooked. First, it is plain that the motor terminal voltage is not a function of load current and remains substantially constant during the accelerating period. Of course, there is some voltage variation in the transformers, but this is negligible, and, from the standpoint of overall power factor, so is the magnetizing current.

Second, note that because of the turns-ratio advantage, the ratio of line current to torque is the same for autotransformer starting as for full-voltage starting. Here we must distinguish between motor current and line current, which are not equal, as they are in resistor and reactor starting.

Autotransformers, also known as compensators or autostarters, consist of an autotransformer, a double-throw switching device, and overload and undervoltage protective devices, all compactly mounted in a sheet-metal case. They can be obtained for either manual (semimagnetic) or magnetic operation. The manual type is provided with a lever outside the case which controls the double-throw-switch mechanism. When the handle is in the off position, the motor and autotransformer are both disconnected from the line. Throwing the lever to the *START* position connects the autotransformer to the line and the motor to the secondary taps of the autotransformer applying the reduced voltage for starting. When the handle is thrown to the *RUN* position, the motor is connected directly to the line and the autotransformer is entirely disconnected from the circuit. The switching mechanism is so designed that it cannot be left in the *START* position but will automatically return to the off position unless thrown to the *RUN* position after the start.

Most manual compensators are provided with a *STOP* button so interconnected with the overload protective device that, if pressed, the button will actuate the device and open the compensator contacts.

In the automatic compensator the same sequence of operations as in the hand-operated type is performed automatically after the operator has pressed the *START* button. The acceleration may be time-limit- or current-limit-controlled. Most automatic compensator starters employ the time-limit method. The closing of the *START* button closes the operating coil of a magnetic contactor which connects the motor to the line through the autotransformer. With time-limit control, after a sufficient time has elapsed, a time-delay relay closes its contacts, completing the operating circuit of a second magnetic contactor. The closing of this second contactor disconnects the autotransformer from the circuit and throws the motor directly across the line. With the current-limit control, a current-limit relay closes the operating-coil circuit of the second contactor after the current has been reduced to the proper value.

To stop the motor it is necessary simply to depress the *STOP* button, which opens the operating coil of the magnetic contactor, allowing the contacts to open and disconnect the motor from the line.

Compensators are provided with two or more sets of secondary taps on the autotransformers so that the voltage best suited to the required starting conditions may be used. Typical compensators are shown in Fig. 7.164 and Fig. 7.167.

The standard compensator does not provide for reversing duty. For such service an additional reversing switch of either the manual or the magnetic type is required.

Overload protection on autotransformer starters is provided by thermal or magnetic overload relays. In manual compensators the overload relay opens the holding-coil circuit, allowing the switch of the compensator to return to the off position. In magnetic compensators the overload relay breaks the circuit of the operating coil of the magnetic contactor so that the contactor opens. Typical connections for overload protection with thermal relays are shown in Figs. 7.166 and 7.167. The relays generally are arranged so that they can be

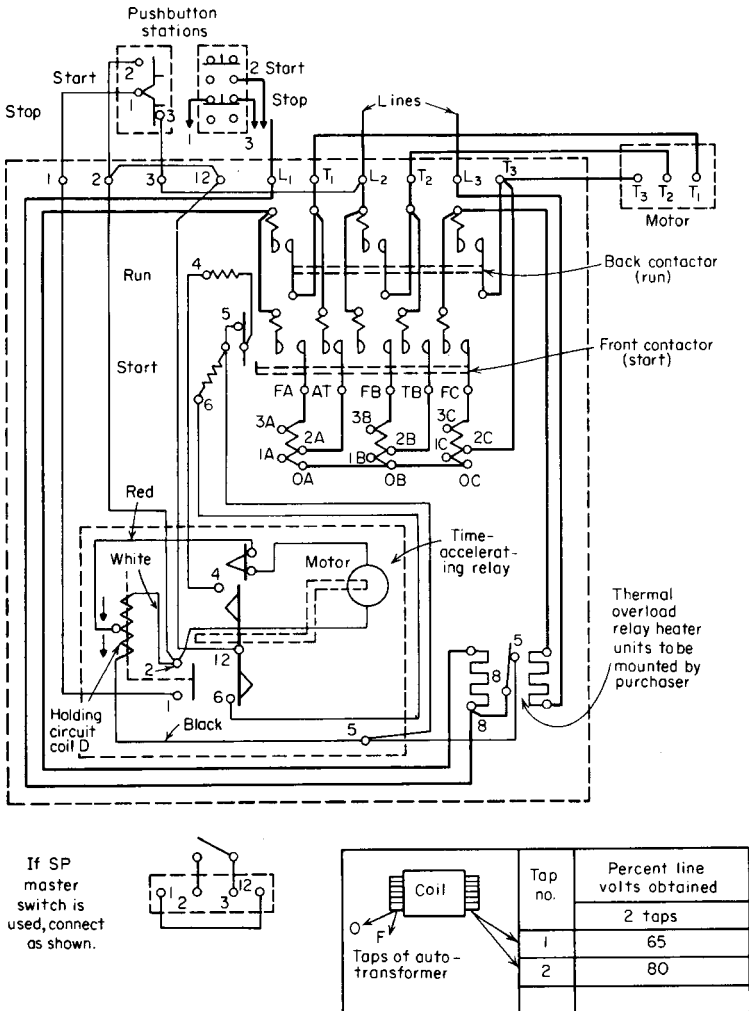

FIGURE 7.166 Connections for a magnetic compensator (autotransformer starter). [General Electric Co.]

FIGURE 7.167 Autotransformer reduced voltage starter. [Square D, Schneider Electric]

adjusted to operate at different currents. Thermal relays inherently have inverse-time characteristics. When the magnetic relays are employed, they generally are equipped with devices to give the inverse-time feature.

Undervoltage protection is almost always provided on autotransformer starters. For magnetic compensators the coil acts as the undervoltage coil (see Fig. 7.166). If the voltage of the line drops sufficiently, this operating coil is deenergized to such an extent that it releases the holding circuit interlock wired in parallel with the *START* button.

The magnetic compensator is diagrammed in Fig. 7.166. It consists of a run contactor, a start contactor, an autotransformer, an accelerating relay, and an overload relay. In the compensator illustrated, acceleration is time-controlled. Figure 7.166 functions as follows. When the *START* button is pressed, a circuit is closed for L_2 , through the *STOP* and *START* buttons, to 2, to 12, through the accelerat-

ing relay contact to 6, through the operating coil of the start contactor to 5, through overload relay contacts to 8, and back to L_1 . The operating coil of the start contactor is thus energized, and the start contactor closes, applying reduced voltage to the motor through the transformer. At the same time a circuit is closed from L_2 , through *STOP* and *START* buttons to 2, through the motor of the accelerating relay to 5, through the overload relay to 8, and back to L_1 . Current through coil *D* closes contact 1–2 and allows current to flow from L_2 through the *STOP* button to 1, through contact 1–2 to 12, through 12–6 to the operating coil of the start contactor, and back to L_1 , even though the *START* button is opened. After a certain definite time the timing motor opens contacts 12–6 and closes contacts 12–4. The opening of contacts 12–6 breaks the circuit of the operating coil of the start contactor, allowing the contactor to open, and closes contact 5. The closing of contacts 12–4 and 5 allows current to flow from L_2 through the *STOP* button to 1, through contact 1–2 to 12, through contacts 12–4, through the operating coil of the run contactor, through contact 5, through the overload relay to 8, and back to L_1 . The operating coil of the run contactor is thus energized, and this contactor closes, applying full voltage to the motor. Opening the overload relay or pressing the *STOP* button will open the circuit of coil *D*. This deenergizing of *D* will allow contact 1–2 to open, which breaks the circuit to the operating coil of the run contactor, allowing this contactor to open and disconnect the motor from the line.

Two types of autotransformer connections of control schemes are in common use today. One is designated *closed-circuit transition or Korndorfer connection*, named after its inventor, and the other *open-circuit transition*. Figure 7.168 is a typical diagram of a closed-circuit transition starter. The taps of the autotransformer are permanently connected to the motor. Three contacts are used. The control sequence is as follows. When the *START* button is pressed, contactors 1*S* and 2*S* close, connecting the motor through the transformer taps to the power line. At the instant that contactor 2*S* is closed, a timing mechanism is activated. After a predetermined time, the time drops out 1*S*, and for a short interval, until *R* closes, part of the transformer windings functions as a reactor. When contactor *R* closes, it bypasses the transformer and connects the motor to full line voltage. A late-break auxiliary contact on *R* drops out 2*S*.

Figure 7.169 is a diagram of a typical open-circuit transition autotransformer starter. It contains two contactors. A pilot device closes the circuit to contactor *S*, which connects the motor to the reduced-voltage taps of the autotransformer and the transformer to the line.

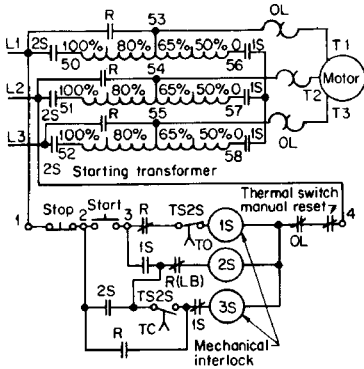

FIGURE 7.168 Typical closed-circuit transition autotransformer starter. [Allen-Bradley Company, Inc.]

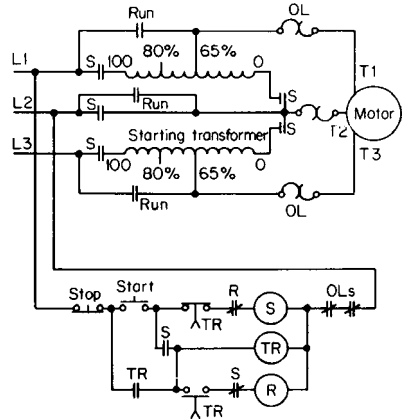

FIGURE 7.169 Typical open-circuit transition autotransformer starter. [Allen-Bradley Company, Inc.]

Simultaneously, a time-delay relay *TR* is energized. After a time interval, *TR* opens *S*, disconnecting the motor and transformer from the line. Contactor *R* then closes to connect the motor across the line. This is an open-circuit device since contacts *R* must not be closed until contacts *S* are open. Any overlap will cause dangerously large currents to flow through part of the transformer windings. The main objection to open-circuit transition is the flow of high transient currents when the motor is reconnected to full-voltage operation.

312. Part-winding starting. If the stator windings of an induction machine are divided into two or more equal parts, with all the terminals for each section available for external connection, the machine may lend itself to what is known as *part-winding starting*. Part-winding starters are designed for use with squirrel-cage motors having two separate parallel stator windings.

Part-winding starters are available in either a two- or a three-step construction. The two-step starter is designed so that when the control circuit is energized, one winding of the motor is connected directly to the line. This winding then draws about 65 percent of normal locked-rotor current and develops approximately 45 percent of normal motor torque. After about 1 s, the second winding is connected in parallel with the first; the motor is then fully across the line and develops its normal torque.

The three-step starter has resistance in series with the motor on the first step. Initially, one winding is connected to the line in series with a resistor. After a short time interval (about 1 s), the resistor is shorted out, and the first winding is connected directly to the line. The second winding is connected to the line in parallel with the first winding 1 s later. The motor then draws full line current and develops normal torque.

By far the most common number of winding sections or parts is two; the stator then consists of two windings, with six leads brought out, and the motor is intended to deliver its rated output with the windings in parallel (see Fig. 7.170). These windings may or may not be identical, but in any case they cannot occupy the same slot simultaneously. Applications of the line voltage to one of the winding sections will cause the motor to draw from 65 to 80 percent of normal starting current, with a torque output of about 40 percent of normal locked torque.

FIGURE 7.170 Part-winding starter.
[Allen-Bradley Company, Inc.]

Torque efficiency is roughly equivalent to that of resistor starting, in that the ratio of starting current to starting torque is fairly poor. The similarity ends there, however, since the part-winding method allows no adjustment of these values. Part-winding schemes almost inevitably lead to increment starting, for the starting torque is so low that the motor rarely starts on the first step. At the start, one winding is carrying up to 50 percent more current than it would on a full-voltage start, and heating increases correspondingly. If this characteristic is unacceptable, it is sometimes the practice to use resistors in combination with part-winding starters to reduce further the starting current and torque. However, since part-winding starting is usually adopted for economic reasons, considerable thought should be given before it is modified with such embellishments. It may well be that another form of conventional starting will perform the task more economically and with more satisfactory starting performance.

Part-winding starting has certain obvious advantages. It is less expensive than most other methods, because it requires no voltage-reducing elements such as transformers, resistors, or reactors, and it uses only two half-size contactors. Furthermore, its transition is inherently closed-circuit.

But it also has several disadvantages. In the first place, the starting torque is poor, and it is fixed; the starter is almost always an increment-start device. Second, not all motors should be part-winding-started, and it is important that the motor manufacturer be consulted before this type of starting is applied. Some motors are wound sectionally with part-winding starting in mind, but indiscriminate application to any dual-voltage motor (for example, a 230/460-V motor which is to run at 230 V) can lead to excessive noise and vibration during start, to overheating, and to extremely high transient currents upon switching. Then, too, since the current requirements in part windings allow the use of smaller contactors and coincidentally smaller overload elements, the fuses must be proportionately small to protect these elements. Time-delay fuses are therefore a virtual necessity.

313. Star-delta starting (also called Y-delta). Probably no other method of starting has been so thoroughly investigated as the European technique of star-delta starting. The first prerequisite of this scheme is, of course, that the motor be wound to run with its stator windings connected in delta and with all leads brought out. Delta-wound motors have not been common in the United States, and it was primarily the interest shown by manufacturers of large centrifugal air-conditioning units which prompted their reappraisal for starting purposes.

The fully automatic version of the star-delta starter consists of a full-size, full-voltage magnetic starter, two contactors for switching the star and delta connections, and a timing unit. When the operator presses the START button, the line and star contactors close and the motor starts. The motor is then star-connected and operates on approximately 58 percent of normal voltage. After the starting period, which is determined by the timer setting, the star contactor opens, and an instant later the delta contactor closes. The line contactor remains closed during this automatic transition.

The star-delta starter is also available in a manual style which allows the operator to perform the switching from star to delta. The components of the manual starter are the

same as those in the automatic starter, except that the timing unit is omitted and the operator utilizes a START-RUN-STOP button instead of the START-STOP button found on the automatic starter.

As shown in Fig. 7.171, the motor windings are first connected to the line in Y or star. Starting current and torque are consequently about one-third normal. In the basic method, the transition to delta must be preceded by opening the circuit to the motor. The star-delta method therefore is inherently one of open-circuit transition.

The appeal of this method, as with the part-winding technique, lies largely in its lack of accessory voltage-reducing equipment. While it has the disadvantage of open-circuit transition, a star-delta starter does give a higher starting torque per line ampere than a part-winding starter. Star-delta is almost always an increment method, because the low starting torque (33 percent) rarely allows the motor to start on the first step. The time delay allows the sagging voltage caused by motor inrush current to recover. Noise and vibration are conspicuously absent, and except for the normal transients associated with open-circuit transition the current inrushes are not excessive at any point.

Figure 7.172 shows a modification using resistors to maintain continuity and thus avoid the difficulties associated with the open-circuit form of transition. The resistors must be carefully proportioned, both in ohmic value and in watts dissipation, for the application in question.

314. Control apparatus for multispeed induction motors. Controllers for multispeed squirrel-cage motors are predominantly two-speed starters, consisting of two contactors, mechanically and electrically interlocked, and two three-pole overload relays, one for each speed. Various contactor-pole configurations are available. Selection is dependent upon the motor winding pattern.

Two-speed motors with a single winding (called *consequent-pole motors*) have tap points on their windings connected differently for each of the two speeds. Controllers for consequent-pole motors consist of a three-pole contactor interlocked with a five-pole contactor (called a 3×5 controller), where two poles of the latter device are used to tie three tap points together to make a star (Y) connection. The ratio of low to high speed is fixed for such motors.

Two-speed motors with two windings can be made with any desired ratio of low to high speed. The windings can be:

1. Y-Y (uses 3×3 controller)
2. Y-delta (uses 3×4 controller)
3. Delta-Y (uses 4×3 controller)
4. Delta-delta (uses 4×4 controller)

Two-speed controllers for these motors are various combinations of three- and four-pole contactors as shown above. A four-pole configuration is required for each delta winding so that the delta winding not in use can be opened when the other motor winding is connected to the line. If the unused delta winding is not opened, induced currents in this winding will cause the motor to overheat. See Fig. 7.173 for connection diagrams.

FIGURE 7.173 (Continued)

315. Controllers for three-speed and four-speed motors have a contactor and a three-pole overload relay for each speed, with the contactors and control stations suitably interlocked. The motor full-load current at each speed must be considered when selecting overload relay elements just as for single-speed and two-speed starters. Often the low speed of a multi-speed starter is also used to clear a jam, and in those cases the phase rotation within the motor must be reversed. A reversing contactor is required in addition to the multispeed starter for such applications, and the operator must select direction (forward or reverse) in addition to speed. Control for direction is often in the form of a maintained-contact selector switch.

316. Controllers for wound-rotor motors are manufactured in dial, drum, and magnetic types. The same piece of equipment is utilized for both starting and speed control when speed control is desired. The same precautions must be taken in using a controller for speed control, however, as are outlined in Sec. 290 for armature speed controllers for dc motors.

317. Dial controllers for wound-rotor ac motors are similar to dial controllers for dc motors, except that they have two or three sets of resistances controlled by means of two or three contact arms. These controllers control the resistance in the rotor (secondary) circuit only, so a separate switch and overload protection must be provided in the stator circuit. It is best to have this primary line switch of the magnetic type so that it can be electrically interlocked with the secondary controller. With such an arrangement the motor cannot be started unless the resistance is cut into the rotor circuit. For reversing service a reversing switch is provided in the stator circuit.

318. Drum controllers for wound-rotor ac motors are similar in appearance and general construction to those employed for dc motors (see Fig. 7.140), except that the movable contacts control two or three sets of resistances instead of only one set. In addition to these contacts for controlling the rotor resistance, some drum controllers are provided with contacts for opening and closing the stator circuit. If the drum is not so designed, it is best to have the line switch of the magnetic type so interlocked with the secondary controller that the switch cannot be closed unless the resistance is cut into the rotor circuit.

Controllers of this type are suitable for nonreversing or reversing service. Overload protection and undervoltage protection, if desired, must be provided in the stator circuit.

319. Magnetic controllers for wound-rotor induction motors consist of a primary contactor and one or more secondary contactors, depending upon the number of steps of secondary resistance employed. They can be obtained for reversing or nonreversing duty. Reversing starters require two electrically interlocked primary contactors. Time acceleration is employed for most of these controllers, but current limit or frequency limit is used for some applications.

A multicircuit-escapement type of timing relay controls the sequence and time of operation of the successive contactors. A controller using frequency control of acceleration is shown in Fig. 7.174.

320. The use of silicon-controlled rectifiers (SCRs) is one of the newer methods of reduced-voltage starting. These starters provide smooth, stepless acceleration of standard squirrel-cage motors in applications such as starting conveyors, compressors, and

FIGURE 7.174 Microprocessor controlled adjustable frequency drive controller designed for reliable control of 3-phase induction motors. [Allen Bradley Company, Inc.]

pumps. A controller with vertical open construction is shown in Fig. 7.175, and a typical simplified wiring diagram in Fig. 7.176. The unique feature of this solid-state starter is the use of start and run contactors. Operation is as follows:

1. When the **START** pushbutton is operated after the disconnect switch has been closed, the start contactor is energized.
2. When the start contactor contacts are closed, the SCRs start to fire. The motor is brought up to speed either with *constant-current acceleration* or with *linear-timed acceleration*.
3. When the sensing circuit of the starter detects a current approaching the full load current of the motor, the run contactor will be energized.

FIGURE 7.175 Solid-state reduced-voltage Smart Motor Controller. [Allen-Bradley Company, Inc.]

FIGURE 7.176 Simplified wiring diagram of an SCR starter. [Allen-Bradley Company, Inc.]

4. When the run contacts are closed, the SCRs are turned off.
5. After the SCRs stop conducting, the start contactor is deenergized, and the motor runs under the control of the run contactor.
6. When the stop pushbutton is energized, the run contactor is deenergized, and the motor is isolated from the line.

321. Adjustable-frequency motor controllers are designed to drive squirrel-cage induction motors over a range of speed that typically varies from one-thirtieth to twice normal rated speed. The virtue of these controllers is their ability to use standard off-the-shelf ac motors that are lightweight, rugged, and easy to maintain and yet provide speed control almost equivalent to that of dc motors.

In an adjustable-frequency motor controller, the incoming ac supply voltage is rectified by a variable-voltage dc level. The dc voltage is then inverted to an adjustable-frequency output by a microprocessor that creates a new sine wave with properly selected pieces of direct current at the desired frequency. The voltage is generally adjusted proportionally to provide a constant-volts-per-hertz excitation to the motor terminals up to normal rated frequency (50 or 60 Hz). Above normal rated frequency, the voltage supplied to the motor remains at rated motor voltage to obtain energy savings.

Selecting the proper size of motor to drive a given load over a 6:1 ratio of speeds when supplied by an adjustable-frequency motor controller is more complex than for a single- or two-speed application. First, the load torque-versus-speed requirements must be determined, and then a single motor that can cover the range must be selected.

Figure 7.177 illustrates the torque-speed characteristic of a typical induction motor when controlled from an inverter over the frequency range of 2 to 120 Hz. From 2 Hz up to the nominal rated frequency of 60 Hz, the motor can supply constant torque T_n . Within this range, the magnitude of the motor slip speed remains the same, in revolutions per minute, for a constant-torque load (Region 1). At 60 Hz, the output voltage reaches its maximum value. As a result, the motor operates in the weakened field range from 60 to 120 Hz, yielding a constant-horsepower characteristic (Region 2). Within this range, the motor's slip speed varies as a constant percentage of its set synchronous speed.

As can be noted from Fig. 7.177, the percentage rated torque shown is 80 percent of the motor nameplate rating. This is to compensate for the additional heating which occurs in a motor owing to the nonsinusoidal output of the inverter.

Figure 7.177 is directly applicable to most separately ventilated and totally enclosed nonventilated Class B rise motors.

FIGURE 7.177 Induction-motor torque-speed characteristic, 2–120 Hz, Class B temperature rise. [Westinghouse Electric Corp.]

322. The starting equipment for the commutator type of polyphase induction motor generally consists simply of some type of across-the-line starter, as described in Secs. 302 to 307. In the special cases in which resistance is connected in series with the secondary for starting, the control would be similar to that employed for wound-rotor motors. The speed control can be regulated by shifting the brushes in any one of the following three ways:

1. By means of a handwheel mounted on the motor
2. By means of a handwheel located conveniently for the operator and connected to the brush-operating shaft by a chain drive
3. By means of a pilot motor and reduction-gear mechanism which is mounted on the main motor frame and controlled by pushbuttons located at the most convenient point for the operator

Typical connections for a magnetic controller used when motor speed is hand-adjusted are shown in Fig. 7.178. The operating coil of the contactor is connected in series with a limit switch on the motor so that the contactor will not operate unless the brushes are adjusted to the low-speed position. When a secondary resistor is employed for special starting conditions or for obtaining creeping speeds, a magnetic controller is always employed. This controller will consist of a primary contactor electrically interlocked with a secondary contactor.

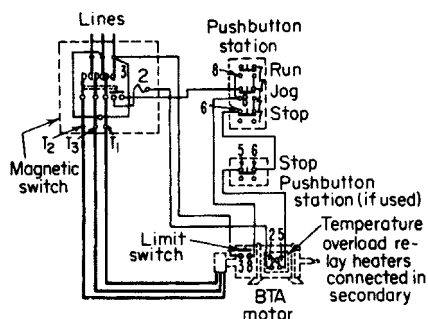

FIGURE 7.178 Connections for control of a commutator-type polyphase induction motor when speed is adjusted by hand. [General Electric Co.]

323. The control equipment for synchronous motors of conventional design is the same as that for squirrel-cage induction motors with the addition of the necessary field-control equipment. Controllers for synchronous motors may be reduced-voltage (Fig. 7.179) or full-voltage.

The essential parts of a fully automatic controller for reduced-voltage transformer starting are a line contactor, an accelerating contactor, a time-delay relay, a field-actuating relay and contactor, an autotransformer, a field rheostat, and overload and undervoltage protective devices. (See Fig. 7.180.) When the controller is in the off position, the field circuit is short-circuited through the proper value of resistance.

Pushing the **START** button energizes the accelerating contactor, which connects the autotransformer to the line and the motor to the secondary taps of the autotransformer. At the same time the time-delay relay is

FIGURE 7.179 Low-voltage auto-transformer reduced-voltage synchronous motor starter. [Allen-Bradley Company, Inc.]

I. Control panel removed from case.

II. Complete starter in case.

FIGURE 7.180 Automatic synchronous-motor full-voltage starter.
[Westinghouse Electric Corp.]

energized. After the time interval set, which corresponds to the setting of the time-delay relay, the accelerating contactor opens and the line contactor closes. The opening of the accelerating contactor disconnects the autotransformer from the line and disconnects the motor from the autotransformer. The closing of the line contactor connects the motor directly to the line and energizes the field-actuating relay. When the motor reaches approximately synchronous speed, the field relay closes and energizes the field contactor, which closes and applies excitation to the field circuit.

An automatic starter for full-voltage starting of synchronous motors (Fig. 7.181) consists of a line contactor, a field-actuating relay and contactor, a field rheostat, and overload and undervoltage protective devices. Pushing the **START** button energizes the line contactor

and connects the motor directly across the line with the field short-circuited through the proper value of resistance. When the motor reaches nearly synchronous speed, the contacts of the field-actuating relay automatically close. After a definite time the field contactor closes, applying excitation to the field circuit.

Resistance starters for synchronous motors of conventional design are generally fully automatic. They are similar to primary-resistance starters for squirrel-cage induction motors with, as mentioned above, the necessary relays and contactors for field control.

A saturable-reactor type of controller is employed sometimes for very large motors when a large number of starting steps are required. The principle of this method of acceleration is illustrated in Fig. 7.181. Each phase is supplied with a saturable reactor, which is built on a three-leg iron core. Coils on the outside legs of the reactors are connected in series with the motor, and coils on the middle leg are connected to a source of direct current in series with a rheostat. In starting the motor the dc coils are at first disconnected from their supply. The reactor then has a high impedance to alternating current and limits the first inrush of current. The dc coils are then energized with all the resistance of their control rheostat cut into the circuit. The current in the dc coils decreases the impedance of the ac coils. As the rheostat cuts resistance out of the dc circuit, the direct current increases still further, reducing the impedance of the ac coils until the reactor core is saturated and the impedance of the ac coils is practically zero. A large number of steps is thus easily available for starting the motor. An actual controller would generally be automatically operated and would include field-control equipment for the motor.

The control equipment for synchronous motors with wound-rotor secondaries will generally consist of a fully automatic magnetic controller of the same general type as that used for wound-rotor induction motors with the addition of relays and contactors for field control.

324. Vacuum contactors for ac applications. In recent years, metallurgy and vacuum technology have progressed to the point where motor controllers using contacts that operate in a vacuum have become more common. In a vacuum contactor, the main contacts are sealed inside ceramic tubes from which all air has been evacuated; i.e., the contacts are in vacuum. No arc boxes are required because any arc formed between opening contacts in a vacuum has no ionized air to sustain it. The arc simply stops when the current goes through zero as it alternates at line frequency. The arc usually does not survive beyond the first half cycle after the contacts begin to separate. The ceramic tube with the moving and stationary contacts enclosed is called a vacuum interrupter or a bottle, and there is one such bottle for each pole of the contactor. A two-pole contactor has two vacuum bottles, and a three-pole contactor has three vacuum bottles. A metal bellows (like a small, circular accordion) allows the moving contact to be closed and pulled open from the outside without letting air into the vacuum chamber of the bottle. Both the bellows and the metal-to-ceramic seals of modern bottles have been improved to the point that loss of vacuum is no longer cause for undue concern.

The moving contacts are driven by a crossbar supported by two bearings that are clamped in alignment.

The contacts in an unmounted bottle (vacuum interrupter; see Fig. 7.182) are normally closed because the outside air pressure pushes against the flexible bellows. For contactor duty, the contacts must be "normally open" when the operating magnet is not energized.

FIGURE 7.181 Connections for starting a synchronous motor with saturable reactors.

FIGURE 7.182 Cross-section view of a vacuum interrupter.

Therefore, the contacts of the vacuum bottles must be held open by a kickout spring. The kickout-spring system pulls against the moving armature and crossbar and thereby forces the bottles into the open position. In the open position, the crossbar is pulling the moving contacts to hold them open.

325. Control equipment for single-phase motors. Single-phase motors are almost always started by throwing directly across the line. Some type of across-the-line starter similar to those discussed in Secs. 302 to 307 for polyphase motors is employed. Some of the manual types with thermal overload protection are frequently called *secondary breakers*. They are not really circuit breakers, for they are not designed to interrupt short circuits. Typical single-phase manual across-the-line starters are shown in Fig. 7.183.

When the starting current of the larger sizes is greater than that allowed by the utility, a dial or drum starting rheostat similar to those for dc motors is generally employed.

FIGURE 7.183 Manual across-the-line starters for single-phase motors. [Allen-Bradley Company, Inc.]

MOTOR DRIVES AND APPLICATION

326. Design of motor drives. The proper design of motor drives for machines is very important. It involves not only the selection of a type and rating of motor but also the selection of a method of connecting the motor to the driven machine and the selection of control equipment. It is affected by power supply, driven-machine requirements, space limitations, safety and working conditions for operators, initial cost and operating costs, production and quality of product, and surrounding conditions. The objective is to obtain a final installation which will be the best when all considerations are taken into account. The manner of attacking and the complexity of the solution of the problem depend upon the particular case. In some cases the limitations are so definitely fixed that they dictate only one answer. For instance, a machine requires a speed of 1600 rpm and full-load power of 24 hp with a very occasional peak of 28 hp and an average load of 20 hp. It is not necessary to maintain an absolutely fixed ratio of speed between driving and driven shaft. No speed control is required, but the speed should not vary by more than 10 percent with load changes. The starting-torque requirements are very light, but the power company will allow only exceptionally low starting currents. The power supply is 60 Hz, 230 V, three-phase. The machine is operated in a dry and clean location with normal temperatures. In this case there is no difficulty in making the proper selection. A normal-torque, normal-starting-current, or a normal-torque, low-starting-current, 25-hp, four-pole, 230-V, three-phase, 1800-rpm, open squirrel-cage induction motor with reduced-voltage starting equipment would be used. The motor would be belt-connected to the machine.

In many cases the problem is not so simple, and it cannot be split into several simple isolated problems that can be answered individually, such as the selection of the type and rating of motor, the method of connection, etc. The selection of the type of motor and the method of connection are interdependent, so that the whole problem must be considered as a unit, carefully weighing all factors involved. Generally several different plans can be used. Each one should be worked out with respect to initial cost, operating costs, and maintenance; then the possible solutions should be weighed against each other, taking into account, in addition to the above costs, the effect of the proposed drives upon the safety and working conditions of operators and upon the production and quality of the product.

It is evident that to design proper motor-drive installations it is necessary to know the different methods of mechanical connections and their advantages and limitations and all the other important factors that will affect the correct selection of motors. In the following sections, the important points that must be considered in the selection of motors and mechanical connections are discussed, followed by tables which, it is believed, will be helpful guides to proper selection.

327. Methods of driving machines. Two methods can be employed for driving the individual machines of a shop. Each machine may be equipped with its own individual motor. This is called *individual drive*. In other cases a single motor may be employed to drive a group of machines by means of shafting and belts. This is called *group drive*. Group drive at one time was widely used. Individual drive, however, has proved to have so many advantages that it is used to drive practically all modern machines.

328. Motors can be mechanically connected to machines in several ways. When the speed of the motor is the same as the speed desired for the machine, direct coupling of the motor shaft to the machine shaft is used. When the speed of the motor is different from the speed of the machine shaft, a connection which will give the proper speed ratio between the motor and the machine must be used. A speed ratio may be secured by

using a flat belt, V belts, a chain, or a set of gears. With belts the speed ratio is inversely proportional to the effective diameter of the two pulleys. With a chain or gears the speed ratio is inversely proportional to the number of teeth on the two sprockets or gears. In some cases a variation in speed can be obtained by using variable-diameter pulleys or more than one set of gears, which can be shifted.

329. The factors to be considered in selecting the method of connection of the motor to the machine are the speed ratio desired, the peak loads to be transmitted, the positiveness of the drive, the space required, the noise, the maintenance, the appearance, and the first cost of the motor and the method of connection. Since the horsepower of a motor is given by the following formula,

$$\text{hp} = \frac{6.28 \times \text{rpm} \times T}{33,000} \text{ (see Sec. 68, Div. 1)} \quad (10)$$

it follows that for a given horsepower, if the speed of the motor is increased, the torque needed is decreased. To produce torque in a motor costs money for windings to create the necessary magnetic flux and for steel to provide a path for the flux. Therefore, the smaller the torque and, consequently, the higher the speed, the cheaper will be the motor. For very high speeds, however, the extra strength which must be built into the rotor to enable it to withstand the high centrifugal force more than offsets the saving due to the lower torque required.

The 1800-rpm motor is usually the cheapest motor, higher-speed motors being more expensive on account of the higher centrifugal force and lower-speed motors being more expensive on account of the greater flux and torque required. Therefore, one of the first factors to consider in selecting the mechanical connection of the motor to the machine is to see if an 1800-rpm motor can be used. The speed of the shaft on the machine to which the motor is to be connected varies with the type of machine and is frequently much lower than 1800 rpm. For example, on forging machines using large flywheels the shaft speed may be as low as 50 to 60 rpm; on machine tools, such as lathes, drills, millers, etc., it may be between 200 and 300 rpm. Speeds as high as 1000 to 2000 rpm occur on grinders and woodworking machines. In most cases, therefore, some reduction in speed is required between the motor and the machine. Direct connection of the motor to the machine shaft with a flexible or rigid coupling is possible only when the speed of the shaft can be the same as the speed of the motor. Belts, gears, or chains must be used in all other cases to effect a change of speed between the motor and the shaft.

For a speed of 1200 rpm, a 1200-rpm motor directly coupled to the shaft will usually be more practical than an 1800-rpm motor with a belt, gear, or chain connection to the 1200-rpm shaft. For speeds between 600 and 13 rpm, gear motors can be used. These motors have a rotor speed of 1800 rpm and gears built into the end frame of the motor to give the output shaft speed desired. These motors cost about twice as much as a high-speed motor with belt drive but are frequently used on account of the saving in space and elimination of troublesome belts. They are available in three classes of construction according to the severity of service (see Sec. 122).

330. Belt drive is the least expensive method of connection when speed ratio is required. The factors to be considered when applying a belt drive are speed ratio, pulley sizes, belt speeds, distance between pulley centers, type of belt, size of belt, number of belts, number of pulleys, use of idler pulleys, and slippage. The maximum speed ratio which can be obtained with belt drive is limited by the practical sizes of pulleys obtainable, the arc of contact of the belt on the smaller pulley, and the practical distance between the pulleys. The maximum practical speed ratio may be as high as 10:1 for fractional-horsepower motors but is about 6:1 for ordinary sizes and not more than 4:1 for motors of 50 hp and up. As the diameter of a minimum size of a motor pulley is reduced, the strains

on the motor bearings and shaft are increased. A minimum size of pulley is therefore specified by NEMA. The maximum diameter of a motor pulley is in nearly all cases limited by the belt speed, which should not exceed 5000 ft/min (25.4 m/s). This will occur only for machines which operate at a higher speed than the motor. Flat belts are slightly cheaper than V belts but have a shorter life and are noisier and more dangerous. Flat belts with a high speed ratio usually require idler pulleys, and space must be available for an idler pulley when required. There is always some slippage between the belt and the pulleys, and a belt drive should be used only when a positive drive is not required.

331. Maximum Horsepower Limits for Two-Bearing Motors for Belt Drive (General Electric Co.)

Motor speed rpm	Flat-belt drive, maximum hp	V-belt drive, maximum hp	Motor speed, rpm	Flat-belt drive, maximum hp	V-belt drive, maximum hp
1,700–1,800	40	60; ball-bearing, 75	680–720	200	300
1,440–1,500	40	60; ball-bearing, 75	560–600	200	300
1,150–1,200	75	100; ball-bearing, 125	500–514	150	300
850–900	125	200	440–450	150	250

332. Chain drive is a more positive drive than belt drive, and although it is more expensive than belt drive, it is used when slippage under varying loads is not desired. The factors to be considered when applying a chain drive are the speed ratio, the size of sprockets, the width of chain, chain speed, and noise. The maximum speed ratio for a chain drive is about 8:1 with a maximum chain speed of 1500 ft/min (7.6 m/s). For quietness and smoothness a speed of 600 ft/min (3 m/s) or less is desirable. A chain drive is noisier than belt drive.

333. Maximum Horsepower Limits for Two-Bearing Motors for Chain Drive (General Electric Co.)

Motor speed, rpm	Maximum hp	Motor speed, rpm	Maximum hp	Motor speed, rpm	Maximum hp
1,700–1,800	5	1,150–1,200	25	720–750	75
1,440–1,500	10	850–900	50		

334. Gear drive is an absolutely positive drive but is the most expensive method of connection. The factors to be considered when applying a gear drive are speed ratio, gear sizes, pitch-line speed, space, and noise. The maximum speed ratio is about 10:1 for a single set of gears, but any speed ratio is obtainable by using several sets of gears. When the pinion of ordinary spur gearing is mounted on the motor shaft, two-bearing motors should be limited to the maximum horsepower values given for chain drive in Sec. 333. The maximum pitch-line speed with steel pinions is about 1300 ft/min (6.6 m/s). Gear drive usually is compact and takes up only a small space but is noisier than the other methods. It should be used on any application in which slippage or breaking of the belt or chain would be seriously dangerous. It can also be used for much larger speed ratios than are practicable with belts or chains.

335. Speed Limitations for Belt, Gear, and Chain Drives

(Allis-Chalmers Corporation)

This table represents good practice, under normal operating conditions for the use of these drives on motors and generators which are not provided with outboard bearings.

Full-load rpm of motor or generator		Max hp rating motor	Max kW rating of generator
Above	Including		
Flat-belt drive			
2,400	3,600	20	15
1,800	2,400	30	20
1,200	1,800	40	30
900	1,200	75	50
750	900	125	75
720	750	150	100
560	720	200	150
V-Belt drive*			
2,400	3,600	20	15
1,800	2,400	40	30
1,200	1,800	76	50
900	1,200	125	75
750	900	200	100
720	760	250	160

900	1,200	25	15
750	900	50	30
560	750	75	50
Chain drive [§]			
2,400	3,600	20	15
1,800	2,400	40	30
1,200	1,800	75	40
900	1,200	125	75
750	900	200	125
720	750	250	150
560	720	300	200

NOTES The limitations are based on the use of pulleys, etc. They will be less than those given when motors are belted to low-speed drives such as countershafts.

The values are not intended to establish a definite dividing line below which the use of outboard bearings is not standard but rather to establish a dividing line which will indicate to the motor user what the manufacturers consider to be good practice in general service.

The use of outboard bearings is approved and recommended for belted motors in frame sizes of 250 hp, 575 to 600 rpm and larger.

When an outboard bearing is specified, it is assumed that the necessary three-bearing type of baseplate and slide rails, if required, are included with the motor.

*Limiting dimensions of V-belt sheaves for general-purpose motors in frames 505 and smaller are given in NEMA MG1-14.42. Limiting dimensions for V-belt sheaves for motors in frames larger than 505 have not been standardized; they are specified by the motor manufacturer.

[†]These values are based on the use of steel pinions.

[‡]In general, for quiet operation and freedom from severe vibration peripheral speed of cut-steel gearing at the pitch diameter should not exceed 1400 ft/min (7.1 m/s).

[§]Limiting dimensions of chain-drive sprockets for general-purpose motors in frames 505 and smaller are given in NEMA MG1-14.7. Limiting dimensions of chain-drive sprockets for motors in frames larger than 505 have not been standardized; they are specified by the motor manufacturer.

336. Comparison of Methods of Connection for Adjustable-Speed Drive

Type of motor	Type of drive	Space required	Speed variation ratio	First cost
Constant speed	Variable pitch motor pulley	Same as V-belt connection	1¼:1	Low
Constant speed	Separate unit with variable-diameter pulleys	Considerable	3¼:1	Medium
Constant speed	Variable-diameter pulley unit built on motor housing	Moderate	3¼:1	Medium
Constant speed	Variable-position rollers	Small	10:1	High
Adjustable speed	Direct coupling	Small	4:1	High

337. Comparison of Methods of Connection for Constant-Speed Drive

Type of drive	Relative noise	Space required	Speed ratio obtainable	Peak load transmitted	First cost
1. Direct coupling, standard motor	0	Small; motor must extend out from end of drive shaft	0	Limited only by motor	1 (considered as 100 percent)
2. Direct coupling, general-purpose gear motor	Slight	Same as 1. Angle drive obtainable in small motors	Any	Full load	2 times the standard motor
3. Direct coupling, special-purpose gear motor	Slight	Same as 2	Any	150 per cent of full load	2½ times the standard motor
4. Direct coupling, heavy-duty gear motor	Slight	Same as 2	Any	200 percent of full load	3 times the standard motor
5. V belt	0	Moderate	10:1 in fractional-horse power sizes; down to 4:1 for 50 hp and up	Any by multiplying motor horsepower by a service factor*	1⅓ times the standard motor
6. Flat belt	Considerable	Considerable	Same as 5	Same as 5	Slightly higher than for standard motor
7. Chain	Considerable	Moderate	8:1	Same as 5	1⅓ times the standard motor
8. Gear	High	Small	10:1 single reduction; 100:1, double reduction	Same as 5	1½ times the standard motor

*Refer to Sec. 382.

338. The important factors to be considered in selecting a motor are:

1. Power supply
 - a. Type of system: dc or ac; frequency; number of phases
 - b. Voltage and frequency conditions
 - c. Effect of motors on power supply system
 - d. Power rates
2. Requirements of driven machine
 - a. Speed
 - b. Mechanical arrangement
 - c. Power and torque
 - d. Special conditions
3. Surrounding conditions
 - a. Ambient temperature
 - b. Atmospheres
 - c. Water
 - d. Altitude
 - e. Quietness
4. Codes, standards, and ordinances

339. The type of power supply system available in most cases answers the question of whether ac or dc motors will be used as well as the frequency of the motors for ac. For most applications either ac or dc motors will be satisfactory. In some cases special requirements of extra-wide speed range, large number of adjustable-speed machines, or severe accelerating or reversing duty may justify the conversion of alternating to direct current.

If a new power plant is to be installed, the operating conditions may sometimes affect the choice of current. Even in this case the characteristics of the new plant generally should agree with those of the nearest central station in order to obtain breakdown service and to operate economically with central-station energy on reduced loads. For certain applications, dc motors are preferable—for example, in adjustable-speed service, as in machine-tool operation, in service when frequent starts must be made with very high torque, or in reversing service, as in the operation of cranes, hoists, etc. The voltage of ac circuits can be so readily transformed up or down that such energy is more economical for distribution over considerable areas. For plants extending over a considerable area or distributing energy to distances, say, of $\frac{1}{4}$ mi ($\frac{2}{5}$ km) or more, alternating current is nearly always more economical.

For ac motors, three-phase, 60 Hz is most desirable except for small fractional-horsepower motors. The demand for two-phase motors is small, and they are therefore not generally available in stock for quick shipment. If a multispeed motor is desired when the power supply is two-phase, it is best to transform to three-phase for this machine, as multispeed motors are difficult to wind for two-phase. Standard 60-Hz motors are usually suitable for operation on 50-Hz systems with some modification in their ratings and characteristics. The demand for 40- or 25-Hz motors is so small that they are not generally available in stock. For special high-speed applications in the woodworking industry and for portable tools, motors of higher frequencies than 60 Hz are available and are sometimes advantageous. The power supply can be obtained by means of an induction frequency changer.

340. The conditions of the supply voltage and frequency, if alternating current, with respect to value and regulation must be known to select the proper motors and control. With ac systems the voltage can, of course, be changed through transformers

whenever it is advisable. Table 341 gives a guide for good practice in the maximum and minimum horsepower limits for the different standard motor voltages.

Motors will operate successfully under some conditions of voltage and frequency variations but not necessarily in accordance with the standards established for operation at normal rating (see Sec. 130). When the variations in voltage and frequency exceed those limits, special motors and control will probably be required.

The voltage regulation of the supply should be known to select motors which will deliver sufficient torque, even with the probable drop in voltage, to start and carry the load. All induction-motor torques and synchronous-motor starting torque and pull-in torque vary as the voltage squared.

The speed of ac motors will be affected by the frequency of the supply voltage as discussed in previous sections for each type of motor.

341. Guide to Horsepower Limits of Individual Motors for Different Systems

Voltage	Min hp	Max hp	Voltage	Min hp	Max hp
Dc			Ac, two- and three-phase		
115	None	30	110-115-120 220-230-240 440-560 2,200 4,000 6,600	None	15
230	None	200		None	200
550-600	1/2	None		None	500
Ac, one-phase				40	None
110-115-120	None	1 1/2	75	None	None
220-230-240	None	10	400	None	None
440-650	5	10			

342. The effects of motors and their control on the power supply system will affect the selection of the proper type of motor.

The effect of motor-starting currents upon the supply and permissible limits for starting currents are discussed in Sec. 132.

With fluctuating loads, care should be taken to see that the following limits are not exceeded:

1. Frequencies of current pulsation in the range of 250 to 600 per minute may cause objectionable light flicker even if the voltage variation is as small as 0.5 percent.
2. The usual limit for current pulsation is 66 percent of motor full-load current, although in some cases the system regulation may require a limit of 30 or 40 percent to avoid light flicker.

343. Effect of power rates on motor selection. When speed adjustment is required, the energy charge in the power rates should be considered in the selection of the type of motor and in choosing between mechanical adjustable-speed drive and an adjustable-speed motor.

The power rates are generally based on the maximum demand of the consumers. The choice of motor and use of flywheels may smooth out the power demand. This will keep the maximum demand down and lower the rate.

A power-factor clause is incorporated in many rate schedules. These adjust the rate according to the power factor of the load or involve a penalty or bonus for power factors that are below or above certain values. In such cases, consideration should be given to the use of synchronous motors or power capacitors.

344. Effect of speed requirements on motor selection. Since there is a great difference in the speed characteristics of different types of motors, the maximum allowable speed regulation (variation in speed with load) on the driven machine is an important factor in the selection of the proper motor. The actual operating speed, number of speeds, and the speed range required are factors which must be considered in the joint selection of type of motor and mechanical connection. See Secs. 328 to 337 for description and comparison of different methods of mechanical connection. When speed control of the driven machine is required, it can be obtained through speed control of a motor of the proper type or by means of a motor coupled to the machine through a mechanical speed-adjusting connection.

Close speed regulation is desirable for many applications such as machine tools, textile machinery, and similar work.

When large peak loads occur, wide speed regulation is desirable. This will allow the motor to slow down under the peak loads and reduce the horsepower carried at these moments. If the motor has a small speed regulation, it may be greatly overloaded at the peak loads unless the machine is equipped with an exceptionally large motor.

For peak loads occurring periodically, when the peaks occur less than 25 times per minute, flywheels should be employed with motors having a wide speed regulation. This will allow the use of a smaller motor and will tend to even out the peaks of power drawn from the supply.

345. Mechanical-arrangement features of the driven machine should be taken into account in motor selection. The General Electric Co. makes the following recommendations:

1. **Horizontal or Vertical Shaft.** Arrangement of the driven machine usually determines whether a horizontal or a vertical motor is needed. Horizontal motors are more generally available and less expensive: most grease-lubricated ball-bearing motors will operate in either position. Fractional-horsepower, waste-packed sleeve-bearing motors are satisfactory for short periods of vertical operation when no thrust is involved.
2. **Tilted Shaft.** If momentary, this will require special construction of bearing housings for oil-ring-lubricated sleeve-bearing motors to avoid loss of lubricant. For long periods of tilted operation, bearings suitable for end thrust may be necessary. Ball-bearing motors with grease lubrication are suitable for tilted operation.
3. **Inverted Operation and Rolling**
 - a. When the driven machine requires mounting the motor with the feet above or to one side of the shaft, rearrangement of the end shields of most motors makes them suitable.
 - b. If the driven machine requires operation of the motor at a changing angle from the horizontal (shaft remaining horizontal) of more than 10 or 12°, ball-bearing motors will usually be required. Within this angle, sleeve-bearing motors with modified oil gages are applicable.
4. **Portable Machines.** A portable type of driven machine may require motors and control of greater compactness and less weight than standard and may necessitate special bearing construction for ring-oiled sleeve-bearing motors.

346. The horsepower and torque requirements of the driven machine are main factors in determining the proper motor rating, type of motor, and motor-control equipment. The greatest care should be exercised in determining as accurately as possible the horsepower required and both the starting- and running-torque requirements. The motor not only must have sufficient horsepower and torque capacity under running conditions but must be able to develop sufficient torque at starting to start the load satisfactorily under the most severe starting conditions that may be encountered in the particular application. Sometimes all these requirements will be known from past experience. In all cases, when it is possible, it is best to conduct tests so that the power and torque requirements can be accurately determined. Money spent in such determinations is wisely expended even if it requires the rental of a motor for conducting the tests. In performing tests it should be remembered that the test-motor losses must be subtracted from the power input to the motor, since the motor to be purchased is rated on horsepower output.

If the power and torque requirements cannot be determined from past experience or test, the information can generally be obtained from the manufacturer of the machine to be driven or from the motor experts of motor manufacturers. Whenever there seems to be any question about the accuracy of such information, it should be carefully checked, since machine-tool manufacturers often overestimate the horsepower required to be on the safe side. The result is that the motors run only partially loaded at considerably reduced efficiency. The electrical losses and interest and depreciation on the unnecessary extra investment may be considerable in a large installation.

Whenever the frequency of the starting period is great (more than 4 to 6 times per hour), it is best to consult the motor manufacturers. Such frequent starting may require special motors and controls.

Many machines work on a definite duty cycle that repeats at regular intervals.* Often this horsepower value occurs during the cycle when the values of power required and the length of their duration are known, and the rating of the motor required can be calculated by the rms method.

Multiply the square of the horsepower required for each part of the cycle by the time in seconds necessary to complete that part of the cycle. Divide the sum of these results by the effective time in seconds to complete the whole cycle. Extract the square root of this last result. This gives the rms horsepower. If the motor is stopped for part of the cycle, only one-third of the rest period should be used in determining the effective time for open motors (enclosed motors use one-half of the rest period). This is due to the reduction in cooling effect when the motor is at rest.

EXAMPLE Assume a machining operation in which an open motor operates at 8-hp load for 4 min, 6-hp load for 50 s, and 10-hp load for 3 min and the motor is at rest for 6 min, after which the cycle is repeated.

$$\text{rms hp} = \sqrt{\frac{(8^2 \times 240) + (6^2 \times 50) + (10^2 \times 180)}{240 + 50 + 180 + \frac{360}{3}}} = \sqrt{59.5} = 7.7 \text{ hp}$$

Use a 7.5-hp motor.

NOTE For fast-repeating cycles involving reversals and deceleration by plugging, the additional heating due to reversing and external WK^2 loads must be taken into consideration,

*Courtesy of Westinghouse Electric Corp.

and a more elaborate duty-cycle analysis than shown above is required. It is necessary to know the torque, time, and motor speed for each portion of the duty cycle, such as acceleration, running with load, running without load, deceleration, and at rest.

For such detailed duty cycles it is sometimes more convenient to calculate on the basis of torque required rather than on the horsepower basis. The following formula for the accelerating time for constant torque may be helpful:

$$\text{Time, s} = \frac{wk^2 \times \text{change in rpm}}{308 \times \text{torque (lb}\cdot\text{ft) available from motor}} \quad (11)$$

This formula can be used when the accelerating torque is substantially constant. If the accelerating torque varies considerably, the accelerating time should be calculated in increments; the average accelerating torque during the increment should be used. The size of the increment used depends on the accuracy required. Fair accuracy is obtained if the minimum accelerating torque is not less than 50 percent of the maximum accelerating torque during the increment.

In addition to determining the horsepower rating with regard to heat capacity, a check should be made to assure that the peak loads imposed by the driven machine, even though of short duration, do not exceed the maximum power that the motor will develop without stalling. From tables of locked-rotor and maximum running-torque values, determine the maximum torque in terms of full-load torque. This value should always exceed peak torque imposed by the duty cycle. Preferably, this should be at least 25 percent greater to compensate for unusual conditions, such as low voltage, high friction, etc.

347. Horsepower rating of motor. After having determined the horsepower requirements of the load, select a motor with sufficient horsepower rating to take care of these requirements. See Sec. 130 for a discussion of motor ratings.

348. Any special conditions of operation of the driven machine must be carefully considered. Some machines such as propeller-type fans and deep-well pumps impose an axial thrust on the motor bearings. In some cases standard ball-bearing motors will furnish sufficient thrust capacity. For extremely heavy thrusts, special plate-type oil-lubricated bearings may be required.

For some tools such as precision grinders, to ensure high quality of the finished product specially balanced motors are required to give very small amplitudes of vibration.

Sometimes the driven machine requires limited or even zero end play. This will necessitate the use of preloaded ball bearings or sleeve bearings with endplay-limiting devices.

349. The surrounding conditions of temperature, atmospheres, and water must be carefully determined in the application of motors. Refer to Sec. 128 for a discussion of the different standard types of enclosures available and a guide to the surrounding conditions under which their applications will be satisfactory. For a discussion of rating of motors and effect of room temperatures upon operation, refer to Sec. 130. The manufacturers should be consulted when the motor and control will be subjected to any unusual risk such as the following:

1. Exposure to chemical fumes
2. Operation in damp places
3. Operation at speeds in excess of specified overspeed

4. Exposure to combustible or explosive dust
5. Exposure to gritty or conducting dust
6. Exposure to lint
7. Exposure to steam
8. Operation in poorly ventilated rooms
9. Operation in pits or where entirely enclosed in boxes
10. Exposure to flammable or explosive gases
11. Exposure to temperatures above 40°C or below 10°C
12. Exposure to oil vapor
13. Exposure to salt air
14. Exposure to abnormal shock or vibration from external sources

350. Water (General Electric Co.). If operation for long periods underwater is required, special enclosed equipment, with counter air pressure to prevent the entrance of water, is usually necessary. For occasional flooding or submersion, extremely tight, totally enclosed nonventilated motors equipped with stuffing boxes may suffice. If hosing down or splashing of water is involved, splashproof motors will usually meet all but extreme conditions, which will require enclosed motors.

351. Altitude (General Electric Co.). No change in design is considered necessary for most electric machines for altitudes not exceeding 3300 ft (1006 m) above sea level. For higher altitudes, the temperature rise of electric machinery generally will increase approximately 1 percent for each 330-ft (101-m) increase in altitude above 3300 ft.

352. Quietness (General Electric Co.). Installations in residences and in public buildings, such as theaters, hospitals, and schools, may require the use of quiet motors and sound-isolating bases. In many cases, special building layout and construction may be needed to ensure the necessary quietness.

353. Codes, standards, and ordinances (General Electric Co.). Motors and control must conform to local and national standards such as those shown below to allow connection of power, satisfy safety and fire requirements, and permit lowest insurance rates:

1. NEMA standards, which specify mounting dimensions for induction motors and, in general, minimum performance characteristics for all types of motors and control
2. IEEE standards, which specify temperature limits for insulation materials and prescribe the methods of rating and testing apparatus
3. The National Electrical Code, which is the general guide of inspectors in determining acceptability of enclosures, protection, and installation of motors
4. State laws, which stress safety and reduction of fire hazards
5. City ordinances, which may specify particular construction considered necessary locally to avoid fires and accidents

354. Standard ratings of motors (NEMA standards).* The standard horsepower ratings of motors are 1, 1.5, 2, 3, 5, 7.5, 10, 15, 25, and 35 mhp and $\frac{1}{20}$, $\frac{1}{12}$, $\frac{1}{8}$, $\frac{1}{6}$, $\frac{1}{4}$, $\frac{1}{3}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, $1\frac{1}{2}$, 2, 3, 5, $7\frac{1}{2}$, 10, 15, 20, 25, 30, 40, 50, 60, 75, 100, 125, 150, 200, 250, 300, 350, 400, 450, 500, 600, 700, 800, 900, 1000, 1250, 1500, 1750, 2000, 2250, 2500, 3000, 3500, 4000, 4500, 5000, 5500, 6000, 7000, 8000, 9000, 10,000, 11,000, 12,000, 13,000, 14,000, 15,000, 16,000, 17,000, 18,000, 19,000, 20,000, 22,500, 25,000, 27,500, 30,000, 35,000, 40,000, 45,000, and 50,000 hp.

The standard full-load speed ratings for constant-speed, integral-horsepower dc motors are 3500, 2500, 1750, 1150, 850, 650, 500, 450, 400, 350, 300, 250, 225, 200, 175, 150, 125, 110, 100, 90, 80, 70, 65, 60, 55, and 50 rpm.

The standard full-load ratings for small constant-speed dc motors from $\frac{1}{20}$ to 1 hp are 3450, 2500, 1725, and 1140 rpm.

The standard speeds for 60-Hz synchronous motors are 3600, 1800, 1200, 900, 720, 600, 514, 450, 400, 360, 327, 300, 277, 257, 240, 225, 200, 180, 164, 150, 138, 129, 120, 109, 100, 95, 90, 86, and 80 rpm.

The standard synchronous speeds for 60-Hz, polyphase and single-phase induction motors, except permanent-split-capacitor motors, are 3600, 1800, 1200, 900, 720, 600, 514, 450, 400, 360, 327, 300, 277, 257, 240, and 225 rpm.

The standard synchronous speeds for 60-Hz, single-phase permanent-split-capacitor motors are 3600, 1800, and 1200 rpm.

The approximate full-load speeds of induction motors can be obtained from the synchronous speeds by means of the approximate full-load slips.

The standard voltages are as follows:

1. Direct-current fractional-horsepower motors intended for use on adjustable voltage rectifier power supplies*	
a. Single-phase primary power source	75, 90, 150, or 180 V
b. Three-phase primary power source	240 V
2. Industrial direct current*	180, 240, 250, 500, 550 or 700 V
3. Universal	115 or 230 V
4. Single phase	
a. 60 Hz	115, 200, or 230 V
b. 50 Hz	110 or 220 V
5. Polyphase	
a. 60 Hz	115,† 200, 230, 460, 575, 2300, 4000, 4600, 6600, or 13,200 V
b. 50 Hz, three-phase	220 or 380 V

*Armature voltage.

†15 hp and smaller.

NOTE It is not practical to build motors of all horsepower ratings for all of the standard voltages.

The standard frequencies are as follows:

1. *Alternating-current motors.* The standard frequency shall be 50 or 60 Hz.
2. *Universal motors.* The standard frequency shall be 60 Hz ac.

NOTE Universal motors will operate successfully on all frequencies below 60 Hz and on direct current.

355. Service factors. A general-purpose ac motor or, when applicable, any ac motor having a rated ambient temperature of 40°C, continuous duty, is suitable for continuous operation at rated load under normal conditions. When the voltage and frequency are maintained at the values specified on the nameplate, the motor may be overloaded up to the horsepower obtained by multiplying the rated horsepower by the service factor shown on the nameplate. When the motor is operated at any service factor greater than 1, it will have a higher temperature rise and may have different efficiency, power factor, and speed than at rated load, while the locked-rotor torque and current and breakdown torque will remain unchanged. Usual service factors are described in the accompanying table.

Service Factors

(NEMA standard)*

Horsepower	Synchronous speed, rpm						
	3,600	1,800	1,200	900	720	600	514
$1/_{20}$	1.4	1.4	1.4	1.4			
$1/_{12}$	1.4	1.4	1.4	1.4			
$1/_{8}$	1.4	1.4	1.4	1.4			
$1/_{6}$	1.35	1.35	1.35	1.35			
$1/_{4}$	1.35	1.35	1.35	1.35			
$1/_{3}$	1.35	1.35	1.35	1.35			
$1/_{2}$	1.25	1.25	1.25	1.15 [†]			
$3/_{4}$	1.25	1.25	1.15 [†]	1.15 [†]			
1	1.25	1.15 [†]	1.15 [†]	1.15 [†]			
$1 1/_{2}$ –125 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]
150 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]	
200 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]	1.15 [†]		
250	1.0	1.15 [†]	1.15 [†]	1.15 [†]			
300	1.0	1.15 [†]	1.15 [†]				
350	1.0	1.15 [†]	1.15 [†]				
400	1.0	1.15 [†]					
450	1.0	1.15 [†]					
500	1.0	1.15 [†]					

*This material is reproduced with the permission of the National Electrical Manufacturers Association from the NEMA Standards Publication MG 1-2006 copyright © 2006 by NEMA.

[†]For polyphase squirrel-cage medium motors these service factors apply only to designs A, B, and C motors.

356. Effects of variation of voltage and frequency upon the performance of induction motors (NEMA standards)*

1. Induction motors are at times operated on circuits of voltage or frequency other than those for which the motors are rated. Under such conditions, the performance of the motor will vary from the rating. The following are some of the operating results caused by small variations of voltage and frequency and are indicative of the general character of changes produced by such variation in operating conditions.
2. With a 10-percent increase or decrease in voltage from that given on the nameplate, the heating at rated horsepower load may increase. Such operation for extended periods of time may accelerate the deterioration of the insulation system.

*This material is reproduced with the permission of the National Electrical Manufacturers Association from the NEMA Standards Publication MG 1-2006 copyright © 2006 by NEMA.

3. In a motor of normal characteristics at full rated-horsepower load, a 10-percent increase of voltage above that given on the nameplate would usually result in a decided lowering in power factor. A 10-percent decrease of voltage below that given on the nameplate would usually give an increase in power factor.
4. The locked-rotor and breakdown torque will be proportional to the square of the voltage applied.
5. An increase of 10 percent in voltage will result in a decrease of slip of about 17 percent, while a reduction of 10 percent will result in an increase of slip of about 21 percent. Thus, if the slip at rated voltage were 5 percent, it would be increased to 6.05 percent if the voltage were reduced 10 percent.
6. A frequency higher than the rated frequency usually improves the power factor but decreases locked-rotor torque and increases the speed and friction and windage loss. At a frequency lower than the rated frequency, the speed is decreased, locked-rotor torque is increased, and power factor is decreased. For certain kinds of motor load, such as in textile mills, close frequency regulation is essential.
7. If variations in both voltage and frequency occur simultaneously, the effects will be superimposed. Thus, if the voltage is high and the frequency low, the locked-rotor torque will be very greatly increased, but the power factor will be decreased and the temperature rise increased with normal load.
8. The foregoing facts apply particularly to general-purpose motors. They may not always be true with special-purpose motors, built for a particular purpose, or as applied to very small motors.

357. Operation of 230-V general-purpose induction motors on 208-V network systems (NEMA standard). A 230-V general-purpose induction motor is not recommended for operation on a 208-V system. A motor for such a system should be rated for 200 V. This is so because utilization voltages commonly encountered on 208-V systems are below the -10 percent tolerance on the 230-V rating for which the 230-V motor is designed. Such operation will generally cause excessive overheating and serious reduction in torque.

358. Characteristics of polyphase two-, four-, six-, and eight-pole, 60-Hz medium induction motors operated on 50 Hz

1. **Speeds.** The synchronous speeds of 60-Hz motors when operated on 50 Hz will be five-sixths of the 60-Hz synchronous speed. The full-load speeds of 60-Hz motors when operated on 50 Hz at the rated 60-Hz voltage will be approximately five-sixths of the 60-Hz full-load speed. When voltages less than the 60-Hz rated voltage are applied, the slip will be increased approximately inversely as the square of the ratios of voltages. For example, when a 60-Hz, 460-V motor is operated at 420 V, 50 Hz, the slip will be increased by approximately 20 percent over the slip at 460 V, 50 Hz. When operated at 380 V, 50 Hz, the slip will be increased by approximately 46 percent over the slip at 460 V, 50 Hz.
2. **Torques.** The full-load torques in pound-feet of 60-Hz motors operated at 50 Hz will be approximately six-fifths of the 60-Hz full-load torques in pound-feet.

The breakdown torques in pound-feet of 60-Hz motors when operated on 50 Hz at the rated 60-Hz voltage will be approximately 135 percent of the 60-Hz breakdown torque in pound-feet. Therefore, the 50-Hz breakdown torque expressed in a percentage of the 50-Hz full-load torque will be approximately 112 percent of the 60-Hz breakdown torque

expressed in a percentage of the 60-Hz full-load torque. When voltages less than the rated 60-Hz voltages are applied, the breakdown torques will be decreased as the square of the voltages. For example, when a 460-V, 60-Hz motor is operated at 420 V, 50 Hz, the breakdown torque will be reduced by approximately 17 percent below the torque at 460 V, 60 Hz; when operated at 380 V, 50 Hz, the breakdown torque will be reduced by approximately 32 percent below the torque at 460 V, 50 Hz. It may thus be seen that a 60-Hz, 460-V motor having 200 percent breakdown torque will also have a 200 percent breakdown torque as a 50-Hz motor operated at approximately 435 V, and when operated on 50 Hz at 380 V, the breakdown torque will be approximately 153 percent of the full-load 50-Hz torque.

The locked-rotor torques of 60-Hz motors operated on 50 Hz will vary in the same manner as the breakdown torques described above. For example, when a 460-V, 60-Hz motor having a 135 percent locked-rotor torque expressed in a percentage of 60-Hz full-load torque is operated on 50 Hz, 380 V, it may have as low as 103 percent locked-rotor torque expressed in a percentage of 50-Hz full-load torque.

3. *Locked-Rotor Current.* The locked-rotor current of 60-Hz motors, when operated on 50 Hz at the rated 60-Hz voltage, will be approximately 15 percent higher in amperes than the 60-Hz values. The 50-Hz value of locked-rotor current will vary in direct proportion to any slight variation in voltage from the rated 60-Hz voltage.

For example, a 60-Hz, 460-V motor with a locked-rotor current of 290 A will have approximately 334 A on 50 Hz at 460 V and approximately 319 A at 440 V and 50 Hz.

The code letter appearing on the motor nameplate to indicate locked-rotor kilovolt-amperes per horsepower applies only to the 60-Hz rating of the motor.

4. *Temperature Rise.* The temperature rises of 60-Hz motors when operated on 50 Hz will be higher than those attained on 60-Hz operation. When 60-Hz general-purpose open motors having a service factor of 1.15 and an ambient-temperature rating of 40°C are suitable for operation on 50-Hz circuits and are operated on 50 Hz at five-sixths of the 60-Hz voltage and horsepower rating, they will have no service factor. In general, the temperature rise of 460-V, 60-Hz 40°C motors when operated at 380 V, 50 Hz, will be approximately the same if the load is five-sixths of the rated load.

359. Operation of small dc motors on rectified alternating current (NEMA standard).*

1. *General.* When direct-current small motors intended for use on adjustable-voltage electronic power supplies are operated from rectified power sources, the pulsating voltage and current wave forms affect the motor performance characteristics. Because of this, the motors should be designed or specially selected to suit this type of operation.

A motor may be used with any power supply if the combination results in a form factor at rated load equal to or less than the motor rated form factor.

NOTES Sixty-Hz motors equipped with speed-responsive switching devices may require mechanical modification for satisfactory operation at 50 Hz.

The information given above is based on motors rated 60 Hz, 460 V. The same relationship will apply to motors of other standard voltage ratings.

*This material is reproduced with the permission of the National Electrical Manufacturers Association from the NEMA Standards Publication MG 1-2006 copyright © 2006 by NEMA.

A combination of a power supply and a motor which results in a form factor at rated load greater than the motor rated form factor will cause overheating of the motor and will have an adverse effect on commutation.

There are many types of power supplies that can be used; some are:

- a. Single-phase, half-wave
- b. Single-phase, half-wave, back rectifier
- c. Single-phase, half-wave, alternating-current voltage controlled
- d. Single-phase, full-wave, firing angle controlled
- e. Single-phase, full-wave, firing angle controlled, back rectifier
- f. Three-phase, half-wave, voltage controlled
- g. Three-phase, half-wave, firing angle controlled

It is impractical to design a motor or to list a standard motor for each type of power supply. The combination of power supply and motor must be considered. The resulting form factor of the combination is a measure of the effect of the rectified voltage on the motor current as it influences the motor performance characteristics, such as commutation and heating.

2. **Form Factor.** The form factor of the current is the ratio of the root-mean-square value of the current to the average value of the current.

Armature current form factor of a motor-rectifier circuit may be determined by measuring the rms armature current (using an electrothermic instrument, electro-dynamic instrument, or other true rms responding instrument) and the average armature current (using a permanent-magnet moving-coil instrument). The armature current form factor will vary with changes in load, speed, and circuit adjustment.

Armature current form factor of a motor-rectifier circuit may be determined by calculation. For this purpose, the inductance of the motor armature circuit should be known or estimated, including the inductance of any components in the power supply which are in series with the motor armature. The value of the motor inductance will depend upon the horsepower, speed, and voltage ratings and the enclosure of the motor and should be obtained from the motor manufacturer. The method of calculation of the armature current form factor should take into account the parameters of the circuit, such as the number of phases, the firing angle, half-wave, with or without back rectifier, etc., and whether or not the current is continuous or discontinuous.

Ranges of armature current form factors on some commonly used motor-rectifier circuits and recommended rated form factors of motors associated with these ranges are shown in the table below.

360. Operation of medium dc motors on rectified alternating current (NEMA standard). When a direct-current medium motor is operated from a rectified alternating-current supply, its performance may differ materially from that of the same motor when operated from a low-ripple direct-current source of supply, such as a generator or a battery. The pulsating voltage and current wave forms may increase temperature rise and noise and adversely affect commutation and efficiency. Because of these effects, it is necessary that direct-current motors be designed or specially selected to operate on the particular type of rectified supply to be used.

Typical combination of power source and rectifier type	Range of armature current form factors*	Recommended rated form factors of motors
Single-phase thyristor (SCR) or thyatron with or without back rectifiers:		
Half-wave	1.86–2	2
Half-wave	1.71–1.85	1.85
Half-wave or full-wave	1.51–1.7	1.7
Full-wave	1.41–1.5	1.5
Full-wave	1.31–1.4	1.4
Full-wave	1.21–1.3	1.3
Three-phase thyristor (SCR) or thyatron with or without back rectifiers:		
Half-wave	1.11–1.2	1.2
Full-wave	1.0–1.1	1.1

*The armature current form factor may be reduced by filters or other circuit means which will allow the use of a motor with a lower-rated form factor.

361. Operation of dc motors by reduced armature voltage (NEMA standard). When a dc motor is operated below base speed by reduced armature voltage, it may be necessary to reduce its torque load below rated full-load torque to avoid overheating the motor.

362. Operating Speeds of Various Machine Tools

Saws, circular, wood	9,000 ft per min at rim
Band, wood	4,000 ft per min at rim
Band, hot iron, and steel	200–300 ft per min at rim
Grindstones	800 ft per min at rim
Emery wheels	5,000 ft per min at rim
Drills, for wrought iron	12 ft per min outer edge
For cast iron	8 ft per min outer edge
Milling cutters, for brass	120 ft per min outer edge
For cast-iron	60 ft per min outer edge
For wrought iron	50 ft per min outer edge
Wrought steel	35 ft per min outer edge
Screw cutting, gun metal, etc.	30 ft per min at circum
Steel	8 ft per min at circum
Boring, cast-iron	10 ft per min at circum
Sawing	
Brass	70 ft per min at circum
Gun metal	30 ft per min at circum
Steel	25 ft per min at circum
Wrought iron	30 ft per min at circum
Cast iron	20 ft per min at circum

363. Motor-driven pumps (Westinghouse Electric Corp.). Either dc or ac motors are satisfactory. For most cases, shunt-wound dc or squirrel-cage ac motors and synchronous motors above 25 hp are suitable, but when starting conditions are severe, as when the pump must be started against a full discharge pipe, compound-wound dc, and wound-rotor

ac motors are preferable. For small centrifugal pumps, squirrel-cage motors are suitable. On large units, squirrel-cage or synchronous motors are used. In many government buildings wound-rotor motors are specified for their low starting currents.

$$\text{Water hp} = \frac{\text{gpm} \times \text{tdh (in ft)}}{3960} = \frac{\text{gpm} \times \text{tdh (in lb)}}{1720}$$

where gpm = gallons per minute and tdh = total dynamic head.

$$\text{bhp} = \frac{\text{gpm} \times \text{tdh (in ft)}}{3960 \times \text{pump eff}}$$

where bhp = brake horsepower.

$$\text{kW input} = \frac{\text{gpm} \times \text{tdh (in ft)}}{5308 \times \text{pump eff} \times \text{motor eff}}$$

$$\text{kWh per million gallons pumped} = \frac{\text{tdh (in ft)} \times 3.1456}{\text{pump eff} \times \text{motor eff}}$$

$$\text{Velocity} = \frac{\text{gpm}}{2.45 \times D^2} \quad \text{Velocity head} = \frac{V^2}{64.4}$$

NOTE When the head is expressed in feet, formulas are correct only for liquids of 1.0 specific gravity.

On plunger pumps high-starting-torque squirrel-cage motors are recommended to take care of the full pump load plus the accelerating load. For boiler-feed service and other applications requiring variable-speed motors, a wound-rotor motor with continuous-duty resistors should be used.

FIGURE 7.184 Curves for horsepower required to drive fans and blowers. [Westinghouse Electric Corp.]

364. Motor-driven fans and blowers

(Westinghouse Electric Corp.). The approximate horsepower required to drive fans and blowers may be obtained from the curve in Fig. 7.184 when the cubic feet per minute and water-gage pressure are known. Horsepower for pressures and quantities not shown on the curves may be figured from the following formula (the average ventilating fan has an efficiency of 60 percent):

$$\text{hp} = \frac{\text{ft}^3/\text{min} \times \text{pressure in inches water gage}}{6.346 \times \text{fan efficiency}} \tag{12}$$

The horsepower required by a fan varies approximately as the cube of the speed; the volume, directly as the speed. Motor horsepower should exceed the rated horsepower of a forward-curved fan by about 20 percent but can be near the rated horsepower of backward-curved fans with non-overload characteristics.

If fan speed will be increased by adjustable pitch sheaves or sheave changes, base the motor rating on the highest speed.

Standard shunt-wound direct-current or normal-torque ac motors have sufficient starting torque. Synchronous motors are used when power-factor correction is desired.

Multispeed variable-torque squirrel-cage motors are recommended when the volume of air must be varied. Any combination of 1800-, 1200-, 900-, and 600-rpm speeds can be supplied. If the volume variation obtained with fixed motor speeds is not suitable, a wound-rotor induction motor with the proper control will allow speed adjustment between 100 and 50 percent of the motor speed.

Shunt-wound dc motors with suitable control give variable-speed adjustment over the same range as wound-rotor motors.

365. Motor-driven compressors. Compressors equipped with unloaders can be started by normal-starting torque ac motors of NEMA Design B. Compressors which start loaded require high-starting-torque ac motors of NEMA Design C.

Most air-conditioning compressors, especially hermetic refrigerant motor-compressors and centrifugal compressors, start unloaded. If the compressor starts loaded, it will require motor-starting torques of 200 to 220 percent of full-load torque. High-starting-torque Type A motors (Design C) will develop these torques when started across the line. With across-the-line starting, the total current inrush is the locked-rotor current of the motor. When a low-starting-current, high-starting-torque motor will not meet the inrush or torque requirements, a wound-rotor motor and Class 13-100 magnetic starter are recommended.

Large reciprocating air compressors are generally driven by high-speed belted or low-speed direct-connected engine-type synchronous motors.

The horsepower required can be determined by using the following instructions applied to the curves in Fig. 7.185.

AIR COMPRESSORS AT ANY LEVEL Curve A can be used when the discharge pressure and cubic feet per minute are known. The curves are lines of constant horsepower. Dotted lines are for two-stage water-cooled units.

AIR COMPRESSORS AT ANY ALTITUDE First select the equivalent sea-level pressure from curve B. This will take care of the increase in compression ratio above sea-level ratio. Then from curve A determine the total horsepower for the pressure corresponding to the equivalent sea-level pressure and free air capacity you desire. Multiply this horsepower by the correction factor from curve C.

AIR-CONDITIONING AND REFRIGERATION The vast majority of compressors used in air-conditioning and refrigeration equipment are hermetic refrigerant motor-compressors (see Sec. 399), which employ special low-starting-torque motors as an integral part of the compressor and must be started unloaded. To estimate accurately the total electrical starting and running load of a hermetic refrigerant motor-compressor and the air-conditioning or refrigerating equipment of which it is a part, it is necessary to know the electrical ratings of the specific motor-compressor or equipment. As detailed in Sec. 399, a hermetic refrigerant motor-compressor is not rated in horsepower. Air-conditioning and refrigerating equipment is rated for its cooling capacity in British thermal units per hour or in tons of cooling capacity. One ton of cooling capacity equals 12,000 Btu/h.

The electrical input per ton of cooling depends not only on the efficiency of the compressor motor but also on the efficiency of the compressor in its system. The efficacy of the system is dependent on many factors, including the cooling temperature (high temperature for air conditioning, medium temperature for unfrozen-food preservation, low temperature for frozen-food storage and food freezing). Other factors affecting the overall efficiency of the system include the system condensing medium, such as water-cooled, evaporatively cooled, or air-cooled, the kind of refrigerant, the number and type (and

FIGURE 7.185 Curves for determining horsepower required to drive compressors. [Westinghouse Electric Corp.]

efficiency) of auxiliary motors, such as fan motors, etc. Even approximate conversion from tons of cooling to electrical-input power is feasible only when there is adequate knowledge of the equipment to be installed.

It is traditional to convert tons of cooling to motor horsepower by estimating 1 hp/ton, but this can result in a 100 percent error on the high side for some high-efficiency equipment and can be as much as 25 percent on the low side for other equipment. It is best to consult the mechanical contractor or the equipment manufacturer to obtain accurate information.

366. Foundations are necessary to support and maintain in alignment generators and other electrical machines of any considerable size. They are made of masonry. Brick or stone set in mortar (preferably cement mortar) will do, but concrete is almost universally

used because it is usually the cheapest. A 1:3:6 mixture of concrete (1 part cement, 3 parts sand, and 6 parts crushed stone or gravel by bulk) or even a 1:3:7 mixture will give excellent results. Brick or stone for foundations can be set in mortar consisting of 1 part cement and 3 parts sand.

367. The size of a foundation is determined by the size of the machine supported and by the stress imposed by the machine. The base area of any foundation must be great enough so that its weight and the weight of the machine supported will not cause it to sink into the soil. If a machine is not subjected to any external forces (i.e., if it is self-contained), the only requirement of the foundation (provided the machine is not one that vibrates excessively) is to keep it from sinking into the ground, and the lightest foundation that will do this is satisfactory. Therefore motor generators and rotary converters do not require foundations heavy enough to resist the tendency of the external apparatus to tip or to displace the foundation. No rule can be given for determining the proper weight for a foundation in such a case. However, with a solid foundation it is usually true that if the foundation is large enough to include all the foundation bolts of the machine and to extend to good bottom, it will be sufficiently heavy. Experience is required to enable one to design the lightest foundation that will do, so it is well for the beginner to be sure that the foundation is heavy enough.

368. Foundation for a gear motor (Westinghouse Electric Corp.). A foundation or mounting which provides rigidity and prevents weaving or flexing, with resultant misalignment of the shafts, is essential to the successful operation of a gear drive. A concrete foundation should be used whenever possible and should be carefully prepared to conform with data regarding bolt spacing and physical measurements contained in the identified dimension leaflet.

Gear motors are designed with a tolerance of $+0$ and $-1/32$ in (-0.794 mm) between the shaft center and the base. Therefore, shimming may be required. Shims of various thicknesses, slotted to slide around the foundation bolts, should be used. After alignment has been secured through shimming, the gear motor should be bolted down and grouted in. When the unit must be installed on structural foundations, a supporting baseplate of steel should be provided to obtain proper rigidity. This baseplate should be of a thickness not less than the diameter of the holding-down bolts.

369. Alignment of motors. After the motor has been properly located and the right kind of mounting has been built, the next step is to align the motor properly with its drive. The following procedure is recommended by the General Electric Co. Belt drive is the most common form of mechanical transmission, but the principles involved and the methods used in aligning generally apply equally well for chain drive. The tools usually used for aligning motors or line shafting are the square, plumb bob, and level. Tool manufacturers also build combination squares and levels and similar tools that aid in quickly and accurately aligning machinery.

The first step in aligning two machines is to see if they are level. It is possible for a machine to be out of line in more than one plane. If by placing a level or plumb on the machine it is found to be out by a certain amount, the motor must be mounted so that it will be out by a like amount.

A simple and easy method of aligning a motor pulley with the driven pulley is shown in Fig. 7.186. First, the crown or centerline of the pulleys must be on the same centerline; second, the motor shaft must be parallel to the driven shaft.

FIGURE 7.186 Method of aligning two pulleys. [General Electric Co.]

By using a plumb bob and drawing a datum line on the floor, a base of operation is established. Next, drop a plumb line from the center of the driven pulley to the floor. With a square, draw a line perpendicular to the datum line. Next, drop a plumb line from the center of the motor pulley and move the motor up or back until the plumb bob rests on the centerline of the driven pulley. From the pulley centerline, perpendiculars can be drawn through the centers of the holes in the motor feet. A level should be used to see that the line shafting is level. If it is not, the motor feet must be shimmed up so that the motor shaft and the line shaft will be out of level by the same amount. Chain drive can be aligned in a similar manner.

With belt drive, a sliding base is nearly always used to allow for belt adjustment. Another method, therefore, is to use the following procedure when aligning two pulleys:

1. Place the motor on the base so that there will be an equal amount of adjustment in either direction, and firmly fasten the motor to the base by the four holding-down bolts.
2. Mount the motor pulley on the motor shaft.
3. Locate the base and motor in approximately the final position, as determined by the length of belt.
4. Stretch a string from the face of the driven pulley toward the face of the motor pulley.
5. Parallel the face of the motor pulley with this string.
6. Using a scratch pin, mark the end positions of the sliding base.
7. Extend these lines.
8. Move the base and motor away from the string by an amount equal to one-half the difference in face width of the two pulleys. Use the two extended lines as a guide to keep the base in its proper position.
9. The belt should now be placed on the pulleys to see if it operates satisfactorily. If it does not operate properly, the base can be shifted slightly until proper operation is obtained.
10. Firmly fasten the base to the floor, ceiling, or sidewalls by lag screws or bolts.

MOTOR CIRCUITS

370. National Electrical Code **rules definitely specify certain requirements** with respect to the size and location of the component parts of motor branch circuits. The following tables and rules are in accordance with the 2008 edition of the Code. Certain cities have adopted motor wiring tables and rules which may be more exacting than those required by the Code. In such communities these local requirements should be followed in preference to the tables presented herein.

Section 370 through 395 are the rules for conventional motors and motor circuits. Sections 399 through 407 are the rules for air-conditioning and refrigerating equipment which includes a hermetic refrigerant motor-compressor. See Sec. 399.

In the following sections the terminology of the National Electrical Code with respect to *within sight* is adhered to. A distance of more than 15 m (50 ft) is considered

equivalent to being *out of sight*, even though there may be no obstructions between the two points.

Full-Load Motor Currents. According to the National Electrical Code, whenever the current rating of a motor is used to determine the ampacity (current-carrying capacity) of conductors or the ampere ratings of switches, branch-circuit overcurrent devices, etc., the values given in Tables 7 to 10 of Div. 12, including footnotes, should be used in lieu of the actual current ratings marked on a motor nameplate. Motor-overload protection should be based on the motor-nameplate current rating. If a motor is marked in amperes but not in horsepower, the horsepower rating should be assumed to be that corresponding to the value given in Tables 7 to 10 of Div. 12, interpolated if necessary.

Exceptions

1. *For multispeed motors, the selection of conductors on the line side of the controller shall be based on the highest of the full-load current ratings shown on the motor nameplate; selection of conductors between the controller and the motor shall be based on the current ratings of the winding(s) that the conductors energize.*
2. *For torque motors, in which the rated current is the locked-rotor current, this nameplate current shall be used.*
3. *For ac motors used on adjustable-voltage, variable-torque drive systems, the maximum operating current marked on the motor and/or control nameplate shall be used. If the maximum operating current does not appear on the nameplate, the ampacity determination shall be based on 150 percent of the values given in Tables 9 and 10 of Div. 12.*

The incoming branch circuit or feeder to power conversion equipment included as part of an adjustable-speed drive system shall be based on the rated input to the power conversion equipment, and is to be taken at 125 percent of that value. If the drive has a bypass mechanism that allows the motor to run directly across the line, the conductors must meet the larger of two calculations, one being 125 percent of the input rating to the drive, and the other being 125 percent of the Div. 12, Tables 7 to 10 tabulation, as applicable.

371. Phase converters. The National Electrical Code defines a *phase converter* as an electric device that converts single-phase electrical power for the operation of equipment that normally operates from a three-phase electrical supply. Such phase converters are of two types: (1) static with no moving parts and (2) rotary with an internal rotor that is required to be rotating before load is applied. Single-to three-phase converters are typically used in rural areas with only single-phase utility power and where three-phase motor use is desirable because of the lower cost and greater efficiency of three-phase motors. The National Electrical Code includes rules for three-phase motor circuits operated using phase converters. The ampacity and overcurrent protection of the single-phase supply conductors shall not be less than 125 percent of the phase converter nameplate single-phase input full-load amperes.

Where the phase converter supplies specific fixed loads, and the conductor ampacity is less than 125 percent of the phase converter nameplate single-phase input full-load amperes, the conductors shall have an ampacity and overcurrent protection rating not less than 250 percent of the sum of the full-load, 3-phase current rating of the motors and other loads served where the input and output voltages of the phase converter are identical.

Where the input and output voltages of the phase converter are different, the current as determined by this section shall be multiplied by the ratio of output to input voltage.

372. Types of motor branch circuits. Branch circuits supplying motors as required by the National Electrical Code may be divided into three types, as follows: (1) a branch circuit supplying only a single motor, (2) a branch circuit supplying several motors but no other equipment except that directly associated with the motors, and (3) a branch circuit supplying one or more motors, lamps, receptacles, and/or electric heaters, etc. (combination load).

373. Rating or setting for an individual motor circuit. The motor branch-circuit short-circuit and ground-fault protective device shall be capable of carrying the starting current of the motor. Torque motor branch circuits shall be protected at the motor-nameplate current rating in accordance with 240.4(B) of the NEC. For motor circuits of 600 V or less, a protective device having a rating or setting not exceeding the values given in Table 43 of Div. 12 shall be permitted. An instantaneous-trip circuit breaker (without time delay) shall be used only if it is adjustable and is part of a listed combination controller having coordinated motor overload and also short-circuit and ground-fault protection in each conductor. A motor short-circuit protector shall be permitted in lieu of devices listed in Table 43 of Div. 12 if the motor short-circuit protector is part of a listed combination motor controller having both coordinated motor overload protection and short-circuit and ground-fault protection in each conductor if it will operate at not more than 1300 percent of full-load motor current for other than Design B energy-efficient motors and 1700 percent of motor full-load current for Design B energy-efficient motors. If the table ratings for instantaneous-trip circuit breakers are insufficient to allow the motor to start, and that has been confirmed by engineering evaluation, they may be increased to the same limits as for motor short-circuit protectors.

Exceptions

- a. *Where the setting specified in Table 430-52 of the NEC is not sufficient for the starting current of the motor, the setting of an instantaneous trip circuit breaker shall be permitted to be increased but shall in no case exceed 1300 percent of the motor full-load current for other than Design B energy efficient motors and no more than 1700 percent of full-load motor current for Design B energy efficient motors. Trip settings above 800 percent for other than Design B energy efficient motors and above 1100 percent for Design B energy efficient motors shall be permitted where the need has been demonstrated by engineering evaluation. In such cases, it shall not be necessary to first apply an instantaneous trip circuit breaker at 800 percent or 1100 percent.*
- b. *Where the motor full-load current is 8 A or less, the setting of the instantaneous-trip circuit breaker with a continuous current rating of 15 A or less in a listed combination motor controller that provides coordinated motor branch-circuit overload and short-circuit and ground-fault protection shall be permitted to be increased to the value marked on the controller.*

Where the values for branch-circuit protective devices determined by Table 43 of Div. 12 do not correspond to the standard sizes or ratings of fuses, nonadjustable circuit breakers, or thermal protective devices or the possible settings of adjustable circuit breakers, a higher size, rating, or possible setting that does not exceed the next higher standard ampere rating shall be permitted.

Exception. Where the values for branch-circuit short-circuit and ground-fault protective devices specified in the tables, or as modified by using the next-higher standard size device, are not sufficient for the starting current of the motor:

1. *The rating of a non-time-delay fuse not exceeding 600 A or a time-delay Class CC fuse shall be permitted to be increased but shall in no case exceed 400 percent of the full-load current.*

2. *The rating of the time-delay (dual-element) fuse shall be permitted to be increased but shall in no case exceed 225 percent of the full-load current.*
3. *The rating of an inverse-time circuit breaker shall be permitted to be increased but in no case shall exceed (a) 400 percent for full-load current of 100 A or less or (b) 300 percent for full-load currents greater than 100 A.*
4. *The rating of a fuse of 601–6000-A classification shall be permitted to be increased but shall in no case exceed 300 percent of the full-load current.*

For a multispeed motor, a single short-circuit and ground-fault protective device shall be permitted for two or more windings of the motor provided the rating of the protective device does not exceed the above applicable percentage of the nameplate rating of the smallest winding protected.

Exception: For a multispeed motor, a single short-circuit and ground-fault protective device shall be permitted to be used and sized according to the full-load current of the highest current winding, provided that each winding is equipped with individual overload protection sized according to its full-load current and that the branch-circuit conductors feeding each winding are sized according to the full-load current of the highest full-load current winding and the controller for each winding has a horsepower rating not less than that required for the winding having the highest horsepower rating.

Where maximum branch-circuit short-circuit and ground-fault protective-device ratings are shown in the manufacturer's overload-relay table for use with a motor controller or are otherwise marked on equipment, they shall not be exceeded even if higher values are allowed as shown above.

Suitable fuses shall be permitted in lieu of devices listed in Table 430.52 of the NEC for power electronic devices in a solid state motor controller system provided that the marking for replacement fuses is provided adjacent to the fuses.

Self-protected combination controllers are also permitted as short-circuit and ground-fault protection for motors, and they have the same rating limitations as for motor short-circuit protectors, covered above. They also have a note attached advising care on delta systems in terms of observing the individual pole interrupting capability. This refers to the fact that on a corner-grounded delta system a ground fault will impose the full line-to-line voltage on a single pole of the breaker, instead of the line-to line voltage divided by the square root of three, as would be the case in conventional wye systems.

374. Several motors or loads on one branch circuit. Two or more motors or one or more motors and other loads shall be permitted to be connected to the same branch circuit under the conditions of 1, 2, or 3 below:

1. *Not more than 1 hp.* Several motors each not exceeding 1 hp in rating shall be permitted on a branch circuit protected at not more than 20 A at 125 V or less, or 15 A at more than 125 V but not more than 600 V if all the following conditions are met:
 - a. The full-load rating of each motor does not exceed 6 A.
 - b. The rating of the branch-circuit protective device marked on any of the controllers is not exceeded.
 - c. Individual running overload protection conforms to Sec. 380.
2. *If the smallest motor is protected.* If the branch-circuit protective device is selected not to exceed that allowed by Sec. 373 for the motor of the smallest rated motor, two or more motors or one or more motors and other load or loads, with each motor having

individual overload protection, shall be permitted to be connected to a branch circuit when it can be determined that the branch-circuit protective device will not open under the most severe normal conditions of service that might be encountered.

3. *Other group installation.* Two or more motors of any rating or one or more motors and other load or loads, with each motor having individual overload protection, shall be permitted to be connected to one branch circuit when the motor controller or controllers and overload device or devices are (a) installed as a listed factory assembly and the motor branch-circuit short-circuit and ground-fault protective device is either factory-provided as part of the assembly or specified by a marking on the assembly, or (b) the motor branch-circuit short-circuit and ground-fault protective device, the motor controller or controllers, and the overload device or devices are field-installed as separate assemblies listed for such use and provided with manufacturers' instructions for use with each other, or (c) all the following conditions are met:
 - a. Each motor-running overload device is listed for group installation with a specified maximum rating for fuse and/or inverse-time circuit breaker.
 - b. Each motor controller is listed for group installation with a specified maximum rating of fuse and/or circuit breaker.
 - c. Each circuit breaker shall be listed and be of the inverse-time type.
 - d. The branch circuit shall be protected by fuses or inverse-time circuit breakers having a rating not exceeding that specified in Sec. 373 for the highest rated motor connected to the branch circuit plus an amount equal to the sum of the full-load current ratings of all other motors and the ratings of other loads connected to the circuit. Where this calculation results in a rating less than the ampacity of the supply conductors, it shall be permitted to increase the maximum rating of the fuses or circuit breaker to a value not exceeding that permitted by 240.4(B) of the NEC.
 - e. The branch-circuit fuses or inverse-time circuit breakers are not larger than allowed by 430.40 of the NEC for the overload relay protecting the smallest rated motor of the group.
4. *Single-motor taps.* For group installations described in 1, 2, and 3 above, the conductors of any tap supplying a single motors shall not be required to have an individual branch-circuit short-circuit and ground-fault protective device provided it complies with any of the following three conditions: The first possibility is that no conductor to the motor has an ampacity less than that of the branch-circuit conductors; and the second is that no conductor to the motor has an ampacity less than one-third that of the branch-circuit conductors, with a minimum in accordance with Sec. 387, the conductors to the motor-running overload protective device being not more than 7.5 m (25 ft) long and being protected from physical damage. The third possibility is the most complicated. If the conductors run from the short-circuit and ground-fault protective device terminate in a manual motor controller additionally marked "Suitable for Tap Conductor Protection in Group Installations" those conductors are permitted to have an ampacity as low as one-tenth that of the rating of the short-circuit and ground-fault protective device. They must be protected from damage and be enclosed in a raceway or within the controller, and they must not exceed 3 m (10 ft) in length. Otherwise their minimum size rises to equal that of the branch-circuit conductors.

375. Motors on general-purpose branch circuits. Overload protection for motors used on general-purpose branch circuits shall be provided as specified in 1, 2, 3, or 4 below.

1. *Not more than 1 hp.* One or more motors without individual overload protection shall be permitted to be connected to general-purpose branch circuits only when the installation complies with the limiting conditions specified in conditions 1a and 1b of Sec. 374, as well as the provisions of parts (2) and (3) of Sec. 380.

2. *More than 1 hp.* Motors of larger ratings than specified in condition 1 of Sec. 374 may be connected to general-purpose branch circuits only when each motor is protected by overload protection selected to protect the motor as specified in Sec. 380. Both the controller and the motor-running overload device shall be approved for group installation with the short-circuit and ground-fault protective device selected in accordance with Sec. 374.
3. *Cord- and plug-connected.* Where a motor is connected to a branch circuit by means of an attachment plug and receptacle and individual overload protection is omitted as provided in condition 1 above, the rating of the attachment plug and receptacle shall not exceed 15 A at 125 V or 250 V. Where individual overload protection is required as provided in condition 2 for a motor or motor-operated appliance that is attached to the branch circuit with an attachment plug and receptacle, the overload device shall be an integral part of the motor or of the appliance. The rating of the attachment plug and receptacle shall determine the rating of the circuit to which the motor may be connected, as is provided in Article 210 of the National Electrical Code.
4. *Time delay.* The branch-circuit short-circuit and ground-fault protective device protecting a branch circuit to which a motor or motor-operated appliance is connected shall have sufficient time delay to permit the motor to start and accelerate its load.

376. Multimotor and combination load equipment. The rating of the branch-circuit short-circuit and ground-fault protective device for multimotor and combination load equipment shall not exceed the rating marked on the equipment.

377. The component parts of a motor branch circuit for an individual motor are shown in Fig. 7.187.

P_1 : *Overcurrent protective device in feeder or main.* It may consist of fuses or a circuit breaker. Refer to Sec. 390.

S_B : *Branch-circuit switch.* It is not required by National Electrical Code rules. It may consist of a switch or a circuit breaker. It must have an ampere rating at least 115 percent of the full-load current rating of the motor. For ac motors of 1200 hp or less and dc motors of 40 hp or less, the switch must be of the motor-circuit type, however, a general-use or isolating switch may be used where plainly marked "Do not operate under load." If a switch is used, it must have fuse clips large enough to accommodate fuses required at P_2 . If a circuit breaker is used as a branch-circuit short-circuit and ground-fault protective device, it will serve the double purpose of a branch-circuit switch and a circuit protective device. Refer to Sec. 386.

P_2 : *Branch-circuit short-circuit and ground-fault protective device.* It may consist of fuses or a circuit breaker. If a circuit breaker is used, it will serve the double purpose of a branch-circuit switch and an overload protective device. Refer to Sec. 385.

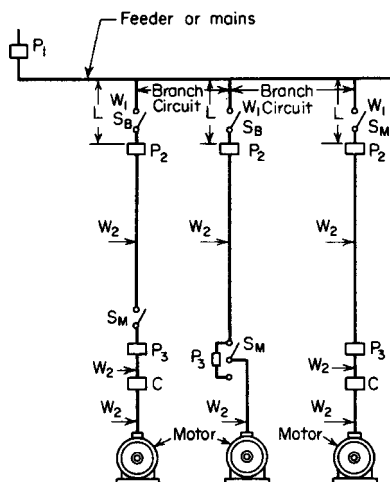

FIGURE 7.187 Single-line diagrams giving requirements for component parts of branch motor circuits with branch-circuit short-circuit and ground-fault protection.

S_M : *Motor switch*. It may consist of a switch or a circuit breaker. It must have a rating and be of a type as described for S_B . If the switch is fused, the fuse clips must be large enough to accommodate the size of fuses required at P_3 . Switch S_M must be located within sight of motor controller C . If switch S_M is of the two-throw or two-position type (Diagram II) for cutting the motor overload protective device out of the circuit during the starting period, the switch must be so arranged that it cannot be left in the starting position. It must be within sight from the location of controller C , and it must also be within sight from the motor and driven machinery location unless it is capable of being locked in the open position.

P_3 : *Motor-overload protective device*. It may consist of fuses, thermal relays, magnetic relays, circuit breakers, or a thermal protector in the motor. It generally is not required for intermittent-duty motors. Except for a thermal protector in the motor, the device shall be rated or selected to trip at not more than 125 percent of the motor full-load current rating for motors marked with a service factor not less than 1.15 or marked to have a temperature rise not over 40°C and at not more than 115 percent for all other types of motors. This value may be modified as permitted by Sec. 380, condition 6. The motor-overload protective device is generally incorporated in controller C and mounted inside the controller case. Refer to Secs. 380 to 382.

C : *Motor controller*. Refer to Sec. 379.

W_1 : *Branch-circuit tap wires from point of connection of feeder to branch-circuit overload protective device*. If a branch-circuit short-circuit and ground-fault protective device is located at the point of connection to the feeder, the ampacity of the tap wires must be at least 125 percent of the motor full-load current. If the length L of the wires from the point of connection to the feeder to the branch-circuit short circuit and ground-fault protective device is 7.5 m (25 ft) or less, the ampacity of the tap wires must be at least one-third of the ampacity of the feeder. If the length L of the wires from the point of connection to the feeder to the branch-circuit short-circuit and ground-fault protective device is greater than 25 ft, the tap wires must be of the same size as the feeder, except in high-bay manufacturing buildings over 11 m (35 ft) high at walls, where the length L is permitted to be not over 25 ft long horizontally and not over 30 m (100 ft) in total length under special conditions detailed in the exception to Sec. 430.28 of the 2008 National Electrical Code.

W_2 : *Branch-circuit wires from motor-overload protective device to motor*. They must have an ampacity of at least 125 percent of the motor full-load current for continuous-duty motors. Refer to Sec. 387.

378. The component parts of a motor branch circuit supplying several motors are shown in Fig. 7.188.

P_1 : *Short-circuit and ground-fault protective device in branch circuit*. It may consist of fuses or an inverse-time circuit breaker listed for group installation. If the motor-overload protective device consists of overload relays, the rating of the fuses or the setting of the circuit breaker must not be greater than is permitted in condition 12 of Sec. 380, unless the motor-overload protective device P_3 and controller C are listed for group installation.

If the motor-overload protective devices are cut out during the starting period, P_1 must consist of fuses or an inverse-time circuit breaker rated not more than 400 percent of the full-load current of the smallest motor so protected. Refer to Sec. 385.

S_M : *Combined motor and branch-circuit switch*. It may consist of a switch or a circuit breaker. It must have a continuous-duty rating of at least 115 percent of the motor

full-load current. For ac motors of 100 hp or less and dc motors of 40 hp or less and for all cases in which a switch is used for shutting down the motor, the switch must be of the motor-circuit type. If the switch is fused, the fuse clips must be large enough to accommodate the size of fuses required at P_3 . If the switch is used for shutting down the motor, it should be located as close as possible to the motor and its driven machinery and in the most accessible location for the operator. If the switch is not used for shutting down the motor, it may be remote from the motor provided that it is located within sight from the controller C and is either located within sight of the motor and its driven machinery or so arranged that it can be locked in the open position. If the switch of the two-position or double-throw type (Diagram II) for cutting the motor overload protective device out of the circuit during the starting period, it must be so arranged that it cannot be left in the starting position. If S_M is a fused switch or circuit breaker, the supply from P_1 is a feeder. Refer to Sec. 386.

FIGURE 7.188 Single-line diagrams giving requirements for motor circuits when a branch-circuit short-circuit and ground-fault protective device is used for more than one motor.

P_3 : *Motor-overload protective device.* It may consist of fuses, thermal relays, magnetic relays, a circuit breaker, or a thermal protector in the motor. Except for a thermal protector in the motor, the device shall be rated or selected to trip at not more than 125 percent of the motor full-load current rating for motors marked with a service factor not less than 1.15 or marked to have a temperature rise not over 40°C and at not more than 115 percent for all other types of motors. This value may be modified as permitted by Sec. 380, condition 6. The motor-overload protective device is generally incorporated in the controller C and mounted inside the controller case. Refer to Secs. 374 and 380 to 382.

C : *Motor controller.* Refer to Secs. 374 and 379.

W_1 : *Individual motor tap wires from points of connection to branch circuit to motor-overload protective device.* If the motor-overload protective device is located at the point of connection to the branch circuit, the ampacity of the wires must be at least 125 percent of the motor full-load current. If the length L of the wires is 7.5 m (25 ft) or less, the ampacity of the wires must be at least one-third of the ampacity of the branch-circuit wires. If the length L of the wires is greater than 25 ft, the wires must be of the same size as the branch-circuit wires.

379. Motor controllers. Each motor must be provided with a suitable controller that can start and stop the motor and perform any other control functions required for the satisfactory operation of the motor, such as speed control. The different types of motor-control equipment are discussed in Secs. 251 and 325. A controller must be capable of interrupting the current of the motor under stalled-rotor conditions. Each motor must have its own individual controller except that, for motors of 600 V or less, a single controller may serve a group of motors under any one of the following conditions:

1. If a number of motors drive several parts of a single machine or a piece of apparatus such as metalworking and woodworking machines, cranes, hoists, and similar apparatus.
2. If a group of motors is under the protection of one overcurrent device as permitted in condition 1 for motor branch circuits as given in Secs. 374 and 375.
3. If a group of motors is located in a single room within sight of the controller location. A distance of more than 15 m (50 ft) is considered equivalent to being out of sight.

The controller must have a horsepower rating that is not less than that of the motor, except as follows:

1. *Stationary motor of $\frac{1}{8}$ hp or less.* For a stationary motor rated at $\frac{1}{8}$ hp or less that is normally left running and is so constructed that it cannot be damaged by overload or failure to start, such as clock motors and the like, the branch-circuit protective device may serve as the controller.
2. *Stationary motor of 2 hp or less.* For a stationary motor rated at 2 hp or less and 300 V or less, the controller may be a general-use switch having an ampere rating at least twice the full-load current rating of the motor. On ac circuits, general-use snap switches suitable for use only on ac (not general-use ac, dc snap switches) may be employed to control a motor having a full-load current rating not exceeding 80 percent of the ampere rating of the switch.
3. *Portable motor of $\frac{1}{3}$ hp or less.* For a portable motor rated $\frac{1}{8}$ hp or less, the controller may be an attachment plug and receptacle.
4. *Circuit breaker as controller.* A branch-circuit inverse time circuit breaker, rated in amperes only, may be used as a controller for all motors including Design E. When this circuit breaker is also used for overload protection, it shall conform to the appropriate provisions of this section governing the type of protection afforded.

A controller need not open all conductors to the motor unless it serves as a disconnecting means or unless one pole of the controller is placed in a permanently grounded conductor, in which case the controller must be designed so that the pole in the grounded conductor cannot be opened without simultaneously opening all conductors of the circuit.

Machines of the following types shall be provided with speed-limiting devices or other speed-limiting means unless the inherent characteristics of the machines, the system, or the load and the mechanical connection thereto are such as to limit the speed safely or unless the machine is always under the manual control of a qualified operator:

1. Separately excited dc motors
2. Series motors
3. Motor-generators and converters that can be driven at excessive speed from the dc end, as by a reversal of current or a decrease in load

Adjustable-speed motors, if controlled by field regulation, shall be so equipped and connected that they cannot be started under a weakened field unless the motors are designed for such starting.

The controller for a motor should be as near as possible to the motor to make the length of the wires between the controller and the motor as short as possible. For motor circuits 600 V or less, a disconnecting means must be within sight from the location of the motor and its driven machinery unless the controller disconnecting means is capable of being locked in the open position. The exception to 430.102 of the NEC outlines conditions where it is not necessary for the disconnecting means to be in sight of the motor. For motor circuits over 600 V, the controller disconnecting means is permitted to be out of sight from

the controller, provided the controller is marked with a warning label giving the location and identification of the disconnecting means to be locked in the open position. See Sec. 383 for type and rating of the disconnecting means.

The control point should be located so that it will be in the most accessible location for the operator of the machine driven by the motor. In the case of manual controllers the location of the control point will be the same as the location of the controller. For magnetic controllers the location of the control point will be the point of location of the START and STOP pushbuttons, which may or may not be the same as the location of the controller.

For motors rated over 600 V, the ultimate-trip current of overcurrent (overload) relays or other motor protective devices used shall not exceed 115 percent of the controller's continuous current rating. Where the motor branch-circuit disconnecting means is separate from the controller, the disconnecting means current rating shall not be less than the ultimate trip setting of the overcurrent relays in the circuit.

380. Overload protection of motors. Each continuous-duty motor must be protected against excessive overloads under running conditions by some approved protective device. This protective device, except for motors rated at more than 600 V, may consist of thermal relays, thermal release devices, or magnetic relays in connection with the motor controller, fuses, an inverse-time circuit breaker, or a thermal protector built into the motor.

Except for a thermal protector in the motor, the National Electrical Code requires that the protection be as follows:

1. More Than 1 hp. Each continuous-duty motor rated more than 1 hp shall be protected against overload by one of the following means:

a. A separate overload device that is responsive to motor current. This device shall be selected to trip or shall be rated at no more than the following percentage of the motor-nameplate full-load current rating:

	<i>Percent</i>
Motors with a marked service factor not less than 1.15	125
Motors with a marked temperature rise not over 40°C	125
All other motors	115

For a multispeed motor, each winding connection shall be considered separately. This value may be modified as permitted by Par. 6.

Where a separate motor-running overload device is so connected that it does not carry the total current designated on the motor nameplate, as for wye-delta starting, the proper percentage of nameplate current applying to the selection or setting of the overload device shall be clearly designated on the equipment, or the manufacturer's selection table shall take this into account.

b. A thermal protector integral with the motor, approved for use with the motor which it protects on the basis that it will prevent dangerous overheating of the motor due to overload and failure to start. The National Electrical Code specifies the level of protection to be provided by the motor manufacturer. If the motor current-interrupting device is separated from the motor and its control circuit is operated by a protective device integral with the motor, it shall be so arranged that the opening of the control circuit will result in an interruption of current to the motor.

c. A protective device integral with the motor that will protect the motor against damage due to failure to start shall be permitted if the motor is part of an approved assembly that does not normally subject the motor to overloads.

d. For motors larger than 1500 hp, a protective device employing embedded temperature detectors which cause current to the motor to be interrupted when the motor attains a temperature rise greater than marked on the nameplate in an ambient of 40°C.

2. 1 hp or Less, Manually Started

a. Each continuous-duty motor rated at 1 hp or less that is not permanently installed, is nonautomatically started, and is within sight from the controller location shall be permitted to be protected against overload by the branch-circuit short-circuit and ground-fault protective device. This branch-circuit protective device shall not be larger than that specified in 430.32 and 430.53 of the NEC, except that any such motor may be used on a nominal 120-V branch circuit protected at not over 20 A.

b. Any such motor that is not in sight from the controller location shall be protected as specified in Par 3. Any motor rated at 1 hp or less that is permanently installed shall be protected in accordance with Par. 3.

3. 1 hp or Less, Automatically Started. Any motor of 1 hp or less that is started automatically shall be protected against overload by the use of one of the following means:

a. A separate overload device that is responsive to motor current. This device shall be selected to trip or be rated at no more than the following percentage of the motor-nameplate full-load current rating:

	<i>Percent</i>
Motors with a marked service factor not less than 1.15 or greater	125
Motors with a marked temperature rise 40°C or less	125
All other motors	115

For a multispeed motor, each winding connection shall be considered separately. This value may be modified as permitted by Par. 6.

b. A thermal protector integral with the motor, approved for use with the motor which it protects on the basis that it will prevent dangerous overheating of the motor due to overload and failure to start. Where the motor current-interrupting device is separate from the motor and its control circuit is operated by a protective device integral with the motor, it shall be so arranged that the opening of the control circuit will result in an interruption of current to the motor.

c. A protective device integral with the motor that will protect the motor against damage due to failure to start shall be permitted (1) if the motor is part of an approved assembly that does not normally subject the motor to overloads or (2) if the assembly is also equipped with other safety controls (such as safety combustion controls of a domestic oil burner) that protect the motor against damage due to failure to start. Where the assembly has safety controls that protect the motor, this fact shall be indicated on the nameplate of the assembly where it will be visible after installation.

d. When the impedance of the motor windings is sufficient to prevent overheating due to failure to start, the motor may be protected as specified in Par. 2a for manually started motors if the motor is part of an approved assembly in which the motor will limit itself so that it will not be dangerously overheated.

Many ac motors of less than $\frac{1}{20}$ hp, such as clock motors, series motors, etc., and also some larger motors such as torque motors come within this classification. It does not include split-phase motors having automatic switches to disconnect the starting windings.

4. Wound-Rotor Secondaries. The secondary circuits of wound-rotor ac motors, including conductors, controllers, resistors, etc., shall be considered to be protected against overload by the motor overload device.

5. Intermittent and Similar Duty. A motor used for service which is inherently short-time, intermittent, periodic, or varying-duty (as illustrated by Table 12 of Div. 12) is considered to be protected against overload by the branch-circuit short-circuit and ground-fault protective device, provided the protective-device rating or setting does not exceed that specified in Table 43 of Div. 12.

Any motor is considered to be for continuous duty unless the nature of the apparatus which it drives is such that the motor cannot operate continuously with load under any condition of use.

- 6. Selection of Setting of Overload Relay.** When the overload relay selected in accordance with Par. 1a or 3a is not sufficient to start the motor or to carry the load, higher size sensing elements or incremental settings shall be permitted to be used. However, it should not exceed 140 percent of the motor full-load current rating of motors marked with a service factor not less than 1.15, and of motors marked to have a temperature rise not over 40°C, and not be higher than 130 percent of the full-load current rating for all other motors. If not shunted during the starting period of the motor, the overload protective device shall have sufficient time delay to permit the motor to start and accelerate its load.
- 7. Shunting during Starting Period.** If the motor is manually started (including starting with a magnetic starter having pushbutton control), the running overload protection may be shunted or cut out of the circuit during the starting period of the motor, provided the device by which the overload protection is shunted or cut out cannot be left in the starting position and provided fuses or inverse-time circuit breakers rated or set at not over 400 percent of the full-load current of the motor are so located in the circuit as to be operative during the starting period of the motor. The motor-running overload protection shall not be shunted or cut out during the starting period if the motor is automatically started, except as follows: (a) the motor-starting period exceeds the time delay of available motor-overload protective devices; and (b) listed means are provided to (1) sense motor rotation and automatically prevent shunting or cutout in the event that the motor fails to start, (2) limit the time of overload protection shunting or cutout to less than the locked-rotor time rating of the protected motor, and (3) provide for shutdown and manual restart if the motor-running condition is not reached.
- 8. Fuses Inserted in Conductors.** When fuses are used for motor-running protection, a fuse shall be inserted in each ungrounded conductor. A fuse shall also be inserted in the grounded conductor if the supply system is three-wire, three-phase, ac with one conductor grounded.
- 9. Devices Other Than Fuses Inserted in Conductors.** If devices other than fuses are used for motor-running overload protection, Table 41 of Div. 12 shall govern the minimum allowable number and location of overload units such as trip coils or relays.
- 10. Number of Conductors Opened by Overload Device.** Motor overload devices other than fuses or thermal protectors shall simultaneously open a sufficient number of ungrounded conductors to interrupt current flow to the motor.
- 11. Motor Controller as Running Overload Protection.** A motor controller shall also be permitted to serve as the overload device if the number of overload units complies with Par. 9 and if these units are operative in both the starting and the running positions in the case of a dc motor and in the running position in the case of an ac motor.
- 12. Overload Relays.** Overload relays and other devices for motor-overload protection that are not capable of opening short circuits or ground shall be protected by fuses, circuit breakers with ratings or settings in accordance with Sec. 373, or a motor short-circuit protector, unless approved for group installation, and marked to indicate the maximum size of fuse or inverse-time circuit breaker by which they must be protected.

13. Automatic Restarting. A motor-overload device that can restart a motor automatically after overload tripping shall not be installed unless approved for use with the motor it protects. A motor overload device that can restart a motor automatically after overload tripping shall not be installed so that its automatic restarting can result in injury to persons.

381. Application of fuses for motor-overload protection. If regular fuses are used for the overload protection of a motor, they must be shunted during the starting period, since a regular fuse having a rating of 125 percent of the motor full-load current would be blown by the starting current. Many cases of dc motor and some wound-rotor-induction-motor installations will be an exception to this rule. Aside from these exceptions it is not common practice to use regular fuses for the overload protection of motors. Time-delay fuses can sometimes be satisfactorily employed for the overload protection of motors, since ones rated at 125 percent of the motor full-load current will not be blown by the starting current for ordinary conditions of motor service. In fact, the manufacturers of these fuses recommend that for ordinary service fuses of a smaller rating than 125 percent of the motor full-load current be employed. Typical heavy-service conditions are:

1. Motors slightly overloaded
2. Motors with severe starting conditions, such as large fans, compressors, etc.
3. Motors which are started frequently or reversed quickly
4. Motors which have the protective time-delay fuses located in places where high ambient temperatures prevail

Even time-delay fuses may not be satisfactory unless they are shunted during the starting period, because the 125 percent value cannot be exceeded and available ratings of fuses may not permit selection close to but not exceeding 125 percent.

Direct-current motors under ordinary conditions of service will not require a starting current of such value that it would blow regular fuses rated at 125 percent of the motor full-load current. Standard manual starters for dc motors are equipped with a starting resistance of a value which will limit the starting current on the first step to 150 percent of the motor full-load current. This current for the normal duration of the starting period would not blow a fuse rated at 125 percent of the full-load current. For ordinary conditions of service, therefore, regular fuses can often be used for the protection of dc motors. In many cases what has been said for dc motors will hold true for wound-rotor induction motors.

382. Thermally protected motors are equipped with built-in overload protection mounted directly in the motor. The built-in protector usually consists of a thermostat which when heated above a certain temperature opens two small contacts within the enclosing case of the thermostat. The thermostat is mounted on the windings or the stator iron of a motor. The contacts may open the motor circuit directly. On three-phase motors, the thermostat may be connected to open the center point of a Y-connected motor winding. When the thermostat does not directly open the motor circuit, the contacts are provided with leads so they may be connected in a control circuit in a manner that will cause the controller to open the motor circuit or give a warning signal when the thermostat operates because of overheating of the motor (see Fig. 7.189).

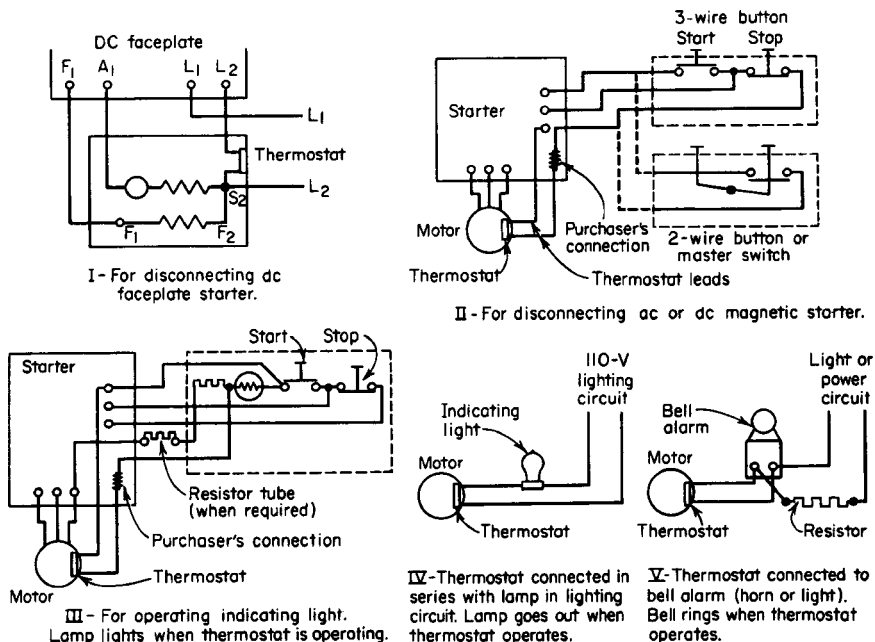

FIGURE 7.189 Connections for thermostats of Thermoguard motors. [Westinghouse Electric Corp.]

The thermostat type of thermal protector employs a bimetallic element which warps on a temperature increase, causing the contact to open. A thermal protector may also consist of PTC thermistors, one in each phase and connected in series for three-phase motors (Fig. 7.190).

At normal winding temperatures, the resistance of the PTC thermistor is low, and it remains virtually constant up to the critical temperature. Beyond this point, a small increase in temperature greatly increases the resistance. When the temperature of any of the PTC thermistors transgresses the critical or switching temperature range, the circuit operates to give a warning or to disconnect the power. When cooling occurs, the circuit returns to normal resistance and the motor can be restarted. Either manual or automatic reset can be used.

On the thermally protected motor designed for warning only, a neon-glow lamp may be mounted on the conduit box for visual warning (see Fig. 7.191, I). This lamp can also be supplied for remote mounting (if specified) for installations in which the motor conduit box would not be visible.

FIGURE 7.190 Method of locating PTC thermistors for the protection of a three-phase motor. [Westinghouse Electric Corp.]

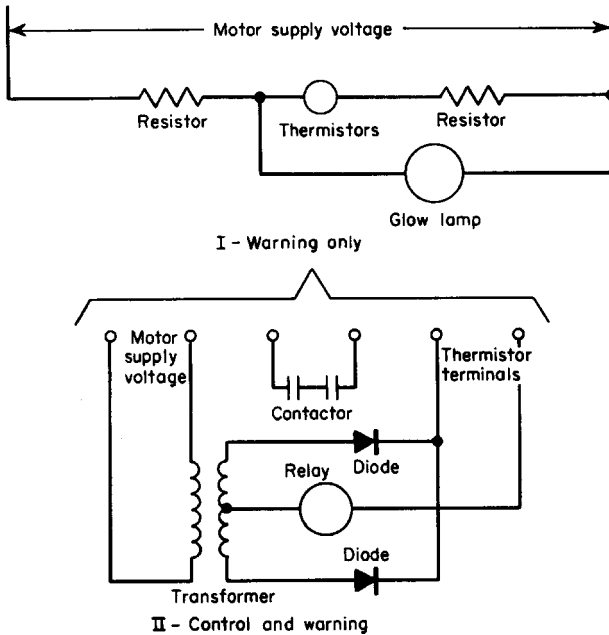

FIGURE 7.191 Basic circuits for Guardistor thermally protected motors. [Westinghouse Electric Corp.]

383. Motor switches. Each motor with its controller must be provided with some form of approved manual disconnecting means, as at S_M in Figs. 7.187 and 7.188. This disconnecting means, when in the open position, must disconnect both the controller and the motor from all ungrounded supply wires, and all poles must operate simultaneously. To qualify as a disconnecting means in this part of the code, the disconnect must not be capable of reclosing automatically. This rule prevents ordinary time clocks from qualifying as motor-circuit disconnects. The switch is also permitted to open a permanently grounded supply wire provided it is so designed that the pole opening the grounded wire cannot be opened without simultaneously opening all supply wires. It must be a type which will plainly indicate whether it is in the open or the closed position. It must be a listed device and may consist of a manually operated air-break switch, a manually operated circuit breaker, a molded case switch (nonautomatic circuit interrupter), or a manually operated oil switch. The oil switch or circuit breaker may be equipped for electrical operation in addition to the hand mechanism. More than one switch may be used in series, as at S_B and S_M in Fig. 7.187, but at least one of the switches must be readily accessible.

For motors rated over 600 V, the ultimate-trip current of overcurrent (overload) relays or other motor protective devices used shall not exceed 115 percent of the controller's continuous current rating. Where the motor branch-circuit disconnecting means is separate from the controller, the disconnecting means current rating shall not be less than the ultimate trip setting of the overcurrent relays in the circuit. See Sec. 385.

No additional switch is required with most types of manual across-the-line starters, since their switch acts as the disconnecting means, although there are rating and location limitations covered in item 9. All magnetic types of starters and controllers must be provided with a switch ahead of the starter and within sight of it. All autotransformer starters require a separate disconnecting switch ahead of the starter.

Every switch in the motor circuit between the point of attachment to the feeder and the point of connection to the motor must be a listed device and be a motor-circuit switch, rated in horsepower, a circuit breaker or a molded-case switch except under the following conditions:

1. For stationary motors of $\frac{1}{8}$ hp or less, the branch-circuit overcurrent device is permitted to serve as the disconnecting means.
2. For stationary motors of 2 hp or less operating at not more than 300 V, a general-use switch having an ampere rating of at least twice the full-load motor current rating is permitted to be used. On ac circuits general-use snap switches suitable only for use on ac (not general-use ac, dc snap switches) are permitted to be used to disconnect a motor having a full-load current rating not exceeding 80 percent of the ampere rating of the switch. A listed manual motor controller is also permitted provided its horsepower rating is not less than the motor and it is marked "Suitable as motor disconnect." See item 9 below for coverage of and additional limitations for these disconnects where the motor exceeds 2 hp.
3. A general-use switch is permitted to be used for motors of a size over 2 hp but not larger than 100 hp which are equipped with a compensator starter, provided that all the following provisions are complied with:
 - a. The motor drives a generator provided with overload protection.
 - b. The controller is capable of interrupting the stalled-rotor current and is provided with a no-voltage release and with running overload protection not exceeding 125 percent of the motor full-load current rating.
 - c. Separate fuses or an inverse-time circuit breaker, rated or set at not more than 150 percent of the motor rated current, is provided in the branch circuit.
4. For stationary motors that are rated at more than 40 hp, dc, or 100 hp, ac, the disconnecting means is permitted to be a general-use switch, or an isolating switch plainly marked "Do not operate under load."
5. For cord- and plug-connected motors, a horsepower-rated attachment plug and receptacle having ratings no less than the motor ratings are permitted to serve as the disconnecting means. Horsepower-rated plugs and receptacles are not required for cord- and plug-connected appliances or a portable motor rated $\frac{1}{3}$ hp or less.
6. A general-use switch is permitted to serve as the disconnecting means for a torque motor.
7. An instantaneous trip circuit breaker that is part of a listed combination motor controller shall be permitted to serve as a disconnecting means.
8. A listed self-protected combination controller is permitted to serve as a disconnecting means.
9. Manual motor controllers are controllers first, and disconnecting means second. They do not meet all the internal spacing requirements of conventional switches and circuit breakers, and therefore there are limitations on their use as disconnecting means. A listed manual motor controller additionally marked "Suitable as motor disconnect" is permitted to serve as a disconnecting means provided it is located after the final branch-circuit and ground-fault protective device. Note that one of these manual motor controllers is also permitted on the line side of electronic-style fuses protecting a solid-state motor controller system, however, where this is the case the fuses become classified as supplementary overcurrent protective devices and one of the other conventional overcurrent protective devices must be installed on the line side of the manual motor controller.
10. The final disconnecting means in this group is a listed system for system isolation, which must be arranged on the load side of the overcurrent protective device and any disconnecting means required for that overcurrent device. These are extremely specialized

listed systems for very complicated industrial processes that use monitored controls, often at multiple locations, which allow for safe access, often from multiple locations, to large continuous process machinery. The description for these disconnecting systems that is used in *NFPA 79, Electrical Standard for Industrial Machinery* is far more enlightening, namely, “redundantly monitored, remotely operated contactor isolating system that incorporates control lockout provisions and is listed for disconnection purposes.”

A motor-circuit switch is intended for use in a motor branch circuit and is rated in horsepower. It must be capable of interrupting the maximum operating overload current of a motor of the same horsepower as the switch at the rated voltage. It also must have a continuous rating of at least 115 percent of the full-load current of the motor. If a fused switch is used, it must be large enough to accommodate the size of fuses employed.

If the motor switch is used for shutting down the motor, it must be located as close as possible to the motor and its driven machinery and in the most accessible location for the operator. One switch may be employed to serve the double purpose of motor- and branch-circuit switch as shown at S_M in III of Fig. 7.187. There are specific code limitations on how far from a motor or the associated controller a disconnect is permitted to be. The first concept, addressed in “a” below, is that usually both the controller disconnect and the motor disconnect must be within sight of the loads they disconnect. Although similar, the rules differ between controller disconnects (covered in “b” below) and motor disconnects (covered in “c” below).

- a. *“In sight from” requirements.* The NEC defines “in sight from” as being visible and not over 15 m (50 ft) from the specified location. If you can see one component from the other but they are more than 15 m (50 ft) apart, they are not “in sight from” each other. This concept, which originated in the NEC motor article, is now formally defined in NEC Article 100 for use throughout the NEC.
- b. *Controller disconnects.* An individual motor disconnecting means must be in sight from each motor controller. The three exceptions to this rule are not commonly used. Medium-voltage (over 600V) controllers can have disconnects that are out of sight if the disconnects can be locked open and a warning sign is posted on the controller giving the location of the remote disconnecting means. A single disconnect can be installed for a group of controllers operating continuous process machinery, provided no controller ends up out of sight of the disconnect, and both the disconnect and all the controllers under it must be within sight of the driven machinery. Note that this last exception waives only the individual disconnect rule, while reinforcing the in-sight requirement. The third exception allows the disconnect to be out of sight of a valve actuator motor assembly containing the controller if an in-sight location would introduce additional hazards. This situation mirrors comparable language that applies to the motor disconnect, covered in more detail in “c” below. When this exception is used, the valve motor and controller assembly must have the disconnect location marked on the assembly.
- c. *Motor disconnects.* A disconnect is required within sight of the motor and its driven machinery. The controller disconnect is permitted to serve for this purpose if it meets the same location requirements. There is an exception that allows the in-sight disconnect to be omitted if the disconnecting means for the controller can be individually locked in the open position; however, that exception is now limited to (1) industrial occupancies with written safety procedures that ensure that only qualified persons will service the motor, or (2) other installations if the additional disconnect would introduce additional hazards or would be impracticable. For example, it would be plainly impracticable to place a disconnect 15 m (50 ft) down a well shaft to be “in sight” (not over 15 m [50 ft] distant) from a submersible pump motor 30 m (100 ft)

down the same shaft. Variable frequency drives should not have the motor disconnected unless the drive itself is first disconnected, and multi-motor equipment may cause hazards unless a coordinated stop is arranged. Large motors (over 100 hp) only need isolation switches anyway, so their disconnects can be remote, and additional disconnects in hazardous (classified) locations only exacerbate the explosion hazards. For many common residential, commercial, and farm applications, however, there must be an additional disconnecting means located within sight of the motor regardless of the lockability of the controller disconnect.

384. Group switching. Under any one of the following conditions, the National Electrical Code rules will allow a single switch to be provided for a group of motors if the motors are rated at not more than 600 V:

1. Where a number of motors drive several parts of a single machine or piece of apparatus, such as metalworking and woodworking machines, cranes, and hoists
2. Where a group of motors is under the protection of one set of overcurrent devices as permitted by the Code (see Sec. 380)
3. Where a group of motors is in a single room within sight of the location of the disconnecting means

The disconnecting means shall have a horsepower rating not less than is required for a single motor, the rating of which equals the sum of the horsepowers or full-load and locked-rotor currents, whichever results in the largest horsepower rating, of all the motors of the group. See Tables 7 through 10 and Tables 44 and 45 of Div. 12 for full-load and locked-rotor currents and equivalent horsepower ratings.

385. Branch-circuit short-circuit and ground-fault protection. The wires of motor branch circuits must be protected against short circuits and ground faults by a protective device located at the point where the branch-circuit wires are connected to the feeder or main, as at location P_2 in Fig. 7.187. National Electrical Code rules, however, allow the size of these branch-circuit protective devices to be considerably greater than the allowable ampacity of the wires. This provision is for the purpose of permitting the passage of the starting current without the employment of excessively large conductors.

With this practice the motor-overload device will protect against overloads of moderate severity, and the branch-circuit protective device will protect against short circuits and ground faults. The recommended maximum rating of fuses and setting of circuit breakers for motor branch circuits supplying an individual motor are given in Tables 42 and 43 of Div. 12.

The National Electrical Manufacturers Association has adopted a standard of identifying code letters that may be marked by the manufacturers on motor nameplates to indicate the motor kilovolt-ampere input with a locked rotor. These code letters with their classification are given in Table 42 of Div. 12. In determining the starting current to employ for circuit calculations, use values from Table 43 of Div. 12.

Although the branch-circuit short-circuit and ground-fault protective device must pass the starting current of the motor, the rating of the protective device need not be as great as the maximum value of the starting current of the motor. Owing to the time-lag characteristics of fuses and inverse-time circuit breakers, the starting current, which lasts for only a short time, will not rupture fuses or operate inverse-time circuit breakers of a considerably smaller rating than the maximum value of the starting current. The percentage of the maximum starting current that fuses must be rated for or inverse-time circuit breakers be set for, so that the starting current will not open the circuit, depends upon the frequency and duration

of the starting periods. Under ordinary starting conditions, fuses rated or inverse-time circuit breakers set at from 50 to 67 percent of the maximum starting current will allow the passage of the starting current. See Secs. 373 and 374 for maximum ratings or settings of short-circuit and ground-fault protective devices for motors rated 600 V or less.

Either fuses or circuit breakers may be employed for the protection of motor branch circuits for motors rated at not more than 600 V. When circuit breakers are used, they must have a continuous current rating of not less than 115 percent of the full-load current rating of the motor.

It is often not convenient or practicable to locate the branch-circuit short-circuit and ground-fault protective device directly at the point where the branch-circuit wires are connected to the main. In such cases, the size of the branch-circuit wires between the feeder and the branch-circuit protective device must be the same as that of the mains, unless the length of these wires is not greater than 7.5 m (25 ft). When the length of the branch-circuit wires between the main and the branch-circuit protective device is not greater than 25 ft, Code rules allow the size of these wires to be such that they have an ampacity not less than one-third of the ampacity of the mains (see Fig. 7.188) if they are protected against physical damage.

Each motor and motor branch circuit and feeder of more than 600 V shall be protected by devices coordinated to interrupt automatically the motor-running overcurrent (overload) and fault currents in the motor, the motor-circuit wiring, and the motor controller.

1. *Motor-overload protection.* This protection can consist of one or more thermal protectors integral with the motor or external current-sensing devices, or both. The operation of the overload interrupting device must simultaneously disconnect all ungrounded conductors and should not automatically reset so as to restart the motor after reset unless such automatic restarting cannot be dangerous. The rating of the controller and disconnect switch must be coordinated with the trip current of the overload device.
2. *Fault-current protection.* Protection against fault currents can be obtained by one of the following means:
 - a. A circuit breaker of suitable type and rating so arranged that it can be serviced without hazard. It must simultaneously disconnect all ungrounded conductors and be able to sense the fault current by integral or external sensing elements.
 - b. Fuses of a suitable type and rating in each ungrounded conductor. Fuses shall be used with suitable disconnecting means, or they shall be of a type that can also serve as the disconnecting means. They shall be so arranged that they cannot be serviced while they are energized.

Differential protection can be employed to provide the protection for both items 1 and 2. A differential protective system is a combination of two or more sets of current transformers and a relay or relays energized from their interconnected secondaries.

The primaries of the current transformers are connected on both sides of the equipment to be protected, both ends of the motor phase windings being brought out for this purpose. All the apparatus and circuits included between the sets of current transformer primaries constitute the protected zone. The current transformer secondaries and the relay elements are so interconnected that the relay elements respond only to a predetermined difference between the currents entering and leaving the protected zone. When actuated, the relay or relays serve to trip the branch-circuit breaker, thus disconnecting the motor, the control apparatus in the motor circuit, and the branch-circuit conductors from the source of power and, in the case of a synchronous motor, deenergizing its field circuit.

386. Branch-circuit switches. National Electrical Code rules do not require a switch to be located on the line side of the short-circuit and ground-fault protective device, as at S_B in Fig. 7.187, unless no switch is located as at S_M in Fig. 7.187, I. When no switch

is located at S_M , a switch must be located at S_B to serve as a motor switch (see Sec. 383). If a circuit breaker is employed for branch-circuit short-circuit and ground-fault protection, it will serve as both a switch and a protective device. Although not required, a branch-circuit switch is very convenient, providing a means of disconnecting the entire branch circuit from the supply. It is recommended that a branch-circuit switch be provided on all circuits operating at a voltage greater than 230 V unless a safety-fuse type of panel is used (see Sec. 86, Div. 4). The branch-circuit switch must have fuse clips large enough to accommodate the branch-circuit fuses, as required by Sec. 385 and Table 43 of Div. 12.

If a branch-circuit switch is used, it must comply with the requirements for a motor switch. Refer to Sec. 383.

387. Size of wire for motor branch circuits. The wires of a branch circuit supplying a single continuous-duty motor must have an ampacity of at least 125 percent of the full-load rated current of the motor. The size of the wires of a motor branch circuit supplying a single motor in short-time-duty service may be different from those for a continuous-duty motor. In most cases, the ampacity of the wires need not be greater than the percentages of the full-load current of the motor given in Table 12 of Div. 12.

The wires between the slip rings and the controller of a wound-rotor induction motor must have an ampacity of at least 125 percent of the full-load secondary current of the motor for continuous-duty motors. For other than continuous-duty motors, the ampacity of the wires must be not less than the percentages of full-load secondary currents as given in Table 12 of Div. 12. If the secondary resistor is separate from the controller, the wires between the secondary controller and the resistance of a wound-rotor induction motor must have an ampacity which is not less than the percentages of the full-load secondary current of the motor given in Table 13 of Div. 12.

The wires of a branch circuit supplying several motors but no other equipment except that directly associated with the motors must have an ampacity of not less than 125 percent of the full-load current rating of the largest motor (highest full-load current rating) plus the sum of the full-load current ratings of the rest of the motors. The more usual applications of multimotor arrangements involve motor feeders supplying multiple branch-circuits. These wires are sized as covered in Sec. 54 of Div. 3 and Sec. 389.

For the size of branch circuit tap conductors, refer to Secs. 377 and 378.

388. Remote-control circuits. Control circuits shall be so arranged that they will be disconnected from all sources of supply when the disconnecting means is in the open position. The disconnecting means is permitted to consist of two separate devices, one of which disconnects the motor and the controller from the source or sources of power supply for the motor, and the other the control circuit from its power supply. Where separate devices are used, they shall be located immediately adjacent to one another, although the National Electrical Code provides exceptions to this rule if more than 12 motor control-circuit conductors must be disconnected and it would be unsafe to open control-circuit conductors because of the nature of the controlled machine or process.

If a transformer or other device is used to obtain a reduced voltage for the control circuit and is located in the controller, such a transformer or other device shall be connected to the load side of the disconnecting means for the control circuit.

The conductors of these control circuits must be protected against overcurrent at their ampacities (7 A for 18 AWG, 10 A for 16 AWG).

1. If the conductors do not extend outside the control-equipment enclosure, they are permitted to be protected by the motor branch-circuit short-circuit and ground-fault protective

device, provided this device is rated at not more than 400 percent of the 60°C ampacity given in Table 19 of Div. 12 of the control-circuit conductors 8 AWG and larger, and at not more than 25 A for 18 AWG, 40 A for 16 AWG, 100A for 14 AWG, 120A for 12 AWG, and 160A for 10 AWG.

2. Conductors which extend outside the control-equipment enclosure and are No. 14 or larger are permitted to be protected by the motor branch-circuit short-circuit and ground-fault protective device if this device is rated at not more than 300 percent of the 60°C ampacity given in Table 18 of Div. 12 of the control-circuit conductors, with an allowance for 45A protection for 14 AWG, 60A for 12 AWG, and 90A for 10 AWG.
3. Except as indicated in item 4, when the conductors are in the secondary of a single-phase control-circuit transformer having only a two-wire (single-voltage) secondary, they are permitted to be protected in the primary (supply) side of the transformer by protective devices suitable to protect the transformer if the primary protection does not exceed the ampacity of the secondary conductors or the values given in items 1 and 2 when the value of primary protection is multiplied by the primary-to-secondary transformer ratio.
4. Where the conductors are in the secondary of a control transformer and the conditions comply with the requirements of Article 725 of the NEC for a Class 1 power-limited circuit or a Class 2 or Class 3 remote-control circuit, the protection provisions set forth in Article 725 supersede these requirements.
5. If the opening of the control circuit would create a hazard, as, for example, in the control circuit of fire pump motors, etc., the branch-circuit short-circuit and ground-fault protective device for the motor is sufficient protection and an additional device need not be installed.

389. Size of motor feeder or mains. For the determination of the size of motor mains or feeders, refer to Div. 3, particularly Sec. 54. In addition to that information, note that duty cycle also plays a role in the calculations. If a motor is operating under other than continuous duty cycle, as covered in Table 12 of Div. 12, the largest motor used to enter the initial calculation may not be the largest motor on the job. For example, suppose a feeder will supply both a 15 hp and a 10 hp 460-V continuous-rated motors. The rating of the 15 hp motor (21 A) has a full-load current from Div. 12, Table 10 of 14 A, and this would usually be the largest motor for calculation purposes and it would immediately have the 125 percent factor added, bringing its contribution to the feeder load to 26 A. However, if the smaller motor were used for varying duty it must be taken at 200 percent, or 28 A, and it becomes the largest motor for calculation purposes. Add the other motors at full load ratings from the tables, as modified for duty-cycle service accordingly.

390. Overload protection of motor feeders or mains. The size of the protective equipment for motor feeders or mains is determined from the so-called starting current of the circuit, as explained in Sec. 54 of Div. 3. Fuses or circuit breakers can be used for the overload protection of motor feeders or mains. The feeder short-circuit and ground-fault protection calculation starts with the largest branch-circuit protective device setting determined under Sec. 373, and then adds the full-load currents of the other motor branch circuits determined by motor horsepower from Tables 7 to 10 of Div. 12. However, if any motor short-circuit protectors or instantaneous-trip circuit breakers are being used, for calculation purposes they must be replaced using the same type of protective device as is being

used for feeder protection. This assures that the feeder protection is not oversized. If there are other (non-motor) loads, they are added to the total calculation.

If the feeder consists of the busbars in a motor control center, then the overall load represented by all the connected circuits must not exceed the rating of the motor control center, but the overcurrent protection for the motor control center must not exceed the rating of the common power bus, even if a conventional motor feeder calculation would otherwise allow a higher rating or setting of the overcurrent device.

391. Motor-wiring data for locked-rotor current and standard switch sizes are given in Tables 44 to 46 of Div. 12.

392. Protection of live parts. The National Electrical Code requires that live parts shall be protected in a manner judged adequate to the hazard involved. The rules state:

1. *Where required.* Exposed live parts of motor and controllers operating at 50 V or more between terminals, except for stationary motors having commutators, collectors, and brush rigging located inside motor end brackets and not connected conductively to supply circuits operating at more than 150 V to ground, shall be guarded against accidental contact by enclosure, or by location as follows:
 - a. By installation in a room or enclosure accessible only to qualified persons
 - b. By installation on a suitable balcony, gallery, or platform so elevated and arranged as to exclude unqualified persons
 - c. By elevation 2.5 m (8 ft) or more above the floor
2. *Guards for attendants.* If the live parts of motors or controllers operating at more than 150 V to ground are guarded against accidental contact only by location as specified in Par. 1 and if adjustment or other attendance may be necessary during the operation of the apparatus, suitable insulating mats or platforms shall be provided so that the attendant cannot readily touch live parts without standing on the mats or platforms.

CONTROL CIRCUITS

393. Electric control circuits constitute a broad subject, and the reader is urged to refer to special books devoted to this important phase of motor circuitry. Such textbooks as the *Motor Control Electronics Handbook* by Richard Valentine, published by McGraw-Hill, provide an excellent insight on how to understand, select, and design control circuits.

394. Arrangement of control wiring in grounded circuits. It is a requirement of the National Electrical Code that if one side of a control circuit is *intentionally* grounded, the control circuit shall be so arranged that an accidental ground in the control circuit remote from the motor controller will not *start* the motor nor bypass manually operated shutdown devices or automatic safety shutdown devices. Figure 7.192 shows two methods that satisfy this code rule. The elementary wiring diagram at the top of Fig. 7.192 shows the arrangement of a START-STOP pushbutton connected to the holding coil of a magnetic starter. Note that all control devices are connected to the *L1* side of coil *C* and that the other side is connected to the grounded circuit conductor *L2*. Note that this rule only applies to control circuits that leave to controller enclosure. It is still permitted (and usually done) to connect

* L1 & L2 from end-grounded delta supply or;

* L1 & L2 from control trans.
where secondary L2 is grounded

When one side of the control circuit is grounded circuit shall be so arranged that an accidental gr. in remote-control devices will not start motor. Drawing shows acceptable arrangements

FIGURE 7.192 Arrangement of control wiring in grounded circuits. [Electrical Construction and Maintenance]

the running overload relays on the grounded side of the contactor. Referring to the upper portion of Fig. 7.192, the three normally closed overload relays could be connected to the right of the contactor holding coil unless the overloads were in a separate enclosure.

The L2 conductor could be the grounded conductor of an end-grounded three-phase delta supply or the grounded conductor of the secondary winding of a control transformer.

395. Control circuits from ungrounded systems. It is significant that the Code rule described in Sec. 394 applies only to grounded-type control circuits and is concerned only with preventing a motor from being accidentally started. In ungrounded three-phase 230- or 460-V three-wire systems, there is always a possibility of one or more accidental grounds occurring in a control circuit connected to such systems. If *two* grounds occur in the same control-circuit conductor at certain critical points, a motor could accidentally start, or if a second ground develops after a motor has been started, it is possible that the motor will not stop after the STOP button is pressed. There are two ways to prevent this. The first method is illustrated in Fig. 7.192, in which a control transformer provides a grounded secondary and the control circuit is wired as shown.

The second method applies when the control circuit is taken directly from an ungrounded supply. The arrangement illustrated in Fig. 7.193 utilizes double-pole START and STOP buttons wired with one pole of each button on opposite sides of coil S. With this arrangement one or more accidental ground will not start the motor; nor will a ground prevent the motor from being stopped after the motor is in operation and a second ground occurs.

FIGURE 7.193 Ideal control circuit when the supply system or the control circuit is ungrounded. [*Electrical Construction and Maintenance*]

The arrangement shown in Fig. 7.193 is ideal when long control circuits are used because pressing the STOP button opens both lines to coil *S* and line-to-line capacitive coupling will not keep the coil energized, as it occasionally has done when standard START-STOP control circuits were used.

INDUSTRIAL CONTROL PANELS

396. New rules in the National Electrical Code **for industrial control panels** may have a significant impact on how these panels are assembled, and by whom. The NEC in Article 409 now defines all control assemblies of *two or more components* as being within the scope of these rules. To provide some context, all combination starters, with a disconnect switch and fuse block or a circuit breaker and contactor with running overload protection are included. See Figs. 7.161, 7.162, and 7.163 as but some of many examples. Most of the article provisions duplicate other NEC rules and are covered elsewhere in this division. However NEC 409.110 has marking requirements that affect anyone who installs or significantly modifies these components in the field. The short-circuit current rating developed as part of this process will govern whether the industrial control panel is allowed to be installed based on the fault current that is available at its line terminals. (See Sec. 48 in Div. 4.) Specifically, the label must include the following information:

- The name of the manufacturer, or a trademark, or other descriptive marking by which the organization responsible for the product can be identified
- The supply voltage, number of phases, frequency, and full-load current for each incoming supply circuit
- The short-circuit current rating of the panel based on one of the following:
 1. Short-circuit current rating of a listed and labeled assembly
 2. Short-circuit current rating established utilizing an approved method. (An explanatory note follows, calling out *UL 508A, Suppl. SB* as an example of an approved method.)

The short-circuit current rating marking *is not required* on an industrial control panel that contains only control circuit components and no power circuit components. This exception exists for the simple reason that *short-circuit current ratings are not assigned to components that are not in the power circuit*, and therefore if a panel is assembled with no power circuits entering, there would be no basis for determining such a rating. Such control panel would still be an industrial control panel, and must otherwise meet all the

marking requirements, but the short-circuit current rating would not be included in those markings.

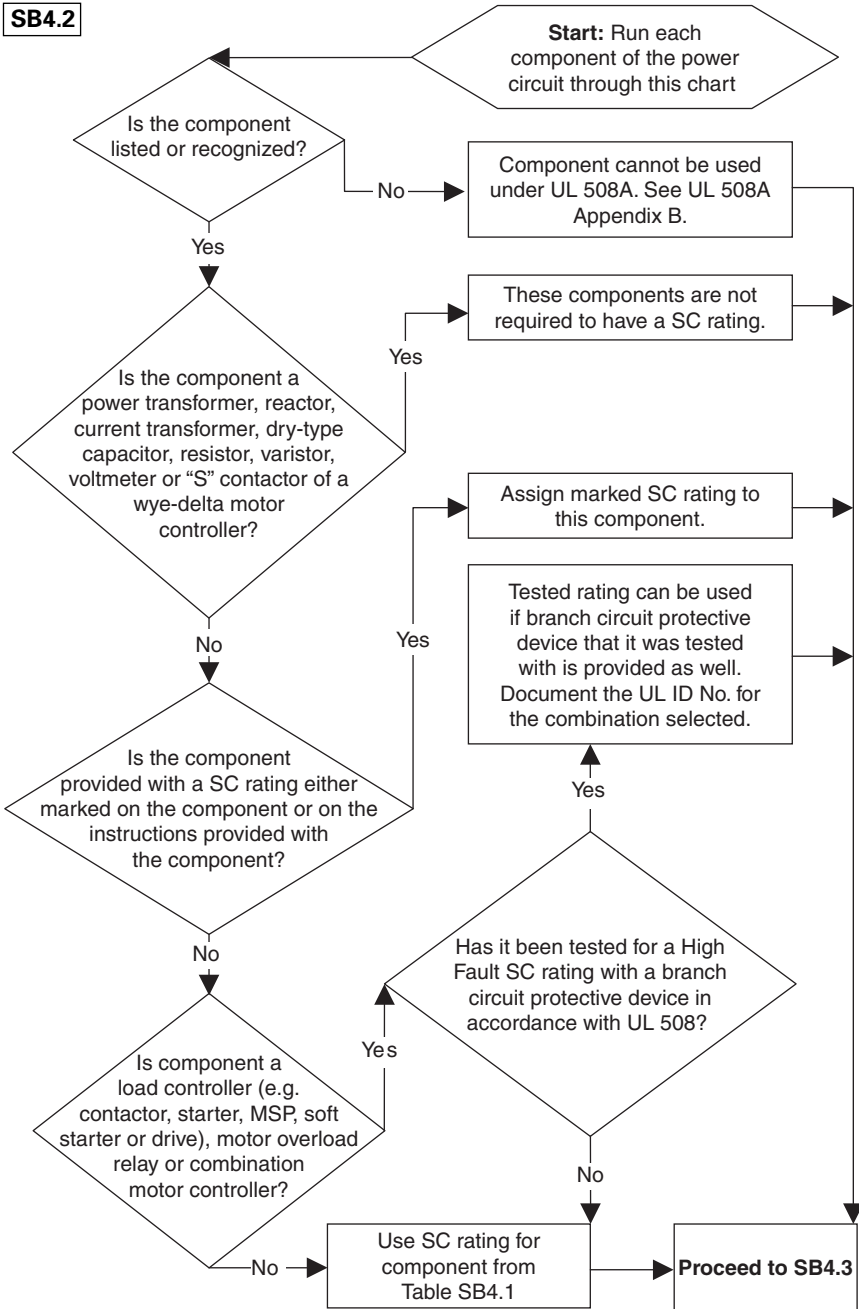

- If the panel will be used as service equipment, it must be evaluated and marked accordingly.
- The panel must include an electrical wiring diagram or the identification number of a separate such diagram or a designation referenced in a separate wiring diagram.
- The enclosure type number (Sec. 253) must be marked on the enclosure.

Most of these requirements are easily met, but the short-circuit current rating provisions are not.

397. Labeling must show the *short-circuit current rating*. If the product is installed as it was shipped from a major manufacturer, or by a UL listed panel assembly shop, this marking will be supplied already. When the assembly is field wired by electricians, this rating must be determined using an “approved method.” The NEC cites *UL 508A, Suppl. SB* as the example of note. This now crucial publication for this work exempts some components such as voltmeters, reactors, and power transformers from short-circuit ratings, and describes how to apply established ratings for other components. It needs to be emphasized, however, that what is included is neither obvious nor intuitive. For example, some terminal blocks are considered by their manufacturers to be control system components and *have not* been tested under high-fault exposures, but others that have a seemingly similar function were evaluated under a different product standard and *have been* so tested. On the weak-link-in-the-chain principle, using the former component instead of the latter would likely result in a dramatic (many tens of thousands of amperes) reduction in the final rating for the assembly. Review the flow chart following for a better idea as to what is involved in determining this rating. The object is to assure that all power components that could be subjected to fault current will not result in catastrophic failures.

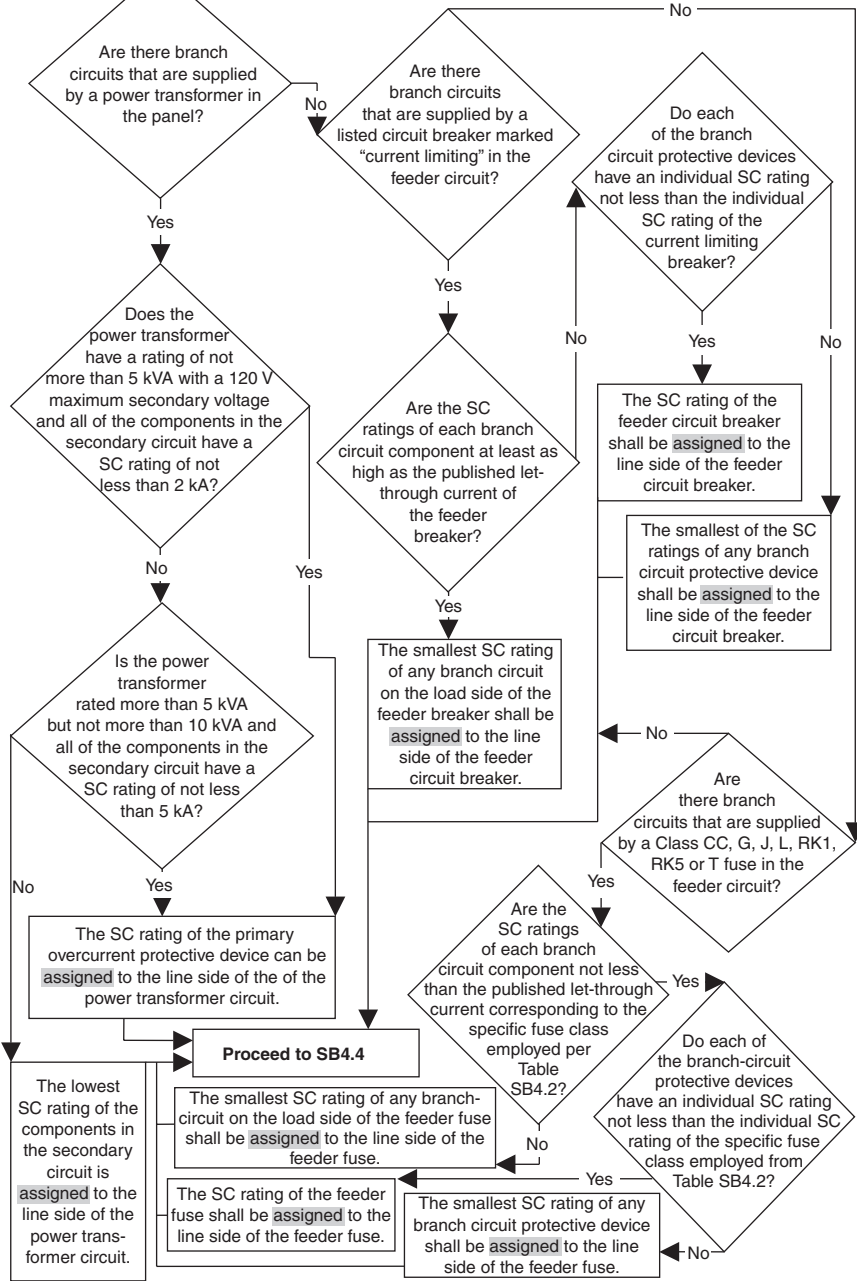

398. The following flowcharts provide an overview as to how short-circuit current ratings are to be determined for industrial control panels, if they are assembled in the field and have no rating. Begin by making a list of all power circuit components and determine their individual short-circuit current ratings using the first flowchart (SB4.2). Then look to see if feeder level protection within the panel (if it is to be provided) mitigates the potential fault current exposure of the branch circuit components by using the second flowchart (SB4.3). Then apply the third flowchart (SB4.4) to arrive at the final rating that will go into the marking. At all times, refer to the current *UL 508A Suppl. SB* for full details. Note that most manufacturers of motor control components publish, in larger formats than in this book, their own flowcharts. The flowcharts that follow have been rearranged to accommodate a smaller page size and still be legible, but the technical content has not changed.

SB4.4

AIR-CONDITIONING AND REFRIGERATING EQUIPMENT

399. The rules in the National Electrical Code for air-conditioning and refrigerating equipment incorporating a hermetic refrigerant motor-compressor and for the circuits supplying such equipment are somewhat different from the rules applying to conventional motors and motor circuits because of the special nature of a hermetic refrigerant motor-compressor. The following sections describe only those rules that differ from those described in Secs. 370 through 395. If a situation is not described in the following sections, the rules of Secs. 370 through 395 apply, except as noted in Sec. 397.

Types of air-conditioning and refrigerating equipment which do not incorporate a hermetic refrigerant motor-compressor and circuits which do not supply such a motor-compressor are not to be installed under the rules given in Secs. 399 through 407. Examples of such equipment are devices that employ a refrigeration compressor driven by a conventional motor, furnaces with air-conditioning evaporator coils installed, fan-coil units, remote forced-air-cooled condensers, and remote commercial refrigerators.

The National Electrical Code defines a hermetic refrigerant motor-compressor as follows:

Hermetic refrigerant motor-compressor. A combination consisting of a compressor and motor, both of which are enclosed in the same housing, with no external shaft or shaft seals, the motor operating in the refrigerant.

FIGURE 7.194 Cutaway of a hermetic motor-compressor. [Tecumseh Products Co.]

Because there is no motor external shaft (see Fig. 7.194), the hermetic refrigerant motor-compressor does not have a horsepower rating. The motor is rated instead by the rated-load current and the locked-rotor current. The National Electrical Code defines the rated-load current as follows:

Rated-load current. The rated-load current for a hermetic refrigerant motor-compressor is the current resulting when the motor-compressor is operated at the rated load, rated voltage, and rated frequency of the equipment it serves.

The rated-load current is established in the equipment driven by the motor-compressor, rather than being the maximum current for a given motor temperature rise, because the motor winding is cooled by the refrigerant and because the degree of cooling depends on the characteristics of the refrigerant used, its flow rate, temperature, density, etc., and these factors are determined by the equipment. Therefore, the manufacturer of the motor-compressor, not knowing all the equipment in

which the motor-compressor will be used, selects the motor-overload protection system to protect the motor and motor-circuit components and wiring at the maximum-load conditions for which the motor-compressor is intended. If the motor-compressor is used in an application in which it is effectively larger than needed for the rating conditions of the equipment, the rated-load current for the motor-compressor marked on the equipment nameplate may be significantly less than its maximum, and the motor-compressor-overload

protection system may not protect the motor-circuit wiring, motor controller, and motor-circuit switches against overheating due to overloads.

The National Electrical Code establishes limiting relationships between the maximum continuous current permitted by the motor-compressor-overload protection system and the ampacity of the motor-circuit wiring, the rating of the motor controller, motor-circuit switches, and motor-circuit short-circuit and ground-fault protective devices (see Sec. 399). When this limiting relationship is exceeded for the marked rated-load current of the motor-compressor in the equipment, an additional equipment-rating current must be marked by the equipment manufacturer. This is designated *branch-circuit selection current* and is defined in the National Electrical Code as follows:

Branch-circuit selection current. Branch-circuit selection current is the value in amperes to be used instead of the rated-load current in determining the ratings of motor branch-circuit conductors, disconnecting means, controllers, and branch-circuit short-circuit and ground-fault protective devices wherever the running overload protective device permits a sustained current greater than the specified percentage of the rated-load current. The value of branch circuit selection current will always be equal to or greater than the marked rated-load current.

A significant portion of air-conditioning and refrigerating equipment incorporating a hermetic refrigerant motor-compressor also incorporates conventional motors, such as fan and/or water-pump motors, and/or electric resistance heaters on the same circuit. The National Electrical Code requires such equipment to be marked with (1) the minimum supply-circuit conductor ampacity (usually shortened to "Min. Circuit Amp.") and (2) the maximum rating of the branch-circuit short-circuit and ground-fault protective device. The ratings marked are to be based on the maximum concurrent loading condition, since all motors and other loads may not be operating at the same time. For example, on an air conditioner with electric resistance space heaters, the motor-compressor does not usually operate at the same time as the heaters, as it does on a heat pump. The National Electrical Code requires that the supply wires have an ampacity at least as great as the marked minimum and that the branch-circuit short-circuit and ground-fault protective device rating not exceed the marked maximum rating. If the type of branch-circuit short-circuit and ground-fault protective device (fuse or circuit breaker) is marked, then that same type of protective device must be used. On the other hand, if the label refers to "maximum overcurrent protective device rating" or equivalent wording, then the installer may choose the type of protective device to use. When these minimum and maximum markings appear, the installer need not calculate the values required for the installation.

Since the marked motor-compressor rated-load current and branch-circuit selection current (if marked) and the marked minimum supply-circuit conductor ampacity and maximum rating of the branch-circuit short-circuit and ground-fault protective device vary somewhat from one make and model of equipment to another, even though the equipment may have the same cooling or heating capacity, the installer must know the marking on the particular equipment to be installed. This information is generally available in the equipment manufacturer's literature, so that the equipment itself need not be available before the supply circuit can be designed and partially installed. However, the equipment marking should be checked before the installation is completed. The National Electrical Code also requires that a short-circuit current-rating be developed for this equipment and that it be included on the nameplate. An exception exempts multimotor and combination-load equipment from this rating requirement, but only if it is used in one- and two-family dwellings, or if cord- and plug-connected equipment, or equipment on a branch circuit rated 60 A or less.

400. Ampacity and rating. For a hermetic refrigerant motor-compressor, the rated-load current marked on the nameplate of the equipment in which the motor-compressor is employed shall be used in determining the rating or ampacity of the disconnecting means,

the branch-circuit conductors, the controllers, the branch-circuit short-circuit and ground-fault protection, and the separate motor-overload protection. If no rated-load current is shown on the equipment nameplate, the rated-load current shown on the compressor nameplate shall be used.

Exception No. 1. Where so marked, the branch-circuit selection current shall be used instead of the rated-load current to determine the rating or ampacity of the disconnecting means, the branch-circuit conductors, the controller, and the branch-circuit short-circuit and ground-fault protection.

Exception No. 2. For cord- and plug-connected equipment the nameplate marking as explained under Par. 2 of Sec. 401.

401. Branch-circuit short-circuit and ground-fault protection. The rules of Sec. 399 generally apply except for the rating of the protective device. As noted in Sec. 399, for multimotor and combination-load air-conditioning and refrigerating equipment, the equipment nameplate is required by the National Electrical Code to specify the maximum rating of the supply-circuit short-circuit and ground-fault protective device. When this rating is marked, a calculation by the installer is not necessary, and the marked maximum rating cannot be exceeded.

- 1. Rating or Setting for an Individual Motor-Compressor.** The motor-compressor branch-circuit short-circuit and ground-fault protective device shall be capable of carrying the starting current of the motor. The required protection shall be considered as being obtained when this device has a rating or setting not exceeding 175 percent of the motor-compressor rated-load current or branch-circuit selection current, whichever is greater, provided that if the protection specified is not sufficient for the starting current of the motor, it shall be permitted to be increased but shall not exceed 225 percent of the motor rated-load current or branch-circuit selection current, whichever is greater. Note that these are not-to-exceed thresholds, and are therefore not subject to a round-up allowance. Hermetic compressor motors are designed to run somewhat overloaded in the conventional sense, because the refrigerant surrounds the motor, and therefore there is less room for error under fault conditions. For this reason, calculations are rounded down to the next lower standard size of overcurrent protective device, although they need not be reduced below 15 A.
- 2. Rating or Setting for Equipment.** The equipment branch-circuit short-circuit and ground-fault protective device shall be capable of carrying the starting current of the equipment. When the hermetic refrigerant motor-compressor is the only load on the circuit, the protection shall conform with Par. 1 above. When the equipment incorporates more than one hermetic refrigerant motor-compressor or a hermetic refrigerant motor-compressor and other motors or other loads, the equipment protection shall conform with Sec. 374 and the following:
 - a.** Where a hermetic refrigerant motor-compressor is the largest load connected to the circuit, the rating or setting of the protective device shall not exceed the value specified in Par. 1 above for the largest motor-compressor plus the sum of the rated-load current or branch-circuit selection current, whichever is greater, of the other motor-compressor or motor-compressors and the ratings of the other loads supplied.
 - b.** Where a hermetic refrigerant motor-compressor is not the largest load connected to the circuit, the rating or setting of the protective device shall not exceed a value equal to the sum of the rated-load current or branch-circuit selection current, whichever is greater, the rating or ratings for the motor-compressor or motor-compressors, and the value specified in Par. 3d of Sec. 374 for other loads supplied.

The following are exceptions to Par. 2 given earlier.

1. Equipment which will start and operate on a 15- or 20-A, 120-V or a 5-A, 208- or 240-V single-phase branch circuit shall be considered as protected by the 15-A or 20-A over-current device protecting the branch circuit, but if the maximum circuit-protective-device rating marked on the equipment is less than these values, the circuit protective device shall not exceed the value marked on the equipment nameplate.
2. The nameplate marking of cord- or plug-connected equipment rated not greater than 250 V, single-phase, such as some room air conditioners (see Sec. 407), household refrigerators and freezers, drinking-water coolers, and beverage dispensers, shall be used in determining the branch-circuit requirements, and each unit shall be considered a single motor unless the nameplate is marked otherwise.

402. Overload protection. Overload-protection provisions in the National Electrical Code for hermetic refrigerant motor-compressors and equipment employing such motor-compressors have the same purpose as overload protection for conventional motor circuits, but there are some significant differences in the rules. Some reasons for this variation are described in Sec. 396. The device that protects the refrigerant-cooled motor against overheating must do so while the motor is being cooled by the refrigerant under running conditions and also under locked-motor conditions without such refrigerant cooling. The conditions necessary to do this and also to protect the other components and wiring in the motor-compressor branch circuit commonly result in the need for both temperature- and current-sensing devices, or *system protection*. The National Electrical Code therefore treats protection of the motor-compressor and protection of the motor-compressor control apparatus and branch-circuit conductors separately, as described in Pars. 1 and 2 below.

1. **Protection of Motor-Compressor.** One of the following means shall be used:
 - a. A separate overload relay which is responsive to the motor-compressor current. This device shall be selected to trip at not more than 140 percent of the motor-compressor rated-load current.
 - b. A thermal protector integral with the motor-compressor, approved for use with the motor-compressor which it protects, on the basis that it will prevent dangerous overheating of the motor-compressor due to overload and failure to start. If the current-interrupting device is separate from the motor-compressor and if its control circuit is operated by a protective device integral with the motor-compressor, it shall be so arranged that the opening of the control circuit will result in an interruption of current to the motor-compressor.
 - c. A fuse or inverse-time circuit breaker responsive to the motor current, which shall also be permitted to serve as the branch-circuit short-circuit and ground-fault protective device. This device shall be rated at not more than 125 percent of the motor-compressor rated-load current. It shall have sufficient time delay to permit the motor-compressor to start and accelerate its load.
 - d. A protective system, furnished or specified and approved for use with the motor-compressor which it protects on the basis that it will prevent dangerous overheating of the motor-compressor due to overload and failure to start. If the current-interrupting device is separate from the motor-compressor and if its control circuit is operated by a protective device which is not integral with the current-interrupting device, it shall be so arranged that the opening of the control circuit will result in an interruption of current to the motor-compressor.
2. **Protection of Motor-Compressor Control Apparatus and Branch-Circuit Conductors.** Except for motor-compressors and equipment on 15- or 20-A branch circuits as

described in Par. 3 below, one of the following means shall be used (the device used may be the same device or system described in Par. 1):

- a.* An overload relay selected in accordance with Par. 1
 - b.* A thermal protector which is applied in accordance with Par. 1 and which will not permit a continuous current in excess of 156 percent of the marked rated-load current or branch-circuit selection current
 - c.* A fuse of inverse-time circuit breaker selected in accordance with Par. 1
 - d.* A protective system which is in accordance with Par. 1 and which will not permit a continuous current in excess of 156 percent of the marked rated-load current or branch-circuit selection current
3. **Motor-Compressors and Equipment on 15- or 20-A Branch Circuits.** Overload protection for motor-compressors and equipment used on 15- or 20-A or 15-A, 208- or 240-V single-phase branch circuits shall be permitted as indicated in *a* and *b* below.
- a.* The motor-compressor shall be provided with overload protection selected as specified in Par. 1. Both the controller and the motor-overload protective device shall be approved for installation with the short-circuit and ground-fault protective device for the branch circuit to which the equipment is connected.
 - b.* The short-circuit and ground-fault protective device protecting the branch circuit shall have sufficient time delay to permit the motor-compressor and other motors to start and accelerate their loads.
 - c.* For cord- and attachment-plug-connected equipment, the rating of the attachment plug and receptacle shall not exceed 20 A at 125 V or 15 A at 250 V.

403. Disconnecting means. The rules of Secs. 383 and 386 generally apply, but the method of determining the required rating of the switch differs, and a disconnecting means must be located within sight from and be readily accessible from the air-conditioning or refrigerating equipment.

1. **Single Motor-Compressor.** A disconnecting means serving a hermetic refrigerant motor-compressor shall be selected on the basis of the nameplate rated-load current or branch-circuit selection current, whichever is greater, and locked-rotor current, respectively, of the motor-compressor as follows:
 - a.* The ampere rating shall be at least 115 percent of the nameplate rated-load current or branch-circuit selection current, whichever is greater, except a listed nonfused motor circuit switch having a horsepower rating not less than the equivalent horsepower determined in accordance with *b* below shall be permitted to have an ampere rating less than 115 percent of the specified current.
 - b.* To determine the equivalent horsepower in complying with the requirements of Sec. 383, select the horsepower rating from Tables 7 to 10 of Div. 12 corresponding to the rated-load current or branch-circuit selection current, whichever is greater, and also the horsepower rating from Tables 44 and 45 of Div. 12 corresponding to the locked-rotor current. If the nameplate rated-load current or the branch-circuit selection current and locked-rotor current do not correspond to the currents shown in Tables 7 to 10 or 44 and 45 of Div. 12, select the horsepower rating corresponding to the next higher value. If different horsepower ratings are obtained when applying these tables, select a horsepower rating at least equal to the larger of the values obtained.
2. **Multimotor and Combination Loads.** When one or more hermetic refrigerant motor-compressors are used together or are used in combination with other motors and/or loads such as resistance heaters and when the combined load may be simultaneous on a single disconnecting means, the rating for the combined load shall be determined as follows.

- a. Determine the horsepower rating of the disconnecting means from the summation of all currents, including resistance loads, at the rated-load condition and also at the locked-rotor condition. Consider the combined rated-load current and the combined locked-rotor current so obtained as a single motor for the purpose of this requirement as follows:
- (1) Select the full-load current equivalent to the horsepower rating of each motor, other than a hermetic refrigerant motor-compressor, from Tables 7 to 10 of Div. 12. Add these full-load currents to the motor-compressor rated-load current or currents or the branch-circuit selection current or currents, whichever is greater, and to the rating in amperes of other loads to obtain an equivalent full-load current for the combined load.
 - (2) Select the locked-rotor current equivalent to the horsepower rating of each motor, other than a hermetic refrigerant motor-compressor locked-rotor current or currents and to the rating in amperes of other loads to obtain an equivalent locked-rotor current for the combined load. When two or more motors and/or other loads cannot be started simultaneously, select appropriate combinations of locked-rotor and rated-load current or branch-circuit selection current, whichever is greater, to determine the equivalent locked-rotor current for the simultaneous combined load.

Exceptions to (1) and (2) are:

1. The rated full-load current for small shaded-pole and permanent split-capacitor fan and blower motors provided as part of multimotor equipment may be used in the calculation instead of the motor horsepower rating.
2. For small motor-compressors not having the locked-rotor current marked on the nameplate or for small motors not covered by Tables 7 to 10 of Div. 12, assume the locked-rotor current to be 6 times the rated-load current.
3. When the rated-load or locked-rotor current as determined above would indicate a disconnecting means rated in excess of 100 hp, the provisions of Par. 4 of Sec. 383 would apply.
4. For cord-connected equipment such as room air conditioners, household refrigerators and freezers, drinking-water coolers, and beverage dispensers, a separable connector or an attachment plug and receptacle are permitted to serve as the disconnecting means.
5. When part of the concurrent load is a resistance load and the disconnecting means is a switch rated in horsepower and amperes, the horsepower rating of the switch shall be not less than the combined load to the motor-compressor or motor-compressors and other motor or motors at the locked-rotor condition, and the ampere rating is permitted to be not less than this locked-rotor load plus the resistance load. This alternative calculation may permit a smaller switch than would otherwise be required, especially when the load of the resistance heaters is large compared with the motor load.

The ampere rating of the disconnecting means must be at least 115 percent of the summation of all currents at the rated-load condition determined in accordance with Par. 2a(1) above.

404. Group switching. The rules of Sec. 384 do not apply to an air-conditioning or refrigeration system incorporating a hermetic refrigerant motor-compressor. Such equipment is considered a single machine and is permitted to have a single switch for a group of motors even if the motors are remote from each other.

405. Controllers. The rules for motor controllers for hermetic refrigerant motor-compressors are generally the same as described in Sec. 379, except for the method of determining the rating.

A motor-compressor controller shall have both a continuous-duty full-load current rating and a locked-rotor current rating not less than the nameplate rated-load current or branch-circuit selection current, whichever is greater, and locked-rotor current, respectively, of the motor-compressor. If the motor controller is rated in horsepower but is without one or both of the foregoing current ratings, determine equivalent currents as follows. Use Tables 7 to 10 of Div. 12 to determine the equivalent full-load current rating and Tables 44 and 45 of Div. 12 to determine the equivalent locked-rotor current rating.

A controller serving more than one motor-compressor or a motor-compressor and other loads shall have a continuous-duty full-load current rating and a locked-rotor current rating not less than the combined load as determined in accordance with Par. 2 of Sec. 401.

406. Size of wire for branch circuits. The rules given in Sec. 387 generally apply to branch circuits supplying hermetic refrigerant motor-compressors that are permanently connected, except that the motor-compressor rating is established as described in Sec. 397. As noted in Sec. 396, for multimotor and combination-load air-conditioning and refrigerating equipment, the equipment nameplate is required by the National Electrical Code to specify the minimum supply-circuit conductor ampacity in accordance with the rules in the Code. When this rating is marked, a calculation by the installer is not necessary. For wye-start delta-run applications, the wires running to each winding must have an ampacity not less than 72 percent of the rated full-load current or 72 percent of the branch-circuit selection current, whichever is greater.

407. Provisions for room air conditioners. The National Electrical Code has special provisions for room air conditioners which are (1) rated not over 250 V ac, single-phase, and (2) which are cord- and attachment-plug-connected. The Code defines for this purpose a room air conditioner (with or without provisions for heating) as an appliance of the air-cooled window, console, or in-wall type which is installed in the conditioned room and which incorporates a hermetic refrigerant motor-compressor.

1. Room air conditioners shall be grounded.
2. A room air conditioner shall be considered a single motor unit in determining its branch-circuit requirements when all the following conditions are met:
 - a. It is cord- and attachment-plug-connected.
 - b. Its rating is not more than 40 A and 250 V, single-phase.
 - c. Total rated-load current is shown on the room-air-conditioner nameplate rather than individual motor currents.
 - d. The rating of the branch-circuit short-circuit and ground-fault protective device does not exceed the ampacity of the branch-circuit conductors or the rating of the receptacle, whichever is less.
3. The total marked rating of a cord- and attachment-plug-connected room air conditioner shall not exceed 80 percent of the rating of a branch circuit where no other loads are supplied.
4. The total marked rating of a cord- and attachment-plug-connected room air conditioner shall not exceed 50 percent of the rating of a branch circuit when lighting units or other appliances are also supplied. Where the circuitry is interlocked to prevent simultaneous operation of the room air conditioner and other outlets are supplied, a cord-and attachment plug-connected room air conditioner shall not exceed 80 percent of the branch circuit rating.

5. An attachment plug and receptacle shall be permitted to serve as the disconnecting means for a single-phase room air conditioner rated 250 V or less if (a) the manual controls on the room air conditioner are readily accessible and are located within 1.8 m (6 ft) of the floor or (b) an approved manually operable switch is installed in the readily accessible location within sight from the room air conditioner.

ENGINE- AND GAS-TURBINE GENERATORS

408. Engine-driven generators (diesel, gasoline, or gas) are the most economical and practical source of *standby power* in a wide range of applications. They are sized from a few hundred watts to several hundred kilowatts. Control is obtained manually, remotely, or automatically. Units are designed as either stationary or mobile power stations. Cooling is obtained by natural-convection fan-forced air or by circulating water.

Generator engines are generally four-cycle units having one to six cylinders, depending on size and capacity. In larger sets, ignition current is supplied by starting batteries. A typical arrangement is shown in Fig. 7.195.

FIGURE 7.195 Typical installation of an engine-generator for a standby or emergency supply system. [*Electrical Construction and Maintenance*]

409. Location. In most instances, the power plant should be close to the normal electric service, in a place where it is warm enough to start easily. Locations where ambient temperatures may be unusually high should be avoided because inefficient cooling may result. On the other hand, in locations where temperatures fall below 50°F (10°C), special accessories, such as an electric water jacket or a manifold heater, may be needed to ensure dependable automatic starts.

410. Mounting. Smaller units, of 10 kW and less, should be installed on a concrete foundation equipped with anchor bolts. In some cases, steel-beam sections will make a satisfactory base. Such a base raises the plant off the floor for convenience in servicing and lessens the chance of accidental damage from loose objects, seepage, etc. For larger plants that are equipped with steel skids, a separate foundation may not be required.

Always allow at least 2 ft (0.6 m) of unobstructed space around the power plant on all sides. This permits room for servicing the unit. If this space is not available, position the plant so that the carburetor, distributor, governor, fuel pump, oil fill, etc., are easily accessible.

411. Battery mounting. Batteries should be mounted in a clean, dry location free from falling dirt or dust, and they should be installed on a wood base rather than on a concrete floor. Allow room for easy maintenance of the battery.

412. Exhaust piping. Exhaust pipes should be of wrought iron, cast iron, or steel. Because exhaust fumes are dangerous, care should be taken to prevent leaks in the exhaust system. The exhaust pipe should terminate outside away from doors, windows, or other openings.

413. Cooling. Ventilation openings must always be provided and located so that cool air can be brought in and forced through the engine-cooling system and directly out without recirculating.

Other important installation considerations include fuel-line and fuel-tank installation, muffler requirements, heaters, battery chargers, and automatic controls.

414. Automatic transfer switches are being used increasingly wherever continuity of light and power is needed to preserve life and to prevent accidents, theft, panic, or loss of goodwill and revenue. An automatic transfer switch is an emergency device that automatically transfers electrical loads from a normal source, usually a utility, to an emergency source, usually an engine-generator set, when the normal source fails or its voltage is substantially reduced. The transfer switch automatically retransfers the load back to the normal source when it is restored. (See Fig. 7.205.)

Construction Considerations. The automatic transfer switch consists of two major components, namely, an electrically operated, double-throw transfer switch and a control panel. The control panel provides the necessary voltage sensing, time delays, and signals for operating the transfer switch.

Automatic transfer switches of double-throw construction are used primarily for emergency and standby power generation systems rated 600 V and less. These transfer switches do not normally incorporate overcurrent protection and are designed and applied in accordance with the National Electrical Code, particularly Articles 517, 700, 701, and 702. They are available in ratings from 30 to 4000 A. For reliability, most automatic transfer switches rated above 100 A are mechanically held and electrically operated from the power source to which the load is to be transferred. To provide maximum versatility and further reliability, today's control panels utilize solid-state sensing and timing circuitry. Transfer switches used for emergency or legally-required standby circuits within the scopes of Articles 700 and 701 of the National Electrical Code must be electrically operated and mechanically held regardless of size, and they must be listed for their application.

An automatic transfer switch is usually located in the main or secondary distribution system which feeds the branch circuits. Because of its location in the system, the abilities which must be designed into the transfer switch are unique and extensive as compared with the design requirements for other electrical devices. For example, special consideration should be given to the following characteristics of an automatic transfer switch: (1) its ability to close against high inrush currents, (2) its ability to carry full-rated current continuously from either normal or emergency sources, (3) its ability to withstand fault currents, (4) its ability to interrupt at least 6 times the full-load currents, and (5) its ability to withstand the stress of two out-of-phase power sources connected to it. In addition to considering each of the above characteristics individually, it is also necessary to consider the effect each has upon the others.

In arrangements to provide protection against failure of the utility service, consideration should also be given to (1) an open circuit within the building area on the load side of the incoming service, (2) overload or fault condition, and (3) electrical or mechanical failure of the electric power distribution system within the building. It is desirable to locate transfer switches close to the load and to have their operation independent of overcurrent protection. It is often desirable to use multiple smaller transfer switches located near the load rather than one large transfer switch at the point of incoming service. As shown in Fig. 7.196, multiple transfer switches can also provide varying degrees of protection, depending upon how critical the loads are.

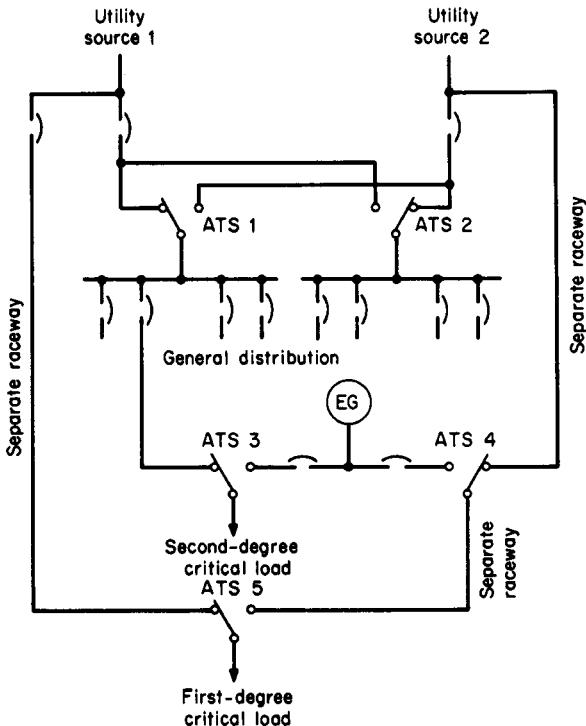

FIGURE 7.196 Two utility sources combined with an engine-generator set to provide varying degrees of emergency power. *ATS* = automatic transfer switch; *EG* = engine-generator set.

Ratings. An automatic transfer switch is unique in the electrical distribution system in that it is one of the few electrical devices that may have two unsynchronized power sources connected to it. This means that the voltages impressed on the insulation may actually be as high as 960 V on a 480-V ac system. A properly designed transfer switch provides sufficient spacings and insulation to meet these increased voltage stresses.

Domestic ac voltage ratings of automatic transfer switches are normally 120, 208, 240, 480, or 600 V, single or polyphase. Standard frequencies are 50 to 60 Hz. Automatic transfer switches can also be supplied for other voltages and frequencies when required.

Today automatic transfer switches are available in continuous-current ratings ranging from 30 through 4000 A. Typical ratings include 30, 70, 100, 150, 260, 400, 600, 800, 1000, 1200, 1600, 2000, 3000, and 4000 A.

Most transfer switches are capable of carrying 100 percent of rated current continuously at an ambient temperature of 40°C. However, some transfer switches, such as those incorporating integral overcurrent protective devices, may be limited to a continuous load current not to exceed 80 percent of the switch rating.

When selecting an automatic transfer switch, it usually is necessary only to determine the maximum continuous load current which the transfer switch must carry. Momentary inrushes, which occur when lighting or motor loads are first energized, can be ignored if the transfer switch is rated for total-system loads according to UL 1008. The automatic transfer switch should be sized equal to or greater than the calculated continuous current.

The *withstand current rating* pertains to the ability of an automatic transfer switch to withstand the magnetic and thermal stresses of high-fault currents until the fault has been cleared by an overcurrent protective device. The overcurrent protective device is usually located externally from the transfer switch, although there are some transfer switches that, for purposes of economy, do include integral overcurrent protection. To differentiate between the two, one recognized standard defines the following type designations:

Transfer switch, Type A means an automatic transfer switch that does not employ integral overcurrent devices.

Transfer switch, Type B means an automatic transfer switch that employs integral overcurrent devices.

In a Type A transfer switch, the main contacts stay closed while the system's coordinated protective devices clear the fault, whereas a Type B transfer switch depends upon trip elements to open the contacts of the transfer switch during a short-circuit fault. The latter arrangement depends upon *interruption rating*, which should not be confused with withstand rating. This discussion addresses itself to the conventional Type A transfer switch as found in most properly engineered and fault-current-coordinated applications.

To evaluate and coordinate transfer switching and overcurrent protection, a short-circuit study should be made on the system to determine the available fault-current magnitude and the *X/R* ratio of the circuit at each point in the distribution system where a transfer switch is to be located. This study is usually made by the system designer.

Solid Neutral on ac and dc Systems. Solid neutrals can be used with the grounding connections made as required in Sec. 250.24 of the 2008 National Electrical Code where automatic ac-to-ac transfer switches are used. Where multiple grounding creates objectionable ground current, the corrective action specified in Sec. 250.6(B) should be taken.

Section 230.95 requires ground-fault protection of equipment. Because the normal source and the emergency source are typically grounded at their locations, the multiple neutral-to-ground connections usually require some additional means or devices to assure proper ground-fault sensing by the ground-fault protection device. Additional means or devices are generally required because the normal alterations to stop objectionable current per Sec. 250.6(B) do not apply when the objectionable current is a ground-fault current. [See Sec. 250.6(C).] Rather, solutions such as an overlapping neutral transfer pole or a

conventional fourth pole are often added to the transfer switch. However, when switching the neutral conductor with a conventional fourth pole, consideration should be given to possible resulting high-voltage transients. Other solutions are isolation transformers and special ground-fault circuits.

On ac-to-dc automatic transfer switches, a solid-neutral tie between the ac and dc neutrals is not permitted where both sources of supply are exterior distribution systems. Section 250.164 regarding location of grounds for dc exterior systems clearly specifies that the dc system can be grounded only at the supply station.

Where the dc system is an interior isolated system, such as a storage battery, solid-neutral connection between the ac system neutral and the dc source is acceptable.

On an ac-to-dc automatic transfer switch where the neutral must be switched, the size of the neutral switching pole must be considered. A four-pole double-throw switch must be used where a three-phase, four wire normal source and a two-wire dc emergency source are transferred. Owing to the neutral being switched, a four-pole double-throw transfer switch would be required. In this instance, one pole of the dc emergency source would carry 3 times the current of the other poles.

Close Differential-Voltage Supervision of Normal Source. Most often the normal source is an electric utility company whose power is transmitted many miles to the point of utilization. The automatic-transfer-switch control panel continuously monitors the voltage of all phases. Because utility frequency is, for all practical purposes, constant, only the voltage need be monitored. For single-phase power systems, the line-to-line voltage is monitored. For three-phase power systems, all three line-to-line voltages should be monitored to provide full-phase protection.

In addition, monitoring protects against operation at reduced voltage, such as brownouts, which can damage loads. Since the voltage sensitivity of loads varies, the pickup (acceptable) voltage setting and dropout (unacceptable) voltage setting of the monitors should be adjustable. The typical range of adjustment for the pickup is 85 to 100 percent of nominal, while the dropout setting, which is a function of the pickup setting, is 75 to 98 percent of the pickup selected. Usual settings for most loads are 95 percent of nominal for pickup and 85 percent of nominal for dropout (approximately 90 percent of pickup).

Consideration must be given to close differential-voltage supervision at installations where the loads are more sensitive to voltage reduction. Starter-type fluorescent lighting is extremely voltage-sensitive, and below 90 percent voltage it becomes uncertain as to whether or not a fluorescent lamp will light. Therefore, close differential sensing is required for this type of lighting.

Electronic-equipment load is frequently voltage-critical. Such installations include patient-care equipment in health care facilities, television stations, microwave communications, telephone communications, computer centers, and similar applications.

Lightly loaded polyphase motors have a tendency to run single-phase, with the loss of voltage in one phase, thus leading to motor burnups. Automatic transfer switches with properly set close differential-voltage levels will help to detect phase outages.

Coordination with Automatically Started Engine-Generator Sets. In these installations, the normal source is usually a utility power line, and the emergency source is an automatically started engine-generator set which starts upon failure of the normal source. To ensure proper operation and maximum reliability, a minimum installation as illustrated in Fig. 7.198 should be arranged to:

1. Initiate engine starting of the engine-generator set from a pilot engine-start contact on the automatic-transfer-switch control panel when utility voltage drops to an unacceptable level.

2. Sustain connection of load circuits to the normal source during the starting period to provide utilization of any existing service on the normal source.
3. Measure output voltage and frequency of emergency source through the use of a voltage-frequency-sensitive monitor and effect transfer of the load circuits to the engine-generator set when both voltage and frequency of the power plant are approximately normal. Sensing of the emergency source need only be single-phase since most applications involve an on-site engine-generator with a relatively short line run to the automatic transfer switch. In addition to voltage, the emergency source's frequency varies during startup. Combined frequency and voltage monitoring will protect against transferring loads to an engine-generator set with an unacceptable output.
4. Provide visual signal and auxiliary contact for remote indication when the emergency source is feeding the load.

FIGURE 7.197 Automatic emergency transfer switch and control panel. [Automatic Switch Co.]

Time Delays. Time delays are provided to program operation of the automatic transfer switch. To avoid unnecessary starting and transfer to the alternative supply, a nominal 1-s time delay, adjustable up to 6 s, can override momentary interruptions and reductions in the normal source voltage but allow starting and transfer if the reduction or outage is sustained. (See Fig. 7.198.) The advantages of this feature are realized in all types of automatic-transfer installations. In standby plant installations the reduced number of false starts is especially important to minimize wear on the starting motor, ring gear, battery, and associated equipment. This delay is generally set as 1 s but may be set higher if reclosers on the high lines take longer to operate or if momentary power dips exceed 1 s. If longer delay settings are used, care must be taken to ensure that sufficient time remains to meet NEC 10-s power restoration requirements.

Once the load has been transferred to the alternate source, another timer delays retransfer to the normal source until that source has had time to stabilize. The timer is adjustable from 0 to 30 min and is normally set at 30 min. Another important function of this timer is to assure that the engine-generator set operates under load for a preselected minimum time, thus assuring continued good performance of the engine and its starting system. This delay should be automatically nullified if the engine-generator set fails and the normal source is available.

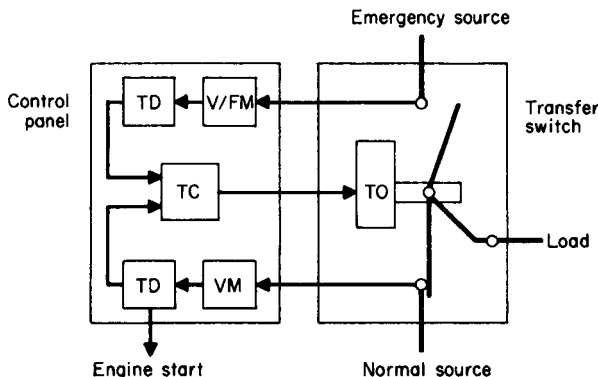

FIGURE 7.198 Block diagram of a typical automatic transfer switch. *TD* = time delay; *TO* = transfer operator; *TC* = transfer controls; *V/FM* = voltage/frequency monitor; *VM* = voltage monitor.

Engine-generator manufacturers often recommend a cooldown period for their sets which allows them to run unloaded after the load has been retransferred to the normal source. A third time delay, usually 5 min, is provided for this purpose. Running an unloaded engine for more than 5 min is neither necessary nor recommended since it can cause deterioration in engine performance.

It is sometimes desirable to sequence transfer of the loads to the alternate source when more than one automatic transfer switch is connected to the same engine-generator. Utilization of such a sequencing scheme can reduce starting kilovolt-ampere capacity requirements of the generator. A fourth timer, adjustable from 0 to 1 min, will delay transfer to emergency for this and similar requirements.

Transfer of Motor Loads. Automatic transfer switches operate rapidly, with total operating time usually less than 0.5 s, depending upon the manufacturer and the rating of the transfer switch. Therefore, transferring motor loads may require special consideration in that the residual voltage of the motor may be out of phase with that of the power source to which the motor is being transferred. On transfer, this phase difference may cause damage to the motor, and the excessive current drawn by the motor may trip the overcurrent protective device. Motor loads above 50 hp with relatively low load inertia in relation to torque requirements, such as pumps and compressors, may require special controls.

Automatic transfer switches can be provided with accessory controls that disconnect motor controllers prior to transfer and reconnect them after transfer when the residual voltage has been substantially reduced. Automatic transfer switches can also be provided with in-phase monitors that allow transfer between sources when both sources are synchronized. Another approach is to use a three-position transfer switch with accessory controls that allow the switch to pause in the neutral position while the residual voltage decays substantially before completing the transfer.

Of the above approaches, many engineers prefer the use of the in-phase monitor because loads are not intentionally disconnected for a period of time, there is no control interwiring between the automatic transfer switch and the motor controllers, and the transfer switch remains a two-position double-throw device.

Manually Operated Transfer Switches. Though this discussion pertains primarily to automatic transfer switches, there are applications that justify the use of non-automatic transfer switches. Manually operated transfer devices are commonly used in applications

where operating personnel are available and the load is not of an emergency nature requiring immediate automatic restoration of power.

Typical applications are found in health-care-facility equipment systems, industrial plants, sewage plants, centers for civil defense control, farms, residences, telephone buildings, and other communication facilities. Double-throw knife switches and safety switches are sometimes used for these applications. However, many of these devices must be operated under "no-load" conditions; i.e., operators must be sure that they have disconnected the load by opening breakers or other load-interrupting devices before they operate the switch. Though some double-throw switches are load-break and may be rated as single-throw switches, they may not be suitable for transferring all classes of load between two unsynchronized power sources. Because these devices are marginal adaptations, there often is a reluctance on the part of personnel to operate them.

There are nonautomatic transfer switches that meet the safety requirements of UL 1008. Such switches are electrically operated by manually actuating a control station. The pole construction of these switches is similar to that of automatic transfer switches, and thus they have the ability to transfer all classes of load between two unsynchronized power sources.

Whether the transfer switch be automatic or nonautomatic, careful consideration should be given to its coordination with upstream overcurrent protective devices. Furthermore, the selection of the transfer switch as well as other emergency power equipment should be based on the required degree of reliability, elimination of unnecessary outages, convenience of operation, and safety of personnel as needed for the application.

415. Gas-turbine generators. In the larger sizes, from about 700 kW up, the turbine-driven generator offers a number of advantages as a source of power. These units are small in size and weight when compared with other types of power sources of the same capacity. They can provide much more power capability in the same space required for standby power-using reciprocating engines.

The installation of gas-turbine generators is relatively simple because foundations either are small and light or are not required at all for some skid-mounted units. Vibration is minimal. Cooling water is not required because the unit is normally air-cooled. However, soundproofing of the room or location in which the unit is installed may be required if the high-frequency vibrations emitted are objectionable. Effective equipment for soundproofing is available.

Other applications in which the gas-turbine generator has been particularly successful include cogeneration systems and utility peak-load service.

Figure 7.199 shows an unclosed gas turbine generator set that provides 4370 kW, 60 Hz (continuous-duty rating at ISO conditions), along with 165,600 lb/h of clean, dry exhaust heat at 927°F for many commercial and industrial applications. The major components are, left to right, the generator, the accessory-reduction gear, and the gas turbine engine. The unit's Centaur Taurus gas turbine is a single-shaft, constant-speed, axial-flow machine with 12 air compressor stages, an annular combustor, and three turbine stages. The unit is mounted on a single skid and measures about 32 ft long, 8 ft wide, and 8.5 ft high. Its weight is approximately 42,500 lb.

416. Matching generating capacity and load in optional standby systems. Where an optional standby system is to be wired, the NEC only requires that it have enough capacity to handle all the load the owner chooses to have remain operational at one time. The owner decides what those loads are to be, but the decision should be reflected in the permanent wiring on site. This is done by creating a standby panelboard that includes the loads the owner has determined are essential to remain energized. Then, knowing what

FIGURE 7.199 A 4-mW gas turbine generator set. [Solar Turbines Inc.]

loads will be represented and using load calculation provisions generally as presented in NEC Article 220, determine the required electrical demand for the standby panelboard. Compare this result with the proposed rating of the generator and the transfer equipment and make sure they both are up to the job. If not, either decrease the anticipated load or increase the intended plant and equipment accordingly.

The 2008 National Electrical Code has made a distinction between automatic and manual transfer switches in this regard. The automatic switch requires the load in the standby panel to agree with the generator size. On the other hand, where the transfer is made manually, the load in the standby panel can exceed the generator capacity. This allows an operator, for example, to turn on breakers controlling space heating, and then, when the desired temperature is reached, shut off those circuits and turn on others that are needed for a limited time. However, sizing the load to the generator is still the best design. Murphy's law holds that when the generator is needed, the least qualified person will be the only one available to make the load decisions, with a likely outcome being an overloaded generator shutting down at an inopportune time.

POLE LINES: GENERAL, CONSTRUCTION, AND EQUIPMENT

1. The reports of the Committee on Overhead Line Construction of the National Electric Light Association contain what are probably the best and most complete specifications for pole-line construction for lighting and power distribution that have ever been compiled. Some of the material in this division regarding pole lines has been abstracted from those reports. The National Electric Light Association (NELA) has been reorganized and succeeded by the Edison Electric Institute (EEI). As specifications and standards of the NELA organization are revised, they will be known as those of the EEI.

2. The National Electrical Safety Code, IEEE ANSI-C2, comprises an exhaustive collection of rules for proper installation, maintenance, and operation of electrical distribution systems. Companies are now, in general, endeavoring to follow these rules. Ultimately, it is believed, their adoption will be universal.

3. There are three principal types of overhead line construction:

1. Bare or weatherproof covered wire supported by insulators mounted on or hung from crossarms located on buildings or near the tops of poles.
2. Weatherproof covered wire supported by insulators mounted on racks on the sides of buildings or poles.
3. Insulated aerial cable which either is self-supporting from clamps bolted to sides of poles or crossarms or is supported by messenger cable from clamps bolted to the sides of poles or crossarms. See Div. 2 for descriptions of the types of wire and cable.

4. There are four main types of poles used for overhead line construction:

1. Wood poles
2. Steel poles
3. Reinforced-concrete poles
4. Structural-steel fabricated towers

5. The most common woods now available for poles are Douglas fir and southern yellow pine (a collective term referring to either the loblolly, longleaf, shortleaf, or slash pines), according to the *Standard Handbook for Electrical Engineers*. Douglas fir is more available in the long lengths required for transmission voltages, but the great majority of poles installed today are for distribution work, and probably 75 percent are southern yellow pine. Many other woods have been used historically and are still in service, including chestnut and northern white cedar, but these are not generally available today. Western Red Cedar is still being used, particularly for applications where its internal rot resistance is critical.

6. Wood poles are classified by three measurements:

1. Length, with standard lengths varying in 5-ft (1.5 m) increments.
2. Minimum circumference at a distance 2 ft below the top of the pole. This distance is important in terms of being able to specify mounting hardware. These measurements are resolved into classes based on 2-in. increments, beginning with Class 1, which has a minimum pole-top circumference of 27 in. There are 10 classes, with higher classifications applying to smaller pole tops, as follows: Class 2, 25 in.; Class 3, 23 in.; Class 4, 21 in.; Class 5, 19 in.; Class 6, 17 in.; Class 7, 15 in.; Class 8, 13 in.; Class 9, 11 in. Class 10 is seldom used today. For heavier loading, the classification system now includes H-6 downward through H-1 sizing, running in 2-in. steps downward from 39 in. (H-6) through 37 in. (H-5), 35 in. (H-4), 33 in. (H-3), 31 in. (H-2), and 29 in. (H-1).
3. Minimum circumference at a distance of 6 ft (1.8 m) from the butt. This distance determines the ability of the pole to resist breakage at the ground line from horizontal forces. This circumference often varies by species, because the species differ in terms of strength, and the point of the classification is to assure equivalent performance in terms of acceptable loading by any pole in a given classification. For example, any Class 6 pole should be able to withstand a 1500-lb (6672 N) load applied horizontally at a point 2 ft (600 mm) below the pole top. Table 6A shows a typical range of pole sizes arranged by class and ground-line circumference for Douglas fir and southern yellow pine.

Table 6B shows the maximum loading for vertical poles of differing heights and classes. The weights given were calculated for three-cluster or crossarm-mounted transformers. The weights must be recalculated if other mounting arrangements produce different bending moments. The numbers are based on kiln-dried wood poles, degraded to 75 percent of standard test values to allow for variations in fiber strength. The calculations also apply a safety factor of 5:1, and assume two 250-lb (113.4 kg) linemen are working on the pole with their usual pole equipment. The tabulated results also account for stress produced by hoisting cables.

8. Wood-pole specifications. The American National Standards Institute (ANSI) has standardized the specifications and dimensions for wood poles. ANSI specifications provide that all poles shall be free from sap rot, cracks, bird holes, plugged holes, injurious checks, and damage by marine borers. All poles shall be free from splits, shakes, hollow, and decay in the tops. Nails, spikes, and other metal shall not be present unless specifically authorized by the purchaser. There are further detailed restrictions regarding blue stain, hollow centers, shakes in the butt surface, splits, grain twist, insect damage, scars, etc., which vary with the different types of poles. Anyone interested in such details is advised to consult the ANSI.

Allowable deviations from straight poles are illustrated in Fig. 8.1. Dimension A should be taken from the following table:

A, ft	3½	4	5	5½	6	6½	7	7½	8	8½	9	9½	10	10½	11
Total length of pole, ft....	16-18	20-22	25	30	35-40	45	50	55	60	65	70	75	80	85	90

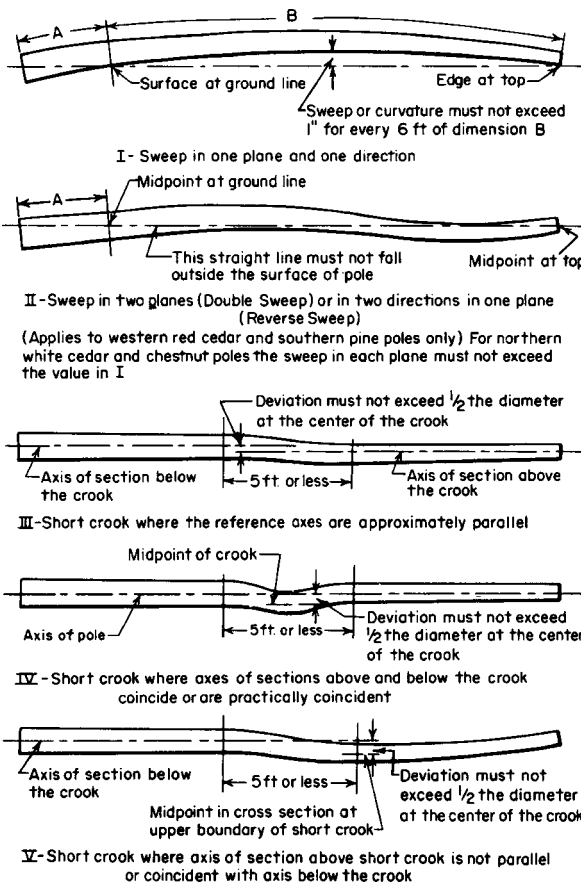

FIGURE 8.1 Allowable sweeps and crooks in wood poles. [American National Standards Institute]

9. Preservation of poles. Owing to the continually increasing scarcity of timber and the labor cost of replacing decayed poles, general practice is to impregnate poles with some substance which resists or retards decay. Southern pine poles generally are pressure-treated for their entire length. Common practice is to treat only the butt of poles of other woods, because since these woods are naturally resistant to decay, practically all decay occurs within the portion 1½ ft (0.46 m) above or below the groundline.

10. Methods of butt treating (Naugle Pole & Tie Co.). The specifications for each of the three methods of treating require that poles be seasoned at least four *seasoning months* before the treatment (see Sec. 11). All fibrous inner bark and foreign substances must be thoroughly removed from that portion of the pole between the points 1½ ft above and 1½ ft below the groundline. In general, the methods of treatment are as follows. *Treatment A* provides for a continuous submersion in hot Carbolineum (a coal-tar derivative) for a minimum interval of 15 min. *Treatment B* provides for a continuous submersion in cold creosote for a minimum interval of 4 h, to be followed by a continuous submersion in cold creosote for a minimum interval of 2 h. In each of these three treatments the poles are placed in upright tanks with the butts continuously submerged to a height of 1½ ft above the groundline.

Figure 8.2 shows, as would be expected, that the softer and more porous woods which suffer most rapid decay are most benefited and have the longest life after treatment. Such woods can absorb the most oil. The cost of treatment varies with the amount of oil injected and with local conditions.

FIGURE 8.2 Life of treated and untreated poles.

11. Calendar months are rated in equivalent seasoning months as follows:

Calendar month.....	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
Seasoning month.....	1/8	1/8	1/4	1/2	3/4	1	1	1	1	3/4	3/4	1/8

Poles which have been properly piled for seasoning must be seasoned for a total of 4 seasoning months, counting the seasoning months as given in the above table. For example, poles which are cut in January or February must be seasoned to the end of August before the time will have equaled 4 seasoning months.

12. Steel poles are made in three general types: (1) latticed, (2) expanded truss, and (3) tubular. The latticed type is made from structural-steel angles or channels joined and braced by latticed crossbars. The expanded truss is made from structural H sections, the web of which has been sheared by a rotary shear at fixed intervals so as to remove some of the metal. The pole is then heated to a cherry red and expanded by a special machine which grips the flanges and pulls them apart to the desired width (see Fig. 8.3). Latticed and expanded-truss steel poles are used for medium-voltage transmission lines with spans 250 to 350 ft (76.2 to 106.7 m) in length. Their life is 25 to 50 years or more, depending on the adequacy of painting and upkeep. Tubular poles are built up from length of steel tubing,

using a large-diameter tube for the base and successively smaller tubes for the upper sections. They were extensively used for street-railway and trolleybus wiring in cities, where appearance is important. Their higher cost prevented their use through open country.

13. Fabricated steel towers are made from four main structural angles as uprights, cross-braced with smaller structural angles. Steel towers are ordinarily used for high-voltage lines with spans of more than 350 ft (106.7 m).

14. The design of reinforced-concrete poles requires considerable skill. When persons unfamiliar with concrete-pole design must build them, they had best accept the proportions of poles that have been built and are giving good service. Figure 8.4 shows some of the major considerations. The pole is proportioned for a 150-ft (45.7-m) span to withstand a gale successfully, with the wind at a velocity of 70 mi/h (113 km/h) and 1/2 in. (12.7 mm)

FIGURE 8.3 Bates expanded steel pole.

FIGURE 8.4 A 30-ft (9.1-m) reinforced-concrete pole. [Universal Portland Cement Co.]

of ice on the wires. The horizontal load thus imposed by the wind on all the 18 wires, tending to overturn the pole, is 2100 lb (9341 N). The sides of the reinforcing bars are 1¼ in. (31.75 mm) in from the faces of the pole. The concrete is a 1:2:4 mixture. It should be mixed wet, using carefully selected materials with the fine aggregate next to the forms. Air bubbles should be eliminated by careful tamping or churning. Corners of the pole should be chamfered off. The square reinforcing rods, which are of the mechanical-bond type, are bound together by a web system not shown in the illustration. The web system consists of a spiral of No. 12 steel wire wound outside the rods and securely bound to them. The rods are also secured together with horizontal ties 1 in. (25.4 mm) wide and ¼ in. (6.35 mm) thick, spaced to 3 to 5 ft (0.9 to 1.5 m) apart. The reinforcement thus forms an independent skeleton which can be assembled and lowered into the forms. It is likely that it is most economical to cast poles exceeding 35 ft (10.7 m) in height in their final vertical positions. Shorter poles are erected with a derrick. Gains for crossarms and holes for bolts are cast in poles. Metal pole steps may be cast in solid also.

15. Reinforced-concrete poles (*Standard Handbook for Electrical Engineers*) are the most durable and usually the most expensive. The life of a properly designed concrete pole is practically unlimited. The facility with which special purposes can be served with reinforced concrete is also a great advantage. The exterior form can easily be modified to harmonize with any desired scheme of decoration. When it is desired to lead wires from the pole top to ground, the poles can be made hollow, and thus at a slight additional cost the wires are completely hidden from view and protected from the weather. Concrete poles may fail, but they will not fall to the ground. The principal drawback to this form of construction has been the cost and the difficulty of manufacture. The poles are heavy and cumbersome to transport, so that, when possible, it is well to make them in the neighborhood where they are to be used. Both concrete and steel poles can be transported in small packages over mountains and erected on the spot, but in this respect steel is much superior to concrete. Concrete poles are classified according to the horizontal load which can be applied to the pole 2 ft (0.6 m) from the top:

Class	A	B	C	D	E
Horizontal load applied 2 ft from top, lb	4000	3000	2000	1500	1000

16. Depth to set poles in the ground. One rule is that poles should, on straight lines, be set in the ground one-sixth of their lengths. The following table indicates good practice for normal soils:

Pole length, overall, ft	Depth to set in ground, ft		Pole length, overall, ft	Depth to set in ground, ft	
	Straight lines	Curves, corners, and points of extra strain		Straight lines	Curves, corners, and points of extra strain
30	5.5	6.0	55	7.0	7.5
35	6.0	6.5	60	7.5	8.0
40	6.0	6.5	65	8.0	8.5
45	6.5	7.0	70	8.0	8.5
50	7.0	7.5	75	8.5	9.0

17. The size of pole to use cannot be definitely specified without knowing local conditions. Municipal ordinances sometimes regulate the heights of poles and wires. If there are trees along the line, the wires should be carried entirely above them or through the lower branches, which interfere less than do the higher ones, on which the foliage is thicker. For lines on highways it is usually customary to place the lowest wire at least 18 ft (5.5 m) above the highway, and 21 ft (6.4 m) is better. Railway companies frequently specify 22 ft (6.7 m) between the top of the rail and the lowest crossarm. Wires should be at least 15 ft (4.6 m) above sidewalks. The height of the pole will depend upon the number of crossarms to be carried. It is desirable to avoid abrupt changes in the level of wire. Hence, if the line runs uphill and downdale, the longer poles should be used in the valleys.

Guy wires should, except when otherwise provided by ordinance, be at least 18 ft above a highway and 12 ft (3.7 m) above a sidewalk.

Also in cities it is a good practice to use 35-ft (10.7-m) poles to carry either one or two crossarms, 40-ft (12.2-m) poles to carry three or four crossarms, and 45-ft (13.7-m) poles to carry more than four crossarms. For suburban lines 30-ft (9.1-m) poles are often used. For very light lines carrying only three or four wires, 6-in. (152-mm) poles 25 ft (7.6 m) long are sometimes used, though so light a pole is inexpedient if the number of wires is likely to increase. The height of a pole is always considered as the total length overall.

18. Poles should be spaced, in straight portions of a line, about 125 ft (38.1 m) apart. The usual maximum is 150 ft (45.7 m), and the minimum about 100 ft (30.5 m). In curves and at corners the spans should be about as indicated in Fig. 8.5. For rural lines the span may be lengthened to 200 or 250 ft (61 or 76.2 m). Spans up to 400 to 500 ft (122 or 152.4 m) have been used for rural feeder lines employing aluminum cable, steel-reinforced.

Note: If the "Pull" is less than 5' the spans adjacent to the angle pole shall be of standard length (125'). If the "Pull" exceeds 5', the spans adjacent to the angle pole shall be reduced to the distance "Span" given in table.

Angle A	Pull in ft	Span	No. of 6000 lb side guys		
			1 Arm 6 wires	2 Arms 12 wires	3 Arms 18 wires
Less than 6°	Less than 5'	125'	NONE	NONE	NONE
6°-11°	5'-10'	115'	NONE	1	1
11°-15°	10'-13'	105'	1	1	1
15°-22°	13'-19'	95'	1	1	2
22°-30°	19'-26'	85'	1	1	2
Over 30°	Over 26'	75'	1	2	2

FIGURE 8.5 Pole spacing and side guys on curves. [Edison Electric Institute]

19. Holes for poles should be large enough to admit the poles without any slicing or chopping and should be of the same diameter from top to bottom. The diameter of the hole should always be at least large enough so that a tamping bar can be worked on all sides between the pole and the sides of the hole.

20. Setting poles. On straight lines poles should be set perpendicularly. On curves poles should slant slightly so that the tension of the wires will tend to straighten them. In filling a hole after the pole is in it, only one should be employed and as many more persons as can conveniently work around the pole should tamp in the earth as the shoveler throws it in. Some of the surplus earth should be piled around the butt of the pole so that the water will drain away. Figure 8.6 illustrates the method of setting a pole with pikes.

FIGURE 8.6 Method of setting a pole with pikes.

21. Setting poles with a gin pole. A few workers can set a large pole with a gin pole, as suggested in Fig. 8.7. The gin pole can be a short wooden pole or, if the poles to be raised are not too heavy, a length of wrought-iron pipe. The gin need be only one-half as long as the pole to be raised. In setting a pole the gin is first raised to an almost vertical position with its top over the pole hole. It is held in that position by fastening the guy lines. Then the hook of the tackle blocks is engaged in a sling around the pole, and the pole is raised, by workers or by a power unit, by pulling on the free end of the tackle-block line. When high enough so that its lower end can be slipped into it, the pole is dropped into the hole and adjusted to a vertical position with pikes, and the earth is tamped in. In modern practice gin poles are permanently mounted on trucks for transportation and are then called *pole derricks*. They are great savers of time and money. The methods illustrated in Figs. 8.6 and 8.7 are shown to assist those who install poles only occasionally.

FIGURE 8.7 Gin pole for raising poles.

22. Setting poles in loose and weak soils. On important lines it is customary to use a concrete setting for the pole (Fig. 8.8, I). A suitable mixture is 1 part cement, 3 parts sand, and 3 parts broken stone or coarse gravel.

For somewhat less important lines when the soil is fairly firm, the sand barrel (Fig. 8.8, II) is a valuable expedient. This consists of a strong barrel or barrels placed at the bottom of the hole into which the pole is set. The barrel is filled with a firm, substantial soil. By this means the pole is given a larger bearing area. Sometimes a temporary sand barrel, consisting of a special iron cylinder that is placed around the pole, is filled with firm dirt and then hoisted away.

In marshy ground another expedient for less important lines is to build a triangular brace from sound portions of old poles (Fig. 8.8, III and IV) bolted together. This provides a bearing area on or near the top of the soil which resists overturning of the pole. The method of Fig. 8.8, III, is preferable to the one in Fig. 8.8, IV, because the ground member will not rot

FIGURE 8.8 Methods of setting poles in poor soils. [General Electric Co.]

so fast when it is completely underground. There is, however, somewhat more labor involved in digging the trench for the ground member. These methods are not so permanent as a concrete foundation and are recommended only when the expense of a concrete foundation does not seem warranted.

23. When poles are set in rock, the hole may be blasted or a hole $1\frac{1}{2}$ in. (38.1 mm) in diameter may be drilled in the rock (Fig. 8.9); in it is placed an iron pin that extends about 6 in. (152.4 mm) above the surface. A similar hole is drilled in the butt of the pole, and the pole mounted on the pin. It must then be braced by three or four wood struts spiked to the pole 6 ft (1.8 m) from the ground, running diagonally to the rock and formed thereto, or it can be braced by guy wires made fast to metal pins set in the rock.

FIGURE 8.9 Method of setting a pole on rock.

24. Wooden poles which have rotted at the butt can be reinforced with a short stub pole set in the ground next to the regular pole and extending a few feet above the groundline. Various methods of stubbing are shown in Fig. 8.10, with the required materials in Fig. 8.11. In all cases two bands should be employed with spacings as given below. In Fig. 8.10 only the top band of the two is illustrated in several cases. If a wire wrap is employed (Fig. 8.10C), four wraps should be made around the pole and six wraps around both the pole and stub for poles up to 40 ft (12.2 m) long. For poles longer than 40 ft, 10 wraps should be used around both pole and stub. In employing the method of Type C, Fig. 8.10, the following dimensions should be used. Dimension C should be not less than 30 in. (762 mm) for poles up to 45 ft (13.7 m) long or 36 in. (914.4 mm) for poles 45 to 50 ft (13.7 to

FIGURE 8.10 Methods of reinforcing with stubs. [Hubbard & Co.]

FIGURE 8.11 Materials for reinforcing with stubs. [Hubbard & Co.]

15.2 m) long; dimension *A* should be not less than 38 in. (965.2 mm) for poles up to 45 ft long or 44 in. (1117.6 mm) for poles from 45 to 50 ft long; dimension *B* should be less than 24 in. (609.6 mm) for poles up to 45 ft long or 30 in. for poles from 45 to 50 ft long. Poles are generally stubbed so that the stub is across the line. Methods *D* and *E* will not be satisfactory if the stub is located along the line. The other methods can be used for either across-the-line or along-the-line stubbing. With Method *B* the 5/8-in. dowels are not required if the poles are stubbed across the line.

25. Reinforcing old poles with concrete and steel. Wooden poles usually become unsafe because of butt rot at the groundline. Such poles can be repaired without moving the wires they support by reinforcing them with steel and concrete as shown in Fig. 8.12. For ordinary poles and conditions, 10 mild-steel rods 1/2 in. (12.7 mm) in diameter and 4 to 6 ft (1.2 to 1.8 m) long are used for reinforcing. The lower end of each

FIGURE 8.12 Reinforcing a pole with concrete.

reinforcing rod is pointed and is driven into the portion of the butt that remains in the hole. The other end is bent at right angles, and pointed. It is driven into the pole above the groundline. A 1:2½:5 mixture of concrete is used for the main body, and a richer mixture is used for the portion above the groundline and is molded in a cylindrical sheet-iron form. The concrete extends to about 1½ ft (0.46 m) above the groundline. Poles 15 to 20 years old have been satisfactorily repaired by this method without moving the supported wires.

26. Repairing steel poles. Metal poles sometimes corrode very rapidly at the ground, and when discovered the corrosion is often too far advanced to make any preventive measures effective. A very satisfactory method (Fig. 8.13) of repairing steel poles is to place a loose-fitting metal sleeve around the butt of the pole and fill the space between the two with portland cement.

FIGURE 8.13 Repairing a metal pole.

27. Crossarm bolts are used for fastening crossarms to the poles. These bolts are standard ¾-in. galvanized machine bolts (see machine-bolt data in Div. 4 for dimensions). A square washer is used under both head and nut, as shown in Figs. 8.47 and 8.70, I.

28. Double-arming bolts (Fig. 8.14) give a more rigid construction and greater economy than the old block-spacer method of tying two crossarms together. The double-arming bolts are furnished with a long rolled thread, galvanized and fitted with four square nuts. A square washer is used under each nut, as shown in Figs. 8.48 and 8.70, II.

FIGURE 8.14 Double-arming bolts. [Line Material Co.]

FIGURE 8.15 Standard eyebolt. [Line Material Co.]

29. Eyebolts (Fig. 8.15) are furnished with a forged oval eye, rolled threads, and a square nut, galvanized. They are used for fastening guys, dead-ending insulators, and suspending insulators to crossarms, as shown in Figs. 8.41, I; 8.87; and 8.88. A square washer is used under nut and eye.

30. Double-arming eyebolts (Fig. 8.16) are furnished with a forged oval eye and three square nuts, galvanized. The opening of the eye is $1\frac{1}{2}$ by 2 in. These eyebolts are used for the same purposes as eyebolts in double-arm construction (see Figs. 8.41, IV; 8.48; and 8.86). Thimble-eye double-arming bolts, which eliminate the use of a separate thimble in attaching guy wires to the eye of the bolt, are also available.

FIGURE 8.16 Double-arming eyebolt. [Line Material Co.]

31. Eye nuts (Fig. 8.17) are used on through bolts, eyebolts, double-arming bolts, straight and angle thimble-eye bolts, crossarm bolts, and anchor rods and for other attachments when it is desired to convert a standard threaded bolt to a thimble-eye bolt. They are commonly used for dead-ending a messenger wire or span guy on the threaded end of an angle thimble-eye bolt on the opposite end of which is a down guy.

FIGURE 8.17 Eye nuts. [Hubbard & Co.]

There are two types of eye nuts: (1) the standard eye (Fig. 8.17, V), which requires the use of a thimble; and (2) the thimble eye, which has a thimble forged in it. The thimble-eye type is also made in a twin style (Fig. 8.17, II) to take two guy strands and in a three-guy style (Fig. 8.17, III) to take three guy strands. The guy eye (Fig. 8.17, I) serves the same purpose as the thimble eye, merely being forged in a slightly different manner. Refer to Fig. 8.71, II, for application.

32. Common, or buttonhead, carriage bolts (see Fig. 8.18) are used for attaching cross-arm braces to crossarms. They are provided with a square shoulder under the head. A round washer is used under the head, as shown in Fig. 8.47.

FIGURE 8.18 Carriage bolt.

33. Lag screws as shown in Fig. 8.19 are made in both fetter-drive and gimlet-point types. The $\frac{1}{4}$ - and $\frac{5}{16}$ -in. screws are generally of the gimlet-point type, while all screws of larger diameter are generally of the fetter-drive type. Fetter-drive lag screws are designed to be driveable like a nail without destroying the wood fibers, allowing them to still hold securely. Some have an increased diameter at the shoulder just below the head, so they will hold steel hardware in place without allowing it to shift laterally. Lag screws are used for attaching crossarm braces to poles, as shown in Figs. 8.47, 8.50, and 8.60.

FIGURE 8.19 Lag screws.

34. Lag-screw eyes (Fig. 8.20) are galvanized and furnished with gimlet-point, lag-screw thread. The forged eye has a $1\frac{3}{4}$ by $1\frac{1}{2}$ -in. opening.

37. Wooden crossarms are generally made of Douglas fir, which, according to tests made by the U.S. Forest Service, is best suited for the purpose. Longleaf yellow pine and Norway pine also are used for crossarms. Crossarm dimensions have not actually been standardized throughout the country. The dimensions of those carried as standard by one manufacturer are given in Sec. 36. Great care should be exercised in ordering crossarms to give full specifications. It is generally best to furnish a sketch (Fig. 8.22) with accompanying dimensions for the required boring.

FIGURE 8.22 Sketch for boring of crossarm.

Figure 8.23 shows the dimensions of crossarms recommended by the Edison Electric Institute. These arms have a spacing between center pins of 30 in. (762 mm), which is believed to provide a safe climbing space. Arms of the EEI cross-sectional dimensions (Fig. 8.23) have not come into extensive use. It is a modern practice not to paint crossarms as soon as they are made. They either are treated with a wood preservative or

FIGURE 8.23 Crossarm dimensions recommended by the Edison Electric Institute.

are permitted to season naturally for at least 3 months and are then painted with two coats of suitable paint before erection. Crossarms of Southern pine generally are pressure-treated against decay. It is not a general practice to treat crossarms of other woods. No crossarm having a spacing of less than 20 in. (508 mm) between center pins or 12 in. (304.8 mm) between side pins should be used. The six-pin arm (Fig. 8.23) is recommended for general use.

38. Galvanized-steel crossarms are made from standard steel angles in three types, as given in Sec. 39. They cost somewhat more than wooden crossarms but are more durable and will carry heavier loads. They are used for installations subjected to heavy strains and for higher-voltage lines.

39. Types of Galvanized-Steel Crossarms
(Hubbard & Co.)

Number of pins	Length, in	Brace style	Pin spacing, in		Size of angle, in	Approximate shipping weight, lb per 100 pieces

4	116	Angle	38	36	$3\frac{1}{2} \times 3\frac{1}{4} \times \frac{5}{16}$	7,645

40. Crossarm braces are made from galvanized flat strap iron (Fig. 8.24, I), ribbed strap iron (Fig. 8.24, II), or angle iron (Fig. 8.24, III). Braces are attached to the back of each crossarm by a carriage bolt, with the head of the bolt at the front with a round washer under it (Figs. 8.47 and 8.60). The braces are secured to the pole with a through bolt or a lag screw. The flat type is used for ordinary loads. It is made in lengths varying in 2-in. (50.8-mm) increments from 20 to 32 in. (508 to 812.8 mm), the 28-in. (711.2-mm) length being the most common. The ribbed type, being about 25 percent stronger, is used for heavier loads. The angle-iron type is used for very heavy lines. The standard sizes are given in Table 41, the first four being the Edison Electric Institute

FIGURE 8.24 Standard crossarm braces. [Hubbard & Co.]

standard for power company use. The alley-arm brace (Fig. 8.25, II) is used to support alley-type crossarms (see Sec. 62). The vertical brace (Fig. 8.25, III) supports the upper crossarms from the lowest crossarm in alley-arm construction (Fig. 8.49). The back brace (Fig. 8.25, IV) is fastened at the back of the crossarm and on the back of the pole. It is used as an alternative to double-arm construction at crossings and at abrupt turns in the line. A back brace for alley arms is shown in Fig. 8.25, I.

43. Insulators are used for insulating the electrical conduction wires and guy wires from the pole structure. The different types may be classified as pin, suspension, spool, strain, and wire-holder insulators. Either pin-type (Fig. 8.26) or suspension-type insulators (Fig. 8.30) are used for supporting the wires of the main electrical circuits. Spool insulators (Fig. 8.32) are used principally in the assembly of insulator racks (Fig. 8.33) for supporting low-voltage distribution mains from the sides of poles or buildings. Combined with a clevis, they are sometimes used for dead-ending low-voltage main electrical circuits. Strain insulators are used principally for insulating guy wires from the pole structure so that contact with the lower portion of the guy will not be dangerous. One type of porcelain strain insulator is frequently used for dead-ending low-voltage main electrical circuits or distribution wires. Wire-holder insulators are used in various assemblies for supporting service wires on buildings and for supporting, on the pole structure, taps for certain street-lighting luminaires. Insulators are made of either glass or porcelain, the choice for any particular size and voltage being determined by weighing the electrical and mechanical characteristics against first cost. Glass has been most commonly used for pin insulators (Fig. 8.26, I) for voltages up to 5000 V. Porcelain has been most commonly used for pin insulators for higher voltages and for the other types of insulators.

FIGURE 8.26 Typical pin-type insulators. [Locke Insulators, Inc.]

44. Pin-type insulators are molded with a central threaded hole so that the insulator is supported from threaded insulator pins mounted on the crossarms. These insulators are made in various shapes and with varying contours to meet the insulating requirements for different voltage classifications. For low-voltage work the insulators are generally grooved on the side for support of the wires. Medium-voltage insulators frequently have wire grooves on both top and sides, and the higher-voltage ones are made with only top grooves. Typical pin-type insulators are shown in Fig. 8.26.

45. Insulator pins. Pin insulators of the type shown in Fig. 8.26 are fastened on crossarms with insulator pins which thread into the cast thread inside the insulator. Insulator pins may be wood, steel, steel and lead, or steel and wood (Fig. 8.27). The wood pins (Fig. 8.27, IV) are made from oak or locust, the latter being preferred as less apt to crack. Wood pins are used on communications circuits and low-voltage distribution circuits on account of their low cost. Steel pins (Fig. 8.27, I and II) are used on the higher-voltage, longer-span lines, where the side loads on the pin are greater. Combination wood-cob-with-steel-bolt pins (Fig. 8.27, III) provide stronger construction than the plain wood at lower cost than all-steel pins. Lead adapters (Fig. 8.27, V) can be used with 1-in. steel pins to fit 1 3/8-in. insulator threads.

FIGURE 8.27 Insulator pins. [Line Material Co.]

FIGURE 8.28 Wooden insulator pin.

46. Wooden insulator pins. All standard insulator pins of 1- and 1³/₈-in. top diameter have four threads to the inch and a tapering diameter of 1/16-in. increase for each inch in length. (See Fig. 8.28.)

1 3/8	2 1/4	9 3/4	12	5	3 1/2	2	1 5/16	1,360

47. Wood pins are held in crossarms with a sixpenny nail, as shown in Fig. 8.29. The nail should not be driven entirely in. Enough of its length should extend so that the cutting jaws of a pair of pliers can be forced under the head and the nail thereby withdrawn. If this suggestion is followed, a pin can readily be removed as required.

FIGURE 8.29 Fastening pin to crossarm.

48. Steel pins are either clamped over the crossarm as in Fig. 8.27, II, or the rod projects through a hole in the crossarm and is held in place with a washer, square-head nut, and pal nut (Fig. 8.27, I). The clamp type does not weaken the crossarm by the drilling of the holes but is more expensive.

49. Suspension insulators are used to support wires from under crossarms. They are used on high-voltage lines, where pin insulators would become large, expensive, and unwieldy, and are sometimes used on lower-voltage lines also. They are made in a number of different styles varying in hardware and petticoat diameters. There are three general types of hardware: hook-and-clevis, ball-and-socket, and the tongue-and-clevis, as illustrated in Fig. 8.30. The hook type (Fig. 8.30, I) is used principally to support street-lighting units. Whether to use the ball-and-socket type (Fig. 8.30, II) or the tongue-and-clevis type (Fig. 8.30, III) on power circuits is mostly a matter of individual choice. With the tongue-and-clevis type a round pin is used to hold the tongue of one unit in the clevis of the other. A cotter pin slips through a hole in the end of the round pin to keep the pin from slipping out. With ball-and-socket hardware the round pin is eliminated. The insulators are assembled by sliding the ball of one insulator into the socket of the next one from the side. A cotter pin is slipped in from the back of the socket, taking up sufficient space in the socket so that the ball cannot slide out. The socket clevis (Fig. 8.30, IV) is used when it is desired to support other hardware from the bottom of the insulator.

FIGURE 8.30 Suspension insulators. [Locke Insulators, Inc.]

FIGURE 8.31 Details of suspension insulator supports.

and the number of units in the string affect the voltage rating. Small-diameter petticoats are preferred for locations where the insulators are subject to malicious damage from stones or bullets. The larger-diameter units are ordinarily used on the longer strings on high-voltage lines, where the wires are at a greater height from the ground.

50. Spool- and wire-holder-type insulators are used in single-wire or rack assemblies for supporting low-voltage circuits on the sides of poles and buildings and for dead-ending service wires on buildings, poles, and crossarms. In the rack assemblies (Fig. 8.33) the insulators are removable from the rack for easy replacement in case of breakage. The racks are made in two-, three-, and four-wire assemblies. Typical spool and wire-holder insulator assemblies are shown in Figs. 8.32 to 8.35.

FIGURE 8.32 Typical spool- and wire-holder-type insulators. [General Electric Co.]

FIGURE 8.34 Typical single-wire insulator assemblies. [General Electric Co.]

FIGURE 8.35 Typical wire-holder rack assembly. [General Electric Co.]

51. Strain insulators are used in guys and are also used in line wires at dead-ending points. Composition, porcelain, and wooden strain insulators (Fig. 8.36) were once popular with some companies and afford excellent insulation but have the objection that if an insulator burns, the wire that it supports falls. Composition and porcelain strain insulators can be made so that even if the insulating material fails, the supported wires will not fall. Figures 8.37 and 8.38 show types meeting these requirements. The strain insulator of Fig. 8.37 is inexpensive and satisfactory and has become very popular in electric-lighting-line construction.

FIGURE 8.36 Wooden strain insulators.

FIGURE 8.37 A porcelain strain insulator.

FIGURE 8.38 Composition strain insulators.

52. Emergency strain insulators can be made by knocking the end out of common glass line-wire insulators, as illustrated in Fig. 8.39. Then break out the end, hold the insulator in one hand and strike the inside of the top a sharp blow with the handle of a pair of pliers or a pair of connectors or with a screwdriver held in the other hand. If one emergency insulator will not give sufficient insulation, two or more can be used in series. Emergency strain insulators thus made are not strong enough for heavy guy wires but are more suitable for insertion in line wires.

FIGURE 8.39 Emergency strain insulators.

53. Clevises are used in making up assemblies connecting insulators, straps, strands, etc., together. Figure 8.40 illustrates some types of clevises. The forged clevises (Fig. 8.40, I) and bent strap clevises (Fig. 8.40, II) are used to connect dead-end insulators to crossarms (Fig. 8.41, I and II). The eye clevis (Fig. 8.40, III) will connect a dead-end insulator to another piece of hardware having a pin connection. The thimble clevis (Fig. 8.40, IV) will connect a stranded cable to an insulator assembly (Fig. 8.41, III). The strain-insulator clevis (Fig. 8.40, V) is used to connect a strain insulator of the type in Fig. 8.37 to an eyebolt or eye nut (Fig. 8.41, IV).

FIGURE 8.40 Clevises.

FIGURE 8.41 Applications of clevises to crossarm connections. [Hubbard & Co.]

FIGURE 8.42 Guy anchor rods. [Line Material Co.]

54. **Guy anchor rods** are used between the anchor and in the ground and the guy strand. Figure 8.42, I, illustrates a roller type which allows the strand to turn on the rod and prevents twisting of the guy strand. Figure 8.42, II, is used to attach to a log anchor. Figure 8.42, III, is used when anchoring to solid rock or masonry. Guy anchor rods are made in $\frac{1}{2}$ -, $\frac{3}{8}$ -, $\frac{3}{4}$ -, and 1-in. diameters.

FIGURE 8.43 Guy hook, thimble-eye bolts, and J bolt. [Line Material Co.]

55. **In connecting a guy strand to the pole**, the strand may be wrapped around the pole or may be connected to a special bolt. When the strand is wrapped around the pole, guy hooks (Fig. 8.43, I) are used to prevent the strand from slipping down the pole, and guy plates (Fig. 8.44, II) or shims (Fig. 8.44, D) are placed under the guy strand to prevent its cutting into the pole. The molding strain plate of Fig. 8.44, III, is used under the guy-wire wrap on poles

when a ground wire runs down the pole. The plate will fit over EEI standard 1-in. ground-wire molding and prevent the guy strand from cutting or crushing the ground-wire molding.

An alternative to this method is to connect the guy to a thimble-eye bolt. The straight thimble-eye type (Fig. 8.43, II) is used when guying between a main pole and a stub pole. The angle thimble-eye type (Fig. 8.43, III) is used when guying into the ground. A J bolt (Fig. 8.43, IV) can also be used for attaching a guy wire to a pole, but this requires the use

FIGURE 8.44 Guy plates and shims. [Locke Insulators, Inc., and Hubbard & Co.]

of a thimble (Fig. 8.43, V) in addition to the bolt. A stubbing washer should be used under the nut of the thimble-eye or J bolt. Under the eye of the bolt a stubbing washer (Fig. 8.44, V) is used for a 90° guy and a guy plate of the type shown in Fig. 8.44, IV, for an angle guy. Guying construction is discussed in Sec. 85.

56. When a guy strand is connected to a bolt or rod of smaller diameter, the strand should be wrapped around a thimble (Fig. 8.43, V) to prevent it being cut or broken from too sharp a bend.

57. Guy clamps (Fig. 8.45) are used for securing the ends of guy-wire strands. They are made in two-, three-, and four-bolt types.

FIGURE 8.45 Guy clamp. [Joslyn Mfg. & Supply Co.]

58. Guy protector guards are installed over guy rods, at locations where the guy might be damaged by traffic, to conceal the connection of the guy strand to the eye of the guy rod, to make the guy more visible, and to minimize accidents. They may be made of a wood strip or of steel. One type of guard (Fig. 8.46) consists of a steel plate rolled into cylindrical form, leaving a split on one side. Special clamps are fastened to the strand, and

FIGURE 8.46 Guy-wire protectors. [Line Material Co.]

the guard is slipped over the strand and held by the clamps. The split is turned down toward the ground so that it is not ordinarily noticeable.

59. For guy wire, seven-strand galvanized-steel cable is used. The National Electrical Safety Code recommends that for Grades A and B construction the maximum load in the guy should not exceed 50 percent of the ultimate strength; for grade C construction 75 percent is allowable. The following table gives the strand sizes, weights, and ultimate strength of guy wire:

Diam, in	Approx weight, lb per 1,000 ft	Approx strength, lb	Diam, in	Approx weight, lb per 1,000 ft	Approx strength, lb
$\frac{3}{4}$	1,200	16,700	$\frac{3}{8}$	273	4,250
$\frac{3}{4}$	813	11,600	$\frac{5}{16}$	205	3,200
$\frac{9}{16}$	671	9,600	$\frac{9}{32}$	164	2,570
$\frac{1}{2}$	517	7,400	$\frac{1}{4}$	121	1,900
$\frac{7}{16}$	399	5,700			

POLE-LINE CONSTRUCTION

60. A single crossarm assembly for a two-wire single-phase circuit is shown in Fig. 8.47. Additional insulators for three- or four-wire lines can be added to the arm $14\frac{1}{2}$ in. (368.3 mm) closer to the pole from the insulators shown. This type of arm is used for normal spans and loads when there is a straight line with no obstructions.

FIGURE 8.47 Single crossarm assembly.

61. Double arms are used whenever the stress on the arms is unusually severe or when every precaution is necessary to ensure safety. Double arms are often used on the poles at each side of a street intersection, at each side of railroad crossings, and at corners or other points where the direction of a line changes. Figures 8.48, 8.51, 8.52, 8.70, 8.86, 8.87, 8.89, and 8.90 show examples of double-armed poles. The two crossarms can be separated by wooden spacing blocks (Fig. 8.51), by spacing bolts or double-arming bolts (Fig. 8.48A), or by spacing nipples (Fig. 8.48B).

FIGURE 8.48 Method of arranging double arms.

The spacing blocks can be sawed from a crossarm. An $1\frac{1}{16}$ -in. (17.462-mm) hole bored through the block and crossarm accommodates a $\frac{5}{8}$ -in. bolt. A washer is used under bolt head and nut. Spacing bolts or double-arming bolts can be used instead of spacing blocks (Fig. 8.48A); the bolts are threaded for most of their length. A galvanized-iron pipe nipple (Fig. 8.48B) can also be used to separate the crossarms. A $\frac{3}{4}$ -in. spacing bolt probably provides the preferable and most economical method; spacing blocks rot readily, and the bolts through them corrode rapidly. When an arm guy is to be attached to the crossarm, a double-arming eyebolt can be used as shown. Single-armed poles are now often used, particularly on junction poles, as shown in the accompanying illustrations, in locations where double arms were formerly thought necessary. The single arms are preferable in that they allow greater climbing space for lineworkers.

62. Alley arms (Figs. 8.49 and 8.50) are used in alleys and other locations where it is necessary to clear obstructions by offsetting the crossarm toward one side of the pole. The crossarms will be special arms, but standard material can generally be used for the rest of the construction. Types of standard braces for sidearm construction are discussed in Sec. 40.

FIGURE 8.49 A side-arm pole.

FIGURE 8.50 Bracing for alley arms. [Hubbard & Co.]

FIGURE 8.51 A buck-armed pole, double arms.

Side guys or crib braces (see Fig. 8.49) are used when the line wires are heavy to counteract the tendency of the pole to tip.

63. Reverse or buck arms are used at corners (see Figs. 8.51, 8.52, 8.86, and 8.87). In placing buck arms, ample room must be provided through which a line-worker can reach the top of the pole. A 20-in. (508-mm) square space is the minimum. Crossarm braces on buck-arm poles should be attached to the arms at a point 23 1/2 in. (596.9 mm) from the center of arm instead of at 19 in. (482.6 mm), the standard distance for ordinary framing. The 3/8-in. (9.525-mm) holes for the brace (carriage) bolts must be specially bored, at the above spacing, in buck arms. The 23-in. (584.2-mm) spacing is correct for 28-in. (711.2-mm) braces.

FIGURE 8.52 Junction pole without double arms.

64. A gain is a flat bearing surface on the pole at the point of attachment of the crossarm used so that the crossarm will be rigid. The gain is usually formed by cutting a notch in the side of the pole, as shown in Fig. 8.53. The gaining template of Fig. 8.54 is convenient in laying out the gains. The gain should be exactly the width of the crossarm, ensuring a snug fit. In good work, gains should always be spaced on 24-in. (609.6-mm) centers and should be $\frac{1}{2}$ in. (12.7 mm) deep. Nothing is accomplished by making them deeper. In using the gaining template (Fig. 8.53, II) the point of the “roof” of the template is placed exactly over the point of the roof of the pole and the template is shifted until its centerline (which should be marked thereon) lies exactly under a cord stretched from the roof point to the center of the pole at the groundline. Then the positions of the crossarm gains are indicated by knife scratches made along the sides of the crosspieces on the template.

FIGURE 8.53, I Gains in pole.

FIGURE 8.53, II Use of gaining template.

FIGURE 8.53, III Locating gain with steel square and crossarm.

Note: The tool illustrated above as a Cant-Hook is properly termed a Peavie. A peavie has a spike in the end of its handle, while a cant-hook has no spike.

FIGURE 8.54 Some line-construction tools.

If a gaining template is not available, a crossarm (Fig. 8.53, III) can be laid on the pole with a steel square held against its lower face, the outer edge of the short limb of the square lying at the center of the pole and the center of the crossarm. Rotate the crossarm in a horizontal plane until, by sighting, it is evident that the edge of the square coincides with an imaginary centerline to a nail in the center of the butt at the groundline. Indicate the gain location by knife scratches along the crossarm sides.

65. Metal gains (Fig. 8.55, I) can be used in attaching the crossarm to the pole instead of notching the pole. By spacing the crossarm about 1/2 in. (12.7 mm) away from the pole metal gains allow for complete drainage of water from the joint and prevent rotting of the pole and crossarm. Also, at double-arming locations, the use of metal gains spaces crossarms about 2 in. (50.8 mm) farther apart, which allows more room between the pin insulators on the two arms and more room for tie wires, an important factor on the higher-voltage lines.

FIGURE 8.55 Metal gains. [Hubbard & Co.]

Metal gains are a great convenience when installing an additional crossarm to an existing pole which did not have the gain cut in it. In using metal gains a square washer can be employed under the head of the through bolt (Fig. 8.55, III). A better construction is to use a reinforcing plate (Fig. 8.55, II) located on the outside of the crossarm (Fig. 8.55, IV). This makes for a more rigid construction and helps to prevent checking and splitting of the crossarm at the attachment point.

66. Pole steps (Fig. 8.56, I) can be located on the pole, as shown in Fig. 8.57. A 3/8-in. (9.525-mm) hole 4 in. (101.6 mm) deep is bored for the iron step. It is driven into the hole until it projects 6 in. (152.4 mm) from the pole and is then turned with a wrench until the

FIGURE 8.56, I Pole steps and socket.

FIGURE 8.56, II Detachable pole step. [Joslyn Mfg. & Supply Co.]

FIGURE 8.57 Location of pole steps on pole.

hook end is vertical. The wooden step is held to the pole with one 40-penny and one 20-penny nail or with cut spikes. Often the wooden steps are omitted. The lowest iron step should be at least $6\frac{1}{2}$ ft (2 m) from the ground or other readily accessible place. One wood block (on a private right-of-way, more than one) may be placed on poles carrying communications cables or conductors below supply conductors, but the lowest block is not to be less than $3\frac{1}{2}$ ft (1.1 m) from the ground or other readily accessible place. On poles carrying only communications conductors, additional wood blocks may be used.

Detachable pole steps are available. The one shown in Fig. 8.56, II, slips over the head of the special $\frac{9}{16}$ -by 4-in. lag screw. Turning is prevented by a punched projection. The steps can be removed to prevent unauthorized climbing.

Pole-step sockets (Fig. 8.56, I) are sometimes substituted for the wooden steps. The sockets drive into a $\frac{7}{8}$ -in. (22.225-mm) hole. To climb the pole a lineworker can temporarily insert bolts or similar pieces of metal into the sockets.

67. Secondary racks are mounted on the sides of poles or buildings to carry low-voltage mains, usually of 440 V or less, to locations where building services are tapped off. Figure 8.58, II, illustrates the rack used as a dead end with a head guy to take the tension of the wires. The building service in this case is tapped with open wires. The higher-voltage wires are shown mounted on the crossarm at the top of the pole. Figure 8.58, I, shows two secondary lines crossing; Fig. 8.58, III, shows a corner pole; Fig. 8.58, IV, shows the secondary wires supported on the side of the pole with an open-wire service tap; and Fig. 8.58, V, shows a similar construction with taps to a service cable.

FIGURE 8.58 Ways of using secondary racks.

68. Distribution transformers reduce the primary-line voltage to a low secondary voltage suitable for customers' use. They are mounted on the side of poles or on a platform between poles. Figure 8.59, I, shows such a transformer mounted on special crossarms in the space between the high-voltage wires at the top of the pole and the low-voltage wires on the secondary rack. Taps connect the primary of the transformer, through fuses mounted on the extra crossarm, to the high-voltage wires. The secondary of the transformer is connected directly to the secondary wires at the secondary rack. Attention should be given to making these connections in a neat manner, using right-angle bends and running the several wires of a circuit parallel to each other. Whenever there is a danger of a wire touching another wire or a crossarm or brace or coming too close to a pole, wire-holder insulators (Fig. 8.32) or pin insulators should be installed on the sides of crossarms to keep the connecting wires in their proper position. Figure 8.59, II, shows a similar arrangement when the secondary wires are closer to the primary wires and the transformer must be mounted below the secondary wires. The insulators on the transformer crossarm keep the primary taps at a safe distance from the secondary wires. A compact installation is shown in Fig. 8.59, III. Such an arrangement is quite satisfactory when there are only two primary wires spaced sufficiently far apart to give plenty of climbing and working space. A three-phase bank consisting of three single-phase transformers can be mounted on a platform supported from two poles located fairly close together. This is a common practice for supplying an industrial plant. For three-phase distribution along city streets the three transformers can be mounted singly or adjacent poles, each one similar to Fig. 8.59, I. This practice is preferable when the transformer platform would be conspicuous and unsightly. Additional details for the mounting of transformers are given in Div. 5.

FIGURE 8.59 Mounting and wiring of distribution transformers.

FIGURE 8.60 Location of circuits on a two-arm pole.

69. In locating circuits on poles, the through wires or trunk lines should be carried on the upper crossarms, and the local wires, those which are tapped frequently, should be carried on the lower crossarms. The two or three wires of a circuit should always be carried on adjacent pins. This is of particular importance with ac circuits, as the inductance, and consequently the inductive voltage drop, is increased as the distance between the wires of a circuit is increased. Wires of a circuit should always take the same pin positions on all poles to facilitate trouble hunting. Series circuits which do not operate during the daytime may often be carried on the pole pins of a crossarm. High-tension multiple circuits that are "hot" continuously are well placed at the ends of the arms out of the way of lineworkers. The neutral wire should always be in the center of a three-wire circuit. Figure 8.60 shows one good arrangement on a pole with two four-pin arms.

70. Joint use of poles for circuits of different power companies or for circuits of a power company and a telephone and telegraph company is frequently advantageous if the lines run along the same route (Fig. 8.61). In the rules for location of conductors and clearances, the power company circuits are frequently called simply *supply wires*; the telephone and telegraph company circuits are called *communications wires*. The National Electrical Safety Code provides that when supply circuits of different companies are located on the same pole, the higher-voltage line should be carried at the higher level except that the lines of each company may be grouped together and always carried in the same relative position. For each company the lines of higher voltage should be located in the higher position. Whenever a lower-voltage line is carried above a higher-voltage one, it must be on the opposite side of the pole. A vertical clearance of at least 4 ft (1.2 m) must be maintained between wires of different power companies, and a clearance of 6 ft (1.8 m) must be used if required by the rules of the NESC. Supply wires must be carried above communications wires, except that minor extensions may be made to existing systems which were installed with the communications wires above. Trolley feeder wires may be carried at the approximate level of the trolley wires irrespective of whether that location brings them above or below the communications wires.

FIGURE 8.61 Construction of jointly used wood-pole lines carrying supply circuits and signal circuits, showing arrangement of attachments and clearances. [Hubbard & Co.]

71. Outside wiring as specified by the National Electrical Code. The article on outside wiring applies to electrical equipment and wiring for the supply of utilization equipment located on or attached to the outside of public and private buildings or run between buildings, structures, or poles on other premises served, but it shall not apply to equipment or wiring of an electric or communications utility used in the exercise of its function as a utility.

1. Application of Other Articles Application of other articles, including additional requirements to specific cases of equipment and conductors, is as follows:

Article 200: polarity identification

Article 210: branch circuits

Article 215: feeders

Article 230: services

Article 240: overcurrent protection

Article 250: grounding

Article 310: conductors for general wiring

Article 396: messenger-supported wiring

Article 398: open wiring on insulators

Article 426: fixed electric deicing and snow-melting equipment

Article 490: circuits and equipment operating at more than 600 V

Article 500: hazardous locations—general

Article 510: hazardous locations—specific

Article 550: mobile homes, manufactured homes, and mobile home parks

Article 553: floating buildings

Article 555 marinas and boatyards

Article 600: electric signs and outline lighting

Article 675: electrically driven or controlled irrigation machines

Article 680: swimming pools, fountains, and similar installations

Article 690: solar photovoltaic systems

Article 725: remote-control, signaling, and power-limited circuits

Article 760: fire alarm systems

Article 800: communications circuits and power-limited

Article 810: radio and television circuits

Article 820: community antenna television and radio distribution systems

2. Calculation of Load

a. Branch circuits. The load on every outdoor branch circuit is to be determined by the applicable provisions of Article 220, as given in Div. 3 of this book.

b. Feeders. The load to be expected on every outdoor feeder is to be determined by the procedure specified in Article 220, as given in Div. 3 of this book.

3. Conductor Covering Where within 3 m (10 ft) of any building or structure, other than supporting poles or towers, open individual (aerial) overhead conductors shall be insulated or covered. Conductors in cables or raceways, except Type MI cable, shall be of the rubber-covered or thermoplastic type and in wet locations shall comply with Sec. 310.8. Conductors for festoon lighting shall be of the rubber-covered or thermoplastic type.

Equipment grounding conductors need not be insulated or covered, and grounded circuit conductors need not be insulated or covered where the code specifically permits them to be uninsulated.

- 4. Size of Conductors** The ampacity of outdoor branch circuits and feeder conductors shall be according to the rating in Tables 18 to 21 of Div. 12 based on the loads as determined under Article 220.

5. Conductor Size and Support

a. Overhead spans. Overhead conductors shall not be smaller than No. 10 copper or No. 8 aluminum for spans up to 15 m (50 ft) in length and not smaller than No. 8 copper or No. 6 aluminum for longer spans.

b. Festoon lighting. Overhead conductors for festoon lighting shall not be smaller than No. 12 unless supported by messenger wires. In all spans exceeding 12 m (40 ft) the conductors shall be supported by messenger wire secured with strain insulators (Sec. 51). Festoon lighting, including both the circuit conductors and the messenger wire if applicable, must not be attached to a fire escape, downspout, or other plumbing equipment.

Definition. Festoon lighting is a string of outdoor lights suspended between two points.

c. Over 600 V. Overhead conductors operating at more than 600 V shall not be smaller than No. 6 copper or No. 4 aluminum where open individual conductors or smaller than No. 8 copper or No. 6 aluminum where in cable.

6. Lighting Equipment Installed Outdoors

a. For the supply of lighting equipment installed outdoors, the branch circuits shall comply with the requirements of Article 210 and Pars. *b* and *c* below.

b. A common neutral may be used for multiple ungrounded circuit conductors. The ampacity of the neutral conductor shall be not less than the calculated sum of the currents in all ungrounded conductors connected to any one phase of the circuit.

c. 277 V to ground may be used to supply luminaires (lighting fixtures) for illumination of outdoor areas of industrial establishments, office buildings, schools, stores, and other commercial or public buildings where a 900 mm (3 ft) clearance to windows, platforms, fire escapes, and the like is maintained.

d. Branch circuits exceeding 277 V for permanently installed luminaires shall be permitted to supply the auxiliary equipment of electric-discharge lamps for area illumination, provided they operate at not more than 600 V between conductors. The luminaires must be at least 6.7 m (22 ft) high on poles, or at least 5.5 m (18 ft) high on other structures such as tunnels.

- 7. Wiring on Buildings** Outside wiring on surfaces of buildings may be installed for circuits when not in excess of 600 V as open conductors on insulating supports, as multi-conductor cable, including UF, MC, or MI cable, as messenger supported wiring, in rigid metal conduit, in intermediate metal conduit, in rigid nonmetallic conduit, in cable trays, as cablebus, in wireways, in auxiliary gutters, in flexible metal conduit, in liquidtight flexible metal conduits, in liquidtight flexible nonmetallic conduit, in busways, or in electrical metallic tubing. Circuits of more than 600 V shall be installed as provided for services in Sec. 300.37. Circuits for signs and outline lighting shall be installed as provided in Article 600.

- 8. Circuit Exits and Entrances** Where outside branch and feeder circuits exit from or enter buildings, the installation shall comply with the requirements of Secs. 230.52 and 230.54 which apply to service-entrance conductors.

- 9. Open-Conductor Supports** Open conductors shall be supported on glass or porcelain knobs, racks, brackets, or strain insulators.

- 10. Open-Conductor Spacings** Conductors shall conform to the following spacings:
- Open conductors exposed to weather.* 600 V or less, as provided in Table 230.51(C).
 - Over 600 V.* As provided in Sec. 110.36 and 490.24.
 - Separation from other circuits.* Open conductors shall be separated from open conductors of other circuits or systems by not less than 100 mm (4 in.).
 - Conductors on poles.* Conductors on poles shall have a separation of not less than 300 mm (1 ft) where not placed on racks or brackets. Conductors supported on poles shall provide a horizontal climbing space not less than the following:

Power conductors, below communications conductors	750 mm (30 in.)
Power conductors alone or above communications conductors:	
300 V or less	600 mm (24 in.)
Over 300 V	750 mm (30 in.)
Communications conductors below power conductors	Same as power conductors
Communications conductors alone	No requirement
- 11. Supports over Buildings** See Sec. 230.29.
- 12. Point of Attachment to Buildings** See Sec. 230.26.
- 13. Means of Attachment to Buildings** See Sec. 230.27.
- 14. Masts as Supports** Masts must have sufficient rigidity to handle the strain, or they must be guyed accordingly. If a raceway mast is used, any fittings must be identified for use with masts, and only the feeder and branch-circuit conductors within the scope of Article 225 can be attached to the mast. For example, a telephone drop is not permitted to be attached to a power circuit mast, regardless of the strength of the raceway or the amount of guy wire support provided.
- 15. Clearance from Ground** Overhead spans of open conductors and open multiconductor cables of not over 600 V shall conform to the following:
- 3.0 m (10 ft): above finished grade, sidewalks, or any platform or projection from which they might be reached where the supply conductors are limited to 150 V to ground and accessible to pedestrians only
 - 3.7 m (12 ft): over residential property and driveways and those commercial areas not subject to truck traffic where the voltage is limited to 300 V to ground
 - 4.5 m (15 ft): for those areas listed in the 3.7 m (12 ft) classification where the voltage exceeds 300 V to ground
 - 5.5 m (18 ft): over public streets, alleys, roads, parking areas subject to truck traffic, driveways on other than residential property, and other land traversed by vehicles such as cultivated, grazing, forest, and orchard land
- 16. Clearances Over Buildings for Conductors Not in Excess of 600 V** See Sec. 225.19 of the NEC.
- 17. Mechanical Protection of Conductors** Mechanical protection of conductors on buildings, structures, or poles shall be as provided for services (Sec. 230.50).
- 18. Multiconductor Cables on Exterior Surfaces of Buildings** Multiconductor cables on exterior surfaces of buildings shall be as provided for service cable (Sec. 230.51).
- 19. Raceways on Exterior Surfaces of Buildings** Raceways on exterior surfaces of buildings shall be arranged to drain and shall be made raintight in wet locations.
- 20. Underground Circuits** Underground circuits shall meet the requirements of Sec. 300.5.
- 21. Outdoor Lighting Equipment: Lampholders** Where lampholders are attached as pendants, they shall have the connections to the circuit wires staggered. If lampholders

have terminals of a type that puncture the insulation and make contact with the conductors, they shall be attached only to conductors of the stranded type.

22. **Outdoor Lighting Equipment: Location of Lamps** Location of lamps for outdoor lighting shall be below all energized conductors, transformers, or other electrical equipment, unless clearances or other safeguards are provided for relamping operations or unless the installation is controlled by a disconnecting means which can be locked in the open position.
23. **Vegetation as Support.** Vegetation, including trees, must not be used to support overhead conductor spans.
24. **More than One Building or Other Structure** Part II of NEC Article 225 provides the requirements covering the supply of one building or structure from another. The majority of the requirements are the same as for service entrances, as covered in Div. 9, Secs. 346 to 356. This part will, therefore, only cover the differences. The principal general difference is that wiring from one building to another, although superficially like service wiring, is not service wiring. A service entrance is the interface between premises wiring and the facilities of the serving utility. It is also the interface between wiring governed by the National Electrical Safety Code (NESC) and premises wiring governed by the National Electrical Code. These codes are very different because the NESC presumes that the maintenance of those systems will be performed by a highly regulated utility workforce operating under a unique workplace culture and environment, and that this will continue for the foreseeable future, given the organizational permanence of utility enterprises. If there is no utility interface, then there is no service. For this reason, it is incorrect to label the disconnecting means for one building fed from another as a “service” disconnect when it is actually a “building” disconnect. Specific differences are as follows:
 - a. Only one source of supply is permitted as a general rule. This is the same general rule as for services, but there are subtle differences. The permission to run multiple service laterals from a common connection to disconnected loads does not apply. The allowance for multiple supplies where the capacity requirement exceeds that which the local utility supplies through one service does not apply for obvious reasons, and the allowance for an exemption on capacity grounds by special permission does not apply either. The final difference is the permission, granted here and not for services, for additional supplies where there are “documented switching procedures” in place for safe disconnection. This normally arises on large, campus-style industrial distributions.
 - b. The six-disconnect rule is almost the same, but in this application, disconnects for surge-protective equipment and power monitoring equipment are not exempted from the allowable total of six. The access requirements, the grouping requirement, the requirement to segregate disconnects for certain critical systems, and the specification of minimum ratings for certain applications are the same as well.
 - c. For services, the allowable distance between a disconnect located outside the building and the point where the conductors enter the building is unspecified, whereas in this part of the code any disconnect, inside or outside, must be at a readily accessible location nearest the point of conductor entry. It is intended that a detached outdoor service disconnect be considered a structure, and if so considered, then the building served ends up in this part of the code and there is no net difference. However, not all building officials will classify a stand-alone service pedestal as a structure, so this will require local interpretation. Inside disconnects follow the same rules, although service disconnects must not be located in bathrooms, which is not a condition placed on building disconnects. Building disconnects also have exceptions that do not apply to service disconnect locations. They have a documented safe switching procedure allowance to place the disconnect at another location, under the same conditions as for additional sources of supply. Buildings qualifying under NEC

Article 685 for integrated electrical systems can relocate the disconnect. Signs and light poles outside need not have local disconnects either.

- d. The rules regarding how the disconnecting means are to be constructed (including the simultaneous opening of poles, the special provisions for a grounded circuit conductor, the method of operation, and the indication requirement) are all the same. However, a building disconnect for a residential outbuilding may use a snap switch as a disconnecting means; this is not permitted for a service entrance for obvious reasons.

25. Over 600 V Part III of NEC Article 225 covers medium voltage supply wiring (over 600 V). Most of this part, as in the case of Part II, matches up with the equivalent requirements for services, and only the differences will be covered here.

- a. Since circuits originating in other buildings will necessarily be either feeders or branch circuits, and not service conductors, they will have overcurrent protection at their supply ends and need simply be sized for the load according to the procedures for comparable circuits set out in the NEC articles covering branch circuits and feeders. Medium voltage service disconnects are often pole-top devices at the edge of a property, and less amenable to a readily access than a building disconnect. The requirements for isolating switches, the construction details of the disconnecting means, and the allowances for remote control operation are the same as for services.
- b. Medium-voltage feeders and branch circuits run overhead need to meet enhanced clearances reflecting the increased hazard involved for circuits operating over 600 V. These conductors must be installed so that they are at least 2.3 m (7.5 ft) away (horizontally separated) from building walls, projections, and windows. They must observe the same horizontal spacing from balconies, catwalks, and similar areas that people would have access to, and the same distance applies to other structures.

The same conductors must be at least 3.8 m (12.5 ft) either above a roof or below a roof (or other projection) where run at that level. For roofs accessible to vehicles (but not truck traffic) such as parking garages, the vertical clearance rises to 4.1 m (13.5 ft), 5.6 m (18.5 ft) if truck traffic uses the roof. Clearances over open ground vary by the type of traffic as well, beginning at 4.1 m (12.5 ft) for walkways and then rising a foot to 4.4 m (14.5 ft) for pedestrian ways and restricted traffic. Water areas not suitable for boating come in at 5.2 m (17 ft) and then open land suitable for grazing, cultivation or vehicles, along with ways subject to vehicular access generally, including roads, driveways, alleys and parking lots, all at 5.6 m (18.5 ft). The highest prescribed clearance, 8.1 m (26.5 ft) applies to runs over railways. These clearances all apply to medium voltages up to and including 22 kV *measured to ground*. Higher voltages add 10 mm (0.4 in.) per kV above 22 kV, and special cases, including clearances over navigable waters and areas with large vehicles such as mining operations may require special engineering and review by the authority having jurisdiction.

72. Tying in wires. Normally the wires should rest in the insulator grooves as shown in Fig. 8.62A, but if there is a side stress, the wires should be so arranged that the pull comes against the insulators rather than away from them (Fig. 8.62B).

FIGURE 8.62 Positions of wire in insulator grooves.

A single tie for the smaller wires is shown in Fig. 8.63, I, and a back tie for the larger wires is shown in II. The single tie wire is about 12 in. (304.8 mm) long, and the back tie about 18 in. (457.2 mm) long. The back tie is made as follows. Bend the tie around the insulator under the line wire, with 4 in. (101.6 mm) on one side of the insulator and the balance on the other side. Wrap the short end 3 times around the line wire, leaving a space equal to the diameter of the tie wire between successive wraps. Now wrap the long end of the wire 3 times completely around the line wire, then back around the insulator, and wrap it in the spaces left between the wraps of the other end of the tie wire. Refer to Fig. 8.63 for instructions regarding cutting of tie wires.

FIGURE 8.63 Methods of tying. Preferably the tie wires should not be cut off flush as shown above. Instead, their ends should be permitted to stick out or to lie along the line wires. This procedure facilitates their removal.

73. Different types of insulator ties which have been standardized by a western power company are shown in Fig. 8.64 and Table 74. The company uses medium-hard-drawn line wire. Although good ties can be made with a medium-hard-drawn weatherproof tie on a weatherproof line wire, medium-hard-drawn ties are not desirable on bare wires, as the bending radius is too small for these stiff wires. Hence, annealed bare-wire ties are used for bare line wires. Annealed ties can be cut from purchased annealed copper. Do not use a tie wire twice, as, after once being bent and strained, it will be brittle. The following table of sizes has been recommended for ordinary stresses. For very heavy stresses heavier tie wires should be used.

Line wire, size	Tie wire, size	Kind of tie	Line wire, size	Tie wire, size	Kind of tie
6	6	Single	1	4	Back
4	6	Single	2/0 and larger	2	Back
2	4	Single			

FIGURE 8.64 Ties of the different types used in ordinary distribution systems (see Table 74).

Tie wire should usually have the same kind of insulation as the line wire which it confines. The National Electrical Code requires this on indoor work, and it is also a good practice on outdoor work.

74. Types of Insulator Ties for Different Services

Size of line wire, gauge or in	Insulator	Top or side	Tie material	Tie length, in	Type of tie	Fig. 8.64
Copper						
6 or 4 WP	DGDP	Side	6 WP mhd	25	Western Union	I
2 WP	DGDP	Side	4 WP mhd	27	Western Union	I
1/0 to 4/0 WP	Cable	Top	4 WP mhd	36	Crosstop	II
1/0 to 4/0 WP	Cable	Side	4 WP mhd	30	Western Union	I
6 or 4 bare	DGDP	Side	6 bare annealed	27	Double	III
6 or 4 bare	11 kV	Top	6 bare annealed	40	High-tension	IV
2 bare	11 kV	Top	4 bare annealed	40	High-tension	IV
1/0 to 4/0 bare	11 kV	Top	2 bare annealed	44	High-tension	IV
6 to 4 bare	11 kV	Side	6 bare annealed	40	Looped WU	V
2 bare	11 kV	Side	4 bare annealed	40	Looped WU	V
1/0 to 4/0 bare	11 kV	Side	2 bare annealed	48	Looped WU	V
Steel						
1/4 and 5/16	DGDP	Side	1 strand, 5/16 in	27	Double	III
1/4 and 5/16	11 kV	Top	1 strand, 5/16 in	44	High-tension	IV
3/8	11 kV	Top	1 strand, 3/8 in	44	High-tension	IV
1/4 and 5/16	11 kV	Side	1 strand, 5/16 in	48	Looped WU	V
3/8	11 kV	Side	1 strand, 3/8 in	48	Looped WU	V

75. The bare tie wires for uninsulated line wires should always be of the same metal as the line wire. If dissimilar metals are employed, electrolytic corrosion and a consequent weakening and possible breakage of the line wire at the tying point may result. That is, bare copper wires should always be used on bare copper line wires and galvanized-iron tie wires on galvanized-iron line wires.

76. In making up line-wire ties, the tie wire should not be drawn too tightly around the line wire. The tendency of the beginner is to do this, with the result that the line wire is weakened and will probably sever when it is first subjected to an unusual stress such as that which is likely to occur when a low temperature prevails.

77. In making ties on ACSR wire (see Div. 2), the conductor must first be reinforced by wrapping with armor rods twisted around the conductor with the aid of two special wrenches.

Armor rods are shipped in sets (bundles) with the ends taped and with the center marked. Remove the tape from one end of the set and thread the rods through the two armor-rod wrenches, making sure that both the wrenches open between the *same two rods*. Leaving the set taped at one end keeps the rods from sliding while the assembly is being sent aloft and keeps ends even while making the first twist.

Center the armor rods on the conductor over the point of support. Open the wrenches and then close them with the rods around the conductor (Fig. 8.65, I). Shift the wrenches on the rods to such a position that the middle third of the armor rods will be twisted with the first turn of the wrenches. Rotate the wrenches counterclockwise to make the lay of the rods in the *same direction* as the lay of the cable. Twist the rods to give them a permanent set, so that the wrenches do not tend to spring back. After twisting the middle third, cut the remaining tape and slide the wrenches halfway to the ends. Turn the wrenches and twist the rods as before. Finally slide the wrenches as close as possible to the ends, twisting this last section the same as for previous settings.

I-Initial step. Wrenches ready to be closed around conductor leaving one end of rods taped.

II-Final step. Wrench in final position ready for application of second V-bolt clip.

FIGURE 8.65 Installing armor rods at insulator support for ACSR wire. [Aluminum Co. of America]

The rods should be twisted snugly with a smooth lay. If they are twisted too tightly, there is a tendency to force one or more rods out of the layer, and the rods will stand away from the cable so that the assembly can be slipped along the conductor before the armor-rod clips are applied. There is a stopping point, which can be felt after a little practice.

The armor-rod (V-bolt) should be applied about 1½ in. (38.1 mm) from the ends of the assembly, which can best be accomplished by installing and tightening the V bolts while the armor-rod wrenches are still in their final twisting position (Fig. 8.65, II). This procedure leaves the ends of the rods slightly flared away from the conductor. If the wrenches are removed prior to tightening the armor-rod clips, the ends of the rods may have to be flared as a separate operation.

After installation of the armor rods the ties are made as shown in Fig. 8.66. Figure 8.66, I, shows a stop tie with the conductor on top of the insulator, and Fig. 8.66, II, shows the conductor tied on the side groove of the insulator. Above each view is shown a sketch of the manner in which the tie wire is wrapped and looped.

I-Double top tie

II-Side tie

FIGURE 8.66 Ties for ACSR wire. [Aluminum Co. of America]

78. For ties on Copperweld wire use annealed-copper tie wires of the size given in the following table as recommended by the Copperweld Corp.

Size of conductor	Size of* tie wire	Length of tie wire [†]	
		Top tie	Side tie
3-Win stranded conductor			
3 No. 6 AWG	6 AWG	54 in	60 in
3 No. 7 AWG	6 AWG	52 in	58 in
3 No. 8 AWG	6 AWG	50 in	56 in
3 No. 9 AWG	6 AWG	48 in	54 in
3 No. 10 AWG	8 AWG	44 in	50 in
3 No. 12 AWG	8 AWG	44 in	50 in
Type F Copperweld-copper conductors			
1/0F	6 AWG	56 in	62 in
1F	6 AWG	54 in	60 in
2F	6 AWG	54 in	60 in
Copperweld-copper 3-wire stranded conductors			
2A	6 AWG	56 in	62 in
3A	6 AWG	54 in	60 in
4A	6 AWG	52 in	58 in
5A	6 AWG	50 in	56 in
6A	8 AWG	46 in	52 in
7A	8 AWG	44 in	50 in
8A	8 AWG	44 in	50 in
8C	8 AWG	44 in	50 in
8D	8 AWG	44 in	50 in
9½D	8 AWG	44 in	50 in

*Sizes listed apply to annealed copper tie wires. When using annealed Copperweld for tie wire, size should be two gage sizes smaller than listed for annealed copper.

[†]Included 4 in. additional length on each end for convenience in applying tie.

For top ties on Copperweld wire, the type shown in Fig. 8.67B is recommended. For side ties, the one shown in Fig. 8.67A with three loops around the insulator is used.

Notes on Tying Practice

1. Use only fully annealed tie wire.
2. Use a size of tie wire which can be readily handled, yet one which will provide adequate strength.
3. Use a length of tie wire sufficient for making the complete tie, including an end allowance for gripping with the hands. The extra length should be cut from each end after the tie is completed.
4. A good tie should
 - a. Provide a secure binding between line wire, insulator, and tie wire
 - b. Have positive contacts between line wire and tie wire to avoid any chafing contacts
 - c. Reinforce line wire in the vicinity of insulator.

I. Bend tie wire around insulator above conductor to form a U. The two legs of the tie wire should be of equal length after bending.

II. Holding the tie wire tightly against the insulator, throw two tight close wraps around conductor on each side of the insulator; then cross legs of tie wire around insulator.

III. Finish in same way as top tie with six tight 45° spiral wraps on each side of the insulator. Bend back ends and cut off extra length of tie wire close to conductor.

FIGURE 8.67A Side tie for Copperweld wire. [Copperweld Corp.]

I. Bend annealed tie wire of proper size and length around insulator under the conductor, forming a U. Both legs of tie wire should be of equal length after bending.

II. Holding the tie wire tightly against the insulator, throw two tight close wraps around the conductor on each side of the insulator, keeping these wraps snugly against the insulator.

III. Cross the legs of the tie wire around the insulator, right to left and left to right.

IV. With both legs of the tie wire crossed, tightly wrap each leg spirally around the conductor at an angle of 45°.

FIGURE 8.67B Top tie for Copperweld wire. [Copperweld Corp.]

V. Complete six spiral 45° wraps on each side of the insulator, bending back the ends and cutting them off short.

FIGURE 8.67B (Continued)

VI. The finished top tie when made properly and tightly will greatly reduce any possibility of the conductor's chafing at the insulator.

5. The ties illustrated can and should be applied without the use of pliers.
6. Avoid nicking the line wire.
7. Do not use a tie wire which has been previously used.
8. Do not use hard-drawn wires for tying or fire-burned wire, which is usually either only partially annealed or injured by overheating.
9. Careful workmanship is essential.

On secondary rack

FIGURE 8.68 Low-voltage dead ends. [Hubbard & Co.]

79. For dead-ending of line wires at the end of a run or at corners, various types of construction may be used. For low-voltage, secondary rack construction, a rack may be located on the front of the pole and the tension taken by bolts through the pole (Fig. 8.68). The wires are looped around the rack insulators, and the end of the wire is wrapped around the line conductor. Other low-voltage dead ends may be made up as in Fig. 8.69. In many current installations a single-wire bracket, similar to the one shown in Fig. 8.69, I, is used to attach triplex or fourplex cables, consisting of two or three insulated cables which are spiral-wrapped around a bare messenger wire (usually the neutral of the supply). For heavier loads a low-voltage dead end on a crossarm can be made by using a strain insulator, as shown in Fig. 8.70, I. For higher voltages one or more suspension insulators with a clamp to grip the conductor, as shown in Fig. 8.70, II and III, can be used. Instead of the conductor clamp, the conductor can be looped around a dead-end thimble (Fig. 8.71).

80. When wires are carried through trees so that they would rub against branches, special tree wire (Fig. 8.72, I) should be used. However, wires through trees should be avoided if at all possible. Tree wire has a tougher insulation which will resist abrasion from the branches better than weatherproof wire. If the tree branches are more or less continuous, tree wire should be used exclusively. If there is a span or more of clearing, it will be economical to splice in weatherproof wire to run through the clear space. For especially severe conditions a length of tree-wire molding (Fig. 8.72, II, III, and IV) should be added to the wire where the wire passes close to heavy limbs or tree trunks. In some

FIGURE 8.72 Tree wiring. [The Okonite Co.]

cases a tree insulator (Fig. 8.73) can be screwed to the limb or trunk of the tree. This insulator has a removable pin, and roller (Fig. 8.73) can be screwed to the limb or trunk of the tree. This insulator has a removable pin and roller (Fig. 8.73, II) so that the wire can be inserted without cutting and the pin replaced. The roller allows the wire to move freely without being cut. Wires should never be attached rigidly to trees because the swaying of the tree might break the wires.

FIGURE 8.73 Tree insulator. [Line Material Co.]

81. Wire and wire sizes for electric light and power lines. No wire smaller than No. 6 is used in good construction for line wire. No. 8 is sometimes used for services not more than 75 ft (22.9 m) long that do not cross a street. Solid wires are often used for sizes up to and including No. 2/0, and cable (stranded wire) is used for larger conductors. Triple-braid weatherproof is the standard insulation of aerial line wires. Annealed or soft-drawn wire is preferable to hard-drawn for services and secondary distribution lines because it is more readily handled and, in the sizes used, has ample tensile strength. Hard-drawn copper wire or steel-reinforced aluminum cable is preferable for transmission lines and feeders.

82. Stringing wire. There are two methods, the choice depending on local conditions and the size and length of the circuit. By one method a reel of wire is set at one end of the line and a rope carried 1500 or 2000 ft (457 or 610 m) over the crossarms and attached to the wire, which is then drawn over the arms. The other way is to place the reel on a cart, and after the end of the wire has been secured to the last pole, the cart is started and the wire paid out till the second pole is reached, and then the wire is hoisted up and laid on the arm. Wire should always be paid out from the coil, the coil revolving, so that the wire will not be twisted. If wire is not received on reels, it should be placed on them before paying out.

POLE-LINE GUYING

83. Guying. Probably there are not so many guys on pole lines as there should be to ensure continuity of service and minimum maintenance expense. Lines should be guyed not for normal conditions but for the more severe conditions that are apt to obtain. The guys should be frequent and heavy enough to sustain the line after the heaviest snowstorm or during the worst possible windstorm. A guy should be used on every pole where the tension of the wires tends to pull the pole from its normal position.

Terminal poles should always be head-guyed, and on lines carrying three or more crossarms the two poles next to the terminal pole should also be head-guyed to distribute the stress.

Line guys are installed on straight pole lines to reinforce them against the excess stresses introduced by storms. It is a good practice to install head line guys, as shown in Fig. 8.74, at about every twentieth pole. This recommendation applies only to lines carrying more than one crossarm.

FIGURE 8.74 Line guys.

The installation of additional side guys, arranged at right angles to the line, to trees, stubs, or anchors is recommended. The side guys are attached to the same pole as the head guys.

Side guys should be installed at curves, the guys taking the direction of radii of the curves. Figure 8.5 shows a table that gives the number of side guys required for a given line with a given *pull*. The pull is the distance from the pole to a line joining two points in the line 100 ft (30.5 m) on either side of the pole (see Fig. 8.5).

FIGURE 8.75 Head-guy locations.

Poles on either side of a long span should be head-guyed as shown in Fig. 8.75, I.

Lines on steep hills should be guyed as shown in Fig. 8.75, II, with head guys.

Poles at each side of a railroad crossing, important highway crossing, or a crossing over another wire line should be head-guyed away from the crossing as in Fig. 8.75, I.

Guy wires should be kept more than 8 ft (2.4 m) from the ground where possible to prevent persons from making accidental contact with them. A clearance of at least 3 ft (0.9 m) should be maintained between guys and electric wires; otherwise changes in temperature may cause the wires to come in contact.

84. A guy assembly consists of the following parts:

1. Attachment to pole being guyed
2. Guy wire containing one or two strain insulators
3. Attachment to stub pole or to lower part of another pole or ground anchor, anchor rod, attachment of strand, and guard.

85. Some of the methods making up a guy on a pole are shown in Fig. 8.76. The method of Fig. 8.76, I, is easy when some of the other materials are not at hand. The methods of Fig. 8.76, II and III, make a neater-looking job when the hardware is available. The method of Fig. 8.76, IV, is used at a stub pole. Refer to Sec. 55 for a discussion of the hardware required. When there is only one guy per pole, it is made around the pole just under the top crossarm as shown in Figs. 8.77 and 8.78. If there are two guys to the pole, one is made up just under the top crossarm and one just under the bottom crossarm. If more than two guys are used, the additional ones should be spaced as equally as possible between the top and bottom guys that are made up under the top and bottom crossarms, respectively. If there are two or more guys to a pole, each should be independent of the others. The different guy wires should not cross one another. If two or more guys support a pole, a turnbuckle should be inserted in all but one to equalize the stresses.

86. Guy-wire insulation. Strain insulators should be inserted in all guy wires to poles carrying electric lighting or power wires. Two insulators should be inserted in each guy. One is located at least 6 ft (1.8 m) from the pole itself or 6 ft below the lowest line wire. The other is located at least 6 ft from the lower end of the guy and at least

FIGURE 8.76 Methods of attaching guys to pole. [General Electric Co.]

FIGURE 8.77 An anchor-guyed pole.

FIGURE 8.78 Poles guyed to stubs.

FIGURE 8.79 Method of making up a strain insulator in a guy strand. [Hubbard & Co.]

8 ft (2.4 m) from the ground. The two strain insulators are sometimes coupled in series in short guys.

The assembly makeup of a strain insulator for a guy is shown in Fig. 8.79. The two ends of the guy strand are looped through the separate holes in the insulator. The guy-wire clamps hold the wire from slipping, and the No. 12 wrapping wire secures the end of the strand to the guy wire and provides a neat appearance for the assembly. Suitable clamps can be used in lieu of the No. 12 wrapping wire at guy-wire ends.

87. The number and size of clamps to use for each looped-back connection on a guy strand are as follows:

Breaking strength of guy strand, lb	No. of clamps	Type of clamp	Breaking strength of guy strand, lb	No. of clamps	Type of clamp
4,000	1	Two bolt	10,000	2	Three bolt
6,000	1	Three bolt	16,000	3	Three bolt

88. The attachment of the guy strand to the anchor rod is shown in Fig. 8.80. Refer to Sec. 54 and Fig. 8.42 for description of anchor rods. The eye of the guy rod should extend about 3 ft (0.9 m) above the surface of the earth. Guy rods should not be installed where they will interfere with traffic. A guy protector guard (see Sec. 58) extending to about 8 ft (2.4 m) above the ground should be placed over anchor guy wires near roadways, as shown in Fig. 8.78. The foot of an anchor guy should be as far away

FIGURE 8.80 Methods of making up guys on guy rods.

from the foot of the pole as possible—at least a distance equal to one-fourth the height of the pole.

89. Anchors can be made from logs cut from the tops of old poles (Fig. 8.81), or patented metal or concrete anchors can be used. Figure 8.82 shows a variety of modern guy anchors which provide an effective support for guy rods. Table 90 gives the minimum size for anchor logs and rods and the depth of setting for anchors.

FIGURE 8.81 A guy rod and anchor.

PLATE ANCHORS are used for general anchoring; are made of malleable iron or steel plates. They provide excellent holding power because pull is against undisturbed earth.

EXPANDING ANCHORS are used for general anchoring. Size of anchors in folded position ranges from 6 to 12 in. dia. Expanded sizes range from 50 to 300 sq. in.

KEY ANCHORS, sometimes called pole keys, are used where standard guying is impossible because of sidewalks, property restrictions, etc. Additional keying is necessary at ground level.

SCREW TYPE ANCHORS can be selected for general anchoring in gravel, sand, clay, fill, silt, and with extension, swamp soils. The corkscrew-like blade is made of drop-forged steel. No anchor hole is required; anchor is screwed into the ground with a wrench or bar.

ROCK ANCHORS are used for anchoring in rock, rocky soil or masonry. The expanding rock anchor is made of malleable iron, develops tremendous holding power through a wedging self-action.

CONE ANCHORS are made of steel and are used in bed rock, laminated rock, slate, sandstone, shale, hardpan, gravel, and medium-firm clay. Sizes range from 6 to 23 in. dia. It develops adequate holding power in class 2 soil through wedging action.

FIGURE 8.82 Types of modern guy anchors.

90. Size of Anchor Logs and Depth of Setting for Anchors

Size and number of guys	Min size of round logs for good soil	Length of rod below ground, ft	Size of guy rod
One No. 6 wire or one 4,000 lb	3 ft × 6 in	4	7 ft × 1/2 in
One 6,000 lb	3 ft × 7 in	4 1/2	8 ft × 5/8 in
One 10,000 lb	4 ft × 8 in	5 1/2	9 ft × 3/4 in
One 16,000 lb	5 ft × 10 in	6 1/2	10 ft × 1 in
Two 6,000 lb	5 ft × 8 in	5 1/2	9 ft × 1 in
Two 10,000 lb	6 ft × 10 in	6 or 6 1/2	10 ft × 1 1/4 in
Two 16,000 lb	6 ft × 12 in	6 1/2 or 7	11 ft × 1 1/2 in

For the depth and holding strength of patented anchors, the catalogs of the particular manufacturer must be consulted.

91. Patented guy anchors can be used in certain kinds of soil very effectively. Figure 8.83 shows one kind of anchor that is screwed into the earth with a wrench. The resistance of this sort of anchor to withdrawal from compact homogeneous soils is not determined by the weight of a column of earth the diameter of the anchor screw, but is determined by that of a cone with sides slating at 45° and having the point of the anchor as an apex. Figure 8.84 illustrates this and shows the formula used for computing the withdrawal resistance. Figure 8.84 shows the anchor inserted perpendicularly, but an anchor should always be inserted at the same angle that the guy wire assumes so that the rod of the

FIGURE 8.83 Matthews Scrulix anchors and wrenches.

FIGURE 8.84 Carpenter's formula for resistance of Matthews anchor to withdrawal.

anchor will be in a direct line with the guy wire. Section 92 gives the actual resistances to withdrawal of the anchors.

92. The actual holding power of patented guy anchors is an uncertain quantity, except in hard clays (adobe, hardpan, or gumbo) for which Carpenter's formula (Fig. 8.84) can be used. The safest procedure is to test the anchor's resistance to withdraw in the soil in which it is to be used. A dynamometer can be employed for measuring the pull. Anchor manufacturers will gladly ship anchors on approval for test and 30 days' trial. In general, the 5-in Matthews Scrulix anchor (Fig. 8.83) should, in other than the hard clays, be used only for the lightest strains, say 1100 to 2500 lb, the 6-in. for 1500 to 2500 lb, the 7-in. for 2500 to 5000 lb, the 8-in. for 5000 to 7000 lb, the 10-in. for 7000 to 10,000 lb, and the 12-in. for 10,000 to 12,000 lb. These holding powers are based on the anchor being screwed into the earth for a depth of at least 5 ft (1.5 m). For anchorages under shallow strands of water or in swampy or caving ground, the 8-, 10-, and 12-in. anchors having the square rods are very convenient.

93. Directions for Installing Matthews Guy Anchors

5-, 6-, 7-, and 8-in. with Rods Remove the eye of the anchor; pass the rod through the wrench and replace the eye, which will serve to hold the wrench rigidly to the anchor; then screw the anchor in, at the same angle as the guy wire is to run, as far as ground conditions will permit. When it is in as far as possible, remove the eye and pull out the wrench. Then replace the eye, thus making anchor ready for guy wires. The handlebars of the wrench are adjustable and held in place with a setscrew. They can be moved back as the anchor screws in.

8-, 10-, 12-in. with Rods Place bar or other lever in eye of anchor and screw it in as far as ground conditions will permit, always at the angle that the guy wire is to run. Time will be saved and the anchor start more easily if a few spadefuls of earth are removed before starting anchor. When the anchor is set, attach the guy strand to the eye. Always pull anchor back as far as possible before finally tying the guy wire.

In Dry, Hard Ground In setting all anchors in hard ground, the work will be much easier if a small hole is first made with an earth auger (Fig. 8.83), a crowbar, or a wood auger with a long shank. This renders the insertion of the anchor easier. A little water poured down this hole before starting the anchor will help considerably if the ground is hard and dry. In installing 8-, 10-, and 12-in. anchors in very hard ground, clamp a lever to the rod by means of a chain a foot or so above the ground. As the anchor is screwed down, the lever can be moved up. The anchor will start more easily if a few spadefuls of earth are removed at the angle desired to set the guy. If someone stands on the helix of the anchor when starting until the point bites the ground, it will be helpful.

In localities where loose gravel or small flat rock occurs, drill a hole with an earth auger, a digging bar, or a crowbar as suggested above. If a small rock is encountered, it can be broken by the bar. If a large rock is "discovered," the bar can be removed and the hole drilled in another place. This will allow the use of anchors in many places where otherwise it would seem impossible to install them.

94. The methods of installing stub guys are shown in Fig. 8.78. The stubs should be long enough so that the guy wires will clear roadways by at least 18 ft (5.5 m), sidewalks by 15 ft (4.6 m), and electric wires by 3 ft (0.9 m). Stubs are used only when a line cannot be guyed properly to trees or poles. Stubs should satisfy the specification for poles as given in Sec. 8.

95. In guying to a tree, tree blocks (Fig. 8.85) should be used, and the wire should pass only once around the tree. Tree guying is undesirable and should not be done unless absolutely necessary. Guys should preferably be attached to trunks or to limbs that are not less than 8 in. (203 mm) in diameter. Do not attach a guy wire to a limb that will swing with the wind and sway the pole. Enough tree blocks should be used so that the guy wire cannot touch the tree.

96. Crossarm guys are used when the pull on a crossarm is unbalanced. Figures 8.48, 8.86, and 8.87 show examples. Crossarm guys usually extend from the arm to a pole or stub, but sometimes for light strains the Y, or bridle, guy (Fig. 8.88) is used.

FIGURE 8.85-I Details of tree blocks.

FIGURE 8.85-II Guy wire fastened to tree.

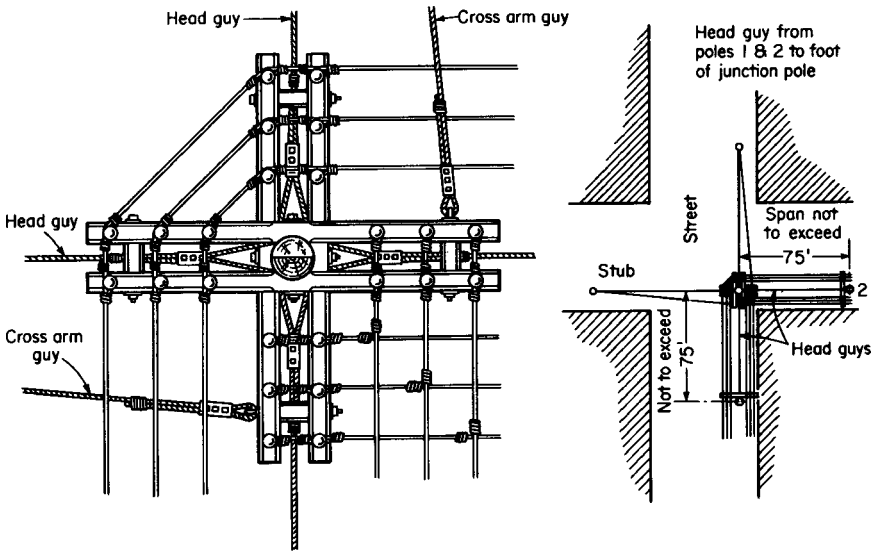

FIGURE 8.86 Method of turning corner with one pole.

FIGURE 8.87 Corner pole without double arms.

FIGURE 8.88 Bridle guy.

97. A line must be thoroughly guyed where it crosses a road. Figures 8.89 and 8.90 show two methods of holding a line at such a point. The method involving the use of side guys is preferable, but the other one will give good service when side guys cannot be installed.

98. When it is impossible to secure guying privileges along the desired route for a line or obstructions make guying difficult, the problem is generally solved by the use of self-supporting poles, a construction commonly referred to as *hog guying*. This

FIGURE 8.89 Guying at road crossing without side guys.

FIGURE 8.90 Guying at road crossing with side guys.

method of strengthening a pole is especially useful on corners, around curves, and at points where space is too limited for ordinary guying. The method of hog guying is illustrated in Fig. 8.91.

99. Vertical or "sidewalk" guy wires are commonly used clear a sidewalk, and can also be used where guying privileges are limited to within 5 ft (1.5 m) of the pole. Refer to Fig. 8.92 for a photo of a completed application. The horizontal strut is 2-in. galvanized iron pipe with a length equal to the distance between the anchor and the pole.

100. Pole braces are used when guying is not feasible. They cost more than equivalent guys. Figure 8.93 shows methods of bracing poles. The upper end of each brace fits in a notch cut in the pole and is bolted thereto.

FIGURE 8.91 Details of self-supporting pole.

FIGURE 8.92 A vertical or "sidewalk" guy completely installed.

FIGURE 8.93 Bracing poles.

UNDERGROUND WIRING

101. Underground systems are of three main types:

1. Duct line
2. Cable buried directly in the ground
3. Conduits located in tunnels

A duct line consists of one or more conduits spaced close together with or without a concrete casing. The duct line is laid in a trench with the top at least 2 ft (0.6 m) underground and covered over with earth; it should be covered with pavement if it is located under a street. The duct lines terminate in underground vaults, called manholes, where transformers and protective equipment are located and where cable splices are made. The cables are drawn into the ducts from one manhole to the next. This system is ordinarily used for general underground distribution work when more than one cable is located in the same run or when the cable may have to be increased in size or replaced. Nonmetallic conduits must be encased in not less than 2 in. (50.8 mm) of concrete, unless listed by a nationally recognized testing agency as suitable for direct burial without encasement, if contained conductors operate in excess of 600 V.

Under the system in which the cable is buried directly in the ground, a trench is dug, and the cable, which is of a type to resist the corrosive effects of the ground (called parkway or nonmetallic-armored cable; see Div. 2), is laid in the trench without any protection other than that afforded by the cable insulation and earth covering (refer to Sec. 129 for further details). This method is used for single-circuit runs on which the load is apt to be steady and definite, as in street or parkway lighting systems. This method is also used for underwater lines, where the construction of a duct line would be difficult or impossible.

For groups of buildings in an industrial plant or institution, where tunnels between buildings must be constructed for steam and water lines, it is quite common to locate the electrical circuits in conduits or cable trays on the walls of the same tunnels.

102. Commercial conduit duct materials are steel conduit (rigid metal or intermediate metal), polyvinyl chloride (PVC), fiberglass (RTRC), high-density polyethylene (HDPE), and monolithic concrete. Refer to the specific wiring methods in Div. 9 for more information.

103. Plastic conduits, such as polyvinyl chloride, and polyethylene, described in Divs. 4 and 9, are being widely used for underground installation because of low cost, ease of installation, and minimum use of labor. Such conduits are available in lengths up to 30 ft (9.1 m), thereby reducing the number of couplings required in a given run. The newest non-metallic conduit material is a fiberglass material ("reinforced thermosetting resin conduit, Type RTRC" in the NEC). These conduits are difficult to bend in the field but will withstand higher ambient temperatures without deforming.

104. Iron conduit is sometimes used for duct lines, but since it costs more than other materials, it has not had general acceptance for this purpose. One important advantage is that it gives the cables better protection from damage during excavation. Wrought iron is preferable to steel conduit, which is often sold for wrought iron, because wrought iron resists corrosion much more effectively than does steel.

Wrought-iron conduit is frequently used to carry parkway lighting circuits if they are laid in filled ground which might be injurious to cable laid directly in the ground. The principal use for wrought-iron conduit in underground work is for laterals (see Sec. 110).

105. Cable-in-duct. A new popular system is cable-in-duct, which consists of a semi-rigid nonmetallic conduit and factory-installed conductors. Shipped in large reels, this system is easy to install, offset fittings and couplings are eliminated, and conductors can be withdrawn if necessary. Typical applications are for parkway, highway, and street-lighting underground systems. This is covered in the NEC as “Nonmetallic Underground Conduit with Conductors” and is discussed in Sec. 22 of Div. 9.

106. Monolithic concrete ducts can be built in two ways, by using flexible Para rubber tubing as a core and by using a duct-forming machine called a “boat.” In the rubber-tubing method, thick rubber tubes which are flexible but not readily collapsible are laid on a concrete base and separated with terra-cotta spacers. Concrete is then poured around them as in the other methods. When the concrete has set for a few hours, the tubings are withdrawn, leaving a very smooth concrete duct. In the boat method a track is built at the bottom of the trench. On this track runs the boat, which is really a die containing as many steel tubes as the number of ducts wanted. Concrete is fed into a hopper at the top and is tamped down around the tubes. The boat moved slowly along the track either by hand or by power from an electric motor, leaving the finished duct extruding from the rear. The concrete is of a special mixture which is sufficiently solid to hold the form of the ducts as the boat moves along.

The rubber-tubing method is especially advantageous when the duct line must be threaded around other underground structures and pipes. It can be used to advantage in bringing duct lines into power stations and substations, as the duct can be formed in one continuous run from the street manhole to the switching-gallery floor. The main advantage of the boat method as well as the rubber-tubing method is that there is no material in the duct to decay. Both methods have proved more expensive than using fiber conduit, so that for normal straight runs they cannot compete economically. For special irregularly shaped curves a section of the monolithic concrete duct formed by the rubber-tubing method may well be inserted even if the main run is made with one of the other materials.

107. In installing any kind of duct line a trench is excavated to such a depth that the top conduit will be 2 to 3 ft (0.6 to 0.9 m) below the surface of the ground and so that the grade of the duct line will pitch toward the manholes about 1 ft in 100 ft (0.3 m in 30.4 m) so as to ensure effective drainage. For power cables the ducts should be arranged either two conduits wide or two conduits deep so that every conduit will have earth on at least one side of it. This is necessary for conduction into the cooler ground of the heat generated by the I^2R losses in the cables. For communications cables the heat loss is low, and the ducts can be arranged in any convenient way. There should be from 1 to 3 in. (25.4 to 76.2 mm) of earth or concrete between conduits for power systems to ensure that flame and heat from a short circuit in one conduit will not affect the adjacent cables. The 3-in. separation should be used on the higher-voltage lines. Conduits are held in position during construction of the duct line by plastic spacers (Fig. 8.94). The width of the trench will depend on the working space required and on whether concrete and concrete forms are used or not. If the soil is firm, the trench may be merely 1 or 2 in. (25.4 or 50.8 mm) wider than the space required

FIGURE 8.94 Construction of duct line.

by the conduits. Where concrete is required, it should be about 3 in. (76.2 mm) thick outside the conduits. In good, firm soils the trench can be dug to exactly this width and forms omitted, the concrete occupying all the space between the conduits and the earth wall. In ordinary and poor soils the trench should be made an additional 3 in. wider on each side to provide space for installing the forms.

The bottom of the trench should be carefully rammed until solid so that undue stress will not be placed on the conduits. With concrete construction the 3-in. bed of concrete is then laid, over which the lower tier of conduits is placed with spacers to ensure the correct separation between conduits. Then the concrete is tamped around them, and thus each level is built up until the duct is completed with 3 in. (76.2 mm) of concrete on top. Sometimes the spacers are removed after the conduits are held firmly in position by the backfill and before the spacers are completely covered over. At other times the spacers are left in to form a permanent part of the duct line.

108. In installing wrought-iron conduit no concrete casing is necessary if only one duct is involved. If there are several ducts in the run, the ducts are sometimes laid on a 3-in. (76.2-mm) foundation of concrete, and concrete is tamped between and around the ducts as shown in Fig. 8.96 for single vitrified duct. When the ducts will not be exposed to the dangers of future excavation, the cost of the concrete is probably not justified. Metal conduits can be obtained in 20-ft (6.1-m) lengths. Joints between adjacent lengths are made with conventional couplings. The burrs at the ends of each conduit must be carefully removed to prevent damage to the cable. When it is inconvenient to use a coupling, a union can be used instead. Metal conduit should be painted on the outside with asphalt or similar coating material to minimize corrosion.

109. Concrete for conduit work should be clean; i.e., foreign substances should not be permitted to enter its composition. If the surface on which it is to be mixed is not smooth and clean, mixing boards or pans should be used. Foreign material impairs the strength of concrete, and it becomes porous and leaky. The concrete should be mixed from portland cement, clean sand, and gravel or broken stone in the proportions, by volume of 1 part cement to 3 parts of sand and 5 parts of gravel or stone. Just sufficient water should be used to wet the mixture thoroughly and to permit a small amount of water to come to the

surface when the concrete is tamped into final position. The cement, sand, and stone should be "turned" on the mixing board at least 3 times dry and at least twice after wetting. The concrete should be placed immediately after mixing. When the concrete has been placed in the trench, several hours should be allowed for it to take its initial set before the trench is filled in. This is necessary to prevent throwing the ducts out of alignment or fracturing the "green" concrete.

FIGURE 8.95 Wrought-iron pipe laterals.

necessary to locate splices in manholes, the distance between manholes cannot exceed these values. Furthermore, it is not advisable to pull in very long lengths of cable, because the mechanical strain on the conductors and sheath may then become too great during the pulling-in process. It is recommended that manholes be located not more than 500 ft (152 m) apart. The lines should preferably be run straight between manholes. If curves are necessary, the offsets from a straight line and the distance between manholes should not exceed the values given in the following tables:

110. For laterals which carry the service cables from the duct lines to the buildings served, concrete construction is usually not justified. Iron conduit has been commonly employed for this purpose. Iron conduit can be bent at will, and it is often necessary to thread a network of underground structures with a lateral, especially if it must cross the street. Usually wrought-iron conduit is used because this material resists the corrosive effect of the ground. An application of wrought-iron conduit from overhead to underground construction is illustrated in Fig. 8.95.

111. Manholes are necessary in a subway system to permit the installation, removal, splicing, and rearrangement of the cables. A manhole is merely a subterranean vault or masonry chamber of sufficient size to permit proper manipulation of the cables. The conduits enter the vault, and on its sides are arranged devices whereby the cables within the manhole can be supported.

The location of manholes is determined largely by the layout of the district that is to be supplied with power. Whenever a branch of lateral extends from the main subway, there must be a manhole, and there must be manholes at intersections of subways. In general, cables are not made in lengths exceeding 400 to 600 ft (122 to 183 m), and as it is

FIGURE 8.96 Offsets for main duct line: (I) single curve, (II) reverse curve.

112. Manholes are made in many shapes and sizes to meet the ideas of the designer and to satisfy local conditions. It is established, however, that the form shown in Fig. 8.97 is best for the average condition. If there are obstacles about the point where a manhole is to be located, the form of the manhole must be modified to avoid them. The form approximating an ellipse (Fig. 8.99, I) is used so that the cables will not be abruptly bent in training them around the manhole. When the rectangular type of manhole is used (Fig. 8.99, II), care must be taken not to bend the cables too sharply. The NEC has detailed rules regarding manhole sizing to prevent damage to conductors during installation, as covered in Sec. 121.

The size of manholes will vary with the number of cables to be accommodated, but in any case there must be sufficient room to work in the manhole. A 5- by 7-ft (1.5- by 2.1-m) manhole (Fig. 8.97) is probably as large as will be required in isolated plant work, while a 3- by 4-ft (0.9- by 1.2-m) manhole (Fig. 8.98) is about as small as should be used. When transformers are located in a manhole, the size should be increased to allow for working space around the transformer and for ventilation. About 2 to 3 ft³ (0.057 to 0.085 m³) of volume should be allowed per kilovolt-ampere of transformer rating.

I-A. 5-by 7-ft brick manhole.

II-A. 5-by 7-ft concrete manhole.

FIGURE 8.97 Typical manholes.

Manholes are built of either brick or concrete or of both of these materials. When many manholes are to be built of one size and there are no subterranean obstructions, concrete is usually the cheapest and best material. But when only a few are to be constructed or when there are many obstructions, a manhole with a concrete bottom, brick sides, and a concrete top is probably the best. Such a manhole can be constructed without having to wait for concrete to set before forms can be removed. There is a growing use of precast concrete manholes, shipped directly to the site.

113. A concrete manhole is built by first depositing the concrete floor (Fig. 8.97, II) and then erecting the form for the sides on this floor. In a self-supporting soil the sides of the hole constitute the form for outside of the manhole. If the soil is not self-supporting, there must be an outer form of rough planks, which is usually left in the ground. Steel

FIGURE 8.98 A 3- by 4-ft (0.9- by 1.2-m) manhole.

reinforcing (old rails are good) must be placed in the concrete top of a large manhole. In a small manhole the manhole head or cover will extend over the sidewalks, and no reinforcing or manhole roof, for that matter, is required. All reinforcing steel should be completely encased in concrete to prevent corrosion.

FIGURE 8.99 Type of manholes.

114. A manhole with brick walls is built (Fig. 8.97, I) by first depositing the concrete floor and then building up the brick walls thereon. If the manhole is large, the roof can be either of steel-reinforced concrete or of brick set between rails. Probably for installations in which only a few manholes are to be built, the brick-between-rails method is the best. For a small manhole no masonry roof is necessary, as the cast-steel manhole head forms the roof.

Cement mortar for building brick manholes or for conduit construction can be made by mixing together 1 part of cement, 3 parts of sand, and about $\frac{1}{3}$ part of water, all by volume.

FIGURE 8.100 A concrete service box.

a smaller manhole. Covers should be round so that they cannot drop into the hole accidentally.

The NEC requires access to be at least 26×22 in. (650×550 mm) if rectangular, otherwise at least 26 in. (650 mm) in diameter. This allows for a ladder to rest against the edge of the opening; if the manhole has a fixed ladder permanently mounted, then the diameter can be reduced to 24 in. (600 mm). A similar reduction is permitted if the only wiring in the manhole is power-limited fire alarm or signaling circuits, or optical-fiber cabling. The access opening must not be directly over electrical equipment or conductors, but if this is not practicable, the manhole must be fitted with a protective barrier or a fixed ladder. The

115. Distribution or service boxes, so called, which are really small manholes, often serve the purpose of and can be used instead of larger vaults in industrial and isolated plant installations. A design for a concrete service box is shown in Fig. 8.100. A brick box would be of approximately the same dimensions. The depressions in the sidewalks are sleeve pockets. The splicing sleeves on the cables lie partially in these, after installation, and therefore less of the valuable working space of the box is occupied by them. In spite of the fact that a square manhole cover can fall into the hole, heads with square covers are often used for distribution boxes to provide an orifice giving maximum working room. These enclosures would be defined as handhole enclosures in the NEC; refer to Sec. 122 for more requirements and some current performance criteria. Today they are readily available preformed in advance that meet recognized standards, in sizes varying from as large as shown here to less than a foot square.

116. Manhole heads are frequently made of cast iron, but cast steel is better; the cover should always be of cast steel. Figure 8.101 shows a design for cast steel for a large manhole, and Fig. 8.102 one for

FIGURE 8.101 Head for large manholes.

cover, if rectangular, must be restrained so it cannot fall into the manhole. Covers must “prominently” identify the manhole’s function by wording (e.g., “ELECTRIC”) or a logo, and they must weigh at least 100 lb (45 kg); if not, then they must be secure so a tool will be required for access.

So-called watertight covers are now seldom used, as it is not feasible to make a satisfactory watertight cover at reasonable expense and water gets into the manholes in any event. Covers should not be fastened down because if they are and accumulated gas in a manhole explodes, the vault and cover will be shattered. A ventilated cover should be used to allow the escape of gas. The newer types have ventilating slots over approximately 50 percent of their area. Dirt and water will get into the hole, but the dirt can be cleaned out, and the water will drain out and no harm will result. If ventilation is not provided, an explosion of gas may occur and do great damage.

FIGURE 8.102 Head for small manholes.

117. Draining manholes. When feasible, a sewer connection should lead from the bottom of every manhole (see Fig. 8.97). The mouth of the trap should be protected by a strainer, made of noncorrodible wire, such as that used for leader pipes. If a sewer connection cannot be made, there should be a hole in the manhole floor so that water can drain out. A pocket under the manhole filled with broken rock will promote effective drainage (see Fig. 8.98).

118. At the point where a conduit line enters a manhole, the walls should be chamfered off as shown in Fig. 8.103 to prevent the damage that might occur if a cable is bent over a sharp corner.

A precast conduit entrance can be made up on forms on the surface of the ground and then lowered into position in the side of the manhole. One type using porcelain duct bells is shown in Fig. 8.104. The smooth, curved surface of the bell prevents the cable sheath from being cut where it starts to bend coming out of the duct line. This is of interest in existing manholes with old-fashioned raceway entries, such as tiled ducts. The NEC now requires all

FIGURE 8.103 Chamfered wall at conduit entrance.

raceways to be listed, which is impossible in such cases. Today's duct lines use NEC recognized wiring methods, usually some form of nonmetallic conduit. When the conduit arrives at an access point, the NEC requires (for conductors 4 AWG or larger) there to be a smooth, rounded, insulated surface for them to bear against, unless they are separated from the edge of the raceway by some other insulated method that is firmly fixed in place. Nonmetallic conduit manufacturers make belled ends that serve this purpose.

FIGURE 8.104 Manhole duct entrance using porcelain bells. [Line Material Co.]

119. A manhole hook, a convenient tool for removing manhole heads, is shown in Fig. 8.105. A common pick can be used, but the tool shown is much more convenient.

FIGURE 8.105 A manhole hook.

120. In installing cables in conduit, if a pull-in wire was not installed at the time the ducts were placed, the conduit is rodded, a pull-in wire or the drawing-in cable is drawn through, cleaners are pulled through, such as the equipment shown in Fig. 8.106, and then the cable is drawn in.

FIGURE 8.106 Scraper and brush for conduit.

121. The NEC devotes Part V of Article 110 to manhole coverage. The rules in this part apply unless an industrial occupancy demonstrates appropriate engineering supervision that supports design differences; those differences being subject to documentation and review by the inspector. The NEC requires that manholes must be designed under engineering supervision and that they must withstand the loading likely to be imposed. Section 116 includes coverage of NEC rules for access and cover specifications. The remainder of this section covers the sizing requirements, which have three components all of which apply where applicable.

- a. *Cabling work spaces.* A clear work space must be provided not less than 3 ft (900 mm) wide where cables run on both sides, and 2½ ft (750 mm) wide if the cables are on only one side, with vertical headroom not less than 6 ft (1.8 m) unless the opening is within 1 ft (300 mm) of the adjacent interior side wall of the manhole. If the only wiring in the manhole is power-limited fire alarm or signaling circuits, or optical-fiber cabling, then one of the work space dimensions can drop to 2 ft (600 mm) if the other horizontal clear work space is increased so the sum of both dimensions is not less than 6 ft (1.8 m).
- b. *Equipment work space.* If the manhole includes equipment with live parts that will require work while energized, then the normal NEC work space rules apply. The headroom rises to 6½ ft (2.0 m), and there must be clear work space at least 3 ft deep and 30 in. (750 mm) wide (wider if the equipment is wider). The depth rises to 3½ ft or 1.1 m over 150 V to ground, and then goes up to 4 ft (1.2 m) for up to 2.5 kV; 5 ft (1.5 m) for up to 9 kV, 6 ft for up to 25 kV. Refer to the NEC for higher voltages and special applications.
- c. *Bending space for conductors.* Essentially, manholes are pull boxes that are large enough for personnel to enter, and therefore they need to be sized to accommodate the installed conductors without violating the rules that normally apply to sizing pull boxes, as covered for applications not over 600 V in Sec. 324 of Div. 9. For medium-voltage applications, where the same conductor passes straight through the manhole (e.g., entering the south wall and leaving the north wall) the minimum distance is 48 times the largest shielded cable diameter (32 times the largest unshielded cable diameter). If a conductor enters one side of a manhole and then makes a right-angle turn, the dimension drops to 36 times (24 times for unshielded conductors), but it is measured in both directions, and it is increased by the sum of the outside diameters of all other cable entries on the same wall. If there are multiple rows or columns of duct openings in any direction, use the row or column that gives you the largest sizing calculation and ignore all other cable entries.

122. Handhole enclosures have minimum requirements as well. The NEC defines them as “provided for use in underground systems, provided with an open or closed bottom, and sized to allow personnel to reach into, but not enter, for the purpose of installing, operating, or maintaining equipment or wiring or both.” They must be identified for use on underground systems, and they must be designed and installed to withstand all loads likely to be imposed.

The NEC identifies a standard (ANSI/SCTE 77-2002) that can be used to evaluate loading on these enclosures. This standard identifies a series of tiers that can be specified based on the expectation of vehicular loading. Tier 5 is for pedestrian use with a safety factor for occasional nondeliberate vehicle traffic; it carries a 5000 lb vertical design load rating. Tier 8 is for sidewalk use with a safety factor for nondeliberate vehicular traffic, with a comparable design load rating of 8000 lb. Tier 15 is for parking lots, driveways, and off roadway uses that are subject to occasional nondeliberate heavy vehicular traffic; here the vertical load rating is 15,000 lb.

Handhole enclosures have the same sizing rules related to wire bending space as for manholes (Sec. 121). There is an instance where a different set of rules apply, however. If a raceway enters through the bottom plane of a bottomless enclosure, the measurements are taken from the end of the conduit or cable assembly. When such an entry is opposite a removable cover, as it would be in this case, the spacing rules change. For wires operating at 600 V and below, the minimum distance becomes the one-wire-per-terminal distance in Table 312.6(A) (see Div. 12, Table 34 which is identical) for the conductor sizes involved. For medium voltage wiring the distance is 12 times the shielded cable diameter and 8 times the diameter for unshielded conductors.

Handhole enclosures are renowned for filling up with sand and water, particularly for the ones without bottoms, which is usually the case. All wiring and splicing provisions must be listed for wet locations for this reason. In addition, if a handhole enclosure has a metal cover, it must be bonded to an equipment grounding conductor (usual case) or to a grounded circuit conductor if the application is on the line side of service equipment. This is a critical safety issue. There have been many fatalities, of both people and their pets, from energized handhole covers.

123. Rodding. Rods are pieces of round hickory about $\frac{3}{4}$ in. (19.05 mm) in diameter and 3 ft (0.9 m) long (Fig. 8.107). Fiberglass wands are commonly used today. The ends of the rods are equipped with brass knuckle-joint fittings so that the rods can be readily joined together and disjoined. In rodding, a rod is pushed into the duct, and a second rod is coupled to it. The two are pushed into the duct, a third rod joined on, and the process is repeated until the rods extend from manhole to manhole. A galvanized-iron wire is attached to the last rod, and the wire is drawn into the duct.

FIGURE 8.107 Rods for conduit.

A rope of flexible steel cable to which are attached a scraper and a brush (Fig. 8.106) is drawn through to ensure that the duct is clear and clean. To the end of this rope or cable is attached another which is used to pull in the electrical conductor cable.

If the conduit is short, a steel fish wire or ribbon, like that used by electricians in wrought-iron conduit work, can be inserted instead of the rods.

124. Pulling in cable. The cable can be attached to the pulling-in wire by any one of several methods. Fig. 8.108C shows one that was formerly much used. Probably the best methods are those illustrated in Fig. 8.108A and B. At A, a galvanized-iron wire is laced around the cable in such a way that the harder it is pulled, the tighter it grips. At B is shown a *grip* spirally laced from flexible steel strands. It slips over the cable sheath readily, but when tension

FIGURE 8.108 Methods of attaching cable to drawing-in line.

is applied, it effectively grips the cable. A swivel should always be inserted in any pulling-in line to prevent the untwisting of the drawing-in line under tension from twisting the cable.

After the cable has been fastened to the pulling-in line, a *protector* is placed in the mouth of the duct to prevent abrasion of the cable. Metal protectors can be purchased, but a good one can be formed from a piece of sole leather.

The cable is bent, as shown in Fig. 8.109, from the cable reel to the mouth of the duct, and the pulling in commences. In the far manhole, sheaves are arranged over which the pulling-in line passes (see Fig. 8.109). If eye-bolts are built in the manhole sides, the sheaves (snatch blocks) can be fastened to them. Otherwise a guide-sheave rack (see Fig. 8.110 for detail and Fig. 8.109 for application) can be set up in the manhole.

FIGURE 8.109 Drawing in cable with a winch.

FIGURE 8.110 Guide-sheave rack and sleeve.

A winch, truck, or tractor can be used for the pulling. Workers can pull a cable in if the run is not too long. The cable sheath should be greased as it is drawn in to ensure easy pulling. When a length of cable longer than the distance between manholes is to be pulled through, it can pass over the sheaves on the guide-sheave rack provided they are large enough in diameter. A manhole capstan (Fig. 8.111) is sometimes used instead of a winch

FIGURE 8.111 Manhole capstan.

on the surface of the ground. Enough cable should be pulled into the manhole to allow for forming it around the hole and splicing it. Do not permit a cable to hang over the sharp edge of a duct. Support it in the rack. For major pulls in general, and for medium-voltage pulls in particular, the pull should be continuous (not stopped and started). Carefully review the coverage of allowable pulling forces and bending radii in Div. 9 in order to be certain that the conductors will not fail after installation.

125. Supporting cables in manholes. Some provision must be made for supporting cables. Creosoted or pressure-treated planks (Fig. 8.112) are sometimes bolted to the manhole sides, and the cables are held to the cleats with pipe straps. In other cases metal supports, several forms of which are on the market, are used. One that can be readily made is shown in Fig. 8.113. A rack made of porcelain arms on a steel framework is shown in Fig. 8.114.

FIGURE 8.112 Creosoted- or pressure-treated-plank cable supports.

FIGURE 8.113 Iron cable support.

FIGURE 8.114 Cable rack. [Line Material Co.]

126. Eyebolts or stirrups should be set in manhole walls to provide means of attachment for the tackle used in pulling in cable (Fig. 8.112). An eyebolt or stirrup should be set opposite the point of entrance of each subway. Figure 8.115 shows the dimensions of a suitable stirrup.

FIGURE 8.115 Stirrup for manhole wall.

127. Several cables should not be placed in one duct. Experience has shown that although it is easy enough to install cables under such conditions and mechanically easy to withdraw them, the removal almost invariably ruins the cable, because after long lying in a duct the cables become so impacted with dust and grit that when one is drawn out, the sheath is stripped either from the cable itself or from one of its companions. Consequently, conduits are now almost exclusively built by arranging a sufficient number of ducts so that each cable can have its own exclusive compartment.

128. In manholes and ducts, cables should be so arranged that there will be a minimum of crossing and recrossing. An underground cable system should be carefully planned, and the ducts should be so chosen for the cables that, as far as feasible, a cable will take the duct in the same relative position throughout the subway.

129. Installation of cable buried directly in the ground. Cable buried directly in the ground finds a wide field of application for installations of single circuits for which the cost of duct construction would be prohibitive. Some of the more common applications are:

1. Street-lighting circuits, especially in cities whose outlying sections are without ducts
2. Lighting and power circuits in parks, on estates, in industrial plants, on parkways, etc.
3. Connecting residences to mains, especially in subdivisions and for underground service in alleys
4. Connecting houses, garages, and other buildings
5. Railroad-yard and airport lighting
6. Lighting and power circuits for amusement parks, baseball, football, and general sports
7. High-wall power cable for strip mines
8. Railway-signal circuits
9. Crossings under small lakes and streams
10. Horizontal runs in mines for power, lighting, and telephone circuits

Both nonmetallic-armored cable and metallic-armored cable (parkway cable) are used for direct burial in the earth. The nonmetallic-armored types are lighter in weight, more flexible, and easier to splice and are not subject to rust, crystallization, induced sheath power loss, or trouble from stray currents. On the other hand, they do not give such good protection against mechanical injury.

The cables are installed either by digging a shallow open trench, laying in the cables, and refilling or by means of a gasoline-powered trencher-cable layer. When a trench is dug, it needs to be made only wide enough for convenient handling of a cable. The cables (600 V or less) need not be laid more than 18 in. (457.2 mm) under the surface except when subject to extreme mechanical hazard, such as at street intersections or under roadways. At such points it is advisable to bury the cable at least 30 in. (762 mm) deep and to cover it with protective pads.

130. Types UF and USE cables are Code-designated single-conductor or multiconductor cables suitable for direct burial in earth. These cables are described in Divs. 4 and 9, where typical applications at 600 V or less are discussed.

131. Underground conductors over 600 V.

The National Electrical Code includes rules for the protection of underground conductors when the supply voltage exceeds 600 V. These rules were introduced to minimize the hazards of “dig-ins,” and Sec. 300.50 of the Code covers such rules.

GROUNDING OF SYSTEMS

132. Grounding of distribution circuits. The National Electric Code requires that on systems supplying interior-wiring circuits one wire of the circuit shall be grounded, provided that the voltage from any other conductor to ground will not exceed 300 V on dc systems or 150 V on ac systems. Grounding helps to prevent accidents to persons and damage by fire to property in case of lightning, breakdown between primary and secondary windings of the transformers, or accidental contact between high-voltage wires and low-voltage wires. If some point on the low-voltage circuit is grounded, (1) lightning striking the wires will be conducted into the ground, and (2) breakdown of the transformer insulation between primary and secondary coils will reveal itself through blowing of the primary transformer fuses if one wire of the primary circuit comes in contact with one of the secondary wires. See Sec. 146 for the importance of a low-impedance ground-path return.

133. The value of grounding is illustrated in Fig. 8.116. One of the primary circuit wires is grounded at the transformer. The secondary is grounded at the customer’s water pipe. An accidental cross between ungrounded primary and secondary wires is shown by

FIGURE 8.116 Ground connections for interior wiring systems.

the dotted line. Current will flow through the cross-connection, the secondary of the transformer, and the customer's water-pipe ground and up the ground connection to the other primary line. The voltage of the secondary wires to ground will be increased by the IZ drop through the water-pipe ground. A current of 100 A times a ground resistance of 2Ω (there is practically no reactance) giving 200 V would represent very severe conditions. This means that the secondary voltage to ground would be the normal 110 V plus the 200 V, giving 310 V, which would probably not do any damage before the primary protective devices would open and break the circuit. This type of accidental cross should open the substation-feeder circuit breaker. If the cross were in the transformer itself, the primary fuse would open. If, however, there were no ground connection, the primary 2300 V would be impressed on the secondary system, which is insulated for only 250 to 600 V, and numerous insulation breakdowns and considerable damage to equipment would occur. Also, there would be danger to human life for anyone touching a fixture at such a time.

134. High-voltage transmission systems are also frequently grounded to reduce the voltage to ground and consequently the line insulation required. For example, if a 220-kV three-phase circuit has the windings of the supply transformer connected in Y, with the midpoint of the Y grounded, the voltage to ground will be $220 \div \sqrt{3} = 127 \text{ kV}$. This reduction of the voltage to ground is of great value in insulating the transformer windings and in the number of insulators required for the line supports. At the same time, the advantage of the 220 kV in reducing the line current and line losses is retained.

135. Ground-wire connections to transformer secondaries should be made to the neutral point or wire if one is accessible. If no neutral point is accessible, one side of the secondary circuit may be grounded. Figure 8.117 shows theoretical diagrams of ground connections to transformer secondaries, and Fig. 8.118 illustrates how some of these connections are arranged with commercial transformers. The neutral point of each transformer feeding a two-phase, four-wire secondary should be grounded unless the motors taking energy from the secondary have interconnected windings. If they are interconnected, the center or neutral point of only one transformer is grounded. No primary windings are shown in Figs. 8.117 and 8.118. In Fig. 8.118 the secondary winding of each transformer is shown divided into two sections, as it is in commercial transformers.

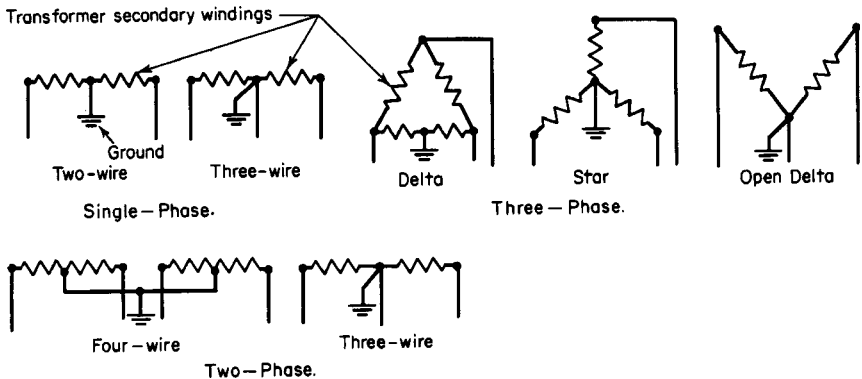

FIGURE 8.117 Theoretical diagrams of secondary-ground connections.

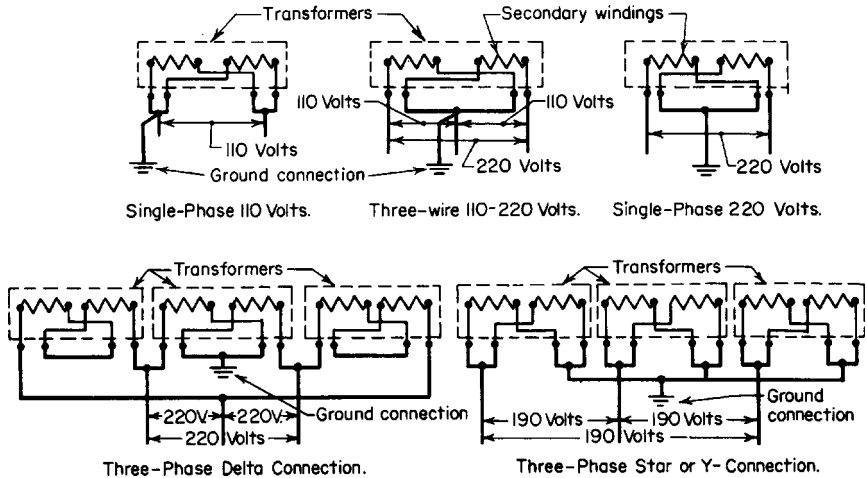

FIGURE 8.118 Ground connections to secondaries of commercial transformers.

136. Ground rods made of steel pipe with copper-welded exterior surface are extensively used. The rod is driven into the ground, and the ground wire fastened by a clamp near the top of the rod. The copper coating provides for a good electrical connection and affords resistance to corrosion from the weather and earth. Ground resistance testing as required by the NEC can be accomplished with a portable digital ground resistance tester that is battery powered with built-in rechargeable batteries and charger. See Fig. 8.119. These testers are designed for larger or more complex grounding systems, including communication grounding systems. Resistivity tests assist the design of a correct grounding system, so that later modifications are minimized.

137. Ground wires should be encased by nonmetallic molding for a distance of at least 8 ft (2.4 m) from the surface to protect against shocks to passersby. Under certain conditions of soil moisture, a shock can be received from a ground wire by a person standing on the earth's surface. The ground pipe extends about 1 ft (0.3 m) above ground and is not usually protected. Some companies encase the entire length of the ground wire in molding to protect the lineworkers.

No copper wire smaller than No. 8 should be used for a ground wire, and some companies use nothing smaller than No. 4. Copper wire is preferable. Bare wire is satisfactory and should be attached to the poles with cleats or straps. Staples, although used, should not be. The National Electrical Code requirements with respect to the size of ground wires are given in Div. 9. There should be a ground for each transformer or group of transformers, and when transformers feed a network with a neutral wire, there should, in addition, be a ground at least every 500 ft (152.4 m). The National Electrical Safety Code specifies that all ground pipes shall be galvanized and have a minimum nominal diameter of $\frac{1}{2}$ in. Steel or iron rods shall have a minimum cross-sectional dimension of $\frac{3}{8}$ in. or, if listed, they can be as small as $\frac{1}{2}$ in. (12.7 mm) in diameter.

138. The National Electrical Safety Code implies that the ground resistance should be measured at the time of installing the ground, and that the ground resistance must not exceed 25Ω for artificial (buried or driven) grounds.

FIGURE 8.119 Digital resistance tester. [Biddle Instruments, AVO International]

139. To measure the ground resistance, two additional temporary grounds, consisting of short rods 2 or 3 ft (610 or 914 mm) long, must be driven in the ground at least 20 ft (6.1 m) away from the ground being tested (Fig. 8.120, I). A direct-reading instrument is then connected to the three grounds by means of insulated leads. A magneto or a battery in the instrument furnishes the necessary power. The instrument reads the ground resistance directly in ohms. If a source of direct or alternating current is available, the resistance can be measured by the fall-of-potential method with a voltmeter and ammeter, connections for which are shown in Fig. 8.120, II. The resistance is then calculated from $R_g = E/I$.

140. When testing ground resistance in city streets there may be no convenient place to drive the auxiliary grounds. In such a case a fire hydrant can be used for the auxiliary ground, or a pad made of several thicknesses of heavy cloth about 1 ft (0.3 m) square and saturated with salt water can be placed on the sidewalk (Fig. 8.121).

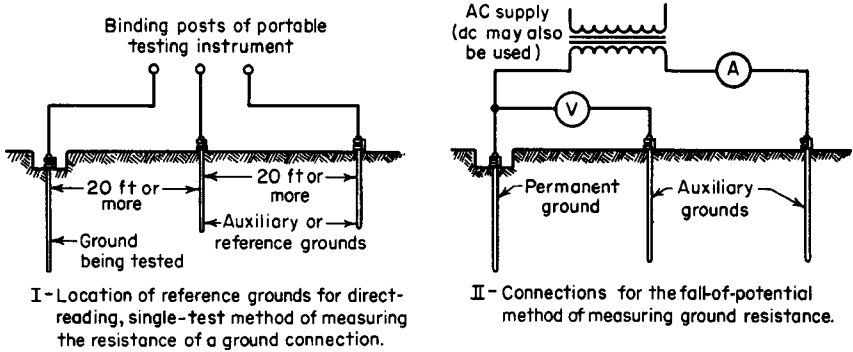

FIGURE 8.120 Circuits for measurement of ground resistance. [Copperweld Corp.]

FIGURE 8.121 Testing ground resistances in paved streets.

141. Reduction of ground resistance when it exceeds the allowable value of 25 Ω can be accomplished in several ways:

1. Use of a larger-diameter ground rod
2. Use of a longer ground rod
3. Putting two, three, or more rods in parallel
4. Chemical treatment of the soil

FIGURE 8.122 Effect of diameter of ground rod on ground resistance. [Copperweld Corp.]

142. The effect of the use of a large-diameter rod is shown in Fig. 8.122. It will be noted that increasing the diameter of the ground rod does not effect much reduction in resistance, and use of ground rods larger than 3/4 in. (19.05 mm) is not recommended. The diameter of the rod should be only large enough to permit it to be driven into the soil without bending.

143. Long ground rods made in sections coupled together are very effective where there is considerable depth of dry sand and good moist soil is many feet underground. Although the 2.5 m (8 ft) minimum depth required by the National Electrical Code is sufficient for normal soil conditions, grounds as deep as 15 m (50 ft) have been used in very poor soil. The calculated effect of the depth of rod on ground resistance is shown in Fig. 8.123. The curve is for uniform soil at all depths. In practice the soil is always firmer and more moist the deeper the ground, so that the decrease of resistance with increase of depth is usually greater than is shown by the curve.

144. Using several rods in multiple is a very effective means of lowering ground resistance, as shown in Fig. 8.124. The recommended distance between rods is at least 6 ft (1.8 m), so that this method is more applicable to large steel-tower lines and substation structures than to wood-pole lines. Spacing rods as close together as the opposite sides of a wood pole is not recommended.

FIGURE 8.123 Effect of depth of ground rod on ground resistance. [Copperweld Corp.]

FIGURE 8.124 Effect on ground resistance of placing ground rods in multiple. [Copperweld Corp.]

145. Chemical treatment of the soil is recommended for reducing ground resistance when the other methods of Secs. 141 to 144 are not practical.

There are two practical ways of accomplishing this result, as shown in Fig. 8.125. In the method of Fig. 8.125, I, a length of tile pipe is sunk in the ground a few inches from the ground rod and filled to within 1 ft (0.3 m) or so of the ground level with magnesium sulfate, copper sulfate, or common rock salt. The magnesium sulfate is the most common, as it combines low cost with high electrical conductivity and low corrosive effect on the rod. This method is effective where there is limited space for soil treating, such as on city streets. The method of Fig. 8.125, II, is applicable where a circular or semicircular trench can be dug around the ground rod to hold the chemical. The chemical must be kept several inches

I- Container method

II- Trench method

FIGURE 8.125 Methods of soil treatment for lowering of ground resistance. [Copperweld Corp.]

away from direct contact with the ground rod to avoid corrosion of the rod. The first treatment requires 40 to 90 lb (18.1 to 40.8 kg) of chemical and will retain its effectiveness for 2 to 3 years. Each replenishment of the chemical extends the effectiveness for a longer period, so that future retreating becomes less and less frequent. When the chemical is first installed, it is well to flood the treated area with water so that the chemical will diffuse through the soil. Thereafter normal rainfall will usually provide the necessary water for carrying the solution into the earth.

FIGURE 8.126 Cadweld is an exothermic welding process suitable for grounding electrode connections and for extensions of the grounding electrode conductor. [Erico Products, Inc.]

146. A low-impedance ground-path return is absolutely essential if line-to-ground faults in grounded systems are to open overcurrent devices in buildings. It is an important rule in the National Electrical Code [Sec. 250.24(B)], which requires a grounded conductor of a grounded utility system to extend to every building served. Such grounded conductors are then bonded to the metallic enclosures of the service equipment, and the grounded conductor is connected to an electrode on the premises by a grounding electrode conductor which usually extends from a neutral bar in the service-equipment enclosure to the electrode. See Div. 9 for detailed Code rules to size grounded and grounding conductors.

When a grounded conductor is properly bonded to the metallic service equipment, any line-to-ground fault from an ungrounded conductor to grounded equipment (raceways, cables, boxes, etc.) on the load side of overcurrent devices will be able to follow a

low-impedance path to the grounded conductor at the supply transformer, thus permitting an overcurrent device to open quickly. All ground faults must be cleared as fast as possible to avoid extended exposure of energized metallic parts, which provides a serious shock hazard. It cannot be stressed too strongly that proper bonding of the grounded conductor of the supply system to the service-entrance equipment is essential for the proper operation of overcurrent devices in the event of line-to-ground faults. For splices of the grounding electrode conductor, see Fig. 8.126. For low-magnitude ground faults, see information on ground-fault circuit interrupters in Div. 4.

Wiring for Commercial and Industrial Occupancies	9.312
Farm Wiring	9.347
Solar Photovoltaic Systems	9.357

GENERAL

1. The NEC rules, which are the recommendations of the National Fire Protection Association (NFPA), should be followed in installing all interior wiring. These rules are revised every 3 years, and so it is inadvisable to include them entirety in this book. A copy of the rules can be obtained from any local inspection bureau or purchased from the NFPA. All statements are made in accordance with the 2008 edition of the Code. The Occupational Safety and Health Act (OSHA) adopted the 1971 National Electrical Code (initially the 1968 edition) as the electrical standard for employee safety in the workplace. NFPA has written a standard title “Electrical Safety Requirements for Employee Workplaces” (NFPA 70E®) that is intended to serve as an enforcement document by compliance officials of the Department of Labor.

2. There are local regulations covering the installation of wiring in force in many localities, which have been enacted by city and state governments. Sometimes these differ from the Code regulations, and so it is always well to be familiar with all the regulations in force before starting any work. The city and state rules are in reality laws and therefore take precedence over the NEC rules, which of themselves have no legal status.

3. Definitions (National Electrical Code). The NEC reserves Article 100 to cover the essential definitions required to properly apply its provisions. Not included are general terms that are commonly defined, or technical terms that are used in the same way as in related codes and standards. In addition, if a term is only used in one article, it will be defined within that article and not in Article 100. Part I of the article applies throughout the NEC; Part II covers definitions that only apply to installations operating over 600 V, nominal. Consult Article 100 if you are unclear as to how a specialized electrical term is defined that appears in the NEC.

There are four definitions, however, that are so widely used that they bear repeating here, along with some commentary, as follows:

a. **AMPACITY** The current, in amperes, that a conductor can carry continuously under the conditions of use without exceeding its temperature rating.

This is covered extensively in Secs. 89 to 106 of Div. 3. Note that ampacity applies to electrical conductors. Other parts of an electrical system may have current ratings, such as switches, circuit breakers, motor contactors, etc., but only electrical conductors have an ampacity, and that ampacity changes with conditions. For example, 12 AWG THHN has an ampacity of 30 A at 30°C with three (or fewer) current-carrying conductors in a raceway. Raise the number of conductors, or raise the ambient temperature, or both, and the ampacity will decrease.

The other three definitions cover the three methods of product acceptance recognized by the NEC. They are crucial to the proper application of the Code. Code making

panels have robust discussions every code cycle about which one to apply in a given situation.

- b. **APPROVED** Acceptable to the authority having jurisdiction.
- c. **IDENTIFIED** (as applied to equipment) Recognizable as suitable for the specific purpose, function, use, environment, application, etc., where described in a particular Code requirement.
- d. **LISTED** Equipment, materials, or services included in a list published by an organization that is acceptable to the authority having jurisdiction and concerned with evaluation of products or services, that maintains periodic inspection of production of listed equipment or materials or periodic evaluation of services, and whose listing states that the equipment or material or service meets appropriate designated standards or has been tested and found suitable for a specified purpose.

NOTE The means for identifying listed equipment may vary for each organization concerned with product evaluation, some of which do not recognize equipment as listed unless it is also labeled. Use of the system employed by the listing organization allows the authority having jurisdiction to identify a listed product.

The word “approved” means acceptable to the inspectional authority (technically, the “authority having jurisdiction”), and nothing more or less. It does not mean “identified” unless the inspector chooses to use compliance with the definition of “identified” as the basis for his or her decision. Similarly it does not mean “listed” unless the inspector chooses that standard as the basis for his or her decision. For this reason, any statements in product literature (and they are common) that something is “approved” by some testing laboratory is necessarily fallacious. A product may be listed by a testing laboratory, but never approved.

The word “identified” is routinely confused with the normal usage in the English language of the word “marked.” It does not mean marked. It means what Article 100 says it means. It means generally recognizable as suitable for the specific application called out in the NEC requirement. This often comes from product literature generated by manufacturers. For an example of correct usage of this term in a Code rule, the NEC requires two-winding transformers reconnected in the field as autotransformers to be *identified* for use at elevated voltage. (Refer to the example in Sec. 117 of Div. 5 for the reasons why.) These transformers are frequently listed, but as two-winding transformers. They could not be listed as autotransformers because they do not leave the factory this way, and they have wide application as two-winding transformers. A listing would be excessive because the transformer manufacturers would have to run two production lines with two different labels for the same product. The installer needs to rely on product literature from the manufacturer to verify suitability for reconnection, and fortunately, these manufacturers all provide specific information on how to make the reconnections so the transformers will buck or boost the voltage as desired.

The word “listed” covers the most specific method of product acceptance, because it means that a qualified testing laboratory, usually with testing facilities that an inspector could not possibly duplicate, has performed exhaustive tests to judge the performance of the product under the conditions contemplated in a specific Code rule. The Code note that follows the definition needs some explanation as well. Although the note is written in a general and explanatory manner, in fact all qualified testing laboratories operating under the current North American electrical safety system do require a label as evidence of the listing. It follows, then, that if a label falls off, the product no longer has the status of being listed. Further, the only way a label can be reapplied is in the presence of an employee of the testing laboratory. Sending labels through the mail is not an option and will result in disciplinary action against the manufacturer by the testing laboratory. The testing laboratories will all send personnel into the field to witness the reapplication of labels.

4. Methods of installing interior wiring (listed in the order of NEC coverage)

1. Armored cable, Type AC
2. Flat cable assemblies, Type FC
3. Flat conductor cable, Type FCC
4. Integrated gas spacer cable, Type IGS
5. Medium voltage cable, Type MV
6. Metal-clad cable, Type MC
7. Mineral-insulated, metal-sheathed cable, Type MI
8. Nonmetallic-sheathed cable, Type NM (and NMC and NMS)
9. Power and control tray cable, Type TC
10. Service-entrance cable, Type SE (and USE)
11. Underground feeder and branch-circuit cable, Type UF
12. Intermediate metal conduit, Type IMC
13. Rigid metal conduit, Type RMC
14. Flexible metal conduit, Type FMC
15. Liquidtight flexible metal conduit, Type LFMC
16. Rigid polyvinyl chloride conduit, Type PVC
17. High density polyethylene conduit, Type HDPE
18. Nonmetallic underground conduit with conductors, Type NUCC
19. Reinforced thermosetting resin conduit, Type RTRC
20. Liquidtight flexible nonmetallic conduit, Type LFNC
21. Electrical metallic tubing, Type EMT
22. Flexible metallic tubing, Type FMT
23. Electrical nonmetallic tubing, Type ENT
24. Auxiliary gutters
25. Busways
26. Cablebus
27. Cellular concrete floor raceways
28. Cellular metal floor raceways
29. Metal wireways
30. Nonmetallic wireways
31. Multioutlet assembly
32. Nonmetallic extensions
33. Strut-type channel raceways
34. Surface metal raceways
35. Surface nonmetallic raceways
36. Underfloor raceways
37. Cable trays
38. Concealed knob-and-tube wiring
39. Messenger-supported wiring
40. Open wiring on insulators

5. Armored cable (Type AC) includes Type AC. Type AC contains insulated conductors of a type accepted for general wiring applications to the NEC. The conductors are enclosed in an armor comprised of steel or aluminum interlocking tape. The armor is arranged with an internal bonding strip of aluminum or copper “in intimate contact with the armor for its entire length.” Type AC cable, which is commonly called BX, has largely been supplanted in the market by the interlocking-armor style of metal-clad cable. However, certain applications, especially patient care areas of health care facilities, require a wiring method where the outer margin of the wiring method, whether raceway or cable assembly, qualify as an equipment grounding return path, and Type AC cable inherently qualifies for this use.

6. Flat cable assemblies (Type FC) are comprised of a flat ribbon of 10 AWG conductors with a special stranding embedded in a flat nonmetallic assembly that is limited to 30-A branch circuits. The conductor ribbon is drawn into a raceway specially formed as an open channel to receive it. After the conductor assembly has been drawn in, special fittings that mount to the channel are added. These have sharp contacts that, when tightened, pierce the insulation mat supporting the conductors and make contact with the embedded conductors. The assembly is used to supply HID luminaires and other small power loads. The nonmetallic insulation is designed to be self-healing, and the tap mechanisms can be repositioned as needed.

7. Flat conductor cable (Type FCC) is a field-installed wiring system for branch circuits incorporated Type FCC cable and associated accessories for installation under carpet squares no larger than 914 mm (36 in.) square. FCC systems shall not be used outdoors or in other wet locations, where subject to corrosive vapors, in any hazardous location, or in residential, school, and hospital buildings.

8. Integrated gas spacer cable (Type IGS) is an assembly of 1 to 19 aluminum rods laid parallel, with kraft paper insulation over the bundle, inside a medium-density polyethylene jacket of 2, 3, or 4 trade size that is pressurized to a nominal 20 lb/sq in. (138 kPa) with sulfur hexafluoride (SF_6) gas. These assemblies are only permitted for use outdoors below grade or in tunnels, and must never be run in contact with a building.

9. Medium-voltage (Type MV) cable is a single or multiconductor cable with solid dielectric insulated conductors rated 2001 V or higher. Type MV cables are permitted to be used on power systems up to 35,000 V in wet or dry locations, in raceways, in cable trays, as permitted in Part II of NEC Article 396 covering messenger supported wiring, or directly buried when installed in accordance with Sec. 300.50 of the NEC. Type MV cables are not permitted in locations exposed to direct sunlight or in cable trays unless identified for these exposures. Type MV cables are permitted in exposed runs where suitable for the use and purpose, and without that qualification where accessible to qualified persons only. Type MV cable with an overall metallic sheath or armor is available with a dual “MV or MC” rating, and as such can be used where Type MC cable would be permitted.

10. Type MC metal-clad cable is a factory assembly of one or more conductors, each individually insulated and enclosed in a metallic sheath of interlocking tape or in a smooth or corrugated tube. The metallic covering may be a smooth metallic sheath, a welded and

corrugated metallic sheath, or interlocking metal-tape armor. This cable is widely used for concealed and exposed wiring when flexibility and ease of installation are important factors. Type MC cable is not permitted to be used when exposed to destructive corrosive conditions, such as direct burial in earth or in concrete or when exposed to cinder fills, strong chlorides, caustic alkalies, or vapors of chlorine or of hydrochloric acids, except when the metallic sheath is suitable for the conditions or is protected by material suitable for the conditions.

11. Mineral-insulated metal-sheathed cable (Type MI) consists of one or more electrical conductors insulated and separated by highly compressed refractory mineral insulation and protected from injury by enclosure in a liquidtight and gastight copper or nickel-clad copper sheath. The wires, insulation, and protective sheathing are manufactured as a unit. The method of installation is similar to that of metal-clad cable. Special approved fittings are used for terminating and connecting the cable to boxes and other equipment. At all points of termination of the cable an approved moisture seal must be provided.

12. Nonmetallic-sheathed cable (Types NM, NMC, and NMS) is made in three types, Types NM, NMC, and NMS. Type NM consists of two or more rubber- or thermoplastic-insulated wires bound together and protected by a plastic jacket. Type NMC cables are protected by an outer flame-retardant, moisture-resistant, fungus-resistant, and corrosion-resistant sheath which contains no cotton or paper. Type NMS cable is a factory assembly of insulated power, communications, and signaling conductors enclosed within a common sheath of moisture-resistant, flame-retardant, nonmetallic material. Nonmetallic cable may be run exposed on walls and ceilings, or concealed in the hollow spaces between partitions or between floors and ceilings. The cable is fastened directly to the surface of the walls, ceilings, or structural members with approved supports. Provision for outlets and switches is made by running the cable into outlet boxes. In most cases such cables contain an equipment-grounding conductor.

13. Power and control tray cable (Type TC) is an assembly of two or more insulated conductors, with or without associated bare or overed grounding conductors, under a nonmetallic jacket. It is not permitted to be made with a metallic cable armor either under or over the nonmetallic jacket; however, metal shielding is permitted, and where employed, the minimum bending radius of the cable must not be less than 12 times the cable diameter. Otherwise, the minimum allowable bend radius is based on the cable diameter, with a four times the diameter allowed for cables 1 in. (25 mm) or thinner, five times for cables up to 2 in. (50 mm), and six times for larger cables. In addition to cable tray usage, Type TC cable is permitted to run within raceways and on messenger wires, but for outdoor applications in direct sun it must be identified for that use. It may be directly buried, but also only if so identified.

Type TC cable is available with a more robust configuration that will meet the crush and impact tests that apply to metal-clad cable, Type MC. This form is identified as Type TC-ER. For industrial occupancies with qualified maintenance and supervision, Type TC-ER is permitted to exit a cable tray and run to utilization equipment or devices, provided also that it has continuous mechanical support, such as strut, angles, or channels. In addition, Type TC-ER is permitted to run unsupported between cable tray transitions, or from cable trays to utilization equipment or devices as long as the unsupported distance does not exceed 6 ft (1.8 m). Where the cable exits the tray, mechanical support must be provided so the required bend radius is maintained.

14. Service-entrance cable (Types SE and USE) (see Div. 2) normally is used for the conduit from the point of attachment of the service conductors on the outside of the building to the service switch, load center, or meter cabinet just inside the building. It may, however, also be employed for the interior wiring on the load side of the service switch. It is not commonly used for general interior wiring but is used for certain special portions of the wiring such as to supply large appliances like an electric range, as a feeder to a distribution panel elsewhere in the building, or as a service cable to other buildings. For unrestricted use all the conductors must be rubber- or thermoplastic-insulated. If an uninsulated neutral is used, the cable must have a final nonmetallic outer covering, the voltage to ground must not exceed 150 V, and it may be used to supply other buildings. The cable is fastened to the surface with straps spaced not over 1.4 m (4 ft 6 in.) apart.

15. Underground-feeder and branch-circuit cable (Type UF) resembles Type USE service-entrance cable in general appearance. The insulation employed may consist of a special synthetic plastic compound. When single-conductor cables are used, all conductors of the circuit must be installed in the same trench or raceway. For multiconductor cable installations all conductors of the circuit together with the protective covering of the cable are installed as a unit, just as in metal-clad or nonmetallic-sheath-cable installations. Provision for outlets is made by running the cable into suitable outlet boxes. Underground-feeder and branch-circuit cable wiring provides a convenient approved method for interior wiring in wet or corrosive locations. It may be installed underground in raceways or be buried directly in the earth. Multiconductor cables usually contain an equipment-grounding conductor.

16. Intermediate metal conduit (Type IMC) is the same as rigid metal conduit (following) except that, although threaded, it has a thinner wall. The alloy is such that it has essentially the same strength and it is permitted for the same uses as rigid metal conduit. The only real difference is that it is only made up to metric designator 103 (trade size 4) and no smaller than metric designator 16 (trade size $\frac{1}{2}$).

17. In the rigid-metal-conduit (Type RMC) method of installing interior wiring the wires are supported and protected from mechanical injury by being installed in ferrous or nonferrous types of rigid metal conduits. Ferrous types are of wrought iron or steel with coatings such as black enamel, electrogalvanizing, hot-dip galvanizing, or similar material. Nonferrous types include aluminum or brass (silicon bronze) conduits. Various types of ferrous and nonferrous metal conduits are available with outer plastic coatings to provide optimum protection from corrosion.

Rigid or intermediate metal conduit may be run exposed, supported directly on walls, ceilings, or roof structures or on suitable hanger assemblies. It may also be concealed in partitions, ceilings, or floors. Provision for connection to the circuit at outlet and switch points is made by the insertion of sheet-steel, cast-metal boxes (steel or aluminum), or special conduit fittings in the conduit run. The special conduit fittings, LB, T, LL, LR, X, etc., are called by various trade names, such as Condulets or Unilets and defined as conduit bodies by the NEC. Although rigid metal conduits are usually employed with threaded fittings and connections, many threadless fittings are available for use without threading the conduit.

Conduit, fittings, and boxes are installed complete without wires. Then the wires are pulled into the conduit from fitting to fitting, box to box, or fitting to box. In hazardous locations only threaded connections (full five threads, or $4\frac{1}{2}$ threads in the case of threads made by the manufacturer on listed equipment) are permitted.

18. The flexible-metal-conduit method (Type FMC) of installing wires is used to a limited degree in frame buildings, or similar applications in which rigid raceways would be difficult to install and a pull-in, pullout conduit system is desirable. (Flexible metal conduit is often referred to as Greenfield.) It is available in metric designators 16 through 103 (trade sizes $\frac{1}{2}$ through 4), with metric designator 12 ($\frac{3}{8}$ trade size) available under special conditions, and as covered in Sec. 170. The runs of conduit, boxes, and fittings are installed first as a complete system. Then the wires are installed in the same manner as in rigid metal conduit. It is not permitted to be used in wet locations. The NEC states that flexible metal conduit may be used as a grounding means if the total ground return path in flexible conduits is no more than 1.8 m (6 ft) and both conduit and fittings are listed for grounding and the circuit conductors are protected by a 20-A overcurrent device or less. If they are not so listed, each run of flexible metal conduit must contain a bare or insulated grounding conductor, and this grounding conductor must be attached to each box or other equipment supplied by such conduit. The separate grounding conductor is also required if the installation requires flexibility after installations, such as for vibration isolation or for connection to moveable parts such as a swinging sign.

19. Liquidtight flexible metal (Type LFMC) has, in the case of LFMC, an outer liquidtight jacket. It is not intended for general-use wiring. Wiring of this kind is expressly permitted to be used for the connection of motors or portable or stationary equipment when flexibility of connection is required. There is no outright prohibition against other uses. It is available in the same sizes and under the same rules as for flexible metal conduit. When used, it must be provided with suitable terminal connectors approved for the purpose. It cannot be used where subject to physical damage, where subject to temperatures above its rating, or in any hazardous location, except for limited flexibility, and motor connection in Div. 2 areas, Class II dust areas, Class III fiber or flyings areas, and as permitted by Sec. 504.20 for intrinsically safe systems. See Tables 4 and 5 (and 5A) in Chap. 9 of the NEC for maximum sizes of conductors allowed. Where listed and marked for the purpose, it can be used for direct burial applications.

20. Rigid polyvinyl chloride conduit and fittings (Type PVC) are constructed of polyvinyl chloride, a polymeric (plastic) material that is resistant to moisture and chemical atmospheres. These conduits can be used above grade in exposed applications generally, and the very heavy wall Schedule 80 version can be used where exposed in areas of physical damage. Such conduits may also be embedded in concrete in buildings or installed in wet locations such as laundries or dairies. Complete lines of nonmetallic fittings and boxes are available. They may also be buried directly in earth. For underground applications refer to Div. 8.

21. High density polyethylene conduit (Type HDPE) is a tubular raceway of circular cross section. It is available in discrete lengths, and also in continuous lengths on a reel. It is available from metric designator 16 (trade size $\frac{1}{2}$) up to and including metric designator 155 (trade size 6). It must not be used above 50°C, either by reason of a high ambient temperature, or high operating temperatures of the enclosed conductors, or both. Polyethylene is flammable, and for that reason it is generally limited to direct burial applications. If not specifically prohibited, it is permitted above grade if encased in a concrete envelope not less than 2 in. (50 mm) thick. It is not permitted to be exposed, and it must not be used inside buildings. NEC Table 354.24 specifies the minimum bending radius for this

material, which is more restrictive than most tubular raceways. The table begins with a 250 mm (10-in.) radius for metric designator 16 (trade size $1/2$) conduit, and rises to a 1.5 m (5 ft) minimum radius for the trade size 4 product. There is no table entry as of the 2008 NEC for metric designator 129 or 155 (trade size 5 or 6) conduit, so the manufacturer's directions would need to be consulted for these sizes.

22. Nonmetallic underground conduit with conductors (Type NUCC) is the same product as Type HDPE conduit, and it follows the same installation rules, but conductors are preinstalled and shipped with the product by the manufacturer. Note that even though conductors arrive with the product preinstalled, it is still classified as a raceway, and the 360° maximum bends-in-the-run rule continues to apply.

23. Reinforced thermosetting resin conduit (Type RTRC) is the fiberglass entry in the nonmetallic conduit market. At one time it was only permitted for below-grade applications, but advances in chemistry have resulted in materials that meet above-grade fire resistance tests and it is now permitted for use in buildings where concealed in walls, floors, and ceilings, and also where exposed if identified for the application. It is stiffer than PVC and has a much lower coefficient of thermal expansion (about 45 percent of the value for PVC). Although the NEC uses the same support distance table as for PVC conduit, it does allow for longer support intervals if the product is listed for larger distances. It is more difficult to bend in the field, although an extensive range of different bend angle sweeps is available to accommodate field installation issues. It must not be used above 50°C unless listed for a higher temperature.

24. Liquidtight flexible nonmetallic conduit (Type LFNC) is a flexible non-metallic raceway of circular cross section, available in three forms. Type LFNC-A has a smooth, seamless inner core and cover bonded together, with reinforcement between the core and cover layers. Type LFNC-B has a smooth inner surface together with reinforcement within the conduit wall. This is its most usual form. Type LFNC-C has a corrugated inner and outer surface, with no reinforcement in the wall. It is generally limited to 6-ft (1.8 m) lengths unless a longer length is required for the amount of flexibility called for at the point of use. However, the "B" style does not carry this length limitation. It can be used for direct burial and concrete encasement if listed and marked accordingly. It is available in the metric designator 16 through 103 ($1/2$ through 4 trade) sizes, with the metric designator 12 ($3/8$ trade size) available to enclose the leads of motors in some cases, and also in runs not over 1.8 m (6 ft) to luminaires as part of a listed assembly, or to utilization equipment.

25. In the electrical-metallic tubing (Type EMT) method of installing wiring the wires are installed in a thin-walled metallic tube or thin-walled conduit, as it is sometimes called. Electrical metallic tubing is similar to rigid conduit, except that it is constructed of much thinner material. Provisions for connecting outlets and switches to the circuit are made by means of special metallic-tubing fittings or by means of regular rigid-conduit fittings provided with an adapter. After the tubing and fittings have been installed as a complete system, the wires are pulled in from fitting to fitting as in the rigid-conduit method. Connectors and couplings are threadless types such as setscrew, compression, indenter, or tap-on.

26. Flexible metallic tubing (Type FMT) is a flexible metallic raceway intended to be used in protected locations such as suspended ceilings. Flexible metallic tubing in the $\frac{3}{8}$ trade size is restricted to 1.8 m (6 ft) lengths and was developed for use in ducts or plenums through which the excursion of smoke or gases from the raceway needed to be controlled. The wiring method is otherwise available in trade sizes $\frac{1}{2}$ and $\frac{3}{4}$, the maximum permitted.

27. Electrical nonmetallic tubing (Type ENT) is a pliable, corrugated raceway of circular cross section with integral or associated couplings, connectors, and fittings listed for the installation of electric conductors. It is composed of a material that is resistant to moisture and chemical atmospheres and is flame-retardant. It is made of the identical PVC from which Type PVC conduit (Sec. 20) is made. It is sold in metric designators up to 53 (trade sizes up to 2), but in a corrugated wall construction that allows it to be bent by hand without the application of heat. It can be supplied in continuous lengths from a reel. It is even available as a prewired assembly with specified conductor combinations already pulled in place. However, it is not a cable, and it is subject to all the normal restrictions for raceways, including the 360° bend rule. It must be supported every 900 mm (3 ft), and within the same distance of terminations. It cannot be used outdoors or for direct burial; however, it can be used in cases where it runs in concrete, even if the concrete is below grade.

You can use the ENT wiring method either exposed or concealed in low-rise construction. However, in buildings that exceed three floors above grade, it must never be exposed, even in the first three floors. Instead, in other than fully sprinklered buildings, it needs to be behind a thermal barrier that has at least a 15-min finish rating as defined in listings of fire-rated assemblies. In the case of walls, this is fairly easy to arrange, since most $\frac{1}{2}$ -in drywall used in commercial construction carries this rating. The same holds true above a drywall ceiling. However, if there is a suspended ceiling (common in commercial occupancies), check with the building inspector. The support grid and the ceiling panels need to be identified as a combination for this duty. For example, having 15-min panels would do no good if the T-bars dumped those panels onto the floor after 11 min of fire exposure.

The first floor is defined as the one with at least half its exterior wall area at or above grade level; one additional floor level at the base is allowed for vehicle parking or storage, provided it is not designed for human habitation. Beginning with the 2002 NEC, ENT can also be used in high-rise buildings (those over three floors above grade) without the use of a thermal barrier if the entire building has a complete fire sprinkler system in full compliance with *NFPA 13, Standard for the Installation of Sprinkler Systems*. The sprinkler system must cover all floors, not just the area where the use of ENT is being considered.

28. Auxiliary gutters differ from wireways only by the way they are applied in the field; they are usually listed for both purposes as they leave a manufacturer. They are available in both sheet metal and nonmetallic forms. They have hinged or removeable covers that allow for conductors to be laid in place after the system is complete. Their function is to supplement wiring spaces at meter centers, distribution centers, switchboards, and similar locations in a wiring system. They are not wireways, which are unlimited in length and intended as a circuit wiring method that connects a line and a load. An auxiliary gutter with a rectangular opening cut to match a similar opening cut in a panelboard, and used to contribute to the wire bending space in the panelboard would be an excellent example. This concept of why the auxiliary gutter article has current carrying limitations for busbars placed in the enclosure, but the wireway article does not address the topic. If a conductor needs to be pulled from the gutter through a nipple to a panel or switchboard, the use may be crossing over into the wireway article. That said, the basic field installation

rules for conductor fill, derating thresholds, use as pull boxes, and distinctions between metallic and nonmetallic versions are similar. Refer to wiring topics in this division for more information.

29. Busway systems of wiring consist of bare or insulated busbars insulated from each other and supported and protected by a sheet-metal housing. The housing and busbars are assembled as a unit in 3.0-m (10-ft) or longer sections. The system is installed by supporting the housing from the ceiling, walls, or roof structure. Busway systems are extensively used for the feeder and main circuits in industrial plants. They are available in three general types: without provision for outlets, with provision for fixed outlets, and with provision for continuously moveable outlets for portable tools and electric-welding work. With the type which has provision for fixed outlets, openings are provided every few inches for branch taps. The connection of a tap to the busbars is accomplished through the insertion of a special power attachment plug in these openings. For the wiring of the branch circuit from the power plug to the apparatus to be supplied with power, flexible conduit, rigid conduit, or metal-clad cable may be employed. This method of wiring provides a very flexible system which meets in an economical manner the requirements of plants in which production conditions necessitate the frequent shifting or replacement of machinery.

30. A cablebus system is an approved assembly of insulated conductors mounted in spaced relationship in a ventilated metal protective supporting structure, including fittings and conductor terminations. Cablebus may be used at any voltage up to 35 kV or current for which the spaced conductors are rated. It is ordinarily assembled at the point of installation from components specified by the manufacturer. First, the supporting structure is installed in the same manner as in a cable-tray support system. Next, the insulated conductors, not less than 1/0 with insulation ratings at 75°C or higher, are inserted. After this, insulating supports are installed so that the conductors are properly separated and supported at intervals of not less than 900 mm (3 ft) for horizontal runs and 450 mm (1½ ft) for vertical runs. Conductor ampacity is based on the values for open conductors.

31. In cellular-concrete-floor-raceway wiring, the floor is constructed of precast reinforced-concrete members. These precast members are provided with hollow voids which form smooth, round cells. The cells form raceways for the wires. Connections to the cells from a distribution center can be made by metal header ducts run horizontally across the precast slabs and embedded in the concrete fill over the slabs. Connection from these headers to the cells is made through handhole metal junction boxes. An outlet can be located at any point along a cell. An opening into the cell at the desired point is formed by drilling a hole through the concrete floor slab. The hole is then fitted with the proper outlet fitting, and the wires fished from a handhole junction box to the outlet.

32. In cellular-metal-floor-raceway wiring, the floor is constructed of special metal structural members containing hollow spaces or cells which form raceways for the wires. Provision for pulling in and splicing wires is made by locating special junction boxes in the floor between sections of the floor members. Outlet openings and fittings may be originally provided at regular intervals along the raceway formed by the cells, or outlets may be provided at any time after completion of the building construction simply by cutting a hole in the floor and cell wall and inserting a special floor-outlet fitting. After the

complete floor structure has been erected and finished over, the wires are pulled through the raceway formed by the floor cell structure and the junction boxes.

33. In the metal wireway method of wiring, the wires are supported and protected in a sheetmetal or nonmetallic trough. The trough is installed exposed, being mounted on the ceiling or walls or supported from the roof structure. One side of the trough is fitted with a sheet-metal cover so that access can be made to the interior sections of the trough throughout its length. After the wireway has been installed as a complete system, the wires are laid in the trough and the cover is installed. Mains and feeders are run in the wireways with taps for branches taken off at the most convenient point through rigid or flexible metal conduit, connected to the wireway through knockouts provided on three sides of the trough. This system provides a flexible distribution system.

34. Nonmetallic wireways are the nonmetallic version of metal wireways. There are some important differences, however. They must be securely supported at not greater than 900-mm (3-ft) intervals [1.2 m (4 ft) for vertical runs], which is far more frequent than the 1.5 m (5 ft) and 4.5 m (15 ft) distances allowed in sheet metal version. In addition, the derating penalties for mutual conductor heating apply to any current-carrying conductor fill above three. This is far more severe than for sheet metal wireways (with 30 or fewer, no penalty), but is justified because the metallic version is a far better heat sink. Refer to Sec. 351 for more information.

35. Multioutlet assemblies are a special form of surface raceway with built-in single receptacle outlets every few inches. The assembly is supported on the surface of walls or in or on top of baseboards. It is used for wiring in dwellings and commercial buildings to provide very convenient and adequate convenience outlets. The assembly is supplied with power through a cable or conduit run concealed in the walls and brought into the back or end of the assembly.

36. A nonmetallic extension is an assembly of two insulated conductors within a nonmetallic jacket or an extruded thermoplastic covering. The assembly is mounted directly on the surface of walls or ceilings. Nonmetallic extensions are permitted only if (1) the extension is from an existing outlet on a 15- or 20-A branch circuit and (2) the extension is run exposed and in a dry location. Nonmetallic extensions are limited to residential or office buildings that do not exceed three stories above grade. This category also includes *concealable nonmetallic extensions*, which are comprised of two, three, or four insulated circuit conductors that mount on wall and ceiling surfaces in a flat configuration that is capable of concealment behind paint, joint compound, wallpaper, etc. In this form, if identified for the purpose, concealable extensions are permitted in buildings of more than three stories.

37. Strut-type channel raceways use steel, stainless steel, or aluminum formed similar to construction strut, but with generally solid surfaces and listed as an electrical raceway. It can be mounted on a building surface or suspended, and must be fastened at least every 3.0 m (10 ft) and within 900 mm (3 ft) of terminations. The strut depth varies from $1\frac{3}{16}$ to 3 in. (20.6 to 76 mm) with the allowable wire fill based on either 25 percent or

40 percent of the internal cross-sectional area, with the lesser fill mandated if the joiners between raceway sections are mounted internally. However, if the wire fill does not exceed 20 percent and the current-carrying conductor count does not exceed 30, then there is no ampacity derating for mutual conductor heating.

38. Surface metal raceways enclose wires that are inserted into a sheet-metal enclosure of various configurations. The raceway is installed exposed on interior building surfaces. The metal molding is made with a flattened-oval or rectangular cross section. Numerous fittings, adapters, and boxes, specially designed for this system, are readily available from major manufacturers of this wiring system. In some configurations the cover is separate from the base, and in others the cover and base are permanently joined and the wires are pulled in similar to tubular raceways. If the raceway exceeds 2500 mm² (4 in²) in cross section, the current-carrying conductor count does not exceed 30, and the wire fill does not exceed 20 percent, then mutual conductor heating derating penalties for wire fill are excused. Where different systems run in opposite halves of a divided raceway in order to accomplish the system segregation required by the NEC, such as communications circuits and power circuits, the separate compartments must be identified by imprinting, stamping, or color coding.

39. Surface nonmetallic raceways are the nonmetallic versions of surface metal raceways and have similar requirements. As in the case of other nonmetallic equivalents, these raceways are not effective heat sinks and the allowances for conductor fill without ampacity derating penalties do not apply to these raceways.

40. In the underfloor-raceway method of wiring the wires are installed in a sheet-metal or fiber casing which is embedded in the concrete or cement fill of the floor. Generally, the ducts or raceways are laid out in the floor to form a network. Provision is made at the intersections of the ducts for the pulling in and splicing of wires by means of special floor junction boxes. Sheet-metal-type raceways are provided with outlet openings spaced at regular intervals along the raceway. These outlet openings are either plugged or equipped with special floor-outlet fittings. With the fiber-duct type of raceway the raceway is first installed in the floor without any outlet openings. After the floor has been finished, outlets may be provided at any desired point along the duct runs simply by cutting a hole in the floor and duct and inserting a special floor-outlet fitting. In the underfloor-raceway systems the wires are pulled through the ducts in the same manner as for rigid-conduit work.

41. Cable tray is a unit or an assembly of units or sections and associated fittings made of metal or other noncombustible materials forming a continuous rigid structure used to support cables. The support system includes ladders, troughs, channels, and similar support systems. Cable tray is not a wiring method and may be used only as the mechanical support for approved raceways or multiconductor cable wiring methods or specially approved multiconductor cables designed for use in cable trays; or 1/0 AWG or larger single conductors in industrial establishments where conditions of maintenance and supervision assure that only qualified persons will service the cable-tray system. First, the cable tray is installed, and then the cables or raceways are installed and secured to the cable tray. This system has particular merit in industrial applications or similar uses for which many power, control, or signal cables are required and flexibility is a major consideration.

42. Concealed knob-and-tube wiring was one of the earliest methods of installing wiring. The wires were mounted on knobs and run through tubes where they pierced structural members of the building. They were then concealed by the wall and ceiling surface. This method is still allowed by the NEC but is not used very often because of the large amount of labor required to install the wiring. In addition, the wiring seldom includes an equipment grounding conductor, which is problematic in terms of meeting installation requirements for most metallic equipment.

43. Messenger-supported wiring encompasses the use of a messenger wire to support other wiring methods, or even individual conductors in some cases. The messenger must be supported at dead ends and at intermediate locations to assure that there will be no tension on the conductors, and that they will not come in contact with the messenger supports, or any structural members, walls, or pipes. The messenger supported wiring can be a factory assembled grouping, either as aerial cable or as a bare conductor twisted with ungrounded conductors such as duplex, triplex, or quadruplex makeups. The conductors can also run through rings or saddles, or they can be attached with a field lashing material. Acceptable wiring methods for messenger support include Types MC (Sec. 10), MI (Sec. 11), TC (both power and power limited cables, Sec. 13), UF (Sec. 15), multiconductor Type SE (Sec. 14) and other factory-assembled multiconductor cables identified for the application. In industrial occupancies with qualified maintenance and supervision, there are additional allowances covering ordinary building wires. If the messenger runs outdoors, such wires must be listed for wet locations and sunlight exposure as applicable. Type MV cable is also permitted assuming the exposed use is permitted by Article 300 (see Sec. 9).

44. In the open-wiring method on insulators of installing interior wiring the wires are run either concealed or exposed on the ceiling, roof structure, or walls. They are supported on porcelain insulators of either the knob (Figs. 4.139, 4.140, and 4.141) or the cleat type (Figs. 4.143 and 4.144) so as to provide the necessary clearance between the wires and the surface being wired over.

OPEN WIRING ON INSULATORS

45. Open wiring on insulators is one of the cheapest methods of installing wiring. It finds application in factories and mills for the installation of feeder circuits in places where appearance is of little consequence. The wires may contain rubber or thermoplastic insulation. Smaller wires must be supported at least every 1.4 m (4½ ft). Conductors 8 AWG and larger may be run across open spaces and supported at distances not greater than 4.5 m (15 ft) if approved noncombustible, nonabsorptive insulating separators providing not less than 65 mm (2½-in.) separation between conductors are installed at intervals of not over 1.4 m (4½ ft). For mill construction in locations where the conductors are unlikely to be disturbed, conductors 8 AWG and larger can be run between cross members on insulators such that the conductors are at least 150 mm (6 in.) apart. Industrial occupancies with a qualified maintenance force may use 250 kcmil or larger conductors supported at 9 m (30 ft) intervals.

46. Knobs and methods of supporting conductors on them. Knobs for supporting conductors in interior work are of porcelain. Split knobs or cleats may be used for supporting conductors smaller than 8 AWG. Some methods of securing wires to knobs are shown in Fig. 9.1. The line tie of I is made by winding the conductor once around the knob,

FIGURE 9.1 Methods of attaching conductors to knobs.

so both ends of the wire must be under tension to hold the wire in position. A tie wire is used at II; in making up the tie wire the slack can be drawn out of the conductor. A dead end, or termination, is shown at III. If it is necessary to change the direction of a run to get the conductor to an outlet or for any other reason, tap ties IV, V, and VI are used. It is not practicable to tie large conductors, so they may be supported as at VII.

For a discussion of types of knobs see Div. 4.

Nails used to support knobs must be not smaller than tenpenny and must be provided with cushion washers. When screws are used, they must penetrate the supporting wood to a depth equal to at least one-half the height of the knob or to at least the thickness of the cleat used.

47. The wires must have an insulation equal to that of the conductors they confine and may be used in connection with solid knobs for the support of wires of size 8 AWG or larger.

48. The method of dead-ending on a cleat at the end of a run is illustrated in Fig. 9.2. After the wire has been passed through the groove, the free end is given several short turns around the line. When a long run is dead-ended, it is often advisable to fasten two sets of cleats in such a way that one bears against the other so that both will assume the strain as shown at II. For types and dimensions of cleats see Div. 4.

FIGURE 9.2 Dead-ending on cleats.

49. Methods of terminating heavy conductors. At the ends of all important open-wire runs of wires larger than, say, 8 AWG, strain insulators engaging in some wire-tightening device should be used. Figure 9.3 illustrates some methods. Either tightening bolts or turnbuckles can be used. The insulator may be of the type extensively used in trolley-line construction as in I, II, and III, or it may be a heavy knob (IV) held to the tightening device with stout wire. When a run changes direction, a cable clamp can often be used with economy, particularly with large conductors. If a cable clamp is used, it is

FIGURE 9.3 Methods of terminating conductors.

unnecessary to cut the conductor to change its direction, and the need to make up turns about the line wire as in I and II is eliminated.

50. Different approved methods of exposed surface wiring are illustrated in Fig. 9.4. Which method should be used in any particular case is determined largely by the size of the wire involved and other local conditions.

FIGURE 9.4 Openwork wiring in a mill building.

51. Physical protection of exposed surface wiring. Wires must be protected on sidewalls from physical damage and, when crossing timbers where they might be disturbed, must be protected by guard strips or running board and guard strips as shown in Figs. 9.5 and 9.6. The guard strips must be at least 25 mm (1 in.) nominal thick and at least as high as the insulators. If a running board is used, it must be at least 13 mm (1/2 in.) thick and must extend at least 25 mm (1 in.) outside the conductors but not more than 50 mm (2 in.). The wires should also be protected by porcelain tubes when passing over pipes (Fig. 9.7) or any other members. Tie wires may be used in lieu of tape.

Conductors within 2.1 m (7 ft) from the floor shall be considered exposed to physical damage. Suitable protection on sidewalls therefore should extend not less than 2.1 m (7 ft) from the floor (Fig. 9.8). This protection may consist of substantial boxing, providing an air space of 25 mm (1 in.) around the conductors, closed at the top (the wire passing through porcelain-bushed holes), or of a conduit with fittings on each providing individual bushed holes for each wire (Fig. 9.8, III).

FIGURE 9.5 Guard strips to protect open wiring crossing ceiling joists.

FIGURE 9.6 Running board with guard strips to protect open wiring crossing ceiling joists.

FIGURE 9.7 Protection of conductor passing over pipe.

FIGURE 9.8 Protection of conductors on sidewalls.

52. Methods of carrying exposed wiring around and through beams are illustrated in Fig. 9.4, which shows tube-and-cleat arrangements. In Fig. 9.9 are shown methods that can be used when wires are supported on knobs.

FIGURE 9.9 Openwork wiring with knobs.

53. In steel-mill buildings heavy conductors may be carried on the lower chords of the roof trusses (Fig. 9.10). This is a good location because the conductors are out of the way and not apt to be disturbed. At each truss the conductors can be supported by one of the methods illustrated in Fig. 9.11. With the method of Fig. 9.11, I, the conductor merely rests in the insulator, and the entire longitudinal strain is taken by strain insulators attached to the tightening bolts or turnbuckles at the ends of the run. This method has the

disadvantage that if the conductor breaks at any point or is burnt in two, it will fall to the floor. The tie-wire method of II is seldom used, though it is satisfactory if cleats are not obtainable. (Split knobs or cleats must be used for conductors smaller than 8 AWG.) The cleat and through-bolt method of III is probably the best, all things considered. After the conductor has been drawn taut with the tightening bolts at the end of the run, the cleat bolts are tightened and each cleat then assumes its share of the stress. Tie wires, which are unreliable and may cut into the insulation of the conductor, are unnecessary. Leather washers should be used between the insulator and the bolt to prevent breakage.

FIGURE 9.10 Conductors carried on roof truss.

FIGURE 9.11 Attaching knobs to truss chords.

54. For supporting conductors on steel angles the Universal Insulator Support (Figs. 9.12 and 9.13 and Table 42) is a convenient fitting. It is of malleable iron and can be clamped on the flanges of steel beams, angles, channels, and Z bars and on round, square, and flat bars. It can also be attached to gas and water pipes and to the edges plates and tanks. Two insulators can be fastened to each support when necessary. Cup-pointed, case-hardened setscrews are used. Leather washers should be used under the bolts that hold the insulators.

FIGURE 9.12 Universal Insulator Supports on an angle.

FIGURE 9.14 Attachment of wiring board to column.

56. For supporting conductors on steel columns a wooden baseboard for the cleats clamped to the column with hook bolts (Fig. 9.14) is a good arrangement. The board must be cut out in back for the rivet heads in the column. Strap-iron cleats through which the hook bolts pass prevent warping and splitting.

57. Wire racks are used to support conductors, principally heavy ones, when there are many conductors in the run. The conductors should have flameproof or slow-burning covering. A wire rack can be made of wood fashioned into a framework somewhat along the lines of the steel ones of Figs. 9.15 and 9.16. The cleats insulating the conductors are held to the frame with wood screws or, preferably, with machine or stove bolts. A commercial wire rack with a cast-iron base that can be bolted to any surface is shown in Fig. 9.17. Generally a steel-frame rack is preferable to a wooden one. The rack of steel angles of Fig. 9.15 was designed for installation in the top of a pipe tunnel. The insulators are held to the cross angles with bolts with a leather washer under the head of each. The structural-steel rack of Fig. 9.16, III, is arranged for supporting from a ceiling. Angle crossarms can be used as at I, or the crossarms can each be formed of two iron straps as at I. With the two-strap method, drilling for the cleat bolts is unnecessary, and the cleats can be shifted along the arm into any desired position and there clamped fast.

FIGURE 9.15 Angle-iron rack for conductors.

FIGURE 9.16 Rack composed of angles and strap iron: I, section A-A; II, section B-B. Wrought-iron yokes are bent to fit the grooves as shown, and 1/2-in (12.7 mm) bolts clamp them in position. Wooden blocks or sections of strap iron can be bolted to the yokes for supporting the wire cleats.

FIGURE 9.17 A commercial insulator rack.

Strain insulators engaging in turnbuckles or tightening bolts should be used at the end of each straight run to assume the strain and to provide for tightening, or else the arms and cleats at the run ends should be reinforced to assume the stress that will come on them.

58. A method of supporting open wiring in concrete buildings is shown in Fig. 9.18. A round groove of 3/8-in (9.525-mm) radius is cast in the faces of the beams, by having 3/4-in (19.05 mm) half-round molding nailed in the forms.

FIGURE 9.18 Supports for open wiring on a concrete beam.

59. When conductors pass through floors, walls, or partitions, they must always be protected. Openwork wires can be protected with porcelain tubes (Fig. 9.19). The tube or bushing must be long enough to bush the entire length of the hole in one continuous piece, or else the hole must first be bushed by a continuous waterproof sleeve of noninductive material and the conductor so installed that it will be absolutely out of contact with the sleeve.

FIGURE 9.19 Protection through walls and partitions.

60. A tube for protecting a wire where it crosses another wire should always be so placed that the tube will not force the unprotected wire against the surface supporting the conductors.

61. Flexible nonmetallic tubing, or "loom" (Fig. 9.20) is used mostly in connection with open wiring and concealed knob-and-tube wiring. When metal outlet boxes or switch boxes are used, flexible tubing is required from the last porcelain support, extending into the outlet box at least 6 mm (1/4 in.), and held in place by an approved fitting such as a universal bushing or a clamp.

FIGURE 9.20 Flexible tubing.

Another application for flexible tubing is in completed buildings where the wires are fished in between the walls and ceilings. Flexible nonmetallic tubing is used as a covering on such wires separately encased. In concealed knob-and-tube work it is frequently impracticable to place wires 75 mm (3 in.) apart and 25 mm (1 in.) from the surface wired over as required by the National Electrical Code, and in such cases the wires must be separately encased in flexible tubing. In open wiring when the amount of separation required by the Code from the surface wired over cannot be maintained, the wires may also be encased in flexible tubing.

The following is a list of places where flexible nonmetallic tubing is applicable: in open-work where wires are exposed nearer each other than 75 mm (3 in.); on wires crossing other wires; on wires crossing gas pipes, water pipes, iron beams, woodwork, brick, or stone; and at distributing centers or when space is limited and the 75 mm (3 in.) separation required cannot be maintained. Each wire must be separately encased in a continuous length of flexible nonmetallic tubing.

Only continuous (unspliced) lengths of flexible nonmetallic tubing can be used for wire protection at outlets.

62. Properties of Flexible Tubing or Loom

63. When conductors cross damp pipes, they should be carried over rather than under so that drippings will not strike the wires. Porcelain tubes, securely taped to the conductors, should be placed on the conductors over the point where they cross.

64. Rosettes for open surface wiring are used to connect drop cords for incandescent lamps to the branch circuits. A rosette with protected (concealed) contact lugs is preferable to one with exposed lugs. Figure 9.21 shows one good type. Another good method of supporting drop cords, particularly if there is vibration, is with the ceiling button illustrated in Fig. 9.22.

FIGURE 9.21 A cleat rosette.

FIGURE 9.22 Ceiling buttons.

65. Switches can be supported in exposed surface wiring as shown in Fig. 9.23. The switch can be mounted on a commercial porcelain switch block.

FIGURE 9.23 Support switches in exposed surface wiring.

66. Entering damp or wet locations (National Electrical Code). Conductors entering or leaving damp or wet locations shall have drip loops formed on them and shall then pass upward and inward from the outside of buildings or from the damp or wet location through noncombustible, nonabsorptive tubes.

CONCEALED KNOB-AND-TUBE WIRING

67. Concealed knob-and-tube wiring was used extensively at one time for the wiring of frame buildings when a low-cost installation was essential. It is still allowed by the National Electrical Code, but only for extensions of existing installations (or otherwise by special permission), and it is rarely used because more labor is required than with common cable systems. It has been superseded for low-cost installations by nonmetallic-sheathed cable.

68. Extensions of concealed knob-and-tube wiring are seldom practical today. (Adapted from *Practical Electrical Wiring*, 20th ed., © Park Publishing, 2008, all rights reserved.) Although this handbook extensively covers concealed knob-and-tube wiring because installers often come across it and need a reference source to help understand it, it is no longer routinely installed. The hardware is generally no longer available, and the existing knobs you might salvage from old jobs have internal spacings for old Type R conductor insulation that won't work on today's thinner insulation. Concealed knob-and-tube, as a wiring method, has no equipment grounding conductor carried with it. Over the generations, NEC provisions have changed to the point that it is almost impossible to wire anything legally without grounding it. For example, until the 1984 NEC, what is now 314.4 only required the grounding of metal boxes used with concealed knob-and-tube wiring if in contact with metal lath or metallic surfaces. Now all metal boxes must be grounded without exception. Meanwhile, grounding has been getting more difficult to arrange to remote extensions of concealed knob-and-tube outlets. Until the 1993 NEC you could go to a local bonded water pipe to pick up an equipment grounding connection, and then extend from there with modern wiring methods. Now NEC 250.130(C), which governs this work, requires that the equipment grounding connection be made on the equipment grounding terminal bar of the supply panelboard, or directly to the grounding electrode system or grounding electrode conductor. You are unlikely to be searching for a method of grounding concealed knob-and-tube wiring in a steel-frame building. Rather you will be attempting this in old wood-frame buildings, probably residential. In such occupancies, even if the water supply lateral is metallic, the water piping system ceases to be considered as an electrode beyond 1.5 m (5 ft) from the point of entry. This means fishing into the basement. If you can fish a ground wire down into the basement, you can fish a modern circuit up in the reverse direction and avoid the entire problem.

It is true that some geographical areas have more extensive use of slab-on-grade construction, and here interior water piping is sometimes permitted to qualify as electrodes because the pipes extend to grade for the minimum threshold distance of 10 ft and thereby allow interior connections. But in almost every case, trying to extend knob-and-tube wiring is like trying to erect a modern structure on a rotten foundation.

Add to these problems the fact that beginning with the 1987 NEC this wiring method cannot be used in wall or ceiling cavities that have "loose, filled, or foamed-in-place insulating material that envelops the conductors." This effectively means that such cavities cannot be insulated, because you'd have to open all the walls to install board insulation products, and if you'd do that, you'd never consider trying to save this wiring method.

69. When changing from open wiring or concealed knob-and-tube wiring to conduit, electrical-metallic-tubing, nonmetallic-sheathed-cable, armored-cable, or surface-raceway wiring, a fitting or outlet box having a separately bushed hole for each conductor must be used.

RIGID-METAL-CONDUIT AND INTERMEDIATE-METAL-CONDUIT WIRING

70. Rigid-metal-conduit wiring is allowed for both exposed and concealed work and for use in nearly all classes of buildings. For ordinary conditions, wiring in metal conduit is probably the best, although it is the most expensive. The advantages of metal conduit are that (1) wires can be inserted and removed, (2) it provides a good ground path, (3) it is strong enough mechanically so that nails cannot be driven through it and so that it is not readily deformed by blows or by wheelbarrows being run over it, and (4) it successfully resists the normal action of cement when embedded in the partitions or walls of concrete buildings.

A recent innovation is intermediate metal conduit, which has a thinner wall and is acceptable whenever rigid metal conduit is permitted.

71. When to use rigid-metal-conduit or intermediate-metal-conduit wiring.

In general, conduit wiring should be used whenever the job will stand the cost. Rigid conduit protects the conductors it contains and provides a smooth raceway, permitting ready insertion or removal.

Conduits and fittings exposed to severe corrosive influences shall be of corrosion-resistant material suitable for the conditions. If practicable, the use of dissimilar metals in contact anywhere in the system shall be avoided to eliminate the possibility of galvanic action.

Meat-packing plants, tanneries, hide cellars, casing rooms, glue houses, fertilizer rooms, salt storage, some chemical works, metal refineries, pulp and paper mills, sugar mills, roundhouses, textile bleacheries, plants producing synthetic staples, some stables, and similar locations are judged to be occupancies where severe corrosive conditions are likely to be present.

Cinder Fill. Conduit, unless of corrosion-resistant material suitable for the purpose, shall not be used in or under cinder fill where subject to permanent moisture unless protected on all sides by a layer of noncinder concrete.

Wet Locations. In portions of dairies, laundries, canneries, and other wet locations and in locations where walls are frequently washed, the entire conduit system, including all boxes and fittings used therewith, shall be so installed and equipped as to prevent water from entering the conduit, and the conduit shall be mounted so that there is at least 6 mm ($1/4$ -in) air space between the conduit and the wall or other supporting surface.

All supports, bolts, straps, screws, etc., shall be of corrosion-resistant materials or be protected against corrosion by approved corrosion-resistant materials.

72. Corrosion-resistant rigid conduit is available in three general types: (1) aluminum, (2) red brass, and (3) plastic-coated.

Aluminum rigid conduit is useful in installations where there are present certain chemical fumes or vapors which have little effect upon aluminum but have a severe corrosive effect upon steel. It is widely used because its light weight reduces installation labor costs. Uncoated or unprotected aluminum conduit should not be embedded in concrete or buried in earth, particularly if soluble chlorides are present.

A conduit of red brass has special corrosive-resistance characteristics. Its use is advantageous for installations exposed to the weather, as on bridges, piers, and dry docks and

along the seacoast; in oil refineries and chemical plants; in sewage-disposal works; underground for water-supply works; and in wiring to underwater lighting fixtures for swimming pools.

Plastic-coated rigid conduit consists of standard galvanized-steel conduit over the surface of which seamless coatings of polyvinyl chloride plastic have been extruded. Thus a uniform nonporous protective coating is formed over the entire length of the raceway. All couplings and fittings should be covered with plastic sleeves or carefully wrapped with three thicknesses of standard vinyl electrical insulating tape. This plastic-coated conduit is flame-retardant and highly resistant to the action of oils, grease, acids, alkalis, and moisture; does not oxidize, deteriorate, or shrink when exposed to sunlight and weather; and provides excellent resistance to abrasion, impact, and other mechanical wear. Typical applications are meat-packing plants, malt-liquor industries, paper and allied industries, production plants for industrial organic and inorganic products, soap and related-products industries, tanneries and leather-finishing plants, canneries, food-processing industries, dairies, fertilizer plants, and petroleum industries.

FIGURE 9.24 Section of conduit.

73. Dimensions of corrosion-resistant rigid conduit.

The internal and external diameters for aluminum conduit are the same as those for rigid steel conduit (see Fig. 9.24). The internal diameter of plastic-coated rigid conduit, of course, is the same as that of standard rigid steel conduit. The outside diameter of the plastic-coated variety is slightly greater, as given in Table 75.

74. Intermediate Metal Conduit

(Allied Tube & Conduit Corp.)

*The wall thickness is +.015 and -.000 for IMC.

[†]Because of the specification of tube dimensions, weight specifications are not part of Underwriters Laboratories (UL) Standard 1242 but have been included for comparative purposes. At regular production intervals, UL inspects wall thicknesses of all trade sizes with a micrometer to check consistency with the specified standard tolerance.

75. Plastic-Coated Rigid Conduit
(General Electric Co.)

Size, in	Weight, lb/1000 ft	Ft per bundle	External diameter, in

3	7860	10	3.560
3 1/2	9433	10	4.060

76. Rigid steel conduit is made in several types, including white (galvanized), black (enameled), green (sheradized), and with an organic (plastic) coating. The white galvanized conduit is the type to be used where exposed to the weather, when embedded in concrete, or when installed in wet locations. The black conduit, which is coated with black enamel, is limited to indoor noncorrosive locations, and is seldom seen today. The green (sheradized) conduit has a special corrosion-resistant coating consisting of zinc applied in a way that alloys it to the underlying steel. It is the hardest of the zinc finishes and accepts paint without primers. Plastic coatings can be applied to the conventional galvanized product, or the sheradized finish for even more resistance to corrosion. Except for special conditions no size smaller than metric designator 16 (trade size 1/2 in. is allowed. The metric designator 12 (3/8 trade size) is allowed to enclose the leads of a motor, as covered in NEC 430.245(B).

NOTE All tubes are threaded both ends, and 10 ft long inclusive of the coupling on one end.

78. Data on conduit couplings and elbows are given in Secs. 77, 81, and 86 (see Fig. 9.25). The weight columns are convenient for estimating transportation charges. The internal area is useful in determining the size of conduit for unusual combinations of conductors, as explained in Sec. 94. Dimensions of elbows and couplings are often used in laying out work on the drawing board or in estimating clearances in advance. Table 82 gives the dimensions of standard conduit threads. (See Fig. 9.26.)

Running threads are not allowed on conduit for connection at couplings.

FIGURE 9.25 Conduit couplings.

FIGURE 9.26 Conduit threads. The taper of threads shall be $\frac{3}{4}$ in/ft, and the perfect thread shall be tapered for its entire length.

79. Rigid aluminum conduit. The use of rigid aluminum conduit has gained acceptance because of its light weight, excellent grounding conductivity, ease of threading, bending, and installation, and low losses for installed ac circuits. Installations of rigid aluminum conduit require no maintenance, painting, or protective treatment in many applications.

When aluminum conduit is buried in concrete or mortar, a limited chemical reaction on the conduit surface forms a self-stopping coating. This prevents significant corrosion for the life of the structure. However, calcium chloride or similar soluble chlorides sometimes are used to speed concrete setting. In limiting the use of such speeding agents, the American Concrete Institute and most building codes recognize that embedded metals can be damaged by chlorides. As a result, if aluminum conduit is to be buried in concrete, the installer should be absolutely sure that the concrete will contain no chlorides. If there is any doubt, rigid steel conduit should be used, because even though chlorides can damage steel conduit to some degree, this will not lead to cracking or spalling of concrete.

Although aluminum conduit can be buried safely in many soils, precautions are recommended because of unpredictable moisture, stray electric current, and chemical variations in almost every soil. To assure protection when buried directly in earth, aluminum or steel conduit should be coated with bituminous or asphalt paint, wrapped with plastic tape, or encased in a chloride-free concrete envelope.

Being a nonmagnetic metal, aluminum conduit reduces voltage drop in installed copper or aluminum wire up to 20 percent of a corresponding steel-conduit installation when ac circuits are involved.

Tables 80 and 81 list important data on rigid aluminum conduit.

*A minus tolerance of one thread applies to the total length of threads.

†A tolerance of ± 0.005 in. applies to the pitch diameter.

‡Dimension not currently recognized in the NEC; no metric designator assigned.

83. Bushings are required to protect wires from abrasion where a conduit enters a box or other fitting unless the design of the box or fitting is such as to afford equivalent protection.

Connections of rigid conduit to enclosures can be made by a single locknut (outside) and a single bushing (inside) if the bushing is tightly fitted against the wall of the enclosure. Double locknuts (one inside and one outside) and a bushing always make a better connection than the single-locknut-bushing method. The NEC requires the double-locknut method if the circuit voltage exceeds 250 V to ground or if wholly insulated bushings are utilized.

When ungrounded conductors of No. 4 and larger size enter a raceway in a cabinet, pull box, junction box, or auxiliary gutter, the conductors shall be protected by a substantial bushing providing a smoothly rounded insulating surface. Figures 9.27 and 9.28 show two types of bushings that provide insulation protection. The bushing in Fig. 9.27 is wholly insulated and constructed of a tough phenolic with reinforced fibers. The bushing in Fig. 9.28 is a metal grounding bushing with provisions for installing a bonding jumper from the bushing lug to a metal enclosure. The throat, or collar, is of insulating material to protect wires.

FIGURE 9.27 Wholly insulated conduit bushing.

FIGURE 9.28 Metal grounding bushing with insulated throat. [Midwest Electric Mfg. Corp.]

Tables 84 and 88 are useful when cutting knockouts into enclosures. The spacings listed in Table 84 allow enough room between adjacent knockouts for locknuts and bushings to be attached. (See Figs. 9.29, 9.30, and 9.31.)

84. Spacings for Conduit with Given Clearances and Punched-Steel Conduit Locknuts

(All dimensions in inches)

The clearance, *C*, values are based on the *D* values given at the top of the next page.

89. Table 85, giving the dimensions of conduit chase nipples, is since the function of the chase nipple is about the same as that of the bushing, used for the same purposes as the bushing table. The chase nipple screws into a coupling (see Fig. 9.30), while the bushing screws onto the threaded end of a length of conduit. The chase nipple is more compact than the bushing and hence is preferable for some work.

90. Punched-steel locknuts are shown in Table 84. Locknuts are used for conduit on the outside of the box whenever the conduit enters an outlet box, and their dimensions must often be known in laying out panel or outlet boxes so that proper turning clearances can be provided for the nuts.

91. Table 84 of conduit spacings for different clearances between conduits and their locknuts or nipples is exceedingly valuable to someone who is designing or erecting conduit work. From it the designer can determine directly just what the distance between centers of conduits should be for given clearances between nipples or conduit. These data are indispensable when laying out the centers of a row of holes through which conduit is to enter a panel box or in laying out the supports for a multiple-conduit run.

92. Bends. The NEC specifies that bends of rigid conduit shall be so made that the conduit will not be injured and that the internal diameter of the conduit will not be effectively reduced. The radius of the curve of the inner edge of any field bend using sequential benders such as hickies shall not be less than shown in Table 93. See Table 86 for the minimum radius permitted for field bends made by one-shot or full-shoe benders.

The NEC also specifies that a run of conduit between outlet and outlet, fitting and fitting, or outlet and fitting shall not contain more than the equivalent of four quarter bends (360° total), including bends located immediately at the outlet or fitting.

93. Minimum Radius of Conduit or Tubing Field Bends, Centerline Measurement. The former column for lead-sheathed conductors was deleted in the 2002 NEC code cycle because these conductors are no longer made.

Raceway size, Metric designator and (trade size)	One shot and full shoe benders	Other bends
16 (1/2)	101.6 mm (4 in.)	101.6 mm (4 in.)
21 (3/4)	114.3 mm (4 1/2 in.)	127 mm (5 in.)
27 (1)	146.05 mm (5 3/4 in.)	152.4 mm (6 in.)
35 (1 1/4)	184.15 mm (7 1/4 in.)	203.2 mm (8 in.)
41 (1 1/2)	209.55 mm (8 1/4 in.)	254 mm (10 in.)
53 (2)	241.3 mm (9 1/2 in.)	304.8 mm (12 in.)
63 (2 1/2)	266.7 mm (10 1/2 in.)	381 mm (15 in.)
78 (3)	330.2 mm (13 in.)	457.2 mm (18 in.)
91 (3 1/2)	381 mm (15 in.)	533.4 mm (21 in.)
103 (4)	406.4 mm (16 in.)	609.6 mm (24 in.)
129 (5)	609.6 mm (24 in.)	762 mm (30 in.)
155 (6)	762 mm (30 in.)	914.4 mm (36 in.)

94. The NEC specifies the size of conduit to use, depending upon the number, type, and size of conductors to be installed therein. The proper size of conduit can be determined through a three-step process using the tables in NEC Chap. 9. First, determine the cross-sectional areas of the conductors to be installed by consulting Table 5 (or 5A for compact conductors), and develop the cross-sectional area of all the conductors taken together that will be part of the fill. Use the sizes in Table 8 if there are bare wires in the group. Note the fill factor from Table 1 that corresponds to the number of conductors involved. Finally, select the raceway size from Table 4, starting with the data for the raceway of choice and using the column that corresponds to the applicable fill factor; any raceway with a usable cross-sectional area equal to or larger than the conductor area will work. If all the conductors are the same size, Annex C has all the calculations done out ahead of time. Just look up the wiring method of choice and select the size that will hold the wires.

These tables incorporate Note 7 to Table 1, which says that if you divide the permitted fill area of a raceway by the area of the wires to be installed, and that calculation carried to one decimal place and truncated results in a decimal of 0.8 or larger, the fill can be rounded up to the next higher number of conductors, *provided all the conductors are the same size.*

95. Outlets for current-consuming equipment and wiring devices require the use of outlet boxes for concealed or exposed work, whereas conduit bodies (Fig. 9.38) are limited to exposed work.

96. Outlet boxes that are used for conduit wiring are of sheet steel, preferably coated with zinc. They not only hold the conduit ends firmly in position and form a pocket for enclosing wire joints but also constitute electrical connectors between the elements of the conduit system, all of which must be in good electrical contact. Each conduit run in an installation must terminate in an accessible outlet box. Outlet boxes are made in many different forms. For complete data and descriptions of outlet boxes see Div. 4. The required size of boxes is given in Sec. 345.

97. All boxes should be installed so that the outer edge of the box or the cover mounted on the box will come flush with the surface of combustible wall surfaces and 6 mm ($1/4$ in.) set back in noncombustible wall surfaces. The top of an outlet or junction box must never be concealed, as the wire splices inside must be accessible for inspection. The conduit must be fastened securely to the box by using a locknut on the outside and a bushing on the inside of the box (see Sec. 83).

98. Conduit junction boxes, which in reality are nothing more than pull boxes on a large scale, are often very convenient at points where several conduit lines intersect, as for instance over a switchboard (Fig. 9.36) from which conduit lines radiate. The junction box is usually supported from the ceiling and is best made of sheet iron on an angle-iron frame. The sides should be held on with machine screws turning into tapped holes in the frame so that they can be readily removed. Round holes can be cut in the sheet-iron sides for the conduits. The conductors within the box can be carried from conduit outlet to conduit outlet in any direction desired, and the use of elbows and troublesome conduit crossings can thereby be avoided.

FIGURE 9.36 A sheet-iron conduit junction box.

99. Pull boxes can often be advantageously substituted for elbows (Fig. 9.37). Large elbows are expensive. If there are three or more right-angle turns in a run, a pull box should be inserted in any event. One pull box may be substituted for several elbows. Wire can be pulled in more readily when there are pull boxes. Pull boxes are generally made of sheet steel (Fig. 9.37, I). Boxes should be made and drilled in the shop, where proper tools are available, rather than on the job. The required size of pull boxes is given in Sec. 324.

FIGURE 9.37 Conduit pull boxes.

100. Conduit bodies are fittings used to adapt conduit to different situations and conditions. Figure 9.38 shows some popular fittings, the applications of which are obvious. The NEC specifies that every conduit outlet must be equipped with an outlet box or approved fitting. Elbows, crosses, and tees can be obtained fitted with either metal or composition or porcelain wire-hole covers or with outlet or other devices. The fittings can be used as pull boxes, to support switches, or for a number of other purposes. Everyone interested in wiring should have the catalogs of the fitting manufacturers. These illustrate a great number of fitting combinations and applications.

FIGURE 9.38 Popular conduit fittings.

101. Threadless fittings (Fig. 9.39) can be used with unthreaded conduit. Tightening glands or setscrews clamp the conduit within the fitting. Threadless fittings materially reduce the labor cost of conduit installation in many instances.

FIGURE 9.39 No-thread conduit body. [Appleton Electric Co.]

The NEC requires that threadless fittings be made tight and that, if installed in wet places or if buried in masonry, concrete, or fill, they be of a type to prevent water from entering the conduit.

102. Conduit should run as straight and direct as possible. There should never be more than the equivalent of four right-angle bends between outlets or fittings.

103. In installing exposed conduit runs where there are several conduits in the run, it is usually better to carry the erection of all of them together rather than to complete one line before starting the others. If all are carried together, it is easier to keep all the raceways parallel, particularly at turns, and the chances are that the job will look better.

105. Conduit can be supported on surfaces with pipe straps made in two-hole (Fig. 9.40) and one-hole (Fig. 9.41) types. On wooden surfaces, wood screws secure the straps in position. On masonry surfaces, machine screws turning into lead expansion anchors can be used. (Refer to Div. 4 for types of expansion anchors.) Wooden plugs should never be used because no matter how well seasoned a plug appears to be, it will usually dry out to some extent and loosen in the hole. The dimensions in Table 104 are valuable, when laying out multiple-conduit runs, to determine the spacings necessary between the conduits to permit proper placing of the straps. The screw-hole dimensions enable one to order, in advance, screws of the proper diameters to support the straps.

FIGURE 9.40 Pipe strap.

FIGURE 9.41 One-hole pipe straps. [General Electric Supply Co.]

106. Location of conduit supports. The NEC states that rigid metal conduit shall be firmly secured within 900 mm (3 ft) of each outlet box, junction box, cabinet, or fitting. Such conduit shall be supported at least every 3 m (10 ft) except that straight runs of conduit made up with approved threaded couplings may be secured as indicated in Table 107, provided such fastening prevents transmission of stresses to termination when conduit is deflected between supports. In addition, the NEC allows the first support rule to be as far as 1.5 m (5 ft) from a termination in instances where there is no structural support available. This accommodates up to 5-ft spacings between bar joists without having to arrange intermediate support.

A new rule in the 2008 NEC covering all rigid tubular raceways (including RMC, IMC, EMT, PVC, and the now separate article for fiberglass type RTRC raceways) addresses the support of short nipples between enclosures. It requires direct support for

all nipples regardless of length unless they meet three criteria. (1) They must not be over 18 in. in length; (2) they must be unbroken (without couplings); and (3) they must not enter through a concentric knockout. These requirements result in some absurd results, such as a support requirement for a 3-in. nipple if it enters a concentric knockout on just one end. You will need to discuss this with the inspector to see the extent to which it is being enforced locally.

107. Spacing of Rigid-Metal-Conduits Supports

Conduit size, in	Maximum distance between Rigid-Metal-Conduit supports, ft
1/2 and 3/4	10
1	12
1 1/4 and 1 1/2	14
2 and 2 1/2	16
3 and larger	20

108. Some commercial I-beam conduit hangers are shown in Figs. 9.42 and 9.43. The one at I is an I-beam clamp formed from wrought-iron strap. The hanger or clamp (the part that grips the beam) of that at II can be purchased of either stamped steel or malleable iron. The support (the yoke in which the conduits rest) is of malleable iron or spring steel and can be purchased to accommodate one or several conduits of different sizes.

FIGURE 9.42 Commercial conduit clamps.

109. Conduit hangers and supports. A variety of conduit hangers and supports and several applications are shown in Fig. 9.43. U-channel supports are ideal for supporting several runs of conduits. In laying out these supports consideration should be given to future conduit runs as well as those to be installed initially. It is a simple matter to provide U channels or trapeze hangers with additional space for future conduits. This procedure greatly reduces the cost of installing new conduit at a later date. With the U-channel system, as shown in Fig. 9.43, special clamps are slipped into the channel slot, and the top bolt of the clamp securely fastens the conduit to the U channel.

The U channel can be directly fastened to a wall or ceiling, or it can be attached to bolted threaded rod hangers, suspended from ceilings, roof structures, or similar members.

Another excellent application for the U channel is in suspended ceilings which contain lift-out ceiling panels. In modern construction these lift-out panels provide ready access to mechanical and electrical equipment within the suspended-ceiling area. Accordingly, it is important that conduits installed in such an area do not prevent the removal of panels or access to the area. Rod-suspended U channels provide the solution to conduit wiring in such areas.

Sections of U channel and associated fittings are available in aluminum or steel types. Another type of material that can be used for supports is slotted-angle-steel units. Numerous prepunched slots allow installers to bolt on rods, straps, and similar material without drilling holes. Slotted steel has unlimited applications in forming special structures, racks, braces, or similar items.

FIGURE 9.43 Beam clamps, rod hangers, and U-channel supports.

110. Conduit in concrete buildings (much of it, at any rate) can be installed while the building is being erected. The outlets should be attached to the forms, and the conduits between outlets should be attached to reinforcing steel with metal tie wires so that the conduit can be poured around them (Fig. 9.44). When several conduits pass through a wall, partition, or floor, a plugged sheet-metal tube (Fig. 9.45, I) should be set in the forms to provide a hole for them in the concrete. When a single conduit is to pass through, a nipple (Fig. 9.45, II) or a plugged sheet-metal tube can be set in the forms.

FIGURE 9.44 Conduit and outlet box in concrete.

FIGURE 9.45 Methods of providing passage through concrete.

111. Conductors in Vertical Conduits must Be Supported within the conduit system as indicated in the following table.

Conductor size	Conductors, m (ft)	
	Aluminum or copper-clad aluminum	Copper
	Not greater than	
No. 18 through No. 8	30 (100)	30 (100)
No. 6 through No. 0	60 (200)	30 (100)
No. 00 through No. 0000	55 (180)	25 (80)
211,601 through 350,000 cmil	41 (135)	18 (60)
350,001 through 500,000 cmil	36 (120)	15 (50)
500,001 through 750,000 cmil	28.5 (95)	12 (40)
Above 750,000 cmil	26.5 (85)	11 (35)

The following methods of supporting cables will satisfy NEC requirements:

1. Approved clamping devices are constructed of or employ insulated wedges inserted in the ends of the conduits (Fig. 9.46). With cables having varnished cambric insulation, it may also be necessary to clamp the conductor.
2. Junction boxes may be inserted in the conduit system at the required intervals. Insulating supports of an approved type must be installed in them and secured in a satisfactory manner so as to withstand the weight of the conductors attached thereto. The boxes must be provided with proper covers.
3. The cables may be supported in junction boxes by deflecting them (Fig. 9.47) not less than 90° and carrying them horizontally to a distance not less than twice the diameter of the cable, the cables being carried on two or more insulating supports and additionally secured thereto by tie wires if desired. When this method is used, the cables shall be supported at intervals not greater than 20 percent of those mentioned in the preceding tabulation.

FIGURE 9.46 Cable support screwed on the end of a conduit.

FIGURE 9.47 Supporting conductors in a vertical conductor run.

112. Properly bent conduit turns look better than elbows and are therefore preferable for exposed work (see Fig. 9.48). If bends are formed to a chalk line, drawn as suggested in Sec. 113, the conduits can be made to lie parallel at a turn in a multiple run as shown in Fig. 9.48, II. If standard elbows are used, it is impossible to make them lie parallel at the turns. They will have an appearance similar to that shown in I.

I With elbows

II With bent conduit

FIGURE 9.48 Right-angle turns with elbows and with bent conduit.

113. Laying out a right-angle conduit bend. Draw a chalk-line diagram of the contour of the bend on the floor as follows (see Fig. 9.49): Draw a base line *CO* of any length. Lay off *AO* 4 units long. (The units may be of any dimensions.) With a cord and piece of chalk with *O* as a center and a radius of 3 units describe the arc *IJ*. With *A* as a center and a radius of 5 units describe the arc *EH*. The line *OD* drawn from *O* through *B*, the intersection of the two arcs, will be at right angles with *CO*.

CO and *OD* can now be prolonged for any desired distance. The arc *CD* is drawn with the cord and chalk with any required radius *R*. The conduit bend should lie parallel to this arc when the bend is laid on the floor for inspection as shown in Fig. 9.50. The radius of curvature of the inner edge of any field bend is required by the NEC to be not less than shown in Table 93.

FIGURE 9.49 Laying out a right angle.

FIGURE 9.50 Forming a conduit to chalk lines.

114. Conduit hickies and benders are used to hand-bend smaller sizes of rigid steel conduit, rigid aluminum conduit, and the new Type IMC (intermediate metal conduit) in 1/2-, 3/4-, and 1-in sizes, as well as in a 1 1/4-in size for small offsets (see Fig. 9.51.) Benders and hickies for thin-wall electrical metallic tubing (EMT) are widely used for all types of bends in sizes from 1/2 to 1 1/4 in inclusive. A typical thin-wall conduit bender, shown in Fig. 9.52A, was invented by Jack Benfield of Delray Beach, Florida. Listed below are the features of this bender that have greatly improved the art of precision-bending conduit and EMT over the years:

FIGURE 9.51 The standard conduit hickey.

1. Bold cast-in symbols not only are recessed but also are paint-filled to serve as permanent benchmarks or guide points for making accurate stub lengths, back-to-back bends, saddles, and offsets.
2. The Benfield formula for making precision offsets is printed in bold letters cast into the metal as a constant reference for the operator at point at use. The formula reads:

$$\text{OFFSET DEPTH} \times \text{MULTIPLIER} = \text{DIST. NEEDED BTWN BENDS}$$

A cast-in degree scale on one side and a cooperating cast-in multiplier scale on the opposite side of the tool guide the operator in this precision offset technique.

3. A patented inner-hook contour prevents the tool from slipping. It will not chew into or nick galvanized surfaces or gouge aluminum conduits.

FIGURE 9.52A No. 1 Benfield bender for 1/2-in electrical metallic tubing (EMT). This tool makes the minimum National Electrical Code radius. [Jack Benfield, patent holder]

4. The hook area also includes a back-pusher contour which allows the bender to grab on in reverse to remove an overbend or to shift the bend from side to side.
5. The back of the hook has a double-width outrigger ground flat (like a T square in relation to the bender groove). This flat shoulder provides stability and maintains floor contact long enough to set the course of the bend in a plane vertical to the working surface.
6. For purposes of safety the socket for a handle has recessed threads. The entire tool is cast of tough pearlitic-alloy malleable iron with heavy sections and guard points to protect the groove from damage.
7. The extended nonskid foot pedal invites foot pressure and increased leverage by 75 percent.
8. The Benfield No. 1 bender (Fig. 9.52A) is designed for bending $\frac{1}{2}$ -in EMT only. A similar model, No. 2, is used for $\frac{3}{4}$ -in EMT, and No. 3 is for bending 1-in EMT. All three tools bend to the minimum NEC radius. If larger radii are not objectionable, the No. 2 bender will bend $\frac{1}{2}$ -in rigid conduit. The No. 3 bender will bend $\frac{3}{4}$ -in rigid conduit.

The Benfield No. 6 Powr-Jack bender, shown in Fig. 9.52B, has every feature of the No. 2 bender plus an extended two-position power step that provides 200 percent more leverage, thereby extending the range for hand benders to include 1-in rigid or IMC conduit and $1\frac{1}{4}$ -in EMT.

The Benfield No. 9 double-grooved bender (Fig. 9.52D) is a one-piece malleable-iron casting with no moving parts. One groove bends $\frac{1}{2}$ -in EMT only; the other groove is for $\frac{3}{4}$ -in EMT or $\frac{1}{2}$ -in rigid conduit (Fig. 9.52C). The No. 9 Benfield makes shorter radii than standard models, i.e., 3-in inside radius for $\frac{1}{2}$ -in EMT and a 4-in radius for $\frac{3}{4}$ -in EMT and $\frac{1}{2}$ -in rigid conduit or IMC. Handles are now available in IPS $\frac{3}{4}$ -, 1-, and $1\frac{1}{4}$ -in sizes and are

FIGURE 9.52B No. 6 Benfield Power-Jack bender for 1-in rigid conduit or $1\frac{1}{4}$ -in EMT. [Jack Benfield, patent holder]

FIGURE 9.52C No. RH7 Benfield hickey for $\frac{1}{2}$ - or $\frac{3}{4}$ -in rigid conduit. [Jack Benfield, patent holder]

FIGURE 9.52D No. 9 Benfield double-grooved bender for $\frac{1}{2}$ - $\frac{3}{4}$ -in EMT and $\frac{1}{2}$ -in rigid conduit. Note that the handle has a weatherproof Zip Guide plus an expanded end permitting its use as a stub straightener. [Jack Benfield, patent holder]

FIGURE 9.52E Model No. 16 series especially designed for rigid steel conduit and Type IMC (intermediate metal conduit). It is heavier throughout than EMT benders and made to bend to the minimum radius that the National Electrical Code allows. [Jack Benfield, patent holder]

factory-engineered ready for use. They are marketed complete with an applied mylar-coated weatherproof bumper-sticker-type Zip Guide to give the operator basic bending allowances at the point of use.

Relatively new to the industry is Type IMC (intermediate metal conduit). To provide the right NEC radii for IMC, a series of Benfield benders is marketed. These models bend all three types: rigid steel conduit, rigid aluminum conduit, and IMC intermediate metal conduit. Figure 9.52E, Benfield Model No. 16, shows an extra-heavy beefed-up hook plus extra-rugged sections throughout to withstand the rigors of bending rigid conduit and Type IMC conduit to the correct NEC radius. The No. 16 bends three conduit types: 1/2-in rigid steel, 1/2-in IMC, and 1/2-in

aluminum rigid conduit. Larger models bend both rigid conduit and IMC in the 3/4- and 1-in sizes. The No. 16 series tools are not suitable for bending EMT.

Figure 9.52F, the Benfield Zip Guide, is an on-the-handle reference that speeds the work. This precalculated table for spacing between bends is accurate for any make of bender, whether hand-type, mechanical, or hydraulic. Zip Guides are a definite aid for the electrician.

The Benfield No. 7 one-shot hickey (Fig. 9.52G) bends 1/2- and 3/4-in rigid or IMC conduit. Model No. 8 bends 1- or 1 1/4-in rigid or IMC conduit. The unbreakable plumb bob swings free on a stainless-steel bolt as a constant degree-of-angle indicator. (Two shots are required for the No. 8 model.) Multiple shots may be used on both models for larger radii and concentric bending.

The Benfield No. 10 series stubber-hickey line (Fig. 9.52H) is unique. These tools are inch-along short-radius hicckeys that bend *both* EMT and rigid or IMC conduit: No. 10 for

$\frac{1}{2}$ -in EMT only, No. 11 for $\frac{1}{2}$ -in rigid IMC or $\frac{3}{4}$ -in EMT, No. 12 for $\frac{3}{4}$ -in rigid IMC or 1-in EMT, and No. 13 for 1-in rigid IMC or $1\frac{1}{4}$ -in EMT.

These Benfield tools are available from wholesale electrical distributors throughout the United States and Canada. A 24-page basic training guide kit for any make of bender or hickey (whether hand type, ratchet type, hydraulic, or electrically powered) is available from Jack Benfield, P.O. Box 2735, Delray Beach, Florida 33447. This training kit dubbed in the trade “Back Pocket Bending Buddy” includes the booklet, a Zip-Guide 9-52E for the bender handle, and a wallet size offset-formula card. It is refreshingly nontechnical, replete with crystal clear diagrams and simple formulas for making stub-ups, back-to-band bends, offsets, concentric bends, and crossover saddles.

Benfield benders are produced in the United States by Klein Tools, Inc., of Chicago, Illinois. Klein Tools, Inc., franchises other manufacturers to market Benfield benders as follows:

1. Appleton Electric Company, Chicago, Illinois 60657
2. Klein Tools, Inc., Chicago, Illinois 60645
3. The Wiremold Company, West Hartford, Connecticut 06110
4. Appleton Electric Ltd., Cambridge, Ontario, Canada N3H 2N1

SURFACE METAL MOLDING BENDERS The Wiremold Benfield catalog No. 600-B (Fig. 9.52I) is a one-sweep bender with no moving parts. It makes 90° bends, offsets, and saddles in both No. 500 and No. 700 Wiremold surface metal raceway. The bender makes smooth sweeps flange-in or flange-out. An adapter that snaps into the bender groove is used to bend No. 200 Wiremold.

NOTE This tool will not bend this rectangular raceway *sideways*. To make sideway turns fittings must be used. Two separate degree scales are cast into the tool, one scale for No. 500 and the other for No. 700 Wiremold. Painted symbols serve as benchmarks to enable the operator to make precision bends as with EMT benders (Fig. 9.52I, and H). The 600-B comes complete with a two-piece handle of $\frac{3}{4}$ -in IPS coupled in the center (Fig. 9.52K). Applied to the handle is a weatherproof 3-in-by-6-in Zip-Guide instruction label, a basic reference at point of use.

FIGURE 9.52I Action view.

FIGURE 9.52K Side view with two-piece handle.

FIGURE 9.52J Top view.

115. Power conduit benders. For larger EMT or conduit sizes, hydraulic benders similar to the one shown in Fig. 9.53 are used in modern practice. Such benders are operated by a hand pump or a motor-driven pump. In general, two types are available. One type utilizes the *progression-bend method*, in which bends are laid out in marked spacings. Then every few degrees the conduit is shifted to the next mark, and so on, until the bend is completed. The second type is called a *one-shot bender*, in which the bend can be made without shifting the conduit. A 90° bend made with a one-shot bender provides a radius about the size of a standard factory elbow. Various shoes are available for different EMT and conduit sizes and for different sweep sizes. Information on the proper use of hydraulic benders is available from manufacturers of such equipment, and their instruction books should be followed to obtain precision bends.

FIGURE 9.53 Hydraulic conduit bender.

Figure 9.54A shows a Condumatic power bender for making precision bends with 1/2-, 3/4-, and 1-in rigid conduit. This motor-operated tool is extremely useful on large construction jobs for which many repetitive bends are required. The Greenlee power bender shown in Fig. 9.54B bends 1/2- through 2-in conduit or EMT.

FIGURE 9.54A Condumatic power bender for 1/2-, 3/4-, and 1-in rigid metal conduit. [The Ridge Tool Co.]

FIGURE 9.54B A power bender provides 90° bends for 1/2" to 2" EMT, IMC, or rigid conduit. [Greenlee Textron, Inc.]

116. A hydraulic pipe pusher is used for underground installations of rigid metal conduit. The pusher eliminates tedious trenching operations. The conduit, which must be equipped with a cap or point, is driven through the ground laterally. A common application is under streets or roadways.

Pipe pushers can be operated at different pressures, depending on the conduit size and the type of ground through which the conduit is driven. Standard pipe pushers permit pushes up to 7 ft (2.1 m) without the pipe clamp being changed.

117. Cable pullers and wire reels (Fig. 9.55) are used for the installation of larger conductor sizes. Both are extremely useful on larger installations and save a great deal of time and labor. Multiple wire reels are also useful when a large number of small conductors are to be pulled into a single conduit. Figure 9.56 shows an electric-motor-operated cable puller which is also helpful in pulling in conductors with minimum effort.

FIGURE 9.55 Hand-crank-operated cable pullet and wire reel.

FIGURE 9.56 Motor-operated cable puller. [Enerpac]

118. Threading conduit. Dies for threading conduit are designed to produce a taper of $\frac{3}{4}$ in. (19 mm)/ft as described in Sec. 82. It is usual practice when a lot of conduit is received to rethread all the ends, which may have become filled with paint or dirt or distorted by blows. Rethreading will save more than its cost in that it ensures rapid erection. Always reream conduit after cutting a thread on it. Pipe-threading machines for threading conduit, preferably those operated by motors, should be used on big jobs, as they will soon pay for themselves in the time that they save.

119. Wrenches for turning conduit. The form of wrench shown in Fig. 9.57, I, appears to be the most popular for turning conduit. Chain wrenches (II) are not as yet much used for conduit work, but when they have been tried, they have proved very satisfactory. Their advantages are that they can be used with one hand after

the chain is around the conduit and that they can be used in confined places and close to walls where a Stilson wrench could not be utilized.

FIGURE 9.57 Wrenches for conduit.

120. Conduit ends should always be reamed.

A reamer like that of Fig. 9.58 which can be turned by a bit brace is a good tool for small and medium-size conduit. For conduit of the larger sizes, reamers which have long handles attached, giving the needed leverage can be obtained. When conduit is received and after it is cut, the ends are frequently turned in (Fig. 9.59, I) and, when screwed together in a coupling, form a knife-like edge which will abrade insulation. When the ends are properly reamed, they appear as shown in Fig. 9.59, II, but if they are screwed together too tightly, they may turn up as at I, defeating the purpose that reaming should accomplish. If no other tool is available, conduit can be reamed by hand with a half-round file.

FIGURE 9.58 A bit-brace reamer.

FIGURE 9.59 Reamed and unreamed conduit ends.

121. The usual tool for cutting conduit

is a hacksaw. Pipe cutters should not be used because they leave a large burr on the inside of the conduit, which takes time to ream out. While the conduit is being cut, it should be held in a vise. On jobs with a great deal of conduit to cut, the installation of a motor-driven cold-cutoff saw, such as is used for cutting structural steel and rails, will prove economical. A rapidly rotating steel disk without teeth cuts the pipe. Water must be sprayed on the disk to keep it cool. Other types of power saws are available, including portable band saws that will cut up to trade size 4 conduits.

122. Fishing wire is tempered-steel wire of rectangular cross section. It can be readily obtained at electrical supply houses. A fishing wire is sometimes termed a *snake* (see Table 126 and Fig. 9.60). So that a fishing wire will slide

FIGURE 9.60 Steel fishing wire.

FIGURE 9.61 Hooks bent in fishing-wire ends.

readily past small obstructions, hooks should be bent in its ends as shown in Fig. 9.61. Before being bent, the ends should be annealed by heating them to a red heat and allowing them to cool slowly. If a small brass knob is riveted to the end of a fishing wire (Fig. 9.62) instead of a hook, the wire can be pushed through conduit more easily. When fishing is difficult, it is sometimes necessary to push two snakes with hook ends into the wireway, one from each of the outlets, as shown in Fig. 9.61. The wires must be worked back and forth and twisted around until the two hooked ends engage. Then one wire can be pulled into the raceway with the other.

FIGURE 9.62 Knob on the end of fishing wire.

FIGURE 9.63 Cord loop on the end of fishing wire.

123. When fishing from two ends, as in Fig. 9.61, it is often advisable to tie a loop of cord, possibly 1 ft (0.3 m) long, in the hook of one wire and bend down the hook (Fig. 9.63). The other wire has an open hook which can be made to engage in the cord loop quite readily. It has been found that a fish wire will go through conduit more readily if prepared as in Fig. 9.64, by loosely winding the end with small wire or cord, so that the wire or cord cannot pull off.

FIGURE 9.64 Fish-wire end prepared with cord.

124. Chain is used for vertical fishing. A small chain can be made to drop down a vertical wireway with little difficulty. Within a partition, the noise made by the lower end of a chain that is jiggled up and down will disclose its location almost exactly.

125. Galvanized-steel wire can be used for fishing. Any size from No. 14 up to, possibly, No. 6 may be utilized, but in nearly every case that flat steel ribbon wire is preferable.

126. Dimensions of Steel Fish Wire

Wire $\frac{1}{8}$ in. wide is the size most frequently used. The wire is usually put up in coils of 50, 75, 100, 150, and 200 ft, and in some cases 240 ft (15.2, 22.9, 30.5, 45.7, and 61 m, and sometimes 130 m).

W, width, in	T, thickness, in	Weight per 100 ft
$\frac{1}{8}$	0.015	11 oz
$\frac{1}{8}$	0.030	1 lb 4 oz
$\frac{3}{16}$	0.030	1 lb 14 oz
$\frac{1}{4}$	0.030	2 lb 8 oz
$\frac{5}{16}$	0.035	3 lb 8 oz
$\frac{3}{8}$	0.035	3 lb 12 oz

127. In drawing wire into conduit it is a mistake to use so much force that the wire cannot be withdrawn. Conduits should be big enough so that excessive force is not necessary. Small conductors (14 and 12 AWG) can be pulled in with the fish wire. Figure 9.65 shows how they can be attached to the fish wire, and Fig. 9.66 shows how the attachment should be served with tape to render pulling easy. It spoils any fishing wire to draw in with its conductors that pull hard.

FIGURE 9.65 Attachment of stranded conductor to fishing line.

FIGURE 9.66 Attachment taped over.

For conductors larger than 14 and 12 AWG, unless the pulls are very easy, a pulling-in line which is drawn into the conduit with the fish wire should be used for hauling in the conductors. Number 10 or 12 Birmingham wire gage galvanized-steel wire makes a good pulling-in line and is probably better for heavy work than rope. Two strands can be used if necessary. Braided cord is better than twisted rope for a pulling-in line, because when tension is applied, rope tends to untwist. Sash cord is satisfactory for light work. Galvanized-steel pulling-in wire can be attached to fish wire as in Fig. 9.67. Nylon rope, attached to a foam piston or even an improvised parachute made from a plastic bag and a rag filler, and blown into conduits by a Jet-Line tool, is also recommended. A Kevlar measuring tape is available for this purpose that has measurements every foot marked on it, so the total length of pull can be anticipated exactly.

FIGURE 9.67 Attachment of pulling-in line to fish wire.

Three or four links from a chain of no greater diameter than the line should be made up in the end of a rope or cord pulling-in line. Wires to be drawn in or a fish line can be attached to the links (Fig. 9.68). One stranded conductor can be attached to a pulling-in line as in Fig. 9.69. The attachment should be taped over to make it smooth. If two conductors are to be pulled in, one of them is made up into a loop in the end of the pulling-in line, as shown in Fig. 9.69. The insulation is trimmed from this conductor for 6 in. (152.4 mm) or more, and the bared end of the other conductor is made up about the first one, forming a long, tapering connection. If a hard pull is expected, it is advisable to solder the connection. The whole should be served with tape as in Fig. 9.66. If three wires are to be drawn in instead of two, the attachment is the same, with the addition that the bared end of the third conductor is made up around the other two. The diameter at any section of the attachment must not exceed the overall diameter of the wires, and the attachment should be in the form of a conical wedge. It is sometimes necessary to cut off possibly half of the strands of the bared ends and make up only the strands that remain to ensure that the attachment will be of sufficiently small diameter. A flexible-metal basket grip (Fig. 9.70), available in many sizes, is also recommended. The weblike grip slips over the ends of cables, and when tension is applied, the grip tightens and the conductors are firmly secured.

FIGURE 9.68 Chain links in the end of pulling-in line.

FIGURE 9.69 Attachment of stranded conductor to pull-in line.

FIGURE 9.70 Metal basket grip.

128. Force for pulling-in wires is, in the case of easy pulls, supplied by the worker. Tackle blocks are permissible for heavy pulls. Cranes can often be used very effectively. Snatch blocks can be used to guide the pulling-in line to some point at which it can be pulled either with the crane hook or by the crane in traveling along its runway. A lever can be used for hard pulls either by repeatedly fastening the pulling-in line to the lever or by gripping it with a pair of pliers and then prying against the pliers with the lever. Only a short pull is possible with each setting, a succession of settings and pries is necessary to draw the conductors in.

129. In feeding conductors into conduit, care must be taken that they go in symmetrically and without lapping or twisting. If one conductor crosses another, it may make a hump that will wedge in the conduit. Liquid paste, commonly known as *wire lube*, is widely used in modern cable-pulling operations. Although in a paste form during cable pulls, the substance dries into a powder form, which aids in withdrawing conductors later on. Newer versions are carefully formulated with water and polymers and do a much better job of reducing friction than previous products.

130. Pulling methods for nonmetallic raceways. Careful consideration must be used both during the design process and while setting up a pull in order to assure that the pulling method will not saw through the inner radius of a sweep. For steel raceways, this is not a major concern, but for nonmetallic raceways it can be very difficult. Some pulling winches use steel aircraft cable that will make short work of a nonmetallic elbow, especially if it is heavily loaded. For this reason, some wiring designs place steel conduit elbows in the middle of nonmetallic conduit runs.

This solves the pulling problem, but raises another issue because normally metal conduits have to be bonded to the equipment grounding conductor that runs with the circuit conductors (in the case of a service, to the grounded circuit conductor). This may be difficult to arrange in the field, particularly where the elbow will not be accessible. On an outdoor pole, the NEC makes an exception to the normal 6-ft (1.8 m) limit on these bonding conductors so the bonding conductor can continue up the pole and connect at the top of the riser. The NEC waives the bonding rule entirely if the elbow is buried so deep that the end nearest to the top of grade is still buried 18 in. (450 mm), or if the steel sweep is encased in not less than 2 in. (50 mm) of concrete.

If the steel sweep approach is impracticable another option is to pay close attention to the pull rope. A polypropylene rope will burn through the inner radius of a PVC sweep in a little over a minute under heavy pulling forces. On the other hand, a braided polyester rope will perform far better, and more than one manufacturer has taken this idea a step further by taking the braided polyester and forming it into a flat tape that distributes the pulling friction over a wide area. Studies have shown that this extends the burn-through time by about two orders of magnitude, such that what would burn through with polypropylene in about 1½ min would take over 2½ h under the same pulling conditions with the flat tape. The tape is available in different sizes with ratings up to 6000 lb.

CABLE PULLING CALCULATIONS FOR RACEWAYS

131. Raceways must be proofed and conductors must be sized and coordinated so conductor insulation is not damaged during installation, by NEC rules. Statistics have shown that over 90 percent of failures to medium-voltage conductors in raceways stem from faulty installation practice during the process of pulling the conductors into the raceway. Statistics aren't available for lower voltage applications, but undoubtedly a large percentage of failures at these voltages have a similar cause. Often these failures don't show up for years, making it difficult to assign blame. It is very important to understand the factors that go into a successful installation that does not overstress the insulation.

The first step is to always *proof the raceway* by running equipment like that illustrated in Fig. 8.106 through it, so it will be clean and there will be no unexpected blockages. The force applied during cable pulling is primarily to overcome oppositional frictional forces, and therefore most of the cable-pulling calculations address the sources of the friction. However, raceway runs almost invariably involve bends. When cables move through a bend on a major pull, the pulling force on their leading end combined with the frictional forces behind the bend, including forces imposed by any prior bends, subject the insulation to enormous crushing forces. This crushing force is the *sidewall bearing pressure*, and it is a major factor in designing cable pulls. What follows are a series of calculations, all of which must be factored into the pulling analysis.

132. Start with the force required to unwind the reel. It requires force to unwind cable from a coiled orientation to straight as it enters the raceway, and there are also frictional forces in play as the reel turns over the support rollers or pay-off axle. A conservative value for this is $T_{in} = 25 \times W$ where T_{in} is the tension applied on the cable entering the raceway, and W is the weight of the cable per foot. If there are multiple reels, the usual case, then multiply this number by the number of reels.

133. Now Analyze the Frictional Forces in the Raceway. The calculations that follow use terms defined in the following table:

Defined term	Definition
D	Inner diameter of the raceway, in inches
d	Outer diameter of one conductor (or cable assembly), in inches
T_{in}	Pulling tension into a specified section of the run, in pounds
T_{out}	Pulling tension out of a specified section of the run, in pounds
ω	Weight correction factor (dimensionless)
μ	Coefficient of dynamic friction (dimensionless)
W	Total weight of cables (or cable assembly) being pulled, in pounds/ft
L	Length of straight section, in feet
θ	Rise or fall angle of straight section from horizontal
φ	Angle of bend, in radians ($360^\circ = 2\pi$ radians; $90^\circ = 1.57$ radians, etc.)
R	Bend radius measured to inner wall, in feet
e	Base for natural logarithms, a mathematical constant ≈ 2.72
SP	Sidewall pressure in pounds/ft

The coefficient of dynamic friction (μ) is the first and most important variable. It is important to remember that dynamic frictional coefficients are always smaller than static coefficients. In simpler words, it takes more force to break free a load at rest than to keep it moving once it is in motion. This is why cable pullers designed for the purpose keep the cable moving once the pull has begun, and why ad hoc methods like tractors, etc., that could allow the pull to stop and start are problematic. Major pulls involve forces on the order of 10,000 lb. An interrupted pull can easily result in a failed pull, because the increased force required to break the cable free may exceed the ratings of the pulling eyes, etc.

This coefficient can range from 0.1 to 1.0, or even higher for unlubricated runs. Many texts advise using a factor of 0.5 for lubricated work, and this analysis will start with this number as well. However, some modern cable lubricants, if properly applied, produce much lower coefficients. In addition, a major wire and cable manufacturer now has a pre-lubricated line of THHN/THWN conductors that have theoretical coefficients as low as 0.15 and has published data suggesting that a coefficient of 0.28 in steel and 0.24 in PVC is actually conservative for their product.

134. How the conductors arrange themselves in the raceway makes a difference.

For these purposes there are four arrangements to consider, as shown in the table below. The first case is the trivial example of one cable in a raceway, and there is no correction factor required for this case. However, for all other cases because the friction is not equally distributed across all conductors, a correction factor must be applied in order for the force to be calculated correctly, as shown in the following table:

Weight Correction Factor Calculations

Number of conductors	Configuration	Formula	Drawing
1	Single	$\omega = 1$	
3	Cradled	$\omega = 1 + \frac{4}{3} \left[\frac{d}{D-d} \right]^2$	
3 (use for 2 also)	Triangular	$\omega = \frac{1}{\sqrt{1 - \left[\frac{d}{(D-d)} \right]^2}}$	
4 (use for 4 or more)	Diamond	$\omega = 1 + 2 \left[\frac{d}{(D-d)} \right]^2$	

The configuration generally follows from the conduit to cable diameter ratio (D/d ratio). The triangular configuration can always be used if the D/d ratio is less than 2.5. If the ratio runs from 2.5 to 3.0, the cables could lay either way and the cradled result should be used because it is conservative. For three conductors installed to NEC requirements, it can be demonstrated geometrically that the D/d ratio under worst case fill condition will be 2.65, so a cradled configuration will be the norm for applications covered here. If the ratio is above 3.0, the cradled configuration will almost certainly be the result. On the other hand, if the cable pull involves triplexed or quadruplexed assemblies, then the configuration follows the combined cable orientation for obvious reasons. For four cables, the diamond configuration will result in most cases where the D/d ratio is less than 3.0; otherwise the cradled configuration is likely. Here again, geometric analysis shows that the worst-case fill on an NEC compliant installation with four conductors will result in a D/d ratio of 3.08, so a cradled configuration will usually result unless the conductors are quadruplexed.

135. The required pulling force for straight sections of raceway can now be determined. There are several possibilities, as follows:

- For horizontal straight sections, $T_{out} = \omega\mu WL + T_{in}$
- For inclined straight sections, $T_{out} = \pm WL (\sin \theta \pm \omega\mu \cos \theta) + T_{in}$ where the “ \pm ” symbol is “+” for rising pulls and “-” for descending pulls.
- For vertical applications same formula applies, however for these 90° angles the term “ $\sin \theta$ ” is 1 and “ $\cos \theta$ ” is 0, so for a *straight up portion* of the pull the *tension added* is WL , and for a *straight down portion* the *tension subtracted* is WL .

136. Raceway bends add significant friction, as follows. Exact bend calculations involve hyperbolic trigonometric functions and are extremely complex, especially where the bends are inclined and the effects of gravity enter the picture. Fortunately there is a relatively simple approximation that is sufficiently accurate for this work. The approximate effect of friction contributed by a bend is:

$$T_{out} = T_{in} \times e^{\omega\mu\varphi}$$

137. How to handle natural logarithms and exponents. This type of mathematical expression will not be familiar to many of the users of this handbook. A logarithm of any number is the exponent, or power, to which a base number must be raised to give the first number. For example, the logarithm of 100 to base 10 is 2, because the base number, 10, raised to the second power is 100. Of course most logarithms don’t work out to be simple numbers. The base number 10 raised to the 0.30103 power is 2.0, etc., which means that the logarithm of 2.0, (written $\log_{10} 2.0$) using base 10, is 0.30103.

The base number used in higher mathematics, given the designation “e” is derived from an evaluation of a certain area under a unit hyperbolic function using calculus. Its value has no perfect decimal representation, but it is approximately 2.72. This number turns out to be extremely useful as a base for logarithms in scientific work, and it also turns out to be essential in making pull calculations. Logarithms using this base are referred to as natural logarithms, and solutions for them are programmed into all scientific calculators. The usual designation for a natural logarithm is “ln.” For example “e” raised to the 0.69315 power is 2.0, so that is the natural logarithm of 2.0, written $\ln 2 = 0.69315$. The process can also be

inverted. Instead of finding the logarithm of a known number, if we know the base and the logarithm, the subject number can also be found. The pull calculation for a bend is exactly this type of work.

The formula gives the tension out of a pull (T_{out}) by multiplying the incoming tension (T_{in}) by a number we will refer to as the *bend multiplier*. This number is “e” raised to a power, specifically the weight correction factor (ω) \times the coefficient of friction (μ) \times the angle of the bend in radians (φ). Radians are routinely used in higher mathematics, and unlike degree measurements, radians measure angles in terms of π . Specifically, a semi-circle of 180° contains 3.14159 (π) radians. Therefore a 90° angle contains half that amount, or 1.57 radians, and a 45° angle contains one quarter that amount, or 0.785 radians.

138. Putting it all together. First calculate the exponent in the formula by simply multiplying three numbers together (ω) \times (μ) \times (φ). This number is the natural logarithm of the bend multiplier, and we need to know what the bend multiplier actually is. To find this number, use the *inversion* of the process that finds a logarithm of a known number. The easy way to do this is to use a scientific calculator. They are commonly available, and one is built into most computer operating systems. Start the calculator, complete the multiplication ($\omega \times \mu \times \varphi$), select the *invert* key or checkbox (usually “INV”), and hit the natural logarithm button (usually “ln”). The result will be the bend multiplier. This result multiplied by the tension just before the bend (T_{in}) will give the tension out of the bend (T_{out}).

This and all prior calculations generate the maximum force that must be applied by the end of the pull in order to complete the work. This will determine what form of pulling attachment is required, and whether the tensile strength of the conductors will stand up to the force, or whether the pull must be reengineered in terms of lubricant selected, or intermediate pull points provided. However, the bend calculations must be carefully recorded, at each stage in the pull, and the tension required (per these calculations) to be applied at the “out” side of each bend must be noted. This allows for the next set of calculations (below) to be performed.

139. Sidewall bearing pressure must be separately evaluated. Every time conductors are drawn through a bend, their insulation is compressed against the inner radius of the bend. The amount of force must not exceed the ability of the insulation to stand up to the pressure. Medium-voltage shielded cables are particularly vulnerable because if the shielding is permanently distorted, there may be a discontinuity that has no stress relief and results in a corona discharge under the outer jacket. If this occurs, the life of the cable will be dramatically curtailed. If the failure occurs within a raceway, the eventual fault will probably be sufficiently destructive to require the raceway to be replaced. Even 600 V applications, however, are susceptible to damage and must take sidewall pressure into account if the anticipated pulling force gets into the four figure range. The actual calculations must be done for each bend, based on the cable configuration and applicable out-of-bend tension, according to the following table:

Determination of Sidewall Bearing Pressure

Number of conductors	Configuration	Formula
1	Single	$SP = \frac{T_{out}}{R}$
3	Cradled	$SP = \frac{(3\omega - 2) \times T_{out}}{3R}$
3 (use for 2 also)	Triangular	$SP = \frac{\omega \times T_{out}}{2R}$
4 (use for 4 or more)	Diamond	$SP = \frac{(\omega - 1) \times T_{out}}{R}$

In each case the table provides a result in the form of pounds of force per foot of bend radius. Frequently the sidewall bearing pressure will be more of a limiting factor than the pulling force limitations. The table below shows acceptable sidewall pressures from a variety of industry sources, including recent research on nylon-jacketed PVC-insulated 600 V conductors (THHN/THWN). Some of these values are higher than those published years ago and reflect current research.

Sidewall Bearing Pressure (SWBP) Limits, by Conductor Type

Cable type	Max. SWBP (lb/ft)
600 V Nonshielded control cable, Type TC	300
600 V Nonshielded power cable, Types THHN, THWN, USE, RHW	1000
600 V XLPE power cable, Type XHHW	1000
PE and XLPE Type MV with concentric wire shield:	
without jacket	1200*
with encapsulated jacket	2000
PE and XLPE insulation, LC shield, LDPE jacket	1500
PE, XLPE, EPR insulation, concentric wire or tape shield	
LDPE and PVC sleeved jackets	2000 [†]
Lead sheathed cable with and without jackets:	
XLPE insulation	2000
EPR insulation	2000
XLPE insulation, copper ribbon shield, MDPE sleeved jacket	2000

*For a pull of three single-conductor cables in the same raceway, a maximum of 750 lb/ft is recommended.

[†]The recommended SWBP limit should be reduced to 1500 lb/ft where the jacket is not applied tightly to the cable core.

140. Internal clearance may need consideration. Some pulling analyses suggest a review of the internal headroom, for other than cradled configurations, between the top of the conductors pulled in and the upper wall of the raceway to assure at least 1/4-in headroom on straight pulls and from 1/2- to 1-in headroom where pulling through bends. It can be shown geometrically that any cable installation that complies with NEC fill limits will necessarily exceed a cable diameter in headroom. Since this analysis presumes NEC compliance, this issue is not considered further here. It may arise in some power-limited applications for which customary fill limits have no safety implication. The question usually arises for utility installations that substantially exceed NEC fill limitations.

141. The tensile strength of the cable assembly cannot be exceeded. If a pulling basket is used, any pulling forces above 1000 lb require careful review of the manufacturer's data regarding the particular basket proposed. Therefore, if a basket will be used, the strength that can be applied is quite simply the rating of the basket. Although there are published ratings for insulation withstand to basket pulls, in general these values exceed the sidewall withstand numbers. Therefore, if the sidewall calculations have been done and the pull will satisfy the sidewall pressure ratings, go ahead and look for a basket of comparable strength.

142. Baskets are often used for lead-covered cables, and there is a special calculation that applies in these cases. The allowable applied force to a lead cable sheath has been found to be 1500 lb/square inch of sheath cross section. Since a sheath t inches thick and D inches outer diameter has an average circumference of $\pi(D - t)$, the sheath cross section will be a hollow cylinder with a total cross-sectional area equal to $\pi(D - t)t$. If the dimensions are in inches, the allowable force on a lead sheath of diameter D and thickness t will be:

$$T = 1500\pi t(D - t) = 4712t(D - t)$$

143. The conductor material itself is the ultimate test of strength in a power cable pull. If a basket will not work, look to the conductor. The allowable tension that can be applied to a copper conductor is related directly to its cross-sectional area "A". If that area is given in circular mills, the relation is as follows:

$$T = 0.008 \times A \text{ (in circular mills)}$$

Some hard-drawn aluminum alloys equal this strength, but since the NEC mandates the use of an AA-8000 series of alloy for almost all 600 V and lower applications, the constant for this alloy (0.006) is the one usually applicable. As a good example of these calculations at work, a 500 kcmil XHHW copper 600 V conductor will safely withstand $500,000 \times 0.008 = 4000$ lb of tension. Multiply this result by the number of cables that *will be providing the resistance to the forward progress of the pull*. In the case of a cradled configuration of three conductors, this will be all of three, but if the configuration will be triangular, only two will be in contact with the raceway surface and that will be the multiplier. In the case of a diamond pull of four conductors, use 60 percent of the entire group of conductors, or 2.4 times the result for a single conductor. This adequately allows for a disproportionate amount of force ending up on a few conductors, and applies to pulls with even higher numbers of conductors as well. Take care to compare such a result with the rating on the pulling eye; the maximum force will be the lesser of the two values.

Note that the tensile strength of different sized conductors differs, for obvious reasons. Pulling different sized conductors into one raceway, particularly on very difficult pulls, is therefore problematic because the smaller conductors will break more easily. Such pulls should be approached very cautiously, and if possible, limited to the tensile strength of the smaller conductors. Note also that if it is necessary to cut some of the strands to seat a large conductor in the pulling eye, judge the allowable tensile strength on the basis of the remaining strands.

144. Example, Part I: This example works through a number of the practical problems that arise when laying out large pulls. Assume a 480Y/277 V 3-phase 4-wire 400 A

feeder with a full-size neutral will be run with 600 kcmil THHN copper conductors through the following trade size 3 EMT components using conventional lubrication:

- a. 10 ft up out of a switchboard
- b. Through a 90° sweep (standard size, C/L radius = 13 in.)
- c. Through a horizontal run of 300 ft
- d. Through another standard sweep turned upwards at a 45° angle to produce an offset
- e. Through a diagonal run of 10 ft
- f. Through a 45° sweep (standard size, C/L radius = 13 in.)
- g. Through a vertical run of 20 ft
- h. Through a final 90° sweep (standard size, C/L radius = 13 in.) ending directly at the back wall of a panelboard

Solution:

- (1) Assign a coefficient of friction; for these purposes use 0.5.
- (2) Determine the tensile strength of the conductors for pulling purposes. Each cable is good for $(0.008)(600,000) = 4800$ lb. There are four cables, taken at 60 percent: $4800(4)(0.6) = 11,520$ lb.
- (3) Look up the pulling capacity of the pulling eye and rope. For the purposes of this example, use 10,000 lb.
- (4) Determine the unit cable weight per foot. From the data sheets provided by the manufacturer, the wire weighs 1987 lb/1000 ft, so the unit weight will be 1.99 lb/ft. Four wires in the pull bring the total to 3.96 lb/ft.
- (5) Calculate the weight correction factor using the formula in the table, using the EMT and conductor diameters from Tables 4 and 5 of the NEC, as follows:

$$\omega = 1 + \frac{4}{3} \left[\frac{d}{(D - d)} \right]^2 = 1 + \frac{4}{3} \left[\frac{1.051}{(3.356 - 1.051)} \right]^2 = 1 + \frac{4}{3} (0.21) = 1.28$$

- (6) Using a scientific calculator, determine the *bend multiplier* for each angle in the pull. First multiply the weight correction factor by the friction coefficient by the bend angle in radians. In this case multiply the weight correction factor just calculated (1.28) by the coefficient of friction (0.5), and then by the bend angle in radians (1.57 for the 90° bends and 0.785 for the 45° bend). On a scientific calculator, enter these results one at a time (1.005 for the 90° bends and 0.502 for the 45° bend), activate the inversion key (or check box) and hit the “ln” button for each. The result will be 2.73 for the 90° bends, and 1.65 for the 45° bend.
- (7) Determine the radius of the inner walls of the bends. Working from published data for standard trade size 3 sweeps, the centerline radius is 13 in, so the inner radius will be $13.000 \text{ in.} - \frac{1}{2}(3.356 \text{ in.}) = 11.322 \text{ in.} = 0.94 \text{ ft}$ for all standard bends.
- (8) Move through the run, one segment at a time, as follows:
 - a. Reel unwind resistance for 4 reels, $25 \times 4 \times 3.96 = 396$ lb
 - b. 10 ft up, add $W \times L = 3.96 \times 10 = 40$ lb; $T_{out} = (396 + 40) = 436$ lb
 - c. First 90° sweep, $T_{out} = 436(\text{bend multiplier}) = 436(2.73) = 1190$ lb
 - d. 300-ft run, horizontal, $T_{out} = \omega \mu WL + 1190 \text{ lb} = (1.28)(0.5)(3.96)(300) + 1190 = 760 + 1190 = 1950$ lb
 - e. Second 90° sweep, $T_{out} = 1950(\text{bend multiplier}) = 1950(2.73) = 5324$ lb
 - f. 10-ft sloping run, 45° rising: $T_{out} = (3.96 \times 10)(\sin 45^\circ + \omega \mu \cos 45^\circ) + 5324 = 40(0.71 + 1.28 \times 0.5 \times 0.71) + 5324 = 47 + 5324 = 5371$ lb

- g. 45° sweep: $T_{out} = 5371(\text{bend multiplier}) = 5371(1.65) = 8862 \text{ lb}$
- h. 20 ft vertical: $W \times L = 3.96 \times 20 = 80 \text{ lb}$; $T_{out} = (8862 + 80) = 8942 \text{ lb}$
- i. Final 90° sweep, $T_{out} = 8942(\text{bend multiplier}) = 7714(2.73) = 24,412 \text{ lb}$

This result is unacceptable because neither the cables nor the pulling hardware would make it through the last bend.

145. Example, Part II: Assume the same layout as before, but as a solution to the previous result, make two key changes. First, reduce the coefficient of friction by using better quality lubrication or consider new formulations of THHN that are prelubricated from the factory, or both. Published data show that the coefficient of friction can be reduced below, often well below 0.30 by doing so. In this case, use the published value of 0.28. In addition, reverse the pull so it goes downhill and with the majority of the bends before the long horizontal run. As before, using a scientific calculator, determine the *bend multiplier* for each angle in the pull, beginning with the lower base factors corresponding to the improved lubrication. For the 90° bends the exponent is $(1.28 \times 0.28 \times 1.57 = 0.56)$ and for the 45° bend the exponent is $(1.28 \times 0.28 \times 0.785 = 0.28)$. With the inversion key activated, hitting the “ln” key for these numbers gives *bend multipliers* of 1.76 for the 90° bend and 1.32 for the 45° bend. The combined results are dramatically different, as follows:

- i. Reel unwind resistance, $25 \times 4 \times 3.96 = 396 \text{ lb}$
- h. 90° sweep: $T_{out} = 396(\text{bend multiplier}) = 396(1.76) = 697 \text{ lb}$
- g. 10 ft down, subtract $W \times L = 3.96 \times 10 = 40 \text{ lb}$; $T_{out} = (697 \times 40) = 657 \text{ lb}$
- f. 45° sweep: $T_{out} = 657(\text{bend multiplier}) = 657(1.32) = 867 \text{ lb}$
- e. 10-ft sloping run, 45° falling: $T_{out} = -(3.96 \times 10)(\sin 45^\circ - \omega\mu\cos 45^\circ) + 867 = -40(0.71 \times 1.28 \times 0.28 \times 0.71) + 8670 = -18 + 867 = 849 \text{ lb}$
- d. 90° sweep, $T_{out} = 849(\text{bend multiplier}) = 849(1.76) = 1494 \text{ lb}$
- c. 300-ft run, horizontal, $T_{out} = \omega\mu WL + 1494 \text{ lb} = (1.28)(0.28)(3.96)(300) + 1494 = 426 + 1494 = 1920 \text{ lb}$
- b. 90° sweep, $T_{out} = 1920(\text{bend multiplier}) = 1920(1.76) = 3379 \text{ lb}$
- a. 10 ft down, subtract $W \times L = 3.96 \times 10 = 40 \text{ lb}$; $T_{out} = (3379 \times 40) = 3339 \text{ lb}$

Both the cables and the hardware easily survive, but *sidewall bearing pressure* has yet to be evaluated and compared with the 1000 lb table limit for these conductors, as follows: First (90°) sweep (now the initial, upper sweep):

$$SP = \frac{(3\omega - 2) \times T_{out}}{3R} = \frac{(3\omega - 2)}{3} \times \frac{T_{out}}{R} = \left(\omega - \frac{2}{3}\right) \frac{T_{out}}{R}$$

$$= (1.28 - 0.67) \frac{T_{out}}{R} = (0.61) \frac{T_{out}}{R} = (0.61) \frac{697}{0.94} = 452 \text{ lb}$$

The first bend is compliant; second (45°) sweep:

$$SP = \left(\omega - \frac{2}{3}\right) \frac{T_{out}}{R} = (0.61) \frac{T_{out}}{R} = (0.61) \frac{867}{0.94} = 563 \text{ lb}$$

The second bend is compliant; third (90°) sweep:

$$SP = \left(\omega - \frac{2}{3}\right) \frac{T_{out}}{R} = (0.61) \frac{T_{out}}{R} = (0.61) \frac{1494}{0.94} = 970 \text{ lb}$$

The third bend is compliant; fourth (90°) sweep:

$$SP = \left(\omega - \frac{2}{3} \right) \frac{T_{out}}{R} = (0.61) \frac{T_{out}}{R} = (0.61) \frac{3379}{0.94} = 3595 \text{ lb}$$

This final result is not acceptable because it far exceeds the sidewall tolerance for this type of conductor. However, a final 90° bend over a switchboard with 10 ft of headroom very likely has enough room for a larger radius sweep. A sweep with a 3-ft radius (center-line measurement, readily available, inner radius 34.322 in. or $2 + (10.322 \div 12) = 2.86$ ft) would solve the problem entirely, as follows:

$$SP = \left(\omega - \frac{2}{3} \right) \frac{T_{out}}{R} = (0.61) \frac{T_{out}}{R} = (0.61) \frac{3379}{2.86} = 721 \text{ lb}$$

146. Strategies to reduce pulling resistance. In general, if a calculation shows that a pull will be difficult or impossible, consider the following strategies:

Reverse the Pull. Every bend takes all prior resistance and multiplies it by an exponential factor, so it is often better to set the pull so most of the bends are at the front end. In addition, all things being equal, it is better to work with gravity instead of against it.

Decrease the Coefficient of Friction. This can involve a better selection of lubricant, or the use of different conductors, or both.

Increase the Radius of Bends. Although this will not change the tensile strength required to make the pull, it will dramatically reduce the sidewall pressure. The sidewall bearing pressure will be the limiting factor in many cases. Frequently the last bend will be the source of difficulty, and it may be in an accessible location where it could be changed.

Staff the Cable Reels. If helpers are turning the reels and actively guiding the cables into the raceway, much or all of the unwinding resistance can be eliminated. Since this occurs at the very beginning of the pull, it will have a disproportionately positive effect in reducing the pulling force and sidewall pressures.

If all of the foregoing options fail, then the run will need to be redesigned with fewer bends or one or more intermediate pull points provided as required. Keep in mind that the NEC requires that all raceways be continuous between established pull points prior to conductor insertion. Do not attempt opening the raceway at an intermediate point and pulling the full length of conductors through and beyond that location, all in the hope of resuming the pull at that intermediate point, and then reassembling the raceway to create the appearance of an end-to-end pull.

147. Potential cable jams on three-conductor pulls require special care. When tubular raceways are bent, they do not retain a perfectly circular form through the bend. Inevitably they become slightly elliptical in cross section in the process. If a three-conductor pull begins in a triangular configuration, and the conductor sizes are in a certain ratio to the diameter of the raceway, they may assume a cradled configuration when passing around the bend, with the midpoint of the cradle falling along the inside radius of the bend. When the leading part of the pull moves beyond the bend, the raceway resumes its circular cross section, and the conductors will try to resume their triangular configuration. If the conductors

cross over each other in the process, the result will be a jam if the inner diameter of the raceway, in its normal circular form, is smaller than approximately three times the diameter of the conductors. Conductors appreciably larger than this will not lose their orientation even when they pass through an oval section of the raceway, and conductors appreciably smaller than this ratio can slip back and forth between relative positions without difficulty.

For these reasons, the NEC has identified three-conductor pulls where the D/d (raceway diameter to cable diameter) ratios run between 2.8 and 3.2 as deserving of special care, because any attempt to pull through such a jam will likely damage the insulation. When making this calculation, increase the raceway diameter by 5 percent (multiply by 1.05) to account for out-of-round raceway problems. The NEC does not prohibit these ratios from being used, but cautions the installer to be alert. It is advisable to mark the cable to be drawn in, or pull in measuring tape with the conductors so if a jam occurs, and the tape measurement corresponds to the position of a known bend, the pull can be temporarily halted before the conductors are damaged. Often pulling back and then repulling will allow the conductors to resume their proper alignment.

148. For bends, the pulling radius is not the same as the training radius.

The NEC addresses how conductors will be maneuvered into the positions in pull boxes or at terminations that will be maintained for the foreseeable future. For example, single conductors must not be bent more sharply than 8 times their diameter if nonshielded and 12 times their diameter if shielded. This is a specification of the allowable *training radius* of a conductor, and it must not be confused with a conductor's allowable *pulling radius*, which will vary with the unique conditions of every installation because it is a function of the allowable sidewall bearing pressure. As the pulling forces increase to overcome friction in the pull, these forces will increase to the point of exceeding the allowable sidewall force, unless the raceway radius increases proportionately. The example above provides a good example of this principle at work, where three of the bends can be standard radius, but one of them at the end of the pull had to be increased.

In addition, the minimum pulling radius directly affects the sizes of intermediate pulling sheaves in instances where a cable is pulled directly through a manhole into another conduit not on the opposite wall. Such sheaves must be well lubricated so the rollers will freely follow the passage of the cable. Otherwise, the sidewall bearing pressure must be calculated based on the radius of the intermediate pulling sheave, just as in fixed portions of the raceway system.

Often a compound roller system will be required for this purpose, including when large conductors are pulled into a complicated cable tray layout. No portion of a bend exceeding 20° should ever be made across a single roller. Therefore, to achieve a 90° bend during a pulling operation using compound rollers, a minimum of five rollers must be used. Arrangements that use just two rollers, one at each conduit end point, impose two sharp 45° bends through small radii on the cable and must never be used, because they defeat the purpose of maintaining a large radius during the pull.

INTERIOR OR ABOVEGROUND WIRING WITH RIGID NONMETALLIC CONDUIT

149. Rigid nonmetallic conduit of the Schedule 40 polyvinyl chloride (PVC) type may be used in walls, floors, and ceilings and for:

1. Portions of dairies, laundries, canneries, and other wet locations
2. Locations where walls are frequently washed

3. Locations subject to severe corrosive influences
4. Damp or dry location not prohibited by Sec. 147
5. Locations subject to chemicals for which the PVC material is specifically approved

It may also be used for exposed work when it is approved for the purpose and is not exposed to physical damage, unless identified for such locations. Schedule 80 is so identified, and may also be used aboveground on poles.

150. Heavy-wall PVC conduit must not be used:

1. In hazardous locations, except as specifically permitted in the articles of the Code that cover those locations.
2. Where exposed to physical damage unless identified for such use, as noted above.
3. For the support of fixtures or other equipment, with the exception of conduit bodies of a trade size not larger than the trade size of the largest entering conduit. Such conduit bodies are only for the purpose of changing the conduit direction, and must not support luminaires or devices beyond incidental splicing equipment employed in unusual instances where the conduit body contains splices.
4. Where subject to ambient temperatures, or conductor operating temperatures, exceeding those for which the conduit is listed.
5. PVC Schedule 40 and Schedule 80 are suitable for use aboveground and underground and for direct burial without encasement in concrete except as required by 300.50(B) of the NEC for over 600 V installations.

151. Underwriters Laboratories lists rigid nonmetallic PVC conduit for aboveground applications with two different labels, as shown in Fig. 9.71. The conduits are manufactured in sizes from 1/2 to 6 in. The extra-heavy-wall-type Schedule 80 conduit is utilized for special applications which require additional physical protection, such as pole risers or similar uses when conduit is subject to physical damage.

FIGURE 9.71 Identification of aboveground PVC conduits.

152. Manufacturers' classifications for rigid nonmetallic PVC conduit are:

1. *Type A*. Thin-wall for underground, encased in concrete
2. *Type 40*. Heavy-wall for direct burial in earth and limited aboveground installations
3. *Type 80*. Extra-heavy-wall for direct burial in earth and aboveground installations for general applications and when subject to physical damage as indicated in Sec. 151

From the classifications indicated in Secs. 147 and 148 it should be noted that only heavy-wall (Type 40) and extra-heavy-wall (Type 80) PVC conduits are suitable for aboveground

applications. The Type A PVC conduit is limited to underground installations when encased in concrete, and such installations should be installed as indicated for underground work in Div. 8.

153. PVC conduit fittings are shown in Fig. 9.72. Also available are a wide variety of outlet boxes constructed of polyvinyl chloride or fiber-reinforced Bakelite.

FIGURE 9.72 Fittings and accessories for PVC conduit.

154. Cutting PVC conduit. This conduit can be easily cut with a fine-tooth handsaw. For sizes from 2 through 6 in. a miter box or similar saw guide should be used to keep the material steady and assure a square cut. After cutting, deburr the conduit ends and wipe off dust, dirt, and plastic shavings. Deburring can be readily accomplished with a pocketknife. Sizes up to 1 $\frac{1}{4}$ trade size can be cut easily with special cutting tools that fit in one hand and advance a sharp blade connected to a ratchet mechanism steadily through the conduit.

155. Joining PVC conduit. The conduit should be wiped clean and dry. Then apply a coat of cement (use a natural-bristle brush or aerosol-spray cement) to the end of the conduit, including the length of the fitting socket to be attached. Finally, push conduit and fittings firmly together, and then rotate the conduit in the fitting about a quarter turn to

distribute the cement evenly. The cementing and joining operation will not require more than 1 min. Many manufacturers supply brush-top cans of PVC solvent cement, which may be used as timesaving expedients. In adapting PVC conduit to existing or metal equipment, a complete range of threaded adapters is available. Standard metallic locknuts are used at these termination points, and bushings normally are not necessary.

156. Bending PVC conduit. Although a complete line of factory elbows (90, 45, or 30°) are available (Fig. 9.72), heat-bending of PVC conduit in the field can be easily accomplished. The most accepted method for sizes from 1/2 through 2 in. is with electric *blankets* of varying sizes and ratings which consist of a 115-V, heating element that wraps around the conduit. Large sizes of conduit utilize *hot boxes* that will accept the larger conduit sizes. The conduit can be rotated to assure even heating.

The larger sizes of PVC conduit require interior support when being bent because their walls, while hot, are not capable of withstanding the force of the bending process, and will collapse. The usual way to provide this support is to insert air-tight plugs into both ends of the conduit section being heated, while the conduit is still cold. As the conduit heats, the air trapped inside heats with it, and becomes pressurized. The result is that the bends can be completed without collapsing the conduit. If bending plugs are not available, and the required bend is not a standard configuration as shown in Fig. 9.72, such as 90°, 45°, or 30° another option is to place a PVC sweep elbow in an oven, set at about 300°F. The manufactured elbow, when it gets hot and pliable, will begin to “remember” its previous form (a straight tube). Wearing gloves, remove the segment from the oven when it relaxes to the desired angle and freeze it in place with a rag wet with cold water.

Under normal conditions a complete bend can be made in less than 1 min. When exact measurements are required, preheat a length of PVC conduit and then form it in place. This is possible because PVC conduit will remain pliable for at least 3 min after it has been heated. Never use flame-type devices as a heat application to PVC conduit, because this excessive heat can ruin the conduit.

The newest method of bending PVC raceways in the smaller trade sizes is to insert special coiled springs specially sized to prevent kinking into the part of the conduit that must be bent, and then bending without heating the conduit, often with a bender such as the one illustrated in Fig. 9.52E. The spring is then withdrawn after the bend is complete.

157. Expansion and contraction. In applications in which the conduit installation will be subject to constantly changing temperatures and the runs are long, consideration must be given to expansion and contraction of PVC conduit. In such instances an expansion coupling, such as shown in Fig. 9.72, should be installed near the fixed end of the run to take up any expansion or contraction that may occur. The coupling shown in Fig. 9.72 has a normal expansion range of 6 in. (152.4 mm). The coefficient of linear expansion of PVC conduit is given in Table 352.44 of the NEC, and exceeds the expansion coefficient of steel by a factor of five. Without properly applied expansion fittings, an aboveground installation subject to the usual range of outdoor temperatures will fail. If the job is installed on a cold winter day, and the conduit cannot freely move when the hot weather arrives, the result will look like an accordion. If the same job is installed on a hot day, come the winter months the conduit will contract to the point of pulling out of glue joints and exposing the conductors within.

In addition, when PVC conduit is exposed to direct sun, it absorbs even more heat than the surface wired over. A leading maker of PVC conduit recommends that at least 140°F be used as the upper temperature design parameter for this reason. If the minimum temperature were 0°F, that change in temperature would cause a 100-ft (30 m) length of conduit to

expand and contract through a range of almost 6 in. (150 mm). The wiring system must be arranged with this in mind. Of course, some parts of the system will handle this movement without difficulty. For example, a service riser running straight up from a meter socket and ending at a weatherhead, if properly supported with clamps designed to allow movement, can expand and contract at will.

Expansion couplings may be used in either underground or exposed applications. In underground or slab applications such couplings are seldom used, because expansion and contraction may generally be controlled by bowing the conduit slightly or by immediate burial. After the conduit has been buried, expansion and contraction cease to be a factor. Care should be taken, however, to assure that contraction does not take place in a buried installation if the conduit should be left exposed for an extended period of time during widely variable temperature conditions.

158. Support of Rigid Nonmetallic Conduit should be not less than specified in the following NEC table:

Maximum spacing between conduit size, in	Supports, m (ft)
1/2–1	0.9 m (3)
1 1/4–2	1.5 m (5)
2 1/2 and 3	1.8 m (6)
3 1/2 to 5	2.1 m (7)
6	2.5 m (8)

In addition, rigid nonmetallic conduit shall be supported within 900 mm (3 ft) of each box, cabinet, or other conduit termination.

159. Number of conductors. The number of conductors permitted in a single non-metallic conduit is determined in the manner described in Sec. 94. In many instances non-metallic conduits will contain equipment-grounding conductors to ground metal-enclosed equipment or grounding-type receptacles supplied by such conduits. If *bare* equipment conductors are used, the cross-sectional areas of these conductors, as listed in Table 57 of Div. 12, may be used in sizing the conduit. Accordingly, smaller conduit sizes may be permitted if bare instead of insulated grounding conductors are used.

It should be noted that extra-heavy-wall PVC conduit (Type 80) has a reduced cross-sectional area available for wiring space. Table 4, Chap. 9 of the NEC can be utilized to calculate conduction fill. The NEC now provides fill tables for Schedule 80 PVC in its Annex C, so if all the wires are of the same size, the permitted fill can be read out of the Code.

160. The number of bends in any run of conduit between outlet and outlet, fitting and fitting (LB, T, X), or outlet and fitting shall not contain more than the equivalent of four quarter bends (360°), including bends located immediately at the outlet or fitting.

161 Nonmetallic conduit lengths are normally available in 10-ft (3-m) lengths. However, lengths up to 30 ft (9.1 m) may be obtained for special applications. The longer lengths require fewer coupling connections and save time and labor.

162. Weight of Heavy-Wall (Type 40) Rigid Nonmetallic PVC Conduit

Trade size, in	Weight, lb/100 ft
$\frac{1}{2}$	16
$\frac{3}{4}$	21
1	31
$1\frac{1}{4}$	42
$1\frac{1}{2}$	50
2	67
$2\frac{1}{2}$	106
3	139
$3\frac{1}{2}$	168
4	197
5	268
6	348

163. PVC is a nonmagnetic conduit, and being nonmetallic, it provides less voltage drop and fewer reactance losses than are possible with metallic conduits with corresponding conductors used on ac circuits.

164. Other types of rigid nonmetallic conduits, such as thin-wall PVC, fiber, asbestos cement, soapstone, fiberglass epoxy, and high-density polyethylene, are designed solely for use in underground work. At one time they were recognized in the NEC for underground use, but today all conduit wiring methods must be listed, and the only other methods recognized are high-density polyethylene (Type HDPE, Sec. 21) and its sister with preinstalled conductors (Type NUCC, Sec. 22) for strictly underground use, and reinforced thermosetting resin conduit (Type RTRC, Sec. 23) that can be used above and below grade. These conduits and installation procedures, where used underground, are described in the underground-wiring sections of Div. 8. For systems of 600 V or less all types of rigid nonmetallic conduits must be 450 mm (18 in.) below the surface if buried directly in earth. Lesser depths 300 mm (12 in.) are permitted if the conduit is run below 50 mm (2 in.) of concrete. Refer to Part II of Article 300 in the NEC for minimum burial depths for high voltages.

165. Conduits emerging from grade have special rules. In addition to accommodating expansion and contraction due to heating and cooling, the wiring must accommodate ground movement, whether upthrust due to frost, or downward pressure due to ground settlement. Generally an expansion fitting as shown in Fig. 9.72 will do the job nicely. In addition, where direct burial conductors enter a riser from below grade, they should have an “S” loop arranged at the entry point so ground movement will not disturb the conductors where they arrive at the upper end of the riser and terminate.

Although the usual wiring method for these transitions is PVC conduit, it is important to note that ground movement affects all raceways equally, and a steel conduit pushed past concentric knockouts and through the bottom of a meter socket through frost action could be even more dangerous than a nonmetallic wiring method. The rules only relate to the potential for ground movement, and not temperature variations. Therefore these rules [NEC 300.5(J)] apply equally to both metallic and nonmetallic conduits in such locations.

FLEXIBLE-METAL-CONDUIT WIRING

166. Flexible metal conduit can be used for many kinds of wiring, being in some cases preferable to rigid conduit (see Fig. 9.73). Its installation is much easier and quicker than the installation of rigid conduit, the latter coming in short pipe lengths, whereas flexible conduit may be had in lengths of 25 to 250 ft (7.6 to 76.2 m), depending on the size of the conduit. The rules governing the insulation on the wires are the same as for rigid conduit: outlet or switch boxes must be installed at all outlets or switches, and the conduit must be continuous from outlet to outlet and be securely fastened to the boxes.

Flexible metal conduit shall not be used (1) in wet locations; (2) in hoistways, except as provided in Sec. 620.21(A)(1) of the NEC; (3) in storage-battery rooms; (4) in any hazardous location, except as permitted by the hazardous location Code articles; (5) where exposed to oil, gasoline, or other materials having a deteriorating effect on the installed conductors; (6) underground or embedded in poured concrete or aggregate or where subject to physical damage.

Flexible metal conduit consists of a single strip of aluminum or galvanized steel, spirally wound on itself and interlocked so as to provide a round cross section of high mechanical strength and great flexibility.

Its flexibility together with the continuous length procurable makes its use practicable when rigid conduit would be out of the question. For this reason it can be employed to advantage in finished frame buildings in place of the other forms of wiring so largely employed in these structures. The conduit is easily fished and requires no elbow fittings. These can be made with the conduit itself, but care should be exercised in properly fastening the conduit at elbows (Fig. 9.74). There are on the market fittings whereby changes from other forms of wiring can be easily made to flexible-conduit wiring. Iron plates should be used to protect the conduit from nails where it passes through slots in floor beams or studding.

FIGURE 9.73 Flexible steel conduit.

FIGURE 9.74 Elbow clamp.

167. Standard Sizes of Flexible Steel Conduit

B, nominal inside diameter, in	A, minimum OD, in	Bending radius in	Approximate ft per coil	Minimum weight, lb/1000 ft
5/16	0.470	1 3/4	250	150
3/8	0.560	2	250	255
1/2	0.860	3	100	470
3/4	1.045	4	100	595
1	1.300	5	50	1020
1 1/4	1.550	6 1/4	50	1250
1 1/2	1.850	7 1/2	25	1625
2	2.350	10	25	2125
2 1/2	2.860	12 1/2	25	2630
3	3.360	15	25	3130
3 1/2	3.860	17 1/2	25	3220
4	4.360	20	25	3740

168. Installation of flexible metal conduit. If exposed, flexible metal conduit can be fastened to the surface with single-hole or two-hole straps (Figs. 9.40 and 9.41). The conduit must be secured at intervals not exceeding 1.4 m (4½ ft) and within 300 mm (12 in.) from every outlet box or fitting except 900 mm (3 ft) lengths at terminals where flexibility is required, and 1.8 m (6 ft) lengths from a fixture terminal connection for tap connections to a lighting fixture. If concealed, the conduit can be fished into place just as any concealed conductors are fished in. In making bends, care must be exercised that the conduit is not damaged.

169. The number and size of conductors to be installed in flexible metal conduits is governed, as in the case of all tubular raceways, by Table 1 of Chap. 9 of the NEC. For metric designator 12 (trade size ¾) conduit, NEC Table 348.22 has a separate wire fill table for this size conduit.

170. The minimum size of flexible conduit that is allowed by the NEC is metric designator 16 (trade size ½), except for metric designator 12 (trade size ¾) as allowed by the Code for limited motor wiring, or for a connection which is not over 1.8 m (6 ft) in length, for taps to luminaires (lighting fixtures), or for utilization equipment, or for manufactured wiring systems, or for listed assembly of wired luminaire (lighting fixture) sections or in hoistways.

171. Flexible metal conduit is joined with couplings as illustrated in Fig. 9.75. Short lengths can be coupled to longer pieces with the clamp of I and waste thereby be prevented. The clamp at II is used for coupling rigid to flexible conduit.

FIGURE 9.75 Couplings for flexible steel conduit.

172. When elbows are formed in flexible conduit, some provision must be made to prevent the conduit from straightening out and thereby preventing the withdrawal of the conductors. Pipe straps can be used in some cases, and in others an elbow clamp (Fig. 9.73) can be applied.

173. Flexible metal conduit can be connected into steel boxes with the connector illustrated in Fig. 9.76. It is clamped to the armor with a bolt which provides a connection between armor and steel box. Figure 9.77 shows flexible metal conduit connected into an outlet box.

174. To cut flexible metal conduit a fine hacksaw should be used. Special vises have a slot across their jaws to guide the saw blade, the conduit being held between grooves in the jaws. Always cut flexible conduit straight across to ensure a proper fit into connectors.

FIGURE 9.76 Connector for attaching flexible steel conduit to an outlet box.

FIGURE 9.77 Flexible-steel-conduit outlet box.

175. For reaming flexible metal conduit a special reamer (Fig. 9.78) has been made, but inasmuch as the burr resulting from the hacksaw cut is very small, it can be readily removed with a three-cornered scraper made from a three-cornered file, or it can be removed with an ordinary file. The reamer illustrated is for conduit with a diameter of 1¹/₄ in. or less.

FIGURE 9.78 Reamer for flexible conduit.

176. Fish plugs for pulling in flexible conduit (Fig. 9.79) are furnished by the conduit manufacturer for ³/₈-, ¹/₂-, and ³/₄-in flexible conduit. After the conduit has been cut off square in a vise with a hacksaw, the fish plug is screwed into the tube and the fish or drawing-in wire attached to the plug for pulling in.

FIGURE 9.79 Plug for pulling in flexible conduit.

177. Pulling in conductors. Conductors are pulled into flexible conduits in much the same manner as in rigid conduits (refer to Sec. 122) with fish tapes or similar pulling means. It should be emphasized that the number of bends in any one run of flexible conduit should never exceed the equivalent of four quarter bends (360°), and preferably there should not be more than two quarter bends in a run. A fish tape which is to be inserted into a flexible conduit to pull in conductors should contain a ball or oval end instead of a hook.

A rounded tip permits the tape to be inserted without hanging onto convolutions of the flexible conduit.

178. Flexible metal conduit and fittings cannot generally be used as a grounding means. The only acceptable applications where they are so recognized is where all of the following conditions are met:

- (1) No enclosed conductor has overcurrent protection above 20 A.
- (2) The total length of the all flexible metal conduits, either ordinary flexible metal conduit or liquidtight flexible metal conduit or flexible metallic tubing or one or more of them together, in any equipment grounding return path must not exceed 1.8 m (6 ft).
- (3) The flexible metal conduit must not be subject to movement after the installation process is complete, such as for vibration isolation or for connections to a swinging sign, etc.

LIQUIDTIGHT FLEXIBLE-METAL-CONDUIT WIRING

179. Liquidtight flexible metal conduit is similar to regular flexible metal conduit, except that it is covered with a liquidtight plastic sheath (Fig. 9.80). It is not intended for general-purpose wiring but has definite advantages in many cases for the wiring of machines and portable equipment. Its use is restricted by the NEC as follows:

1. It is allowed in exposed or concealed locations where conditions of installation, operation, or maintenance require flexibility or protection from liquids, vapors, or solids. It is permitted for direct burial where listed and marked for the purpose.
2. Its use is not allowed (a) when subject to physical damage; (b) under any combination of ambient and conductor temperature conditions such that its operating temperature exceeds the rating of the material; and (c) in any hazardous location except as expressly permitted in the relevant Code articles.

FIGURE 9.80 Liquidtight flexible metal conduit. [Electri-Flex Co.]

Care must be exercised in its installation to employ only suitable terminal fittings that are approved for the purpose. Liquidtight flexible metal conduit in metric designators 41 (trade sizes 1½ in.) and larger shall be bonded in accordance with Sec. 250.118 of the NEC. Metric designator 35 (trade sizes of 1¼ in.) and smaller are suitable for grounding in any ground return path of 1.8 m (6 ft) or less if metric designators 12 and 16 (trade sizes ¾ and ½) are protected at 20 A or less, and 60 A or less for metric designators 21 through 35 (trade sizes ¾ in through 1¼) and the fittings are listed for grounding.

The Code specifies that the maximum size used must not be larger than the metric designator 103 (4 trade size).

180. Dimensions of Liquidtight Flexible Metal Conduit

Metric designator, conduit	Trade size, conduit	Actual			
		ID, in		OD, in	
		Minimum	Maximum	Minimum	Maximum
12	$\frac{3}{8}$	0.484	0.504	0.690	0.710
16	$\frac{1}{2}$	0.622	0.642	0.820	0.840
21	$\frac{3}{4}$	0.820	0.840	1.030	1.050
27	1	1.041	1.066	1.290	1.315
35	$1\frac{1}{4}$	1.380	1.410	1.630	1.660
41	$1\frac{1}{2}$	1.560	1.590	1.870	1.900
53	2	2.005	2.045	2.335	2.375
63	$2\frac{1}{2}$	2.449	2.489	2.855	2.895
78	3	3.048	3.088	3.480	3.520
91	$3\frac{1}{2}$	3.500	3.540	3.960	4.000
103	4	4.000	4.040	4.460	4.500

181. Conductor size. The NEC specifies that the maximum number of conductors installed in liquidtight flexible metal conduit is governed, as in the case of all tubular raceways, by Table 1 of Chap. 9 of the NEC. For metric designator 12 (trade size $\frac{3}{8}$) conduit, NEC Table 348.22 controls the wire fill for this size conduit.

METAL-CLAD-CABLE WIRING: TYPES AC AND MC

182. Type AC cable is a fabricated assembly of insulated conductors in a flexible metallic enclosure.

183. Type AC cables (generally referred to as *armored cable*) are branch-circuit and feeder cables with armor or flexible metal tape (Fig. 9.81). Cables of the AC type must have an internal bonding strip of copper or aluminum in intimate contact with the armor for its entire length. Most manufacturers use a flat aluminum ribbon as the bonding strip. At terminations, the bond wire is simply folded back without connection to the enclosure or other such conductors. Being in intimate contact with the metal armor, the bond wire is intended to reduce the overall impedance of the cable armor during the performance of its electrical function as an equipment grounding return path. For cables of the AC type, insulated conductors must be one of the types listed in NEC Table 310.13(A). In addition, the conductors must have an overall moisture-resistant and fire-retardant fibrous covering. For ACT (thermoplastic conductors), a moisture-resistant fibrous covering is required only on the individual conductors.

FIGURE 9.81 Type AC cable with bond wire.

When not subject to physical damage, Type AC cable may be installed in both exposed and concealed work. Type AC cable may be used in dry locations and may be embedded in

plaster finish on brick or other masonry, except in damp or wet locations. It is permitted to be fished in air voids or masonry block or tile walls where such walls are not exposed or subject to excessive moisture or dampness. It must not be used where subject to corrosive fumes or vapors, or in any wet locations, including direct burial in the earth.

184. Manipulating Type AC cable. Type AC cable must never be spliced except at outlets. Many methods of fastening cable in outlet boxes are in vogue. Clamps or box connectors can be used. Outlet and switch boxes containing internal cable clamps designed for this wiring can be used. Special cutters are available. Type AC cable must not be bent more sharply than a radius of five times the outer diameter of the cable, with the radius measured to the inner side of the bend.

185. For cutting the cable to length, a shear, bolt cutter, or hacksaw can be used. At each outlet or junction box the armor must also be cut back about 8 in. (203.2 mm) in order to leave sufficient free ends of wire for splicing. This cutting is done with a hacksaw held so as to cut across the armor at an angle of about 60° with the axis of the cable. Great care must be taken not to cut into the insulation on the conductors.

Seatek Co., has developed a Flex Splitter rotary tool (Fig. 9.82) that is far superior for cutting Type AC cable. An adjustment knob varies the depth of the cut and a rotary crank easily cuts the sheath.

FIGURE 9.82 Method of cutting armor back from the end of cable. [Seatek Co., Inc.]

186. The wires at the ends of Type AC cable should be protected by fiber bushings. The fiber bushings employed for this purpose are called *antishort insulating bushings* (Fig. 9.83). The split bushing is pinched together and slipped over the wires inside the armor, as illustrated in Fig. 9.84. It protects the insulation of the wires from the rough edges of the cut ends of the armor.

FIGURE 9.83 Antishort fiber bushing.

FIGURE 9.84 Method of protecting wires with antishort bushings.

187. For fastening Type AC cable to outlet boxes a connector (Fig. 9.85) can be slipped over the end of the cable. The setscrew is tightened down against the armor. The threaded end of the connector slips into standard conduit knockouts, and the locknut is then put on, holding the connector tight to the box. Another method is to use outlet boxes of the type shown in Fig. 9.86, which contain built in cable clamps in which the clamp tightens down against the armor and holds it firmly in place.

FIGURE 9.85 Box connector for Type AC armor-clad cable. [General Electric Supply Co.]

FIGURE 9.86 Outlet box with clamps for Type AC armor-clad cable. [General Electric Supply Co.]

188. Type AC cable for old-building wiring. Type AC cable can be used to great advantage in this work. It can be run with almost utter disregard of its contact with pipes or other materials and can be fished for long distances. Its own weight is sufficient to carry it down partitions, and it is stiff enough to fish between joists without the use of a fish wire. It or nonmetallic-sheathed cable can also be installed more quickly and with less cutting of walls, floors, etc., than can wires in flexible tubing.

189. The loop system of wiring is nearly always used for concealed work in order to avoid the use of junction boxes. The cables loop from one outlet to the next outlet, and splices are made only at outlet boxes. All splices must be accessible for inspection, and if a junction box is used, the cover must be left accessible.

190. Supports. Type AC cable must be secured by approved staples, straps, hangers, or similar fittings so designed and installed as not to injure the cable. The cable may be installed on the underside of floor joists in basements when it is supported at each joist and is so located as not to be subject to physical damage. The cable must be secured within

300 mm (12 in.) of every terminating location. This means it must be prevented from movement through the use of a staple or clip. This is different from elsewhere in the run, where mere support is required. For example, it is permitted to entrain the cable through holes in studs or joists, as long as a staple, clip, or equal is set within a foot of terminations. However, when it is run through an accessible ceiling, the last 1.8 m (6 ft) prior to a termination is permitted without additional securement. The cables must be supported not less than every 1.4 m (4½ ft) in the middle of the run in all other locations.

191. Through studs, joists, and rafters. Type AC cable can be run through bored holes in studs, joists, or rafters. The holes must be bored at the approximate centers of the wood members or at least 32 mm (1¼ in.) from the nearest edge when practical. If there is no objection because of weakening of the structure, the Code will allow the cable to be laid in notches in the studding or joists, provided that the cable is protected against the driving of nails into it by having the notch covered with a steel plate at least 1.6 mm (⅙ in.) thick (or thinner if so listed) before the building finish is applied.

Type AC or MC cables installed in other than vertical runs through bored or punched holes in wood or metal framing members, or through notches in wooden framing members and protected by a steel plate at least 1.6 mm (⅙ in.) thick, shall be considered supported and secured where such support does not exceed 1.4 m (4½ ft).

192. In accessible attics. Type AC and MC cables in accessible attics shall be installed as follows:

1. If run across the top of floor joists, or within 2.1 m (7 ft) of the floor or floor joists across the face of rafters or studs, in attics or roof spaces which are accessible, the cable shall be protected by substantial guard strips which are at least as high as the cable. If this space is not accessible by permanent stairs or ladders, protection will be required only within 1.8 m (6 ft) of the nearest edge of the scuttle hole or attic entrance.
2. If cable is carried along the sides of rafters, studs, or floor joists, neither guard strips nor running boards shall be required.

193. Ampacity. Where run in thermal insulation, the cable construction must employ conductors rated for 90°C, but the usable ampacity is to be taken under the 60°C column in NEC Table 310.16. This accommodates the deleterious effect that thermal insulation has on the ability of electrical conductors to dissipate heat developed during operating conditions. Refer to the coverage on this topic under “interior wiring with service-entrance cable” for more information on this subject.

FIGURE 9.87 Type MC cable with aluminum sheath and aluminum conductors. [Kaiser Aluminum & Chemical Corp.]

194. Type MC cables are power and control cables (Fig. 9.87) limited in size to conductors not smaller than No. 18 AWG and larger for copper and No. 12 AWG and larger for aluminum. The metal enclosure shall be either a smooth metallic sheath, corrugated metallic sheath, or interlocking metal tape armor. Supplemental protection of an outer covering of corrosion-resistant

material must be provided when such protection is required by Sec. 300.6 of the NEC. The cables must provide an adequate path for grounding purposes, either over their armor or by incorporating one or more additional grounding conductors within the assembly. For cables of the MC type, insulated conductors must be of a type listed in NEC Table 310.13(A), and 18 and 16 AWG may employ a fixture-wire insulation.

Except as otherwise specified in the Code and where not subject to physical damage, circuits, services, or feeders in both concealed and exposed work as follows.

The cable may be used in partially protected areas, as in cable trays and the like, in dry locations; and when any of the following conditions are met, it may be used in wet locations:

1. The metallic covering is impervious to moisture.
2. A lead sheath or moisture-impervious jacket is provided under the metal covering.
3. The insulated conductors under the metallic covering are approved for use in wet locations and a corrosion-resistant jacket is provided over the metallic armor. If identified for the use, Type MC cable may be directly buried (Fig. 9.88).

FIGURE 9.88 Interlocking-armor Type MC cable in smaller branch-circuit sizes. The upper cable has an outer nonmetallic jacket that is suitable for direct burial, and is so marked.

195. Type MC cable connectors require care in selection. At all points where Type MC cable terminates, suitable fittings designed for use with the particular wiring cable and the conditions of service must be used (see Fig. 9.89). For Type MC cable, this requires great attention to detail. For example, the armor of interlocking armor MC cable is thinner than the corresponding armor for Type AC cable, and in general a single-screw clamp of the type shown in Fig. 9.85 will not be listed for such thinner armor. Acceptable designs use wraparound clamps as in Fig. 9.89, or some form of two-screw saddle or double-grip fastener will be used in order to properly distribute the pullout forces, in accordance with listings. In addition, connectors will be listed in reference to specific cable diameters and styles, or numbers of conductors. Because these markings are so complex, the information cannot be shown on the smallest unit carton.

FIGURE 9.89 Connectors for Type MC cables.

196. Bends. All bends shall be so made that the cable will not be damaged; and the radius of the curve of the inner bend of any bend must not be less than 7 times the diameter of Type MC cable with an interlocked or corrugated sheath, and 10 times the diameter of a smooth sheath of a size not more than 19 mm ($3/4$ in.), 12 times the diameter for cables larger than 19 mm ($3/4$ in.) but not more than 38 mm ($1\frac{1}{2}$ in.), and 15 times the diameter for cables more than 38 mm ($1\frac{1}{2}$ in.) in diameter. For shielded conductors, as are routinely used in medium voltage work, the inner radius must be at least 12 times the overall diameter of an individual shielded conductor or 7 times the overall diameter of a multiconductor cable, whichever is greater. Type AC cable carries a minimum bending radius of five times the cable diameter, also measured to the inner radius of the cable assembly.

197. Equipment grounding. In general, interlocking-armor type MC cables require equipment grounding conductors as part of the cable assembly. Larger cables often have this conductor subdivided into three or more segments. Smooth-type and corrugated-type MC cables usually have enough metal in a sheath that is not wound in convolutions so the armor can serve as an equipment grounding conductor. Figure 9.90 shows two such examples. Although the upper cable appears to have an interlocking tape armor, it is actually a continuous tube merely formed in a way that superficially resembles an interlocking metal tape. It does, however, contain a full-sized green-insulated conductor. This feature allows it to be used in patient-care areas of health care facilities, which require both the outer margin of the wiring method and an incorporated conductor to qualify for equipment grounding.

There is a new form of interlocking-armor Type MC cable on the market that has a full-sized bare aluminum equipment grounding conductor run outside of the Mylar sheath that is placed over the circuit conductors, such that it is in constant contact with the aluminum cable armor. In this it is comparable to the bonding strip in Type AC cable. This cable does not need to have this conductor brought into an enclosure for terminations, also like Type AC cable. However, some enclosures such as panelboards and other cabinets equipped with concentric knockouts may not qualify for equipment grounding continuity, particularly for circuits operating over 250 V to ground. In such cases, instead of being cut off, the bare aluminum wire is carried into the enclosure and terminated in the same location as the green wire in conventional interlocking-armor Type MC cables.

FIGURE 9.90 Corrugated Type MC cable comes in several configurations. Both these cables have an outer armor that is fully qualified as an equipment grounding return path; however, the upper cable has an additional grounding conductor for other reasons.

SURFACE-RACEWAY WIRING

198. Wiring in surface metal raceway can be used for exposed work for branch-circuit or feeder conductors. It may be installed in dry locations. It shall not be used (1) where concealed except under raised floors of information technology equipment; (2) when subject to severe physical damage unless approved for the purpose; (3) when the voltage is 300 V or more between conductors unless the metal has a thickness of not less than 1.02 mm (0.040 in.); (4) when subject to corrosive vapors; (5) in hoistways; or (6) in any hazardous location, except as expressly permitted in those specialized articles. The number of conductors installed in any raceway shall be no greater than the number for which the raceway is designed. Metal raceway must be continuous from outlet to outlet, junction box, or approved fittings designed especially for use with metal raceway. All outlets must be provided with approved terminal fittings which will protect the insulation of conductors from abrasion unless such protection is afforded by the construction of the boxes or fittings. Metal raceway should not be used in damp places.

When combination raceways are used for the installation of signal, power, and lighting circuits, each system shall be run in a separate compartment of the raceway.

Raceways may be extended through dry walls, dry partitions, and dry floors if in unbroken lengths where passing through, and provided access to the conductors is maintained on both sides of the partition.

199. Surface nonmetallic raceway is intended as a raceway for baseboard receptacles and other circuit supplies. It also serves a dual function as an attractive baseboard trim and replaces conventional baseboards.

Basically, the baseboard system contains a plastic backplate which is secured directly to the wall. Where receptacles are to be located, a metal bracket is attached through the backplate into the wall with wood screws or other fastening devices. Wires are then pulled in, and receptacles are mounted in place and wired. The wires are held in place along the raceway by a retaining clip strip, which is fastened to the wall of the raceway about every 1.5 m (5 ft). This holds the wiring in place. Finally, the external baseboard cover and receptacle cover are snapped into place. Covers over receptacles are doubly anchored by means of a flange and a 6-32 screw into the outlet body.

The material used in this system is the same as is used with rigid PVC conduit. End caps and inside or outside corners are available. One side of each of these fittings is cemented to the baseboard cover.

National Electric Code rules state that surface nonmetallic raceway and fittings must be of suitable nonmetallic material which is resistant to moisture and chemical atmospheres. It must also be flame-retardant and resistant to impact and crushing, distortion due to heat under conditions likely to be encountered in service, and resistant to low-temperature effects.

Surface nonmetallic raceways may be installed in dry locations. They must not be used (1) when concealed, (2) when subject to severe physical damage, (3) when the voltage is 300 V or more between conductors unless listed for higher voltage, (4) in hoistways, (5) in any hazardous location, except as permitted by the applicable specialized code articles, (6) when subject to ambient temperatures exceeding the listing, or (7) for conductors whose insulation exceeds those for which the nonmetallic raceway is listed.

Other Code rules such as the number and size of conductors are the same as for surface metal raceways.

200. Wiremold metal raceways are made in three general types by the Wiremold Co. These types are designated as (1) Wiremold surface raceway, used for general surface-raceway wiring systems; (2) Pancake overfloor raceway, used for overfloor surface-raceway wiring;

and (3) Plugmold raceway, used primarily for multioutlet-assemblies wiring (see Sec. 303). Plugmold can be used without receptacles as a general high-capacity surface-wiring raceway. The Wiremold surface raceway is a unit assembly, while the other two types consist of two separable parts, the base and the cover. (See Figs. 9.91 and 9.92.)

FIGURE 9.91 A flat 90° turn.

FIGURE 9.92 Inside 90° turn; outside turns are comparable.

The appearance and dimensions of the different types and sizes are shown in Fig. 9.93. The wire capacities are given in Secs. 201 to 204 inclusive. Wiremold No. 2000 is made in 5-ft (1.5-m) lengths. The standard length for the other types is 10 ft (3.05 m), although some types are available also in 5-ft lengths.

WIREMOLD Surface Metal Raceways

FIGURE 9.93 Types and dimensions of Wiremold raceways. [The Wiremold Co.]

Wiremold surface metal raceway consists of a metal capping with its edges crimped over a slightly curved base. The capping is crimped on the base at the factory so that capping and base are installed as a unit. The wires are pulled through the raceway from fitting to fitting in a manner similar to that employed in conduit work. The lengths are fastened together with a coupling (Fig. 9.94, I), which is fastened to the wall surface with a wood screw or toggle bolt. The base of the raceway is slipped under the end of the coupling before the screw or bolt is drawn up tight. A connection cover (Fig. 9.94, II) snaps over the ends of the raceway, closing the joint. Each section of raceway is secured at one or two intermediate points between the couplings by means of either one- or two-hole straps (Fig. 9.94, III and IV) screwed or bolted to the wall surface. The fittings and capping of Wiremold were traditionally finished in a neutral brown tint which blended well with most surroundings. Although that color is still available, it is now usually shipped in an off-white or ivory color that is more popular. The larger profiles (such as 4000 and 6000), formerly only available in an industrial shade of gray, are now also routinely available in the same off-white or ivory color. The base of the raceway and the baseplates of all fittings are given a special zinc treatment to prevent corrosion.

FIGURE 9.94 Wiremold metal raceway and support details.

Pancake overfloor raceway consists of two steel parts, a base and a cover. The parts have a natural galvanized finish. When this raceway is installed, the base is fastened to the floor by the appropriate means of wood screws, expansion shields, toggle bolts, etc. The conductors are then laid flat in the base of the raceway. After the connections have been completed, the cover is snapped in place over the base.

Plugmold raceway consists of two steel parts, a channel base and a snap-on cover. Both base and cover are available in the standard brown Wiremold finish or in a gray finish. When this raceway is installed, the channel base is fastened to the supporting structure with the appropriate means. The conductors are laid in the channel base, the necessary connections made, and the installation completed by snapping the cover over the base.

A very complete line of fittings, outlets, and receptacles is available for the different Wiremold raceways to meet the varied needs of installation.

201. Wire Capacities for Nos. 500 to 3000 Wiremold Raceways

ELECTRICAL-METALLIC-TUBING WIRING

206. Wiring employing electrical metallic tubing (EMT) is widely used for commercial and industrial wiring systems. The NEC allows the installation of EMT, either concealed or exposed, when either during construction or afterward it will not be subject to severe physical damage. Electrical metallic tubing may be supported in buildings of fire-resistive construction on the face of masonry or other material of which walls or ceilings are composed. It may then be buried in concrete or plaster finish. Connections between lengths of tubing and between tubing and any fitting shall provide adequate mechanical strength and electrical continuity.

In installations having cinder concrete or fill, EMT must be protected on all sides by a layer of noncinder concrete at least 50 mm (2 in.) thick unless the tubing is at least 450 mm (18 in.) under the fill. In general, EMT should not be used for direct burial applications because of limitations in its listing. If directly buried in earth, it generally requires additional corrosion protection applied over and above the galvanizing. Although asphalt paint or something comparable might be used for this purpose, it should be noted that testing laboratories do not recognize any specific nonmetallic supplementary coating for this purpose, which leaves it entirely in the hands of the inspector as to whether or not any particular coating will be approved.

In installations in which corrosive fumes or vapors may exist, as in meat-packing plants, tanneries, hide cellars, casing rooms, glue houses, fertilizer rooms, salt storage, some chemical works, metal refineries, pulp mills, sugar mills, roundhouses, some stables, and similar locations, EMT requires additional protection that must be approved for the corrosive exposure in question.

When installed in wet locations, such as dairies, laundries, and canneries, and in locations where the walls are frequently washed, the entire tubing system, including all its boxes and other fittings, shall be installed and equipped so as to prevent water from entering the tubing system, and the tubing shall be mounted so that there is at least a 6 mm (1/4 in.) air space between it and the wall or other supporting surface. For these installations all the supporting materials, such as straps, bolts, and screws, must be of corrosion-resistant material or be protected against corrosion by approved materials.

The rules regarding bends, minimum size, and allowable number of conductors are the same as for rigid metal conduit. The maximum allowable size of tubing is 4 in.

207. Table 208 gives the sizes and weights of electrical metallic tubing. Since the inside diameters are the same as those for rigid metal conduit, the same tables of number of allowable wires in a conduit apply to the tubing. The wall is thinner, however, and the outside diameters of tubing are less than those for conduit. The regular metallic tubing has a round cross section and is made of galvanized steel. However, sizes over metric designator 53 (trade size 2) have the same outside diameters as corresponding sizes of rigid metal conduit. Accordingly, the internal diameters of these larger sizes are slightly greater than those of other types of conduit.

208. Electrical Metallic Tubing

Metric designator	Trade size	Approximate weight per 1,000 ft, lb	Diameter, in		Wall thickness, in
			Inside	Outside	
16	1/2	295	0.622	0.706	0.042
21	3/4	445	0.824	0.922	0.049

209. All outlet boxes and fittings for use with EMT must be of the threadless type, since owing to the thin wall it is not permissible to thread the tubing. Special threadless fittings similar to those employed for standard rigid conduit are manufactured for tubing. Standard rigid conduit fittings can be used with tubing if an adapter is employed. Sections

FIGURE 9.95 Standard radius, 90° elbow.

of tubing can be joined by means of threadless couplings, which are available in steel, malleable-iron, and diecast construction. Tubing is connected to outlet boxes by means of connectors. One end of the connector is made for threadless attachment to the tubing, and the other end is threaded and supplied with a locknut for attachment to the box through a knockout. Raintight connections can be made to the tubing with some couplings and connectors. Standard 90° elbows (Fig. 9.95) are attached to the tubing by means of the above-described couplings. The dimensions of standard elbows are given in Sec. 210. Raintight elbows and angle-box connectors are available with the ends fitted with threadless fittings.

210. Standard 90° Elbows for EMT

Metric designator of tubing	Trade size of tubing	Smallest acceptable radius R to center line of tubing	Shortest acceptable length L_s of each straight end portion of tubing
16	$\frac{1}{2}$	4	$1\frac{1}{2}$
21	$\frac{3}{4}$	$4\frac{1}{2}$	$1\frac{1}{2}$
27	1	$5\frac{3}{4}$	$1\frac{7}{8}$
35	$1\frac{1}{4}$	$7\frac{1}{4}$	2
41	$1\frac{1}{2}$	$8\frac{1}{4}$	2
53	2	$9\frac{1}{2}$	2
63	$2\frac{1}{2}$	$10\frac{1}{2}$	3
78	3	13	$3\frac{1}{3}$
103	4	16	$3\frac{3}{8}$

211. Threadless couplings and connectors for EMT are of setscrew, compression, indenter, tap-on, two-piece, or squeeze-types. Such fittings are classified as concrete-tight only, or raintight and concrete-tight. Accordingly, only fittings that are classified as being raintight can be used outdoors exposed to the weather or in wet locations. Except for indenter-type fittings, EMT couplings and connectors can be installed with common hand tools. Indenter-type fittings require a special tool, and these fittings are made only up to metric designator 27 (trade size 1).

In the past, it has been routinely assumed that any split-ring compression connector (as opposed to indenter or set-screw designs) provided a watertight connection. This has proven false, and now connectors and couplings that are in fact watertight and suitable for wet locations are marked accordingly. They usually have an inner nonmetallic gland of some sort, although one manufacturer has a solid (not split) compression ring design that requires the application of a torque wrench to a crow's-foot end and special calculations in order to correctly seat the ring.

212. Support for EMT. The NEC requires EMT to be securely fastened in place at least every 3 m (10 ft) and within 900 mm (3 ft) of each outlet box, junction box, cabinet, or fitting. Methods of support are similar to those described for rigid metal conduit. Figure 9.96 shows the use of spring clips to secure EMT to U-channel supports. If there are no available structural support points, the permitted distance to termination points increases to 1.5 m (5 ft), just as for rigid metal conduit and intermediate metal conduit (see Sec. 106), but with one significant difference: the tubing must be unbroken. If there is a coupling near the box or conduit body, then the maximum distance remains at 900 mm (3 ft) EMT used as a pipe nipple between enclosures is also subject to the new restrictions on support in such applications; review Sec. 109 for more information.

213. Bending EMT. Bends in EMT must also be made so that the tubing will not be injured and the internal diameter of the tubing will not be effectively reduced. The radius of the curve of the inner bend or any field bend shall not be less than shown in Secs. 86 and 93. For metric designators 16 through 35 (trade sizes $\frac{1}{2}$ through $1\frac{1}{4}$) EMT, a hand bender, as shown in Fig. 9.97, I, is used. The EMT hickey shown in Fig. 9.97, II, is only for making

FIGURE 9.96 Spring clips secure EMT to U-channel supports.

EMT bender I EMT hickey II

FIGURE 9.97 Typical EMT bender and hickey.

small offsets in metric designator 41 or 53 (1½ or 2 trade size) EMT. The wall thickness of EMT is not generally amenable to significant bends with a hickey, because there is not enough side wall support. Almost all bends in sizes larger than metric designator 35 (trade size 1¼) are made with hydraulic benders, and many rigid-metal-conduit hand *benders* are suitable for EMT. Refer to discussion in Secs. 114 and 115.

214. Installation methods. The techniques of installation described in the sections for rigid metal conduit will apply, in general, to EMT. Such items as junction or pull boxes, number of conductors permitted in a single raceway, and support hardware apply to both these wiring methods.

NONMETALLIC-SHEATHED-CABLE WIRING

215. Nonmetallic-sheathed cable is used for the wiring of new and old residences and for small offices and stores. For decades it was only permitted in one- and two-family dwellings or in multifamily dwellings or other structures not exceeding three floors above grade. This limitation was significantly relaxed in the 2002 NEC, as described at the

end of this section. This cable is frequently employed for extensions to existing installations and is commonly used in small apartment houses. Nonmetallic-sheathed cable can be run either exposed on ceilings and walls or concealed in hollow partitions or between floors and ceilings. It provides a reasonably safe and reliable wiring installation of low first cost. It is made in three types: Type NM, Type NMC, and Type NMS. Conductors are copper, aluminum, or copper-clad aluminum.

Types NM and NMS may be used only in normally dry locations which are free from corrosive vapors or fumes. It may be run or fished in air voids in masonry-block or tile walls where not exposed or subject to excessive moisture or dampness. Types NM and NMS must not be embedded in masonry, concrete, fill, or plaster or run in a shallow chase in masonry, concrete or adobe and covered with plaster, adobe or similar finish.

Type NMC is moisture- and corrosion-resistant, so that its use is allowed in dry, moist, damp, or corrosive locations and in outside and inside walls of masonry block or tile. If embedded in plaster or adobe or run in a shallow chase in masonry walls and covered with plaster or adobe, it shall be protected against damage from nails by a cover of corrosion-resistant coated steel at least 1.59 mm ($1/16$ in.) thick, or a listed alternative verified to be of equal or better hardness, under the final surface finish.

Neither Types NM and NMC, nor Type NMS is allowed to be used (1) as service-entrance cable, (2) in commercial garages, (3) in theaters and similar locations except as provided in Article 518 of the NEC, (4) in motion-picture studios, (5) in storage-battery rooms, (6) in hoistways, or on elevators or escalators, (7) in any hazardous location except as permitted by specific allowances in the hazardous location articles, or (8) embedded in poured cement, concrete, or aggregate. The cable is also not permitted to be run exposed above a suspended ceiling in other than one- or two-family dwellings. Since the definition of "exposed" in NEC Article 100 includes areas behind lift-out panels, this effectively precludes the use of this wiring method above such ceilings, even if it is firmly attached to structural members at all points.

The NFPA Standards Council made a dramatic change in the allowable uses of Type NM cable when it released the 2002 NEC. The Council agreed that Type NM cable could now be used in any building permitted to be of Types III, IV, or V construction, even if actually constructed as Type I or II, provided (for nonresidential uses) the cable is located behind the same sort of thermal barrier normally required for ENT (Sec. 27) in high-rise buildings. There is no NEC waiver for buildings with a sprinkler system; however, building codes generally permit more extensive buildings to be constructed as Type III, IV, or V if a full sprinkler system is in place. The Council action was based on the entire record before it, including NFPA fire statistics that showed no association between Type NM cable and fire prevalence, and the report of the NFPA Toxicity Advisory Committee to the effect that in a fire the contribution of Type NM cable jacketing materials is a negligible fraction of the total smoke load.

This is the first time the NEC has put building construction types at the center of a rule governing the use of a wiring method, although some rules on transformer installations include these references. Refer to *Annex E, Types of Construction* in the NEC for the complete descriptions. They can be roughly summarized as follows:

Type I—All structural members are noncombustible (or limited-combustible) and have fire ratings generally of 3 or 4 h (less in some cases), depending on the specific usage.

Type II—All structural members are as in Type I but the fire resistance generally drops to 2 or 1 h (less in some cases), depending on the specific usage.

Type III—All exterior bearing walls are noncombustible (or limited combustible) and have fire ratings of at least 2 h, but interior structural elements can be of approved combustible material.

Type IV—All exterior and interior bearing walls are noncombustible (or limited combustible) and interior columns, beams, girders, arches, trusses, floors, and roofs are of heavy timber construction without concealed spaces.

Type V—Buildings constructed of approved combustible material, that for some structural elements is subject to a minimum 1-h fire resistance rating.

216. Nonmetallic-sheathed cable, with grounding wires, is manufactured in two-, three-, and four-conductor cables in sizes running from 14 up to 2 AWG. (See Fig. 9.98.) Each wire is insulated with rubber or thermoplastic of the same thickness as required on single wires, except that the cable will have an approved size of covered or bare conductor for grounding purposes only. In Type NM cable the conductors have an outer flame-retardant and moisture-resistant coverings. Type NMC cable is similar in construction to Type NM cable except that it is protected by an outer covering that is flame-retardant and moisture-, fungus-, and corrosion-resistant. Type NMS cable can contain power, communications, and signaling conductors enclosed within a common sheath of moisture-resistant, flame-retardant, nonmetallic materials. Although part of the cable assembly, these other conductors must be firmly separated from the power conductors by the cable sheath, and thereby respect the system separation rules in the NEC.

FIGURE 9.98 Type NM cable marked NM-B has insulation rated 90°C with a final cable ampacity that given in NEC Table 310.16 for 60°C conductors.

217. When nonmetallic-sheathed cable is installed exposed, it is supported directly on the walls or ceiling with straps or staples. The distance between supports must not be greater than 1.4 m (4½ ft), and there must be a support within 300 mm (12 in.) of each outlet box or fitting. The cable must follow the surface of the wall or ceiling and not break from beam to beam. Whenever nonmetallic-sheathed cable does not follow the building finish, it must be protected from physical damage. This protection may consist of a wooden running board or metal protecting strip or a piece of conduit or EMT. It is preferable to use either conduit, especially Schedule 80 rigid PVC conduit, or EMT, especially where the cable passes through floors.

218. When nonmetallic-sheathed cable is installed concealed in new buildings, the cable is fastened to the joists or beams by means of staples. The distance between supports should not be greater than 1.4 m (4½ ft). In wiring finished buildings, when it is impracticable to support the cable between outlets, it can be fished from outlet to outlet in the same manner as Type AC cable. Where the cable is run through holes bored in studs, joists, etc., no protection is required. The holes should be bored as near to the center of the timber as possible and not less than 32 mm (1¼ in.) from the nearest edge when practical. There are cable supports that have slots to hold the cables parallel to and away from the framing member, allowing the 32 mm (1¼-in.) spacing to be maintained for multiple cables even on narrow framing members. An approved method of installing nonmetallic-sheathed cable in a new building is shown in Fig. 9.99.

FIGURE 9.99 Method of installing nonmetallic-sheathed cable concealed in new buildings.

219. No joints or splices should be made in nonmetallic-sheathed-cable wiring except in outlet or junction boxes. This rule applies to both exposed and concealed installations. The loop system is employed generally for concealed work. The cable is looped from outlet to outlet, and the use of junction boxes is avoided.

220. Bends in cable (National Electrical Code) shall be so made and other handling shall be such that the protective coverings of the cable will not be injured, and no bend shall have a radius less than five times the diameter of the cable.

221. An approved outlet box or fitting must be provided at all outlets or switch locations. The cable must be attached to the box with some form of approved device which will substantially close the opening in the box. This connection of the cable to the box can be accomplished by means of a box with a built-in clamp, or a clamp connector (Fig. 9.100) can be employed with a box having conduit knock-outs. For data on metal boxes, see Sec. 115 of Div. 4.

FIGURE 9.100 Nonmetallic-sheathed cable attached to outlet box by means of clamp connectors.

222. NEC rules require that outlet boxes be grounded, and most receptacles and switch yokes must be grounded as well. This means the equipment grounding wire in Type NM cable must be terminated properly so the required grounding connections can be made. This grounding wire is covered by the same 6-in (150 mm) minimum-length-of-conductor rule as the insulated conductors, and 8 in. (200 mm) is an advisable minimum length for workability. If outlet boxes with built-in clamps are employed, the required contact between the box and the grounding wire can be made by means of a small grounding clip. The connection is made by fastening the clip over the grounding wire and box (Fig. 9.101). These copper grounding clips are commonly called G clips. The wire can also be connected to the box with a ground screw that has no other function.

FIGURE 9.101 Grounding clip attached to metal box. In actual practice, *both* the circuit conductors *and* the grounding conductor must not be less than 6 in. (150 mm) in length from the point where they emerge from the cable jacket, and they must be long enough to extend out of the box by at least 3 in. (75 mm). [*Electrical Construction and Maintenance*]

223. Boxes of insulating material (Fig. 4.156 of Div. 4) can be used with nonmetallic-sheathed cable instead of metal boxes. With these boxes, grounding is limited, and it is not necessary to connect each box to a grounding conductor. The boxes shown in Fig. 4.156 of Div. 4 are made of plastic. Cables shall be secured to the box except that size 2¹/₄ in. by 4 in. and smaller may be fastened within 200 mm (8 in.) of the box measured along the sheath. Thin sections of material are knocked out to provide openings to bring the cable into the box. In the case of nonmetallic boxes, the bare wires are spliced together and to jumpers extending to grounding terminals on receptacles and snap switch yokes.

224. A line of outlets for surface mounting with exposed nonmetallic-sheathed-cable wiring is available (Fig. 9.102). They are made of porcelain or plastic; a clamp inside the case holds the cable. There are terminal screws near each end so that cables can be brought in from both ends. NEC requirements for these devices are given in Sec. 225.

225. Devices of insulating material. Switch, outlet, and tap devices of insulating material may be used without boxes in exposed cable wiring and for concealed work for rewiring in existing buildings when the cable is concealed and fished. Openings in such devices shall form a close fit around the outer covering of the cable, and the device shall fully enclose that part of the cable from which any part of the covering has been removed.

If connections to conductors are by binding screw terminals, there shall be available as many terminals as conductors.

FIGURE 9.102 Surface outlets for use with nonmetallic-sheathed cable.

226. Methods of installing nonmetallic-sheathed cable in accessible attics or roof spaces are shown in Fig. 9.103. When the cable is carried across the top of floor beams or across the face of rafters within 2.1 m (7 ft) of the floor, the cable should be protected by guard strips, as shown at *B*. If the attic is accessible only through a scuttle hole without permanent stairs or ladders, the protection is required only within 1.8 m (6 ft) of the edge of the scuttle hole. The cable may be supported along the sides of rafters, studs, or floor joists without any additional protection, as at *D*.

FIGURE 9.103 Methods of installing nonmetallic-sheathed cable in accessible attics or roof spaces.

227. Methods of installing nonmetallic-sheathed cable in unfinished cellars or basements are shown in Fig. 9.104. The cable may be run through bored holes in the floor joists and along the sides or faces of joists without any additional protection such as running boards or guard strips, as shown at *A* and *B*. When the cable is run at angles across the bottom faces of floor joists, the cable must be supported on the underside of running boards as shown in *C*. Assemblies containing not smaller than two No. 6 or three No. 8 conductors may be secured directly on the bottom of the joists. Cables run through or parallel to framing members or furring strips must be at least 1 1/4 in. (32 mm) from their front edges, or else protected with steel at least 1/16-in thick (or listed as equivalent), or sleeved in listed conduit or tubing equipped with a bushing where the cable

FIGURE 9.104 Methods of installing nonmetallic-sheathed cable in unfinished cellars or basements.

enters. The cable must be secured within 12 in. (300 mm) of where it enters the raceway, and the cable jacket must remain intact through the length of the raceway and into the box not less than $\frac{1}{4}$ in. (6 mm).

228. Special rules apply to Type NM cable ampacities.

(Adapted from *Practical Electrical Wiring*, 20th ed., © Park Publishing, 2008, all rights reserved.) Although the individual conductors must have a 90°C temperature rating, the final allowable ampacity must not exceed that given in the 60°C column in NEC Table 310.16 (reproduced in Table 18 of Div. 12). This applies after adjustments for ambient temperature and for mutual conductor heating have been factored. Although mutual conductor heating may seem odd, you must apply this to all the conductors in a group of cables if those cables are “bundled” for

longer than 24 in. This includes routing more than one cable through a succession of single bored holes; the NEC now requires the use of derating penalties if multiple cables are run together through thermal insulation. You need to consider this requirement in a basement, for example, where you might be tempted to run large numbers of cables back to the panelboard through a set of holes lined up through the floor joists and ending at the panel. The derating penalties in NEC 310.15(B)(2)(a) (see Div. 12, Sec. 17, item 5) apply to this condition, as well as to any instance in which more than two cables with two or more wires pass through a common opening in wood framing that is caulked or fire- or draft-stopped.

In addition, a special restriction (which also applies to any wiring method) prevents making use of the general permission to round up to the next higher overcurrent protective device if a branch circuit supplies multiple receptacle outlets. These two conditions mean that for any branch circuits supplying multiple receptacle outlets, if the resulting derated ampacity drops below the branch circuit size even by a single ampere, then you must separate the conductors. For example, the ampacity of 12 AWG in the 90°C column is 30 A, and for 14 AWG it is 25 A. Suppose just five 2-wire cables run through a common set of bored holes. Since the derating penalty is 50 percent, the resulting diminished ampacity condemns any 14 AWG cables on 15-A circuits, and any 12 AWG cables on 20-A circuits—the usual assumption. You could, of course, increase the wires by a cable size, but normally it is better to bore a parallel set of holes.

MINERAL-INSULATED METAL-SHEATHED-CABLE WIRING

229. Mineral-insulated metal-sheathed cable (Type MI) was developed to fill the need for an electrical cable which would have high heat and water resistance and would not be bulky or difficult to install. It provides a general wiring system which is suitable for a great variety of applications for systems with voltages up to and including 600 V. Type MI is approved for use in almost any type of installation. The NEC states that MI cable may be used for services, feeders, and branch circuits in both exposed and concealed work, in

dry or wet locations, and embedded in plaster finish on brick or other masonry. It may be used where exposed to weather or continuous moisture, for underground runs and embedded in masonry, concrete, or fill, in buildings in the course of construction or where exposed to oil, gasoline, or other conditions not having a deteriorating effect on the metal sheath. The sheath of mineral-insulated metal-sheathed cable exposed to destructive corrosive conditions, such as some types of cinder fill, must be protected by materials suitable for those conditions. In addition, MI cable is approved for installation in all hazardous locations.

Type MI cable is composed of only two materials, which are assembled as three components: the conductor, the insulation, and the outer sheath. The conductors are fabricated from high-conductivity copper. The insulation is a specially selected, highly compressed pure magnesium oxide which is processed to maintain permanently the excellent electrical characteristics inherent in this material. The sheath is a round, seamless copper or steel tube which provides the requirements of heat and flame resistance, mechanical protection, and ductility. The wires, insulation, and protective copper or alloy steel sheath are manufactured as a unit, as shown in Fig. 9.105. MI cable is available in single-, two-, three-, four-, and seven-conductor assemblies. Refer to Sec. 100 of Div. 2 for data. The cable possesses exceptional ability to withstand severe mechanical abuse, as shown in Sec. 230 by the summary of mechanical properties as determined from tests.

FIGURE 9.105 Type MI cable [General Cable Co.]

Both ends of each coil of cable are factory-sealed to prevent ingress of moisture into the cable. It is advisable to reseal unused cable in coils that will stand around for any length of time and to apply permanent seals to each cable run as promptly as possible. Should moisture enter cable ends during field handling and installation, the affected insulation will normally be discarded in the process of stripping back and terminating the cable. If necessary, the cable can be further dried by careful application of a torch over approximately a 2-ft (0.6-m) section of cable adjacent to the end. Insulation-resistance measurements checked by an insulation tester should indicate adequate dryness.

The general method of installation is similar to that of metal-clad cable. Standard junction or outlet boxes may be used at each point of termination or when two lengths of cable are to be joined. The tap size of these units should be the same as listed under “Corresponding Conduit Size,” as given in Sec. 96 of Div. 2.

230. Summary of Mechanical Tests on Mineral-Insulated Cable

	Type MI	Metal-clad cable	EMT Type T	Rigid conduit Type T
Impact	B	D	C	A
Crushing	A	D	C	B

NOTES. Performance is indicated by the letter “grades”; A signifies best performance. EMT is electrical metallic tubing. Type T refers to Underwriters’ Code Grade thermoplastic-insulated conductors. In the impact test, the cable was laid over an anvil hardy having a smoothly rounded edge with a 1/4 in. radius. Weights of 50, 20, and 10 lb were dropped on the cable, and the length of drop determined which produced not more than two failures in 10 separate blows. In the crushing test the cable was crushed against the same anvil hardy used in the impact test by a flat steel plate in a compression-testing machine. The force required to crush the cable to 50 percent of its original diameter was determined.

231. Installation of MI cable. It is suggested that the MI be trained into position where the installation allows. The cable can also be snaked and fished into and through congested areas. In some cases, a simple rotating X frame has been used to advantage, facilitating paying off the cable as it is snaked through barriers. After training to position, the cable can be secured with one-hole clips, as offered by many manufacturers of conduit clips, multicable gang straps, channel and spring-set clip-supporting arrangements, cable trays, conduit hangers, and spacing bars and straps.

The cable can be trained into final position by hand in most cases. True alignment can be ensured by tapping the cable lightly along its axis with a wooden mallet. True round sweeps can be made in the larger-sized cable runs with a hand hickey, but this usually is not necessary.

NOTE NEC requires that the radius of bends (at the inner edge of the bend) shall be not less than five cable diameters for cable not more than 20 mm ($3/4$ in.) in external diameter and 10 times cable diameters greater than 20 mm ($3/4$ in.) in external diameter. Cable (except where fished) is to be supported at intervals not exceeding 1.8 m (6 ft).

The copper itself being in an annealed condition, MI is easily worked. Keeping the cable straight when unwinding the coil facilitates final training. The cable is cut after measurement, allowing for conductor tails (stretching steel wire over the proposed run is an ideal method of measuring). MI can be terminated before or after it is laid in position. If undue stressing and sharp bending are avoided during preliminary handling and roughing in work, hardening of the cable will be minimized, resulting in a more readily installed system.

In portions of dairies, laundries, canneries, and other wet locations and in locations where walls are frequently washed, the entire wiring system, including all boxes and fittings used therewith, shall be made watertight, and the cable shall be mounted so that there is at least 6 mm ($1/4$ in.) air space between it and the wall or other supporting surface.

The Code states that at all points where mineral-insulated metal-sheathed cable terminates, a seal shall be provided immediately after stripping to prevent the entrance of moisture into the mineral insulation and that, in addition, the conductors extending beyond the sheath shall be insulated with an approved insulating material. Also, when Type MI cable is connected to boxes or equipment, the fittings shall be identified for such use. MI cable terminal fittings (Fig. 9.106) are designed to seal the cable ends hermetically to prevent the entrance of moisture into the cable as well as secure mechanically the cable to the outlet box, motor, or other apparatus. The complete terminal consists of an end seal and a threaded gland.

When the gland connector is assembled the compression ring locks on to the cable sheath providing a watertight joint.

To complete the seal, the brass pot is filled with a cold plastic insulating compound. The cap is pushed into the pot and the seal is completed with a compressing tool.

All components used in MI terminations are available from General Cable.

FIGURE 9.106 Standard termination for mineral-insulated cables suitable for use at temperatures up to 85°C [General Cable Co.]

232. Termination Dimensions

(Dimensions in Inches)

Group size	Pot						
	A	B	C*	D	E	F	G
Type O gland							
3/8	1 ⁵ / ₁₆	1/2-20	3/8-18	1 ¹ / ₁₆	3/8	9/16	18/32
1/2	1 ⁹ / ₁₆	5/8-18	1/3-14	7/8	3/4	27/32	19/32
3/4	1 ³ / ₄	7/8-14	3/4-14	1 ¹ / ₁₆	1	1 ¹ / ₈	25/32
1	1 ¹⁵ / ₁₆ [†]	1-14	1-11 ¹ / ₂	1 ⁵ / ₁₆	1 ¹ / ₆	1 ¹ / ₈	31/32
Type G gland							
1/2	1 ³ / ₄	3/4-16	1/2-14	7/8	7/8	27/32	18/32
3/4	2 ¹ / ₈	7/8-14	3/4-14	1 ¹ / ₁₆	1	1 ¹ / ₈	25/32
1	2 ¹ / ₂	1 ¹ / ₈	1-11 ¹ / ₂	1 ⁵ / ₁₆	1 ¹ / ₄	1 ⁵ / ₈	31/32

*STD electrical conduit pipe thread.

[†]This dimension is 2⁵/₁₆ on sizes 637 and 684.

233. Termination Selection Chart

Application	Seals			
	Designation	Sleeving	Sealant	Glands
General use up to 85°C, wet and dry location—UL listed	Type O	PVC	Type O plastic	Type O
Hazardous locations, wet and dry up to 85°C—UL listed epoxy	Type H	PVC	Type H	Type G
Low temperatures (below -10°C)	Low temperature	Silicone rubber (Fiberglass reinforced)	Type O plastic	Type O
High temperatures (up to 125°C)	High temperatures	Silicone rubber (Fiberglass reinforced)	Type O epoxy	Type O

Ceramic-to-metal seals are available for temperature in excess of 125°C.

NOTES.

1. Type G glands may be used as an alternative for Type O glands in any application.
2. Silicone rubber Fiberglass-reinforced sleeving may be used as an alternative for PVC sleeving in any general-use application.
3. Type H epoxy may be used as an alternative sealant in any application.
4. Type O Plastic and Type O epoxy may be used as alternative sealants in Class I, Group B, and Class II, Groups E, F, and G, hazardous location.

234. Termination procedure for MI cable

Cable End Seal. Basic parts of the cable-seal termination and the complete seal are shown in Fig. 9.107. The following parts are required for making the seal.

1. Screw-on pot, a self-thread brass cylinder
2. Silicone rubber or PVC tubing, for insulating the exposed conductor ends
3. Insulating cap
4. Sealing compound, a soft plastic material or two-part epoxy compound
5. Crimping and stripping tools

FIGURE 9.107 End seal for MI cable. [General Cable Co.]

The cable-seal termination is made by removing the copper sheath with the stripping tool to expose the length of conductors needed for the connections, screwing the self-threading screw-on pot onto the end of the cable sheath, filling the pot with sealing compound, slipping the insulating tubing and cap assembly over the exposed conductors and pressing the cap down into the end of the screw-on pot, and, finally, securing in place by crimping the edge of the pot down over the insulating cap. This insulates the end of each exposed conductor and provides a moisture seal over the insulation.

Threaded Gland. Figure 9.108 shows the parts of the threaded gland, with the gland in place before tightening and, finally, with the gland locked in the final position. The following parts are included:

1. Gland body
2. Compression ring
3. Gland nut

FIGURE 9.108 Threaded gland for MI cable. [General Cable Co.]

These gland parts are slipped over the end of the cable before the termination is applied, in the order of first the gland nut, then the compression nut, and finally the gland body. When the gland nut is screwed into the gland body over the compression ring, the ring is compressed onto the cable sheath, which anchors it into position. This can be applied at any point on the cable, but usually it is brought clear up to the end with the cable-seal termination seated into the counterbored end of the gland body. The outer end of the gland body is threaded for locknuts.

Assembly Tools

1. One hand vise
2. One screwdriver or nut driver
3. One copper tube cutter
4. One diagonal cutting pliers
5. Two pipe wrenches
6. One crimping and compressing tool
7. One stripping tool

235. Details of termination procedure for MI cable

(General Cable Co.)

1. Mark sheath only with a pencil at point which will expose desired conductor length

2. Use diagonal cutters to start the rip.

3. Use wrist motion to tear up "tag."

4. Engage the tag in the slot of the rod and twist it around the cable. Wrist motion is continued as rod revolves about cable axis.

5. Keep rod at about 45° to the line of the cable. Keep bare rod against sheath and 45° will be regulated. Do not force tearing.

6. Bring stripping tool perpendicular to axis of cable. Then ring the cable sheath at the pencil mark using a copper tube cutter. The depth of the cut should be approximately one half the thickness of the cable sheath. Do not cut through sheath.

7. After ringing, continue stripping as shown in Fig. 5 and tear off squarely at the ring. Remove any burrs at the end of the cable sheath with diagonal cutters.

235. Details of termination procedure for MI cable (Continued)

- 8. Slip the gland connector parts on to the cable in this order: gland nut, compression ring, gland body.
- 9. Engage the self-threading pot finger tight. See that pot is square. Then screw on with pipe wrench engaging all threads. Examine inside of pot for cleanliness and metallic slivers or dust. Test for alignment by bringing gland body up to enclose pot.

- 10. Press plastic compound into sealing pot until it is packed tightly. Important: Be sure the hands are free from metal dust or filings while feeding compound into pot.

- 11. Slip cap and sleeving sub assembly into position

- 12. Force the insulating cap assembly into position on top of compound.

- 13. Slip the compression and crimping tool over the insulating leads

- 14. After positioning crimping tool on pot, compress the insulating washer into place flush with the top of the pot by tightening the two slotted cap screws. This operation compresses the compound in the pot and crimps the edge of the pot into the insulating cap, holding it in place. Remove compression tool.

- 15. Completed termination in box utilizing standard lock nut.

MEDIUM-VOLTAGE-CABLE WIRING

236. Type MV cable is a single-conductor or multiconductor cable with extruded solid dielectric insulation. The cable may have an extruded jacket, a metallic covering, or a combination of both over the single conductors or the cabled conductors. (See Figs. 9.109, 9.110, and 9.111.)

FIGURE 9.109 UniShield EP power cable, 5 kV to 35 kV. [Anaconda Company]

FIGURE 9.110 UniBlend EP shielded power cable, Type MV 90 copper conductor, 15,000 V, 90°C. [Anaconda Company]

FIGURE 9.111 Compact stranded medium-voltage cable. [Anaconda Company]

237. Type MV cables are rated from 2001 V up to 35,000 V. The ampacities are governed by Sec. 310.60 of the National Electrical Code.

238. The construction of Type MV cable shall be in accordance with Article 310 of the NEC and may have aluminum, copper, or copper-clad aluminum conductors.

239. Power systems up to 35,000 V use Type MV cable, which is permitted in wet or dry locations, in raceways, in cable trays if identified for such use in messenger-supported wiring, or directly buried, installed in accordance with Sec. 300.50 of the NEC.

UNDERGROUND-FEEDER AND BRANCH-CIRCUIT-CABLE WIRING

240. Underground-feeder and branch-circuit cable provides an economical wiring system for wet and corrosive installations. Single-conductor Type UF cable resembles Type USE service-entrance cable in general appearance. The insulation employed consists of a plastic compound, NEC statements with respect to its use are: Underground-feeder and branch-circuit cable may be used underground, including direct burial in the earth, as feeder or branch-circuit cable where provided with overcurrent protection not in excess of the rated current-carrying capacity of the individual conductors. If single-conductor cables are installed, all cables of the feeder circuit, subfeeder circuit, or branch circuit, including the neutral and equipment grounding conductor, if any, shall be run together in the same trench or raceway. If the cable is buried directly in the earth, the minimum burial depth permitted is 600 mm (24 in.) if the cable is unprotected and 450 mm (18 in.) when a supplemental covering, such as a 50 mm (2 in.) concrete pad, metal raceway, pipe, or other suitable protection, is provided. Type UF cable may be used for interior wiring in wet, dry, or corrosive locations under the recognized wiring methods of the Code, and where installed as nonmetallic-sheathed cable it shall conform to the provisions of Article 334 and be of a multiconductor type. It must also be of a multiconductor type if installed in cable tray.

This type of cable shall not be used (1) as service-entrance cable, (2) in commercial garages, (3) in theaters, (4) in motion-picture studios, (5) in storage-battery rooms, (6) in hoistways, (7) in any hazardous location, (8) embedded in poured cement, concrete, or aggregate except as provided in Article 424 of the Code, and (9) where exposed to direct sunrays, unless identified as sunlight-resistant (Fig. 9.112).

FIGURE 9.112 Type UF two-conductor cable suitable for direct burial.

INTERIOR WIRING WITH SERVICE-ENTRANCE CABLE

241. Service-entrance cable of Type SE or Type USE may be employed for interior wiring, installed either concealed or exposed. The construction of these cables is described in Sec. 244. Cables with all the conductors insulated may be used for general interior wiring. Those without insulation on the grounded conductor may be used only on systems not exceeding 150 V to ground as branch circuits to existing ranges and clothes dryers. The cables with uninsulated grounding conductors must have a final nonmetallic outer covering. Cables which are used for interior wiring must be installed in accordance

with the rules for nonmetallic sheathed cable discussed in Secs. 215 to 228. In such cases the uninsulated wire becomes an equipment grounding conductor only, and is not allowed to be a circuit conductor.

242. Ampacity rules change; effects of thermal insulation. An exemption from the Type NM requirement that the final ampacity be based on the 60°C ampacity column (see Sec. 228) was removed in the 2008 NEC cycle. The results, where enforced, will be dramatic. For example, 4/0 AWG Aluminum Type SE cable made with three insulated conductors and a smaller bare conductor has been in common use for decades as a 200 A feeder run to dwelling unit panels in multifamily housing. It has an ampacity of 180 A under the 75°C ampacity column. Since the next higher standard-size overcurrent device is 200 A, it could have been used for this purpose unless the actual load ran in the 180 to 200 A window, a very unusual circumstance. Now it must be taken as a 60°C conductor, reducing the ampacity to 150 A.

The change in the ampacity rule is technically questionable in most instances; however, there is one application where the change is entirely justified, and might even not go far enough. When wiring is embedded in thermal insulation, the ampacity is significantly degraded. The results tend to get progressively worse for larger cable sizes, because larger cables are generally installed to meet an expectation of higher current draw. The heat generated by a conductor is I^2R . Larger cables carrying larger currents reduce the heat by the first power due to larger radiating surface areas, and increase the heat by the square of the current increase. This means that large cables tend to be worse than smaller ones, because the latter increase in heat ($+\Delta I^2$) usually overwhelms the former decrease ($-\Delta R$). The present rule for 60°C works well for branch circuits, but not as well for large feeders.

In the 1987 NEC cycle, this was confirmed by actual NEMA testing, with dramatic results. The test used 2 AWG aluminum Type SE cable of the “SEU” style (two insulated conductors and the grounded conductor configured as a spirally-wrapped conductor around the ungrounded conductors). This cable is used routinely for 100 A residential services [due to the special ampacity accorded for this purpose by 310/15(B)(6)]. It was run through thermal insulation under controlled test conditions. Specifically, the cable was run embedded in cellulose insulation with 7 in above it. Thermocouples were placed on the cable, and the various loads under test were maintained for long periods. This cable has a Table 310.16 ampacity (terminations not considered for this purpose) of 100 A. When the cable was loaded to 100 A, the cable jacket was “completely charred” as well as adjacent “charred wood members,” all while the cable was operating within its table ampacity limitations. In fact, the testing showed (65 A caused 96°C operation) the cable exceeded its rated operating temperature at any time the continuous current exceeded about two-thirds of the table ampacity.

These results strongly demonstrate the fact that the ampacity of a conductor is not necessarily what a table may predict. The ampacity of a conductor is its ability to carry current continuously *under the conditions of use*. This is determined by thermodynamics. The ampacity of 2 AWG aluminum XHHW configured as 2/3 Al SEU cable and embedded in cellulose insulation is approximately 60 A. Actually, the ampacity corresponding to Table 310.16 would be even less than that, because Table 310.16 is structured around three current-carrying conductors and this testing only used two of the three conductors in the test circuit.

This testing focused on Type SE cable, but a test run using 6 AWG copper in metal conduit embedded in foam insulation overheated those conductors as well. There is no ampacity table for thermal insulation, and it would be impossible to create one, because variations in R factors significantly change end results. However, it is fair to say, for example, that the ampacity of 4/0 Al SE cable (table ampacity of 205 A) embedded in thermal insulation is

far less than even the 60°C table result of 150 A would predict. The NEC, in 310.10, requires that no conductor may be operated above the temperature limitations of its insulation. That is the only NEC rule that covers this point, and it is referenced in a number of cable articles for this reason. To the extent practicable, good practice is to route larger circuits in such a way as to avoid contact with thermal insulation.

243. The principal use of service-entrance cable for interior wiring in dwellings is for branch circuits supplying ranges or water heaters and in farm wiring as feeders from the master service to supply the other buildings that are wired for electricity. It is also commonly used for both indoor and outdoor feeders, even for 3-phase 4-wire commercial applications. The cable is supported on the building structure by means of single-hole or two-hole cable straps made in different sizes to accommodate the size of cable. They are similar in appearance to those used for rigid conduit. Connection to switch or outlet boxes is made by means of a connector (Fig. 9.113), which is made in watertight and nonwatertight types. A typical range installation is shown in Fig. 9.114.

I Watertight Screw Connector.

II Nonwatertight Connector.

FIGURE 9.113 Box connectors for service-entrance cable. [General Electric Co.]

244. Types of cables, indoor-use exclusion.

Two common types of cables are shown in Figs. 9.115 and 9.116. The three-conductor Type SE cable in Fig. 9.115 consists of two insulated conductors and one concentric-stranded insulated conductor (generally used as the grounded-neutral conductor). This cable is limited to services that do not exceed 150 V to ground, such as a 120/240-V single-phase supply. If used as a three-wire 120/240-V branch circuit to a range, wall-mounted oven, counter-mounted cooking unit, or clothes dryer, this cable must originate at the service equipment. In such instances, the uninsulated neutral conductor may be used to ground the metal frame of the equipment supplied, but such application is limited to existing branch-circuit installations only.

FIGURE 9.114 Installation of electric range wired with service-entrance cable.

FIGURE 9.115 Four-conductor Type SE cables uses three insulated conductors and a bare equipment ground.

FIGURE 9.116 Single-conductor Type USE cable suitable for direct burial.

Figure 9.116 shows a single-conductor 4/0 aluminum Type USE cable. This cable, if it has no other designation, is limited to underground applications with an allowance for an outdoor only, above-grade termination. It must never be brought into a building unless it also has a building wire classification to go along with the USE designation. For example, it is not uncommon to see a Type USE/RHW cable that has been evaluated for use within buildings as well as for direct burial. When used in direct-burial applications, such a cable has a 75°C rating. The ampacity ratings of conductors are listed in Tables 19 through 23 of Div. 12. For underground applications Type USE cable should be buried not less than the depths specified for Type UF cables in Sec. 240. For over 600 V refer to Sec. 131 of Div. 8.

UNDERFLOOR-RACEWAY WIRING

245. Underfloor-raceway systems are used principally in office buildings for the installation of the wiring for telephone and signal systems and for convenience outlets for electrically operated office machinery. They provide a flexible system by which the location of outlets may be easily changed to accommodate the rearrangement of furniture and partitions. The NEC allows their use when embedded in the concrete or in the concrete fill of floors. Their installation is allowed only in locations which are free from corrosive or hazardous conditions. No wires larger than the maximum size approved for the particular raceway shall be installed. The voltage of the system must not exceed 600 V. The total cross-sectional area of all conductors in a duct must not be greater than 40 percent of the interior cross-sectional area of the duct.

246. An underfloor-raceway system consists of ducts laid below the surface of the floor and interconnected by means of special cast-iron floor junction boxes. The ducts for underfloor-raceway systems are made of either fiber or steel. Fiber ducts are made in two types, the open-bottom type and the completely enclosing type. Steel ducts are always of the completely enclosing type, usually having a rectangular cross section. In the underfloor-raceway system, provision is made for outlets by means of specially designed floor-outlet fittings which are screwed into the walls of the ducts. When fiber ducts are employed, the duct system is laid on the floor with or without openings or inserts for outlets. After the floor has been poured and finished as desired, the outlet fittings are installed into inserts or at any points along the ducts at which outlets are required. The method of installing outlet fittings is described in Sec. 261. When steel ducts are employed, provision for the outlet fittings must be made at the time that the ducts are laid, before the floor or floor fill is poured. The steel ducts are manufactured with threaded openings for outlet connections at regularly spaced intervals along the duct. During the installation of the raceway and the floor these outlet openings are closed with specially constructed plugs whose height

FIGURE 9.117 Dimensions of ducts for underfloor raceways.

can be adjusted to suit the floor level. The shapes and dimensions of the different types of ducts for underfloor raceways are shown in Fig. 9.117. For telephone and similar circuits, much wider ducts can be obtained.

247. General rules for the installation of underfloor raceways. In general, underfloor raceways should be installed so that there is at least 20 mm ($\frac{3}{4}$ in.) of concrete or wood over the highest point of the ducts (see Figs. 9.118 and 9.119). However, in offices approved raceways may be laid flush with the concrete if covered with linoleum or equivalent floor covering (see Fig. 9.120). When two or three raceways are installed flush with the concrete, they must either be contiguous with each other and joined to form a rigid assembly. Flat-top ducts over 100 mm (4 in.) wide but not over 200 mm (8 in.), spaced less than 25 mm (1 in.), must be covered with at least 38 mm (1½ in.) of concrete (see Fig. 9.121). It is a standard practice to allow 200 mm ($\frac{3}{4}$ in.) clearance between ducts run side by side. The centerline of the ducts should form a straight line between junction boxes. If the spacing between raceways is 1 in. or more, the raceway may be covered with only 1 in. of concrete. All joints in the raceway between sections of ducts and at junction boxes should

FIGURE 9.118 Any flat-top raceway 100 mm (4 in.) or less in width must be covered with wood or concrete at least 20 mm ($\frac{3}{4}$ in.) in thickness except in office occupancies.

FIGURE 9.119 Any fiber raceway 100 mm (4 in.) or less in width must be covered with wood or concrete at least 20 mm ($\frac{3}{4}$ in.) in thickness.

FIGURE 9.120 Approved raceways flush with concrete and covered with linoleum in an office occupancy.

FIGURE 9.121 Any flat-top raceway over 100 mm (4 in.) wide must be covered with concrete at least 38 mm (1½ in.) in thickness if raceways are spaced less than 25 mm (1 in.) apart.

be made waterproof and with good electrical contact so that the raceways will be electrically continuous. Metal raceways must be properly grounded.

248. Wires of signal or telephone systems must not be run in the same duct as wires of lighting systems. Combination junction boxes accommodating the two or three ducts of multiple-duct systems may be employed, provided separate compartments are furnished in the boxes for each system. (See Fig. 9.122.) It is best to keep the same relative location of compartments for the respective systems throughout the installation.

All joints or taps to the conductors must be made in the junction boxes. No joints or taps should be made in the ducts of the raceway or at outlet insert points. (See Figs. 9.123, and refer to Figs. 9.136, and 9.137.)

FIGURE 9.122 Three compartment floor junction box. [Walker Systems, Inc.]

FIGURE 9.123 Flush, pedestal, and multiplex service fittings. [Walker Systems, Inc.]

249. Junction boxes for use with underfloor raceways are specially constructed metal boxes. They are available in single-compartment types and in combination boxes to accommodate multiple-duct systems having two or three raceways run side by side. The general construction of the junction boxes is similar for both fiber- and steel-duct systems. Most boxes are equipped with leveling screws so that they can be leveled up with the duct runs. The covers of the boxes also are adjustable with respect to height so that they can be accurately leveled to agree with the surface of the finished floor. Different types of covers that will be suitable for the different types of floor finishes are available. With plain cement-finished floors a plain brass cover set flush with the floor (Fig. 9.124) is sometimes used. In other cases a recessed cover filled with cement is employed. For linoleum- or cork-covered floors a cover with a recess for a cork or linoleum insert is provided, as illustrated in Fig. 9.125. For marble or hardwood floors a recessed cover with a marble insert (Fig. 9.126) may be employed. With the recessed covers only a thin ring of brass shows in the finished floor, marking the location of the junction box.

FIGURE 9.124 Floor junction-box cover for cement-finished floors.

FIGURE 9.125 Floor junction-box cover for linoleum-covered floors.

FIGURE 9.126 Floor junction-box cover for terrazzo floors. [Walker Systems, Inc.]

250. Fittings must be installed at every end of a line of raceway with a marker extending through the floor to show the line of the duct. All dead ends of raceway must be closed with a suitable fitting.

251. In installing raceways every effort should be made to avoid low points which could form traps for water.

All connections to a raceway except those made through the inserts provided in the raceway shall be made by means of flexible metal conduit where not installed in concrete, rigid conduit, intermediate metal conduit, EMT, or a special approved fitting (refer to Fig. 9.127). Where a metallic underfloor raceway system provides for the termination of an equipment grounding conductor, rigid nonmetallic conduit, electrical nonmetallic tubing, or liquidtight flexible nonmetallic conduit where not installed in concrete unless so listed may be used.

252. Inserts (National Electrical Code) shall be leveled to the floor grade and sealed against the entrance of concrete. Inserts used with metal raceways shall be metal and shall be electrically continuous with the raceway. Inserts set in or on fiber raceways before the floor has been laid shall be mechanically secured to the raceway. Inserts set in fiber raceways after the floor has been laid shall be screwed into the raceway. In cutting through the raceway wall and setting inserts, chips and other dirt shall not be allowed to remain in the raceway, and tools shall be so designed as to prevent the tool from entering the raceway and injuring conductors that may be in place.

253. Reinsulation of conductors in underfloor raceways prohibited. When an outlet is discontinued, the conductors supplying the outlet shall be removed from the raceway. The general practice is to loop wire intermediate receptacles between the header and the end of the run. This requirement assures that reinsulated conductors will not be resting in the raceway below an abandoned outlet. This in turn prevents a fish wire inserted afterward from a downstream location from getting caught on a reinsulated conductor, with very destructive consequences. It is often advisable to wire each outlet on its own pair of conductors back to the header or other junction point. Then, when an outlet is abandoned, the associated pair of conductors can be withdrawn without disrupting other outlets on the run. Take care, however, to keep track of the total number of conductors at all portions of the duct, because the ampacity derating factors for mutual conductor heating (Div. 12, Sec. 17, item 5) will apply. Some jurisdictions provide limited waivers to these derating factors in underfloor applications; however, in order to encourage this practice and thereby discourage the reinsulation of conductors. When the conductors are withdrawn, leave a pull string in their place so the outlet can be easily reactivated in the future as necessary.

FIGURE 9.127 Component parts and method of installation for two-level steel underfloor raceways. [General Electric Co.]

254. Steel-duct raceways are made for two types of underfloor electrical distribution systems:

1. The two-level system, recommended for use when electrical growth and expansion of facilities are anticipated
2. The single-level system, recommended for underfloor wiring installations when cost and design limitations are a factor

The features of a two-level system showing raceways, junction boxes, typical supports, and other fittings are given in Fig. 9.127. Duct details are shown in Fig. 9.128.

The features of a one-level system showing raceways, junction boxes, typical supports, and other fittings are given in Fig. 9.129. Duct details for the raceway of one manufacturer

FIGURE 9.128 Duct and duct insert for a two-level raceway system. [General Electric Co.]

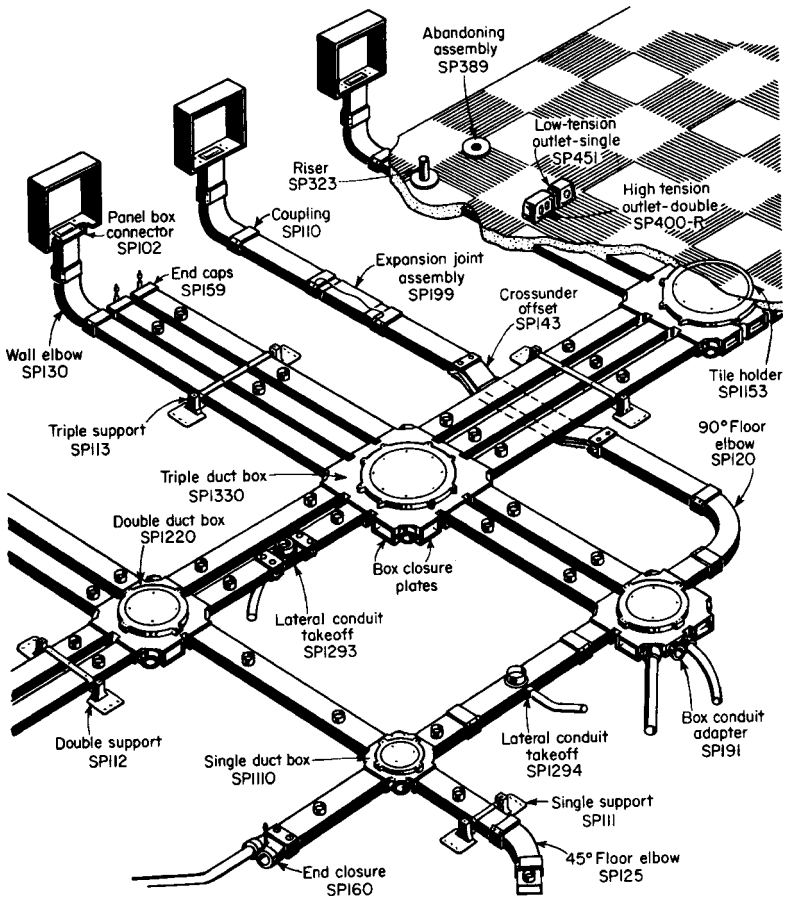

FIGURE 9.129 Component parts and method of installation for a single-level steel underfloor raceway. [General Electric Co.]

FIGURE 9.130 Duct and duct inserts for single-level raceway system. [General Electric Co.]

are given in Fig. 9.130. For dimensions of ducts available from other manufacturers refer to Fig. 9.117 and the catalogs of such manufacturers.

255. Installation of steel-duct raceways. The method of installing Walker-duct, the steel-raceway system manufactured by the Walker Systems, Inc., in the concrete fill of floors is illustrated in Fig. 9.131. The ducts are supported by saddle supports, which consist, as shown in Fig. 9.132, of two detachable parts, a base and a saddle. These supports are available for single-duct runs and in various combinations for supporting multiple-duct runs. Support should be located not more than 5 ft (1.5 m) apart. After the locations of junction boxes and duct runs have been marked out, the bases of the saddle supports are fastened to the floor by expansion bolts for concrete construction or by special toggle wires for hollow-tile work (see Fig. 9.131). The saddle is then assembled to the base, and the ducts fastened to the saddle by tie wires. The complete raceway is then leveled and adjusted to the proper height by means of the height-adjusting bolts of the saddles and the leveling screws of the couplings and junction boxes. The adjacent sections of duct are fastened together by duct couplings (Fig. 9.133). The pointed set-screws of the couplings fasten the duct to the coupling and at the same time provide an electrical ground connection between the duct and the coupling. Special fittings are available for connecting ducts and junction boxes to conduit, for connecting ducts directly to distribution cabinets, for blanking off the ends of ducts, etc.

256. The outlet openings in the ducts are closed by means of outlet plugs whose height can be adjusted to coincide with the floor level. A marker screw can be inserted in one plug of each 10-ft (3-m) length of duct if it is desired to facilitate the location of the outlets. The appearance of a duct after the installation of the floor fill with an outlet opening

FIGURE 9.131 Method of installing a steel underfloor raceway. [Walker Systems, Inc.]

FIGURE 9.132 Saddle supports for one small and one large steel underfloor duct. [Walker Systems, Inc.]

FIGURE 9.133 Coupling for a steel underfloor raceway. [Walker Systems, Inc.]

closed by means of an outlet plug is as shown in Fig. 9.134. When the floor is covered with linoleum, rubber, cork, etc., the outlets are not extended through the covering until needed. It is a good practice to indicate the location of the outlet inserts by means of an escutcheon marking screw in the plugs on each side of the junction boxes. (See Fig. 9.135.) Wood or marble floors can be laid over the outlet inserts and the outlets are not extended through the finished floor until actually needed.

FIGURE 9.134 Appearance of outlet opening in a steel underfloor raceway with opening closed by means of an outlet plug. [Walker Systems, Inc.]

FIGURE 9.135 Outlet opening in a steel underfloor raceway closed with an outlet plug and concealed with linoleum floor covering.

257. When the raceway is installed in the concrete of the floor, the ducts are supported from the forms by saddle supports, and the whole system is accurately leveled and adjusted for the proper height, by means of the leveling screws and bolts on the fittings and saddle supports, before the floor is poured. In concrete-joist construction when building codes will not allow the saddle support to be mounted directly on the concrete pans, a saddle bridge must be used to support the duct saddles.

258. Installation of outlet fittings in steel-duct-raceway systems. When a duct outlet is to be used for service, the small amount of concrete is removed from the top depression of the outlet plug. The plug is removed by unscrewing it from the duct with a plug-removal wrench. The removal of the plug forms a neat preformed passage through the concrete to the duct-outlet opening. The necessary wires are pulled in from the nearest junction box and threaded through the service fitting. The service fitting is then screwed into the duct-outlet opening, and the floor flange adjusted. Figures 9.136 and 9.137 illustrate this process.

When it is desired to locate an outlet at a point in a raceway where there is no pre-set insert plug, an afterset insert for the outlet can be made by the use of special tools available from the manufacturer. The method of making an afterset insert is illustrated in Fig. 9.138.

FIGURE 9.136 Pedestal service fittings for above-floor service. [Walker Systems, Inc.]

FIGURE 9.137 Flush service fittings for single service power or low voltage applications. [Walker Systems, Inc.]

FIGURE 9.138 Method of making an outlet with an afterset insert. [General Electric Co.]

259. Trenchduct. Several makes of steel underfloor raceways are suitable for use with Trenchduct. Figure 9.139 shows a section of Trenchduct supplying two runs of under-floor steel raceways. Trenchduct is available in standard 6-ft (1.8-m) lengths at a depth of 2 1/8 in. (53.975 mm). Other depths are available on special order. Ducts are shipped complete with three 18-in- (457.2-mm-) long cover sections. Cover plates are 1/4-in- (6.35-mm-) thick roller-leveled steel. The Trenchduct is used to extend branch circuits from a panel-board to the underfloor raceways, and the Trenchduct shown in Fig. 9.139 has a cross-sectional area of 22 1/2 in² (145.15 cm²) which allows many more conductors than a conduit feed.

Cover plates for Trenchducts are adjustable upward to 3/8 in. (9.525 mm) and downward to 3/8 in. from a standard position by means of leveling screws flush with the top surface cover. Adjustment to finished-floor height is made by a screwdriver from the top.

Side-feed connectors provide bushed openings for feeds into the side of the Trenchduct. When specified, openings in Trenchduct are precut by the manufacturer.

FIGURE 9.139 Typical components of a Trenchduct used in connection with an underfloor steel raceway. [Triangle Conduit & Cable Co., Inc., subsidiary of Triangle Industries, Inc.]

The Trenchduct is, in effect, a continuous junction box, because the cover plates are flush with the finished floor and one or more sections can be easily removed as required.

Vertical elbows turn the Trenchduct system up to a panelboard with full duct capacity. Figure 9.139 shows typical components of the system.

260. Installation of completely enclosing fiber-duct raceways. Completely enclosing fiber-duct underfloor raceways may be installed in either the concrete or the concrete fill of floors in a manner similar to that described for steel-duct raceways in Sec. 255. With fiber-duct raceways there are preinserted provisions for outlets, or they can be provided without any openings for outlets. After the finished floor has been laid, an outlet may be provided at any preset insert or at any point desired along the duct runs, as described in Sec. 261. The main component parts of a fiber-duct underfloor-raceway system are illustrated in Figs. 9.140 and 9.141. The different sections of duct are clamped together by means of a combination steel coupling and support provided with leveling screws for leveling the runs and adjusting to the proper height.

261. Installation of outlet fittings in fiber-duct-raceway systems. To establish outlets in a preset system after the finish is in place, it is necessary to determine the location of the insert. This can be done by means of an insert finder. Then the flooring is chipped down to expose the insert cap. The cap is removed and a hole cut in the duct so that wires can be fished through and connected to the receptacle.

FIGURE 9.140 Component parts of a completely enclosed fiber underfloor-raceway installation.

FIGURE 9.141 Junction box and associated fittings for a completely enclosed fiber underfloor-raceway system.

The procedures shown in Fig. 9.142 should be employed in installing an outlet fitting at any point in a fiber underfloor raceway of the completely enclosing type. The special tools provided by the manufacturers for this purpose should be used to ensure satisfactory workmanship.

262. Layout of underfloor-raceway systems. A very simple layout for an underfloor-raceway system, called the *single-runaround layout*, is shown in Fig. 9.143. Such a layout provides only the minimum of flexibility in the location of outlets. It is satisfactory for certain types of buildings when the installation cost must be limited and desks will be located only around the sidewalls. This layout will provide outlets only for telephone and signal systems. A similar layout is shown in Fig. 9.144. This layout, having two separate raceways, provides outlets for electrically operated office machines from one raceway and outlets for telephones and signal systems from the other raceway.

FIGURE 9.142 Method of installing afterset inserts into fiber underfloor raceways.

FIGURE 9.143 Single-runaround layout for an underfloor raceway.

FIGURE 9.144 Double-runaround layout for an underfloor raceway.

263. To provide greater flexibility in the possible location of outlets over the entire area than is accomplished with the runaround layouts, grid layouts are employed. A typical single-grid layout is shown in Fig. 9.145, and a double-grid layout in Fig. 9.146. The flexibility provided for the location of outlets depends upon the distance between parallel duct lines. For maximum flexibility the parallel lines of ducts should be located approximately 5 ft (1.5 m) apart with the outside runs located 3 ft (0.9 m) from the outside walls. The distance between rows of junction boxes should be from 20 to 60 ft (from 6.1 to 18.3 m), depending upon the estimated number of outlets that will be required at any one time between junction boxes.

FIGURE 9.145 Single-grid layout for an underfloor raceway.

FIGURE 9.146 Double-grid layout for an underfloor raceway.

WIREWAY WIRING

264. Wireways may be installed only for exposed work, except as extensions to pass transversely through walls. They must not be used where they will be subjected to severe physical damage or to corrosive vapors or in any hazardous location, except as specifically permitted in the hazardous location articles in the NEC. Wireways for outdoor use shall be of approved raintight construction. Their chief application is for the installation of mains and feeders in industrial plants or other locations where a flexible means of supplying branch circuits is advantageous or where many wires must be located in one run. They permit access to the wires and cables at all points in the system for tapping, splicing, rerouting, inspection, installation of additional wiring, or other changes, all without disturbing the existing work. Three long sides (and the ends) may or may not be provided with knockouts for wiring entries. The fourth long side consists of a removeable cover which may be hinged or secured with screws, and provides access for installing wires and making splices. Multiple lengths can be coupled together with nuts and bolts running through a connecting coupling. A typical use of wireway is shown in Fig. 9.147. Note the use of a power distribution block for splicing purposes in this wireway section. The wire bending space must comply with Div. 12, Table 34 limits for the conductors terminated, and all uninsulated live parts must be protected as shown so they will not be exposed whether or not the wireway cover is in place.

Wireways are available in sizes 2, 2½, 3, 3½, 4, 4½, 5, 6, 8, 10, and 12 in. (50.8, 63.5, 76.2, 88.9, 102, 114, 127, 152, 203, 254, 305 mm) square. No conductor larger than that for which the wireway is designed shall be installed in wireways, provided that the sum of the cross-sectional area of all the conductors at any cross section does not exceed 20 percent of the interior area of the wireway. Splices and taps may be located within the wireway, provided the cover is left accessible. The conductors including the splices must not fill the wireway to more than 75 percent of its area at that point. The wireway must not contain more than 30 conductors at any point except for signaling circuits or for control conductors between a motor and its starter, used only for starting duty. More than 30 *current-carrying* conductors may be installed in a wireway, at a 20 percent maximum fill, if the reduction factors specified in 310.15(B)(2)(a) (Div. 12, Sec. 17, item 5) are applied. Figure 9.148 shows a more elaborate application where three wireway sections connect four panelboards to a pull box at the upper left that has been field-modified to serve as a common junction point. By distributing the approximately 85 current-carrying circuit conductors leaving the four panelboards over the three wireway runs, the installation avoids derating entirely.

Horizontal runs of wireways must be supported at each end and every 1.5 m (5 ft) unless specifically listed for supports at greater intervals, but in no case shall the distance between supports exceed 3 m (10 ft). Vertical runs of wireway shall be securely supported

FIGURE 9.147 Length of wireway with power distribution blocks, each with a clear plastic cover over the uninsulated live parts.

FIGURE 9.148 Metal wireways can often avoid derating penalties for mutual conductor heating.

at intervals not exceeding 4.5 m (15 ft) and shall not have more than one joint between supports. Adjoining wireway sections shall be securely fastened together to provide a rigid joint. An unbroken length of wireway may extend transversely through walls. Very short wireway sections are often bought and placed in service as a rectangular pull box. This is permitted but the required wire bending space and conduit spacings that apply to pull boxes generally (see Sec. 349) apply to these applications.

265. Cross-Sectional Areas of Wireways

Wireway size, in	Cross-sectional areas, in ²		
	100%	75%	20%
2½ × 2½	6.25	4.68	1.25
4 × 4	16.00	12.00	3.20
6 × 6	36.00	27.00	7.20
8 × 8	64.00	48.00	12.80

266. In computing the proper size of wireway, refer to Secs. 264 and 265. Then determine the total cross-sectional area of the conductors to be installed from Table 5 in NEC Chap. 9.

267. Nonmetallic wireways are available and are very helpful in areas where metal wireways would likely corrode. They follow essentially the same rules as metal wireways with one major exception. Because nonmetallic materials do not work as well as metal in their ability to function as a heat sink, the contained conductors, even if fewer than 30, are always subject to derating penalties for mutual conductor heating, just as if they were running in a conduit.

BUSWAY WIRING (NEMA)

268. Busway is a modern system of power distribution. It provides a flexible means for distributing power and light in industrial and commercial buildings and/or connecting branch motor circuits to the mains so that the location of the branch taps can be readily and economically changed to suit the conditions of rearrangement of machines. This system finds wide use in industrial plants when the layout of machines must be continually changed to meet changing manufacturing conditions because busway's flexibility in accommodating such change is its greatest advantage. (See Fig. 9.149.)

FIGURE 9.149 Low-voltage-drop feeder busway system.

By definition (NEMA standard BU1) a *busway* is a prefabricated electric distribution system consisting of busbars in a protective enclosure, including straight lengths, fittings, devices, and accessories. Busways are of the following types:

1. *Feeder busway*. A feeder busway is a busway without plug-in openings which is intended primarily for conducting electric power from the source of supply to centers of distribution but which can have provisions for bolt-on devices (see Fig. 9.150).

FIGURE 9.150 Feeder busway.

2. *Plug-in busway*. A plug-in busway is a busway having plug-in openings on one or both sides at spaced intervals, offering means for electrical connection of plug-in or bolt-on devices to the busbars. Such plug-in or bolt-on devices (bus plugs) may incorporate switches, circuit breakers, transformers, motor controllers, or other auxiliary equipment (see Fig. 9.151).

FIGURE 9.151 Fusible bus plug installed on a plug-in busway.

269. Major requirements related to the application and testing of low-voltage busway. This material is intended to assist in understanding the application and testing of low-voltage busway by summarizing the principal codes and standards applicable to the product. Since all codes and standards are revised from time to time and requirements vary from locality to locality, contact your local inspection authority and the manufacturer for the latest requirements applicable to your installation.

Groups which maintain standards enumerating busway construction and installation practices include:

1. Underwriters Laboratories Inc.
2. The National Electrical Manufacturers Association
3. The National Fire Protection Association (The National Electrical Code)
4. State and local electrical codes
5. Power companies, which frequently specify minimum conductor sizes and spacing for connection to their equipment.

Underwriters Laboratories Requirements. Busway bearing the Underwriters Laboratories listing mark must pass a series of performance tests (see UL 857). Among the tests which may be required here are:

Heating (temperature-rise) test. Busway with suitably plated joint connections must carry its rated current continuously without any part showing a temperature rise above ambient of more than 55°C. Tests are conducted on three 10-ft (3-m) sections bolted together, at any convenient voltage, at design frequency, with rated current flowing.

Resistance-to-impact test. The resistance-to-impact test will ordinarily not be required for nonventilated busway if its construction conforms to the specifications spelled out in Table A. However, all other busway must be tested to ensure that no hazardous condition will exist after any side of the enclosure has been subjected to a blow from a 50-lb weight suspended from a 30-in- (762-mm-) long pendulum arm going through a 60° angle from the vertical.

TABLE A Thickness of Sheet Metal

Maximum inside width of widest surface		Minimum acceptable thickness of sheet metal					
		Steel				Aluminum	
		Zinc-coated		Uncoated			
in	mm	in	mm	in	mm	in	mm
12*	305	0.056	1.42	0.053	1.35	0.075	1.91
18	457	0.070	1.78	0.067	1.70	0.095	2.41
30	762	0.097	2.46	0.093	2.36	0.122	3.1
More than 30	More than 762	0.126	3.20	0.123	3.12	0.153	3.89

*18 in if enclosure does not support the weight of the busbar assembly.

Dielectric test. A busway shall withstand for 1 min without breakdown of the application of a 60-Hz potential of 1000 V plus twice the maximum rated voltage between live parts and the enclosure and between live parts of opposite polarity.

Resistance-to-bending test. Busway intended for a spacing of not more than 5 ft (1.5 m) between mounting supports will ordinarily be accepted without a bending test. However, to qualify for horizontal mounting on a 10-ft (3-m) support basis or on 16-ft (4.9-m) centers in vertical risers, a busway must withstand for 5 min without rupture of the joint, appreciable permanent distortion, or short-circuiting or grounding of the phase or neutral busbars a bending moment equivalent to the weight of a 10-ft section plus an additional 100-lb (45.36-kg) force applied at the end of the 10-ft section.

Resistance-to-crushing test. Busway intended to employ a spacing of not more than 5 ft (1.5 m) between mounting supports and whose construction is in accordance with Table A will ordinarily be accepted without a crushing test. However, if the busway does not meet these spacing or construction requirements, it shall be tested to ensure that it will be able to withstand a crushing force of 200 lb (90.7 kg) plus 3 times the weight of a 10-ft (3-m) section.

Busbar pullout test. Busway intended for mounting in a vertical run shall be capable of supporting a downward force equal to 4 times the weight of an individual busbar in a 10-ft (3-m) section applied simultaneously to each of the busbars without rupture or permanent distortion of busbar supports.

Insulation-resistance and dielectric-strength test after exposure to rain. Outdoor busway must withstand a simulated rain for 8 h per day for 5 successive days without dielectric breakdown.

Short-circuit test. All busway and fittings rated 100 A or less and having a short-circuit current rating of more than 5000 A shall be tested and marked with their respective rating(s). Busway and fittings rated over 100 A and having a short-circuit current rating over 10,000 A shall be tested and marked with their respective ratings. To verify these rating(s), representative samples of the busway shall be subjected to phase-to-phase, phase-to-enclosure, and phase-to-ground conductor (when applicable) short-circuit tests. Tests may be conducted either with or without fuse or circuit-breaker protection ahead of the busway being tested, and the ratings and markings will so indicate.

Tests when busway enclosure is used as an equipment-grounding conductor. For the busway enclosure to be accepted as an equipment-grounding conductor, the busway shall be subjected to the short-circuit tests described above. In addition, two other conditions shall be met: (1) the busway enclosure shall comply with minimum cross-sectional-area requirements, and (2) a maximum resistance of 0.005 Ω is allowed when passing a direct current of 30 A between adjacent busway sections.

National Electrical Manufacturers Association Standards. In addition to the Underwriters Laboratories tests listed above, the NEMA standard for busways specifies the following:

Short-circuit current ratings. There are no minimum or maximum standards on short-circuit current ratings specified by Underwriters Laboratories. The minimum rating depends upon the maximum short-circuit available at the line and of the installed busway run. However, NEMA recommends the following minimum ratings:

Continuous current rating of busway, A	Short-circuit current ratings, symmetrical amperes	
	Plug-in busway	Feeder busway
100	10,000	
225	14,000	
400	22,000	
600	22,000	42,000
800	22,000	42,000
1000	42,000	75,000
1200	42,000	75,000
1350	42,000	75,000
1600	65,000	100,000
2000	65,000	100,000
2500	65,000	150,000
3000	85,000	150,000
4000	85,000	200,000
5000	200,000

Voltage drop. There are no minimum or maximum standards on voltage drop since these values may vary considerably depending upon several factors, including (1) the design, (2) the conductor material, (3) the continuous-current rating, (4) the current load, (5) the power factor of the load, (6) the operating temperatures, (7) the length of the run, and (8) the distribution of the load. Actual values of voltage drop in given situations can best be determined by obtaining the necessary data from a busway manufacturer and applying it to the specific situation. In general, the line-to-line voltage drop of fully loaded, three-phase busway will usually be less than 6 V/100 ft. Voltage drops for plug-in busway are

based upon an evenly distributed load along the run and are one-half that of a load concentrated at one end.

Resistance, reactance, and impedance. There are no minimum or maximum values of resistance, reactance, or impedance since these values vary considerably with different ratings and busway constructions. Busway manufacturers can supply these data for their particular products. These data are used for calculating the voltage drop for a specific application.

Unusual service conditions. For applications in which the ambient temperature is higher than 40°C, the busway current rating should be derated in accordance with the manufacturer's recommendations, if furnished, or the following:

TABLE B

	Ambient-temperature limits	NEMA standards publication no.
Busway lengths and fittings	-30°C through +40°C	NEMA BU 1
Low-voltage-power circuit breakers	Not to exceed +40°C	NEMA SG 3
Molded-case circuit breakers	0°C through +40°C	NEMA AB 1
Enclosed switches	-30°C through +40°C	NEMA KS 1
Low-voltage cartridge fuses	See applicable UL standards	NEMA ICS 1
Electromagnetic and manual motor controls at 6000 ft and less	0°C through +40°C maximum	ICS 2 ICS 3

270. National Electrical Code requirements. The National Electrical Code, which is sponsored by the National Fire Protection Association, outlines the general guidelines which are necessary for the safe application of electrical equipment. Article 368 of the Code specifically applies to busways, although other articles in the Code are applicable in certain situations. Thorough familiarization with the NEC requirements for busways is recommended before attempting to apply busways to specific applications.

Some of the major requirements for safe application of busways as outlined in the 2008 NEC are as follows:

368.10. Uses permitted

- a. *Exposed.* Busways shall be permitted to be located in the open where visible, except as permitted in 368.10(C).
- b. *Concealed.* Busways shall be permitted to be installed behind access panels, provided the busways are totally enclosed, of nonventilating-type construction, and installed so that the joints between sections and at fittings are accessible for maintenance purposes. Where installed behind access panels, means of access shall be provided, and either of the following conditions shall be met:
 - 1. The space behind the access panels shall not be used for air-handling purposes.
 - 2. Where the space behind the access panels is used for environmental air, other than ducts and plenums, there shall be no provisions for plug-in connections, and the conductors shall be insulated.
- c. *Through walls and floors.* Busways shall be permitted to be installed through walls and floors in accordance with (C)(1) and (C)(2).
 - 1. *Walls.* Unbroken lengths of busway shall be permitted to be extended through walls.
 - 2. *Floors.* Floor penetrations shall comply with (a) and (b).
 - (a) Busways shall be permitted to be extended vertically through dry floors if totally enclosed (unventilated) where passing through and for a minimum distance of 1.8 m (6 ft) above the floor to provide adequate protection from physical damage.

- (b) In other than industrial establishments, where a vertical riser penetrates two or more dry floors, a minimum 100 mm (4 in.) high curb shall be installed around all floor openings for riser busways to prevent liquids from entering the opening. The curb shall be installed within 300 mm (12 in.) of the floor opening. Electrical equipment shall be located so that it will not be damaged by liquids that are retained by the curb.

368.12. Use not permitted. Busways shall not be installed (1) where subject to severe physical damage or corrosive vapors; (2) in hoistways; (3) in any hazardous (classified) location, unless specifically approved for such use; or (4) outdoors or in wet or damp locations unless identified for such use.

Lighting busway and trolley busway shall not be installed less than 2.5 m (8 ft) above the floor or working platform unless provided with a cover identified for the purpose.

368.30. Support. Busways shall be securely supported at intervals not exceeding 1.5 m (5 ft) unless otherwise designed and marked.

300.21. Spread of fire or products of combustion. Electrical installations in hollow spaces, vertical shafts, and ventilation or air-handling ducts shall be so made that the possible spread of fire or products of combustion will not be substantially increased. Openings around electrical penetrations through fire-resistance-rated walls, partitions, floors, or ceilings shall be fire-stopped by using approved methods to maintain the fire-resistance rating.

368.17(B). Reduction in ampacity size of busway. Overcurrent protection shall be required where busways are reduced in ampacity.

Exception: For industrial establishments only, omission of overcurrent protection shall be permitted at points where busways are reduced in ampacity, provided that the length of the busway having the smaller ampacity does not exceed 15 m (50 ft) and has an ampacity at least equal to $\frac{1}{3}$ the rating or setting of the overcurrent device next back on the line, and provided further that such busway is free from contact with combustible material.

State and Local Electrical Codes. Many states and cities have electrical codes which supplement the National Electrical Code. Before attempting to apply or install busway as well as any other type of electrical equipment, contact your local electrical inspection authority for a copy of the latest requirements applicable to the location of the installation.

Electric-Power-Company Requirements. Busways are commonly used for the main services of buildings, in which case they are usually connected to one or more distribution transformers owned by the local electric power company. This connection may be made by either cable or busbars, depending upon local practices. Since the various electric power companies throughout the United States often prefer different methods of connection to busway services, it is recommended that the local company supplying the power be contacted before applying or installing a service-entrance busway run.

Contacting Busway Manufacturers. Since the practical applications and uses of busway are nearly unlimited, it is not possible to outline here all the technical information available pertaining to busway. For this reason, it is advisable to contact one or more of the manufacturers of busway for more specific information whenever a possible application for busway is contemplated. All companies in the industry have technical experts who will assist in properly selecting and applying the busway system best suited to the specific requirements.

271. Busway layout. Present-day busway systems are designed for flexibility of layout and can be applied on applications such as a simple straight run of plug-in busway fed from a cable-tap box or a complex run with multiple feeders and plug-in devices for a high-rise building. However simple or complex, the system must be planned in advance.

The purpose of this section is to show how to plan the layout in an easy, step-by-step approach. A number of examples and details of how the busway is applied, as well as specific details on how to coordinate the installation of busway with other products, are included.

This section should be used as a reference guide only. The final decision on any system must be dictated by the particular details of the application.

When busway manufacturers receive orders for busway, an approval drawing is generally required. Experience has shown that a complete, detailed approval drawing as shown in Fig. 9.152 expedites release for manufacture. It is therefore important that the information sent to the manufacturer be as nearly complete as possible. If it is incomplete, a great deal of time can be wasted in obtaining missing information.

FIGURE 9.152 Typical customer-approval drawing.

The following is some of the information typically missing from sketches or drawings received by busway manufacturers:

1. Front location of switchgear, switchboards, transformers, or other cubicles
2. Floor heights and floor thicknesses on risers
3. Location of busway risers in relation to closet walls
4. Location of plugs on a riser in relation to closet walls
5. Location of walls and wall thickness

The approval drawing that is sent back to the field for approval may require additional dimensions for the complete busway layout. The electrician will be required to fill in these dimensions after field-measuring the job, approve the drawing for manufacture, and submit it through channels to the busway manufacturer.

Guidelines for Getting Basic On-Site Measurements. Before even looking at a busway job, you should have these basic materials for measuring: a sketch pad, a 50- or 100-ft (15- or 30-m) measuring tape, an 8- or 10-ft (2.4- or 3-m) folding wood rule, chalk and chalk line, plumb bob and string, and a yellow lumber crayon. Armed with these tools, you are prepared to lay out a busway system successfully.

First, it is always a good practice to walk through the entire facility to get an idea of general routing. While walking through, watch for obstructions, both vertical and horizontal. At the same time, try to establish one elevation so that offsets are not required. To do so, you must check floor elevations between rooms or various parts of the building. Otherwise, the busway installed at a specific elevation in one part of the building might be too high or too low at another point.

After the walk-through, you are ready to begin measuring the system. For reference points, use structures already available in the building, such as walls or columns. To save time, don't attempt to break the run down into specific lengths of busway. A busway manufacturer's engineer will do this and at the same time prepare an erection drawing to show the breakdown.

Actual measurement should start in the area where the switchboard or switchgear is located. If the switchboard has not been installed, chalk in the specified location and the point of entry for the busway. At this time, if the service entrance run is part of the job, you can measure its location.

One of the most important steps in planning a large busway layout is coordination between the trades. This is a good time for the electrician to meet with plumbing, heating, ventilating, and sprinkler-system trades to establish a definite right of way throughout the construction area. Once this has been established, hours of frustrating rerouting can be saved. Immediately after the right of way has been determined, electricians will often install busway hangers to claim and identify their areas.

The next step is to establish the busway elevation, then start horizontal measurements using the following examples as a guide. The examples indicate the dimensions required (see Figs. 9.153 through 9.162).

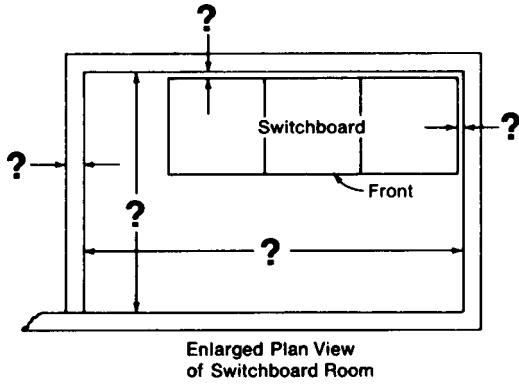

FIGURE 9.153 Basic site dimensions required before starting busway layout.

West Elevation View

Plan View 2nd Floor

Plan View 1st Floor

FIGURE 9.162 Multifloor.

272. Busway-riser applications. Several conditions will dictate the number of plug-in units that will fit physically on each floor: floor height, size of plugs, maximum height of plug-operating handle, other equipment or walls in close proximity to the busway riser, and orientation and phasing. Let's consider each of these conditions in turn.

Floor-Height Measurements. The basic dimensions (height from finished floor to finished floor plus floor thickness) required for every busway riser are shown in Fig. 9.163. Do not assume that all floors are of the same height.

NOTE See NEC rule in Sec. 270. If a curb is to be supplied around the floor opening, specify the height of the curb.

FIGURE 9.163 Basic height measurements required for risers.

Floor Height. The individual planning the riser should realize that clearance above the floor must be maintained to install vertical mounting hangers and joint-cover plates. Generally a distance of 15 to 24 in. (381 to 609.6 mm) above the floor to the centerline of the joint is required.

273. Size of plug-in devices. The floor height will dictate the number of plug-in openings physically possible for each riser on each floor. If the floor height is less than 12½ ft (3.8 m) and floor thickness remains at 6 in. (152.4 mm), it is impossible to use a 10-ft (3.05-m) straight length of plug-in busway. Instead, a shorter straight length would be used.

Using the manufacturer's plug-in unit dimensions, you can experiment with plugs to be supplied and determine the number that can fit on each floor.

Maximum Height of Plug-Operating Handles. Generally, there is no maximum height for plug-in units when a suitable means of operating such as a hook stick, rope, or chain is provided (see Sec. 404.8(A) Exception No. 1 in the NEC). However, since requirements

vary from locality to locality, contact the local inspection authority and busway manufacturer for the latest requirements applicable to your installation.

Other Equipment or Walls in Close Proximity to the Busway Riser. Applying busway with plug-in or bolt-on units in a vertical riser requires preplanning. See Figs. 9.164, 9.165, and 9.166 for examples of busway risers in an electrical closet. Busway with plug-in or bolt-on units must be arranged to clear other equipment and walls in the wiring closet. In particular, make sure that the plug-in or bolt-on hinged cover can be opened fully for maintenance.

Orientation and Phasing. To ensure that plug-in units are properly located, consult the manufacturer for coordination of busway orientation and phasing.

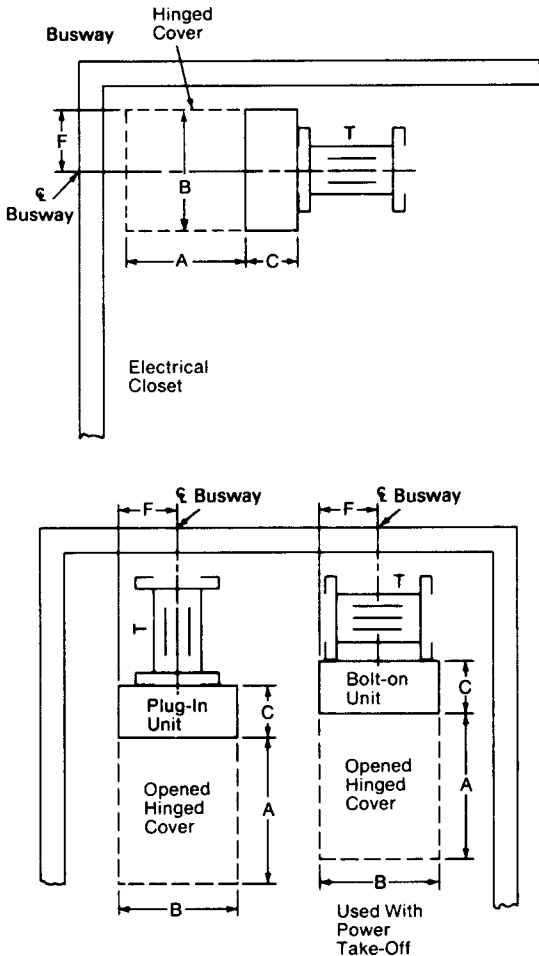

FIGURE 9.164 Examples of busway risers in an electrical closet.

FIGURE 9.165 Plug-in position on busing.

FIGURE 9.166 Busway riser in an electrical closet.

Busway Connections from Switchgear through Wall and Floor Openings. Wall and floor openings (see Fig. 9.167) for busway should be at least 1 in. (25.4 mm) larger than the outside dimensions of the busway. In some areas where there is doubt about the accuracy of the measurement, a flange must be installed through a wall, the hole must be large enough for the largest dimension.

FIGURE 9.167 Minimum clearances for wall and floor openings.

Special Conditions. Certain conditions require preplanning to circumvent installation problems. Figure 9.168 is an example. If the X or Y dimensions are below the minimum needed to permit a joint between the elbow and the walls or floor, the joints must fall as shown. It then follows that openings in the walls or floors must be made large enough to install the busway. (See Fig. 9.169.) Wall thickness must also be considered.

FIGURE 9.168 Example of an installation problem.

FIGURE 9.169 Solution to an installation problem.

Busway Plug-in Application. When plug-in units are to be installed, consideration must be given to providing adequate clearance from the plug-in busway to obstructions to allow the plug-in unit to swing in place. Consult the manufacturer for specific requirements. (See Fig. 9.170.)

FIGURE 9.170 Clearances required to mount plug-in units on a busway.

Customer Erection Drawings. Prior to shipment of busway from the factory, the installer will receive a customer drawing. A sample appears in Fig. 9.171. This drawing contains a complete layout of the entire installation and a bill of material that includes (1) an item number which can be correlated with the drawing and a description of each piece and (2) the identification number and quantity of each piece.

FIGURE 9.171 Typical drawing sent by a busway manufacturer to an installer.

274. Busway installation (see Fig. 9.172)

General. To ensure maximum reliability and long life for a busway system proper installation is imperative. Manufacturers supply installation drawings on all but the simplest busway layouts. Study these drawings carefully. If drawings are not supplied, make your own. Verify actual components on hand against those shown on installation drawings to ensure that there are no missing items. Manufacturers' drawings identify components by catalog number and specify their location in the installation. Catalog numbers appear on nameplates and carton labels. Read the manufacturers' instructions for installation of the individual components. If you are still in

FIGURE 9.172 Installing busway.

doubt, ask for more information; *never guess*. Almost all busway sections are built with a busway joint on one end. Refer to the installation drawing to orient each component properly. Pay particular attention to “Top” labels and other orientation marks where applicable.

Storage and Handling. Busway sections and fittings which are not to be installed and energized immediately upon receipt should be stored in a clean, dry place that has a uniform temperature to prevent condensation. Preferably, they should be stored in a heated building having adequate air circulation and protected from dirt, fumes, water, and physical damage. Because of moisture it is extremely risky to store busway outdoors. If busway must be stored outdoors, it must be securely covered for protection from weather and dirt. Temporary electrical heating should be installed beneath the cover to prevent condensation.

Indoor busway must always be protected from exposure to moisture, plaster, and other types of contaminants. This is extremely important during initial installation when the busway may be exposed to higher levels of dust and moisture.

Outdoor busway must be treated exactly the same as indoor busway until it is installed. It is not weather-resistant until it is completely and properly installed. Care must be used in unpacking. Band cutters should be used on all banding securing the package. If a crane is employed to install busway, use nylon straps and distribute, or balance, the weight of each lift. If cables are employed, spurs should be used to avoid damage to the metal housing. Do not drag busway across the floor. When installing vertical sections, it is easier to lower the busway from the floor above where it will be installed. Vertical sections are often stored on the floor above their final location to facilitate lowering them into position.

Supports and Hangers. Use the hangers or the hanging recommendations supplied by the manufacturer in the manner prescribed to afford a secure installation and proper hanger spacing. A busway which is mounted horizontally should be supported at 5-ft (1.5-m) intervals and not more than 10-ft (3-m) intervals if it is marked as being suitable for such intervals. Consider sway bracing for plug-in busway. Caution must be emphasized when all plug-in units are used on one side of a busway or when there are more plugs on one side than the other. Large plug-in units are cubicles which have considerable weight and when mounted on a horizontal run of busway should be separately supported from the building structure to prevent twisting or deformation of the busway. A busway which is to be mounted vertically should be marked to indicate that it is suitable for that purpose. When the distance between floor supports is more than that for which the busway is marked as suitable, the manufacturers’ recommendation regarding intermediate supports should be followed; however, support intervals should not exceed 16 ft (4.9 m). Busway cubicles and bus plugs should be separately supported by the building structure when so recommended by the manufacturer. (See Figs. 9.173 and 9.174.)

FIGURE 9.173 Installing busway on hangers.

FIGURE 9.174 Riser busway section with floor support.

Testing. Be sure to recheck all steps to ensure that you have followed the manufacturer's recommendations for installation and that you have not forgotten anything. At this point the busway installation should almost be complete. Before energizing it, the complete installation should be properly tested. The testing procedures should first verify that the proper phase relationships exist between the busway and associated equipment. This phasing and continuity test can be performed in the same manner as similar tests on other pieces of electrical equipment on the job. All busway installations should then be tested with a megohmmeter or high-potential-voltage tester to be sure that excessive leakage paths between phases and ground do not exist. Megohmmeter values depend on busway construction, type of installation, size and length of busway run, and atmospheric conditions. Acceptable values for a particular busway should be obtained from the manufacturer.

Energizing. When the equipment is energized for the first time, qualified electrical personnel should be present. Energizing a run of busway for the first time is potentially dangerous. If faults caused by damage or poor installation practices have not been detected in the checkout procedure and corrected, serious damage can result when the power is turned on. There should be no load on the busway when it is energized. Since busway typically extends through several rooms and floor levels, care should be taken to see that all devices fed from the busway are switched to the off position. The equipment should be energized in sequence by starting at the line end of the system and working toward the load end. In other words, energize the main devices, then the feeder devices, and then the branch-circuit devices. Turn the devices on with a firm, positive motion. Protective devices which are not quick-acting should not be teased into the closed position. After all the devices have been closed, loads such as lighting circuits, contactors, heaters, and motors may be turned on. Busway, when operating properly, will have a moderate 60-Hz hum. However, excessive noise may be an indication of hardware that has not been tightened or of metal parts that have been improperly assembled. Occurrence of sparking at any joint along the busway is an abnormal condition. The busway should be deenergized until the sparking condition has been corrected.

275. Busway-system inspection and maintenance

Warning. Turn off power ahead of the busway before performing any of the following maintenance operations. Check incoming line terminals with a voltmeter prior to proceeding with work. *Do not attempt to work on energized busway.*

276. Busway should be inspected once each year or after any severe electrical faults. Look for any moisture or signs of previous wetness or dripping onto the busway or onto connection boxes from leaky roofs, pipes, sprinklers, or other sources of moisture. Look for any recent changes in sprinklers or other plumbing that might now be a source of trouble to the busway. Eliminate the source of any liquids dripping onto the busway and any other source of moisture (indoor busway). Replace or thoroughly dry and clean any insulating material which is damp or wet or shows accumulation of deposited material from previous wettings. If there is an appreciable accumulation of dust and dirt, clean it off by using a brush, vacuum cleaner, or clean, lint-free rags. To avoid blowing dust into busway joints, circuit breakers, or other equipment do not use a blower or compressed air. Carefully inspect all visible electrical joints and terminals, checking for tightness of bolts, nuts, etc., in accordance with the manufacturers' instructions (see Fig. 9.175). If joints or terminations appear to be badly discolored, corroded, or pitted or show evidence of having been subjected to high temperatures, the parts should be disassembled and replaced or cleaned. Do not remove plating on aluminum parts, joints, or terminations. Damaged

FIGURE 9.175 Tightening a joint bolt by using a torque wrench.

nism quickly and positively throws contacts fully on and fully off. Check the mechanisms of all electrical and mechanical interlocks and padlocking means. Check for missing or broken parts, proper spring tension, free movement, rusting or corrosion, dirt, and excessive wear. Examine all readily accessible arc chutes and insulating parts for cracks or breakage and for arc spatter, sooty deposits, oil, or tracking. Clean off arc spatter, oil, and sooty deposits. Replace the device if appreciable material has burned away or if parts are charred or cracked. Closely examine the fuse clips. If there is any sign of overheating or looseness, check the spring pressure, tightness of clamps, etc. Replace the fuse clips if the spring pressure compares unfavorably with that of identical fuse clips and other equipment. Look for any signs of deterioration in insulating material or melting of the sealing compound. Replace such insulating parts and assemblies where the sealing compound has melted. Be sure that the condition which caused the overheating has been corrected. Lubricate the operating parts of switch mechanisms, etc., according to the manufacturer's instructions.

FIGURE 9.176 Power tap-off cubicle with a molded-case circuit breaker.

aluminum parts should normally be replaced. Check the insulation resistance prior to reenergizing the busway. A permanent record should be kept of resistance readings. If readings decrease appreciably with time, deterioration is taking place. If resistance readings are below recommended manufacturer's values, contact the busway manufacturer for the appropriate corrective action.

277. Busway plugs and protective devices.

Check the operation of all mechanical components. Check all switch-operator mechanisms and external operators of circuit breakers. Make sure that each operator mechanism quickly and positively throws contacts fully on and fully off. Check the mechanisms of all electrical and mechanical interlocks and padlocking means. Check for missing or broken parts, proper spring tension, free movement, rusting or corrosion, dirt, and excessive wear. Examine all readily accessible arc chutes and insulating parts for cracks or breakage and for arc spatter, sooty deposits, oil, or tracking. Clean off arc spatter, oil, and sooty deposits. Replace the device if appreciable material has burned away or if parts are charred or cracked. Closely examine the fuse clips. If there is any sign of overheating or looseness, check the spring pressure, tightness of clamps, etc. Replace the fuse clips if the spring pressure compares unfavorably with that of identical fuse clips and other equipment. Look for any signs of deterioration in insulating material or melting of the sealing compound. Replace such insulating parts and assemblies where the sealing compound has melted. Be sure that the condition which caused the overheating has been corrected. Lubricate the operating parts of switch mechanisms, etc., according to the manufacturer's instructions.

Use a clean nonmetallic light grease or oil as instructed. Do not oil or grease parts of molded-case circuit breakers (see Fig. 9.176). If no instructions are given on the devices, sliding copper contacts, operating mechanisms, and air locks may be lubricated with clean, light grease. Operate the switch or circuit breakers several times to make sure that all mechanisms are free and in proper working order. Retighten all wire connections. Check fuses to make sure that they have the proper ampere rating and interrupting rating. Make sure that non-current-limiting fuses are not used as replacements for current-limiting fuses. If the bus plug has been removed from the busway, check the insulation resistance of the device prior to its reinstallation.

278. Specific-purpose busway. Lighting busway and trolley busway are considered to be special-purpose busway. *Lighting busway* provides a low-cost, flexible power-distribution system for supplying low-capacity loads. It provides maximum flexibility for these low-capacity loads, since a power tap-off can be located at any point along the busway. It is used effectively as a power supply system for lighting fixtures, small power

tools, and machines in industrial and assembly plants, office and commercial buildings, department stores, vocational schools, garages, warehouses, truck and rail terminals, shipping docks, museums, and galleries. *Trolley busway* provides a completely mobile and flexible power-distribution system for such applications as cranes, hoists, monorails, conveyors, assembly lines, observatories, rotating restaurants, industrial trolley cars, and portable tools.

Lighting busway (Fig. 9.177) provides the greatest flexibility in the location of outlets for low-current-capacity loads. Several ampere ratings (20, 30, 35, 50, and 60 A) are available in two-, three-, and four-wire systems, with a maximum voltage rating of 300 V, ac or dc, to ground. Lighting busway may be used as a branch-circuit or feeder circuit as defined in Article 100 of the National Electrical Code, subject to the ampere limitations in Sec. 210.23. It may be utilized in exposed areas except in unsuitable locations where subject to mechanical injury, corrosive vapors, hoistways, battery rooms, outdoors, or in wet or hazardous locations (see Sec. 368.12 of the NEC).

FIGURE 9.177 Example of a lighting busway.

Standard straight sections are typically available in 4- and 10-ft (1.2- and 3-m) lengths, while nonstandard sections are typically available in lengths of 1, 2, 3, 5, 6, 7, 8, and 9 ft (0.3, 0.6, 0.9, 1.5, 1.8, 2.1, 2.4, and 2.7 m). In this type of busway, the steel housing serves as the ground path. A continuous narrow opening or slot along the bottom of the housing provides power tap-off capability along the entire length of the busway run by allowing the insertion of plugs at any point. If required, a rubber slot closure which can be field-cut to length is available to close off openings between plugs to prevent the entrance of dust or other objects.

Standard components, along with straight sections, include coupling for joining section to section, feed-in devices for supplying power to individual runs, and caps to terminate a run, various types of hangers and heavy-gage-steel channels to suspend and support lighting runs with fixtures attached, and a variety of tap-off devices in both terminal and receptacle types with or without circuit protectors (fuses or circuit breakers).

Couplings (Fig. 9.178) serve three functions: first, to connect electrically the circuit conductors between sections; and, second, to join section housing rigidly and securely to section housing. A third function is available with a trolley-entrance coupling which allows the insertion of a trolley-type tap-off device for moveable-load applications.

FIGURE 9.178 Couplings.

Feed-in boxes serve to power lighting busway circuits and are designed to attach at the end (Fig. 9.179) or in the center of a run (Fig. 9.180).

End caps serve to terminate or seal off the end of a run (Fig. 9.181). Similar in design to couplings, they snap into place and can be easily removed and reused when extending a lighting busway run.

FIGURE 9.179 Feed-in boxes.

FIGURE 9.180 Typical center feed-in box.

FIGURE 9.181 Typical end cap.

Methods of Suspension. (Figs. 9.182 and 9.183) Lighting busway can be suspended by various methods. Manufacturers provide a variety of hangers for flush or surface mounting, drop-rod suspension, or the messenger-cable method. The distance between points of suspension depends on the weight loads directly supported by the busway, building truss or beam locations, and manufacturers' allowable limits. Hangers can be positioned anywhere along the busway housing. When heavy loads (such as high-bay lighting fixtures) are to be supported or when building trusses are spaced beyond standard allowable limits, a supplementary steel support channel (hat section) can be provided by busway manufacturers. By using the support channel and roller-type rod hangers, lighting busway can be rolled into position, with lighting fixtures prepositioned (installed on the busway and electrically connected), from one of a building.

FIGURE 9.182 Hat section, suspension-roll-in.

FIGURE 9.183 Hat section, suspension-fixed.

279. Power tap-off devices (twistouts and trolleys; Figs. 9.184, 9.185, and 9.186) are typically available as follows:

1. *Without circuit protection.* Polarized.
2. *Receptacle twistouts.* Rated 15 A at 125 V, ac or dc; for three-wire (line, neutral, and ground) convenience gaps.
3. *Terminal twistouts.* Rated 20 A at 125 V, ac or dc, and 15 A at 300 V ac; for three-wire (line, neutral, and ground) permanent connection to electrical devices.
4. *Terminal trolleys.* Rated 20 A at 300 V, ac, for three-wire (line, neutral, and ground) permanent connection to electrical devices.

FIGURE 9.184 Twistout.

FIGURE 9.185 Twistout.

FIGURE 9.186 Trolley.

Terminal twistouts and trolleys are equipped with cord strain-relief clamps or can be furnished with outlet boxes with a standard convenience three-wire receptacle installed.

5. *With circuit protection* (Figs. 9.187 and 9.188). Tap-off devices (twistout and trolley types) can be provided with outlet boxes containing circuit protection devices and accessories prewired to line side terminals.

FIGURE 9.187 Twist-type tap-off device with circuit protection.

FIGURE 9.188 Trolley-type tap-off device with circuit protection.

Application Data. Lighting busway can be furnished in two-, three-, or four-pole configuration. All are polarized, use conductors rated at 300 V, ac or dc, with four available ampere ratings: 20, 35, 50, and 60 A. Neutrals are sized at 100 percent cross-sectional area of the conductor bars.

For single-circuit loads, two-pole lighting busway is normally used for low-initial-cost installations. It can be used for 120-, 240-, or 277-V ac systems or dc systems up to 300 V.

Three-pole lighting busway is used for most applications, as it offers two-circuit capability at only slightly higher installed cost and provides greater load-carrying capacity. While a two-pole system rated at 277 V, 60 A can carry 16.6 kVA, a three-pole system of the same rating can carry 33.2 kVA.

Four-pole lighting busway may be used where there is a need to serve both single-phase and three-phase loads.

Three-pole systems are normally operated at either 120/240 or 120/208 V, ac or dc, up to 300 V. They can also be connected to a 480Y/277-V system provided the ungrounded legs are all connected to the same phase or that the maximum voltage between any two conductors never exceeds 300 V, the maximum rating of lighting busway.

In effect, three-pole lighting busway provides two independent circuits in the same housing, thus providing greater switching capability, extra circuits at low cost, and greater service continuity.

Independently controlled circuits are desirable whenever it is necessary to control separate loads or separate portions of the same load. For example, a department store may require two different lighting circuits, depending on the material displayed, and an industrial plant may require one circuit for work periods and another for maintenance crews. By using single-pole switching in each of the hot legs with a grounded neutral, it is easy to obtain maximum flexibility with three-pole lighting busway.

In most distribution systems, normal day-lighting circuits are paralleled by other branch circuits. These additional circuits supply night lighting, convenience outlets, small offices

or washrooms, heaters, fans, portable tools, etc. If two-pole busway is used, other loads must be supplied by other independent circuits, which may be either lighting busway or wire and conduit. In many instances, a considerable saving can be effected by using three-wire lighting busway to supply two, three, or more of these circuits.

If service continuity is essential, as in emergency lighting systems, it is desirable to split the loads in a three-pole, two-circuit single housing. Then, if a temporary overload should occur on one circuit, the single-pole breaker protecting that circuit may trip but the other circuit will be left in operation. Thus, only a portion of the load will be shut down, and all production will not be lost.

280. Typical installation procedures for lighting busway. After the suspension method has been put into place and hangers located as required, the installer may select any desired location along the designated run to install the first section of lighting busway. A coupling can first be installed by snapping it onto the end of a section. A tab on the coupling engages a square slot on the top of the section housing which locks it into place. As no tools are required, couplings can be attached after a section has been installed on the hangers.

To install lighting busway, simply slide each section through the hanger(s), snap the sections together at the coupling, and repeat the process until the run has been completed. Lighting fixtures and tap-off devices, as well as end or center feed-ins and end caps, can be installed at the same time.

Lighting busway is designed for simplicity of installation and reusability. It can be removed and reinstalled, affording flexibility and cost savings for future changes.

Trolley Busway. (Fig. 9.189) This is a modern enclosed, mobile power-distribution system designed to provide moving-current tap-off for applications such as cranes, hoists, maintenance hanger doors, and rotating platforms. Automobile plants, for example, use trolley busway to provide mobile power for portable assembly tools and parts carrying monorail systems. Direct-current trolley busway is also used for testing the vehicle electrical system as it moves down the assembly line. Appliance manufacturers use trolley busway for assembly and testing of their products. When compared with a bare bar or cable used in the same application, trolley busway offers not only lower installed cost but greatly reduced maintenance in addition to safety, as the conductor bars are enclosed and protected in a single steel housing.

FIGURE 9.189 Typical example of a trolley busway.

Two- and three-pole trolley busway (Fig. 9.190) is available in continuous ampere ratings of 100, 225, 375, 400, 500, 600, and 800 A. All have 150 percent intermittent ratings based on 1-min-on, 1-min-off duty cycles and can be used on system voltages up to 600 V ac

FIGURE 9.190 Typical section of a trolley busway.

(50, 600, 400, or 800 Hz) or 250 V dc. Four-pole trolley busway is rated 100/150 A at 480 V ac or 250 V dc. All use copper conductor bars. In this type of busway the steel housing serves as the ground path. Trolley busway is usually furnished in standard 10-ft (3-m) straight sections. However, section lengths from 1 ft 2 in. to 10 ft (0.35 to 3 m), in any increments, are available as well as horizontal or vertical curved sections (Fig. 9.191). For exceptionally long straight runs or where rigidly supported on the building structure or at both ends of the run or where a run crosses a building expansion joint, a trolley busway expansion section should be included.

FIGURE 9.191 Horizontal and curved section.

Polarized dropout sections, which provide trolley access points, may be built into a standard section and may be installed at any convenient location along the run. Sections can also be sectionalized (for circuit isolation) or be provided busless for trolley return on closed-loop applications. When switching trolleys from one run to another run, insulated flared ends are installed on the end of each facing section. These serve to align trolleys when transferring from one run to the other.

FIGURE 9.192 Coupling.

Accessories include couplings, hangers, and plates, feed-ins, and a variety of trolleys.

Couplings are used to join section to section together mechanically and electrically (Fig. 9.192) and also serve as the hanger. Intermediate hangers are used on long-radius curves or straight sections subject to heavy hanging loads between couplings. [Trolleys can support up to 25-lb (11.3-kg) loads.]

End plates close off or terminate a trolley-busway run and prevent trolleys from traveling beyond the end of a run.

Feed-in adapters attach to the top of a coupling and provide means to power a run at the ends or at any coupling location in between. This permits feeding a run in several locations to control voltage drop or to maintain or increase system capacity, as, for example, on assembly test lines.

Trolleys serve as the power tap-off and transverse inside the trolley-busway housing. Contacts on the trolley move along the copper busbars for power collection. Trolleys are available in several types and should be selected in accordance with the application and tap-off-ampere requirement. Contacts (button, roller, and shoe types) are typically made of an alleged graphite-impregnated bronze and are replaceable, as they are intended to wear instead of the copper busbars. Contact life varies depending on the severity of the duty and working atmospheric conditions. To prevent incorrect phasing, trolleys are polarized. The number and type of contacts determine trolley tap-off capacities. Ampere ratings range from 30 to 200 A, 600 V or less, ac or dc. Trolleys can be close-coupled and interconnected for higher-rating applications (Fig. 9.193).

FIGURE 9.193 Typical busway trolley.

The steel carriages on trolleys are equipped with sealed ball-bearing wheels which support and guide the trolley inside the trolley-busway housing. Side wheels, which are of copper-impregnated steel, provide positive ground contact between trolley and busway housing. Undercarriage wheels prevent the trolley from riding up and down when being pushed or towed in either direction.

Accessory boxes, which attach directly to trolley carriages, can be equipped with fuses, circuit breakers, receptacles, contactors, starters, timers, pilot lights, and pushbuttons (Fig. 9.194). A tool hanger with wiring box is also available (Fig. 9.195).

FIGURE 9.194 Busway trolley with accessory box.

FIGURE 9.195 Busway trolley with wiring box.

Nylon-brush cleaning trolleys are used to clean the copper conductor bars when a trolley busway is subject to dusty conditions. An abrasive cleaning trolley can be used intermittently to resurface the copper conductor bars if they become rough or coated from severe operating conditions.

Trolley busway, being manufactured in bolt-together sections, can easily be disassembled and moved to a new location within a facility or a new operation.

281. Definitions from NEMA BU1

ACCESSORY Non-current-carrying component of a busway system used to mount or adapt the busway to the building structure.

ADAPTER Fitting which permits the joining together of lengths and fittings of different shapes or designs.

AMBIENT TEMPERATURE Temperature of the surrounding air that comes in contact with the outside of the busway enclosure, device, or fitting.

ASYMMETRICAL CURRENT Alternating current having a waveform which is offset with respect to the zero axis. The offset occurs at the initiation of a short circuit or other change in current. It usually decays quickly until steady-state conditions are reached and the current becomes symmetrical. Asymmetrical current is composed of the alternating symmetrical component. It is expressed in rms asymmetrical amperes at a specific time (normally one-half cycle) after initiation of a short circuit or other change in current. Peak current refers to the maximum instantaneous amperes within this first half cycle.

AVAILABLE SHORT-CIRCUIT CURRENT Maximum current which a circuit is capable of delivering at the system terminals ahead of the apparatus being supplied. Available short-circuit current may be expressed in either rms symmetrical amperes or rms asymmetrical amperes.

BOLT-ON DEVICE Power takeoff means which can be bolted to the busways at a joint between lengths and fittings, at the end of a run, or at any predetermined location, and which makes electrical connection to the busbars.

BUSBARS Conductors which carry current through busway lengths and fittings and which have one of the following arrangements: (1) single-bar arrangement, which refers to a busway having one conductor per pole; and (2) multibar arrangement, which refers to a busway having two or more conductors for one or more of its poles.

BUSWAY Prefabricated electric distribution system consisting of busbars in a protective enclosure, including straight lengths, fittings, devices, and accessories. Busways are of the following types: (1) feeder busway, a busway that has no plug-in openings and is intended primarily for conducting electric power from the source of supply to centers of distribution but can have provisions for bolt-on devices; and (2) plug-in busway, a busway having plug-in openings on one or both sides at spaced intervals, offering means for electrical connection of plug-in or bolt-in devices to the busbars.

CENTER CABLE TAP BOX Fitting or device which provides for the attachment of cables at a location other than the end of a busway run.

CIRCUIT BREAKER Device designed to open and close a circuit by nonautomatic means and to open the circuit automatically on a predetermined overcurrent without injury to itself when properly applied within its rating.

CONTINUOUS-CURRENT RATING Designated maximum direct current or alternating current in rms amperes at rated frequency which a busway can carry continuously without exceeding its temperature-rise limits when subjected to specified heating tests.

CROSS Fitting suitable for connection in four directions.

CUBICLE Enclosure attached to a length or fitting for the purpose of enclosing electrical components.

DEVICE Enclosed component used on rather than in a run of a busway system. The device may carry current from the busway system to supply a load circuit or be a nonload-supplying unit, such as a ground detector.

ELBOW Angular fitting.

END CABLE-TAP-BOX Fitting which provides for the attachment of cables and conduits at the end of the busway run.

END CLOSURE Fitting which terminates and closes the end of a busway run.

EQUIPMENT-GROUNDING CONDUCTOR Conductor which is used to connect noncurrent-carrying metal parts of the busway.

EXPANSION FITTING Fitting which accommodates expansion and contraction of the busway or building.

FITTING (BUSWAY) Component in a run of a busway system, other than a straight length. It may be either current-carrying, such as an elbow, tee, or cross, or noncurrent-carrying, such as an end closure.

FLANGED END (OR SWITCHBOARD STUB) Fitting which provides means for mechanically and electrically connecting a busway run to other apparatus.

FLOOR FLANGE Accessory on the outside of a busway enclosure that provides means for the installer to cover the floor opening penetrated by the busway.

INDOOR Suitable for installation within a building which protects the busway from exposure to the weather.

NEUTRAL CONDUCTOR Conductor which is connected to the midpoint of a three-wire single-phase system, center point of a Y-connected three-phase system, or midpoint of one side of a delta-connected three-phase system.

OFFSET Fitting providing two or more angles.

OUTDOOR So constructed that exposure to the weather will not interfere with successful operation. **NOTE** Outdoor busway is not suitable for outdoor use until completely and properly installed as recommended by the manufacturer.

PLUG-IN CIRCUIT BREAKER Plug-in device containing an externally operable circuit breaker.

PLUG-IN DEVICE (OR BUS PLUG) Power takeoff means which can be plugged into a plug-in busway and which makes electrical connection to the busbars.

PLUG-IN FUSIBLE SWITCH Plug-in device containing an externally operable fusible switch. A *handle-operated switch* is a switch which is externally operated without opening or closing the cover; a *cover-operated switch* is a switch which is operated by opening and closing the cover.

PLUG-IN GROUND DETECTOR Plug-in device which indicates a ground on any of the normally ungrounded busway conductors.

PLUG-IN POTENTIALIZER (OR NEUTRALIZER) Plug-in device having means for limiting the potential difference between a busway enclosure and the busbars.

RATING Designated limit(s) of the rated operating characteristic(s) of a busway length, fitting, or device. **NOTE** Such operating characteristics as current, voltage, frequency, etc., may be given in the rating.

REDUCER Fitting designed for connection between lengths and fittings of different ampere ratings.

ROOF FLANGE Accessory on the outside of a busway enclosure that provides means for the installer to weatherproof the roof opening penetrated by the busway.

STRAIGHT LENGTH Straight section of a busway system.

SWITCH Device for opening and closing or for changing the connection of a circuit.

SYMMETRICAL CURRENT Alternating current having no offset or transient component and therefore having a waveform essentially symmetrical about the zero axis. Symmetrical current is expressed in rms amperes.

TEE Fitting suitable for connection in three directions.

TOTALLY ENCLOSED So constructed as to prevent the free exchange of air between the inside and outside of a housing but not sufficiently enclosed to be termed *airtight*.

TRANSFORMER FITTING Fitting wherein busbar positions are interchanged to equalize the impedance of the different phases or to change the phase relationship.

TRANSFORMER TAP Fitting having busbars extended through its housing or end barrier for connections by open cable to terminals of the transformer(s).

TRANSFORMER THROAT Fitting which provides enclosed busbar connections to transformer terminals.

TRANSVERSE BARRIER Dividing barrier or other means of restricting the free flow of either air or moisture through the inside of a busway.

VAULT TERMINATION Fitting having open busbars extending from one end which provides for connections to vault equipment.

VENTILATED So constructed as to provide for the circulation of external air through an enclosure to remove heat.

VOLTAGE DROP Arithmetical difference between voltages at the load and supply ends.

WALL FLANGE Accessory on the outside of a busway enclosure that provides means for the installer to cover the wall opening penetrated by the busway.

CELLULAR-METAL-FLOOR-RACEWAY WIRING

282. Cellular-metal-floor raceways are formed by employing for the floor construction of the building structural members made of corrugated sheet steel. Seven types of cellular steel floor, as made by the H. H. Robertson Co. of Pittsburgh, are shown in Fig. 9.196. Cross-sectional views of completed floors and their adaptation for the installation of the electric wiring system are given in Figs. 9.197 and 9.198.

FIGURE 9.196 Types of cellular-steel floors. [H. H. Robertson Co.]

FIGURE 9.197 Model illustrating cellular-metal-floor-raceway wiring. [H. H. Robertson Co.]

FIGURE 9.198 Model illustrating typical 5-ft (1.5-m) staggered module of cellular-metal-floor raceway. [H. H. Robertson Co.]

283. The cells which are not filled with concrete from the raceways for wiring and piping. In all types the cells are 6 in. (152.4 mm) apart on centers, and the members are manufactured four cells wide with varying lengths to suit the span between beams. The cells are cross-connected by headers formed over the beams in the space left between adjacent lengths of flooring. When headers connected to alternate cells are used, one raceway system can be formed for signal wires and another for power wires, with both systems kept entirely separate from each other. If any cells are used for piping, those cells must not be interconnected to the electrical raceway system.

284. In forming these floors, close cooperation is required between the structural and the electrical workers. The structural workers lay the floor members across the spans from beam to beam, fastening them to the beams and leaving about 4½ in. (114.3 mm) of space on top of the beams between the abutting ends of the floor members for formation of the header.

The raceway headers are formed by the electrical workers in the space between members on top of the floor beams. A line of cells which is to form a raceway is interconnected at the ends of the sections by locating an access unit (Fig. 9.199) between the open ends of the aligning cells of adjacent sections.

FIGURE 9.199 Access unit for cellular-metal floors which have concrete fill. [H. H. Robertson Co.]

The other cells are closed off with connecting units (Fig. 9.200) so as to form a continuous header across the beam to the raceway line of cells. When one raceway system is to be built for power wiring and another for telephone wiring, the header for one system is built on one junction of floor beams and the header for the other system on another junction (Fig. 9.201). The wires for one system will pass through the lower portion of its cells under the header for the other system. The joints at the edges of the header units are sealed with a cold-flowing asphaltic compound.

FIGURE 9.200 Connecting header unit.

FIGURE 9.201 Method of forming separate headers for power and for telephone wiring.

285. The connection from a header to a panelboard is made from special fittings as shown in Fig. 9.202. Connection to the header is made with an adapter (Fig. 9.203, II) to which is connected the vertical elbow (Fig. 9.203, I). Straight sections of duct 1 ft (0.3 m) long (Fig. 9.203, IV) coupled together with couplings (Fig. 9.203, V) form the vertical run up the wall. The final section to the panelboard is cut to length with a hacksaw. The box connector (Fig. 9.203, III) holds the duct to the panelboard. It requires an opening $1\frac{7}{8}$ by $5\frac{3}{4}$ in. (47.625 by 146.05 mm) in the bottom of the panelboard box.

FIGURE 9.202 Connection of cellular-metal-floor raceways to panelboards. [H. H. Robertson Co.]

FIGURE 9.203 Fittings for connecting cellular-metal-floor header to wall panelboard. [H. H. Robertson Co.]

286. Method of installing floor outlets. A hole of $1\frac{5}{8}$ -in (41.275-mm) diameter is cut in the center of a cell with a saw-type drill (Fig. 9.204, I). A forming tool (Fig. 9.204, II) is turned into the hole to prepare the hole for reception of the outlet tap. For floors with a concrete fill of 2 to $3\frac{1}{4}$ in. (50.8 to 82.55 mm) a standard adjustable tap (Fig. 9.205, I) is then screwed into the hole. For fills of 1 to 2 in. (25.4 to 50.8 mm) a special tap is available. For fills of less than 1 in a shallow tap (Fig. 9.205, IV) is set in the hole and held in place with three No. 12 self-tapping screws. Holes for the screws must be drilled in the cell with a No. 9 drill. The top of the standard tap can be adjusted in height to the floor level, and a blanking cover (Fig. 9.205, II) installed until after the floor is poured. When a floor outlet is installed, the blanking cover is removed, and an extension (Fig. 9.205, III) is screwed into the tap. The floor outlet is then screwed onto the extension, using a Warnock wrench (Fig. 9.204, III) or other type of fabric wrench to avoid marring the fitting. With the shallow tap (Fig. 9.205, IV) the fitting screws onto the tap directly without the use of the extension. The complete outlet assembly is shown in Fig. 9.206. A duplex convenience outlet is shown in Fig. 9.207.

FIGURE 9.204 Tools for installing outlets in cellular-metal-floor raceways. [H. H. Robertson Co.]

FIGURE 9.205 Fittings for cellular-metal-floor raceways. [H. H. Robertson Co.]

FIGURE 9.206 Assembly of floor outlets with cellular-metal-floor raceway. [H. H. Robertson Co.]

FIGURE 9.207 Outlets for use with cellular-metal-floor raceways. [H. H. Robertson Co.]

287. Cell markers should be located on the center of each cell near the opposite side of the room from the header to facilitate future location of cells when outlets are not installed initially. The access units in the header will identify the cell locations at the header. A straight line between the center of an access unit and a cell marker will then identify the cell so that an outlet can be located accurately at any time in the future. Several types of cell markers are shown in Fig. 9.208. The double-slot screw (Fig. 9.208, I) can be used to identify power-wire cells, and the single-slot one (Fig. 9.208, II) to identify telephone-wire cells. In installing these markers (Fig. 9.209) a hole is drilled and tapped in the top of the cell for a 12-24 screw before the floor fill is laid. The brass marker with a headless screw is then fastened in place and adjusted in height to the level of the finished floor. The marker should then be grouted in place. After the floor has been poured and the finished floor covering laid, the headless screw is replaced with one of the grommeted brass screws (Fig. 9.208, I or II).

FIGURE 9.208 Markers for cellular-metal-floor raceways. [H. H. Robertson Co.]

FIGURE 9.209 Detail showing cell marker. [H. H. Robertson Co.]

288. Underside (ceiling) headers (Fig. 9.210) are generally used with Types FK inverted, UK inverted, RK, and UK floors of Fig. 9.196 because there is not sufficient room for the other headers in the shallow floor fill. Two sizes are available:

1. 2½ in. (63.5 mm) deep and 5 in. (127 mm) wide
2. 4 in. (101.6 mm) deep and 6 in. (152.4 mm) wide

A ceiling header mounted in the corner formed by the ceiling and wall so as to be as inconspicuous as possible is shown in Fig. 9.211. It is held in place with No. 12 self-tapping screws which pass through holes drilled in the bottom of the raceways. Connection to a panelboard is made with a special cell (Fig. 9.212, II), as shown in Fig. 9.213. Connection between the cells and the header is made by drilling a 2-in (50.8-mm) hole in the cell to line up with the pilot opening in the header. A grommet (Fig. 9.212, I) with the locknut removed is then inserted in the hole diagonally, as shown in Fig. 9.214. After the grommet has been adjusted to its proper position, the locknut is screwed on and holds the grommet firmly in place. At least two markers, as explained in Sec. 287, should be located on top of the floor for each cell which does not have outlets installed initially.

FIGURE 9.210 Underside header with cover removed. [H. H. Robertson Co.]

FIGURE 9.211 Location and mounting of underside header. [H. H. Robertson Co.]

FIGURE 9.212 Fittings for underside header. [H. H. Robertson Co.]

FIGURE 9.213 Method of connecting between underside header and panel. [H. H. Robertson Co.]

FIGURE 9.214 Method of inserting grommet into hole in cell. [H. H. Robertson Co.]

289. Ceiling lighting fixtures can be hung and wired from cellular-metal-floor raceways as shown in Fig. 9.215. At I is shown a fixture-stud mounting using the stud illustrated in Fig. 9.216, I. The fixture stud is inserted through a 2-in (50.8-mm) hole cut in the cell similar to the grommet assembly of Fig. 9.214. A mounting for fixtures which fasten on the cover of a 4-in (101.6-mm) box is shown in Fig. 9.215, II. The box (Fig. 9.216, II) is held in place with a grommet. The knockouts in the box can be used for surface conduit wiring if desired. A conduit-hung fixture is supported from the cell by means of a hanger as shown in Fig. 9.215, III. The hanger (Fig. 9.216, III) is held in place with a locknut in the same way as the grommet.

FIGURE 9.215 Methods of mounting ceiling fixtures from cellular-metal-floor raceways. [H. H. Robertson Co.]

FIGURE 9.216 Fittings for ceiling fixtures. [H. H. Robertson Co.]

290. Trench header duct. A trench header duct can be used in lieu of the standard headers shown in Figs. 9.197 and 9.198. A typical trench-header-duct installation is shown in Fig. 9.217. It is run across the floor cells at right angles, and access to each cell is made through a grommet connection. The trench header duct shown in Fig. 9.217 contains barriers so that feeders, branch circuits, and telephone circuits are separated. The cover is flush with the floor, and flush screws secure the cover to the header duct. Each cover section is 3 to 6 ft (0.9 to 1.8 m) long.

FIGURE 9.217 Trench header duct used for cellular-metal-floor raceways. [H. H. Robertson Co.]

Trench header duct is made in widths of 9 to 36 in. (228.6 to 914.4 mm) and arranged to accept standard floor tiles or similar floor coverings. This header system makes a neat installation, and access openings to the header duct are practically unnoticeable after the covers have been installed. One or more cover sections can be easily removed when access to the trench duct or floor cells is necessary.

291. The cellular raceways are wired by fishing the wires from the access units to the outlets. No conductor larger than No. 1/0 may be installed except by special permission.

The number of conductors in a cell is not limited as long as the total cross-sectional area of the conductors and cables does not exceed 40 percent of the internal area of the header or cell. All splices and taps must be made in the trench header duct or at junction boxes. So-called loop wiring (continuous, unbroken conductors) is not considered a splice or tap. The internal areas of the raceways are as follows:

	Entire area, sq in	40 percent
K cells	20.25	8.10
RK cells	11.25	4.50
FK, FK inverted cells	14.62	5.85
UK, UK inverted cells	5.62	2.24
DK cells	29.24	11.70

All junction boxes and inserts must be leveled to the floor grade and sealed against the entrance of concrete. They must be made of metal and so installed that they will be electrically continuous with the raceway. In cutting a cell and in setting inserts great care must be exercised so that chips or other dirt will not remain in the raceway. Only tools which are specially designed so that they will not enter the cell and injure the conductors should be used.

The NEC requires that when an outlet is discontinued, the conductors supplying it must be removed from the raceway, as discussed in depth in Sec. 253. Connections to cabinets and extensions from cells to outlets unless made by approved fittings must be made by means of flexible metal conduit where not installed in concrete rigid, intermediate, or electrical metallic tubing. Where there are provisions for the termination of an equipment grounding conductor, nonmetallic conduit, electrical nonmetallic tubing, or liquidtight flexible nonmetallic conduit where not installed in concrete may be used.

292. Cellular-metal-floor-raceway wiring is not allowed in any hazardous location except Class I, Div. 2 locations as permitted by express allowances in the appropriate articles of the NEC or where subject to corrosive vapors. It is not allowed in commercial garages except for supplying ceiling outlets or extensions to the area below the floor but not above. Any cell or header that is used for electrical conductors may not be used for any other service, such as steam, water, air, gas, and drainage.

293. Cellular-metal-floor raceways are used principally for office buildings in which the needs of the tenants for wiring outlets are not known definitely in advance and in which a high quality of adequacy and convenience of outlets and interior appearance without exposed wiring is desired. The position of the raceways may be varied in 6-in (152.44-mm) increments, and a very flexible system of outlets for telephones, business machines, and desk lamps provided, with all outlets located under the desks out of sight. The cost may be lower than would be incurred if a standard floor with a large number of underfloor raceways were installed. The wiring for ceiling-lighting outlets is also simplified by use of a type of floor in which the underside of the raceways serves as the ceiling.

CELLULAR-CONCRETE-FLOOR-RACEWAY WIRING

294. Cellular-concrete-floor raceways provide a complete underfloor electrical distribution system. For this system the floor is constructed of precast reinforced-concrete members (Fig. 9.218). These precast members are provided with hollow voids which form smooth, round cells. The cells form raceways for the electrical wires. Connections to the cells from a distribution center are made by means of metal header ducts which are run horizontally across the precast slabs and embedded in the concrete fill over the slabs. Connection from these headers to the cells is made through handhole metal junction boxes. An outlet can be located at any point along a cell. An opening into the cell at the desired point is formed by drilling a hole through the concrete floor slab. The hole is then fitted with the proper outlet fitting, and the wires fished from a handhole junction box to the outlet.

FIGURE 9.218 Typical cross section of a cellular-concrete floor. [The Flexicore Co., Inc.]

295. The National Electrical Code describes “cellular concrete floor raceways” in the scope of Article 372 as “the hollow spaces in floors constructed of precast cellular-concrete slabs, together with suitable metal fittings designed to provide access to the floor cells.” A *cell* is defined in NEC Sec. 372.2 as a single, enclosed tubular space in a floor made of precast cellular-concrete slabs, the direction of the cell being parallel to the direction of the floor member. A *header* is defined in the same section as transverse metal raceways for electrical conductors, providing access to predetermined cells of a precast cellular-concrete floor, thereby providing for the installation of electrical conductors from a distribution center to the floor cells.

296. Use of cellular-concrete-floor-raceway wiring (National Electrical Code). Conductors shall not be installed in precast-cellular-concrete-floor raceways (1) where subject to corrosive vapor; (2) in hazardous locations except as specifically permitted in the hazardous location articles in the NEC; or (3) in commercial garages except for supplying ceiling outlets or extensions to the area below the floor but not above. No electrical conductors shall be installed in any cell or header which contains a pipe for steam, water, air, gas, drainage, or any service other than electrical, as set forth in NEC Sec. 300.8.

297. Electrical distribution by means of cellular-concrete-floor raceways is illustrated in Figs. 9.219, 9.220, and 9.221.

FIGURE 9.219 Electrical distribution with cellular-concrete-floor-raceway wiring. [The Flexicore Co., Inc.]

FIGURE 9.220 General principles of electrical distribution by means of cellular-concrete-floor raceways. [The Flexicore Co., Inc.]

FIGURE 9.221 Details of installation of a cellular-concrete-floor-raceway wiring system. [The Flexicore Co., Inc.]

The precast slabs are available in two sizes as shown in Fig. 9.222. Flexicore Hi-Stress Deck is available in five sizes, as shown in Fig. 9.223.

Headers are available in different sizes.

The NEC makes the following specifications for headers: The headers shall be installed in a straight line, at right angles to the cells. It shall be mechanically secured to the top of the precast cellular-concrete floor. The end joints shall be closed by metallic closure fittings and

FIGURE 9.222 Cellular-concrete floor slabs. [The Flexicore Co., Inc.]

Deck size	Cell area (Sq. in.)
4"	13.9
6"	14.1
8"	27.1
10"	50.2
12"	67.0

FIGURE 9.223 Flexicore Hi-Stress Deck. [The Flexicore Co., Inc.]

sealed against the penetration of concrete. The header shall be electrically continuous throughout its length and be electrically bonded to the enclosure of the distribution center.

The method of making connection to cabinets or other enclosures is shown in Figs. 9.219, 9.220, and 9.224.

When the panel box or cabinet is located at right angles to the header (Types A and B, Fig. 9.224), the connection is made by an elbow and riser duct to the panel box. This is simply a continuation of the header up to the panel box.

When the panel box is parallel to the header (Type C), the connection is made with a T junction box, a short piece of header duct, an elbow, and a riser.

When parallel to the header, telephone and intercom cabinets are usually connected to the header as shown by Type D. The wire drops from the header through a handhole junction into a cell, through the cell, up through a jack junction box, and then to the cabinet.

FIGURE 9.224 High-capacity system with trench header ducts. [The Flexicore Co., Inc.]

The NEC requires that these connections be made by means of listed metal raceways and listed fittings.

Handhole junction boxes and their relation to the header and concrete cells are shown in Fig. 9.224. The NEC requires that junction boxes be leveled to the floor grade and sealed against the free entrance of water or concrete. Junction boxes shall be of metal and be mechanically and electrically continuous with the header.

Markers (Figs. 9.224 and 9.225) are installed along each cell for the determination of its location and to mark the location of all hidden access points between a header and a cell which is intended for future use. These markers must extend through the floor covering, and a suitable number must be used to locate the cells and provide for system identification.

FIGURE 9.225 Details of installation of a cellular-concrete-floor raceway. [The Flexicore Co., Inc.]

298. High-capacity system. The system shown in Fig. 9.226 is designed to handle eighty-two 100-pair plus one hundred thirty-seven 25-pair telephone cables, or the equivalent in other sizes. The cables feed from the panel through the channel slab, transversely through the 24-in (609.6-mm) trench header duct, then down into the cells of the Flexicore deck. Wiring can run in either direction to telephone floor outlets located at any point along the cells. Every second cell is assigned to telephones, providing lines of availability only 16 in. (406.4 mm) apart.

Electrical distribution is handled through the high-capacity trench-header-duct system shown. Many variations of both systems are possible.

FIGURE 9.226 Installation of outlets and markers. [The Flexicore Co., Inc.]

FIGURE 9.227 Outlet drive plug. [The Flexicore Co., Inc.]

FIGURE 9.228 Outlet fittings: *left*, electric-outlet fitting; *right*, telephone or intercom outlet. [The Flexicore Co., Inc.]

299. Inserts for the location of outlets can be located at any point along a cell. Typical outlets and their installation are shown in Figs. 9.224, 9.225, 9.227, and 9.228. The procedure in installing an outlet is as follows:

1. Mark location of outlet. Use cell markers to line up center of cell.

2. Drill hole for outlet using 17/8-in (47.625-mm) core bit.

3. Drive in outlet drive plug.

4. Screw in floor-outlet nipple.

5. Fish wire to outlet location.

6. Install outlet box. Floor outlets can be installed at any time during the life of the building.

300. NEC requirements for inserts are as follows: Inserts shall be leveled to the floor grade and sealed against the entrance of concrete. They shall be of metal and be fitted with receptacles of the grounded type. A grounding conductor shall connect the insert receptacles to a positive ground connection provided on the header. In cutting through the cell wall for setting inserts or other purposes (such as providing access openings between header duct and cells), chips and other dirt shall not be allowed to remain in the raceway, and the tool used shall be so designed as to prevent it from entering the cell and damaging the conductors.

301. Discontinued outlets (National Electrical Code). When an outlet is discontinued, the conductors supplying the outlet shall be removed from the header and cell. No splices or reinsulated conductors such as abandoned loop wiring shall be allowed in raceways. Refer to Sec. 253 for more information on this topic.

302. Conductors (National Electrical Code). No conductor larger than No. 1/0 shall be installed except by special permission. The total cross-sectional area of all conductors or cables in a header or in an individual cell shall not exceed 40 percent of the interior cross-sectional area of the header or cell.

Splices and taps shall be made only in header-duct access units or junction boxes.

WIRING WITH MULTIOUTLET ASSEMBLIES

303. Multioutlet assemblies consist of a metallic or nonmetallic assembly with convenience outlets built in every few inches. In one type made by the Wiremold Co. (Fig. 9.229) the outlets may be spaced as desired along the raceway and connected by wires laid in the raceway. In another type (Fig. 9.230) the outlets are built in at fixed intervals and connected by copper strips which terminate in terminal screws at each end of each length of raceway. This type is made in three styles according to the position in which it is to be used: (1) the chair-rail style for flat-surface mounting, (2) the baseboard-cap style for mounting on the top of baseboards or in the corners of mantels and cabinets, and (3) the baseboard-insert style for

FIGURE 9.229 Installation of multioutlet assembly of the Plugmold-Snapicoil type: (1) Remove knockout (from inside out) for feed connection and fasten $\frac{1}{2}$ -in connector into base with a locknut *A*. No special fittings are needed: there is plenty of room to spin the locknut. (2) At the end of the run, install a No. 2010B blank-end fitting in the base, *B* and *C*. (3) Mount base to surface through screw piercings or knockouts, using No. 6 flathead screws. (Some types of surfaces require other methods of fastening.) (4) Lay out Snapicoil, and cover sections to avoid having outlet directly in a corner or over a feed connection. (5) Splice feed wires into Snapicoil conductors *D*. NOTE In a three-wire harness, black wire with yellow lettering should be used for the switch leg. (6) Snap Snapicoil receptacles into 2000C Holecut cover, *E* and *F*: a wire clip can be used to cover *G* or base to keep wires inside raceways. (7) Snap cover, complete with receptacles, into base. [The Wiremold Co.]

recessing in the baseboard or in a plastered wall. Blank sections through which standard-type wires may be run to join plug-in sections are available for use behind radiators or for other inaccessible places where the expensive plug-in strip is not needed. Multioutlet assemblies are used to provide adequate plug receptacles for the utmost convenience in the use of appliances, in dwelling-type use, and for industrial and commercial applications. The multioutlet assembly classification also includes the vertical assemblies that are fed from above a suspended ceiling and anchored to the floor to provide power or communications or both to any desired location, particularly on commercial office environments (Fig. 9.231).

NEC specifications for the use of multioutlet assemblies are as follows: A multioutlet assembly may be used in dry locations. It shall not be used (1) when concealed; (2) where subject to severe physical damage; (3) where the voltage is 300 V or more between conductors unless the assembly is of metal having a thickness of not less than 1.02 mm (0.040 in.); (4) where subject to corrosive vapors; (5) in hoistways; or (6) in hazardous locations, except as specifically allowed by the hazardous location articles of the NEC. A metal multioutlet assembly may be extended through (not run within) dry partitions, provided arrangements are made for removing the cap or cover on all exposed portions and no outlet falls within the partitions.

FIGURE 9.230 Plug-in strip.

FIGURE 9.231 The relocatable pole assembly diagrammed here is also classified as a multioutlet assembly.

304. Various ways of mounting the chair-rail style on plastered walls are shown in Fig. 9.232. Toggle bolts are used unless a wood strip is available, as in III, when wood screws can be used. The chair-rail style is intended for mounting on flat surfaces at a considerable height above the baseboard. The curved surfaces on the top and bottom give the installation a neat appearance.

FIGURE 9.232 Methods of mounting chair-rail style of plug-in strip.

305. The baseboard-cap type has a flat surface on one edge and is curved on the other edge. It is used as illustrated in Fig. 9.233, when there is a corner against which the flat edge can be placed. The curved edge gives a finished appearance to the corner. In this type of mounting, there is usually a wood background so that wood screws can be used for fastening.

FIGURE 9.233 Methods of mounting baseboard-cap style of plug-in strip.

306. The baseboard type is set into the wall so that the surface of the strip is flush with the wall surface. When finished buildings are wired with this type, the molding on top of the baseboard is removed, the plug-in strip is placed on top of the baseboard, and the molding is placed against the plug-in strip (Fig. 9.234, III). For new installations a channel can be left in tile, glass, or marble surfaces as shown in Fig. 9.234, I and II, or the plaster can be channeled as shown in Fig. 9.234, IV.

FIGURE 9.234 Methods of mounting baseboard-insert style of plug-in strip.

307. Plug-in strip is made in various lengths from 6 in. to 9 ft (from 152.4 mm to 2.7 m). The lengths are joined together as shown in Fig. 9.235. Copper links connect the terminal screws on two adjoining lengths of plug-in strip (Fig. 9.235, I). Then insulating plates are placed over the terminals (Fig. 9.235, II), and the joint is covered with a coupling (Fig. 9.235, III).

FIGURE 9.235 Method of coupling plug-in strips together.

308. The method of bringing in the supply circuit is shown in Fig. 9.236. Junction boxes are available for either metal-clad cable or rigid conduit. The junction box has a hub in the back with a setscrew for clamping metal-clad cable or threaded for $\frac{1}{2}$ -in conduit connection (Fig. 9.236, I). The circuit wires are stripped as shown, and two short lengths of building wire are spliced to them so that the circuit will feed both ways from the junction box. The junction box is then placed against the wall, and the wires are connected to the terminal screws in the adjoining plug-in strips (Fig. 9.236, II). The middle section of the junction box is closed by means of a cover, held in place by two screws. Over each pair of terminals an insulating plate is placed and then covered with a coupling plate.

FIGURE 9.236 Method of bringing supply circuit into plug-in strip.

309. Heavier-duty multioutlet assemblies. The types of multioutlet assemblies discussed in the preceding sections are of the light-duty type. Heavier-duty multioutlet assemblies are available in the following types:

1. Two-wire grounding strip for grounding of equipment
2. 20-A receptacle type
3. 30-A receptacle type
4. 50-A receptacle type
5. Combination raceway and multioutlet assembly (Fig. 9.237)

Baseboard types of combination multioutlet assembly and surface raceway are available. Two types are shown in Figs. 9.238 and 9.239.

FIGURE 9.237 Combination raceway and multioutlet assembly. Up to three No. 12 Type TW electric conductors can be installed in the raceway space located beneath the standard plug-in-strip assembly. The additional conductors may be wired either three-phase or single-phase.

FIGURE 9.238 Installation of Plugmold baseboard: (1) Remove knockout (from inside out) for feed connection and fasten $\frac{1}{2}$ -in connector into base with a locknut A. No special fittings are needed. (2) At the end of the run, install No. 2410B blank-end fitting in the base, B and C. (3) Mount base to surface through screw piercings or knockouts, using No. 6 flathead screws. (Some types of surfaces require other methods of fastening.) (4) Lay out Snapicoil, and cover sections to avoid having outlet directly in a corner or over a feed connection. This method is also available with the receptacles already installed. (5) Splice feed wires onto Snapicoil conductors D. NOTE In a three-wire harness, black wire with yellow lettering should be used for the switch leg. (6) Insert Snapicoil receptacles into 2400C Holecut cover, and snap device clip in place, E and F. The clip can also be used in the base to keep wires inside raceways. (7) Snap cover, complete with receptacles, into 2400B base G. [The Wiremold Co.]

FIGURE 9.239 Base duct.

CABLEBUS WIRING

310. Cablebus is an approved assembly of insulated conductors mounted in a spaced relationship in a ventilated metal protective supporting structure including fittings and conductors. Typical components are shown in Fig. 9.240, which also includes some of the major NEC rules for cablebus.

FIGURE 9.240 Elements of a typical cablebus system and major National Electrical Code requirements. [*Electrical Construction and Maintenance*]

The original manufacturer of the cablebus wiring system was Husky Products, Inc., subsidiary of Burndy Corp. The system is highly desirable in industrial applications for larger feeders or branch circuits at 600 V or less and in higher distribution voltages of 5 or 15 kV. It can also be used for primary feeders in high-rise buildings or commercial buildings in which load-center unit substations are to be used. Cablebus can be used indoors or outdoors in wet or dry locations. The entire system is factory-fabricated with bottom support blocks (Fig. 9.240) in place.

The sizes of cablebus structures will vary according to the number of conductors. Figure 9.241 shows the four sizes of some of the insulator blocks that are presently available: 3-conductor, 6-conductor, 12-conductor, and 18-conductor; 24- and 27-conductor blocks are also available. Phase arrangements for three-phase circuits are also shown in Fig. 9.241 to provide a closely balanced impedance. Because of carefully selected conductor spacing, transposition of conductors is not required. Controlled spacing also assures low impedance and low voltage drop. The cablebus framework is an all-welded construction for maximum strength, and 12-ft (3.7-m) spacing of supports is standard, but 20-ft spacing is also available. High-pressure splice joints between framework sections provide an excellent path or ground, and the installed framework serves as a grounding conductor.

FIGURE 9.241 Sizes of insulating blocks and three-phase conductor arrangements. [Husky Products, Inc., subsidiary of Burndy Corp.]

311. Types of conductor. The manufacturer of cablebus recommends that only thermoplastic or thermosetting conductors be used in cablebus. At the present time, combining the insulation's electrical and physical qualities with the cost, the preferred insulation is cross-linked polyethylene. Since cablebus is a ventilated enclosure and conductors are separated by insulating blocks, conductor ampacities may be determined on the basis of single conductors in free air, as in Tables 19 and 22 of Div. 12. Generally, 90°C-rated conductors are recommended and 75°C is the minimum permitted.

312. Installation procedures. The basic installation of the cablebus framework is similar to that of a cable-tray system (Sec. 314). Typical arrangements are shown in Fig. 9.242, in which cablebus is used for primary and secondary feeders and circuits. The conductor-pulling tools are the same as those shown in Fig. 9.248 for cable tray. Conductors are pulled in after the basic framework has been completely installed. After conductors have been pulled in and arranged in proper phase sequence, they are secured to the insulating blocks. The final step is the installation of top covers.

FIGURE 9.242 Typical cablebus runs for primary and secondary distribution. [Husky Products, Inc., subsidiary of Bunnell Corp.]

313. National Electrical Code rules. The following Code rules apply to cablebus:

1. Cablebus shall be installed only for exposed work. It may be installed outdoors or in corrosive, wet, or damp locations if identified for such use.
2. Cablebus shall not be installed in hoistways or hazardous locations unless specifically approved for such use.

3. If adequately bonded, cablebus framework may be used as the equipment-grounding conductor for branch circuits and feeders.
4. Cablebus may be used for systems in excess of 600 V, nominal.
5. The current-carrying conductors in cablebus shall have an insulation rating of at least 75°C and be of an approved type.
6. The size and number of conductors shall be that for which the cablebus is designed, and in no case less than 1/0.
7. Insulated conductors shall be supported on blocks or other mounting means designed for the purpose.
8. The individual conductors in a cablebus shall be supported at intervals not greater than 900 mm (3 ft) for horizontal runs and 450 mm (1½ ft) for vertical runs. Vertical and horizontal spacing between conductors shall be not less than one conductor diameter at the points of support.
9. Where the ampacity of cablebus conductors does not correspond to a standard rating of the overcurrent device, the next-higher-rated overcurrent device may be used, only if the rating does not exceed 800 A.
10. Cablebus shall be securely supported at intervals not exceeding 3.7 m (12 ft). Where spans greater than 12 ft are required, the structure shall be specifically designed for the required span length.
11. Cablebus may extend transversely through partitions or walls, other than fire walls, provided the section within the wall is continuous, protected against physical damage, and unventilated.
12. Except when fire stops are required, cablebus may extend vertically through dry floors and platforms and in wet locations where (a) there are curbs or other suitable means to prevent water flow through the floor or platform opening and (b) the cablebus is totally enclosed at the point where it passes through the floor or platform and for a distance of 1.8 m (6 ft) above the floor or platform.
13. Except when fire stops are required, cablebus may extend vertically through dry floors and platforms, provided the cablebus is totally enclosed at the point where it passes through the floor or platform and for a distance of 1.8 m (6 ft) above the floor or platform.
14. Cablebus shall utilize approved fittings for changes in the horizontal or vertical direction of the run, dead ends, terminations in or on connected apparatus or equipment or the enclosures for such equipment, and additional physical protection where required, such as guards for severe mechanical protection.
15. Approved terminating means shall be used for connections to cablebus conductors.
16. Sections of cablebus shall be electrically grounded and bonded.
17. Each section of cablebus shall be marked with the manufacturer's name or trade designation and the maximum diameter, number, voltage rating, and ampacity of conductors to be installed. Markings shall be so located as to be visible after installation.

CABLE TRAYS

314. A cable-tray system is a unit or an assembly of units or sections, with associated fittings, forming a rigid structural system used to support cables and raceways. Cable trays include ladders, troughs, channels, solid-bottom trays, and similar structures.

The National Electrical Code allows cable tray to contain any approved conduit or raceway with its contained conductors; mineral-insulated metal-sheathed cable (Type MI); armored cable (Type AC); metal-clad cable (Type MC); power-limited tray cable (Type PLTC); nonmetallic-sheathed cable (Types NM, NMC, and NMS); multiconductor service-entrance cable (Types SE and USE); multiconductor underground-feeder and branch-circuit cable (Type UF); power and control tray cables (Type TC); instrument tray cable (Type ITC); and other factory-assembled multiconductor control, signal, or power cables which are specifically approved for installation in cable trays. In practice, the most common types used in cable trays are Type MC metal-clad cable (Fig. 9.87) and Type TC tray cables (Figs. 9.243, 9.244, and 9.245) listed by Underwriters Laboratories Inc. for cable-tray systems. The cable shown in Fig. 9.243 is a polyvinyl chloride- and nylon-insulated 600-V power cable with three 2/0 conductors and a grounding conductor. The cable shown in Fig. 9.244 has the same insulation and contains 19 No. 12 stranded conductors, suitable for 600-V power or control circuits. Figure 9.245 also has the same insulation, and contains three 4/0 power conductors and four No. 12 control conductors, all suitable for 600 V. Cables similar to these can be obtained with a wide variety of conductor sizes. These nonmetallic cables and Type MC metal-clad cables can be installed in cable trays much more easily than other types of cables. Refer to Sec. 13 for a discussion of required wiring configurations for Type TC cable where it exits a cable tray system.

FIGURE 9.243 A 600-V power tray cable for use in cable trays. [Plastic Wire & Cable Corp., subsidiary of Triangle Industries, Inc.]

FIGURE 9.244 A 600-V 19-conductor tray cable suitable for power-control circuits and for use in cable trays. [Plastic Wire & Cable Corp., subsidiary of Triangle Industries, Inc.]

FIGURE 9.245 A 600-V power and control tray cable for use in cable trays. [Plastic Wire & Cable Corp., subsidiary of Triangle Industries, Inc.]

315. Types of cable tray. There are several manufacturers of cable tray, and the types shown in Figs. 9.246 and 9.247 are manufactured by the Globe Division of United States Gypsum. These drawings show various types of cable tray (channel type, solid-cover type, louvered-cover type, ladder type, and solid-bottom type). Also illustrated are a variety of fittings used with the support system, such as elbows or offsets, blind ends, tees, crosses, reducers, dividers, and box connectors. As can be seen in Figs. 9.246 and 9.247, cable trays provide a highly flexible system in any application in which a number of power and/or control cables are required. Cable trays are secured in a manner similar to that described in the sections on rigid metal conduit and busways.

FIGURE 9.246 Typical components of a CABLE-STRUT system. [Globe Division, United States Gypsum Co.]

FIGURE 9.247 Typical components of a CABLE-STRUT system. [Globe Division, United States Gypsum Co.]

An excellent feature of the cable-tray system is that cables can be added, revamped, or removed with minimum effort. When laying out such systems, it is well to plan for future needs by obtaining trays larger than necessary for the initially installed cables. Manufacturers offer many different widths and lengths for each section of cable-tray system, and it is recommended that representatives of these firms be approached when such installations are contemplated.

316. Installation aids. The tools shown in Fig. 9.248 to simplify the pulling of cables into cable trays are typical of those offered by manufacturers of these systems. Locating rollers and pulleys at the proper locations in the system speeds up the installation of cables and prevents damage to them during installation. After cables have been installed, they should be spaced and supported as indicated in Sec. 317.

FIGURE 9.248 Installation aids available to simplify the cable pulling in cable trays. [Electrical Construction and Maintenance]

317. National Electrical Code rules for cable trays are as follows:

1. They shall have suitable strength and rigidity to provide adequate support for all contained wiring.
2. They shall not present sharp edges, burrs, or projections injurious to the insulation or jackets of the wiring.
3. If made of metal, they shall be adequately protected against corrosion or shall be made of corrosion-resistant material.
4. They shall have side rails or equivalent structural members.

5. They shall include fittings or other suitable means for changes in direction and elevation of runs.
6. Nonmetallic cable trays shall be made of fire-retardant material.
7. Cable trays shall be installed as a complete system. Field bends or modifications shall be so made that the electrical continuity of the cable-tray system and support for the cables shall be maintained. In instances where a tray segment is not mechanically continuous, either to the next tray segment or to the equipment where the conductors will terminate, the distance cannot exceed 1.8 m (6 ft), the conductors or cable assemblies must be secured to the cable tray at the transition points, and the open run must not be subject to physical damage. This must be assured through guarding or by location.
8. Each run of cable tray shall be completed before the installation of cables.
9. Supports shall be provided to prevent stress on cables where they enter another raceway or enclosure from cable-tray systems. Cable trays shall be supported at intervals in accordance with the installation instructions.
10. In portions of runs where additional protection is required, covers or enclosures providing the required protection shall be of a material compatible with the cable tray.
11. Multiconductor cables rated 600 V or less shall be permitted to be installed in the same cable tray.
12. Cables rated over 600 V shall not be installed in the same cable tray with cables rated 600 V or less except where separated by either solid fixed barriers of a material compatible with the cable tray or by the metallic cable armor in the case where the cables over 600 V are Type MC.
13. Cable trays shall be permitted to extend transversely through partitions and walls or vertically through platforms and floors in wet or dry locations where the installations, complete with installed cables, are made in accordance with the requirements of Sec. 300.21 of the Code.
14. Cable trays shall be exposed and accessible except as permitted by Par. 13.
15. Sufficient space shall be provided and maintained around cable trays to permit adequate access for installing and maintaining the cables.
16. Metallic cable trays which support electrical conductors shall be grounded as required for conductor enclosures in Article 250 of the Code.
17. When steel or aluminum cable-tray systems are used as equipment-grounding conductors, all the following provisions shall be complied with:
 - a. The cable-tray sections and fittings shall be identified as an equipment grounding conductor.
 - b. The minimum cross-sectional area of cable trays shall conform to the requirements in Table 392.7(B) of the NEC.
 - c. All cable-tray sections and fittings shall be legibly and durably marked to show the cross-sectional area of metal in channel-type cable trays or cable trays of one-piece construction and the total cross-sectional area of both side rails for ladder or trough-type cable trays.
 - d. Cable-tray sections, fittings, and connected raceways shall be bonded in accordance with Sec. 250.96 of the NEC, using bolted mechanical connectors or bonding jumpers sized and installed in accordance with Sec. 250.102 of the Code.
18. Cable splices made and insulated by approved methods shall be permitted to be located within a cable tray provided they are accessible. The splices are now permitted to project above the side rails, provided their location does result in exposure to physical damage.
19. In other than horizontal runs, the cables shall be fastened securely to transverse members of the cable trays.

20. A box shall not be required where cables or conductors are installed in bushed conduit or tubing used for support or for protection against physical damage.
21. Where single-conductor cables comprising each phase or neutral of a circuit are connected in parallel as permitted in Sec. 310.4 of the NEC, the conductors shall be installed in groups consisting of not more than one conductor per phase or neutral in order to prevent current unbalance in the paralleled conductors due to inductive reactance.

Single conductors shall be securely bound in circuit groups to prevent excessive movement due to fault-current magnetic forces, unless single conductors are twisted together, as in triplexed assemblies.
22. Single conductors installed in ladder or ventilated trough cable trays that are 1/0 through 4/0 AWG shall have all single conductors installed in a single layer. Conductors that are bound together to comprise each circuit group can be installed in other than a single layer. For ladder-type tray, the rung spacing under these conductors must not exceed 225 mm (9 in). Single-conductor equipment grounding conductors are permitted to be as small as 4 AWG.
23. A cable tray is not a wireway without a cover. Single conductors in cable trays are only permitted in very restricted circumstances. Specifically, single conductors are only permitted in industrial occupancies with qualified maintenance and supervision, in sizes 1/0 AWG and larger. Medium-voltage conductors run as Type MV cable are permitted to run as single conductors provided they follow the same rules.

GENERAL REQUIREMENTS FOR WIRING INSTALLATIONS

CONDUCTOR REQUIREMENTS

318. Size of conductors. No wire smaller than 14 AWG is allowed for general interior-wiring work. Wires of 18 or 16 AWG may be used for fixture wiring, flexible cords, and some other special applications as given in Sec. 32 of Div. 3. Although 14 AWG wire is allowed for branch circuits, it is a good practice not to use wire smaller than 12 AWG. The larger 12 AWG wire costs only about 20 percent more than 14 AWG, can usually be placed in the same-size conduit or raceway, will have greater mechanical strength, and will reduce the voltage drop and the I^2R heating loss in the wires by approximately 40 percent. Solid conductors of larger size than 10 AWG are not allowed to be used in conduit or raceways. For ease in handling, it is a good practice to use stranded conductors in the larger sizes for open wiring also. The size of wire required, according to the amount of current to be carried by the circuit, is discussed in Sec. 31 of Div. 3, and the ampere current-carrying capacities are given in Tables 18 to 23 of Div. 12.

319. All ungrounded conductors must be protected by fuses or circuit breakers rated in accordance with the allowable ampacity of the conductors as given in Sec. 320 and located at the point where the conductor receives its supply, with the following exceptions. What follows are what is known as the tap rules in the NEC, and one must never be applied to another. That is, it is never permitted to “tap a tap”:

1. For building-service conductors the overcurrent protection is located at the same point as the other service-entrance equipment, which may be at the load end of the service-entrance conductors or at the outer end.
2. The overcurrent protection may be omitted provided the overcurrent unit farther back on the circuit is rated not greater than the ampacity of the smaller conductor.

3. Taps to individual outlets and circuit conductors supplying what constitutes collectively a single household electric range, as in the case of a separate wall-mounted oven and a counter cooktop, shall be considered to be protected by the branch-circuit overcurrent devices when in accordance with the requirements of Sec. 210.19(A)(3) Exception No. 1 of the NEC.
4. If a feeder tap conductor or transformer secondary is not over 3 m (10 ft) long, does not extend beyond the switchboard, panelboard, disconnecting means or control devices which it supplies, is enclosed in a raceway, and has an ampacity not less than the sum of the computed loads of the circuits which it supplies, not less than the rating of the device supplied by the tap conductor, or not less than the rating of the overcurrent protective device at the termination of the tap conductors, it need not be separately protected. For field installations where the tap conductors leave the enclosure or vault in which the tap is made, the rating of the overcurrent device on the line side of the tap conductors shall not exceed 10 times the ampacity of the tap conductor.
5. If the feeder tap conductor is not over 7.5 m (25 ft) long, is protected from physical damage, has an ampacity not less than one-third the rating of the feeder overcurrent device, and terminates in a single circuit breaker or set of fuses that will limit the load to the ampacity of the tap conductors. This device may supply any number of additional overcurrent devices on its load side.
6. For individual motor branch circuits, refer to Sec. 385, Div. 7.
7. For feeders or main conductors supplying more than one motor, refer to Sec. 390, Div. 7.
8. *Protection of fixture wires and cords.* Where flexible cord used in listed extension cord sets is connected to a branch circuit of Article 210 of the NEC, a 16 AWG or larger conductor may be protected by a 20 A circuit.

Flexible cord or a tinsel cord approved for use with specific listed appliances or portable lamps shall be considered to be protected by the overcurrent device of the branch circuit of Article 210 of the NEC where applied within the listing requirements.

Fixture wire shall be considered to be protected by the overcurrent device of the branch circuit of Article 210 of the NEC when conforming to the following:

- 20-A circuits: 18 AWG up to 15 m (50 ft)
- 20-A circuits: 16 AWG up to 30 m (100 ft)
- 20-A circuits: 14 AWG and larger
- 30-A circuits: 14 AWG and larger
- 40-A circuits: 12 AWG and larger
- 50-A circuits: 12 AWG and larger

9. **Feeder Taps Supplying a Transformer (Primary Plus Secondary Not Over 7.5 m [25 ft] Long).** Conductors supplying a transformer shall be permitted to be tapped, without overcurrent protection at the tap, from a feeder where all the following conditions are met:

- a. The conductors supplying the primary of a transformer have an ampacity at least $\frac{1}{3}$ of the rating of the overcurrent device protecting the feeder conductors.
- b. The conductors supplied by the secondary of the transformer shall have an ampacity that, when multiplied by the ratio of the secondary-to-primary voltage, is at least $\frac{1}{3}$ of the rating of the overcurrent device protecting the feeder conductors.
- c. The total length of one primary plus one secondary conductor, excluding any portion of the primary conductor that is protected at its ampacity, is not over 7.5 m (25 ft).
- d. The primary and secondary conductors are suitably protected from physical damage.
- e. The secondary conductors terminate in a single circuit breaker or set of fuses that will limit the load current to not more than the conductor ampacity that is permitted by Sec. 310.15 of the NEC.

- 10. Busway Taps.** Busways and busway taps shall be permitted to be protected against overcurrent in accordance with Secs. 368.17 of the NEC.
- 11. Conductors from Generator Terminals.** Conductors from generator terminals that meet the size requirements of 445.13 are to be protected against overload by the generator overload protective device required by 445.12 of the NEC.
- 12. Feeder Taps Over 25 ft (7.62 m) Long.** Conductors over 7.5 m (25 ft) long shall be permitted to be tapped from feeders in high bay manufacturing buildings over 7 m (25 ft) 11 m (35 ft) high at walls, where conditions of maintenance and supervision ensure that only qualified persons will service the systems. Conductors tapped, without overcurrent protection at the tap, to a feeder shall be permitted to be not over 7.5 m (25 ft) long horizontally and not over 30 m (100 ft) total length where all the following conditions are met:
- The ampacity of the tap conductors is not less than $\frac{1}{3}$ of the rating of the overcurrent device protecting the feeder conductors.
 - The tap conductors terminate at a single circuit breaker or a single set of fuses that will limit the load to the ampacity of the tap conductors. This single overcurrent device shall be permitted to supply any number of additional overcurrent devices on its load side.
 - The tap conductors are suitably protected from physical damage or are enclosed in a raceway.
 - The tap conductors are continuous from end-to-end and contain no splices.
 - The tap conductors are sized 6 AWG copper or 4 AWG aluminum or larger.
 - The tap conductors do not penetrate walls, floors, or ceilings.
 - The tap is made no less than 9 m (30 ft) from the floor.
- 13. Transformer Secondary Conductors for Industrial Installations.** Under conditions of qualified maintenance and supervision, conductors shall be permitted to be connected to a transformer secondary for industrial installations, without overcurrent protection at the connection, where all the following conditions are met:
- The length of the secondary conductors does not exceed 7.5 m (25 ft).
 - The ampacity of the secondary conductors is not less than the secondary current rating of the transformer, and the sum of the ratings of the overcurrent devices does not exceed the ampacity of the secondary conductors. Since taps cannot be tapped, as a practical matter this provision would be limited to tap conductors arriving at the main lugs of a switchboard. A motor control center would not qualify, because overcurrent protection in the form of a singular device is required in accordance with the rating of the common power bus.
 - All overcurrent devices are grouped.
 - The secondary conductors are suitably protected from physical damage.
- 14. Outside Feeder Taps of Unlimited Length.** Outside conductors shall be permitted to be tapped to a feeder or to be connected at the transformer secondary, without overcurrent protection at the tap or connection, where all the following conditions are met:
- The conductors are suitably protected from physical damage.
 - The conductors terminate at a single circuit breaker or a single set of fuses that will limit the load to the ampacity of the conductors. This single overcurrent device shall be permitted to supply any number of additional overcurrent devices on its load side.
 - The tap conductors are installed outdoors, except at the point of termination.
 - The overcurrent device for the conductors is an integral part of a disconnecting means or shall be located immediately adjacent thereto.
 - The disconnecting means for the conductors are installed at a readily accessible location either outside of a building or structure, or inside nearest the point of entrance of the conductors. If it is necessary to extend power conductors into a

building beyond where their disconnecting means and overcurrent protection would normally be located, the NEC allows such conductors to continue to be considered, for enforcement purposes, outside the building under any of the following four conditions. The point of entry is artificially extended where the wiring is (1) below at least a 50-mm (2-in) concrete slab under a building, or (2) if installed encased in not less than 50 mm (2 in.) of concrete or brick, or (3) if run within a transformer vault that meets the fire protection requirements of Article 450 Part III, and as covered in Div. 5, Secs. 142 to 148, or (4) run in conduit and placed at least 450 mm (18 in.) of earth beneath a building or other structure.

320. Rating of the overcurrent protective devices. The rating of the overcurrent protective device must be as given below except for the exceptions referred to in Pars. 6 to 8 of Sec. 319. Fuses or circuit breakers shall have ratings not greater than the allowable ampacity of the conductor which they protect, except that when the standard ampere ratings and settings of overcurrent devices do not correspond with the allowable ampacity of conductors, the next-higher standard rating and setting may be used in ratings of 800 A or less.

The effect of the temperature on the operation of thermally controlled circuit breakers should be taken into consideration in the application of such circuit breakers when they are subjected to extremely low or extremely high temperatures.

The allowable ampacity of wires is given in Tables 18 to 23 of Div. 12, and the common sizes of fuses and circuit breakers in Table 38 of Div. 12 and Sec. 240.6 of the NEC.

321. Grounded conductors must not be fused and must not have a circuit breaker in them unless the circuit breaker opens all the wires of the circuit at the same time. The size of a grounded conductor may be changed whenever the sizes of the other conductors are changed, provided the other conductors are protected as outlined in Secs. 319 and 320 (see Div. 8, Sec. 137, for an explanation of the reason for grounding one conductor of a wiring system).

322. Overcurrent devices in parallel. Except for fuses or circuit breakers which are factory-assembled and listed as a single unit, overcurrent devices must not be arranged or installed in parallel.

323. Enclosures for protective devices (National Electrical Code). Overcurrent devices shall be enclosed in cutout boxes or cabinets unless they are a part of an assembly which affords equivalent protection or unless they are mounted on open-type switchboards, panelboards, or control boards, they shall be located in rooms or enclosures free from easily ignitable material and dampness and accessible only to qualified personnel. The operating handle of a circuit breaker may be accessible without opening a door or cover.

Damp or Wet Locations. Metallic enclosures for overcurrent devices in damp or wet locations shall be mounted so there is at least a 6 mm (1/4 in.) air space between the enclosure and the wall or other supporting surface. Enclosures installed in wet locations shall be weatherproof. Nonmetallic enclosures must also comply with the air space rule if the surface on which they are mounted is absorbent, such as wood. The space is not required for nonmetallic enclosures on tile, concrete, or similar surfaces.

Vertical Position. Enclosures for overcurrent devices shall be mounted in a vertical plane unless in individual instances this is shown to be impracticable and the handle position is clearly identified as to “on” and “off” in accordance with Sec. 240.81 of the NEC.

Disconnection of Fuses before Handling. Disconnecting means shall be provided on the supply side of all fuses in circuits of more than 150 V to ground and cartridge fuses in circuits of any voltage, if accessible to other than qualified persons, so that each individual circuit containing fuses can be independently disconnected from the source of electrical energy, except that a single disconnecting means may be used to control a group of circuits each protected by fuses under the conditions described in Secs. 430.112 and 424.22(C) of the NEC and current-limiting devices on the supply side of the service disconnecting means permitted by 230.82 of the NEC.

Arcing or Suddenly Moving Parts. Arcing or suddenly moving parts shall comply with the following:

1. *Location.* Fuses and circuit breakers shall be so located or shielded that persons will not be burned or otherwise injured by their operation.
2. *Suddenly moving parts.* Handles or levers of circuit breakers and similar parts which may move suddenly in such a way that persons in the vicinity are likely to be injured by being struck by them shall be guarded or isolated.

324. Flexible cords are used for wiring fixtures, for the connection of pendants, wiring of luminaires (fixtures) or portable lamps, portable and mobile signs, or appliances, for elevator cables, for the wiring of cranes and hoists, for the connection of stationary equipment to facilitate their frequent interchange, to prevent transmission of noise or vibration, or to facilitate the removal of fixed or stationary appliances for maintenance or repair and the appliance is intended or identified for flexible cord connection, for data processing cables, and connection of moving parts, or for temporary wiring as permitted in 590.4(B) and (C) of the NEC. If the load connected to them is not greater than their carrying capacity, they are considered to be sufficiently protected by the branch-circuit overcurrent device of the branch circuit from which they are tapped. For the ampacity of fixture wire see Table 25, Div. 12. Cords must be connected to devices so that tension in a cord will not be taken by the terminal screws. This can be accomplished by knotting the cord inside the device (Fig. 9.249), by winding it with tape, or by using a clamp fitting. When flexible cords pass through the cover of an outlet box, the hole must have a smooth, well-rounded surface; when they enter lampholders, they must be protected by insulating bushings. Flexible cords shall be installed in continuous lengths without splice or tap. For voltages between 300 and 600,

FIGURE 9.249 Method of tying a supporting knot in flexible cord (see Sec. 299 for description).

cords of No. 10 and smaller shall have at least 1.14 mm (45 mils) of thermoset or thermoplastic insulation on each conductor unless Type S, SO, SE, SEO, SEOO, SOO, STO, STOO, or ST cord is used.

In the wiring of fixtures, use conductors having insulation suitable for the current, voltage, and temperature to which they will be subjected. The splice between the fixture conductors and the circuit conductors must be easily accessible for inspection without requiring disconnection of the wiring. (See Fig. 9.250.) This is accomplished by making the canopy so that it will slide down the fixture stem (Fig. 9.251).

FIGURE 9.250 Support for an outlet box in a terracotta ceiling.

FIGURE 9.251 Method of supporting a fixture from a fixture stud.

325. Splicing of conductors. Conductors in conduit or raceway systems must be continuous from outlet to outlet and must not be spliced or tapped within the raceway or conduit itself, except in wireways or auxiliary gutters. Instructions for the proper splicing of conductors are given in Div. 2.

326. Conductors may be placed in parallel in sizes 1/0 and larger, provided they are of the same length and size and have the same type of insulation and conductor material. The conductors shall be arranged and terminated at each end in such a manner as to ensure equal division of the total current between all the parallel conductors. If the parallel circuits should be carried in different conduits or raceways, at least one wire of each phase must be carried in each conduit or raceway.

327. Induced currents in metal enclosures (National Electrical Code). In metal enclosures, the conductors of circuits operating on alternating current shall be so arranged as to avoid overheating of the metal by induction. When the capacity of a circuit is such that it is impracticable to run all conductors in one enclosure, the circuit may be divided and two or more enclosures may be used, provided each phase conductor of the circuit and the neutral conductor, when one is used, are installed in each enclosure. The conductors of such an installation must conform to the provisions of Sec. 326 for paralleled conductors.

Induced currents in an enclosure can be avoided by so grouping the conductors in one enclosure that the current in one direction will be substantially equal to the current in the opposite direction.

Where the conductors of a circuit pass through individual holes in the wall of a metal cabinet, the effect of induction may be minimized by passing all the conductors in the circuit through an aluminum wall or insulating block used to cover a hole in the metal cabinet sufficiently large for all the conductors of the circuit.

328. At outlets and switch locations at least 150 mm (6 in.) of free conductor must be left for the making of joints and the connection of wiring devices, except when conductors are intended to loop without joints through boxes and fittings. The distance is to be measured from the point the conductors emerge from the enclosing cable sheath in the box, or from the bushing or connector in the case of a raceway. In addition, in the case of deep boxes or boxes with several extension rings, there is an additional requirement that the free conductor be long enough to extend at least 75 mm (3 in.) into the open beyond the box or plaster ring opening. This assures that the conductors will be able to be spliced in a sound manner. This additional rule is waived in the event that all dimensions of the box opening equal or exceed 200 mm (8 in.), because such a large opening allows for a person to work the splice with both hands in the enclosure.

329. When ungrounded conductors of No. 4 and larger enter a cabinet, junction, or pull box, they shall be protected by a smoothly rounded insulating bushing unless they are separated from the raceway fitting by substantial insulating material securely fastened in place. If conduit bushings are constructed wholly of insulating material, a locknut to which the conduit is attached shall be provided both inside and outside the enclosure. If the conductors enter the cabinet vertically, a wiring space must be provided with a width as specified in Sec. 85, Div. 4.

330. Conductors of different systems

1. Conductors of light and power systems of 600 V or less may occupy the same enclosure, without regard to whether the individual circuits are alternating-current or direct-current, only if all conductors are insulated for the maximum voltage of any conductor within the enclosure.
2. Conductors of light and power systems of over 600 V shall not occupy the same enclosure with conductors of light and power systems of 600 V or less.
3. Secondary wiring to electric discharge lamps of 1000 V or less may occupy the same enclosure as the branch-circuit conductors.
4. Control, relay, and ammeter conductors used in connection with any individual motor or starter may occupy the same enclosure as the motor-circuit conductors.
5. Primary leads of electric discharge lamp ballasts, insulated for the primary voltage of the ballast, when contained within the individual wiring enclosure may occupy the same luminaire (fixture) sign, or outline lighting enclosure as the branch-circuit conductors.

331. When conductors or cables are run through bored holes in studs and joists, the holes should be bored at the approximate centers of wood members or at least 32 mm (1¼ in.) from the nearest edge when practical. If there is no objection because of

weakening the building structure, cables or raceways may be laid in notches in the studding or joists if the cable at those points is protected against the driving of nails into it by having the notch covered with a steel plate at least 1.6 mm ($1/16$ in.) thick before the building finish is applied. Plates made of harder steel alloys that have equivalent resistance to penetration may be used, provided they have been listed for this purpose.

332. Conductors in vertical raceways (any metallic enclosure for conductors) must be supported at intervals not greater than those given in Sec. 111.

333. Wiring in ducts, plenums, and other air-handling spaces (National Electrical Code). No wiring systems of any type shall be installed in ducts used to transport dust, loose stock, or flammable vapors; nor shall any wiring system of any type be installed in any duct, or shaft containing only such ducts, used for vapor removal or ventilation of commercial-type cooking equipment.

Only wiring methods consisting of mineral-insulated metal-sheathed cable, Type MC cable employing a smooth or corrugated impervious metal sheath without an overall non-metallic covering, electrical metallic tubing, flexible metallic tubing, intermediate metal conduit, or rigid metal conduit without an overall nonmetallic covering shall be installed in ducts or plenums specifically fabricated to transport environmental air. Flexible metal conduit shall be permitted, in lengths not to exceed 1.2 m (4 ft), to connect physically adjustable equipment and devices permitted to be in these ducts and plenum chambers. The connectors used with flexible metal conduit shall effectively close any openings in the connection. Equipment and devices shall be permitted within such ducts or plenum chambers only if necessary for their direct action upon, or sensing of, the contained air. Where equipment or devices are installed and illumination is necessary to facilitate maintenance and repair, enclosed gasketed-type luminaires shall be permitted.

Only totally enclosed, nonventilated insulated busways having no provisions for plug-in connections and wiring methods consisting of mineral-insulated metal-sheathed cable, Type MC cable without an overall nonmetallic covering, and Type AC cable and other factory-assembled multiconductor control or power cable which is specifically listed for the use or listed prefabricated cable assemblies of metallic manufactured wiring systems without a nonmetallic sheath shall be used for wiring in systems installed in other space used for environmental air. Other types of cables and conductors and raceways shall be permitted to be installed in electrical metallic tubing, flexible metallic tubing, intermediate metal conduit, rigid metal conduit without an overall nonmetallic covering, flexible metal conduit, or where accessible metal surface raceway or metal wireway with metal covers or solid bottom metal cable tray with solid metal covers.

Electric equipment with a metal enclosure or with a nonmetallic enclosure listed for the use and having adequate fire-resistant and low-smoke-producing characteristics, and associated wiring material suitable for the ambient temperature may be installed in such other space unless prohibited elsewhere in the NEC. Integral fan systems are permitted where specifically identified for such use.

Habitable rooms or areas of buildings the prime purpose of which is not air handling are not considered ducts or plenums. The space above a suspended ceiling that is used as a collection point for environmental air returning to an air handler is a good example of the space in which these provisions apply.

NFPA *Standard for the Installation of Air Conditioning and Ventilating Systems*, No. 90A, sets forth requirements of building used for ducts and plenums.

The wiring systems used for information technology equipment and located within air-handling areas created by raised floors are permitted in accordance with Article 645 of the NEC.

334. The approved types of insulation of conductors for different installations are given in Div. 2, Secs. 25 to 36.

335. Insulation resistance. To provide a reasonable factor of safety against short circuits and grounds, completed wiring systems should undergo an insulation-resistance test. The proper instrument for making this test is a megohmmeter. The NEC formerly contained recommended values of resistance for various circuit sizes. However, these values were deleted from the Code because they were misleading. Cable and conductor installations provide a wide variation of conditions with respect to the resistance of insulation. These variations are due to the many types of insulating materials used, insulation thickness, voltage rating, and the length of the circuit. Long circuits may be subject to wide variations in temperature, and this can influence the insulation-resistance values in a test.

While insulation-resistance readings are quantitative, they are also relative and comparable. Accordingly, such readings can be used to indicate the presence of moisture, dirt, and deterioration. Although the operation of a megohmmeter insulation tester is fairly simple, one must know how to interpret the results, and instructions provided for such instruments should be carefully followed.

Because a discussion of all the factors involved with these instruments and various test methods is beyond the scope of this book, anyone interested in this subject should review an instruction manual for insulation testers. Such manuals include instructions for connecting and operating Megger insulation-testing instruments, directions for making insulation-resistance tests on various types of electrical equipment, supplementary instructions and explanations to assist the person who makes the test, and valuable material on how to interpret insulation-resistance readings.

336. Grounded conductor. Every interior-wiring system must have a grounded conductor except as allowed by the Code for certain specific conditions. The grounded conductor must be continuously identified throughout the system.

If a neutral (grounded) conductor is run to a lampholder or any other screw-shell device, the neutral (grounded) conductor must be connected to the screw shell. This requirement does not apply to screw shells that serve as fuseholders.

GENERAL INSTALLATION REQUIREMENTS

337. Working space about electric equipment, 600 V or less (National Electrical Code). Sufficient access and working space shall be provided and maintained around all electric equipment to permit ready and safe operation and maintenance of such equipment. Enclosures housing electrical apparatus that are controlled by lock and key shall be considered accessible to qualified persons.

1. Working Clearances. Except as elsewhere required or permitted in the NEC the dimension of the working space in the direction of access to live parts operating at 600 V or less and likely to require examination, adjustment, servicing, or maintenance while energized shall not be less than indicated in Table 337A. In addition to the dimensions shown in Table 337A, the work space shall not be less than 762 mm (30 in.) wide in front of the electric equipment. Distances shall be measured from the live parts if such are exposed or from the enclosure front or opening if such are enclosed.

TABLE 337A. Working Clearances*
(Table 110.26(A)(1), 2008 NEC)

Voltage to ground	Minimum clear distance, ft		
	Condition 1	Condition 2	Condition 3
0–150	914 mm (3)	914 mm (3)	914 mm (3)
151–600	914 mm (3)	1.07 m (3½)	1.22 m (4)

*Reprinted with permission from NFPA 70-2008, National Electrical Code®. Copyright © 2007, National Fire Protection Association, Quincy, Massachusetts 02269. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

The conditions are as follows:

Condition 1. Exposed live parts on one side and no live or grounded parts on the other side of the working space, or exposed live parts on both sides effectively guarded by suitable wood or other insulating materials. Insulated wire or insulated busbars operating at not over 300 V shall not be considered live parts.

Condition 2. Exposed live parts on one side and grounded parts on the other side. Concrete, brick, or tile walls shall be considered as grounded.

Condition 3. Exposed live parts on both sides of the work space (not guarded as provided in Condition 1) with the operator between.

Dead-Front Assemblies. Working space shall not be required in back of assemblies such as dead-front switchboards or motor-control centers where there are no renewable or adjustable parts such as fuses or switches on the back and where all connections are accessible from locations other than the back or sides. Where rear access is required to work on nonelectrical parts on the back of enclosed equipment, a minimum working space of 762 mm (30 in.) horizontally shall be provided.

Low Voltage. By special permission smaller spaces may be permitted where all uninsulated parts are at a voltage no greater than 30 V rms, 42 V peak, or 60 V dc.

Existing Buildings. In existing buildings where electrical equipment is being replaced, Condition 2 working clearance shall be permitted between dead-front switchboards, panelboards, or motor control centers located across the aisle from each other where conditions of maintenance and supervision ensure that written procedures have been adopted to prohibit equipment on both sides of the aisle from being open at the same time and qualified persons who are authorized will service the installation.

- 2. Clear Spaces.** Working space required by this section shall not be used for storage. When normally enclosed live parts are exposed for inspection or servicing, the working space, if in a passageway or general open space, shall be suitably guarded.
- 3. Access and Entrance to Working Space.** At least one entrance of sufficient area shall be provided to give access to the working space about electric equipment. For equipment rated 1200 A or more and over 1.8 m (6 ft) wide, containing overcurrent devices, switching devices, or control devices, there shall be one entrance to and egress from the required working space not less than 610 mm (24 in.) wide and 2.0 m (6½ ft) high at each end of the working space.

Unobstructed Exit. Where the equipment location permits a continuous and unobstructed way of exit travel one means of exit is permitted.

Extra Work Space. Where the work space required by Sec. 110.26(A)(1) of the NEC is doubled, only one entrance to the working space is required and it shall be so located that the edge of the entrance nearest the equipment is the minimum clear distance given in Table 337A away from such equipment.

4. **Illumination.** Illumination shall be provided for all working spaces about service equipment, switchboards, panelboards, or motor control centers installed indoors. Additional lighting fixtures shall not be required where the work space is illuminated by an adjacent light source or as permitted by 210.70(A)(1), Ex. 1 of the NEC for switched receptacles. In electrical equipment rooms, the illumination shall not be controlled by automatic means only.
5. **Headroom.** The minimum headroom of working spaces about service equipment, switchboards, panelboards, or motor control centers shall be 2.0 m (6½ ft). Where the electrical equipment exceeds 2.0 m (6½ ft) in height, the minimum headroom shall not be less than the height of the equipment.

Exception. Service equipment or panelboards in existing dwelling units that do not exceed 200 A.

338. All cables and raceways must be continuous from outlet to outlet and from fitting to fitting and must be securely fastened in place. Fittings must be mechanically secured to conduits, raceways, and boxes; and the entire metallic enclosure system must form an electrically continuous conductor. If different portions of a conduit or raceway system or sleeving for cables are exposed to widely different temperatures, as in refrigerating or cold-storage plants, or for passages from outdoors to indoor areas using conditioned air, provision must be made to prevent circulation of air through the raceway from a warmer to a colder section by sealing.

339. Protection against corrosion and deterioration. Raceways, cable trays, cablebus, auxiliary gutters, cable armor, boxes, cable sheathing, cabinets, elbows, couplings, fittings, supports, and support hardware shall be of materials suitable for the environment in which they are to be installed.

1. Ferrous raceways, cable trays, cablebus, auxiliary gutters, cable armor, boxes, cable sheathing, cabinets, metal elbows, couplings, fittings, supports, and support hardware shall be suitably protected against corrosion inside and outside (except threads at joints) by a coating of approved corrosion-resistant material, such as zinc, cadmium, or enamel. If protected from corrosion solely by enamel, they shall not be used outdoors or in wet locations as described in Par. 4. Where boxes or cabinets have an approved system of organic coatings and are marked "Raintight," "Rainproof," or "Outdoor type," they may be used outdoors. Where corrosion protection is necessary and conduit is threaded in the field, the threads shall be coated with an approved electrically conductive, corrosion-resistant compound. Stainless steel is not required to have protective coatings.

Unless made of materials judged suitable for the condition or unless corrosion protection approved for the condition is provided, ferrous or nonferrous metal raceways, cable armor, boxes, cable sheathing, cabinets, elbows, couplings, nipples, fittings, supports, and support hardware shall not be installed in concrete or in direct contact with the earth or in areas subject to severe corrosive influences.

2. Aluminum raceways, cable trays, cablebus, auxiliary gutters, cable armor, boxes, cable sheathing, cabinets, elbows, couplings, nipples, fittings, supports, and support hardware embedded or encased in concrete or in direct contact with the earth shall be provided with supplementary corrosion protection.
3. Nonmetallic raceways, cable trays, cablebus, auxiliary gutters, boxes, cables with a nonmetallic outer jacket and internal metal armor or jacket, cable sheathing, cabinets,

elbows, couplings, nipples, fittings, supports, and support hardware shall be made of material approved for the condition. Where exposed to sunlight, the materials shall be either listed or identified as sunlight resistant. Where subject to exposure to chemical solvents, vapors, splashing, or immersion, materials or coatings shall be either inherently resistant to chemicals based on their listing or be identified for the specific chemical reagent.

4. In portions of dairies, laundries, canneries, and other indoor wet locations, and in locations where walls are frequently washed or where there are surfaces of absorbent materials, such as damp paper or wood, the entire wiring system where installed exposed, including all boxes, fittings, conduits, and cable used therewith, shall be mounted so that there is at least a 6 mm ($\frac{1}{4}$ in.) air space between it and the wall or supporting surface except for nonmetallic boxes and raceway systems installed on nonabsorbent surfaces such as concrete, masonry, or tile.

340. Outlet boxes (see Div. 4) must be provided at each outlet, switch, or junction point for all wiring systems except open wiring. The boxes must be made of metallic material, except that for open wiring on insulators, concealed knob-and-tube wiring, nonmetallic-sheathed or similar cables with entirely nonmetallic sheaths, flexible cords, or nonmetallic raceways the boxes may be of nonmetallic construction. Nonmetallic boxes are permitted with metallic wiring methods if internal bonding is provided between all entries, such as the use of bonding bushings on metallic conduit or tubing entries. In addition, specialized nonmetallic boxes with integral bonding provisions, such as those with embedded metal framework in fiberglass enclosures developed for hazardous locations that are also corrosive, are permitted with metal wiring methods. These boxes must have a means provided within the enclosure to attach an equipment bonding jumper. Whenever a change is made from open or concealed knob-and-tube wiring to one of the other types of wiring, a box or terminal fitting which has a separately bushed hole for each conductor must be used. In terminating conduit wiring at switchboards and control-apparatus locations an insulating bushing instead of a box may be used. If conductors are lead-covered, the bushing need not be insulated.

Care must be exercised in installing boxes and fittings in damp or wet locations so that they are either placed or equipped to prevent moisture or water from entering and accumulating within the box or fitting. In wet locations the boxes or fittings must be listed for use in wet locations.

Round outlet boxes are not allowed when conduits or connectors requiring the use of locknuts or bushings are to be connected to the side of the box.

341. Supports. Boxes shall be securely and rigidly fastened to the surface upon which they are mounted or securely and rigidly embedded in concrete or masonry. Except as otherwise provided in this section, boxes shall be supported from a structural member of the building either directly or by using a metal, polymeric, or wooden brace. If of wood, the brace shall not be less than nominal 25 mm \times 50 mm (1 in. \times 2 in.) thickness. If of metal, it shall be corrosion-resistant and shall be not less than 0.51 mm (0.020 in.) uncoated.

When mounted in new walls in which no structural members are provided or in existing walls in previously occupied buildings, boxes shall be affixed with approved anchors or clamps so as to provide a rigid and secure installation.

Enclosures not exceeding 1650 cm³ (100 in³) in size which do not contain devices, receptacles, or switches and do not support luminaires (fixtures) may be considered adequately supported if two or more conduits are threaded into the box wrenchtight and are supported

within 900 mm (3 ft) of the box on two or more sides; or boxes or conduit bodies containing devices or supporting luminaires may be supported by the connecting conduit when at least two connecting conduits are threaded into the box and rigidly supported within 450 mm (18 in.) of the junction box. The conduit entries must be at hubs that are an integral part of the box or that are identified for the purpose if added in the field. Conduit bodies that are no larger than the largest entering raceway and contain no splices do not require independent support.

342. Ceiling outlet boxes may be supported with wood screws projecting through the holes in the bottom of the box, in frame construction when a wood background is available. If boxes must be supported between wooden beams, bar hangers as shown in Sec. 119 of Div. 4 are used. The hangers are fastened with nails or wood screws to the beams. The box is fastened to the hanger by means of the fixture stud or with two bolts. With concealed conduit wiring in reinforced-concrete ceilings the conduits and the edges of the backing plate of the concrete boxes, bearing against the concrete, support the box. With terra-cotta ceilings a tee made of $\frac{3}{8}$ -in pipe substantially bearing on the top of the terra-cotta should be used (Fig. 9.250). The pipe projects through the fixture-stud knockout in the back of the box and forms the fixture stud. For exposed wiring on concrete ceilings, screws and lead expansion sleeves should be used. For exposed wiring on steelwork the box should be bolted or clamped to the steel. For exposed wiring on plastered ceilings the box may be fastened on the surface with toggle bolts.

343. Wall outlet boxes in frame construction are fastened to the studs with side hangers which form part of the box (see Sec. 117, Div. 4). With concealed wiring in concrete or brick walls the masonry, being built tight around the box, supports it. The conduit prevents the box from coming loose from the wall. If a pocket has been cut in a brick wall to receive an outlet box and the wall has been channeled for the conduit, the box should be fastened to the wall by two expansion sleeves. With concealed wiring in concrete construction, for the support of a fixture which is too heavy to be safely hung on an ordinary $\frac{3}{8}$ -in fixture stud, the outlet box should be supported by a pipe support similar to that of Fig. 9.250, embedded in the concrete. For exposed wiring on concrete and brick walls the box may be fastened with wood screws in lead expansion sleeves.

344. Luminaires (lighting fixtures) are usually supported from the fixture stud in the outlet box (Fig. 9.251). A hickey is screwed onto the fixture stud, and the fixture stem is screwed into the hickey. The fixture wires are brought out of the fixture stem through the holes in the hickey and spliced to the circuit wires. The canopy is then slipped up against the ceiling and fastened to the fixture stem with a setscrew. In many cases it is preferable to use outlet boxes which have the fixture stud made integral with the back of the box. In case that type of box is not available, a separate fixture stud (Fig. 9.252) may be installed. The no-bolt type (Fig. 9.252, I) is used for supporting the box from a bar hanger. The body of the stud is on the back of the hanger with the threaded portion projecting through the hanger and through a hole in the center of the box. The nut is screwed on the stud inside the box and holds the box to the hanger. The bolted type (Fig. 9.252, II) either is bolted to the back of the box or, when the box is supported from a wooden member, is held in place with wood screws. The NEC requires that a fixture

FIGURE 9.252 Fixture studs.

which weighs more than 3 kg (6 lb) or exceeds 400 mm (16 in.) in any dimension must not be supported by the screw shell of the lampholder. Small lighting fixtures consisting of a lampholder and a small shade may be supported from a pendant cord. In this case a box cover with a round hole in the center is used. A knot is tied in the cord inside the box (Fig. 9.249) so that the knot will bear against the cover and support the weight of the fixture. With exposed conduit wiring, elbow or tee conduit fittings are frequently used. The fixture is supported with a short length of conduit which threads into the fixture and into the hub which projects down from the fitting. Sometimes the upper part of the fixture is designed to be fastened to the cover on a 3¹/₄- or 4-in outlet box. A fixture which weighs more than 23 kg (50 lb) must be supported independently of the outlet box unless the outlet box is listed for the weight to be supported. Figure 9.253 shows a typical method of attaching a lightweight fixture to a nonmetallic box.

FIGURE 9.253 Method of securing and connecting a lightweight fixture to a nonmetallic box.

345. Number of conductors in outlet, device, and junction boxes, and conduit bodies. Boxes and conduit bodies shall be of sufficient size to provide free space for all enclosed conductors. In no case shall the volume of the box, as calculated in 1. below, be less than the fill calculation as calculated in 2. below. The minimum volume for conduit bodies shall be as calculated in 3. below.

The provisions of this section shall not apply to terminal housings supplied with motors. Boxes and conduit bodies enclosing conductors, size No. 4 or larger, shall also comply with the provisions of Sec. 314.28 of the NEC.

1. **Box volume calculations.** The volume of a wiring enclosure (box) shall be the total volume of the assembled sections, and, where used, the space provided by plaster rings, domed covers, extension rings, etc., that are marked with their volume or are made from boxes the dimensions of which are listed in Table 314.16(A) of the NEC.
 - a. **Standard Boxes.** The volumes of standard boxes that are not marked with a cubic inch capacity shall be as given in Table 314.16(A) of the NEC.
 - b. **Other Boxes.** Boxes 1650 cm³ (100 in³) or less, other than those described in Table 314.16(A) of the NEC, and nonmetallic boxes shall be durably and legibly marked by the manufacturer with their volume. Boxes described in Table 314.16(A) of the NEC

that have a larger volume than is designated in the table shall be permitted to have their volume marked as required by this section.

2. Box fill calculations. The volumes in paragraphs a. through e. below, as applicable, shall be added together. No allowance shall be required for small fittings such as lock-nuts and bushings.

a. Conductor Fill. Each conductor that originates outside the box and terminates or is spliced within the box shall be counted once, and each conductor that passes through the box without splice or termination shall be counted once. The conductor fill, in cubic inches, shall be computed using Table 314.16(B) of the NEC. A conductor, no part of which leaves the box, shall not be counted.

Exception. Where an equipment grounding conductor or not over four fixture wires smaller than No. 14, or both, enter a box from a domed luminaire (fixture) or similar canopy and terminate within that box, it shall be permitted to omit these conductors from the calculations.

b. Clamp Fill. Where one or more internal cable clamps, whether factory or field supplied, are present in the box, a single volume allowance in accordance with Table 314.16(B) of the NEC shall be made based on the largest conductor present in the box. No allowance shall be required for a cable connector with its clamping mechanism outside the box.

c. Support Fittings Fill. Where one or more luminaire (fixture) studs or hickies are present in the box, a single volume allowance in accordance with Table 314.16(B) of the NEC shall be made for each type of fitting based on the largest conductor present in the box.

d. Device or Equipment Fill. For each yoke or strap containing one or more devices of equipment, a double volume allowance in accordance with Table 314.16(B) of the NEC shall be made for each yoke or strap based on the largest conductor connected to a device(s) or equipment supported by that yoke or strap. If the supported item is wide enough such that it cannot be installed in a single-gang box as listed in Table 314.16(A), such as 3-pole 4-wire grounding 125/250-V, 30- or 50-A receptacles commonly used for ranges and clothes dryers, then the allowances will be calculated based on the required number of gangs. In the example given a two-gang box would be required for mounting, and therefore there would be a double allowance for each of the two required gangs, for a total of four allowances.

e. Equipment Grounding Conductor Fill. Where one or more equipment grounding conductors enters a box, a single volume allowance in accordance with Table 314.16(B) of the NEC shall be made based on the largest equipment grounding conductor present in the box. Where an additional set of equipment grounding conductors, as permitted by Section 250.146(D) in the NEC is present in the box, an additional volume allowance shall be made based on the largest equipment grounding conductor in the additional set.

3. Conduit Bodies. Conduit bodies enclosing No. 6 conductors or smaller other than short radius conduit bodies as described in Sec. 314.5 of the NEC shall have a cross-sectional area not less than twice the cross-sectional area of the largest conduit or tubing to which it is attached. The maximum number of conductors permitted shall be the maximum number permitted by Table 29 of Div. 12 for the conduit to which it is attached.

Conduit bodies shall not contain splices, taps, or devices unless they are durably and legibly marked by the manufacturer with their volume. The maximum number of conductors shall be computed using the same procedure for similar conductors in other than standard boxes. Conduit bodies shall be supported in a rigid and secure manner.

346. Conductors entering boxes or fittings (National Electrical Code). Conductors entering boxes, conduit bodies, or fittings shall be protected from abrasion and conform to the following:

1. *Openings to be closed.* Openings through which conductors enter shall be adequately closed.
2. *Metal boxes and conduit bodies.* If metal outlet boxes, or conduit bodies, are used with open wiring or concealed knob-and-tube work, conductors shall enter through insulating bushings or, in dry places, through flexible tubing extending from the last insulating support and firmly secured to the box or conduit body. Where raceway or cable is used with metal outlet boxes or conduit bodies, the raceway or cable shall be secured to such boxes and conduit bodies.

Nonmetallic Boxes. Nonmetallic boxes shall be suitable for the lowest-temperature-rated conductor entering the box. Where nonmetallic boxes are used with open wiring or concealed knob-and-tube wiring, the conductors shall enter the box through individual holes. Where flexible tubing is used to encase the conductors, the tubing shall extend from the last insulating support to no less than 6 mm ($\frac{1}{4}$ in.) beyond any cable clamps inside the box. Where nonmetallic-sheathed cable or multiconductor type UF is used, the cable assembly, including the sheath, shall extend into the box no less than $\frac{1}{4}$ in. through a nonmetallic-sheathed cable clamp. Where nonmetallic-sheathed cable is used with nominally sized 57 by 100 mm ($2\frac{1}{4}$ - by 4-in.) boxes mounted in walls or ceilings and the cable is fastened within 200 mm (8 in.) of the box measured along the sheath and where the sheath extends into the box no less than 6 mm ($\frac{1}{4}$ in.), securing the cable to the box shall not be required. In all instances all permitted wiring methods shall be secured to nonmetallic boxes. Conductors 4 AWG and larger are covered in Sec. 300.4(G) of the NEC.

347. Location. Conduit bodies and junction, pull, and outlet boxes shall be so installed that the wiring contained in them can be rendered accessible without removing any part of the building or, in underground circuits, without excavating sidewalks, paving earth, or other substance that is to be used to establish the finished grade.

Exception. Listed boxes shall be permitted where covered by gravel, light aggregate, or noncohesive granulated soil if their location is effectively identified and accessible for excavation.

In walls or ceilings of concrete, tile, gypsum, plaster or other noncombustible material (National Electrical Code), boxes shall be so installed that the front edge of the box will not set back of the finished surface more than 6 mm ($\frac{1}{4}$ in.). In walls and ceilings constructed of wood or other combustible material, outlet boxes shall be flush with the finished surface or project therefrom.

348. Covers and canopies (National Electrical Code). In completed installations each outlet box shall be provided with a cover, faceplate, lampholder, or luminaire fixture canopy, except where the installation complies with 410.24(B).

1. Nonmetallic or metal covers and plates may be used with nonmetallic outlet boxes. Where metal covers or plates are used, they are subject to the grounding requirements of Sec. 404.9(B) of the NEC.

2. If a luminaire (fixture) canopy or pan is used, any combustible wall or ceiling finish exposed between the edge of the canopy or pan and the outlet box shall be covered with noncombustible material.
3. Covers of outlet boxes and conduit bodies having holes through which flexible-cord pendants pass shall be provided with bushings designed for the purpose or shall have smooth, well-rounded surfaces on which the cords may bear. So-called hard-rubber or composition bushings shall not be used.

349. Pull and junction boxes (National Electrical Code). Boxes and conduit bodies used as junction boxes shall conform to the following:

1. **Minimum Size.** For raceways containing conductors of 4 AWG or larger (if required to be insulated), and for cables* containing conductors of 4 AWG or larger, the minimum dimensions of a pull or junction box installed in a raceway or cable run shall conform to the following:
 - a. *Straight pulls.* In straight pulls the length of the box shall be not less than 8 times the trade diameter of the largest raceway.
 - b. *Angle or U pulls, or Splices.* Where angle or U pulls, or splices are made, the distance between each raceway entry inside the box and the opposite wall of the box shall not be less than 6 times the trade diameter of the largest raceway in a row. This distance shall be increased for additional entries by the amount of the sum of the diameters of all other raceway entries in the same row on the same wall of the box. Each row shall be calculated individually, and the single row that provides the maximum distance shall be used.

Exception. Where a raceway or cable entry is in the wall of a box or conduit body opposite a removable cover and where the distance from that wall to the cover is in conformance with the column for one wire per terminal in Table 312.6(A) in the NEC.

The distance between raceway entries enclosing the same conductor shall not be less than 6 times the trade diameter of the larger raceway.

- c. Boxes or conduit bodies of lesser dimensions than those required in Subpars. *a* and *b* of this section may be used for installations of combinations of conductors that are less than the maximum conduit or tubing fill (of conduits or tubing being used) permitted by Table 1 of Chap. 9 of the NEC, provided that the box has been listed for and is permanently marked with the maximum number of conductors and the maximum AWG size permitted.

Exception. Terminal housings supplied with motors which shall comply with the provisions of Sec. 430.12 of the Code.

2. **Conductors in Pull or Junction Boxes.** In pull boxes or junction boxes having any dimension over 1.8 m (6 ft), all conductors shall be cabled or racked up in an approved manner.

*When transposing cable size into raceway size in Subpars. *a* and *b*, the minimum trade-size raceway required for the number and size of conductors in the cable shall be used.

3. **Covers.** All pull boxes, junction boxes, and conduit bodies, shall be provided with covers compatible with the box or conduit body construction and suitable for the conditions of use. Where metal covers are used, they shall comply with the grounding requirements of Sec. 250.110 of the NEC.
4. **Permanent Barriers.** Where permanent barriers are installed in a box, each section shall be considered as a separate box.

350. Cabinets, cutout boxes, and meter socket enclosures. The field-wiring requirements of the NEC with respect to cabinets, cutout boxes, and meter socket enclosures are as follows:

1. **Damp or Wet Locations.** In damp or wet locations, surface-type enclosures shall be so placed or equipped as to prevent moisture or water from entering and accumulating within the cabinet or cutout box and shall be mounted so there is at least a 6 mm ($1/4$ in.) air space between the enclosure and the wall or other supporting surface. Enclosures installed in wet locations shall be weatherproof. Nonmetallic cabinets and cutout boxes may be installed without the air space on a concrete, masonry, tile, or similar surface. Raceways or cables entering enclosures in wet locations must use entrance fittings listed for wet locations if the entry point is above the level of uninsulated live parts.
2. **Position in Wall.** In walls of concrete, tile, or other noncombustible material, cabinets shall be so installed that the front edge of the cabinet will not set back of the finished surface more than 6 mm ($1/4$ in.). In walls constructed of wood or other combustible material, cabinets shall be flushed with the finished surface or project therefrom.
3. **Repairing Noncombustible Surfaces.** Noncombustible surfaces that are broken or incomplete shall be repaired so there will be no gaps or open spaces greater than 3 mm ($1/8$ in.) at the edge of the cabinet or cutout box employing a flush-type cover.
4. **Conductors Entering Cabinets or Cutout Boxes.** Conductors entering cabinets or cutout boxes shall be protected from abrasion and shall conform to the following:
 - a. **Openings to be closed.** Openings through which conductors enter shall be adequately closed.
 - b. **Metal cabinets cutout boxes and meter socket enclosures.** If metal enclosures are used with open wiring or concealed knob-and-tube wiring, conductors shall enter through insulating bushings or, in dry locations, through flexible tubing extending from the last insulating support and firmly secured to the cabinet, cutout box or meter socket enclosure.
 - c. **Cables.** Where cable is used, each cable shall be secured to the enclosure. An elaborate exception to this rule covers the acceptable use of a raceway sleeve to entrain a group of nonmetallic cables into an enclosure. These rules are covered in detail in Sec. 85 of Div. 4.
5. **Deflection of Conductors.** Conductors at terminals or conductors entering or leaving cabinets or cutout boxes and the like shall conform to the following:
 - a. **Width of wiring gutters.** Conductors in parallel shall be judged on the basis of the number of conductors in parallel. Conductors shall not be deflected within a cabinet or cutout box unless a gutter having a width in accordance with Table 312.6(A) of the NEC is provided. Conductors in parallel in accordance with 310.4 shall be judged on the basis of the number of conductors in parallel.
 - b. **Wire Bending Space at Terminals.** Wire bending space at each terminal shall be provided in accordance with 1. or 2. below.
 1. **Conductors Not Entering or Leaving Opposite Wall.** Table 312.6(A) of the NEC (see Div.12, Table 33) shall apply where the conductor does not enter or leave the enclosure through the wall opposite its terminal.

2. *Conductors Entering or Leaving Opposite Wall.* Table 312.6(B) of the NEC (see Div. 12, Table 34) shall apply where the conductor enters or leaves the enclosure through the wall opposite its terminal. This table requires greater spacings, but there are two exceptions:

a. Where the distance between the wall and its terminal is in accordance with Table 312.6(A), a conductor shall be permitted to enter or leave an enclosure through the wall opposite its terminal provided the conductor enters or leaves the enclosure where the gutter joins an adjacent gutter that has a width that conforms to Table 312.6(B) of the NEC for that conductor.

b. A conductor not larger than 350 kcmil shall be permitted to enter or leave an enclosure containing only a meter socket(s) through the wall opposite its terminal, provided the terminal is a lay-in type where either:

1. The terminal is directed toward the opening in the enclosure and is within a 45° angle of directly facing the enclosure wall, or

2. The terminal is directly facing the enclosure wall and offset is not greater than 50 percent of the bending space specified in Table 312.6(A) of the NEC.

NOTE: Offset is the distance measured along the enclosure wall from the axis of the centerline of the terminal to a line passing through the center of the opening in the enclosure.

c. *Insulated fittings.* In accordance with NEC 300.4(G), where raceways contain 4 AWG insulated circuit conductors and these conductors enter a cabinet, box, enclosure, or raceway, the conductors shall be protected by a substantial bushing providing a smoothly rounded insulating surface unless the conductors are separated from the raceway fitting by substantial insulating material securely fastened in place. If conduit bushings are constructed wholly of insulating material, a locknut shall be provided both inside and outside the enclosure to which the conduit is attached. The insulating bushing or insulating material shall have a temperature rating not less than the insulation temperature rating of the installed conductors.

Exception. Where threaded hubs or bosses that are an integral part of a cabinet, box enclosure, or raceway provide a smoothly rounded or flared entry for conductors.

d. Wire bending space in enclosures for motor controllers with provisions for one or two wires per terminal is covered by Sec. 430.10(B) of the NEC.

6. *Space in Enclosures.* Cabinets and cutout boxes shall conform to the following:

a. Cabinets and cutout boxes shall have sufficient space to accommodate all conductors installed in them without crowding.

b. *Enclosures for Switches or Overcurrent Devices.* Enclosures for switches or overcurrent devices shall not be used as junction boxes, auxiliary gutters, or raceways for conductors feeding through or tapping off to other switches or overcurrent devices unless adequate space for this purpose is provided. The conductors shall not fill the wiring space at any cross section to more than 40 percent of the cross-sectional area of the space, and the conductors, splices, and taps shall not fill the wiring space at any cross section to more than 75 percent of the cross-sectional area of that space.

7. *Side- or Back-Wiring Spaces or Gutters.* Cabinets and cutout boxes shall be provided with back-wiring spaces, gutters, or wiring compartments as required by Sec. 312.11(C) and (D) of the Code.

351. Auxiliary gutters (National Electrical Code). Auxiliary gutters, used to supplement wiring spaces at meter centers, distribution centers, switchboards, and similar points of wiring systems, may enclose conductors or busbars but shall not be used to enclose

switches, overcurrent devices, appliances, or other similar equipment. Refer to Sec. 28 for general information, including distinctions between auxiliary gutters and wireways. They are available in both sheet metal and flame-retardant nonmetallic forms. The enclosures have hinged or removeable covers for housing and protecting electrical wires, cables, and busbars. The enclosures are designed for conductors to be laid in place after the enclosures have been installed as a complete system.

1. **Uses not Permitted.** An auxiliary gutter shall not extend a greater distance than 9 m (30 ft) beyond the equipment which it supplements, except in elevator work. Any further extension shall comply with the rules for wireways or busways. Auxiliary gutters must not be used to enclose switches, overcurrent devices, appliances, or other similar equipment.
2. **Supports.** Sheet metal gutters shall be supported throughout their length at intervals not exceeding 1.5 m (5 ft). Nonmetallic auxiliary gutters shall be supported at intervals not to exceed 900 mm (3 ft) and at each end or joint, unless listed for other support intervals. In no case shall the distance between supports exceed 3 m (10 ft).
3. **Covers.** Covers shall be securely fastened to the gutter.
4. **Number of Conductors.** The sum of the cross-sectional areas of all contained conductors at any cross section of sheet metal and nonmetallic auxiliary gutters shall not exceed 20 percent of the interior cross-sectional area of the gutter. Sheet metal auxiliary gutters shall not contain more than 30 conductors at any cross section unless the conductors are made subject to the derating factors in 310.15(B)(2)(a). Signaling circuit or controller conductors between a motor and its starter and used only for starting duty are not considered current-carrying conductors. Nonmetallic auxiliary gutters are subject to the same fill limitations.
5. **Ampacity of Conductors.** Where the number of current-carrying conductors contained in a sheet metal auxiliary gutter is 30 or fewer, the adjustment factors specified in 310.15(B)(2)(a) of the NEC, shall not apply. If the number of current-carrying conductors, including neutral conductors classified as current carrying under the provisions of 310.15(B)(4), exceeds 30, the derating factors specified in 310.15(B)(2)(a) of the NEC, shall be applicable to all current-carrying conductors in the sheet metal auxiliary gutter. The current carried continuously in bare copper bars in auxiliary gutters shall not exceed 1.5 A/mm^2 (1000 A/in^2) of cross section of the conductor. For bare aluminum bars, the current carried continuously is limited to 1.09 A/mm^2 (700 A/in^2). Nonmetallic auxiliary gutters do not have any exemption from the 310.15(B)(2)(a) derating factors, so for them, derating applies anytime the current-carrying conductors exceed three, just as for tubular raceways.
6. **Clearance of Bare Live Parts.** Bare conductors shall be securely and rigidly supported so that the minimum clearance between bare current-carrying metal parts of different potential mounted on the same surface shall be not less than 50 mm (2 in.) or less than 25 mm (1 in.) for parts that are held free in the air. A spacing not less than 1 in. shall be secured between bare current-carrying metal parts and any metal surface. Adequate provision shall be made for expansion and contraction of busbars.
7. **Splices and Taps.** Splices and taps shall conform to the following:
 - a. Splices or taps, made and insulated by approved methods, may be located within gutters if they are accessible by means of removeable covers or doors. The conductors, including splices and taps, shall not fill the gutter to more than 75 percent of its area.
 - b. Taps from bare conductors shall leave the gutter opposite their terminal connections and conductors shall not be brought in contact with uninsulated current-carrying parts of different potential.

- c. All taps shall be suitably identified at the gutter as to the circuit or equipment which they supply.
 - d. Tap connections from conductors in auxiliary gutters shall be provided with over-current protection in conformity with the provisions of Secs. 319 and 320.
- 8. Construction and Installation.** Auxiliary gutters shall comply with the following:
- a. Gutters shall be so constructed and installed that adequate electrical and mechanical continuity of the complete raceway system will be secured.
 - b. Gutters shall be of substantial construction and shall provide a complete enclosure for the contained conductors. All surfaces, both interior and exterior, shall be suitably protected from corrosion. Corner joints shall be made tight, and if the assembly is held together by rivets, bolts or screws, these shall be spaced not more than 300 mm (12 in.) apart.
 - c. Suitable bushings, shields, or fittings having smooth, rounded edges shall be provided where conductors pass between gutters, through partitions, around bends, between gutters and cabinets or junction boxes, and at other locations where necessary to prevent abrasion of the insulation of the conductors.
 - d. Where insulated conductors are deflected within the auxiliary gutter, either at the ends or where conduits, fittings, or other raceways or cables enter or leave the gutter, or where the direction of the gutter is deflected more than 30°, dimensions correspond to those required for one wire per terminal in cabinets and cutout boxes as given in Sec. 312.6(A) of the Code (reproduced in Div. 12, Table 33). If a short section of the auxiliary gutter is used as a pull box, the spacing rules in Sec. 349 apply for both straight and angle pulls.
 - e. Sheet metal auxiliary gutters installed indoors or outdoors in wet locations shall be suitable for such locations.
 - 1. Nonmetallic auxiliary gutters installed outdoors shall:
 - a. Be listed and marked as suitable for exposure to sunlight; and
 - b. Be listed and marked as suitable for use in wet locations; and
 - c. Be listed for the maximum ambient temperature of the installation, and marked for the installed conductor insulation temperature rating.
 - d. Have expansion fittings installed where the expected length change due to expansion and contraction due to temperature change is more than 6 mm (0.25 in.).
 - 2. Nonmetallic auxiliary gutters installed indoors shall:
 - a. Be listed for the maximum ambient temperature of the installation and marked for the installed conductor insulation temperature rating.
 - b. Have expansion fittings installed where expected length change due to expansion and contraction due to temperature change is more than 6 mm (0.25 in.).
- 9. Grounding.** Grounding shall be in accordance with Article 250.

352. There are two types of grounds in interior-wiring systems:

1. System grounds (grounding electrode conductors)
2. Equipment and conductor-enclosure grounds

A system ground refers to the condition of having one wire of a circuit connected to ground. The reason for doing this is explained in Secs. 132 and 133, Div. 8.

An equipment or conductor-enclosure ground refers to connecting the noncurrent-carrying metal parts of the wiring system or equipment to ground. This is done so that the metal parts with which a person might come in contact are always at or near ground potential. With this condition there is less danger that a person touching the equipment or conductor

enclosure will receive a shock. Also metal conduit, raceways, and boxes may be in contact with metal parts of the building at several points. If an accidental contact occurs between an ungrounded conductor and its metal enclosure, a current may flow to ground through a stray path made up of sections of metal lath, metal partitions, piping, or other similar conductors. If the equipment is grounded, the resistance of the path through the grounding conductor will usually be much less than the resistance through the stray path, and not much current will flow through the stray path. Sufficient current will usually flow through the grounded path to blow the circuit fuse or trip the circuit breaker and thus open the circuit until repairs can be made. On the other hand, if the equipment is not grounded, sufficient current may flow through the stray path to heat up some section to a sufficient temperature to ignite wood or other flammable material with which it is in contact. The current may not be sufficient to operate the fuse or circuit breaker, especially if the contact occurs on large-size feeders.

353. The following items of equipment and conductor enclosures must be connected to the equipment grounding conductor:

1. ***Metal Conductor Enclosures.*** Unless exempted by the provisions of 3i, in general all such enclosures shall be connected to the equipment grounding conductor. There are limited exceptions, including runs of less than 7.5 m (25 ft), that are extensions of existing installations comprising wiring methods that do not include an equipment grounding conductor, that are free from probable contact with ground, grounded metal, metal lath, or other conductive material, and that are guarded against contact by persons. Short sections of metal enclosures or raceways used to provide support or protection of cable assemblies from physical damage need not be grounded, and metal elbows installed in nonmetallic raceway runs need not be grounded if the metal elbow is isolated from contact by direct burial to a depth of not less than 450 mm (18 in.) measured from all points of the elbow, or by concrete encasement not less than 50 mm (2 in.) thick.
2. ***Fixed Equipment: General.*** Under any of the following conditions, exposed noncurrent-carrying metal parts of fixed equipment, which are likely to become energized, shall be connected to an equipment grounding conductor
 - a. Where equipment is supplied by means of a wiring method that provides an equipment grounding conductor except as noted in 1. above.
 - b. Where equipment is located in a wet or damp location and is not isolated.
 - c. Where equipment is located within 2.5 m (8 ft) vertically and 1.5 m (5 ft) horizontally of grounded objects or ground and within reach of persons.
 - d. Where equipment is in a hazardous location.
 - e. Where equipment operates with any terminal at more than 150 V to ground.
 - f. The following are exceptions to these rules requiring grounding connections:
 - (1) Metal frames of electrically heated appliances, exempted by special permission, in which case these metal frames shall be permanently and effectively insulated from ground
 - (2) Transformers and capacitor cases and other distribution apparatus mounted on wooden poles at a height of more than 2.5 m (8 ft) from the ground
 - (3) Listed equipment protected by a system of double insulation, or its equivalent, is not required to be grounded. Where such a system is used, the equipment shall be distinctively marked.
3. ***Fixed Equipment: Specific.*** Exposed noncurrent-carrying metal parts of the kinds of equipment listed in *a* through *k*, and enclosures listed in *l* and *m* even where not exposed, shall be connected to the equipment grounding conductor regardless of voltage:

- a. Switchboard frames and structures supporting switching equipment, except that frames of 2-wire dc switchboards need not be grounded where effectively insulated from ground.
 - b. Generator and motor frames in an electrically operated pipe organ unless effectively insulated from ground and the motor driving it.
 - c. Frames of motors as specified in Sec. 430.242 of the Code.
 - d. Enclosures for motor controllers unless attached to ungrounded portable equipment.
 - e. Electric equipment of elevators and cranes.
 - f. Electric equipment in commercial garages, theaters, and motion-picture studios, except pendant lampholders on circuits of not more than 150 V to ground.
 - g. Electric signs, outline lighting, and associated equipment.
 - h. Motion-picture projection equipment.
 - i. Equipment supplied by Class 1 circuits shall be grounded unless operating at less than 50 V. Equipment supplied by Class 1 power-limited circuits, by Class 2, and Class 3 remote-control and signaling circuits and by fire alarm circuits shall be grounded when Part II or VIII of Article 250 of the Code requires system grounding of those circuits.
 - j. Luminaires (lighting fixtures) as provided in Part V of Article 410 of the NEC.
 - k. Permanently mounted electrical equipment and skids on skid-mounted equipment grounded with an equipment bonding jumper sized per 250.122.
 - l. Motor-operated water pumps including the submersible type.
 - m. Metal well casings where a submersible pump is used shall be bonded to the pump circuit equipment grounding conductor.
4. **Nonelectrical Equipment.** The following metal parts shall be connected to the equipment grounding conductor:
- a. Frames and tracks of electrically operated cranes and hoists
 - b. The metal frame of a nonelectrically driven elevator car to which electric conductors are attached
 - c. Hand-operated metal shifting ropes or cables of electric elevators

NOTE If extensive metal in or on buildings may become energized and is subject to personal contact, adequate bonding and grounding will provide additional safety.

5. **Equipment Connected by Cord and Plug.** Under any of the following conditions, exposed noncurrent-carrying metal parts of cord- and plug-connected equipment which are likely to become energized shall be connected to the equipment grounding conductor:
- a. In hazardous locations (see Articles 500 to 517 of the Code).

Exception. Listed tools, listed appliances, and listed equipment covered in “b” through “d” and protected by a system of double insulation or its equivalent need not be grounded. Where such a system is employed, the equipment shall be distinctively marked.

- b. Where operated at more than 150 V to ground, except:
 - (1) Motors, where guarded
 - (2) Metal frames of electrically heated appliances exempted by special permission, in which case the frames shall be insulated from ground.
- c. In residential occupancies, (1) refrigerators, freezers, and air conditioners; (2) clothes-washing, clothes-drying, and dish-washing machines, waste disposers, information technology equipment, sump pumps, and electrical aquarium equipment; and (3) hand-held, motor-operated tools and motor-operated appliances of the following types: hedge clippers, lawn mowers, snowblowers, and wet scrubbers; and (4) portable hand lamps.

Portable tools or appliances are not intended to be used in damp, wet, or conductive locations unless they are grounded, double-insulated, or supplied by an isolation transformer.

- d.* In other than residential occupancies, (1) refrigerators, freezers, and air conditioners; (2) clothes-washing, clothes-drying, and dish-washing machines, information technology equipment, sump pumps, and electrical aquarium equipment; (3) hand-held, motor-operated tools, stationary and fixed motor-operated tools, and light-industrial motor-operated tools; (4) motor-operated appliances of the following types: hedge clippers, lawn mowers, snowblowers, and wet scrubbers; (5) portable hand lamps; (6) cord- and plug-connected appliances used in damp or wet locations or by persons standing on the ground or on metal floors or working inside metal tanks or boilers; (7) tools that are likely to be used in wet and conductive locations.

Exception. Tools and portable hand lamps that are likely to be used in wet and conductive locations need not be grounded when supplied through an isolating transformer with an ungrounded secondary of not over 50 V.

354. The types of wiring systems required to have a system ground are as follows:

1. Two-wire dc systems of not more than 300 V supplying premises wiring unless the system supplies industrial equipment in limited areas and is equipped with a ground detector as described in Div. 1. A system operating at 50 V or less between conductors need not be grounded.
Rectifier-derived dc systems supplied by an ac system complying with Sec. 250.20 of the Code and dc fire alarm circuits having a maximum current of 0.030 A need not be grounded.
2. Three-wire dc systems supplying premises wiring.
3. AC systems, provided the grounded conductor can be so arranged that the maximum voltage to ground is between 50 and 150 V. Systems that are three-phase wye-connected with the neutral conductor used as a current-carrying conductor must be grounded, and three-phase delta-connected systems where the midpoint of one phase winding is used as a circuit conductor, must be grounded. Any uninsulated service conductor must be grounded. AC systems of 1 kV and higher must be grounded when they are used to supply mobile or portable equipment. High-impedance grounded systems are permitted as in Sec. 356.
4. AC systems of less than 50 V if supplied by transformers from systems of more than 150 V to ground, or if the transformer supply system is ungrounded, or if run overhead outside buildings.
5. AC systems of 50 to 1000 V supplying premises wiring of the following types are not required to be grounded; in all instances such ungrounded systems must employ ground detectors:
 - a.* Electric systems used exclusively to supply industrial electric furnaces for melting, refining, tempering, and the like.
 - b.* Separately derived systems used exclusively for rectifiers supplying only adjustable-speed industrial drives.
 - c.* Separately derived systems supplied by transformers that have a primary voltage rating less than 1000 V, provided that all the following conditions are met:
 - (1) The system is used exclusively for control circuits.
 - (2) The conditions of maintenance and supervision assure that only qualified persons will service the installation.
 - (3) Continuity of control power is required.
 - d.* Other systems not required to be grounded in accordance with item (3) above.

355. Circuits which must not be grounded. Circuits for electric cranes operating over combustible fibers in Class III hazardous locations as provided in 503.13 of the NEC (refer to Sec. 383 for description of hazardous locations), isolated circuits in health care facilities, and circuits to electrolytic cells and secondary circuits of lighting systems as provided in 411.5(A) of the NEC.

356 High-impedance grounded-neutral systems (Adapted from Practical Electrical Wiring, 20th ed., © Park Publishing, 2008, all rights reserved) combine the best features of the ungrounded systems in terms of reliability, and the best features of the grounded systems in terms of their ability to dissipate energy surges due to their grounding connection. This procedure is covered in NEC 250.36.

These systems behave like ungrounded systems in that the first ground fault will not cause an overcurrent device to operate. Instead, alarms required by NEC 250.36(2) will alert qualified supervisory personnel. Remember, a capacitor is two conductive plates separated by a dielectric. A plant wiring system consists of miles and miles of wires, all of which are separated by their insulation. This means that a plant wiring system is a giant though very inefficient capacitor, and it will charge and discharge 120 times each second. The resistance is set such that the current under fault conditions is only slightly higher than the capacitive charging current of the system. Since a fault will often continue until an orderly shutdown can be arranged, the resistor must be continuously rated to handle this duty safely.

As shown in Fig. 9.254, the grounding impedance must be installed between the system neutral and the grounding electrode conductor. Where a system neutral is not available, the grounding impedance must be installed between the neutral derived from a grounding transformer and the grounding electrode conductor. The neutral conductor between the neutral point and the grounding impedance must be fully insulated. Size it at 8 AWG minimum. This size is for mechanical concerns; the actual current is on the order of 10 A or less.

Contrary to the normal procedure of terminating a neutral at a service disconnecting means enclosure, when the system is high-impedance grounded, the grounded conductor is prohibited from being connected to ground except through the grounding impedance. In addition, the neutral conductor connecting the transformer neutral point to the grounding impedance is not required to be installed with the phase conductors. It can be installed in a separate raceway to the grounding impedance. The normal procedure (usually performed by the utility) of adding a grounding electrode outside the building at the source of a grounded system (should one be used as the energy source for an impedance-grounded system) must *not* be observed, because any grounding currents returning through the earth to the outdoor electrode will bypass and therefore desensitize the monitor.

An equipment bonding jumper must be installed unspliced from the first system disconnecting means or overcurrent device to the grounded side of the grounding impedance. The grounding electrode conductor can be attached at any point from the grounded side of the grounding impedance to the equipment grounding connection at the service equipment of the first system disconnecting means.

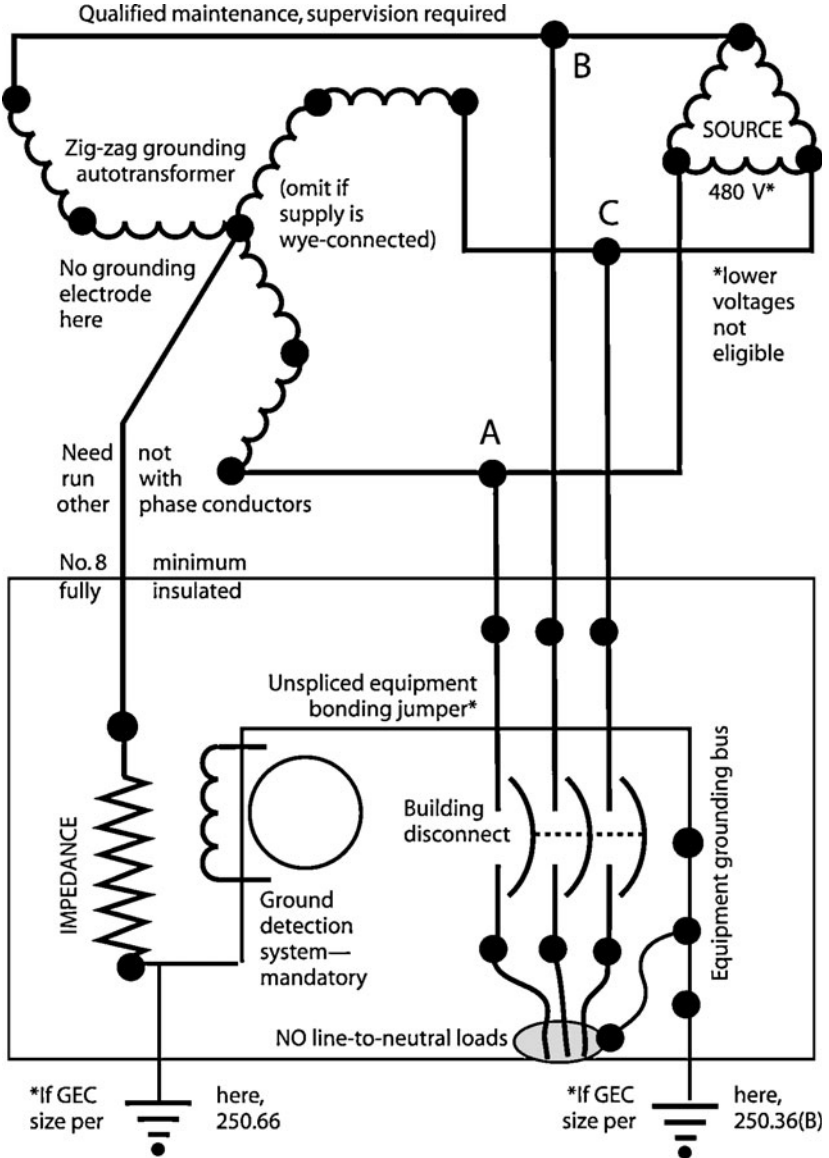

FIGURE 9.254 This drawing shows a likely retrofit on a formerly ungrounded installation, with its neutral conductor created through a zig-zag grounding autotransformer. Note that the size of the equipment bonding jumper depends on the end to which the grounding electrode conductor is connected. A connection at the line (left) end makes the bonding jumper a functional extension of the grounding electrode conductor, and it must be sized accordingly. A connection at the load (right) end makes the bonding jumper a functional extension of the neutral, normally sized at 8 AWG.

357. Location of the system ground (Fig. 9.255)

1. For off premise dc systems the ground must be at the supply station and nowhere else.
2. For ac systems there must be a ground at the secondary of the transformer supplying the system. There must be another ground at each building service to the grounded service conductor at an accessible point from the point of connection of the service drop or service lateral conductor to the service disconnecting means.
3. For multiple buildings served by a single service in one of them, and with other buildings supplied by feeders or branch circuits or both, the system ground must be located at the service. System grounding connections are generally prohibited at all electrically downstream locations from the service connection. Instead, an equipment grounding conductor run with the other supply circuit conductors provides the grounding protection for wiring and equipment in each building. For “existing premises wiring systems only,” a special exception allows downstream system grounding connections, provided there are no parallel metallic return paths that would allow current that should flow over the grounded circuit conductor to instead return to the service through other paths. Examples include an equipment grounding conductor, including a wiring method to the second building that is itself an equipment grounding conductor, such as rigid metal conduit. In such a case a system grounding connection in the second building would send normal circuit current through the conduit in parallel with the enclosed grounded circuit conductor (usually a neutral). Another example would be a metallic water piping system common to both buildings; since such systems must be bonded to the grounding systems in each building the water pipes would become parallel conductors for the same reason.

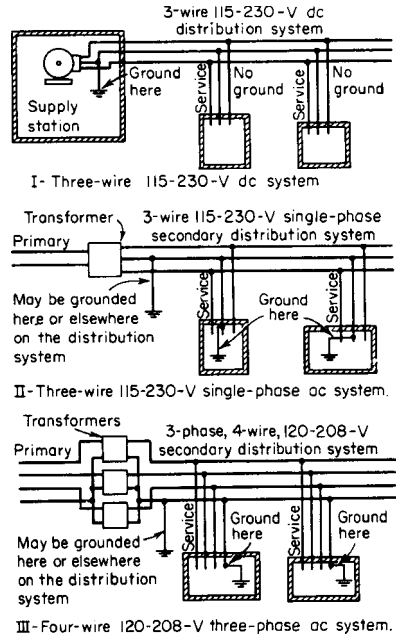

FIGURE 9.255 Location of system grounds.

4. For a separately derived system the common main grounding conductor shall be made at the transformer, generator, or other source of supply or at the switchboard, panelboard, or other disconnecting means location, on the supply side of the first switch controlling the system.

358. The conductor to be grounded. For alternating-current premises-wiring systems the conductor to be grounded shall be as follows:

1. Single-phase two-wire: the grounded-circuit conductor
2. Single-phase three-wire: the neutral conductor
3. Multiphase systems having one wire common to all phases: the common conductor
4. Multiphase systems where one phase is grounded; one phase conductor
5. Multiphase systems in which one phase is used as in Par. 2: the neutral conductor

Grounded conductors shall be identified by the means specified in Article 200 of the NEC.

359. The noncurrent-carrying metallic parts of fixed equipment are considered to be satisfactorily grounded under any one of the following conditions (fixed equipment includes boxes, cabinets, and fittings):

1. They are metallically connected to grounded cable armor or the grounded metal enclosure of conductors in accordance with the applicable provisions of Sec. 250.118 for the wiring method employed.
2. By a grounding conductor run with circuit conductors, this conductor may be uninsulated, but if an individual covering is provided for this conductor, it shall be finished to show a green color.
3. DC electrical equipment secured to and in contact with the grounded structural metal frame of a building may be considered to be grounded; this option is prohibited for ac equipment. On dc circuits, the equipment grounding conductor may run in a separate location than the circuit conductors. Equipment grounding conductors added as part of modern wiring extended from older circuits that have no equipment grounding conductor available may be connected to a remote grounding location as provided in NEC 250.130(C). In such cases the equipment grounding conductor may, of necessity, run apart from the circuit conductors.
4. Metal car frames supported by metal hoisting cables attached to or running over metal sheaves or drums of elevator machines shall be deemed to be grounded if the machine is grounded in accordance with 250.134 of the Code.

360. Portable and/or cord- and plug-connected equipment. The noncurrent-carrying metal parts of cord- and plug-connected equipment required to be grounded may be grounded in one of the following two ways:

1. By means of a grounding conductor run with the power supply conductors in a cable assembly or flexible cord that is properly terminated in a grounding-type attachment plug having a fixed grounding contact.

Exception. The grounding contacting pole of grounding-type ground-fault circuit interrupters may be of the moveable self-restoring type on circuits operating not over 150 V between any two conductors or over 150 V between any conductor and ground.

2. A separate flexible wire or strap, insulated or bare, connected to an equipment grounding conductor and protected as well as practicable against physical damage may be used where part of the equipment.

361. Bonding at service equipment. The electrical continuity of the grounding circuit for the following equipment and enclosures shall be assured by one of the means given in Sec. 362.

1. The service raceways, cable trays, or service cable armor or sheath, except as provided in Sec. 250.84 of the Code for underground service cable
2. All service equipment enclosures containing service-entrance conductors, including meter fittings, boxes, or the like, interposed in the service raceways or armor

362. Continuity at service equipment. Electrical continuity at service equipment shall be assured by one of the following means:

1. Bonding equipment to the grounded service conductor in a manner provided in Sec. 250.8 of the Code
2. Threaded couplings and threaded bosses on enclosures with joints made up wrenchtight
3. Threadless couplings and connector made up tight for rigid and intermediate metal conduit metal-clad cables, and electrical metallic tubing
4. Other listed devices such as bonding locknuts and bushings, or bushings with bonding jumpers

Bonding jumpers meeting the other requirements of NEC Article 250 shall be used around concentric or eccentric knockouts which are punched or otherwise formed so as to impair the electric connection to ground. Standard locknuts or bushings shall not be the sole means used for the bonding required by this section.

363. Intersystem bonding termination provisions must be made at service locations to connect bonding and grounding conductors from other systems, such as telephone and CATV systems. These provisions must also be made at the main disconnecting means for each other building on the premises. The bonding means must be external to service or building disconnect enclosures, accessible for inspections and for system connections, and it must allow for no fewer than three such system connections. It must be so installed that any enclosure on which it is installed, if any, can still be opened for inspection or maintenance. The intersystem bonding termination may be any of the following three items:

- a. A set of terminals listed as grounding and bonding equipment and securely mounted to the meter socket, and electrically connected thereto
- b. A bonding bar near the service equipment enclosure, meter enclosure, or raceway for service conductors, and connected to the equipment grounding bar for the service disconnect or building disconnect as applicable with a bonding conductor not smaller than 6 AWG copper
- c. A bonding bar near the grounding electrode conductor, and connected to the grounding electrode conductor with a bonding conductor not smaller than 6 AWG copper

Existing buildings and structures with comparable intersystem bonding means already installed may continue to use those earlier methods.

364. The equipment and conductor-enclosure ground should be located as close to the service entrance or source of supply as practicable. This ground must be so located that no system is grounded through a grounding electrode conductor smaller than required by Table 366. A common method is to run the grounding electrode conductor from the service-switch enclosure. As far as practicable, all other equipment is then connected to ground by electrically continuous conductor enclosures or by separate equipment grounding conductors from the service switch. Bonding jumpers or ground wires are used to connect isolated equipment to grounded equipment. Figure 9.256 shows a single common grounding conductor which grounds a grounded system and the metallic equipment of both an ungrounded system and the grounded system.

FIGURE 9.256 A single grounding conductor for grounded and ungrounded systems.

365. Rules for sizing system grounding conductors

1. For dc systems: not smaller than the largest conductor supplied by the system and in no case smaller than No. 8. An exception to this rule is a system supplied by a balancer set. In such installations, if the grounded circuit conductor is a neutral derived from a balancer winding or a balancer set with overcurrent protection in accordance with 445.12(D) of the NEC, the size of the grounding electrode conductor shall not be less than that of the neutral conductor but in no case smaller than No. 8.
2. For ac systems and service equipment as follows:
 - a. The size of the grounding electrode conductor for an ac system shall not be less than is given in Sec. 366.
 - b. If the wiring system is not grounded at the premises, the size of a grounding conductor for a service raceway, for the metal sheath or armor of a service cable, and for service equipment shall be not less than is given in Sec. 366.
 - c. Grounding electrode conductors run to the three categories of grounding electrodes below need not be larger than that given by the following specific provisions, whether the system is ac or dc:
 - (1) Where connected to rod, pipe, or plate electrodes that portion of the grounding electrode conductor connected solely to such an electrode need not be larger than 6 AWG.
 - (2) Where connected to a concrete-encased electrode, that portion of the grounding electrode conductor connected solely to such an electrode need not be larger than 4 AWG.
 - (3) Where connected to a ground ring, that portion of the grounding electrode conductor connected solely to such an electrode need not be larger than the conductor that comprises the ground ring.

366. Sizing Grounding Electrode Conductors for AC Systems*
 (Table 250.66, 2008 NEC)

Size of largest service-entrance conductor or equivalent for parallel conductors, [†] AWG or 1000 cmil		Size of grounding electrode conductor, AWG or 1000 cmil	
Copper	Aluminum or copper-clad aluminum	Copper	Aluminum or copper-clad aluminum [‡]
2 or smaller	1/0 or smaller	8	6
1 or 1/0	2/0 or 3/0	6	4
2/0 or 3/0	4/0 or 250 kcmil	4	2
Over 3/0	Over 250 kcmil	2	1/0
through 350 kcmil	through 500 kcmil		
Over 350 kcmil	Over 500 kcmil	1/0	3/0
through 600 kcmil	through 900 kcmil		
Over 600 kcmil	Over 900 kcmil	2/0	4/0
through 1100 kcmil	through 1750 kcmil		
Over 1100 kcmil	Over 1750 kcmil	3/0	250 kcmil

This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

[†]This table also applies to the derived conductors of a separately derived ac system.

[‡]See installation restrictions in Sec. 250.64(A) of the NEC.

NOTE Where there are no service-entrance conductors, the size of the grounding electrode conductor shall be determined by the equivalent size of the largest service-entrance conductor required for the load to be served. Where multiple sets of service-entrance conductors are used as permitted in Sec. 230.40, Exception No. 2, of the NEC, the equivalent size of the largest service-entrance conductor shall be determined by the largest sum of the areas of the corresponding conductors of each set.

367. Size of Equipment Grounding Conductors for Grounding Raceway and Equipment*

(Table 250.122, 2008 NEC)

Rating or setting of automatic overcurrent device in circuit ahead of equipment, conduit, etc., A not exceeding:	Size of wire, AWG or 1000 cmil	
	Copper	Aluminum or copper-clad aluminum [†]
15	14	12
20	12	10
30	10	8
40	10	8
60	10	8
100	8	6
200	6	4
400	3	1
600	1	2/0
800	1/0	3/0
1000	2/0	4/0
1200	3/0	250 kcmil
1600	4/0	350 kcmil
2000	250 kcmil	400 kcmil
2500	350 kcmil	600 kcmil
3000	400 kcmil	600 kcmil
4000	500 kcmil	800 kcmil
5000	700 kcmil	1200 kcmil
6000	800 kcmil	1200 kcmil

[†]See installation restrictions of Sec. 250.120 of the NEC.

NOTE Equipment grounding conductors may need to be sized larger than specified in this table in order to comply with Sec. 250.4(A)(5) or (B)(4) of the NEC.

368. NEC specifications for the material and installation of grounding conductors are as follows:

1. Material

- a. *For grounding electrode conductor.* The grounding electrode conductor of a wiring system shall be of copper, aluminum, or copper-clad aluminum. The material selected shall be resistant to any corrosive condition existing at the installation, or shall be suitably protected from corrosion. Aluminum and copper-clad aluminum conductors must not be used in direct contact with the earth or masonry, and where used outside, these conductors must not be terminated within 450 mm (18 in.) of the earth. The conductor may be solid or stranded, insulated, covered or bare. The grounding electrode conductor must be without joint or splice throughout its length, unless it is spliced using exothermic welding or irreversible compression connectors. Busbar sections are permitted to be bolted together for obvious reasons.

If there are multiple service enclosures, the unbroken conductor rule applies to the conductor that runs to the general service location. If the service consists of two to

six disconnects supplied from separate service laterals joined only at their supply ends in accordance with NEC 230.2 and 230.40 Exception No. 2, or connected to separate sets of service entrance conductors extending from a single service drop or lateral in accordance with 230.40 Exception No. 2, the grounding electrode conductor will be arranged with taps extending into each service enclosure. In this case the tap connections shall be made using exothermic welds or with connectors listed as suitable for grounding and bonding, and those taps must leave the common grounding electrode conductor without a joint or splice. If multiple service enclosures are supplied from a common location, such as a wireway above the multiple enclosures, the grounding electrode conductor will run to this enclosure and taps will extend into each enclosure using connectors listed for grounding and bonding connections, or the exothermic welding process can be used. If desired, separate grounding electrode conductors may be run to the grounding electrode system from each disconnecting means.

b. For conductor enclosures and equipment only. The equipment grounding conductor for equipment and for conduit and other metal raceways or enclosures for conductors may be a conductor of copper, aluminum, or copper-clad aluminum, stranded or solid, insulated, covered or bare, in the form of a wire or busbar of any shape, or one of thirteen qualifying wiring methods, as follows:

- (1) Rigid metal conduit
- (2) Intermediate metal conduit
- (3) Electrical metallic tubing
- (4) Flexible metal conduit, provided it and its fittings are listed, and the overcurrent protection ahead of any circuit contained in the run does not exceed 20 A. The flexible metal conduit must not be installed where flexibility is required after the installation is complete, such as for vibration isolation or connections to moveable equipment. The total length of flexible raceways covered in items (4), (5), and (6) of this list cannot exceed 1.8 m (6 ft) in any equipment grounding return path. The wiring method can be used for larger or longer applications, but a wire in accordance with the first paragraph above must be added.
- (5) Liquidtight flexible metal conduit, provided it and its fittings are listed, and the overcurrent protection ahead of any circuit contained in the run does not exceed 20 A in the metric designator 12 through 16 (trade size $\frac{3}{8}$ through $\frac{1}{2}$) sizes, and 60 A in the metric designator 21 through 35 (trade sizes $\frac{3}{4}$ through $1\frac{1}{4}$) sizes. The liquidtight flexible metal conduit must not be installed where flexibility is required after the installation is complete, such as for vibration isolation or connections to moveable equipment. The total length of flexible raceways covered in items (4), (5), and (6) of this list cannot exceed 1.8 m (6 ft) in any equipment grounding return path. The wiring method can be used for larger or longer applications, but a wire in accordance with the first paragraph above must be added.
- (6) Flexible metal tubing, provided it and its fittings are listed, and the overcurrent protection ahead of any circuit contained in the run does not exceed 20 A. The total length of flexible raceways covered in items (4), (5), and (6) of this list cannot exceed 1.8 m (6 ft) in any equipment grounding return path. The wiring method can be used for larger or longer applications, but a wire in accordance with the first paragraph above must be added.
- (7) Armor of type AC cable, where manufactured so as to provide a suitable fault return path in accordance with NEC 320.108.
- (8) The copper sheath of mineral-insulated, metal-sheathed cable.
- (9) Type MC cable where listed and identified for grounding using one of the two possible approaches. For the interlocking-metal tape form, the armor

and grounding conductor in combination are evaluated. For the smooth and corrugated tube forms the metallic sheath is evaluated, together with any enclosed grounding conductors if any and as required to meet the required performance criteria.

- (10) Cable trays as permitted in NEC 392.3 and 392.7.
- (11) Cablebus framework as permitted in 370.3.
- (12) Other listed electrically continuous metal raceways and listed auxiliary gutters.
- (13) Surface metal raceways listed for grounding.

All bolted and threaded connections at joints and fittings shall be made tight by the use of suitable tools.

2. Installation

- a. Grounding electrode conductor.** A grounding electrode conductor, 4 AWG or larger, may be attached to the surface on which it is carried without the use of knobs, tubes, or insulators. It need not have protection unless exposed to severe physical damage. A 6 AWG grounding conductor, which is free from exposure to physical damage, may be run along the surface of the building construction without metal covering or protection when it is securely fastened to the construction; otherwise it shall be in rigid metal conduit, intermediate metal conduit, rigid nonmetallic conduit, electrical metallic tubing, or cable armor. Grounding conductors smaller than No. 6 shall be in rigid metal conduit, intermediate metal conduit, rigid nonmetallic conduit, electrical metallic tubing, or cable armor. Ferrous metal enclosures for grounding conductors shall be electrically continuous from the point of attachment to cabinets or equipment to the grounding electrode and shall be securely fastened to the ground clamp or fitting. Ferrous metal enclosures which are not physically continuous from cabinet or equipment to the grounding electrode shall be made electrically continuous by bonding each end to the grounding conductor. Where a raceway is used as protection for a grounding conductor, the installation shall comply with the appropriate raceway article of the Code.

The requirement to bond both ends of ferrous metal enclosures is critical for grounding electrode conductors in ac systems because the current only goes one way, so there is no opportunity for magnetic field cancellation. Any current will attempt to flow over the outer perimeter of the wiring method, which in this case would be the steel conduit. Actual testing shows, for example, that with a 100 ft run of $3/4$ -in rigid metal conduit enclosing 6 AWG copper wire, if 100 A is flowing through this system, 97 A will be flowing through the raceway, and only 3 A will flow over the copper wire. If this natural process is obstructed through a failure to bond both ends, the 100 A will flow through the wire, but at over double the impedance.

- b. Conductor enclosures and equipment only.** An equipment grounding conductor for conductor enclosures and equipment must run with or enclose the associated circuit conductors, with two exceptions. DC circuit equipment grounding conductors may be run in separate locations. Equipment grounding conductors installed to provide grounding connections for receptacles added to or replaced on, or branch-circuit extensions made from branch circuits that do not contain an equipment grounding conductor must connect to the grounding electrode system or to suitable grounding terminations in upstream panelboards, etc. These conductors are often fished through walls, and where so located away from sources of physical damage, they may run without a raceway enclosure regardless of the conductor size. If an equipment grounding conductor does run in the open for any reason, it is subject to the size and raceway protection rules that apply to grounding electrode conductors, as covered in **a** above.

369. Cord-connected equipment (National Electrical Code). The equipment grounding conductor in flexible cord must not be smaller than 18 AWG and not smaller than the circuit conductors for all cord assemblies up to and including 10 AWG conductors. Cord assemblies with larger conductors are permitted to have the size of the equipment grounding conductor reduced in size, but not smaller than the size shown in Table 367.

370. Grounding electrode system. If present on the premises at each building or structure served, each item Nos. 1. through 7. shall be bonded together to form the grounding electrode system. The bonding jumpers shall be sized in accordance with Sec. 365, installed in accordance with Sec. 368 (2a) and shall be connected in the manner specified in Sec. 372. However, for an existing building, a concrete-encased electrode does not have to be made part of the grounding electrode system where the reinforcing steel is not accessible without disturbing the concrete.

Metal underground gas-piping systems and aluminum electrodes of any form shall not be used in a grounding electrode system. Where practicable, rod, pipe, or plate electrodes shall be embedded below permanent-moisture level, and they shall be free from nonconductive coatings, such as paint or enamel. If more than one electrode system is used (including systems used for lightning rods), each electrode of one grounding system shall not be less than 1.83 m (6 ft) from any other electrode of another grounding system. Two or more electrodes that are effectively bonded together are to be treated as a single grounding electrode system in this sense. This rule pertains to the electrodes of different systems so they can function as designed. It does not prohibit bonding different systems together, and the NEC specifically requires that lightning protection system grounding terminals shall be bonded to the premises wiring grounding electrode system.

Rod, pipe, or plate electrodes shall, if practicable, have a resistance to ground not to exceed 25 Ω . If the resistance is not as low as 25 Ω , an additional electrode connected in parallel shall be used. Such additional electrodes must be spaced not less than 1.8 m (6 ft) apart. If two such electrodes in parallel result in a net resistance to ground in excess of 25 Ω , however, the NEC does not require any additional steps to decrease the resistance to ground. Continuous metallic underground water systems, particularly those using cast iron street mains, in general have a resistance to ground of less than 3 Ω . Metal frames of buildings and local metallic underground piping systems, metal well casings, and the like have, in general, a resistance substantially below 25 Ω .

1. A metal underground water pipe in direct contact with the earth for 3 m (10 ft) or more (including any metal well casing bonded to the pipe) and electrically continuous (or made electrically continuous by bonding around insulating joints or sections or insulating pipe) to the points of connection of the grounding electrode conductor and the bonding conductors. Continuity of the grounding path or the bonding connection to interior piping shall not rely on water meters or filtering devices and similar equipment. A metal underground water pipe shall be supplemented by an additional electrode of a type specified in Pars. 2 through 8. Interior metal water piping located more than 1.52 m (5 ft) from the point of entrance to the building shall not be used as a part of the grounding electrode system in some cases. In industrial, institutional, and commercial occupancies only, an exception allows remote connections to the water piping system, provided there is qualified maintenance and supervision, and provided the entire length of water pipe used in the connection to earth is exposed other than incidental short sections passing directly through walls, ceilings, etc. Note that the area above a suspended ceiling with removable panels is exposed within the NEC definition.

2. The metal frame of the building, where connected to earth in one or more of the following methods: (a) A 3.0 m (10 ft) length of structural steel is in direct contact with earth, or encased in concrete that is in direct contact with earth; or (b) connected to a concrete-encased electrode as in Par. 3 below or to a ground ring as in Par. 4 below; or (c) bonded to rod, pipe, or plate electrodes as covered in Par. 5 or Par. 7 below that meet the resistance provisions given at the end of this section; or (d) connected using some other means that has been approved by the authority having jurisdiction.
3. An electrode encased by at least 50 mm (2 in.) of concrete, located horizontally within and near the bottom of a concrete foundation or footing, or vertically within that portion of a concrete foundation or footing that is in direct contact with the earth, consisting of at least 6 m (20 ft) of one or more bare or zinc galvanized or other electrically conductive coated steel reinforcing bars or rods of not less than 13 mm (1/2-in) diameter or consisting of at least 6.0 m (20 ft) of bare copper conductor not smaller than No. 4 AWG. If multiple such electrodes are present, it is sufficient to make connections to only one of them. If no reinforcing steel is present at the bottom of a foundation, there is no requirement to add this electrode. However, it is one of the very best electrodes, and even with no steel in the footing, if the timing can be worked out, the alternative of 6.0 m (20 ft) of bare copper laid into an open footing should be strongly considered. The result will be far better than rod, pipe, or plate electrodes with lower material cost and less time to install. Be sure to prop the wire up on stones or other supports so the concrete will be able to fully encase the bare copper.
4. A ground ring encircling the building or structure, in direct contact with the earth, consisting of at least 6 m (20 ft) of bare copper conductor not smaller than No. 2 AWG. It must be installed at least 750 mm (30 in.) below grade.
5. *Rod and pipe electrodes.* Rod and pipe electrodes shall not be less than 2.44 m (8 ft) in length, shall consist of the following materials, and shall be installed in the following manner:
 - a. Electrodes of pipe or conduit shall not be smaller than metric designator 21 (3/4 trade size) and, where of iron or steel, shall have the outer surface galvanized or otherwise metal-coated for corrosion protection.
 - b. Electrodes of stainless steel and copper or zinc coated steel rods of steel shall be at least 15.87 mm (5/8 in.) in diameter, unless listed and not less than 12.7 mm (1/2 in.) in diameter.
 - c. If rock bottom is not encountered, the electrode shall be driven to a depth of 2.5 m (8 ft). If rock bottom is encountered, the electrode may be driven at an oblique angle not exceeding 45° from the vertical. If the rock bottom does not permit the electrode to be driven as described, then the electrode shall be buried in a trench at least 750 mm (2 1/2 ft) deep. The upper end of the electrode shall be flush with or below ground level unless the aboveground end and the grounding electrode conductor attachment are protected against physical damage as specified in Sec. 250.10 of the NEC. Since the minimum driven distance is 2.5 m (8 ft), an above grade attachment is only possible if the electrode exceeds 8 ft in length.
6. *Other listed grounding electrodes* are permitted. These include specially fabricated and chemically enhanced electrodes featuring heavy-wall copper tubing packed with electrolytic salts that slowly percolate into the surrounding soil to reduce soil resistivity in difficult areas.
7. *Plate electrodes.* Each plate electrode shall expose not less than 0.186 m² (2 ft²) of surface to exterior soil. Electrodes of iron or steel plates shall be at least 6.35 mm (1/4 in.) in thickness. Electrodes of nonferrous metal shall be at least 1.52 mm (0.06 in.) in thickness. They must be installed at least 750 mm (30 in.) below grade.
8. Other local metal underground systems or structures, such as piping systems, underground tanks, and underground metal well casings that are not bonded to a metal water pipe.

371. Location of connection to grounding electrode (National Electrical Code)

1. **To Water Pipes.** System or common grounding conductors shall be attached to a water-piping system on the street side of the water meter or on a cold-water pipe of adequate ampacity as near as practicable to the water service entrance to the building. If the source of the water supply is a driven well in the basement of the premises, the connection shall be made as near as practicable to the well. The point of attachment shall be accessible. If the point of attachment is not on the street side of the water meter, the water-piping system shall be made electrically continuous by bonding together all parts between the attachment and the street side of the water meter or the pipe entrance which are liable to become disconnected, as at meters, valves, and service unions.
2. **To Other Electrodes.** The grounding conductor shall be attached to other electrodes permitted in Sec. 370 at a point which will assure a permanent ground.

372. Attachment of grounding conductors (National Electrical Code)

Attachment to Wiring Components and Equipment. Connections that depend solely on solder shall not be permitted. Grounding connections must employ one of the following 8 methods:

1. Listed pressure connectors
2. Terminal bars
3. Pressure connectors listed for grounding and bonding equipment
4. The exothermic welding process
5. Machine screw-type fasteners that engage no fewer than two threads in the enclosure or are secured with a nut
6. Thread-forming machine screws that engage no fewer than two threads in the enclosure
7. Connections that are part of a listed assembly
8. Other listed means

Attachment to Electrodes. The grounding electrode conductor shall be attached to the grounding electrode by means of exothermic welding, listed lugs, listed pressure connectors, listed clamps, or other listed means, except that connections which depend upon solder shall not be used. Not more than one conductor shall be connected to the grounding electrode by a single clamp or fitting unless the clamp or fitting is of a type listed for multiple conductors. One of the following methods shall be used.

1. A listed bolted clamp of cast bronze or brass or of plain or malleable iron
2. A pipe fitting, plug, or other approved device, screwed into the pipe or into the fitting
3. For indoor telecommunications purposes only, a listed sheet-metal-strap-type ground clamp having a rigid metal base that seats on the electrode and having a strap of such material and dimensions that it is not likely to stretch during or after installation, or
4. Other equally substantial approved means

Ground Clamps. Ground clamps for use on copper water tubing and copper, brass, or lead pipe should preferably be of copper, and those for use on galvanized or iron pipe should preferably be of galvanized iron and so designed as to avoid physical damage to pipe. Ground clamps used with aluminum grounding conductors should be listed for the

purpose. Note that limitations in the listing process for clamps require that clamps that will be used on copper water tubing must be marked for this service. Clamps that will be used on reinforcing steel must be marked accordingly, including the size of the reinforcing bar(s) for which the clamp was listed. Any clamp used for direct burial in earth or where embedded in concrete must be marked "direct burial" or "DB" as the available space allows.

Protection of Attachment. Ground clamps or other fittings shall be approved for general use without protection and shall be protected from ordinary physical damage.

Figure 9.257 shows some types of grounding clamps. For the smaller ground wires, which must be enclosed in conduit, the type in Fig. 9.257, I, is used. For bare ground wire connected to a water pipe, use the type in Fig. 9.257, II. The type in Fig. 9.257, III, is for a bare wire to be attached to a ground rod.

FIGURE 9.257 Ground-wire clamps.

373. On grounded wiring systems the circuit conductor which is connected to ground must be identified throughout the system. This grounded conductor is referred to as the identified conductor.

1. Insulated conductors of 6 AWG or smaller, except conductors of Type MI cable and multiconductor cables covered under Sec. 200.6(E) of the NEC, fixture wires and multiconductor varnished-cloth-insulated cables, shall have an outer identification of white or gray color along its entire length. The grounded conductors of Type MI cable shall be identified by distinctive marking at the terminals during the process of installation, as is the case for varnished cloth multiconductor cables. A single-conductor, sunlight-resistant, outdoor-rated cable used as a grounded conductor in photovoltaic power systems as permitted by Sec. 690.31 of the NEC shall be identified at the time of installation by a distinctive white marking at all terminations. Three continuous white stripes on other than green insulation is permitted. Aerial cables can be identified with the customary white or gray coloring on the grounded conductors, or they can use a ridge running along the conductor to be grounded. Multiconductor cables operating under conditions of qualified maintenance and supervision are permitted to have a colored conductor permanently identified at the time of installation by a distinctive white marking or equal.
2. Insulated conductors larger than No. 6 shall have an outer identification of white or gray color or shall be identified by distinctive white marking at terminals during the process of installation, which shall encircle the conductor. Multiconductor flat cable No. 4 or larger may employ an external ridge on the grounded conductor. Three continuous white stripes on other than green insulation is permitted.

3. Where grounded conductors of different systems are installed in a common cable, raceway, box, or other enclosure, each grounded conductor shall be identified by system. Since white and gray are both permitted color choices for a grounded conductor, this is one way to distinguish voltage systems. For example, many installations use white as the identified conductor of a 208Y/120-V system and gray as the identified conductor of a 480Y/277-V system. If additional systems are present in common enclosures, white or gray wire with a colored stripe (other than green) can be used. Whatever method is used, it must be permanently posted at each branch-circuit panelboard.
4. The continuity of a grounded circuit conductor must not depend on connections to enclosures, raceways, or cable armor. This problem frequently arises in service panelboards with multiple busbars. Figure 9.258 shows an example of the problem, and how to correct it. The NEC Committee has spent considerable effort in recent years trying to assure that normal circuit current is confined to recognized conductors, and does not pass over raceways and enclosures that were never designed to be current-carrying conductors.
5. In general, conductors colored white or gray, or colored with three continuous white stripes, or identified with white or gray markings at terminations, must be used as grounded circuit conductors and for no other purpose. There are a few limited exceptions to this principle, as follows:
 - a. On circuits of less than 50 V, wires using white or gray markings may be used for other purposes, *unless system grounding is required by 250.20(A)*. Refer to Sec. 354 (4) for when this is the case. If it does apply, then the use of an identified conductor follows.
 - b. On circuits of 50 V or more, a white or gray wire that is part of a cable assembly may be used as an ungrounded conductor provided it is reidentified as some color other than white or gray (or green) at all terminations and other locations where it is visible and accessible. The same procedure holds for a cable used in a switch loop, with the added proviso that the wire running to the load will not be reidentified, only the one supplying the switch, or running between 3- and 4-way switches where used. Flexible cord is also permitted to have its white or gray wires used as ungrounded conductors for appliance and equipment connections, without the necessity of reidentifying its white or gray wires.
6. For approximately 75 years (since 1923) the NEC described the customary identification rule in terms of “white or natural gray” coloring. This originally referred to the color of latex insulation and the unbleached muslin put over it. It wasn’t exactly either white or gray, but installers knew what it was. It was never intended to be the controlled color gray, and conductors manufactured in this way have not been produced for many decades. In fact, the controlled color gray could always have been used, and occasionally

FIGURE 9.258 The feeder neutral has been terminated on the equipment grounding bus in this service panelboard. The neutral current must flow over the enclosure in order to reach the service neutral, thereby making the continuity of the grounded conductor depend on the enclosure. This is a violation of NEC 200.2(B), and the feeder neutral must be reterminated on the neutral busbar above.

was used as an ungrounded conductor. However, with the advent of 480Y/277-V systems, the controlled color gray was increasingly used as an identified conductor based on an improper interpretation of the old terminology "natural gray." The 2002 NEC ratified what had become the convention, dropped the term "natural gray" completely, and recognized the controlled color gray as a permitted color for identified conductors for the first time. However, since gray wires were permitted, at least theoretically, for use as ungrounded conductors the NEC advises caution when working with gray wires on existing systems.

7. At the terminals of wiring devices the grounded conductor must be connected to the nickel- or zinc-colored terminal, which must have a whitish appearance in contrast to the copper or brass-colored terminals. Alternatively, the grounded terminal may be marked "W" or by the use of the word "white," and this marking is mandatory in cases where the actual terminals are not visible and only the conductor entry hole can be seen. On screw-shell lampholders the grounded conductor must be connected to the screw shell itself. Appliances with a single-pole switching device shall have means to identify the appropriate terminal for the grounded circuit conductor (if any). No single-pole switch or circuit breaker and no fuse shall be used in a grounded conductor.

374. Identification of grounded conductors in flexible cord and fixture wire is different than for ordinary building wire. Identification for the grounded circuit conductor in flexible cord must comply with one of the following six methods:

1. A braid finished to show a white or gray color provided the braid on the other conductor(s) is finished to show readily distinguishable color(s).
2. A tracer in a braid of any color contrasting with that of the braid, and no tracer in the braid of any other conductor. No tracer shall be used in the braid of any conductor of a cord containing a conductor with a braid finished to show white or gray. Cord types C and PD, however, have the identified conductor as solid white or gray, and all other conductors with a colored tracer in the braid.
3. A white or gray insulation on one conductor and insulation of a readily distinguishable color(s) on the other conductor(s) for cords having no braids on the individual conductors. For jacketed cords furnished with appliances, one conductor having its insulation finished light blue, and with the other conductors having insulation of a readily distinguishable color other than white or gray. This limitation does not apply to cords with the insulation on the individual conductors integral with the jacket. The insulation is permitted to be covered with an outer finish to provide the desired color.
4. A white or gray separator on one conductor and a separator of a readily distinguishable solid color on the other conductor(s) of cords having insulation on the individual conductors integral with the jacket.
5. One conductor having the individual strands tinned and the other conductor(s) having the strands untinned for cords having insulation on the individual conductors integral with the jacket.
6. One or more ridges, grooves, or white stripes located on the exterior of the cord so as to identify one conductor for cords having insulation on the individual conductors integral with the jacket.

Fixture wires intended for use as grounded circuit conductors shall be identified by one or more continuous white stripes on other than green insulation, or by one of the means above for flexible cord.

375. Permitted colors for ungrounded conductors. All ungrounded conductors must be finished in black or red or any color contrasting to white, gray, or green. Where more than one nominal voltage system exists in a building, each ungrounded system conductor shall be identified by phase or line, and by system, at all termination, connection, and splice points. The specific code is left to the owner, but each panelboard must have the code in use for circuits originating in that panelboard. Alternatively, for facilities with sophisticated recordkeeping, the code can be “documented in a manner that is readily available.”

If, on a four-wire delta-connected secondary, the midpoint of one phase is grounded to supply lighting and similar loads, that phase conductor having the higher voltage to ground shall be indicated by the color orange or by tagging or other effective means at any point at which a connection is to be made if the grounded conductor is present. In addition, every switchboard and panelboard must be field marked with a warning label “Caution ___ Phase Has ___ Volts to Ground.”

SERVICE-ENTRANCE REQUIREMENTS AND INSTALLATION

376. Service entrances for the electrical system of a building may be supplied by means of overhead or underground service conductors. The source of energy for any service is an electrical utility. If the source is an on-premises source, then there is no service, only a separately derived system. A service consists of the service conductors and the service equipment. The service conductors are the conductors which supply a building with electrical energy from an electric power system outside the building. They consist of that portion of the supply conductors which extend from the street distribution main or distribution transformer to the service equipment of the building. The service conductors may be located overhead or underground. For overhead conductors the service conductors include the conductors from the last line pole to the service equipment. The service conductors of an overhead service are further classified into two parts: the service-drop conductors and the service-entrance conductors. The *service-drop conductors* are the overhead service conductors from the last line pole or other aerial support to and including the splices, if any, connecting to the service-entrance conductors at the building or other structure. The *service-entrance conductors* of an overhead service are that portion of the service conductors between the terminals of service equipment and a point usually outside the building, clear of the building walls, where they are joined by tap or splice to the service drop.

377. The service equipment must consist of an externally operated disconnecting device and overcurrent protective device. The disconnecting device must provide a readily accessible means for disconnecting all the service conductors from the source of supply. It may consist of a single switch or manually operated circuit breaker or not more than six switches or six manually operated circuit breakers. In Fig. 9.259, if there had been only six occupants in the building, the main service switch would not have been required. In multiple-occupancy buildings each occupant must have access to his or her disconnecting means except where maintenance is under continuous building management supervision. Circuit breakers may be equipped with electrical remote control, provided that the breaker has in addition a manually operable handle. The disconnecting means must be of a type which will plainly indicate whether it is in the open or the closed position. The service switch or breaker must be located as close as is feasible to the point of entrance of the service conductors to the building. It may be located either outside or inside the building. If the switch or breaker does not open the grounded conductor, other means must be provided

at the service entrance for disconnecting the grounded conductor of the supply from the interior wiring. The connection to a neutral terminal bar in the service switch will constitute a satisfactory disconnecting means.

A service switch must have a rating which is not less than the fuseholder in series with it, and the rating must be at least as great as the minimum allowable load (refer to Sec. 52 of Div. 3). Except in special cases of very small occupancies, it is not a good practice to install a service switch or circuit breaker that has a rating less than 60 A. A 30-A switch should not be used for a two-wire service supplying more than two branch circuits. A one-family dwelling shall have a service disconnecting means rated not less than 100 A, 3-wire.

Each ungrounded service conductor must be provided with overcurrent protection. The protection may consist of a single set of fuses or circuit breakers or not more than six sets of fuses or six circuit breakers. For the rating of fuses or the setting of circuit breakers, refer to Secs. 319 and 320. No overcurrent device shall be inserted in a grounded conductor, except a circuit breaker which simultaneously opens all conductors of the service. The protective devices must be located at the same point as the disconnecting means or be located immediately adjacent thereto.

In addition to the disconnecting means and the protective devices, when the building is supplied directly from public-utility mains, the service equipment will include the kilowatt-hour meter for the measurement of power consumption. For small or multiple-occupancy buildings, the branch-circuit distribution equipment frequently is grouped along with the service equipment (see Fig. 9.259). If the service overcurrent protective devices are locked or sealed or otherwise not readily accessible, the branch-circuit overcurrent devices must be installed as close as is practicable to the load side of the service equipment. They must be in a readily accessible location and be of a lower rating than the service overcurrent device.

The construction and types of service equipment are discussed in Div. 4.

FIGURE 9.259 Arrangement of meters and service for a multitenant building.

378. There are six possible different arrangements or sequences for service equipment consisting of switch, fuses, and meter, as follows:

1. Switch-fuse-meter
2. Switch-meter-fuses
3. Fuses-switch-meter
4. Fuses-meter-switch
5. Meter-switch-fuses
6. Meter-fuses-switch

When circuit breakers are employed, there are, of course, only two possible sequences: meter–circuit breaker or circuit breaker–meter.

The proper order for placing the switch, fuses, and meter in the circuit has been the subject for much dispute and not enough standardization, each power company reserving for itself the decision on the proper method. Each method has its advantages, and it has been a matter for local decision as to which advantage seems most important to the individual power company.

379. A main service is a service which supplies more than one building under single management. If the buildings are supplied from a private distribution system, the services should be installed in accordance with the general requirements for services from a public utility. In installations which include properties with their own generating plant, the conductors running from one building to another are not considered service conductors.

The supply to each building must be separately controlled and properly protected by overcurrent devices. The control should consist of an externally operable enclosed safety switch or a circuit breaker. Refer to Div. 8, Sec. 71, topic 24 for an analysis of NEC rules covering this topic, particularly where they differ from the rules presented here on actual services. Garages and outbuildings of residences and farms come under this class of installation. Methods of meeting these requirements are illustrated in Figs. 9.260 and 9.261. The protection for each building should have a lower rating or setting than the protection at *F* in the figures, so that in case of trouble the protection of any one building will function without operating the device at *F*.

No service should supply one building from another unless they are under the same management.

FIGURE 9.260 Two buildings under single management. No service fuses are required in building 2 if fuses *F* are of proper rating to protect conductors *C*. A switch *S* must be installed to control conductor *C*.

FIGURE 9.261 Three buildings under single management. If properly protected by fuses *F*, conductors *C* require no other fuse protection. A switch *S*₂ must be provided to control the wiring in building 2, and a switch *S*₃ to control the wiring in building 3. Because wire *C* is not controlled by *S*₂, it must not pass through Building no. 2.

380. No building should be supplied by more than one set of service conductors from the same secondary distribution system or from the same transformer except as follows:

1. **Fire Pumps.** If a separate service is required for fire pumps.
2. **Continuity of Power.** If a separate service is required for emergency, legally required standby, optional standby, or parallel power production systems, or systems designed for the connection of multiple sources of supply for the purposes of enhanced reliability.
3. **Capacity Requirements.** If capacity requirements make multiple services necessary, due to capacity exceeding 2000 A at a supply voltage of 600 V or less, or where the load requirements of a single-phase installation exceed what the serving agency normally supplies through one service, or in other cases by special permission from the authority having jurisdiction.
4. **Buildings of Large Area.** By special permission, if more than one service drop is necessary owing to the area over which a single building extends.

FIGURE 9.262 Two sets of service-entrance conductors tapped from one service drop.

FIGURE 9.263 Four sets of service-entrance conductors tapped from one set of main service conductors.

5. **Multiple-Occupancy Buildings.** By special permission, in multiple-occupancy buildings where there is no available space for service equipment accessible to all the occupants. See Figs. 9.262 and 9.263 for multiple metering supplied by one service drop.
6. **When Additional Services Are Required for Different Classes of Use.** These include needs for different voltage, frequency, or phase or different rate schedules for different types of use of electric power.
7. Underground conductors 1/0 or larger, connected at their supply ends but not at their load ends, and serving two to six disconnecting means that are grouped in one location and that supply multiple loads are considered a single service and are therefore permitted.

Separate services may be brought into a single building for power and light, respectively, when the lighting is supplied from a separate secondary distribution main, as shown in Fig. 9.264. Separate services may be brought into a single building for power and light, respectively, if each service is supplied through a separate transformer (Fig. 9.265) or if the lighting service is supplied from one transformer of a polyphase bank of transformers supplying the power.

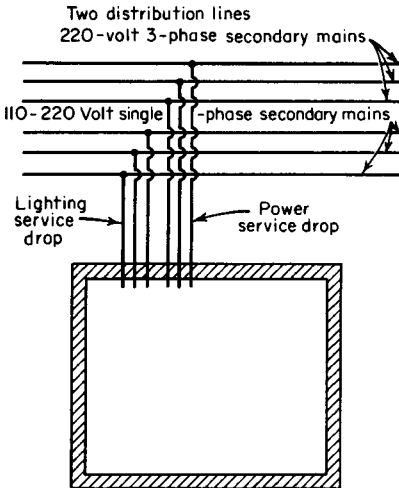

FIGURE 9.264 Separate services for power and light.

FIGURE 9.265 Separate services for power and light.

381. Size of service conductors. Service conductors must have an ampacity sufficient to supply the load of the building (refer to Div. 3) and regardless of the actual load must have an ampacity not less than that required by the minimum load requirements of Div. 3. They must have a minimum size in some cases for mechanical strength. They must also have a minimum size corresponding to the minimum rating of the service disconnecting means as required for certain specified loads. Therefore, no service conductor can be

smaller than the following (adjusted for aluminum if applicable), and may be larger if required by the actual load:

Conductors	Minimum allowable copper size
Service entrance for all installations, except ones specified below	6 AWG (to supply a 60 A minimum disconnect size using 75°C terminations)
Service entrance supplying a single branch circuit	14 AWG (to supply a 15 A minimum disconnect size)
Service entrance supplying a two-circuit installation	10 AWG (to supply a 30 A minimum disconnect size)
Service entrance supplying a single-family house	4 AWG [to supply a 100 A minimum disconnect size, using 310.15(B)(6)]
Service drop or lateral	12 AWG (overhead: hard-drawn) for a single circuit installation
Service drop or lateral	8 AWG, for other installations
Service of over 600 V	No. 6, except that in multiconductor cables No. 8 may be used

382. Splicing of service conductors. Service conductors in the form of underground service laterals and all service entrance conductors are permitted to be spliced as long as the splicing method complies with the usual rules in the NEC for general wiring of comparable size and location. The NEC does not expressly cover splices in overhead service drops, but given the other rules as long as the splice meets industry standards for strain tolerance and workmanship, it would normally be permitted subject to the judgment of the authority having jurisdiction.

383. Typical service installations of proper and improper construction are shown in Fig. 9.266. Overhead services to occupancies having relatively small loads, such as residences and small stores, are generally made with one of the installations shown in Fig. 9.266, II and III. The installation in Fig. 9.266, I, violates Code rules because the service head is not located above the point of attachment of the service-drop conductors to the building. The present trend is toward installations of the types shown in Figs. 9.266, II and III, and 9.267. A good service installation for a low-roof building is shown in Fig. 9.267. Occasionally the service switch is also mounted outside the building along with the meter.

In congested city residential districts an underground service using underground service-entrance cable is frequently run from overhead lines when a change to underground distribution is planned at a later date. This procedure facilitates the changeover, as the part of the cable which is aboveground may in the future be taken down and placed underground and run directly into the underground distribution box. In cities where the distribution is all underground, direct-burial cable or nonmetallic raceway is the most common method of running services. The advantage of the conduit system is that in case the service needs to be replaced for any reason, the cable may be pulled out of the conduit and another one installed without having to dig up the pavement or sidewalk. For apartment-house service a meter trough in which are mounted the meter sockets, one for each apartment, in one or more horizontal rows (Fig. 9.259), is installed. Directly under each meter is a branch-circuit distribution panel containing fuses or circuit breakers for the branch-circuit protection for the apartment. In some cases a service switch is provided for each apartment, and a feeder is run to the apartment with the branch-circuit distribution panel located in the apartment.

FIGURE 9.266 Various types of service installations. Drawing I violates the National Electrical Code. [Electrical Construction and Maintenance]

FIGURE 9.267 Low-roof service installation. [Hubbard & Co.]

384. For commercial or industrial services the maximum demand is usually metered as well as the kilowatthours. When the demand is of the order of a few kilowatts, this may be done with a single meter which has a demand-indicating pointer as well as the usual meter dials (Fig. 9.268). For larger installations a separate indicating-demand meter is installed (Fig. 9.269). A recording type of demand meter may also be employed for larger installations; Current transformers are usually required on larger installations to reduce the current which the meter has to handle; self-contained metering is currently available up to 400 A, although the cut-off point is a matter for the local utility to decide. For an underground service from an urban network system, the service equipment consists of a main fused switch or circuit breaker, a set of current transformers in a sheet-metal cabinet, and meters as outlined above. If the supply comes from a radial feeder system, a transformer bank with an oil circuit breaker and disconnect switches is installed at the building ahead of the above service equipment. For an overhead service a transformer bank is installed just

FIGURE 9.268 Dial for a watthour meter with demand-indicating pointer. [Westinghouse Electric Corp.]

FIGURE 9.269 Indicating-demand meter. [Westinghouse Electric Corp.]

outside the building, on a concrete foundation on the ground or on an elevated platform between two poles. The bank will contain high-voltage fuses and lightning arresters in addition to the transformers. The service conductors are then brought into the building in conduit or as individual wires to the service equipment. Sometimes the metering is installed so as to measure the input to the transformers so that the customer pays directly for the transformer losses. When this is done, high-voltage current and potential transformers are installed in the leads to the primary of the transformers. The meters may then be located in a weatherproof cabinet outside the building or located inside the building wall, as before, with a conduit to carry the secondary leads from the instrument transformers.

385. Connections ahead of the service disconnect. The National Electrical Code, in Sec. 230.82, allows eight types of equipment to be connected ahead of the service disconnecting means, as follows:

1. Cable limiters or other current-limiting devices.
2. Meters or meter sockets nominally rated not in excess of 600 V, provided all metal housings and service enclosures are grounded in accordance with Part VII and bonded in accordance with Part V of Article 250.
3. Meter disconnect switches nominally not rated in excess of 600 V that have a short-circuit current rating equal to or greater than the available short-circuit current, provided all metal housings and service enclosures are grounded in accordance with Part VII of Article 250 and bonded in accordance with Part V of Article 250. A meter disconnect switch shall be capable of interrupting the load served.
4. Instrument transformers (current and voltage), high-impedance shunts, load management devices, surge arresters, and Type 1 surge-protective devices.
5. Taps used only to supply load management devices, circuits for standby power systems, fire pump equipment, and fire and sprinkler alarms, if provided with service equipment and installed in accordance with requirements for service-entrance conductors.
6. Solar photovoltaic systems, fuel cell systems, or interconnected electric power production sources.

7. Control circuits for power-operable service disconnecting means, if suitable overcurrent protection and disconnecting means are provided.
8. Ground-fault protection systems or Type 2 surge-protective devices, where installed as part of listed equipment, if suitable overcurrent protection and disconnecting means are provided.

CRANE WIRING

386. Wiring for cranes consists of the following elements:

1. Collector switch
2. Main collector contact conductors
3. Cab main-line switch
4. Bridge collector contact conductors
5. Motor-circuit wiring

387. A collector switch or circuit breaker must be installed in every circuit feeding crane wires. A fused switch is most frequently used to provide overload protection, although in important installations, where reliability is essential (where equipment must be placed back in service after an accident, in minimum time), circuit breakers are used. From an electrical standpoint the best location for the switch is at the center of the run.

The switch must be readily accessible and operable from the ground or floor, be within view of the runway contact conductors, and be of a type which can be locked in the open position. It shall open all ungrounded conductors simultaneously.

388. The main collector contact conductors are bare copper trolley wires or structural-steel conductors that are erected parallel to the crane runway. The location of the conductors is determined by conditions. Sometimes the crane builder specifies that the conductors must be located in a certain position, and in other cases the purchaser selects and specifies the position of the conductors, and the crane manufacturer arranges the current collectors on the crane accordingly.

389. Trolley wire for cranes is hard-drawn copper, the same as used in electric traction. Hard-drawn wire must be used to prevent excessive stretching. Round wire is erected when the method of support adopted does not involve the use of trolley ears for holding it at intermediate points between the ends of the run. When trolley ears are used, figure-eight or, preferably, grooved trolley wire should be used, because it can be readily held in screw-clamp trolley ears. Round wire can be used with trolley ears, but the ear flanges of these must be hammered down around the wire, a time-consuming operation requiring some skill; also, a round-wire ear introduces a hump on the wire and makes the trolley wheel jump and draw an arc when the wheel passes over the raised place. Either 1/0, 2/0, 3/0, or 4/0 AWG wire is usually required. The wire size required is ordinarily specified by the crane builder, but in any case it should be large enough so that the voltage drop in it will not much exceed 3 or 4 percent of the line voltage with all the crane motors operating at full load. In no case should the wires be smaller than the minimum allowable sizes given in Sec. 400 for bridge collector conductors.

390. Trolley rails of structural steel are being used to some extent instead of copper trolley wire to supply current to cranes and other moving electrical machinery. The steel rails are made sufficiently heavy so that they cannot break and fall, as copper wires occasionally do. Sometimes strap-steel bars are used, but more frequently a section such as an angle or a tee, which has considerable stiffness in all directions, is adopted. Steel conductors should be painted, except on the contact edge or face, to prevent corrosion. Either a shoe or a trolley wheel can be used to collect current from a steel conductor rail. A shoe or spoon, which makes a rubbing contact, is probably preferable for the average application. Trolley-wheel collectors that travel at high speeds are not successful for current collection from steel conductors, because the wheel tends to bounce and jump from the rigid rail at joints and uneven places.

391. The main collector contact conductors must be isolated by elevation or provided with suitable guards so that persons cannot inadvertently touch the live parts while in contact with the ground or with conducting material connected to the ground. If the crane travels over easily ignitable combustible fibers and materials, the collector conductors must be protected by barriers so arranged as to prevent the escape of sparks or hot particles. Probably the best location for the collector conductors on a bridge-crane runway is between the flanges of and parallel to one of the crane girders. Here the conductors are out of the way and well protected and can be readily supported. It is not often that they are erected in any other position. Occasionally the trolley wires can be supported from the roof trusses above the crane runway and are installed similarly to the trolley wires for trolley cars. A pole collector with a wheel at its upper end, exactly like a trolley-car pole but much shorter, is used. When the spacing between roof trusses is very great, this method may not give good results because of the wire swinging and the trolley coming off. The main contact conductors, when carried along runways, should normally be supported on insulating supports at intervals not exceeding 6 m (20 ft) and separated from each other at least 150 mm (6 in.), except that a spacing of not less than 75 mm (3 in.) may be used for monorail hoists. If wires are used, they should be secured at the ends with approved strain insulators and so mounted on intermediate insulators that the extreme displacement of the wires will not bring them closer than 38 mm (1/2 in.) from the surface wired over. If necessary, the intervals between supports may be increased up to 12 m (40 ft), provided that the separation between conductors is increased proportionately. All sections of the conductors must be so joined that

a continuous electrical connection is provided.

The collector conductors must not supply any equipment other than that of the crane or cranes which they are designed to serve.

FIGURE 9.270 Intermediate bracket for trolley wire.

392. Methods of supporting crane trolley wires differ with conditions. If the crane is provided with hook-shoe collectors

(Fig. 9.270), which slide along under and carry the weight of the trolley wire, the wire is rigidly held only at the terminations at the ends of the run and is kept from sagging by intermediate insulating brackets like those shown in Fig. 9.270. If trolley-wheel current collectors are used, the tension in the wire is taken by the terminations, and the wire is also rigidly held by trolley ears at intermediate points.

393. Terminations are made as shown in Fig. 9.271. Strain insulators separate the trolley wire electrically from the building members, and either a turnbuckle or an eyebolt with a long thread can be used for pulling the slack from the wire and adjusting its tension. The terminations should be depended upon to assume the entire tension of the wire. The intermediate supports are placed merely to prevent excessive sagging. The members which take the stresses of the eyebolts at the terminations should be very substantial or thoroughly braced, because on them depends the reliability of the entire installation. The eyebolts, turnbuckles, and strain insulators should be not smaller than the $\frac{5}{8}$ -in size.

FIGURE 9.271 Trolley supports at ends of run.

394. Intermediate supports for crane trolley wires, the supports installed between the terminations to prevent sagging, can be arranged as shown in Figs. 9.270, 9.272, and 9.273. The bracket of Fig. 9.270 is, as above explained, applicable only if the crane has hook-shoe collectors. The block of wood that supports the insulating spools should be thoroughly dry and treated with an insulating paint. The bolt holes in it should be deeply countersunk to eliminate the possibility of grounds. The spools should be of porcelain. Porcelain tubes with porcelain knobs at the ends to form flanges will do. The length of the insulator between flanges should be at least 4 in. (101.6 mm). Spools turned from fiber are sometimes used. The spools should be so arranged that there will be at least a $\frac{1}{2}$ -in (12.7-mm) clearance between them and the hook shoe when it passes along.

In a fireproof building, when the crane has trolley-wheel collectors, the wires can be supported by trolley ears as in Fig. 9.273. The wooden supporting block must be thoroughly painted, and the bolt holes in it deeply countersunk to prevent the possibility of grounds. Tap bolts, screwing in from the rear, support the screw-clamp trolley ears which seat against washers. Figure-eight or,

FIGURE 9.272 Trolley hanger support.

FIGURE 9.273 Trolley ear supports.

preferably, grooved trolley wire is used. The wire should be drawn tightly at the terminations, and the ears should be installed every 8 or 10 ft (2.4 or 3 m).

For an outdoor crane, as well as for indoor applications, the wires can be supported in some cases as shown in Fig. 9.272. Standard street-railway-type trolley hangers and ears, which provide excellent insulation, are used. The hangers can, provided a proper location of the trolley wires results, be bolted directly to the crane girder.

395. There are almost numberless ways in which steel conductor rails can be arranged and supported.

The arrangement of a structural-steel tee conductor or trolley rail is shown in Fig. 9.274. Although the arrangement illustrated was developed for serving monorail cranes, which travel on the lower flanges of I beams, only minor modifications in the supporting forging would be required to adapt it for serving bridge cranes or other similar

traveling electrical machines. Note that a feature of the method is that no drilling or close fitting is required in the field. The only piece that is different for different jobs is the supporting forging, but this can be formed and drilled in the shop. The only tools required to erect the rail are a hacksaw for cutting the tee, which is purchased in 30-ft (9.1-m) lengths, and a wrench for setting the bolts. No bolt smaller than $\frac{3}{8}$ -in diameter is used, because smaller ones than this can be twisted asunder too easily. A $1\frac{1}{2}$ - by $1\frac{1}{2}$ - by $\frac{3}{16}$ -in T bar was selected, because this is about the smallest size that is rigid enough to sustain itself effectively between supports. A T bar of this size has a conductivity equivalent to that of a 109,800-cmil copper conductor, that is, a copper conductor between Nos. 1/0 and 2/0 in size.

The insulating hanger (Fig. 9.274, II) is similar to a trolley hanger but smaller. A malleable-iron bell encloses the molded material that supports and insulates the hanger stud. The splicing plate (IV) and the clamp (V) are castings, preferably of malleable iron, and the only machine work on them is the drilling and tapping of the holes. The section insulator (VI) consists of two castings, a fiber dividing block, and two wrought-iron clamping plates. Directions for spacing the insulating supports when erecting the conductor are given on the illustration. The terminal lug (VIII) is forked instead of annular so that it can be readily disconnected for isolating circuits for testing without taking out a bolt.

Rigid collector conductors must have insulating supports spaced at intervals of not more than 80 times the vertical dimension of the conductor, but in no case greater than 4.5 m (15 ft), and spaced apart sufficiently to give a clear electrical separation of conductors or adjacent collectors of not less than 25 mm (1 in.).

396. Track as circuit conductor (National Electrical Code). Monorail, tramrail, or crane-runway tracks may be used as a conductor of current for one phase of a three-phase ac system furnishing power to the carrier, crane, or trolley, provided the following conditions are fulfilled:

1. The conductors for supplying the other two phases of the power supply shall be insulated.
2. The power for all phases shall be obtained from an insulating transformer.
3. The voltage shall not exceed 300 V.
4. The rail serving as a conductor shall be bonded to the equipment grounding conductor at the transformer and may also be grounded by the fittings used for the suspension or attachment of the rail to a building or structure.

397. In computing the resistance of steel trolley rails the area in square inches of the section involved can be taken from one of the steel companies' handbooks, such as those issued by the Cambria and Carnegie steel companies; the area in circular mils can then be obtained by using the rule given below. By dividing this area by 6.14, which is the approximate ratio of the resistance of mild steel to that of copper, the equivalent copper area of the steel conductor results. Then by using the standard formula for the resistance of a copper conductor, the actual resistance of the steel is obtained.

FIGURE 9.275 Section of 1 1/2- by 1 1/2- by 3/16-in steel angle.

EXAMPLE What is the resistance of 160 ft of 1 1/2- by 1 1/2- by 3/16-in steel angle? (See Fig. 9.275 for a picture of the section.)

SOLUTION By referring to a handbook, it will be noted that the area of 1 1/2- by 1 1/2- by 3/16-in steel angle is 0.53 in². Then, to find its area in circular mils,

$$\begin{aligned} \text{Cmil} &= \frac{\text{area in in}^2}{0.000,000,785,4} = \frac{0.53}{0.000,000,785,4} \\ &= 674,800 \text{ cmil} \end{aligned}$$

$$\begin{aligned} \text{Equivalent in copper} &= \frac{\text{cmil area of steel}}{6.14} \\ &= \frac{674,800}{6.14} = 109,800 \text{ cmil} \end{aligned}$$

Then the resistance of the 160-ft length will be

$$\text{Resistance (for copper)} = \frac{11 \times \text{ft}}{\text{cmil}} = \frac{11 \times 160}{109,800} = 0.016 \Omega$$

The resistance, therefore, of 160 ft of 1 1/2- by 1 1/2- by 3/16-in steel angle is 0.016 Ω . It is evident from the equivalent copper area of the steel (109,800 cmil) that the conductivity of the steel section will lie between the conductivities of No. 1/0 (105,500 cmil) and No. 2/0 (133,100 cmil) copper wire.

The equivalent copper area in circular mils can be used in any of the wiring formulas for computing drop in a steel conductor, just as the actual area of a copper conductor is used in the same formulas, and the result will be a correct one for the steel section. Obviously the above method is approximate because the constants are approximate, but it is quite accurate enough for wiring computations, which always involve necessarily inaccurate assumptions.

398. Disconnecting means for cranes and monorail hoists (National Electrical Code). A motor-circuit switch, molded-case switch, or circuit breaker shall be provided in the leads from the runway contact conductors or other power supply on all cranes and monorail hoists. The disconnecting means shall be capable of being locked in the open position. The provision for locking or adding a lock to the disconnecting means shall be installed on or at the switch or circuit breaker used as the disconnecting means and shall remain in place with or without the lock installed. Portable means for adding a lock to the switch or circuit breaker shall not be permitted.

Where a monorail hoist or hand-propelled crane bridge installation meets all of the following, the disconnecting means shall be permitted to be omitted:

1. The unit is controlled from the ground or floor level
2. The unit is within view of the power supply disconnecting means
3. No fixed work platform has been provided for servicing the unit

Where the disconnecting means is not readily accessible from the crane or monorail hoist operating station, means shall be provided at the operating station to open the power circuit to all motors of the crane or monorail hoist.

The continuous ampere rating of the switch or circuit breaker specified above shall be not less than 50 percent of the combined short-time ampere ratings of the motors nor less than 75 percent of the short-time ampere rating of the motors required for any single motion.

Note that the NEC crane article (Art. 610) uses the wording “in view” in several places instead of “in sight” consciously in order to avoid the 15 m (50 ft) limitation built into the NEC definition of “in sight”. Many large industrial cranes are too big to make the 15 (50 ft) limit workable.

399. Contact conductors are required across the crane bridge for carrying the circuit to the carriage and hoist motors. They are usually made of bare copper wires supported in the general way described in Secs. 391 to 394, except that bridge collector conductors shall be kept at least 65 mm (2½ in.) apart, and if the span exceeds 25 m (80 ft), insulating saddles shall be placed at intervals not exceeding 15 m (50 ft).

400. Contact conductors. The National Electrical Code requires that the size of contact wires shall be not less than the following:

Distance between end strain insulators or clamp-type intermediate supports, ft	Size of wire
Less than 9.0 m (30 ft)	6 AWG
9.0 m–18 m (30–60 ft)	4 AWG
Over 18 m (60 ft)	2 AWG

401. The motor-circuit wiring must be enclosed in raceways or Type AC cable with insulated grounding conductor, Type MC cable, or Type MI cable unless otherwise permitted for specific conditions. Contact conductors and short lengths of exposed conductors at resistors, collectors, and other equipment shall not be required to be in raceways. Conductors exposed to external heat or connected to resistors shall have a flame-resistant outer covering or be covered with a flame-resistant tape individually or as a group.

The conductors must be of a size as given in Table 610.14(A) of the NEC. When flexible connections to motors or controllers are necessary, flexible metal conduit, liquidtight flexible metal conduit, liquidtight flexible nonmetallic conduit, multiconductor cable, or an approved nonmetallic flexible raceway may be used. Short runs for control equipment in the cab or on the bridge may be enclosed in auxiliary gutters. A common-return conductor may be used for the several motors of a single crane or hoist. The ampacities of conductors used with crane motors are as given in Table 610.14(A).

402. Motor control and protective equipment. The hoist of cranes must be provided with a limit switch which will control the upper limit of travel. It is best practice to arrange the control levers of all traveling cranes, in any one installation, in the same relative position in all the cages of the different cranes. The NEC allows two motors with their leads, which operate a single hoist, carriage, truck, or bridge and are controlled as a unit by one controller, to be protected by a single overload device. The device should be located in the cab if there is one.

403. A crane-wiring diagram is given in Fig. 9.276, which is typical for a dc, three-motor, traveling bridge crane. Variations in crane wiring and control schemes are practically numberless. For dc cranes, series motors are almost invariably used, while for ac cranes, wound-rotor motors are used.

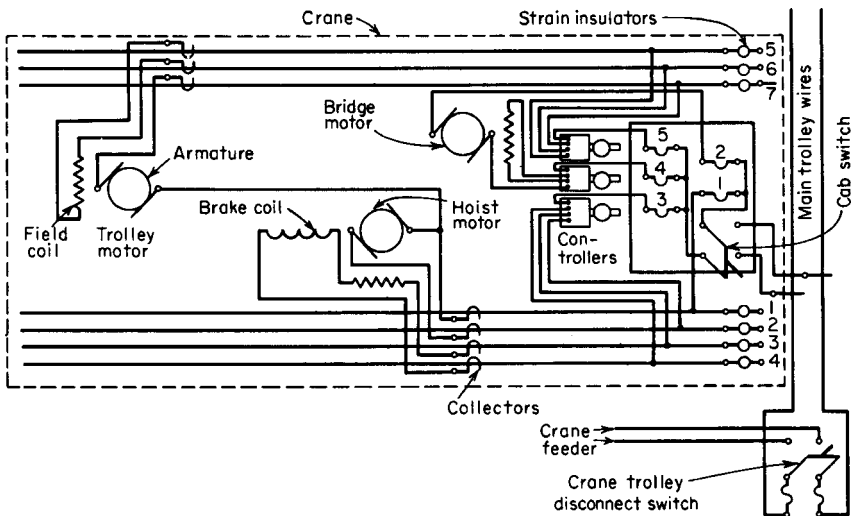

FIGURE 9.276 Direct-current crane-wiring diagram.

WIRING FOR CIRCUITS OF OVER 600 VOLTS

404. For wiring circuits operating at more than 600 V, the conductors must have an insulation sufficient for the particular voltage employed. The aboveground conductors must be installed in rigid or intermediate metal conduit, in rigid nonmetallic conduit, in electrical metallic tubing, as busways, in cable trays, as busways, as cablebus, in other identified raceways, or in open runs of metal-clad cable suitable for the use and purpose, except that in locations accessible to qualified persons only, open runs of Type MV cable, bare conductors, and bare busbars may also be used. Open runs of braid-covered insulated conductors must have flame-retardant braid, or the braid covering must be treated with a flame-retardant saturant after installation. The braid covering must be stripped back at conductor terminals to a safe distance according to the operating voltage, and is not less than 25 mm (1 in.) for each kilovolt of the conductor-to-ground voltage.

The metallic and semiconducting insulation shielding components of shielded cables shall be stripped back to a safe distance according to the circuit voltage at all terminations of the shielding, as in potheads and joints. At such points, suitable methods such as the use of potheads, terminators, stress cones, or similar devices shall be employed for stress reduction, and the metallic shielding tape and semiconducting components shall be connected to a grounding conductor, grounding busbar, or a grounding electrode.

405. Circuit interrupting devices for medium-voltage applications are covered in 490.21 of the NEC. Specific devices covered in this code section are as follows:

- (A) Circuit breakers
- (B) Power fuses and fuseholders
- (C) Distribution cutouts and fuse links
- (D) Oil-filled cutouts
- (E) Load interrupters

406. Isolating means (National Electrical Code). Means shall be provided to isolate an item of equipment completely. The use of isolating switches is not necessary if there are other ways of deenergizing the equipment for inspection and repairs, such as draw-out-type metal-enclosed switchgear units and removeable truck panels. Isolating switches not interlocked with an approved circuit-interrupting device shall be provided with a sign warning against opening them under load. A fuseholder and fuse designed for the purpose may be used as an isolating switch.

407. Space separation. The NEC requires that a minimum air separation in field fabricated installations between live conductors and between such conductors and adjacent grounded surfaces be not less than the values given in Table 490.24 of the NEC. These spacings do not apply to equipment designed, manufactured, and tested to accepted national standards.

408. Work space and guarding. The National Electrical Code requires the following protection:

- 1. Working Space.** The minimum clear working space in front of electrical equipment likely to require examination, adjustment, servicing, or maintenance while energized shall not be less than set forth in Table 110.34(A) of the NEC unless otherwise specified in the Code. Distances shall be measured from the live parts if such are exposed, or from the enclosure front or opening if such are enclosed.

The conditions are as follows:

- a.** Exposed live parts on one side and no live or grounded parts on the other side of the working space or exposed live parts on both sides effectively guarded by insulating materials.
- b.** Exposed live parts on one side and grounded parts on the other side. Concrete, brick, or tile walls will be considered grounded surfaces.
- c.** Exposed live parts on both sides of the work space.

Exception. Working space is not required in back of equipment such as dead-front switchboards or control assemblies where there are no renewable or adjustable parts (such as fuses or switches) on the back and where all connections are accessible from locations other than the back. Where rear access is required to work on deenergized parts on the back of enclosed equipment, a minimum working space of 762 mm (30 in.) horizontally shall be provided.

- 2. Separation from Low-Voltage Equipment.** Where switches, cutouts, or other equipment operating at 600 V, nominal, or less are installed in a vault, room, or enclosure where there are exposed live parts or exposed wiring operating at over 600 V, the high-voltage equipment shall be effectively separated from the space occupied by the low-voltage equipment by a suitable partition, fence, or screen.

Exception. Switches or other equipment operating at 600 V, nominal, or less and serving only equipment within the high-voltage vault, room, or enclosure shall be permitted to be installed in the high-voltage enclosure, room, or vault if accessible to qualified persons only.

- 3. Locked Rooms or Enclosures.** The entrances to all buildings, rooms, or enclosures containing exposed live parts or exposed conductors operating at over 600 V, nominal, shall be kept locked, except where such entrances are at all times under the observation of a qualified person at all times.

Where the voltage exceeds 600 V, permanent and conspicuous warning signs shall be provided, reading substantially as follows: "DANGER—HIGH VOLTAGE—KEEP OUT."

- 4. Illumination.** Illumination shall be provided for all working spaces around electrical equipment. The lighting outlets shall be arranged so that persons changing lamps or making repairs on the lighting system are not endangered by live parts or other equipment. The points of control shall be located so that persons are not likely to come into contact with any live part or moving part of the equipment while turning on the lights.

409. Isolation by elevation. The National Electrical Code requires that the distances above working spaces to unguarded live parts be not less than those specified in Table 110.34(E).

WIRING FOR CIRCUITS OF LESS THAN 50 VOLTS

410. For wiring circuits of less than 50 V, conductors not smaller than 12 AWG must be used. If the conductors supply more than one appliance or appliance receptacle, they must not be smaller than 10 AEG. Receptacles must be rated at not less than 15 A; in kitchens, laundries, and other locations where portable appliances are likely to be used, the receptacles must be rated at not less than 20 A.

WIRING FOR HAZARDOUS (CLASSIFIED) LOCATIONS

411. Hazardous location classifications (Adapted from *Practical Electrical Wiring*, 20th ed., © Park Publishing, 2008, all rights reserved) arise because of the presence or handling of explosive gases, liquids, flammable dusts, or easily ignitable fibers. The basic rules for wiring in such locations are covered by NEC Articles 500 through 506, and more specific information is covered in Articles 510 through 517—altogether more than 88 pages. This handbook can discuss only the barest details of this intricate subject.

The NEC uses three basic classes to indicate the type of hazard involved, and those classes (I, II, and III) are further subdivided into divisions (1 and 2) to indicate the prevalence of hazard, and also into lettered groupings to specify the exact type of hazard. Area classifications are seldom performed by an electrical inspector; they are done by qualified engineers subject to review. The reviewer may be the chief of the fire department or some other official. The NEC now requires that hazardous (classified) locations be completely documented, and that those documents be made available to the inspector.

412. Class I locations are those “in which flammable gases, flammable liquid-produced vapors, or combustible liquid-produced vapors are or may be present in the air in quantities sufficient to produce explosive or ignitable mixtures.” Combustible liquids will burn, but have flash points (the temperature at which enough liquid vaporizes to create an ignitable fuel-air mixture at the surface of the liquid) at or above 38°C (100°F). Note that the flash point of a liquid is much different than the ignition temperature of its vapor.

Class I, Division 1 locations are those in which hazardous concentrations of gas (1) exist continuously or intermittently under normal operations, (2) exist frequently because of maintenance or leakage, or (3) might exist because of breakdowns or faulty operation that might also result in simultaneous failure of electric equipment in such a way as to cause the electrical equipment to become an ignition source. Examples are paint-spraying areas, systems that process or transfer hazardous gases or liquids, portions of some cleaning and dyeing plants, and hospital operating rooms in countries that still use ethers and related flammable anesthetic agents. These anesthetizing materials are no longer used in the United States, but they are still used in some countries.

Class I, Division 2 locations are locations (1) in which flammable gases or volatile flammable liquids are normally confined within containers or closed systems from which they can escape only in case of breakdown, rupture, or abnormal operation; (2) in which the hazardous concentrations are prevented by mechanical ventilation from entering but which might become hazardous upon failure of the ventilation; or (3) that are adjacent to a Class I, Division 1 location and might occasionally become hazardous unless prevented by positive-pressure ventilation from a source of clean air by a ventilation system that has effective safeguards against failure. Examples are storage in sealed containers and piping without valves.

413. Class II locations are those having combustible dust.

Class II, Division 1 locations are those in which combustible dust is or may be in suspension in the air in sufficient quantity to produce an explosive or ignitable mixture (1) continuously or intermittently during normal operation, (2) as a result of failure or abnormal operation that might also provide a source of ignition by simultaneous failure of electric equipment, or (3) in which combustible dust that is electrically conductive may be present. Examples are grain elevators, grain-processing plants, powdered-milk plants, coal-pulverizing plants, and magnesium-dust-producing areas.

Class II, Division 2 locations are those in which combustible dust is not normally in suspension in the air and is not likely to be under normal operations in sufficient quantity to produce an explosive or ignitable mixture but in which accumulations of dust (1) might prevent safe dissipations of heat from electric equipment or (2) might be ignited by arcs, sparks, or burning material escaping from electric equipment. Examples are closed bins and systems using closed conveyors and spouts.

414. Class III locations are those in which there are easily ignitable fibers or flyings, such as lint, but in which the fibers or flyings are not in suspension in the air in sufficient quantity to produce an ignitable mixture.

Class III, Division 1 locations are those in which easily ignitable fibers or materials that produce combustible flyings are manufactured, used, or otherwise handled, such as textile mills, cotton gins, and woodworking plants.

Class III, Division 2 locations are those in which such fibers are stored, such as a warehouse for baled cotton, yarn, and so forth.

415. Groups. Equipment for use in Class I locations is divided into Groups A, B, C, and D; for Class II into Groups E, F, and G. Each group is for a specific type of hazardous material, which you can determine by consulting your copy of the NEC. All equipment for hazardous locations must be marked to show the class and the group for which it is approved; some equipment is suitable for more than one group and is so marked. Note that for Group E, which encompasses the electrically conductive metallic dusts, there are no Division 2 locations. These dusts are so hazardous that if they are present in any quantities, no matter how infrequently, the location must be wired to Class II, Division 1 standards, using equipment evaluated for Group E exposure.

416. Basic principles apply to hazardous (classified) location equipment. Enclosures for equipment in Class I, Division 1 locations and enclosures for devices with ignition-capable arcing contacts in Class I, Division 2 locations must be explosionproof. This does not mean that explosive gases or vapors cannot enter into them. The eventual entrance of such gases or vapors is assumed to be inevitable, resulting in ignition, but the enclosure is made to withstand and contain the force of the explosion. Moreover, the hot exploded gas does escape, but not until it has passed through a tight joint that is either threaded or has a wide ground-finish flange. In either case, before it finally escapes to the outside of the enclosure, it has cooled to a temperature below the ignition temperature of the gas in the surrounding atmosphere. The cooling takes place while the gas passes through the long circuitous path of a threaded joint, or across the wide, tight-fitting, ground-finish flange.

For Class II locations, enclosures must be dust-ignition-proof. Dust can be prevented from entering enclosures by means of gaskets, and enclosures can be made with large exposed surfaces for more rapid heat dissipation.

If a Class II dust-ignition-proof enclosure is used in a Class I location, gas can get in, explode, and blow the enclosure to pieces, possibly setting off a larger explosion in the general area, leading to fire or injury. Likewise, if a Class I explosionproof enclosure is installed in a Class II location, it can overheat when blanketed with dust and start a fire.

For a Class III location, equipment only has to be totally enclosed to prevent the entry of fibers and flyings, and to prevent the escape of arcs, sparks, or hot particles.

417. Other protective approaches may work better. The best approach is to use ingenuity and keep electrical equipment out of the hazardous environment. Failing that, another approach is to keep the power circuits somewhere else, and just maintain sensors near the combustible material. If the energy level can be assured to be sufficiently low, any failure in the wiring system won't be ignition capable. These energy levels are very low. For example, an energy level of just $\frac{1}{4}$ milliwatt-second (mW-s) will ignite methane, and levels one-tenth of that will ignite unsaturated hydrocarbons like ethylene. Nevertheless, many sensors can and do function on what are called *intrinsically safe circuits* (covered in NEC Article 504). These circuits use zener diodes in their supplies, arranged so that even a direct short circuit with its associated potential arcing and heating would not be ignition capable. These circuits can be used with ordinary wiring methods in hazardous (classified) locations for which they are rated.

Nonincendive wiring is closely related to intrinsically safe wiring. Under all normal operating conditions it can't produce ignition-capable energy, but under very unusual (but foreseeable) operating conditions, might produce such an effect. These circuits are allowed in ordinary wiring in Division 2 locations, but not Division 1. The principle here is that given two low-likelihood probabilities, the probability of them occurring at the same moment is infinitesimal—the two low probabilities in this case being a Division 2 vapor release and a nonincendive circuit failing in a way that is ignition capable.

Another strategy is to exclude all gases and vapors through positive pressure, called "purged and pressurized" in the NEC. This equipment must be connected to a source of clean air under constant pressure. It must be arranged with automatic means to disconnect power if the air supply fails, and it must be equipped with a time-delay function so that its interior can purge prior to the restoration of power. There are three levels of purged and pressurized enclosures. Type X purging reduces a Division 1 environment to unclassified, Type Y purging reduces from Division 1 to Division 2, and Type Z purging goes from Division 2 to unclassified.

Other strategies involve hermetic seals to exclude the hazardous atmosphere, and oil-immersed contacts, which also exclude the hazardous gas or vapor. These two methods are allowable in Division 2 locations only.

418. Zone classification system (NEC Article 505) is a new approach. A number of international standards take the Class and Division system a step further, dividing Division 1 into areas where the specified environment exists routinely and areas where it would exist only for brief periods, probably not long enough to be taken up into the interior of a wiring system and exploding, conditions for which Division 1 equipment must be designed. The result is the Zone system, which is now in the NEC as a parallel classification system. Zone 0 is the worst case, and all power wiring is excluded from it. Zone 1 gets the balance of the traditional Division 1, and since the routine or continual exposure doesn't apply, most explosionproof requirements do not apply to Zone 1 either. Zone 2 is essentially the same as Division 2.

An occupancy can be designed to the Zone system, or to the Class and Division system, but there must be no overlap or intersection between them, except that Zone 2 and

Division 2 locations can adjoin but not overlap. It is permitted to reclassify an existing Class- and Division-classified area under the Zone system, provided the entire space classified on the basis of a single flammable gas or vapor is reclassified under Zone system requirements. The Zone system classifications and equipment selection must be under the control of a qualified person.

The 2005 NEC (Article 506) extended the zone concept to environments with combustible dust, comparable to Class II under the traditional system, with supervisory requirements comparable to Article 505 applications. The traditional Class and Division system has proven very durable, however, in large part because Zone 2 and Division 2 are functionally identical. The principal economic benefit of the Zone system derives from the more lenient treatment of Zone 1 wiring in comparison to Division 1. However, the overwhelming majority of hazardous (classified) locations today are Division 2, because environmental concerns have made the sort of chemical releases that create Division 1 environments largely nonexistent, or confined to extremely small areas from which it is quite practical to exclude most wiring other than instrumentation. Many facilities are finding no net benefit in changing classification systems.

419. Proper installation and maintenance is essential. In all cases, enclosures such as luminaires and panelboard enclosures must be kept reasonably cleaned of accumulations of residue, fibers, dust, or whatever is contained in the atmosphere. And they must be properly installed. For example, if one of four screws in the cover of an explosionproof switch enclosure is left untightened, or if the flanged joint of a cover or box is scratched, exploded gas will escape before it has sufficiently cooled, and an explosion or fire could result.

A threaded joint must have at least five full threads fully engaged (four and a half threads if factory threaded). Figure 9.277 shows an explosionproof box with threaded hubs for threaded metal rigid conduit, and a threaded cover. Figure 9.278 shows an explosionproof receptacle and plug. The box containing the receptacle has a ground-finish flange joint with four screws, and a threaded hub for conduit. The plug and receptacle are designed so the plug can be withdrawn only part of the way, which breaks down the circuit; an arc, if it forms, will explode the small amount of vapor in the interior. This takes place during the brief time it takes to twist the plug before it can be withdrawn.

Many plugs and receptacles are designed so the plug cannot be inserted or removed unless a switch is in the off position, and the switch cannot be turned on unless the plug is fully inserted.

FIGURE 9.277 A typical explosionproof box.

FIGURE 9.278 An explosionproof receptacle and plug to fit.

An explosionproof HID luminaire is shown in Fig. 9.279. Explosionproof fluorescent luminaires are also available, as are explosionproof panelboards, disconnecting means, circuit breakers, motors, and various other equipment—even telephones.

FIGURE 9.279 An explosionproof luminaire.

420. Sealing fittings compartmentalize the wiring system. Explosive gases or vapors can pass from one enclosure to another through conduit. The conduit itself can contain a substantial amount of such material, and without seals to compartmentalize the system the quantity of fuel available to an internal explosion will be enough to cause a rupture, a phenomenon known as *pressure piling*. To avoid these outcomes, sealing fittings of the general type shown in Fig. 9.280 must be installed. The sealing fitting is installed in the conduit adjacent to the enclosure, and thereby completes the enclosure. Then after the wires are pulled into place, the fitting is filled with a sealing compound that effectively prevents explosive or exploded gases from passing from one part of the electrical installation to another, or from passing from a hazardous location to a nonhazardous location where unexploded gases might reach a source of ignition. Note the qualification of the word “prevents.” The actual NEC text uses the term “minimizes” because seals will pass some gases over time, particularly if the gas is pressurized. The principal function of these seals is to isolate sections of conduit or enclosures in the event of an internal explosion; seepage over long periods must be addressed through other approaches. A worker was killed and a catastrophic fire resulted from a disconnect being opened in an enclosure that had accumulated a hazardous quantity of gas resulting from this type of seepage.

FIGURE 9.280 By pouring sealing compound into a fitting of this kind, one run of conduit is sealed off from another, minimizing the possible accumulation of large fuel-air mixtures in one conduit segment subject to ignition.

The fitting shown in Fig. 9.280 is for a vertical run of conduit. A different type consists of a T-shaped explosionproof fitting or box with a screw-on cover having a spout, with a plug to close the end of the spout. This kind (Fig. 9.281) can be used in either vertical or horizontal runs of conduit. Seals must always be accessible after installation. Seals are also required at hazardous (classified) location boundaries, but those at the boundary between a Division 2 and an unclassified location need not be explosionproof, but must be identified for the purpose of minimizing the passage of gasses under normal operating conditions.

FIGURE 9.281 This seal can be used in any position.

The product standards for seal fittings were reorganized under the 1968 NEC, which at the time set a limit of 25 percent wire fill for new work, and 40 percent for old work. Since seals cannot be opened and reused, the standards presumed a 25 percent fill. When the NEC changed to allow 40 percent fill for even new installations, these standards were overlooked until comparatively recently. The NEC now requires seals to be figured on the basis of 25 percent fill unless listed otherwise. A number of manufacturers now have seals with larger bodies that will accommodate a 40 percent fill. In addition, the seal in Fig. 9.281 clearly allows for easy spreading of the conductors, solving the major problem of undersized seals.

A seal with two wires touching, and the seal compound incomplete at that point, is no seal at all. A major manufacturer has developed a new sealing compound, however, that can be squirted into its seal fitting with no damming or conductor separation, and it will harden into an acceptable seal. This should be very beneficial.

421. Wiring methods for hazardous locations are limited. Threaded rigid metal conduit, intermediate metal conduit, and Type MI cable are acceptable in all locations. Rigid nonmetallic conduit is permitted for underground use below 600 mm (24 in.) of cover, with steel conduit ends over the final 600 mm (24 in.) of the run in both directions, allowing a conventional threaded steel end to mate a seal to, because in many cases the hazardous environment is assumed to extend to the point of conduit emergence. In industrial locations with restricted public access, a special type of Type MC cable with a gas/vapor-tight corrugated aluminum armor under a nonmetallic jacket can be used in hazardous locations. Where flexibility is required, there are explosionproof flexible fittings. If additional flexibility is required, extra-hard-usage cord is permitted under conditions of qualified maintenance and supervision, guarding or equivalent protection, and suitable seals where terminated.

In Division 2 locations, most metal-clad or metallic wiring methods are permitted. Where flexibility is required, the usual metallic flexible wiring methods are allowable, along with extra-hard-usage flexible cord. Heavy-wall nonmetallic conduits (Type PVC, Schedule 80, and fiberglass Type RTRC, marked “-XW”) are allowed where very corrosive environments are anticipated in industrial occupancies, but only with qualified service and supervision and restricted public access.

422. Commercial repair garages are covered by NEC Article 511. A commercial garage is a location used for servicing and repairing self-propelled vehicles that use flammable liquid fuels, including cars, trucks, buses, or tractors. The 2005 NEC greatly revised many key portions of this material in order to correlate it with the NFPA 30A standard covering these facilities, and the 2008 NEC rewrote 511.3 to simplify the area classification process. Under NFPA 30A, repair garages fall into one of two principal types, described as “major” and “minor.” A *minor* facility does tune-ups, oil and other fluid changes, brake repairs, tire rotations, etc. This classification includes the popular “quick lube” type of facility. In contrast, a *major* facility does (in addition) engine overhauls, body and painting work, and (most critically in terms of area classification) repairs that require draining of a fuel tank. Area classification for these facilities focuses on three areas (floor, ceiling, and subfloor pits), and the requirements in each depend on whether specified ventilation is provided.

To summarize, make three assessments: (1) Are you in a major, or minor, repair garage? (2) Are you considering a ceiling, floor, or a pit? (3) Is the space you are considering ventilated per the applicable code specification? In 511.3, the NEC breaks the garage classifications out first (major vs. minor) in lettered subsections. Then it breaks out the locations in numbered paragraphs under each. Finally, under each of those headings come two lettered paragraphs (ventilation provided or not provided).

Major Repair Garages. The general floor areas in major repair garages are considered as Class I, Division 2 to a height of 450 mm (18 in.) above the floor unless the space is ventilated to provide at least four air changes per hour, or 0.028 m³/min (1 cfm) of fresh air per 0.093 m² (ft²) of floor area. The ventilation must be taken from no higher than 300 mm (1 ft) above the floor, and arranged to exchange air across the entire floor area. Ceiling areas are classified to the same extent (i.e., unclassified if there is 1 cfm/ft² ventilation provided,

otherwise, Div. 2), except the 450 mm (18 in.) measurement for Div. 2 extends down from the ceiling. The classification does not apply if the facility will not be working on vehicles using lighter-than-air fuels such as hydrogen or natural gas. If classification does apply, the exhaust port must be within 450 mm (18 in.) from the ceiling high point. For pit areas, their classification is reduced from Div. 1 to Div. 2 if, and only if, they are ventilated at the rate of at least six air changes per hour.

Minor Repair Garages. The general floor areas in minor repair garages are unclassified as long as there are no subfloor work areas or pits. If the work area includes these subfloor areas, the floor areas are classified exactly the same as in the case of major repair garages. Ceiling areas are unclassified unless lighter-than-air fuels are transferred. For pit areas, they are unclassified if they are separately exhausted in a similar manner as major repair garages. Pits not so ventilated in a minor repair garage become Class I, Division 2 locations.

Office areas, stock rooms, toilets, etc., are all classified as nonhazardous locations if they have at least four air changes an hour, or if they are effectively cut off from the repair area by partitions. Areas that are adjacent to the repair area but not cut off by partitions and do not have four air changes an hour may be classified as nonhazardous locations if they have either sufficient ventilation for ordinary needs, an air pressure differential, or spacing that presents no hazard in the judgment of the authority having jurisdiction. [A pressure differential means that the air pressure is slightly higher in the adjacent area than in the hazardous (repair) area so that no vapors will flow from the hazardous area to the adjacent area.]

Wiring Methods. The wiring in nonhazardous areas of commercial garages may be any type discussed in this division.

Exceptions: In an area above a hazardous location that is not cut off by a ceiling, the wiring must be in a metal raceway, rigid nonmetallic conduit, ENT, Type AC or MC or MI cable, or manufactured wiring systems, or Type TC cable, or for signaling purposes, Type PLTC. EMT is very commonly used in such areas.

Luminaires in the area above vehicle lanes must be not less than 3.7 m (12 ft) above the floor, or be constructed in a way that prevents sparks or hot particles from falling to the floor. Where fluorescent lighting is used and the luminaires are neither 3.7 m (12 ft) above the floor nor equipped with a glass or plastic bottom, there are plastic sleeves and similar devices available to hold a broken fluorescent tube (lamp) and prevent the hot cathode ends of the lamp from falling to the floor. Other equipment above the hazardous location, such as motors or switches, must be totally enclosed if less than 3.7 m (12 ft) above the floor. Drop lights, unless restrained against coming within 450 mm (18 in.) of the floor, must be suitable for Class I, Division 1 locations.

Wiring in the hazardous location must be of a type specifically described in this part of Div. 9 for Class I, Division 1 or Division 2 (whichever it is). A sealing fitting is required to be installed where the wiring enters or leaves the hazardous location so that there is no coupling or other fitting between the sealing fitting and the boundary between the hazardous and the nonhazardous locations. A sealing fitting is also required at an equipment enclosure, such as a receptacle or switch box, that is within the hazardous location, but it is common practice to keep all such wiring and equipment above the 450 mm (18-in) level where practical. Equipment can almost invariably be kept above the 450 mm (18-in) level, but sometimes the wiring is brought in from underground or installed in the floor slab. In all such cases, install threaded rigid metal conduit, use gasoline- and oil-resistant wire, and seal the conduit so there is no coupling or other fitting between the sealing fitting and the 450 mm (18-in) level. Install a sealing fitting at the panelboard end as the last fitting above grade.

Battery chargers and their control equipment must not be installed in the hazardous location. If batteries are charged in a separate compressor room, tire-storage room, or similar

area, the room must be well ventilated to allow dissipation of the hydrogen gas. (There is not enough hydrogen gas involved for a battery room to be classified as a hazardous location, but the small amount that is developed must be allowed to dissipate.)

423. Service stations are covered in the NEC as “Motor Fuel Dispensing Facilities” in Article 514. The service area (such as a “lubritorium”), office, storage room, toilets, etc., are treated the same as similar areas in a commercial garage. The gasoline-dispensing areas are classified as follows:

The area within the gasoline dispenser (pump) is no longer classified by language in the NEC; due to differences in modern dispenser designs, this area classification is now left to the product standards as part of the listing process. However, any pit or below-grade space that extends upward into a classified location within the dispenser is Class I, Division 1. In addition, the entire area within 450 mm (18 in.) horizontally of the dispenser enclosure, or of any liquid-handling components within the enclosure, is Class I, Division 2. Moving outward from the dispenser, the entire area extending 6.0 m (20 ft) horizontally in all directions from the dispenser enclosure and extending up to 18 in. above grade is a Class I, Division 2 location. This includes any indoor area not suitably cut off by partitions. The below-grade area is unclassified because there is not enough air to support combustion. However, conduits routed beneath these areas can accumulate fumes and must be sealed.

The requirement to seal applies to the point of conduit emergence from grade. This allows the seal, which must always be accessible and usually within a conduit length of the required location, to be at a convenient point. Otherwise installers would be installing hand-holes in areas of unbroken pavement to accommodate sealing requirements.

The area within 3.0 m (10 ft) horizontally of a storage-tank fill pipe (for a loose-fill connection) or 1.5 m (5 ft) horizontally of the tight-fill connections more common today because of environmental concerns, and extending to 450 mm (18 in.) above grade is a Class I, Division 2 location; the below-grade area beneath this is a Class I, Division 1 location. For storage tank vent pipes, the spherical volume within a 900-mm (3 ft) radius of the discharge point of a storage-tank vent pipe is a Class I, Division 1 location; the spherical volume between the 0.90-m and 1.5-m (3-ft and 5-ft) radius is a Class I, Division 2 location.

Any wiring to pole lights, signs, etc., must be kept out of the hazardous locations or be made to comply with the rules for the location, which include a sealing fitting at each end of a conduit that passes through a hazardous area. It also means that any below-grade wiring within any hazardous location must be in rigid metal conduit and be nylon-covered gasoline- and oil-resistant wire, since gasoline can and often does get into below-grade conduit in hazardous locations. (Under some conditions, as noted in the general discussion, rigid non-metallic conduit and Type MI cable may also be installed underground.) For wiring to a gasoline dispenser, a sealing fitting must be the first fitting in the conduit where the conduit emerges from below grade at the dispenser and also where the conduit emerges from below grade at the panelboard. An explosionproof flexible fitting is frequently required between the sealing fitting and the equipment inside the dispenser, since the conduit may not quite line up with the internal fittings, and there is not much room for bending rigid metal conduit underneath the dispenser.

Any branch circuit supplying a dispenser or passing through a dispenser (such as to supply a lighting standard near the dispenser) must have a circuit breaker or switch that disconnects all conductors of the circuit, including the grounded (white) conductor. There are special circuit breakers made for this specific purpose; they have a switching pole for the grounded conductor as well as for the ungrounded conductor, but there is no overcurrent device in the grounded conductor pole of the breaker. If such a circuit breaker is not used, a switch without a fuse in the grounded conductor, but that opens all conductors (including the grounded conductor) simultaneously, must be used.

424. Paint-spraying booths are covered in NEC Article 516, which include paint-spraying booths and areas. Some repair garages have a body shop with a paint-spraying booth. No electric equipment, and no wiring except threaded rigid metal (or intermediate metal) conduit, or Type MI cable, or metal boxes (or fittings), provided they contain no splices or terminal connections, are permitted in a paint-spraying booth unless the equipment and the splice and terminal enclosures are approved for both Class I, Division 1, Group D locations, *and* for accumulations of readily ignitable residues. Luminaires are the only equipment available (as of this writing) meeting both these requirements. To wire such a booth, proceed as follows:

Luminaires (in conjunction with transparent baffles, exhaust-air movement, and careful placement) can often be installed where they will not be covered with paint residue, but it is sometimes difficult to do and not always acceptable to some inspectors. So use luminaires that are approved for both Group D and for paint residue. Then wire them with threaded rigid (or intermediate) metal conduit (or Type MI cable) without splice boxes or switches inside the booth. Explosionproof boxes, as shown in Fig. 9.277, may be used as long as there are no splices in the box; and switches must be installed outside the booth.

If luminaires other than the type that are approved for residue are used, install them outside the booth so that light will enter the booth interior through extra-strength glass panels in the roof or sides of the booth (or both). Wire these luminaires as required for the garage location in which they are located.

The exhaust fan (which must have nonferrous blades, that is, not iron or steel but rather aluminum or brass) must have the fan motor installed outside the exhaust stack and connected to the fan by a metal shaft or by a staticproof belt. Wire the motor as required for the location. That is, if it is inside the garage repair area, wire it accordingly; if it is outdoors, wire it for an outdoor location. (In some cases one wall of a booth may be the exterior building wall; so in some cases, the motor could be outdoors.)

INSTALLATION OF APPLIANCES

425. Connection to circuit and protection. A portable appliance may be connected only to a receptacle having a rating at least as great as the appliance. The standard duplex convenience-outlet receptacle is rated at 15 A and may supply a single 15-A fixed appliance or a 12-A portable appliance if used on a 15-A branch circuit. Heavy-duty receptacles rated at 20, 30, and 50 A may be obtained for higher-current appliances. On new installations all 15- and 20-A receptacles must be of the grounding type. (Refer to Div. 4 for a description of receptacles.) Most household appliances, such as toasters, hot plates, percolators, flatirons, waffle irons, refrigerators, radiant heaters, roasters, portable ovens, etc., are rated at less than 12 A, so that they may be used in the standard outlet on a 15-A circuit.

Appliances other than motor-operated ones are not generally required to have individual overload protection.

426. In wiring appliances one of the approved types of cords listed in Div. 2 should be used. If the appliance is rated at more than 50 W and temperatures of more than 121°C (250°F) are produced on surfaces with which the cord is apt to be in contact, one of the types of heater cords must be used. Every heating appliance which is intended to be applied to combustible material as a smoothing iron must be equipped with a stand, which may be separate or a part of the appliance. Each heating appliance intended to be located in a fixed

position must have ample protection provided between the appliance and adjacent combustible material.

427. Disconnecting means (National Electrical Code). Each appliance shall be provided with a means for disconnection from all ungrounded conductors as follows:

1. **Portable Appliances.** For portable appliances (including household ranges and clothes dryers) a separable connector or an attachment plug and receptacle may serve as the disconnecting means. The rating of a receptacle or of a separable connector shall not be less than the rating of any appliance connected thereto, except that demand factors authorized elsewhere in the NEC may be applied. Attachment-plug caps and connectors shall conform to the following:
 - a. **Exposed parts.** They shall be so constructed that there are no exposed current-carrying parts, except the prongs, blades, or pins. The cover for the wire terminations shall be a part that is essential for the operation of an attachment plug or connector (dead-front construction).
 - b. **Rating.** The rating of a receptacle or of a separable connector shall not be less than the rating of any appliance connected thereto.
 - c. **Noninterchangeability.** They and their mating receptacles shall be constructed such receptacles or cord connectors do not accept an attachment plug with a different voltage or current rating from that for which the device was intended. However, a 20-A T-slot receptacle or cord-connector shall be permitted to accept a 15-A attachment plug of the same voltage rating. Nongrounding receptacles and connectors shall not accept grounding-type attachment plugs.

For cord- and plug-connected appliances, where the separable connector or plug and receptacle are not accessible, the appliance shall be provided with a disconnecting means in accordance with the provisions for permanently connected appliances. For household electric ranges, a plug-and-receptacle connection at the rear base of a range, if it is accessible from the front by removal of a drawer, is considered as meeting the intent of the accessibility rule.

2. **Permanently Connected Appliances.** For permanently connected appliances rated not over 300 VA or $\frac{1}{8}$ hp, the branch-circuit overcurrent device may serve as the disconnecting means. For permanently connected appliances of greater rating, the branch-circuit switch or circuit breaker within sight from the appliance, or is capable of being locked in the open position, may serve as the disconnecting means.
3. **Unit Switches with a Marked "Off" Position.** Switches that are a part of an appliance and that disconnect all ungrounded conductors shall not be considered as taking the place of the single disconnecting means required by this section unless there are other means for disconnection as follows:
 - a. **Multifamily dwellings.** In multifamily (more than two families) dwellings, the disconnecting means shall be within the apartment or on the same floor as the apartment in which the appliance is installed and may control lamps and other appliances.
 - b. **Two-family dwellings.** In two-family dwellings, the disconnecting means may be outside the dwelling in which the appliance is installed. This will permit an individual switch for the dwelling to be used and shall also be permitted to control lamps and other appliances.
 - c. **One-family dwellings.** In one-family dwellings, the service disconnecting means may be used.
 - d. **Other occupancies.** In other occupancies, the branch-circuit switch or circuit breaker, if readily accessible to the user of the appliance, may be used for this purpose.

4. **Switch or Circuit Breaker to Be Indicating.** Switches or circuit breakers used as disconnecting means shall be of the indicating type.
5. **Motor-Driven Appliances.** A switch or circuit breaker which serves as the disconnecting means for a permanently connected motor-driven appliance of more than $\frac{1}{8}$ hp shall be located within sight of the motor controller.

Exception. A switch or circuit breaker that serves as the other disconnecting means as required in Par. 3 shall be permitted to be out of sight from the motor controller of an appliance which is provided with a unit switch or switches with a marked-off position and which disconnects all ungrounded conductors.

428. Portable appliances need to be grounded as specified in Sec. 250.114 of the NEC.

429. Signals and temperature-limiting devices for heated appliances. In other than dwelling-type occupancies, each electrically heated appliance or group of electrically heated appliances intended to be applied to combustible material shall be provided with a signal unless the appliance is provided with an integral temperature-limiting device.

430. Overcurrent protection for nonmotor-operated appliances must not exceed the marking on the appliance (if any). If the appliance is not marked, the overcurrent protection must not exceed 20 A on appliances rated 13.3 A or less, and must not exceed 150 percent of the rating of larger appliances. Rounding up to the next higher standard sized overcurrent device is permitted.

Electric ranges, cooktops, and similar appliances with surface-type heating elements that present a load in excess of 60 A after the application of the demand factors in Table 2 in Div. 12 shall have that load subdivided into two or more circuits. The resulting circuits shall have overcurrent protection rated at not over 50 A.

ELECTRIC COMFORT CONDITIONING

431. Introduction. As a practical guide to electric comfort conditioning, these sections are designed to provide a general understanding of when to use electric heating and cooling systems, how to estimate heat loss, what type of equipment is available, and where comfort conditioning equipment should be located.

432. When to use electric heating and cooling. Electric heating and cooling systems are used in all types of buildings, and there are outdoor spot-heating systems in addition to snow-melting and deicing systems.

433. Residential buildings. Electric heating and cooling systems for single-family dwellings and many multifamily dwellings, widely accepted at one time throughout the United States, are now used far less frequently due to the cost of energy. Whether such a

system is most desirable economically, a personal preference, or a luxury depends upon its usage by the occupants, the construction of the building, and the local electric utility rates (cost per kilowatthour of electricity for heating).

- 1. Advantages of Electric Heating** include individual room control, long life of the equipment, space-saving features, cleanliness, and safety. However, the user can abuse these advantages by leaving doors, windows, or fireplace chimney flues open; overheating; or improper building construction or insulation. Improper usage by the occupant is usually the reason for excessive utility bills.
- 2. Insulation.** If electric heat is to be operated economically, it is important to consider the value of insulation. A well-insulated residence requires less equipment and incurs lower operating costs. Savings in equipment cost and annual operating costs generally pay for the increased cost of added insulation, storm windows, and storm doors.
- 3. Selecting Insulation.** It is important to consider the effectiveness of insulation in terms of resistance to heat transfer and not just thickness. The effectiveness of insulation (for ceilings, walls, and floors) is judged in terms of its *R* (resistance) value. The insulation manufacturer will indicate the *R* value for a given thickness. For buildings with electric comfort conditioning, the National Mineral Wool Insulation Association at one time specified a minimum resistance as follows: ceilings = *R*19; walls = *R*11; floors = *R*13. Building codes today generally move these numbers far higher, and should be consulted prior to designing an installation.
- 4. Construction of the Wall or Ceiling Roof.** The construction is not very significant if the minimum *R* value is provided. Storm windows (and doors) or double-glazed glass more than double the *R* value of the glass area.
- 5. House with a Heated Basement.** Such a house need not have insulation under the floor, but there should be insulation under a floor which is over an exposed crawl space. The most effective insulation for concrete slabs is around the exposed outside edge. Perimeter-slab insulation can be extended down vertically about 24 in. (609.6 mm) or can be installed around the edge of the slab at about the same distance.
- 6. Insulation Protection.** To protect insulation from the negative effect of moisture from within the house, a vapor barrier on the inside face of the insulation is recommended. The vapor barrier must be protected from damage, and any tears or holes must be repaired.
- 7. Well-Insulated Buildings.** A well-insulated building may become an excessively humid building. To avoid excessive humidity buildup, a *humidistat* should be used to control one or more exhaust fans or a fresh-air ventilator. The humidistat closes the circuit to the fans when the relative humidity exceeds the preselected humidistat setting.
The operation of a humidistat is similar to that of a thermostat, except that the sensing element responds to humidity instead of heat. Also, the element in a humidistat most commonly consists of a series of human hairs, which respond to changes in the relative humidity. In a home the relative humidity rises because of the use of dish-washers, dryers, washing machines, showers, sinks, and similar sources when use of water or production of moisture occurs.
- 8. Heat Loss.** A residential building, insulated to the previously indicated specification, will have a heat loss of about 10 W/ft² (0.93 W/m²) or 1 W/ft³ (0.028 W/m³).
- 9. Heat-Loss Survey.** Before actual load requirements are determined, a heat-loss survey of all exposed rooms should be made. If, for example, in the New York City area, with an outside design temperature of 0°F (−18°C) and an inside design temperature of 70°F (18°C), the heat loss is to be determined for a frame residence, the loss for each exposed room can be calculated in the same manner as in the following example for a 12- by 10- by 8-ft (3.7- by 3- by 2.4-m) corner bedroom (bedroom A).

	Sq-ft		Factor		Heat loss, W
Gross outside wall windows (and doors)	176		–		–
	24	×	12	=	288
Net outside walls	152	×	1.6	=	243
Ceiling	120	×	1.0	=	120
Floor	120	×	2.0	=	240
Infiltration	960	×	0.4	=	384
Total heat loss					1,275

10. Steps in Calculating Heat Loss

- Determine heat-loss factor in watts per square foot by the R value. Refer to the *NEMA Electric Heating Guide*, *The Electric Heating and Cooling Handbook* (published by Edison Electric Institute), or the *ASHRAE Guide and Data Books*.
- Multiply the total square-foot area for all exposed areas by this factor. (Deduct exposed-glass and door area from the gross wall area to determine the net wall area.)
- Multiply the cubic-foot volume by the infiltration or air-change factor.
- Add all products for the total heat loss of the room.
- Add the heat loss of all the rooms to determine the total heat loss of the house. See the following example:

Rooms	Heat loss, each room, W
Living room	2,350
Bedroom A	1,275
Bedroom B	980
Bathroom	610
Kitchen-dining	1,420
Hall	735
Total heat loss	7,370

- Determining Annual Operating Cost.** Check with the local utility for the conversion factor for kilowatthours. If the heat loss is 7370 W and the conversion factor is 1.4, multiply the heat loss of 7370 W by 1.4, which equals 10,318, the total number of kilowatthours required to provide a 70°F (18°C) indoor temperature during the heating period. A similar heat-gain study can be made to determine the cooling load. Once the kilowatthour consumption is estimated, multiply 10,318 kilowatthours by 0.0458 (4.58 cents), the 1985 base rate for electric heating in Chicago. The product is \$472.56, which is the estimated annual operating cost for electric heating. On the basis of an 8-month heating season, the average operating cost per month is \$59.07. Today's unit energy costs are frequently double this number or even more, so make a proportional increase based on local energy costs. Heat-loss calculations of this type may also be made for apartment buildings, small commercial buildings, and other small buildings. For large commercial or institutional buildings, other factors, particularly that of fresh-air changes, must be considered.

434. Commercial or industrial buildings. Many factors are involved in considering the use of electric heating in a commercial, industrial, or institutional building. Usually, a consulting engineer or heating specialist will perform a feasibility study which compares electric heating with other types of heating systems. The study will compare not only the cost of fuel but also the annual capital costs and maintenance costs over a period of years. The selection of electric heating, however, will generally depend upon the cost of electricity.

435. Types of equipment. There are many types of electric heaters, varieties of housings, heating elements, and methods of distributing the heat into the heated area.

1. **Electric Heaters.** There are convector, fan-forced, or radiant types of heaters. Each heater contains a resistance element which heats air or water. All such heaters provide both radiant and convection heat. The ratio depends upon the type of heater. Radiant heaters provide the highest radiation-to-convection ratios.
2. **Residential Buildings.** A centralized system may be an electric furnace, boiler, or heat-pump system. A decentralized system could include the use, entirely or in combination, of baseboard heaters, wall heaters, floor-drop-in heaters, ceiling heaters, or ceiling panels or heating cables. The decentralized systems permit individual room control. Central systems have central control but often have the advantage of combining heating and cooling in the same duct system. The conversion of a fossil-fuel-fired hot-air or hot-water system can be readily accomplished by replacing the existing furnace or boiler with an *electric* furnace or hot-water boiler.
3. **Commercial Buildings.** Central systems are available with large banks of electric duct heaters in conjunction with air handlers. Electric hot-water or steam boilers are available in large kilowatt capacities. Central heating and cooling systems can be used in conjunction with perimeter-baseboard-type heaters.
Perimeter heaters will counteract external-wall heat loss and allow control of the heaters in modular sections.
4. **Unitary Systems.** In commercial buildings unitary systems permit combinations of heating and cooling with control of each room or area.
5. **Through-the-Wall Heating and Air-Conditioning Units.** Particularly in school buildings, such units help to reduce engineering and maintenance costs. Unitary-equipment breakdown affects only a single room or area instead of the entire building or large section that is affected when a central system becomes defective.
6. **Roof-top Equipment.** Such equipment saves building space in low-ceiling commercial buildings while providing large-capacity electric heat and cooling into a ceiling plenum or duct system.
7. **Electrically Heated Buildings.** Most such buildings will use electricity for domestic hot water. All-electric kitchens complete the application of electricity in the *total-electric* concept.
8. **Partial-Building Heat.** This is another common application for unitary heaters.
9. **Infrared Heaters.** These provide spot heating for indoor or outdoor heating applications. Electric-heating cables or mats for snow melting, deicing, or pipeline heating offer convenience and reduction of costs unavailable in other systems.

436. Equipment capacities. The following equipment is described for various applications in Secs. 437 to 443.

437. Electric furnaces (Figs. 9.282 and 9.283) are made in capacities of 4 to 35 kW at 240 V, single-phase or three-phase.

This heating assembly is a compact package heating system for new buildings or conversion applications in homes, apartments, or small commercial buildings. The furnace can be positioned in the ducts so that it can be used for upflow, downflow, or horizontal discharge in basements, attics, utility rooms, or utility closets.

FIGURE 9.282 An electrical residential-type furnace. [King Electrical Mfg. Co.]

FIGURE 9.283 Central electric furnace for homes with heating elements, controls, blower motor, and ac cooling coil.

Heating elements can be internally wired to be energized in 5-kW stages, at 60-s intervals, to prevent power surges. As part of the electric-furnace system, summer air conditioning or an electronic air cleaner may be added at any time without changing the blower or duct system. Some units are designed to be used with a split-system air conditioner. Low-voltage wall-mounted controls are usually installed in a central part of the building.

438. Hydronic boilers have capacities from 6 to 30 kW at 240 V, single-phase. These wall-mounted hot-water boilers are compact in size (between 2 and 8 ft³, or between 0.057 and 0.227 m³) and weigh about 120 lb (54.4 kg). A typical boiler has incremental stages (5 kW or less), which sequence at 30- to 45-s intervals to eliminate a large power surge. Centrally located low-voltage wall-mounted controls operate the boiler.

439. Heat pump

Capacities range from 23,000 to 236,000 Btu for heating and 2 to 20 tons for cooling, single-phase or three-phase, at several voltage ratings.

The residential heat pump is a boxlike unit which is installed inside or outside the building, although it is usually outside with air-to-air heat transfer. The heat pump designed for outdoor installation is roof-mounted, through-the-wall, or remote-mounted. In cold climates (below 20°F, or -7°C, outdoor design) supplementary space-heating equipment is used in conjunction with the heat pump. An accessory kit is available for low-ambient operation.

The heat pump is regarded as a low-operating-cost heating and cooling system with a centrally mounted combination heating-cooling thermostat. Figure 9.284 shows a 3-ton residential central condensing unit for an air conditioning system; heat pumps run in the cooling mode will have comparable capacities. Large-capacity heat pumps are sometimes used for commercial or industrial buildings.

FIGURE 9.284 A 3-ton residential central air-conditioning condensing unit.

440. Residential unitary systems include several types of electric heaters or combination units:

1. **Baseboard Heaters.** Figure 9.285 shows a typical unit of these commonly used heaters. Capacities range from 375 to 3500 W at 120, 208, or 240 V.

These heaters are usually surface-mounted convector units with finned-tubular or cast-aluminum (Fig. 9.285) heating elements. Ratings are in terms of watt density. *Low watt density* is about 175 W/ft, *medium watt density* is about 225 W/ft, and *high watt density* is about 275 W/ft.

FIGURE 9.285 Baseboard heating section. [King Electrical Mfg. Co.]

Heater lengths range from 2 to 12 ft (from 0.6 to 3.7 m), and heights are usually from 6 to 9 in. (from 152.4 to 228.6 mm). The heaters are controlled by integral line-voltage thermostats, thermostat sections, line-voltage wall thermostats, or low-voltage wall thermostats.

These heaters are most commonly used to provide perimeter heating, particularly under the windows of outside walls. They can be easily installed in both new or existing buildings. Many baseboard heaters provide a full-length wireway. They have knockouts in the bottom, side, and back for electrical-supply connections. A plastic seal can be provided on the back of the heater to maintain a neat appearance when the heater is installed against an uneven wall. An air deflector directs heated air away from the wall. A free-floating element reduces expansion and contraction noises.

Heater accessories include blank sections which can be cut on the job for wall-to-wall installations. A thermostat section is available with or without duplex receptacles, although a receptacle section itself is available with some heaters. A control section, with or without a thermostat, may be used to switch the same source of power from an off position to a heat position or to a cool position. A room air conditioner is plugged into the top of this section. Also available is a section that contains a relay or transformer-relay for use with a low-voltage thermostat.

- 2. Radiant Wall Heaters.** These heaters are also widely used. Capacities range from 500 to 6000 W at 120, 208, or 240 V.

Residential units of this type are for surface or recessed mounting. Small-capacity (500- to 1500-W) heaters are used in bathrooms or other small rooms. Large-capacity (2- to 6-kW) heaters are designed for add-on rooms, new construction, or existing room areas. The radiant heater may have a resistance element or glass panel with embedded resistance material. A typical glass unit, rated at 750 W, is shown in Fig. 9.286.

FIGURE 9.286 A 750-W recessed heater with a glass heating panel. [Berko Electric Mfg. Corp., division of Weil-McLain]

This heater features a built-in thermostat and shallow depth for recessed applications (2 in, or 50.8 mm, in some cases). For ease of installation, there are knockouts on the back, bottom, or side.

3. **Forced-Air Wall Heaters.** Such a heater is shown in Fig. 9.287. Capacities range from 660 to 4000 W at 120, 208, 240, or 277 V.

These residential units can be recessed, semirecessed, or surface-mounted. Most commonly, this type of heater has a built-in thermostat with a positive off position. The lower-capacity heaters (660 to 1500 W) are used in bathrooms and other small rooms. The higher-capacity heaters (2 to 4 kW) are commonly used in basements, recreation rooms, or add-on rooms. The larger heaters have a fan-delay switch, a built-in safety switch, a fuse-disconnect, or a low-voltage transformer. A self-lubricating motor is common in the larger heaters. Also, a permanent type of filter is available in large-capacity heaters.

Some of these heaters utilize the counterflow principle of heat and air distribution. They may be controlled by a separate line- or low-voltage thermostat in conjunction with an integral or remote relay. A fan switch permits summer operation.

4. **Convactor Wall Heaters.** Such a heater is shown in Fig. 9.288. Capacities range from 500 to 5000 W at 120, 208, or 240 V.

These convactor units can be surface- or recess-mounted with integral or remote controls. Low wattage heaters can be used in shops, corridors, breezeways, and basements. Larger-wattage convectors can be used to heat basements, attics, or any area where limited wall space prevents the use of baseboard heaters.

FIGURE 9.287 A recessed forced-air wall heater with built-in thermostat and fan switch. [King Electrical Mfg. Co.]

FIGURE 9.288 Convactor wall heater listed for Class I, Group D, hazardous locations. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

5. **Fan-Forced Kick-Space or Baseboard Heaters.** Such a heater is shown in Fig. 9.289. Capacities range from 750 to 2000 W at 208 or 240 V.

Such heaters can be surface- or recess-mounted. They are well suited to locations where baseboard radiation is desired but only limited space is available. The kick-space heater has a quiet tangential blower and is particularly suitable for kitchens or bathrooms where adequate wall space is not available. It is recessed into the kick-space area under a cabinet or counter. Control is by a separate wall-mounted line-voltage thermostat.

FIGURE 9.289 Fan-forced recessed kick-space heater. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

6. **Wall-Mounted Electric Fireplaces.** Such a fireplace is shown in Fig. 9.290. Capacities range from 2000 to 5000 W at 240 V.

This unit is a forced-air surface-mounted heater designed to look like a fireplace. It has a glowing grate with realistic logs in a steel cabinet which is finished in matte black or copper-tone enamel. It is ideal for dens, beach and mountain cabins, offices, motels, restaurants, and lounges. The electric fireplace can have a built-in thermostat and fan-delay control; it is also available with a remote wall-mounted low-voltage thermostat.

FIGURE 9.290 Wall-mounted electric fireplace.

7. **Radiant-Heat Ceiling Units.** Such a unit is shown in Fig. 9.291. The capacity of the heater is 1500 W at 120 V. Lighting consists of two 60-W incandescent lamps, and the small exhaust fan is rated at 60 ft³/min (0.028 m³/s).

This unit is recessed in the ceiling of bathrooms. A wall-mounted switch or time-control switch provides individual control of the heater and lamps.

FIGURE 9.291 Radiant heater with fan circulation for ceiling mounting.

8. **Radiant and Forced-Air Ceiling Heaters.** These heaters are available in capacities of 600 to 1250 W at 120 V.

A typical unit is attached directly to a flush 3¹/₂- or 4-in ceiling outlet box. This heater is commonly used in small bathrooms, playrooms, and powder rooms. A small fan is used to force heat away from the ceiling; the primary heat is radiant. In some heaters, a center-mounted 100-W incandescent lamp is available for lighting.

9. **Forced-Air Ceiling Heaters.** Such heaters range in capacities from 1000 to 1525 W at 120, 208, or 240 V.

Forced-air units can be surface-mounted on a standard flush 3¹/₂- or 4-in ceiling outlet box. Commonly used in bathrooms or powder rooms, the fan-forced heater is approved for standard 60°C supply wires, such as Type TW. It is available with adjustable mounting brackets and an automatic plug-in connection. Control is by a wall-mounted thermostat.

10. **Radiant Ceiling Heaters.** These range in capacities from 600 to 1500 W at 120, 208, or 240 V.

The ceiling-mounted residential radiant heater can be recessed or surface-mounted on a standard flush 3¹/₂- or 4-in ceiling outlet box. Available with a center-located 100-W incandescent lamp and plug-in connections, the heaters are approved for 60°C supply wires. The radiant ceiling heater is commonly used in bathrooms, powder rooms, or other small rooms. Control is by a wall-mounted thermostat.

11. **Radiant Ceiling Panel Heaters.** These heaters range in capacities from 235 to 1000 W at 120, 208, or 240 V.

The residential radiant ceiling panel is constructed of laminated glass, gypsum dry-wall, or radiant metal. It can be surface-mounted, recessed, or used in a T-bar construction module, usually in panels 2 to 4 ft (0.6 to 1.2 m) wide and 3 to 12 ft (0.9 to 3.7 m) long. The depth of the heater is ³/₄ to 1 in. (19.05 to 25.4 mm). The surface finish can be painted. A typical unit contains a 4-in terminal box and a 3-ft (0.9-m) flexible metal conduit. Controlled by a separate wall-mounted thermostat, the ceiling panel may be used for small rooms, spot heating, or complete area heating.

12. **Ceiling Heating Cable.** A typical run of this cable is shown in Fig. 9.292. Capacities range from 200 to 5000 W at 120, 208, or 240 V, and lengths are from 75 to 1800 ft (from 22.9 to 548.6 m).

Ceiling cable is embedded in plaster or laminated ceiling construction for individual rooms or complete house heating. Color-coded cables are electrically insulated and

A 3-in. min. of the nonheating lead at the splice shall be embedded in plaster or between dryboard layers

Ceiling cables

6 in. min.

Gypsum board or plaster

Nonheating leads to thermostat. Excess leads shall not be cut off, but shall be embedded in ceiling finish.

FIGURE 9.292 Installation of ceiling heating cable. Adjacent cable runs must be spaced not less than 38 mm (1½ in.) on centers. [*Electrical Construction and Maintenance*]

resistant to high temperature, water absorption, aging effects, and chemical action. The cables are usually rated at 9 W/m (2¾ W/ft). They must not be cut in the field, and identification labels must not be removed.

Nonheating lead wires, 2.1 m (7 ft) or longer, extend to the thermostat or a junction box. For installation (Fig. 9.293), the cable is stapled to a nonmetallic fire-resistant surface at least every 400 mm (16 in.). After the first plaster coat has been applied, cables should be tested for continuity and for insulation resistance (at least 100,000 Ω measured to ground).

Minimum spacing between cable runs is 38 mm (1½ in.) on centers with the closest spacing near the outside walls. Cables should clear lighting fixtures by at least 200 mm (8 in.). General electrical wiring (for lights, etc.) should be run over the thermal insulation and at least 50 mm (2 in.) over the heated ceiling surface.

- 13. Floor Heating Cable.** Such cable has unlimited heat capacities which vary with the conductor resistance, type of cable, and length of cable. Ratings are from 120 to 600 V. In residential occupancies ratings are 120, 208, or 240 V.

Heating cables are used in floors to form radiant panel systems. Cables most commonly used are polyvinyl chloride-sheathed cables or mineral-insulated (MI) copper-sheathed cables. In concrete, cables must be of a material that is resistant to any chemical action in the concrete. Cables may be interwoven as part of a properly

grounded prefabricated mat. They may be of predesigned lengths which are spaced to provide a desired radiant-heat output. Cables such as Type MI are available at several different resistances. Single- or two-conductor cables at specified lengths will have varied heat capacities, depending upon the applied voltage. Heating cables may be installed in one or two pours with adjacent runs not less than 25 mm (1 in.) on centers and with adequate spacing between cable runs and metallic bodies embedded in the floor. Nonheating leads must be protected when they leave the floor by rigid metal conduit, IMC, or EMT or, with MI cable, by approved current-carrying non-heating cable sections. Control of floor heating systems is by a thermostat with a capillary and sensing element attached. The sensing bulb is embedded in the slab so that it will respond to typical temperature changes.

14. **Floor Drop-In Heaters.** Such a heater is shown in Fig. 9.294. Capacities range from 300 to 2000 W at 120, 208, 240, or 277 V.

Residential floor drop-in heaters are resistance convactor units, fan-forced units, or units that have a chamber with antifreeze water sealed in and heated electrically. They are best applied to counteract downdrafts from floor-to-ceiling windows or sliding glass doors. They can be installed in wood or concrete floors. A fan-forced heater may have an integral thermostat, but the control for most units is by a line- or low-voltage wall thermostat.

FIGURE 9.293 Three steps in installing ceiling heating cable.

FIGURE 9.294 Fan-forced drop-in floor heater. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

441. Central systems for commercial-type occupancies are of the types described in the following paragraphs.

- 1. Outdoor Roof-Mount Heating and Cooling Units.** Such a unit is shown in Fig. 9.295. Electric-heating capacities are custom-designed for a particular installation. Cooling capacities range from 2 to 200 tons at 208 V, single- or three-phase; 277 V, single-phase; and 480 V, single- or three-phase.

All-electric heating and cooling machines are designed for roof-mount outdoor conditions. Custom fabrication provides machines with job-specified heating and cooling capacities. Multizone staging from a remote monitoring panel can establish the roof-mount machine as the heating and cooling plant for a one- or two-story building. Supermarkets, office buildings, laboratories, warehouses, machine shops, and aircraft plants are good applications for roof-mount equipment. Space-saving economy is a major feature of such equipment. Staged or step control for the heating section, with fresh-air damper control, provides a well-balanced automated system.

FIGURE 9.295 Large-capacity electric heating-cooling central-system unit mounted on roof.

- 2. Commercial Steam or Hot-Water Boilers** (Fig. 9.296). These boilers are available in capacities up to 3000 kW at 208, 240, and 480 V, single- or three-phase.

Commercial steam or hot-water boilers are designed for conversion of electric energy to heat in the form of steam or hot water. Hot-water boilers are used as a replacement for fuel-fired boilers; as the heating component for a chilled water-cooling system; as a safe method of heating a hazardous area; or as a side-arm-faucet water heater. A typical boiler is provided with a low-water cutoff, a safety relief valve, temperature control, a water gage, a high-temperature limit switch, contactors, internal fusing, full insulation, and an enameled-steel jacket. The electric boiler occupies a much smaller floor area than other types of boilers and does not require retubing, flue cleaning, burner cleaning, damper adjusting, or chemical additives.

Steam boilers are available with $\frac{1}{2}$ to 30 boiler hp (4.9 to 294.3 kW), 1 to 250 lb/in², and are built to ASME and Underwriters Laboratories standards. Boilers include a safety valve, a boiler steam pressure gage, a pressure regulator, a low-water cutoff, an automatic-feed control, a control switch, a pilot light, outlet valves, and drain valves. A condensate tank is recommended to reuse the condensed steam.

FIGURE 9.296 Commercial-type electric boiler.

442. Commercial unitary systems are described in the following paragraphs.

1. **Infrared Heaters.** Such a heater is shown in Fig. 9.297. Capacities are 500 to 7600 W at 120, 208, 240, 277, 440, 480, and 600 V.

FIGURE 9.297 An infrared heater with quartz lamps. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

The heating elements consist of metal-sheathed units, quartz tubes, or quartz lamps. The following table describes the characteristics of these three infrared sources:

Characteristics of Three Infrared Sources

Characteristic	Quartz lamp	Quartz tube	Metal sheath
Relative heat intensity	Very high	Low to medium high	Medium to high
Splash resistance	Very good	Very good	Very good
Color blindness	Fair	Very good	Very good
Life expectancy	5,000 h or more	5,000 h or more	Consult manufacturers
Visible light	High	Low	Low
Heat-up and cool-down time	A few seconds	2 min or more	About 2 min
Relative cost per kW	Medium high	Medium	Medium
Filament or source temperature	About 4,000°F	About 1,200 to 1,800°F	About 1,200 to 1,800°F
Vibration resistance	Medium	Medium	Very good

Infrared heaters are used for complete indoor heating, spot heating, outdoor heating, and outdoor snow melting. For outdoor heating and snow melting it is preferable to use the quartz lamp and to shield the element and fixture from strong winds as much as possible. Rapid cooling of the element diminishes radiation effectiveness. For spot heating, use two fixtures aimed at the center of the target area at about a 45° angle. Do not irradiate outside walls or surfaces over 6 ft (1.8 m) above the floor. For complete comfort heating, install $\frac{1}{2}$ W for each degree of operational temperature desired above the minimum ambient ever reached in a specific area. For spot heating provide 1 W/ft²/degree of temperature difference. For outdoor heating provide 2 W/ft²/degree of temperature difference. If, for example, the area to be heated is a storefront sidewalk 100 ft (30.5 m) long by 10 ft (3 m) wide in New York City, proceed as follows (assuming an outside design of 0°F and a desired temperature of 50°F):

$$\begin{array}{r}
 100 \times 10 = 1000 \text{ ft}^2 \\
 \quad \quad \quad \times 2 \text{ W/ft}^2 \\
 \hline
 \quad \quad \quad 2000 \\
 \quad \quad \quad \times 50 \\
 \hline
 100,000 \text{ W, or } 100 \text{ kW}
 \end{array}$$

Select fixtures in accordance with the manufacturers' recommendations. The radiation patterns are determined by the reflector design and the resulting beam pattern. Beam patterns range from a 30° to a 90° angle. They may be symmetrical or asymmetrical. Fixtures may have one, two, or three elements. Marquee-type heaters are recessed into an overhead masonry canopy. For snow-melting applications, twice the suggested outdoor capacity is recommended. Provide 150 to 200 W/ft² of area for most applications. Control of infrared heaters is by switch, input control, ambient-temperature thermostat, or any combination of these devices. A high-limit thermostat is recommended for most applications.

- 2. Horizontal Unit Heaters.** Such a heater is shown in Fig. 9.298. Capacities range from 1.5 to 50 kW at 120 or 208 V, single- and three-phase; 240 V, single- and three-phase; 277 V, single-phase; and 480 or 600 V, single- and three-phase.

Horizontal unit heaters can be installed on the wall or hung from the ceiling with bracket or swivel adjustments. They are ideal for use in warehouses, factories, or entranceways. Unit heaters are normally located along the outside wall with the direction

of airflow in a circular fashion. Large-capacity heaters can be provided with duct collars or deflectors. Unit heaters are commonly controlled by a remote thermostat and may have remote or built-in contactors. A fan-delay switch can be provided to prevent the fan from operating until the heating elements have reached the desired temperature. An explosionproof model is available to conform with Class I, Group D, requirements.

3. **Vertical Unit Heaters.** Several types of these heaters are shown in Fig. 9.299. Capacities are 10 to 50 kW at 208 and 480 V, single- or three-phase. The ceiling-suspended vertical unit heater has integral relays and one- or two-stage remote control. It can be surface-mounted or recessed with air discharge through four optional louver arrangements which permit virtually any desired air pattern at the floor level. Diffusers are of the radial, cone, anemostat, or louver type. Internally mounted automatic-control relays and over-heat and motor-overload protection are usually provided. These heavy-duty units can be used in factories, garages, and warehouses, with high-bay mounting up to 33 ft (10.1 m) above the floor.

FIGURE 9.298 Horizontal unit heaters can be mounted on wall or ceiling. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

FIGURE 9.299 Vertical unit heaters. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

4. **Auditorium Unit Ventilators.** Such a ventilator is shown in Fig. 9.300. Capacities are 12 to 400 kW; 1200 to 15,000 ft³/min (0.57 to 7.08 m³/s), and 208, 240, or 480 V, three-phase. This unit ventilator provides the proper heating, ventilating, and natural cooling required in school auditoriums, gymnasiums, libraries, and other areas where large-capacity systems and quiet operation are essential. It may be installed for horizontal, upright, or inverted operation on the ceiling, wall, or floor; directly in the area to be

FIGURE 9.300 Auditorium unit ventilator, 15 kW.

served; or in an adjacent location and connected by ductwork. Such a unit features a special attenuator and an enclosed motor and drive designed for quiet operation. Step control is frequently used.

5. **Wall Convector Units.** A typical unit is shown in Fig. 9.301. Capacities are 750 to 4000 W at 208, 240, and 480 V, single- and three-phase. Commercial wall convectors can be surface-mounted or recessed with front or top discharge. These units are used in commercial, industrial, or institutional buildings in offices, corridors, and entrances. Cabinet convectors are available with integral or remote controls.

FIGURE 9.301 Wall convector unit for surface mounting. [King Electrical Mfg. Co.]

- 6. Commercial Forced-Air Wall Heaters.** This type of heater is similar to the heater shown in Fig. 9.287. Capacities are 1.5 to 4 kW at 120, 208, 240, or 277 V, single-phase. The commercial forced-air heater can be surface-mounted or recessed. Tamperproof construction makes this unit ideal for entryways, lobbies, corridors, stairwells, and rest rooms in all types of commercial buildings. Fan and discharge louvers direct air downward, keeping the floor warm and dry.
- 7. Sill-Line Convector Units.** Such a unit is shown in Fig. 9.302. Capacities are 120 to 750 W/ft at 208, 240, 277, and 480 V, three-phase, in one- or two-stage control. Commercial sill-line heaters are available at different heights and many different wattage outputs. Lengths vary from 2 to 8 ft (0.6 to 2.4 m) to provide modular or wall-to-wall design. Units of this type are available with blank sections, filler sections, matching sleeves, end caps, inside and outside corners, and conduit covers. Sill-line heaters are surface-mounted with front or top discharge when perimeter radiation is desired. They should be mounted at least 2 in. (50.8 mm) above the floor. Built-in controls may be integral to the unit, or they can be provided in a filler section. The filler section can contain a relay for a 120-V remote-control circuit, a disconnect switch, or a circuit breaker.

FIGURE 9.302 Sill-line convector heater. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

- 8. Pedestal Convector Heaters.** Such a heater is shown in Fig. 9.303. Capacities range from 500 to 3500 W at 208, 240, and 277 V, single-phase. This heater is a convector which is used to heat floor-to-ceiling glass areas. It can be mounted on a new concrete floor or be bolted to the surface of an existing floor. Pedestal-type heaters can be installed individually or end to end in continuous runs. They provide a basic perimeter system designed especially for corridors, lobbies, foyers, and entryways, particularly for hard-to-heat areas where floor-to-ceiling glass creates cold downdraft problems and prohibits the use of wall-mounted equipment. This special downdraft heater is controlled by a separate wall-mounted thermostat with an optional integral relay for remote control by a time clock.

FIGURE 9.303 Pedestal convector heater. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

- 9. Draft-Barrier Wall Heaters.** Such a heater is shown in Fig. 9.304. Capacities are 100 to 200 W/ft at 120, 208, 240, and 277 V, single-phase. The draft-barrier wall heaters are low-silhouette units (3 to 6 in., or 25.4 to 76.2 mm, high) designed to counteract down-draft at window areas. They are mounted under the sill, from wall to wall at floor level, or within modular confines in commercial office buildings. Electric connections can be made from either end on some units or through the back. Built-in thermal relays and thermostats are available.

FIGURE 9.304 An architectural electric convection heater provides a draft barrier when installed along glass curtain walls. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

- 10. Commercial Baseboard Heaters.** These heaters are similar to the unit shown in Fig. 9.304. Capacities are 300 to 1250 W at 120, 208, 240, and 277 V, single-phase. Commercial-grade baseboard heaters are available in lengths of 2, 5, and 8 ft (0.6, 1.5, and 2.4 m). They are surface-mounted 2 in. (50.8 mm) off the floor. These units can be controlled by an attached thermostat section or by a wall-mounted line- or low-voltage thermostat. End caps, blank sections, and inside and outside corners for wall-to-wall installation are available as required.
- 11. Cabinet Unit Heaters.** Such a heater is shown in Fig. 9.305. Capacities are 1.5 to 30 kW at 208, 240, 277, and 480 V, single-phase or three-phase.

The commercial cabinet unit heater can be used freestanding, wall-mounted, or ceiling-mounted. Surface or recessed installation is applicable to wall- or ceiling-type heaters. An inverted model is available for unusual installations. The cabinet unit heater can be provided with tamperproof integral or remote wall-mounted controls. A two- or three-speed fan motor, providing 200 to 1250 ft³/min (0.094 to 0.59 m³/s), may have a fan selector switch to provide quiet operation. A fan-delay thermostat is used to prevent circulation of unheated air. This type of heater is designed primarily for

FIGURE 9.305 Cabinet unit heater with top discharge and front inlet. [Chromalox, Wiegand Industrial Division of Emerson Electric Co.]

entranceways, corridors, and lobbies in offices, airport terminals, schools, and retail stores. There are some units which can provide a choice of 25 or 100 percent outside air with dampers for ventilation cooling and air filters that can be cleaned.

- 12. Unit Ventilators and Air Conditioners.** Such a ventilator and air conditioner is shown in Fig. 9.306. Heating capacities are 1.3 to 36 kW at 208, 240, 277, and 480 V, single- or three-phase. Cooling capacities range from 8000 to 27,000 Btu.

The packaged electric unit ventilator and its companion unit, the unitary air conditioner, are through-the-wall machines. The electric unit ventilator is installed under windows, has a wall sleeve and louvered opening in the wall, and is designed for use in school classrooms, auditoriums, gymnasiums, offices, libraries, or other high-occupancy areas. It heats, cools, and ventilates with outdoor air (600 to 1500 ft³/min, or 0.28 to 7.08 m³/s). Usually, there is internal wiring for step-control switching. An optional built-in electric demand limiter is available. Controls may be integral or remote; electric, electronic, or pneumatic. The controls of one unit (the master) may be used in the same area to control other units (slaves). The unit ventilator is usually installed against an outside wall, though it may also be ceiling-mounted. The through-the-wall heating and cooling unit may have an integral cooling (compressor) section, or it may be remote-mounted.

FIGURE 9.306 Combination heating-cooling ventilator.

- 13. Duct Heaters.** A typical heater is shown in Fig. 9.307. Wattage combinations are virtually unlimited with single- and three-phase connections and multistage control at 120 to 600 V. Electric duct heaters are used in ducts, plenums, or air handlers for primary heat, terminal booster heat, or air-conditioning reheat. Open-coil or metal-sheathed finned tubular heaters (Fig. 9.307) are available for insertion into an existing duct or, with a flange, as part of a new duct. To conform to duct sizes, heaters are manufactured in different horizontal and vertical dimensions for mounting on the side or bottom of the duct. Integral controls may include automatic reset of thermal cutouts, built-in relays, a transformer, fuses or circuit breakers, a fan interlock relay, pilot switches, and pilot lights. The NEC specifies a maximum 60-A branch circuit for overcurrent protection with a maximum connected load of 48 A, and zero clearance, automatic reset of thermal overload, and separate manual reset for a backup thermal overload system. Duct heaters are controlled by duct stats or remote wall controls. For large-capacity heaters a step controller is used.

FIGURE 9.307 Duct heater section with six elements.

443. Electric snow-melting systems consist of resistance-type wire or cable embedded in concrete or asphalt. The design of snow-melting systems depends on the area, geographical conditions, wind conditions, and expectations of the user (see Table 30 of Div. 12). Generally, for melting snow at temperatures between 32 and 0°F (between 0 and -16°C), the system will be designed at 40 to 60 W/ft². Depending on wind factor, temperature, and the rate of snowfall, the area will be kept free and clear of any snow formation if the system is energized about 30 min prior to a snowfall.

The heat-transfer environment may be asphalt or concrete, and the heating element may be in the form of a mat or a heating cable. In asphalt, install the mats 12 in. (304.8 mm) from the edge with the largest mats on a straight run. Mats may be installed on an existing slab with a 2-in. (50.8-mm) blacktop surface cover. The surface asphalt should be fine-grain with no stones larger than 3/8-in. (9.525-mm) diameter.

In concrete, the mats or cable should be located within expansion joints generally no farther than 20 ft (6.1 m) apart. The concrete slab should contain crushed-rock aggregate (not river gravel) and should be at least 4 in. (101.6 mm) thick. There should be a well-prepared base with adequate drainage and suitable reinforcement.

Junction boxes for connection of feeders to cables or mat lead wires should be located out of the area or in a nearby wall. They should not be installed flush with the snow-melting-surface area. Mats or cables should be installed from 1½ to 2 in. (from 38.1 to 50.8 mm) below the surface. If they are installed in two pours of concrete, a binder or bonding agent should be used between pours. Cables should be tested before installation, during installation, and on completion of installation.

Snow-melting mats for walkways, driveways, or steps (Fig. 9.308) are made of resistance wires embedded in a polyvinyl chloride sheath, interwoven in chicken wire or plastic webbing. The wire may have a copper overbraid for positive grounding.

Single- or two-conductor Type MI (mineral-insulated) cable with varied resistances is factory-fabricated at specified lengths of heating leads and nonheating leads. Hot-to-cold wire connectors and end caps are factory-brazed. Type MI cable is semirigid and can be hand-bent at the construction site to conform to desired spacing (usually 3 to 9 in., or 76.2 to 228.6 mm). It has the advantage of being durable in different asphalt or concrete environments.

Heating cables may be controlled by switch or by automatic snow control (Fig. 9.309). It is recommended that a high-limit thermostat be installed in the slab to prevent the system from operating at higher temperatures (50°F, or 10°C, or more).

FIGURE 9.308 Snow-melting cable for steps.

FIGURE 9.309 Automatic snow-control device that can be actuated by a pavement mounted sensor, snow sensor or gutter ice sensor. [Environmental Technology, Inc.]

444. Electric-heating controls. Electric space-heating equipment may be specified with a built-in thermostat and relay or with a wall thermostat. Commercial installations often require the use of a contactor. Step controllers or solid-state controls may be used with electric comfort heating equipment. For safety, most heaters are provided with spot or linear overheat protection.

445. Sizing room air conditioners. As a general rule, room air conditioners are sized on the basis of 30 Btu/h/ft² of space in a given room. Room air conditioners are rated in Btu (British thermal units) of cooling capacity. Units are available at 120-V ratings up to 12,000 Btu in most cases. Current ratings range from 7½ to 12 A for 120-V units. In planning outlets, however, it is important to know whether the room air conditioner (window or through-the-wall type) will be 120 or 240 V, because some manufacturers provide 240-V ratings for units of 9000 Btu or more.

446. Code rules for fixed space-heating equipment. Article 424 of the NEC covers installations of fixed electric space-heating equipment. The following paragraphs describe the major provisions of this article.

1. Branch Circuits. All circuits for space-heating, snow-melting, and deicing equipment are considered continuous loads. As such, the load on any single or multioutlet branch circuit cannot exceed 80 percent of the branch-circuit rating (12 A on a 15-A circuit, 16 A on a 20-A circuit, etc.). Generally, space-heating equipment can be connected to 15-, 20-, or 30-A multioutlet branch circuits. Infrared systems can be connected to 15-, 20-, or 30-A multioutlet branch circuits. In other than residential occupancies, fixed infrared heating equipment can be supplied from branch circuits rated not over 50 A. Refer to Div. 3 for feeder or service calculations for a group of heaters.

2. Controllers and Disconnecting Means

- a.* Thermostats and thermostatically controlled switching devices which indicate an off position and which interrupt line current shall open all ungrounded conductors when the control device is manually placed in this off position.
- b.* Thermostats and thermostatically controlled switching devices which do not have an off position are not required to open all ungrounded conductors.
- c.* Remote-control thermostats need not meet the requirements of Pars. *a* and *b*. These devices shall not serve as the disconnecting means.
- d.* Switching devices consisting of combined thermostats and manually controlled switches that serve both as controllers and disconnecting means shall open all ungrounded conductors when manually placed in the off position or be so designed that the circuit cannot be energized automatically after the device has been manually placed in the off position.

3. Duct Heaters

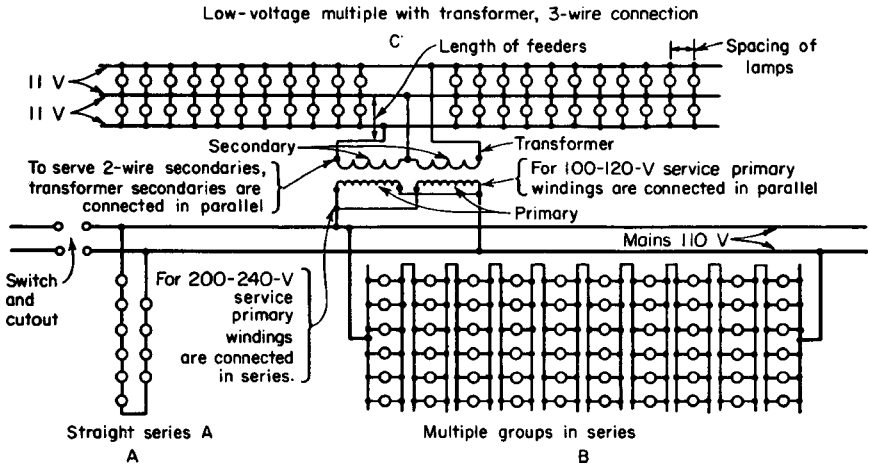

- a.* Means shall be provided to assure uniform and adequate airflow over the heater.
- b.* Means shall be provided to ensure that the fan circuit is energized when the first heater circuit is energized. However, time- or temperature-controlled delay in energizing the fan motor shall be permitted.
- c.* Each duct heater shall be provided with an integral approved automatic-reset temperature-limiting control or controllers to deenergize the circuit (or circuits). In addition, an integral, independent, supplemental control or controllers shall be provided in each duct heater which will disconnect enough conductors to interrupt current flow. This control shall be manually resettable or replaceable.
- d.* Duct-heater controller equipment shall be either accessible with the disconnecting means installed at or within sight of the controller except as permitted by Sec. 424.19(A) of the Code.

447. Other reference material. With the continued development of the electric-heating market, reference should be made to the latest NEMA standards and publications of the Electric Heating Association (EHA).

WIRING FOR ELECTRIC SIGNS AND OUTLINE LIGHTING

448. Types of signs. Electric signs or outline lighting may consist of incandescent lamps or gaseous-discharge tubing (commonly called *neon signs*). Today light-emitting diodes (LEDs) are increasingly used given their long life and efficient use of energy. Installing a brand new sign using incandescent lamps with mechanical flashers would be almost unheard of. However, this equipment is still in use, and will be covered so users will have a reference source in case they are called upon to service it. Refer to Div. 10 for a discussion of lamps and tubing.

449. Methods of wiring incandescent electric signs (National Electric Light Association, *Data on Electric Signs*). Lamps burning in multiple may be connected either two-wire or three-wire, as shown in Fig. 9.310. In series wiring, lamps may be connected in either straight series or multiple series, as shown. If transformers (see Sec. 60 of Div. 5 for information on sign transformers) are used to obtain low voltage, lamps may be connected either two-wire or three-wire as in standard multiple wiring, the transformer reducing the voltage from the regular 120- or 240-V circuits to the voltage required by the lamp. The ordinary multiple wiring can be changed to straight series wiring by merely clipping the alternate connections between lamps (Fig. 9.311).

NOTE: Diagram C for alternating current only; others may be used on ac or dc.

FIGURE 9.310 Methods of connecting sign lamps.

FIGURE 9.311 Method of changing sign wiring from multiple to series.

In a large sign any combination of series or multiple series may be used. With straight series wiring, should one lamp in the series burn out, all the lamps in that series will be out. If the lamps are connected in multiple series, the failure of one lamp does not cause any of the other lamps to go out. However, there should not be less than 8 to 10 lamps in each multiple group, or the failure of one lamp will cause too much current to flow through the other lamps of the same group, thus shortening their lives.

450. Different effects of flashing or motion can be obtained with incandescent signs by the use of a sign flasher. Cams or a drum are mounted on a shaft that is rotated by a small electric motor (Fig. 9.312). The circumferences of the cams or drums are so cut that, in brush-type flashers, the brushes will make contact only during certain predetermined portions of a revolution and thereby complete the electric circuit through the sign lamps only during that period. In the carbon-type flashers the cams, instead of carrying current and making and breaking the contacts directly, operate to open and close carbon-break contact switches which control the sign lamps. The possible variations in arrangement of cams and drums for producing different effects are almost numberless. Flashers are available for high- or low-voltage circuits.

FIGURE 9.312 The elementary sign flasher.

451. Method of wiring neon-lamp signs. Neon lamps used for signs are of the high-voltage type (see Div. 10). The lamps are supplied from ordinary lighting circuits through small step-up transformers. The voltage required depends upon the length of neon-lamp tubing used in the sign. The maximum voltage employed on the lamps is 15,000. When the length of tubing is greater than can be illuminated with 15,000 V, two or more transformers are employed as required. Practically always, neon signs are completely wired and installed by the manufacturers, the purchaser simply providing the necessary outlets from the general-lighting system. Also, the servicing and maintenance of the signs generally are handled by specialists. Section 460 includes requirements for this type of equipment.

452. The installation of all signs or outline lighting, whether of the incandescent, LED, or the gaseous-discharge type, must meet the following requirements: All electric

signs, section signs, and outline lighting, whether fixed, mobile or portable, shall be listed unless exempted by special permission. However, field-installed skeleton tubing is not required to be listed if installed per NEC rules, and outline lighting need not be listed as a system if it consists of listed luminaires wired using Chap. 3 methods. All equipment and devices used with signs must be enclosed in metal boxes, unless the enclosures are listed. All devices, such as switches, flashers, and similar devices controlling transformers shall be either rated for controlling inductive loads or must have a current rating which is not less than twice the current rating of the transformer supplying the sign. The circuits should be so arranged that none will have a load of more than 16 A.

453. Marking of signs and outline lighting systems are identified by the manufacturer's name, trademark, or other means of identification, and maximum wattage per lamp for incandescent lamp illuminated signs, and input voltage and current rating for electric-discharge signs. Section signs must be marked to indicate that field wiring and installation instructions are required.

454. Branch circuits must comply with the following:

1. A 20-A outlet supplying no other loads, for each commercial building and each commercial occupancy accessible to pedestrians, located at each entrance to each tenant space.
2. The maximum rating is 20 A for circuits supplying incandescent, fluorescent forms of illumination. For neon tubing, the maximum rating is 30 A. HID light sources are not addressed in the NEC sign article; however if they have heavy-duty mogul lampholders (most do) per 210.21(A) they could be used for 30 A circuits as well.
3. Each required branch circuit shall be computed at a minimum of 1200 VA.
4. Any suitable wiring method in Chap. 3 of the NEC may be used and must terminate within a sign or outline lighting enclosure.

455. A disconnect must be provided for each sign or outline lighting installation, consisting of an externally operable switch or circuit breaker that opens all ungrounded conductors, except a disconnect is not required for exit directional signs located within buildings, or cord-connected signs. In addition, signs and outline lighting systems must comply with the following:

The disconnect must be located within the sight of the sign. If any of the sections of a sign are out of sight of the disconnecting means, then the disconnecting means must be capable of being locked in the open position. A similar rule applies when the sign is operated by a remote controller; the disconnect must be placed within sight of the controller, and the disconnect must be capable of being locked in the open position.

456. The location of signs or outline lighting systems is restricted as follows:

1. Areas accessible to vehicles, unless protected from physical damage, shall be located at least 4.3 m (14 ft) above the vehicle area.
2. Areas readily accessible to pedestrians shall have neon tubing protected from physical damage, except for portable signs in dry locations.

3. Adjacent combustible materials shall not be subjected to temperatures exceeding 90°C (194°F), and HID lamps or lampholders shall be located at least 50 mm (2 in.) from wood or other combustibles.
4. Signs and outline lighting system equipment for wet location use, other than listed watertight type, shall be weatherproof and have drain holes neither smaller than 6 mm (1/4 in.) nor larger than 13 mm (1/2 in.). Every low point or isolated section must have at least one drain hole. The drain holes must be positioned so that there will be no external obstructions.

457. Portable or mobile signs must be installed as follows:

1. Signs must be adequately supported and be readily moveable without the use of tools.
2. An attachment plug shall be provided.
3. In wet or damp locations, a GFCI located in the supply cord must be provided. The cord must include an equipment grounding conductor and must be rated for hard service or junior hard service.
4. In dry locations, the cord length is limited to 4.5 m (15 ft). The cord shall be type SP-2, SPE-2, SPT-2, or heavier.

458. Ballasts shall be listed and identified for the use and shall be thermally protected. Ballasts, transformers, and electronic power supplies are to be installed as follows:

1. They are to be located where accessible and securely fastened in place.
2. The ballasts, transformers, and electronic power supplies are to be located as near to the lamps or neon tubing as is practicable.
3. Ballasts, transformers, and electronic power supplies used in wet locations shall be weatherproof type or of the outdoor type where protected from the weather.
4. Ballasts, transformers, and electronic power supplies require a working space at least 900 mm (3 ft) high, 900 mm (3 ft) wide, by 900 mm (3 ft) deep where not installed in a sign.
5. Power supplies may be located in an attic or soffit, provided they meet the access requirements of Sec. 600.21(E) of the NEC. There must be an access door at least 900 mm by 562.5 mm (36 in. by 22 1/2 in.), a passageway at least 900 mm (3 ft) high by 600 mm (2 ft) wide, and a permanent walkway at least 300 mm (12 in.) wide extending from the point of entry to each component.
6. Power supplies may be located above suspended ceilings if securely fastened in place and not dependent on the suspended ceiling grid for support.

459. Transformers and electronic power supplies must be listed and identified for the use. They must meet the following criteria:

1. Transformers and electronic power supplies must have secondary-circuit ground-fault protection. Transformers with isolated ungrounded secondaries and with a maximum open circuit voltage of 7500 V, or transformers with integral porcelain or glass secondary housing for the neon tubing and requiring no field wiring on the secondary side are exempted from this rule.

2. The secondary voltage must not exceed 15,000 V, nominal, under any load condition. The maximum voltage to ground of any transformer secondary circuit output terminals must not exceed 7500 V under any load condition.
3. The secondary current rating must not exceed 300 mA.
4. Secondary circuit outputs must not be connected in parallel or series.
5. Transformers and power supplies must be marked to indicate that they have secondary-circuit ground-fault protection.
6. Class 2 power supplies and power sources must be listed for use with electric signs and outline lighting systems, and meet the requirements for Class 2 power sources in NEC 725.121. Metal parts of signs and outline lighting systems must meet the grounding and bonding requirements for signs generally. Secondary circuit wiring must either use one of the conventional wiring methods in Chap. 3 of the NEC, or meet the requirements for power-limited circuits in NEC 725.130(B).

460. Field installed skeleton tubing must meet the following specific requirements:

1. Neon secondary circuit conductors of 1000 V or less are to comply with the following:
 - a. Use any wiring methods in Chap. 3 of the NEC that is suitable for the conditions.
 - b. Conductors shall be insulated, listed for the purpose, and not smaller than No. 18.
 - c. Raceways are limited to the conductor fill permitted by Table 1 in Chap. 9 of the NEC.
 - d. Conductors are to be installed so they are not subject to physical damage.
 - e. Bushings are to be used to protect wires passing through an opening in metal.
2. Neon secondary circuit conductors over 1000 V are to comply with the following:
 - a. Conductors can be installed, in rigid metal conduit, intermediate metal conduit, PVC or RTRC nonmetallic conduit, liquidtight flexible nonmetallic conduit, electrical metallic tubing, flexible metal conduit, liquidtight flexible metal conduit, electrical nonmetallic tubing, metal enclosures, on insulators in metal raceways, or other equipment listed for the purpose. Only one conductor can be installed per length of conduit or tubing, which must not be smaller than metric designator 16 (trade size 1/2). Metal parts of a building cannot be used as a grounded or equipment grounding conductor.
 - b. Conductors shall be insulated, listed for the purpose, rated for the voltage, not smaller than No. 18, and have the minimum temperature rating of 105°C (221°F).
 - c. Conductors are not to be subjected to physical damage.
 - d. Sharp bends in insulated conductors are to be avoided.
 - e. Other than at insulators or neon tubing, or between a conductor and the inner wall of its enclosing raceway, conductors must have 38 mm (1 1/2 in.) spacing from each other and all other objects. Other than the points of connection to a metal enclosure or sign body, nonmetallic raceways containing a conductor operating at 100 Hz or less must be separated at least 38 mm (1 1/2 in.) from grounded or bonded parts, with the distance increasing to 45 mm (1 3/4 in.) at higher frequencies.
 - f. Insulators and bushings for conductors are to be listed.
 - g. The insulated portions of conductors in metal raceways must extend not less than 65 mm (2 1/2 in.) beyond the end of the raceways.
 - h. Conductors may run from the leads of neon tubing to the grounded midpoint of a transformer or electronic power supply listed for the purpose and provided with terminals at the midpoint. The conductors should be as short as possible.
 - i. Dwelling occupancy equipment is limited to an open circuit voltage of 1000 V.

- j.* High voltage cable run in a metal raceway or tubing from a transformer or electronic power supply to the first neon tube electrode is limited to 6 m (20 ft) lengths. Similar cables in nonmetallic raceways or tubing is limited to 15 m (50 ft).
 - k.* Splices in high-voltage secondary circuit conductors shall be made in listed enclosures rated over 1000 V. The enclosures shall be accessible after installation and shall be listed for the location where they are used.
3. Neon tubing is to comply with the following:
- a.* The length and design of the tubing should be such that transformers or electronic power supplies are not subjected to continuous overcurrent beyond their design loading.
 - b.* Listed tubing supports shall be used.
 - c.* Other than at its support, neon tubing shall have a spacing of 6 mm ($\frac{1}{4}$ in.) from the nearest surface. The tubing shall be supported within 150 mm (6 in.) from the electrode connection.
 - d.* Field-installed skeleton tubing is not to be subject to physical damage. If readily accessible to other than qualified persons, it shall be provided with suitable guards or protected by other approved means.
4. Electrode connections are to comply with the following:
- a.* Where high-voltage secondary conductors emerge from the wiring methods in **2a** above, they shall be enclosed in a listed assembly.
 - b.* Unqualified persons are not to have access to the terminals of an electrode.
 - c.* Connections to an electrode are to be made by a connection device, twisting the wires together, or by the use of an electrode receptacle. An enclosure listed for the purpose shall be used and the connections shall be electrically and mechanically secure.
 - d.* Neon secondary conductors are to be supported within 150 mm (6 in.) from the electrode connection to the tubing.
 - e.* Electrode receptacles are to be listed for use in signs.
 - f.* Bushings listed for signs are to be used where electrodes penetrate enclosures, unless receptacles are provided.
 - g.* If receptacles penetrate a building at a wet location, a listed cap shall be used to close the opening. If bushings or neon tubing penetrate a building, the opening between neon tubing and the bushing shall be sealed.
 - h.* Electrode enclosures shall be listed. For dry locations an enclosure listed for use in either dry or damp or wet locations may be used. For damp or wet locations the enclosure must be listed and identified accordingly.

461. Current-carrying capacities of flashers. Double-pole flashers are made in four sizes that will carry respectively 15, 30, 45, or 60 A per switch. Single-pole carbon flashers that will carry 5 A per switch are made. Brush-type flashers are rated at from 2 to 5 A on each brush and are not reliable for greater currents.

Switches, flashers, and similar devices controlling transformers and electronic power supplies shall be rated for controlling inductive loads or have a current rating at least twice the current rating of the transformer.

462. Grounding and bonding of signs and outline lighting systems must meet special requirements that, in some cases, supersede the provisions in Article 250. The grounding or bonding requirements that differ in some way, or that have a different focus from conventional NEC rules are as follows (refer to NEC 600.7 for the complete provisions):

1. Metal parts and equipment of signs and outline lighting systems shall be bonded together and to the associated transformer or power supply, together with the equipment grounding conductor of the supply circuit. Portable signs are permitted to be exempt from this rule if they are protected with a system of double insulation and are marked accordingly. Small metal parts not exceeding 50 mm (2 in.) in any dimension, not likely to be energized, and spaced at least 19 mm ($\frac{3}{4}$ in.) from neon tubing need not be bonded. Where listed, flexible metal conduit or listed liquidtight flexible metal conduit is used to enclose the secondary circuit conductor from a transformer or power supply for use with neon tubing; it may be used as a bonding method provided the total accumulative length does not exceed 30 m (100 ft).
2. Metal parts of a building are prohibited from use as either a secondary return conductor or an equipment grounding conductor, or for bonding together the metal parts and equipment of signs or outline lighting systems, or for bonding such parts to the transformer or to the equipment grounding conductor of the supply circuit.

REMOTE-CONTROL, SIGNALING, AND POWER-LIMITED CIRCUITS

463. A remote-control circuit is any electric circuit that controls any other circuit through a relay or an equivalent device.

464. Class 1 circuit power source. Remote control or signaling circuits in this classification are either power-limited, or not. The Class 1 power-limited circuits are supplied from sources limited to 30 V and 1000 VA. The nonpower-limited Class 1 circuits are limited to 600 V, but the source output power is unlimited.

465. A signal circuit is any electric circuit that energizes signaling equipment. Such circuits include circuits for doorbells, buzzers, code-calling systems, signal lights, and the like.

466. Safety-control devices. Remote-control circuits to safety-control devices, the failure of operation of which would introduce a direct fire or life hazard, shall be considered Class 1 circuits.

Room thermostats, service hot-water temperature-regulating devices, and similar controls used in conjunction with electrically controlled domestic heating and air conditioning equipment are not considered to be safety-control devices.

467. Remote-control, power-limited, and signal circuits in communication cables. Class 2 and 3 remote-control, power-limited, and signal circuits, which use conductors in the same cable with communication circuits, shall, for the purpose of this discussion, be classified as communication circuits and meet the requirements of such circuits (refer to Article 800 of the NEC).

468. Hazardous locations. Any remote-control or signal circuit or any circuit considered such by the Code which is installed in a hazardous location must meet the Code

requirements for hazardous-location installation in addition to the requirements for remote-control circuits. Cables installed in hazardous locations shall be Type PLTC.

469. Remote-control, power-limited, and signal circuits are divided by the NEC into two power-limited classes (in addition to the Class 1 classification described in Sec. 464) as follows:

1. **CLASS 2** Systems in which the voltage and power is limited in accordance with Sec. 725.121 of the NEC. A Class 2 circuit considers safety from a fire initiation standpoint and provides acceptable protection from electric shock.
2. **CLASS 3** Systems in which the voltage and power are limited, also in accordance with Sec. 725.121 of the NEC. A Class 3 circuit considers safety from a fire initiation standpoint, however, since higher levels of voltage and current than for Class 2 are permitted, additional safeguards are specified to provide protection from an electric shock hazard that could be encountered.

CLASS 1 SYSTEMS

470. The installation of Class 1 systems must be in accordance with general NEC requirements for the installation of electrical circuits except as stated in the special Code specifications given in Secs. 471 to 480 inclusive.

471. Conductor sizes. Numbers 18 and 16 AWG conductors may be used if installed in a raceway, an approved enclosure, or a listed cable. Flexible cords shall comply with the provisions of Article 400 of the Code.

472. Conductor insulation. Conductors larger than 16 AWG may be any of the conductors listed in Article 310 of the NEC for general wiring. Conductors of 18 and 16 AWG shall have an insulation of a type listed in Sec. 725.49(B) of the NEC.

473. Number of conductors in raceways. The number of conductors of remote-control or signal circuits in a raceway must be determined according to the conventional wire-fill rules in the NEC using the information in Chap. 9. Section 310.15(B)(2) of the NEC applies only to continuous loads (3 h or more) in excess of 10 percent of the ampacity of the conductor.

474. Conductors of different systems. Conductors of two or more Class 1 remote-control and/or signal circuits may occupy the same cable, enclosure or raceway without regard to whether the individual systems or circuits are ac or dc, provided all conductors are insulated for the maximum voltage of any conductor in the cable, enclosure or raceway. Class 1 circuits and power circuits may occupy a common raceway only where the equipment powered is functionally associated.

475. Physical protection of remote-control circuits. If damage to a remote-control circuit would introduce a hazard as covered in Sec. 466, all conductors of such

remote-control circuits shall be installed in rigid metal conduit, intermediate metal conduit, rigid nonmetallic conduit, electrical metallic tubing, Type MI cable, or Type MC cable or be otherwise suitably protected from physical damage.

476. Overcurrent protection. Conductors shall be protected against overcurrent in accordance with the general Code requirements except for 18 and 16 AWG conductors, which shall not exceed 7 A for No. 18 and 10 A for No. 16 except when other articles of the Code have other protection requirements.

477. Location of overcurrent protection. Overcurrent devices shall be located at the point where the conductor to be protected receives its supply unless the overcurrent device protecting the larger conductor also protects the smaller conductor in accordance with the current-carrying-capacity tables of Div. 12; or the overcurrent protection is provided in accordance with other specific NEC rules, such as 430.72 for motor control circuits and 610.53 for cranes and hoists. Where a control circuit is tapped from the light or power circuit that the control circuit is affecting, the overcurrent protection is permitted to be for short-circuit and ground-fault protection only, defined for these purposes as not exceeding 300 percent of the Class 1 circuit conductor ampacity. For two-winding transformers, with only one winding connection on the primary side and one on the secondary side, the overcurrent protection can be on the primary side with its effective value as adjusted by the transformer winding ratio. Electronic source output conductors supplied from listed equipment is generally permitted to rely on the overcurrent protection ahead of the electronic power source.

478. Circuits extending beyond one building. Class 1 circuits which extend aerially beyond one building shall also meet the requirements of Article 225 of the Code.

479. Grounding. Class 1 remote-control and signal circuits shall be grounded as required by Sec. 250.20 of the Code for ac circuits, and 250.162 for dc circuits. If system grounding does apply to one of these control circuits, refer to the discussion in Sec. 487 for direction on how to proceed.

480. Transformers. Transformers used to supply power-limited Class 1 circuits shall comply with Article 450 of the NEC and the power limitations of Sec. 725.41 of the NEC.

CLASS 2 AND CLASS 3 SYSTEMS

481. NEC requirements for the installation of Class 2 and Class 3 systems are given in the following Secs. 482 to 487, inclusive.

482. Overcurrent protection. If current is limited in Class 2 and Class 3 systems by means of overcurrent protection, such overcurrent protection devices shall not be interchangeable with protection of a higher rating. The overcurrent protection may be an integral part of the power supply.

483. Power limitations. Protection for power-limited circuits shall comply with Sec. 725.121 of the NEC.

484. On the supply side of overcurrent protection, transformer, or current-limiting devices. Conductors and equipment on the supply side of overcurrent protection, transformers, or current-limiting devices shall be installed in accordance with the appropriate requirements of Chaps. 1 through 4 of the Code. Transformers or other devices supplied from electric-light and power circuits shall be protected by an overcurrent device with a rating or setting not exceeding 20 A, except the input leads of a transformer or other power source supplying Class 2 and Class 3 circuits may be smaller than 14 AWG, but not smaller than 18 AWG if they are not over 300 mm (12 in.) long and if they have insulation that complies with Sec. 725.49(B) of the NEC.

485. On the load side of overcurrent protection, transformer, or current-limiting devices. Conductors on the load side of overcurrent protection, transformer, or current-limiting devices shall be insulated and shall comply with Sec. 725.179 and not less than the requirements of Secs. 725.133 and 725.154 of the Code. The cables must be listed with respect to fire resistance, and generally applied in accordance with a four-level hierarchy based on that criterion. The level is evidenced by the cable marking, which for remote-control and signaling circuits is CL2 or CL3 as applicable. This determines the power level, and the marking has space for an additional letter that determines the permitted locations. A suffix of "X" (as in "CL2X" for doorbell wire) is the least rigorous, and it indicates suitability for low-intensity dwelling use, such as short lengths in nonconcealed spaces generally and in concealed spaces only in one- and two-family dwellings only. CL2 with no suffix is generally suitable for commercial work whether concealed or exposed. CL2R is the next better grade of cable, and it can be used in risers from floor to floor. The top of the hierarchy is the cables, marked CL2P, which can run in plenum cavities used for environmental air such as above a suspended ceiling that connects to the intake of a large air handler. Better cables can always substitute for poorer cables, as shown in NEC Table 725.154(G). For example, CL3R can substitute for CL2R, which can substitute for CL2, etc.

486. Circuits extending beyond one building. Class 2 and Class 3 circuits which extend beyond one building and are so run as to be subject to accidental contact with light or power conductors operating at a potential exceeding 300 V to ground shall also meet the requirements of Secs. 800.44, 800.50, 800.53, 800.93, 800.100, 800.170(A), and 800.170(B) for other than coaxial conductors for communication circuits in the Code and 820.44, 820.93, and 820.100 for coaxial conductors used in CATV systems.

487. Grounding. Class 2 and Class 3 circuits and equipment shall be grounded as required by Sec. 250.20(A) of the NEC for ac circuits, and 250.162 for dc circuits. Note that ac systems of less than 50 V must be connected as grounded systems complete with a grounded circuit conductor (usually colored white, etc.) if supplied by transformers whose primaries are connected to systems of more than 150 V to ground, or if the transformer supply system is ungrounded, or if the transformer primary circuit is run overhead outside buildings.

The overwhelming majority of power-limited control circuits are fed from transformers with 120-V primaries running on grounded systems, and are therefore unaffected by these

system grounding requirements. However, there are numerous applications, such as 277-V duct heaters supplied with Class 2 transformers for thermostat connections, and some power supplies for 277-V lighting applications, where these rules will be important.

Should such an application arise, there are additional considerations. Such a grounded system must be connected to a grounding electrode, although this is seldom a problem because the systems normally qualify as separately derived, and NEC 250.30(A)(3) Exception No. 3 generally allows the use of the equipment grounding conductor connection for the supply transformer (limited in the exception to 1 kVA) to function as a grounding electrode conductor in such cases. Another wrinkle is the requirement in 250.112(I) that these systems incorporate an equipment grounding conductor. Such a conductor must normally be colored green; however, 250.119 Exception [erroneously written as though 250.112(I) didn't exist] allows green wire for other than grounding purposes in power-limited cabling, so the color is at best unclear. What is clear is that some conductor in the cable must be an equipment ground, and green is obviously the best choice. Note also that the size of this wire can be the same as the others in the circuit because 250.122(A) never requires an equipment grounding conductor to be larger than the associated circuit conductors. The likely result is two wires in the power-limited cable assembly (white and green) will have code required functions and connections at odds with the traditional color code for HVAC wiring diagrams. Take care to plan accordingly.

488. Power-limited circuits must be neat and workmanlike. They must be supported so they will not be damaged by normal building use. They can use ordinary cable ties or similar fittings designed and installed so as to not damage the cable for securement, but they must not be tied to electrical raceways or cables except as noted in Sec. 489. Abandoned cables must be removed to the extent they are accessible. A *cable* is defined as abandoned if it is not terminated, and not identified for future use with a tag. The tag must have sufficient durability to withstand the environment involved.

489. System separation. Class 2 and Class 3 conductors must be divorced from Class 1 and power conductors. The general rule allowing conductors of differing voltages to run in a common raceway as long as all conductors are insulated for the maximum voltage present does not apply to power-limited circuits, because you must never rely on conductor insulation alone, no matter how robust, to provide the system separation required by the NEC for over 70 years. For this reason the general prohibition against tying cables to a raceway is relaxed to allow a power-limited cable tied to a raceway where the systems are functionally associated. A good example of this principle at work is running the thermostat cable for an oil burner down a conduit (or tubing) riser for a furnace.

However, there are times when power-limited conductors must land on equipment with power connections, and the NEC has evolved many complicated rules, now covered in Sec. 725.136, to cover the topic. For example, suppose a Class 2 circuit will run to the coil of a relay that controls the activity of a power circuit. Both power levels will necessarily enter a common enclosure, and 725.136(D)(1) allows this provided the two systems are routed to maintain a 6 mm (1/4 in.) of air separation between them. Another example, commonly used in industrial settings, is to reclassify the power-limited circuit as a Class 1, allowing it to enter the wiring channels in an industrial control panel. Take care, however, before applying this technique, because once the circuit is reclassified, all devices connected thereto must be fully rated for Class 1 standards. For industrial control components that may be feasible, but for commercial or residential use it may be unrealistic, such as for a conventional thermostat that must be connected to a Class 2 control circuit under the terms of its listing.

WIRING FOR SPECIAL OCCUPANCIES

490. The NEC should be consulted for special rules on installations in the following special occupancies or for the following special equipment or conditions:

Commercial garages
Aircraft hangars
Motor fuel dispensing facilities
Bulk-storage plants
Spray application, dipping, and coating processes
Health care facilities
Assembly occupancies
Theaters, audience areas of motion picture and television studios, performance areas, and similar locations
Control systems for permanent amusement attractions
Carnivals, circuses, fairs, and similar events
Motion-picture and television studios and similar locations
Motion-picture projection rooms
Manufactured buildings
Agricultural buildings
Mobile homes, manufactured homes, and mobile home parks
Recreational vehicles and recreational vehicle parks
Park trailers
Floating buildings
Marinas and boatyards
Temporary installations
Electric signs and outline lighting
Manufactured wiring systems
Office furnishings (consisting of lighting accessories and wired partitions)
Cranes and hoists
Elevators, dumbwaiters, escalators, moving walks, platform lifts, and stairway chairlifts
Electric vehicle charging systems
Electrified truck parking spaces
Electric welders
Audio signal processing, amplification, and reproduction equipment
Information technology equipment
Sensitive electronic equipment
Pipe organs
X-ray equipment
Induction and dielectric heating equipment
Electrolytic cells

Electroplating
Industrial machinery
Electrically driven or controlled irrigation machines
Swimming pools, fountains, and similar installations
Natural and artificially made bodies of water
Integrated electrical systems
Solar photovoltaic systems
Fuel cell systems
Fire pumps
Emergency systems
Legally required standby systems
Optional standby systems
Interconnected electric power production sources
Critical operations power systems (COPS)
Circuits and equipment operating at less than 50 V
Class 1, class 2, and class 3 remote-control, signaling, and power-limited circuits
Instrumentation tray cable, Type ITC
Fire alarm systems
Optical fiber cables and raceways
Communications circuits
Radio and television equipment
Community antenna television and radio distribution systems
Network-powered broadband communications systems

DESIGN OF INTERIOR-WIRING INSTALLATIONS

491. Factors affecting wiring layouts (*Standard Handbook for Electrical Engineers*). In conduit work the space available often dictates that feeders be split into two or more feeder lines so as to guard against complete shutdown should anything happen to one feeder.

In reinforced-concrete floors a cross section of the floor must be studied to see that there will be sufficient space for the reinforcing rods, conduit or raceways, and necessary thickness of concrete. This is especially true when conduits cross. The local building code should be consulted to see what restrictions are placed on floor installations. A minimum thickness of 1 in. (25.4 mm) of concrete over conduits and raceways should be used to prevent cracking.

EXAMPLE The building code may allow floors 4 in. (101.6) thick with $\frac{3}{4}$ -in reinforcing rods located with 1 in. (25.4 mm) of concrete covering the underside (Fig. 9.313). This would mean that there is a minimum space of $1\frac{1}{4}$ in. (31.75 mm) between the top of the reinforcing rods and the top of any conduit. For this installation, $\frac{3}{4}$ -in conduit, which has an outside diameter of 1.05 in. (Sec. 63), would be the largest size allowable. There could be no crosses of conduit because even two $\frac{1}{2}$ -in conduits would take up $2 \times 0.84 = 1.68$ of space, which is more than the $1\frac{1}{4}$ in. available.

FIGURE 9.313 Study of space available for conduits in reinforced-concrete floors.

In brick walls there must be two thicknesses of brick to conceal conduits, and the distance between them must be studied to determine the maximum size for vertical runs of conduit. These are only a few of the possible examples in which space for wiring must be considered. Very often the mistake of installing feeders just large enough to carry the present load is made, and when additions are called for, the feeders are overloaded and additional feeders must be installed at great expense. Conduits for feeders and mains

should be of sufficient size to permit the installation of feeders or mains of a carrying capacity of 150 percent of the present connected load. Also, spare conduits can be installed.

492. Wiring methods to be used are determined by a consideration of national and local code requirements, reliability, appearance, and cost. Those planning a wiring installation should decide which methods of wiring are allowable for the particular occupancy and electric system being considered. Then the cost of each allowable method should be weighed against the appearance, the degree of protection afforded, reliability, and probable years of service that will be realized. Both cost of material and cost of labor must be considered.

1. **Residences.** Type MC cable concealed in partitions is very practical, giving good reliability at moderate cost. If a less expensive installation is desired, nonmetallic-sheathed cable may be used. Sometimes this is used for a few large-size circuits such as a circuit to the electric range if the difference in cost is considerable, even if the rest of the wiring is metal-clad cable. The expense of metal raceways is usually not justified except in very large residences of the highest grade of construction. When the highest degree of adequacy for convenience outlets is desired, multioutlet assemblies should be employed for this part of the wiring.
2. **Rewiring Old Buildings of Residential or Commercial Occupancy.** Surface raceways, Type AC cable, nonmetallic-sheathed cable, and electrical metallic tubing are the usual expedients in rewiring. Surface raceways give the best appearance if the wiring must be exposed. Type AC cable or nonmetallic-sheathed cable is the most practical for that part of the wiring which can be fished through the partitions.
3. **Small Commercial Buildings and Apartment Buildings.** For buildings of frame or brick and frame construction, Type MC cable, nonmetallic-sheathed cable, or electrical metallic tubing concealed in the partitions is generally the most practical.
4. **Office and Public Buildings.** For buildings of steel, concrete, terra-cotta, or similar construction, the cost of wiring is only a small percentage of the total cost of the building. To keep the offices rented to business firms, the electric system should provide the very best in appearance and adequacy of service. Therefore the wiring should be concealed, and rigid metal conduit, intermediate metal conduit, or electrical metallic tubing be employed for ceiling lights and feeders, and under-floor raceways or cellular-floor raceways for desk outlets for power and signaling circuits.
5. **Industrial Buildings.** Metal raceways are generally used for branches, with busways, metal-clad cables, or conduits for feeders.
6. **Large-Sized Main Feeders.** The method of wiring should be considered very carefully because the high unit costs may make a considerable difference in the total cost of the installation.

Very often, combinations of wiring methods are used in the same building, each method being used where its advantages make it desirable.

493. In rewiring buildings using existing conduits, the use of new insulations with thinner insulations permits more conduit fill, depending on the type and size of conductors (see Tables 4 and 5 of Chap. 9 of the NEC.).

494. The branch circuits used in interior wiring may be classified as follows:

TYPE 1 This is an individual branch circuit that supplies only one utilization equipment.

TYPE 2 This is a branch circuit that supplies two or more outlets. Such branch circuits are further classified by the NEC according to the rating of the fuse or circuit breaker that protects the circuit. The Code recognizes five types of these multioutlet branch circuits. They are 15-, 20-, 30-, 40-, and 50-A branch circuits, respectively. The Code provides certain restrictions on the rating of outlets, size of wire, and equipment to be supplied, as given in Sec. 497.

495. Maximum loads for branch circuits. Type 1 branch circuits may supply loads of any capacity. If the load consists of a motor-operated appliance, the load must not exceed 80 percent of the branch-circuit wires. Also the load must not exceed 80 percent of the rating of the branch circuit when any load will continue for 3 h or more. For details of the requirements for motor branch circuits refer to Div. 7.

Branch circuits are required by the Code to have maximum loads which conform to the following:

- 1. APPLIANCES CONSISTING OF MOTORS AND OTHER LOADS** When a circuit supplies only motor-operated appliance loads, Article 430 of the Code shall apply (refer to Div. 7). For other than a portable appliance, the branch-circuit size shall be calculated on the basis of 125 percent of motor load if the motor is larger than $\frac{1}{8}$ hp plus the sum of the other loads.
- 2. OTHER LOADS** The total load shall not exceed the branch-circuit rating and shall not exceed 80 percent of the rating when the load will continue for 3 h or more, as for store lighting and similar loads. In computing the load of lighting units that employ ballasts, transformers, or autotransformers, the load shall be based on the total of the ampere rating of such units and not on the wattage of the lamps.

Exception: range loads. See Note 4 of Table 2 in Div. 12.

496. Permissible loads for Type 2 branch circuits are specified by the NEC as follows:

- 1. 15- AND 20-A BRANCH CIRCUITS** Lighting units and/or appliances: the rating of any one portable appliance shall not exceed 80 percent of the branch-circuit rating; the total rating of fixed appliances shall not exceed 50 percent of the branch-circuit rating if lighting units or portable appliances are also supplied.
- 2. 30-A BRANCH CIRCUITS** Fixed lighting units with heavy-duty lampholders in other than dwelling occupancies or utilization equipment in any occupancy: the rating of any one portable appliance shall not exceed 24 A.

3. 40- AND 50-A BRANCH CIRCUITS Fixed lighting units with heavy-duty lampholders or infrared heating appliances or utilization equipment in other than dwelling occupancies or fixed cooking appliances in any occupancy.
4. Branch circuits larger than 50 A shall supply only nonlighting loads.

The term *fixed* as used in this section recognizes cord connections when otherwise permitted.

497. Lighting and Appliance Branch Circuits^a

(Table 210.24, 2008 NEC)

Circuit rating, A	15	20	30	40	50
Conductors (minimum size):

498. The minimum required loads for which branch circuits and feeders must be supplied shall meet the Code requirements as determined from Table 5, Div. 12. If the maximum load of a branch circuit will continue for 3 h or more, as with store lighting and similar loads, the minimum unit loads specified in Table 5 of Div. 12 shall be increased by 25 percent so that the wiring system may have sufficient branch-circuit and feeder capacity to ensure safe operation. Refer to Secs. 89 to 107 in Div. 3 for a comprehensive analysis of this topic.

499. Branch circuits required. The NEC requires that branch circuits shall be installed as follows:

1. LIGHTING AND APPLIANCE CIRCUITS For lighting and for appliances, including motor-operated appliances, not specifically provided for in Par. 2, branch circuits shall be provided for a computed load not less than that determined by Part II of Article 220 of the Code.

The number of circuits shall be not less than that determined from the total computed load and the capacity of circuits to be used, but in every case the number shall be sufficient

for the actual load to be served, and the branch-circuit loads shall not exceed the maximum loads specified in Secs. 495 to 497.

Where the load is calculated on a volt-amperes per unit area basis, the wiring system up to and including the branch-circuit panelboard(s) shall be provided to serve not less than the calculated load. This load shall be evenly proportioned among multioutlet branch circuits within the panelboard(s). Branch circuit overcurrent devices and circuits shall be required to be installed only to serve the connected load.

2. **SMALL-APPLIANCE BRANCH CIRCUITS: DWELLING OCCUPANCIES** For the small-appliance load, including refrigeration equipment, in kitchen, pantry, dining room, or similar area of dwelling occupancies, two or more 20-A small-appliance branch circuits in addition to the branch circuits specified in Par. 1 of this section shall be provided for all wall and floor receptacle outlets covered by NEC 210.52(A) and counter receptacle outlets covered by 210.52(C) in these rooms, and such circuits shall have no other outlets except clock outlets or supplemental equipment and lighting on gas-fired ranges, ovens, or counter-mounted cooking units. In addition to the required receptacles, switched receptacles are permitted in lieu of lighting outlets in other than the kitchen and bathroom.

Receptacle outlets supplied by at least two appliance-receptacle branch circuits shall be installed in the kitchen to serve countertop surfaces.

At least one 20-A branch circuit shall be provided for a laundry receptacle (or receptacles) required in Sec. 210.52(F) of the Code.

Receptacle outlets installed solely for the support of and the power supply for electric clocks may be installed on lighting branch circuits or small appliance circuits.

A 120/240-V multiwire branch circuit is the equivalent of two 120-V receptacle branch circuits.

When a grounding receptacle is required as in Sec. 406.3(A) of the Code, the branch circuit shall include or provide an equipment grounding conductor to which the grounding contacts of the grounding receptacle shall be connected. Refer to Sec. 368, sub-heading 1b, for the list of acceptable equipment grounding conductors.

3. **OTHER CIRCUITS** For specific loads not otherwise provided for in Pars. 1 or 2, branch circuits shall be as required by other sections of the Code.

500. Feeder loads should be determined in accordance with instructions given in Div. 3. Instructions for determining the minimum allowable loads required by the Code are given in Sec. 5, Div. 12.

501. The size of conductors required with respect to both carrying capacity and voltage drop is discussed in Div. 3. For Type 2 branch circuits also refer to Sec. 497 of this division.

502. Overcurrent protection of circuits. In general, the rating of the overcurrent protective devices of a circuit shall not be in excess of the carrying capacity of the circuit conductor. However, there are many examples where this general principle is not workable and the Code either allows for limited exceptions from, or imposes additional limitations on this general principle:

- a. Overload protection, but not short-circuit protection, may be omitted where the operation of a circuit protective device due to overload would cause a greater hazard, as in the case of fire pump circuits.

- b.* For overcurrent devices rated 800 A or less, when the ampacity of a conductor does not coincide with a standard rating of an overcurrent device, the next higher standard size may be used. Note that this does not allow a conductor to be knowingly operated in the window between its ampacity and the next higher standard size device. For example, the ampacity of 4/0 aluminum Type SE cable for load connection purposes (refer to Div. 3 for a detailed analysis of termination ratings, etc.) is 180 A. The next higher standard size overcurrent device is 200 A. Although the cable can be protected with the 200 A device, if the actual load (as determined by NEC Article 220) is expected to run above 180 A, then a 250 kcmil aluminum Type SE cable would be required. In addition, the next-higher standard-size allowance does not apply to a multioutlet branch circuit supplying receptacles for cord-and-plug-connected portable loads.
- c.* There are special allowable ampacity values established for small conductors, unless specifically permitted for tap conductors or for specific applications as covered in item *f* below. The values are as follows:
1. 18 AWG copper is 7 A provided any continuous loads do not exceed 5.6 A, and there is special overcurrent protection provided by branch-circuit-rated circuit breakers or fuses listed and marked for use with 18 AWG copper wire, or Class CC, J, or T fuses are used for this purpose.
 2. 6 AWG copper is 10 A provided any continuous loads do not exceed 8 A, and there is special overcurrent protection provided by branch-circuit-rated circuit breakers or fuses listed and marked for use with 16 AWG copper wire, or Class CC, J, or T fuses are used for this purpose.
 3. 14 AWG copper is 15 A.
 4. 12 AWG aluminum and copper-clad aluminum is 15 A.
 5. 12 AWG copper is 20 A.
 6. 10 AWG aluminum and copper-clad aluminum is 25 A.
 7. 10 AWG copper is 30 A.
- d.* Tap conductors, and secondary conductors from transformers with no overcurrent protection at the point of supply, all as covered in Sec. 319.
- e.* Specific applications covered in specialized Code articles, as follows:
1. Air conditioning and refrigeration equipment conductors, as covered in Div. 7 in Secs. 400 to 402.
 2. Capacitor circuit conductors, as covered in Sec. 138 of Div. 4.
 3. Control and instrumentation circuit conductors using the special protocol allowed in NEC Article 727, as covered in NEC Sec. 727.9. This method is not covered in this handbook.
 4. Electric welder circuit conductors, as covered in NEC Sec. 630.12 and 630.32. These details are not covered in this handbook.
 5. Fire-alarm circuit conductors, as covered in NEC Sec. 760.43, 760.45, 760.121, and Chap. 9, Tables 12(A) and 12(B). For nonpower-limited circuits, the rules generally follow the provisions for comparable conductors of signaling circuits covered in Sec. 477, although the 300 percent allowance does not apply. For power-limited circuits, the overcurrent protection is generally governed by the activities of the listing agencies because the applicable tables in Chap. 9 effectively only apply to a listing evaluation.
 6. Motor conductors, both power and control, and motor-operated appliances are entirely governed by provisions in Article 430, as covered in Div. 7. Note that those provisions do not generally follow the small conductor limitations covered here. For example, the table allowable ampacity of a 14 AWG conductor under the usual termination conditions is 20 A. The rating of a 1 hp 115-V single phase motor per Div. 12, Table 8 is 16 A. The minimum ampacity for a motor conductor in this case (refer

to Sec. 387 of Div. 7) is 125 percent of full load, or 20 A for this motor. Assume that the motor will be protected by an inverse-time circuit breaker. As covered in Table 43 of Div. 12, the allowable protection ratio is 250 percent, allowing for a 50-A circuit breaker ahead of 14 AWG conductors to this motor. This assumes the motor has appropriate running overload protection, generally set at not over 125 percent of full-load current, or 20 A in this case.

7. Phase converter supply conductors, as covered in Sec. 371 of Div. 7.
8. Remote-control, signaling, and power-limited circuit conductors, as covered in NEC Sec. 725.43, 725.45, 725.121, and Chap. 9, Tables 11(A) and 11(B). For nonpower-limited circuits, the rules are covered in Sec. 477. For power-limited circuits, the overcurrent protection is generally governed by the activities of the listing agencies because the applicable tables in Chap. 9 effectively only apply to a listing evaluation.
9. Secondary tie conductors, as covered in Sec. 126 of Div. 5.

503. The voltage on branch circuits supplying lampholders within their voltage ratings, auxiliary equipment of electric discharge lamps, and cord-and-plug-connected or permanently connected utilization equipment shall not exceed 120 V between conductors; however, higher voltages are permitted in a number of cases, subject to the occupancy limitation in Sec. 504.

Branch circuit voltages exceeding 120 V between conductors but not exceeding 277 V to ground (which allows for 480 V supplies on 480Y/277-V systems) are permitted to supply listed electric discharge luminaires (fixtures) and a special form of listed incandescent luminaire with an integral stepdown autotransformer between the supply and the screw shell. This voltage bracket is also permitted to supply luminaires with mogul-base screw-shell lampholders or other lampholders applied within their voltage rating, auxiliary equipment of electric-discharge lamps, and cord-and-plug-connected or permanently connected utilization equipment.

Conductors running up to 600 V between conductors, and with no voltage to ground limitation, are permitted to supply the ballasts for electric discharge lamps mounted in permanently installed fixtures on poles for the illumination of areas, such as highways, roads, bridges, athletic fields, parking lots, at a height not less than 6.7 m (22 ft), or on other structures such as tunnels at a height not less than 5.5 m (18 ft) shall not exceed 600 V between conductors. They are also permitted to supply luminaires powered from dc systems that incorporate listed dc ballasts that provide isolation between the dc source and the lamp circuit and shock protection during relamping operations. This allowance is designed for dc photovoltaic output circuits (Sec. 551) that often approach this voltage, and this allows for directly-connected lighting without the inherent inefficiencies of a central inverter.

The above limitations do not apply to lampholders of industrial infrared heating appliances as covered in NEC Sec. 422.14, nor do they apply to railway properties where a limited permission is available to power equipment from a trolley wire system with a ground return. Medium voltages (over 600 V) are permitted to supply utilization equipment in occupancies with qualified maintenance and supervision of the electrical system. For example, many industrial occupancies use very powerful motors in ranges of thousands of horsepower and operating at 4.8 or even 13.8 kV.

504. In dwelling occupancies, and guest rooms or suites of hotels and motels, the voltage between conductors supplying luminaires (lighting fixtures), and cord- and plug-connected loads 1440 VA, or less, or less than $\frac{1}{4}$ hp shall not exceed 120 V between conductors. This limitation is by occupancy and therefore supersedes allowances for higher voltages generally, as covered in Sec. 503.

WIRING FOR RESIDENTIAL OUTDOOR LIGHTING

505. General considerations. The following recommendations for wiring for residential outdoor lighting have been taken from a booklet on the subject published by the Construction Materials Division of the General Electric Co.

Factors that must be considered before making any outdoor wiring installation are family habits and the facilities that the family wishes to enjoy, the style and construction of the house, the size and topography of the property, and, most important of all, whether spare circuits are available at the panelboard or new circuits must be added, and the length of the circuits required for the various outdoor lighting and outlet installations.

In general, it will probably be found that permanently installed outdoor wiring to be used beyond the house should be run underground from the point where it emerges from the house to the point where the equipment is to be used. There are, of course, exceptions. When the house is multistoried, overhead wiring may be used. In almost all other cases, from the viewpoint of both safety and aesthetics, underground circuits will be preferable. Sometimes a combination of overhead and underground wiring will be most satisfactory.

Any circuit installed in an existing dwelling for outdoor use should be a new circuit originating at the panelboard rather than an extension of an existing circuit. In all cases circuits for outdoor use should be restricted to this purpose only.

In laying out new outdoor wiring, it should be recognized that even though the homeowner considers that the primary purpose of the new circuits is to provide lighting only, this cannot be taken for granted. Once the circuits are installed and outdoor outlets are available, there will probably be a heavy demand from this source for power for appliances and tools. Not less, therefore, than two 20-A circuits or one three-wire 120/240-V circuit should be installed.

506. Running the circuits from panelboard to the outside. The style and construction of the house will determine how the circuits are run from the panelboard to the outside. Most installations will be either (1) from a basement when the walls are concrete or cement-block or (2) from above ground level when the panelboard is located either in the garage or in another interior location at first-floor level.

- 1. WHEN THE PANELBOARD IS IN THE BASEMENT** In this situation, wiring is generally brought to the outside either through the masonry wall of the basement or through the sill on top of the foundation. Factors to be considered are whether the installation is to be underground or overhead. If it is underground, going directly through the basement wall and coming out below ground level (Fig. 9.314) on the outside is the least conspicuous. If convenient shrubbery will hide the conduit, it may be easier to come out through the sill (Fig. 9.315).

FIGURE 9.314 Running the circuit from the panelboard through masonry.

FIGURE 9.315 Running the circuit from the panelboard through the sill.

Either of these methods may be chosen when the wiring is to be overhead. In this case, since a length of conduit will have to run up the side of the house, it is well to come out of the basement at a point where shrubbery will partially conceal the installation. Occasionally, in frame construction, the circuit for overhead wiring can be fished up through the walls to a point of departure at the desired elevation of the house.

2. **WHEN THE PANELBOARD IS IN THE GARAGE OR THE HOUSE** In many newer houses, especially those without basements, the panelboard is installed in the attached garage or in some other handy but inconspicuous part of the house. In such cases, the circuit is run from the panelboard through the wall of the garage or house (Fig. 9.316) at the most convenient point. Thought should be given to the point selected so that the installation is as unobtrusive as possible.

FIGURE 9.316 Running the circuit from the panelboard through the garage wall.

507. Underground circuits. Circuits run underground offer a number of advantages to the homeowner. They are not subject to damage from storms or exposed to mechanical damage. Most important, such circuits are invisible and do not, therefore, mar the appearance of the grounds and gardens.

The most economical underground installation for both feeders and branch circuits is Type UF (underground-feeder) cable. This cable is approved by the NEC for direct burial in the ground without additional protection.

Underground cable is laid in a trench at least 600 mm (24 in.) or (12 in.) 300 mm (12 in.) deep if 20 A or less and protected with a GFCI to prevent possible damage from normal spading. The bottom of the trench should be free from stones. This is easily accomplished by using a layer of sand or sifted dirt in the bottom of the trench (Fig. 9.317). Cable is laid directly on top of this layer. When cable enters the building or leaves the ground, slack should be provided in the form of an S curve to permit expansion with extreme changes in temperature. After the cable has been installed, fill all openings through the foundation with sealing compound so that water from rain or melting snow cannot follow the cable into the building.

FIGURE 9.317 Type UF cable used for underground circuits.

It is desirable that underground-feeder cables be installed in continuous lengths from outlet to outlet and from fitting to fitting. Splices can be made only without a splice box in accordance with Sec. 110.14(B) of the NEC. Note that the individual conductors of Type UF cable are not listed for direct burial; only the complete cable assembly has that rating. Therefore, any cable splices for this wiring method must run complete from intact cable sheath to intact cable sheath. There are twist-on wire connectors with direct burial ratings, and that are suitable for single-conductor Type USE cables, but they cannot be used for the customary Type UF cable underground.

In some areas of a yard, when it is felt that digging might accidentally occur to the depth of the cable, a concrete pad or a 1- by 2-in. (25.4- by 50.8-mm) running board can be laid

over the cable before the trench is filled (Fig. 9.317). Under driveways or roadways or where heavy loading might occur, it is also desirable to use a board, concrete pad, or conduit.

For outdoor wiring in sections of the United States that are known to be termite-infested or subject to attack by rodents, or whenever extra protection to the Type UF underground circuits is required, rigid galvanized-steel conduit may be used for mechanical protection. When rigid conduit for the complete circuit run is used, feeders and branch circuits may be of any approved type of moisture-resistant wire such as Types TW, RHW, or THWN.

508. Multiple-family buildings or apartments. The recommendations for residences can be applied to individual apartments for lighting and convenience outlets, and switch locations. If central heating is supplied, it is unlikely that an electric heater will be used in the bathroom or that many heavy-duty appliances will be used at one time. Therefore the two 20-A small-appliance branch circuits supplying convenience outlets in the dining room and kitchen generally will be sufficient. It is recommended that a three-wire, 120/240-V, No. 8 range circuit be installed for each apartment.

For nonrentable areas under the control of the building management the following rules from the *Handbook of Interior Wiring Design*, prepared by the Industry Committee on Interior Wiring Design, represent good practice:

1. Entrances

- a. Sufficient outlets shall be installed to provide electrical service consistent with the general architectural treatment, but in no case shall there be less than one outlet for an outside lantern or two for outside wall brackets.
- b. At least one ceiling outlet shall be installed for each 150 ft² (13.9 m²) of vestibule space.
- c. At least one wall outlet shall be installed over each group of letter boxes covering a lineal distance of 8 ft (2.4 m) or less.

2. Lobby or Main Hallway

- a. At least one ceiling outlet per 125 ft² (11.6 m²) of floor area shall be installed provided that:
 - (1) No area has outlets spaced more than 15 ft (4.6 m) apart.
 - (2) No elevator door or stairwell is more than 6 ft (1.8 m) from the nearest ceiling outlet.
- b. At least one convenience outlet shall be installed for every 12 ft (3.7 m) of wall space for portable lamps and general-utility purposes (vacuum cleaners, floor polishers, and so on). Hallways 10 ft or longer require a minimum of one convenience outlet.
- c. Provision shall be made for additional outlets to furnish such illumination as is demanded by the architectural treatment. This may be in the form of decorative wall brackets, urns, pedestals, built-in units, etc.

3. Upper Hallways

- a. At least one ceiling outlet shall be installed per 150 ft² (13.9 m²) of floor area, provided that:
 - (1) No area has ceiling outlets spaced more than 15 ft (4.6 m) apart if they are arranged on alternate circuits or 30 ft (9.1 m) if adjacent outlets are on the same circuit.
 - (2) No elevator door or staircase is located more than 6 ft (1.8 m) from the nearest ceiling outlet.
 - (3) No section of a hallway not in a straight line from another shall be without at least one ceiling outlet.
- b. At least one convenience outlet shall be installed per floor, with additional outlets spaced so that no point in a hallway is located more than 25 ft (7.6 m) from a convenience outlet, and a minimum of one for hallways 10 ft or longer.

4. *Hall Switches*

- a. All ceiling outlets plus the outlets for entrance lighting shall be controlled by switches.
- b. When all ceiling outlets on any one floor are controlled by a single switch, this switch shall be of a type or shall be located so as to be inaccessible to the general public.
- c. When more than one switch controls the ceiling outlets on a particular floor, at least one switch shall be inaccessible to the general public. This switch shall control outlets installed under the following provisions:
 - (1) It must control the outlet nearest the stairwell or the elevator door.
 - (2) It must control outlets so that the spacing between any two is not greater than 30 ft (9.1 m).
 - (3) It must control an outlet in every space not in a direct line from the outlet near the stairwell or the elevator door.

5. *Stairwells*

- a. When enclosed stairwells are installed (as in masonry construction), there shall be an outlet for lighting on each landing.
- b. If exit lights are required, they shall be installed in accordance with all rules and regulations covering their use.
- c. Interior stairways with six risers or more require a wall switch at each floor level.

6. *Basement Areas.* Lighting outlets shall be provided in basement areas on the basis of at least one ceiling outlet per 200 ft² (18.6 m²), plus additional outlets and necessary switch control if such basement areas are available to tenants for laundry, storage, or other purposes.

7. *Oil Burners, Air-Conditioning Equipment, etc.* Circuits shall be individually provided for each such piece of equipment in accordance with the size and rating of each motor or heater.

8. *Elevators.* Power and light feeders for elevator service shall be of the size required by the elevator manufacturer.

509. The arrangement of the service and feeders will depend on the system of metering employed. When each apartment is to be metered and billed for all its power, a meter service switch and meter should be provided for each apartment and one or two for the building management. These should be located in rows along the walls in the basement. Each apartment must be on an individual feeder from the meter service switch. The load on the feeder should be computed in accordance with the instructions given in Div. 3. If an electric range is supplied, three-wire feeders should be used. When the power company will bill the building management on a lower rate for power than it does for lighting, two meters with separate circuits for each should be provided. If there are more than six meter service switches, the service must be brought in through a single circuit breaker or fused service switch, the size to be determined in accordance with the instructions of Div. 3. When the power is to be billed to the building management and included in the rent, the circuit is brought in through a single circuit breaker or fused service switch as before.

Circuits for either one or two meters, depending on whether the power company bills the power on a separate rate from the lighting, should be provided. A distribution center with a safety enclosed fused knife switch or circuit breaker for each feeder should be installed. With steadily increasing energy costs at hand, the trend is toward including all tenant loads on a tenant meter. This also promotes energy conservation, since a tenant pays directly for any energy wasted. The method of wiring is with Type MC cable or nonmetallic-sheathed cable for small buildings permitted to be of frame construction. Conduit or tubing wiring is often employed, at least for feeders, for larger buildings of masonry construction.

510. With any of the above plans each apartment should have its own distribution panelboard containing circuit breakers for the branch circuits. Circuit breakers can be easily reset and are unlikely to provoke a service call by a tenant squeamish about changing a cartridge fuse. Note that every tenant must have ready access to his branch-circuit overcurrent devices, regardless of how a rental agreement may have been worded. He must also have ready access to his feeder and service devices unless there is continuous supervision by building management, and the management is responsible for electrical maintenance. This exemption only applies in multiple-occupancy buildings; a tenant in a single-family house must have this access regardless of how a rental agreement may describe the electrical maintenance responsibility.

WIRING FOR COMMERCIAL AND INDUSTRIAL OCCUPANCIES

511. Electrical distribution systems for commercial and industrial use (Joseph F. McPartland, *Electrical Systems Design*). In any electrical system, the distribution system involves the methods and equipment used to carry power from the service equipment to the overcurrent devices protecting the branch circuits. The distribution system carries power to lighting panelboards, power panelboards, and motor-control centers and to the branch-circuit protective devices for individual motor or power loads. Depending upon the type of building, the size and nature of the total load, various economic factors, and local conditions, a distribution system may operate at a single voltage level or may involve one or more transformations of voltage. A distribution system might also incorporate a change in frequency of ac power or rectification from ac to dc power.

Design of a distribution system, therefore, is a matter of selecting circuit layouts and equipment to accomplish electrical actions and operations necessary for the conditions of voltage, current, and frequency. This means relating such factors as service voltage, distribution voltage or voltages, conductors, transformers, converters, switches, protective devices, regulators, and power-factor corrective means to economy, load conditions, continuity of service, operating efficiency, and future power requirements. Of course, the factors of capacity, accessibility, flexibility, and safety must be carefully included in design considerations for distribution.

Basically, distribution systems are classified according to the voltage level used to carry the power either directly to the branch circuits or to load-center transformers or substations at which feeders to branch circuits originate. The most common types of distribution systems based on voltage are discussed in Div. 3.

512. Types of electrical distribution systems. The descriptions and discussions of the different types of electrical distribution systems given in this section and Secs. 513 to 524 inclusive are reproduced from *Westinghouse Architects' and Engineers' Electrical Data Book* through the courtesy of the Westinghouse Electric Corporation.

In the great majority of cases, power is supplied to a building at the utilization voltage. In practically all these cases, the distribution of power within the building is achieved through the use of a simple radial distribution system. This system is the first type described on the following pages from the low-voltage bus to the loads.

When service is available at the building at some voltage higher than the utilization voltage to be used, the system design engineer has a choice of a number of types of systems.

This discussion covers seven major types of distribution systems and practical modifications of several of them.

- Simple radial
- Loop-primary radial
- Banked-secondary radial
- Primary-selective radial
- Secondary-selective radial
- Simple network
- Primary-selective network

513. Simple radial system. The conventional simple radial system receives power at the utility supply voltage at a single substation and steps the voltage down to the utilization level. Low-voltage feeder circuits run from the substation bus to switchgear assemblies and panelboards that are located with respect to the loads as shown in Fig. 9.318. Each feeder is connected to the substation bus through a circuit breaker. Relatively small circuits are used to distribute power to the loads from the switchgear assemblies and panelboards.

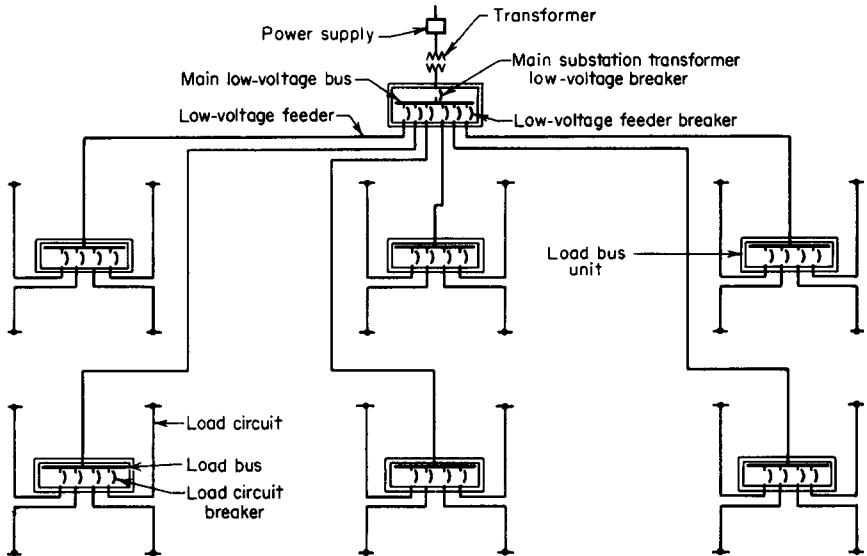

FIGURE 9.318 Conventional simple radial system.

Since the entire load is served from a single source, full advantage can be taken of the diversity among the loads. This makes it possible to minimize the installed transformer capacity. However, the voltage regulation and efficiency of this system are poor because of the low-voltage feeders and single source. The costs of the low-voltage feeder circuits and their associated circuit breakers are high when the feeders are long and the peak demand is above 1000 kVA.

A fault on the substation bus or in the substation transformer will interrupt service to all loads. Service cannot be restored until the necessary repairs have been made. A low-voltage feeder-circuit fault will interrupt service to all loads supplied over that feeder circuit.

A modern and improved form of the conventional simple radial system distributes power at a primary voltage. The voltage is stepped down to utilization level in the several load areas within the building through power-center transformers. The transformers are usually connected to their associated load bus through a circuit breaker, as shown in Fig. 9.319. Each power center is a factory-assembled unit substation consisting of a three-phase liquid-filled or air-cooled transformer, an integrally mounted primary switch, and low-voltage metal-enclosed circuit breakers. Circuits are run to the loads from these circuit breakers.

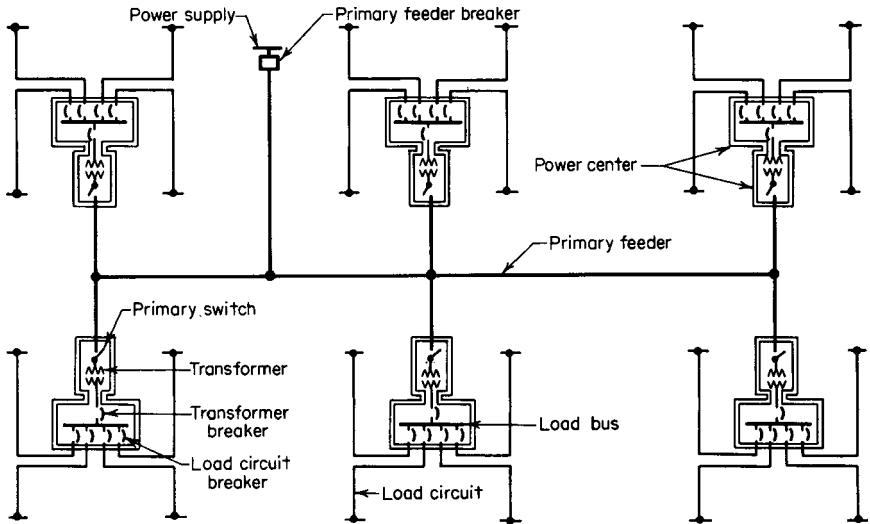

FIGURE 9.319 Modern simple radial system.

Since each transformer is located within a specific load area, it must have sufficient capacity to carry the peak load of that area. Consequently, if any diversity exists among the load areas, this modified system requires a greater transformer capacity than the basic form of the simple radial system. However, because power is distributed to the load areas at a primary voltage, losses are reduced, voltage regulation is improved, feeder-circuit costs are reduced substantially, and the large low-voltage feeder circuit breakers are eliminated. In many cases the interrupting duty imposed on the load circuit breakers is reduced.

This modern form of the simple radial system will usually be lower in initial investment than any other type of distribution system for buildings in which the peak load is above 1000 kVA. It is poor, however, from the standpoints of service continuity and flexibility. A fault on the primary feeder circuit or in one transformer will cause an outage to all loads. In the case of the feeder fault, service is interrupted to all loads until the trouble has been eliminated. When a transformer fault occurs, service can be restored to all loads except those served by the faulty transformer by opening the transformer primary switch and reclosing the primary feeder breaker.

Reducing the number of transformers per feeder by adding primary feeder circuits will improve the flexibility and service continuity of this system. This, of course, increases the investment in the system but minimizes the extent of an outage due to a transformer or feeder fault.

If one primary feeder is used per transformer, as in Fig. 9.320, the system is comparable in service continuity to the single substation form of the simple radial system. This

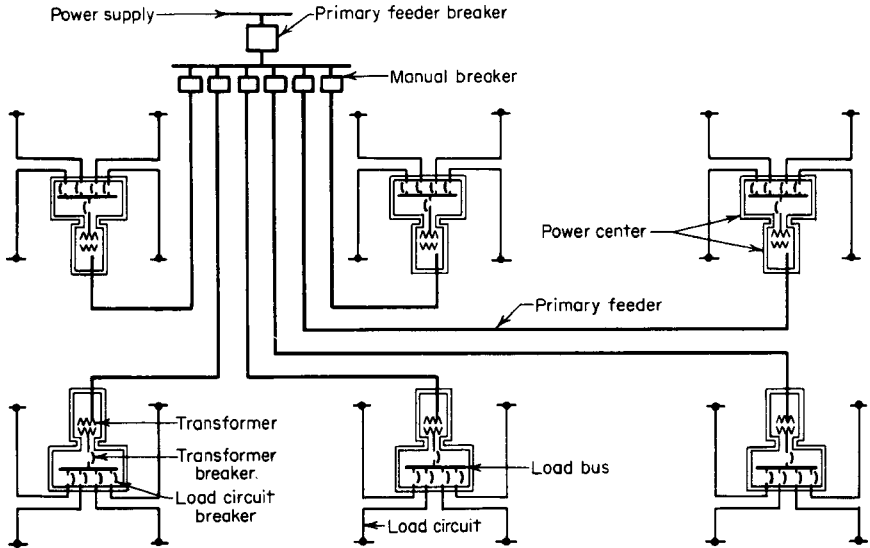

FIGURE 9.320 Modified modern simple radial system.

system arrangement will usually be very expensive. The cost can be materially reduced, however, by replacing the automatic feeder circuit breakers with manually operated breakers or load-break switches and by backing up a number of these switches with one automatic circuit breaker.

In this modified form of the simple radial system, a primary feeder fault interrupts service to all loads. Service can be restored to all loads except those associated with the faulted system element by opening the load-break switch on the faulted circuit and closing the circuit breaker. Service can be restored to the remaining loads when the necessary repairs are made.

514. Loop-primary radial system. This system is similar in principle to the modern form of simple radial system. It provides for quick restoration of service when a primary feeder or transformer fault occurs, as does the modified simple radial system of Fig. 9.320, and at a lower investment. A sectionalized primary loop controlled by a single primary feeder breaker as shown in Fig. 9.321 is used rather than a radial primary feeder.

Manually operated load-break switches are installed in the feeder for sectionalizing purposes. Two are located where the feeder branches to form the loop, and the others are located at the transformers. This makes it possible to disconnect any transformer and its associated section of loop from the rest of the system.

When a transformer or primary-feeder fault occurs, the main feeder breaker opens and interrupts service to all loads. Increasing the number of primary loop feeders will reduce the extent of the outage from a fault but will also increase the system investment. The faulty section of loop and its associated transformer can be disconnected from the system by the load-break switches. Service can then be restored to all but the disconnected portion of the system by closing the primary feeder breaker. Service cannot, however, be restored to the loads in the area where the transformer or primary loop section is in trouble until the necessary repairs have been made.

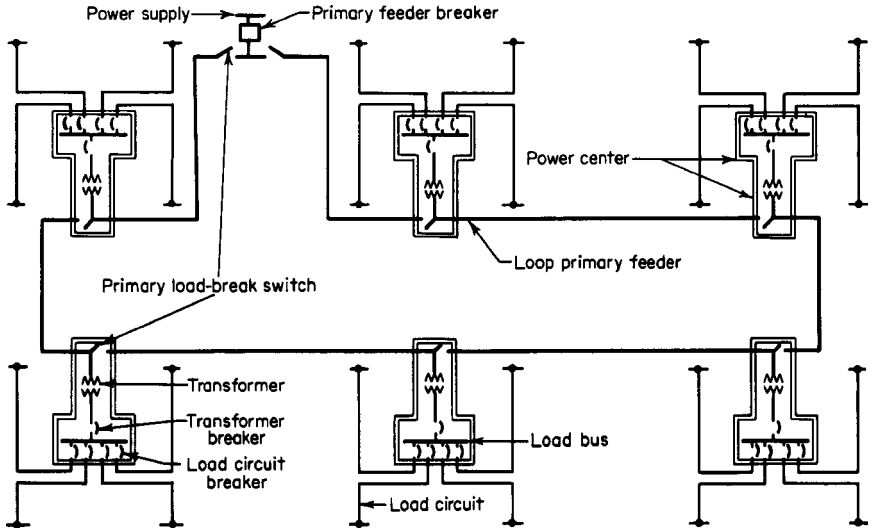

FIGURE 9.321 Loop-primary radial system.

The cost of this system as illustrated is only slightly more than that of the modern simple radial system of Fig. 9.319. The primary-cable cost is a little greater, and there are two additional load-break switches in the system. The load-break switches associated with the transformers will cost little more than the disconnecting switches in the primary leads of the transformers of the simple radial system.

515. Banked-secondary radial system. This system permits quick restoration of service to all loads following a primary-feeder or transformer fault. It uses a secondary loop, as shown in Fig. 9.322, to provide an emergency supply when a fault occurs in a transformer or a section of the primary loop. The primary-circuit arrangement is the same as that in the loop-primary radial system of Fig. 9.321.

The primary-feeder arrangement of the simple radial system of Fig. 9.320 can be used to give the same results, but it usually will be more costly.

A primary-feeder or transformer fault causes the main breaker to operate and drop all load. Service can be restored by opening the two load-break switches and the low-voltage breaker of the transformer adjacent to the fault and closing the primary feeder breaker. When the primary feeder breaker is reclosed, service is restored to all loads. Those loads connected to the load bus associated with the disconnected transformer are supplied over the secondary loop from adjacent load buses.

The secondary loop gives a number of important advantages other than providing an emergency supply to restore service. It helps equalize the loads on all transformers and thus makes it unnecessary to match the transformer capacity at each load center to the load connected to each load bus.

Balancing transformer capacity and load in each load area may be a real problem on all other types of radial systems, except the radial system of Fig. 9.318. The secondary loop permits 1 kVA rating of transformer to be used throughout the system, and load circuits can be run directly from the nearest bus to the loads.

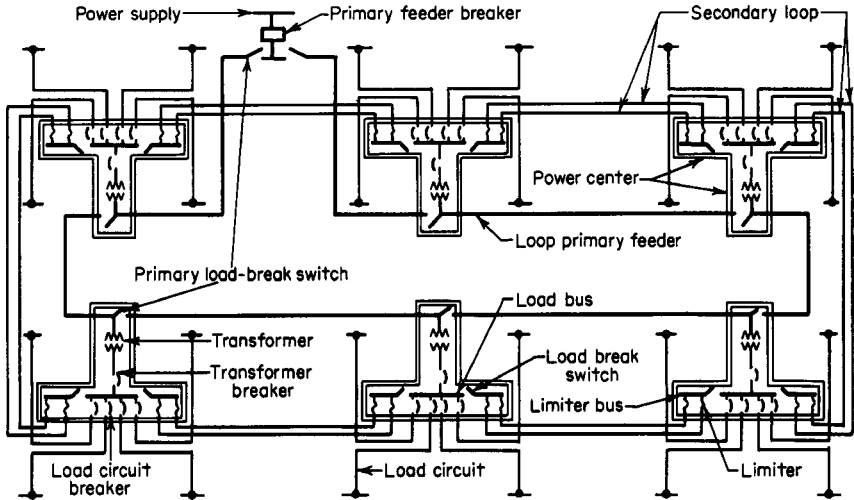

FIGURE 9.322 Banked-secondary radial system.

Advantage is taken of the diversity among the loads because all transformers are connected in parallel. As a result, there usually is a saving in transformer capacity over that required in any other form of radial system except the simple radial system of Fig. 9.318. Also, this system is better adapted for across-the-line starting of relatively large motors than is any other type of radial system because the starting current is supplied through several transformers in parallel rather than through a single transformer. Thus, if the starting of large motors is involved, the use of this system may result in a saving in the cost of motor-starting equipment. Likewise, it is the most satisfactory type of radial system for combined light and power secondary circuits.

In the banked-secondary radial system, fault current flows not only through the transformer associated with a faulted load bus or circuit but also through other transformers and over the secondary loop to the fault. The resulting increase in fault current may require the use of load circuit breakers having a higher interrupting rating than needed in other types of modern radial systems. This possible increase in cost may or may not be offset by savings in transformer capacity and secondary conductors.

It is difficult to make a general cost comparison between this system and the loop-primary radial system. In some buildings the additional cost of the secondary loop will be offset by the saving in transformer capacity and secondary conductors. In other buildings, because of lack of diversity and a relatively uniform distribution of load, these savings are very small, and the system will cost more than the loop-primary radial system by about the cost of the secondary loop. However, the advantages of quick restoration of service to all loads, greater flexibility, higher efficiency, and better voltage conditions may justify the extra cost.

516. Primary-selective radial system. The primary-selective radial system, as shown in Fig. 9.323, differs from the systems previously described in that it employs at least two primary-feeder circuits in each load area. It is designed so that when one primary circuit is out of service, the remaining feeder or feeders have sufficient capacity to carry the total load. While three or more primary feeders may be used, usually only two feeders are employed. Half of the transformers are normally connected to each of the two feeders.

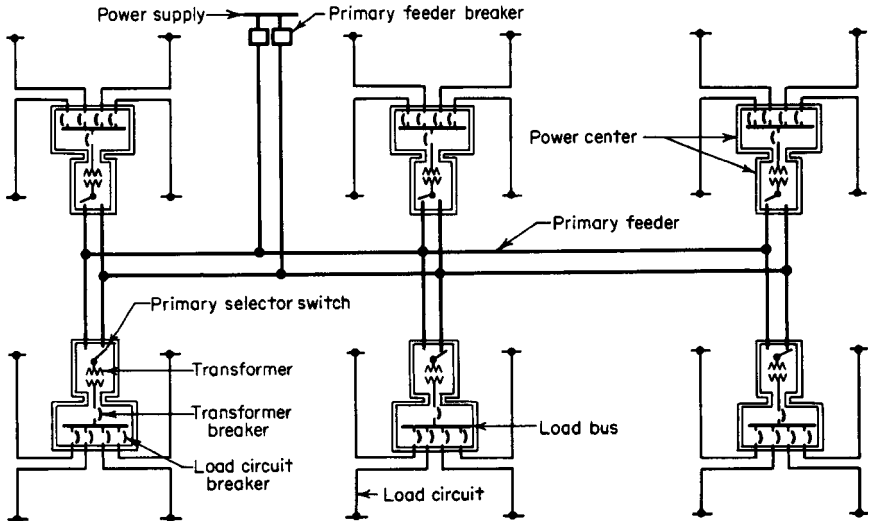

FIGURE 9.323 Primary-selective radial system.

When a fault occurs on one of the primary feeders, only half of the load in the building is dropped. In the systems discussed previously a primary-feeder fault causes an outage to all loads in the building.

Double-throw or primary selector switches are used with all transformers so that when a primary-feeder fault occurs, the transformers normally supplied from the faulted feeder can be switched to the good feeder and restore service to all loads.

The short-circuit duty on the load circuit breakers is less than in the banked-secondary radial system and is about the same as for all other types of radial systems using transformers within the load areas.

If a fault occurs in one transformer, the associated primary-feeder breaker opens and interrupts service to half of the load in the building, just as when a primary feeder fails. The faulted transformer is disconnected by moving its primary selector switch to the open position. Service is then restored to all loads except those normally supplied by the defective transformer by closing the primary-feeder breaker.

Service cannot be restored to the loads normally served by the faulted transformer until the transformer is repaired or replaced.

Cost of the primary-selective radial system is greater than that of the simple radial system of Fig. 9.319 because of the additional primary-feeder breaker, the use of primary selector switches, and the greater amount of primary-feeder cable required. The benefits derived from the reduction in the amount of load dropped when a primary-feeder or transformer fault occurs, plus the quick restoration of service to all or most of the loads, may more than offset the greater cost.

The primary-selective radial system, however, is not so good as the banked-secondary radial system from the standpoint of restoring service to the loads after a primary-feeder or transformer fault. It is only a little better than the loop-primary radial system in this respect. In some cases, particularly in fairly large buildings with medium- or light-load density, about the same quality of service can be rendered at less cost by using the loop-primary radial system employing two separate loops instead of one. In this case, half of the transformers are connected to each loop of the system. (See Fig. 9.323.)

517. Secondary-selective radial system. This system uses the same principle of duplicate feed from the power supply point as the primary-selective radial system. In this system, however, the duplication is carried all the way to each load bus on the secondary side of the transformers instead of just to the primary terminals of the transformers. This arrangement permits quick restoration of service to all loads when a primary-feeder or transformer fault occurs, as does the banked-secondary radial system.

The usual form of secondary-selective radial system is shown in Fig. 9.324. Each load area in the building is supplied over two primary feeders and through two transformers. The capacity of each of these transformers must be such that it can safely carry the entire load in the area served by both transformers. Each transformer is connected through a transformer breaker to a secondary bus section to which half of the radial load circuits are connected.

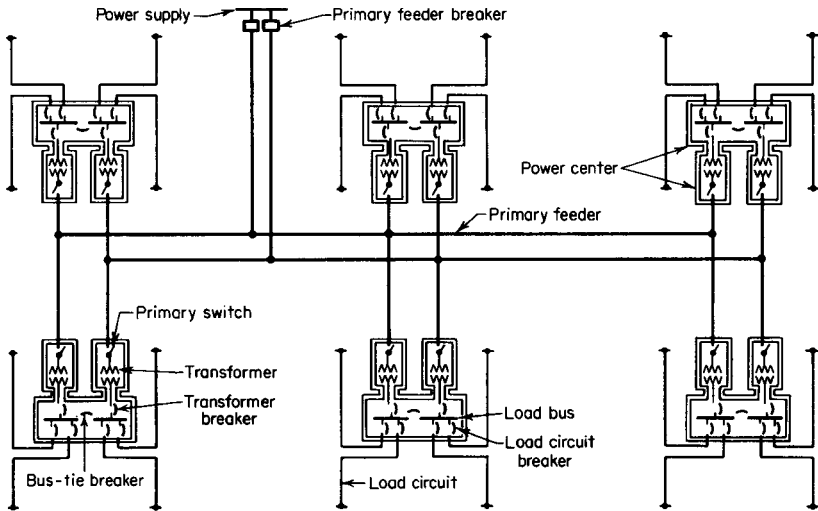

FIGURE 9.324 Secondary-selective radial system.

A bus-tie breaker is provided for connecting the two secondary or load-bus sections at each load center. Normally this bus-tie breaker is open, and the system operates as two parallel systems entirely independent of each other beyond the power supply points. The bus-tie breaker is interlocked with the two transformer breakers so that it cannot be closed unless one of the transformer breakers is open. This is done to keep the interrupting duty imposed on the load circuit breakers to a minimum.

A primary-feeder fault causes half of the load in the building to be dropped, as with the primary-selective radial system. Service can be restored by opening the transformer breakers associated with the faulted feeder and closing all bus-tie breakers. When this is done, the entire load is fed over one primary feeder and through half of the transformers. Therefore, both primary feeders must be capable of carrying the entire load, as with the primary-selective radial system, and a much greater transformer capacity is required.

A fault in a transformer causes the associated primary feeder breaker to trip and interrupts service to half of the building load. Service can be restored by opening the disconnecting switch on the primary and the circuit breaker on the secondary of the faulted transformer, closing the associated bus-tie breaker, and reclosing the primary-feeder breaker. This manual switching restores the system to normal operating conditions, except that the faulted transformer is deenergized and its load is being supplied through the adjacent transformer.

Cost of the secondary-selective radial system usually will be considerably more than that of the radial systems previously discussed with the exception of the system shown in Fig. 9.318, which uses one large substation and low-voltage feeders, and the banked-secondary radial system of Fig. 9.322. This is due chiefly to the large amount of transformer capacity required to provide complete duplicate power supply to the secondary load buses. Because of this spare transformer capacity, the regulation provided by the secondary-selective radial system under normal conditions is better than that of the systems previously discussed, with the possible exception of the banked-secondary radial system.

From the standpoint of voltage fluctuation when a load such as a relatively large motor is thrown on the system, this system is not as good as the banked-secondary radial system. The advantage that the secondary-selective radial system offers over the banked-secondary radial system is that a primary-feeder or transformer fault causes only one-half of the load to be dropped instead of all the load in the area. Both systems permit the quick restoration of service to all loads when a primary-feeder or transformer fault occurs.

The banked-secondary radial system has greater flexibility and can be more readily adapted to changing load conditions than can the secondary-selective radial system.

A modified form of secondary-selective radial system that will often be less costly than the common form previously described as shown in Fig. 9.325. In this system there is only one transformer at each load center instead of two. Pairs of adjacent load buses are connected by secondary cables or bus and thus permit picking up the load of any bus when a primary-feeder or transformer fault occurs.

Each tie circuit is connected to each of its two load buses through a secondary-tie circuit breaker. Each secondary-tie breaker is interlocked so that it cannot be closed unless one of the two transformer breakers is open.

There are two ways in which this single-transformer-substation form of secondary-selective radial system can be handled. One is to use the same number and rating of transformers as in the usual form of the system. Essentially, this results in twice as many load areas with half as much load in each area. This arrangement has the advantage of reducing the average length of the radial load circuits and thereby lowering the cost of the secondary

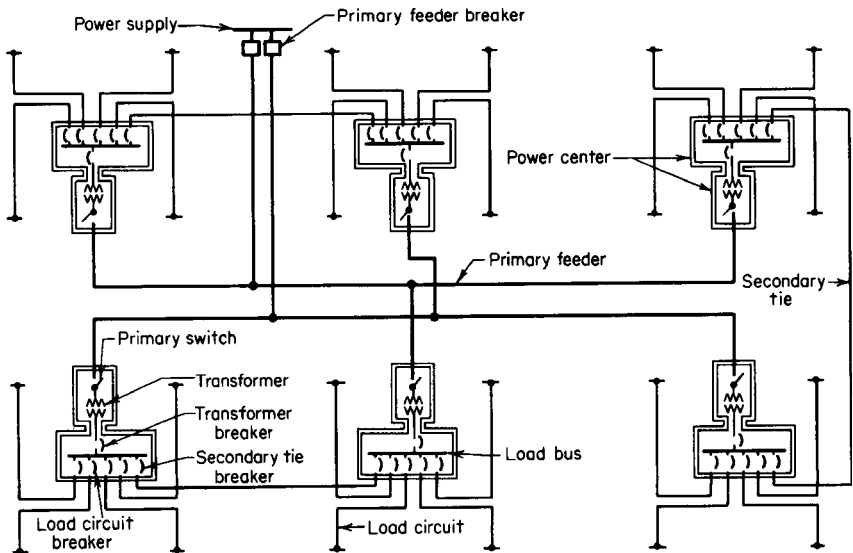

FIGURE 9.325 Modified secondary-selective radial system.

conductors. When compared with the other types of distribution systems, both this and the usual form of secondary-selective radial system introduce the problem of balancing the loads on twice the usual number of load buses.

The other way in which the system can be handled is to use the same number of load areas as in Fig. 9.324. With one transformer of twice the kVA rating at each load center, the result is half of the number of transformers but the same total transformer capacity. Because of the smaller number of transformers of larger rating, this will often be the lowest-cost form of secondary-selective radial system.

Basically, the single-transformer-substation form of secondary-selective radial system, regardless of the number and size of the transformers used, functions as described in connection with the more usual form of this system.

518. Simple network system. The ac secondary network system is the system that has been used for many years to distribute electric power in the high-density, downtown areas of cities. Modifications of this type of system make it applicable to serve loads within buildings.

The best-known advantage of the secondary network system is continuity of service. No single fault anywhere on the system will interrupt service to more than a small part of the system load. Most faults will be automatically cleared without interrupting service to any load. Another outstanding advantage that the network system offers is its flexibility to meet changing and growing load conditions at minimum cost and with minimum interruption of service to the other loads. In addition to flexibility and service reliability, the secondary network system provides exceptionally uniform and good voltage regulation, and its high efficiency materially reduces the cost of losses.

Three major differences between the network system and the simple radial system account for the outstanding advantages of the network. First, a network protector is connected in the secondary leads of each network transformer in place of the usual transformer secondary breaker, as shown in Fig. 9.326. Second, the secondaries of all transformers are connected together by a ring bus or secondary loop from which the loads are supplied over

FIGURE 9.326 Simple network system.

short radial circuits. Third, the primary supply has sufficient capacity to carry the entire building load without overloading when any one primary feeder is out of service.

A network protector is a specially designed, motor-closed, and shunt-tripped air circuit breaker controlled by network relays. The network relays function to close the breaker automatically only when voltage conditions are such that the associated transformer will supply load to the secondary loop and to open the breaker automatically when power flows from the secondary loop to the network transformer. The purpose of the network protector is to protect the secondary loop and the loads served from it against transformer and primary-feeder faults by disconnecting the defective feeder-transformer unit from the loop when a back feed occurs.

The chief purpose of the secondary loop is to provide an alternative supply to any load bus when the primary feeder which normally supplies it is deenergized, so as to prevent any service interruption when a transformer or feeder fault occurs. The use of the loop, however, gives at least four other important advantages. First, it saves transformer capacity. It permits lightly loaded transformers to help those which are more heavily loaded and thus tends to equalize the load on all transformers. Second, it saves secondary load circuit conductors and conduit. The secondary loop makes it unnecessary to match the load supplied from any one load bus with the transformer capacity at that point. Loads can be served from the loop at load buses located between network transformers, and the load circuits can be run directly to the loads from the nearest load bus. This permits the use of very short radial circuits and results in a considerable saving in secondary cable and conduit when compared with the load circuits of a simple radial system. Third, the use of the loop gives lower system losses and greatly improved voltage conditions. The voltage regulation on a network system is such that both lights and power can be fed from the same load bus. Much larger motors can be started across the line than on a simple radial system. This factor often results in greatly simplified motor control and permits the use of relatively large low-voltage motors with their less expensive control.

The fourth important advantage resulting from the use of the secondary loop is the much greater system flexibility it provides. New or relocated loads can be supplied directly from the nearest load bus without the necessity of reconnecting other loads to keep within the transformer capacity of the secondary substation to which the load is to be added. Complete network power centers or load-bus units can be relocated in the loop, or new units can be added to the loop to meet changing load conditions. The loop capacity requires no change when additional network power centers are connected to it if each new transformer is of no larger rating than those originally used. The loop permits these system changes to be made without interrupting service to existing loads. This greater flexibility of the network system permits the system to be changed more easily, more quickly, and at less cost to meet changing load conditions that can be done with a radial system.

Since the length of the secondary loop (which is in essence an extended bus) is considerably longer than the buses used with the usual radial systems, the probability of faults on it is greater. It therefore becomes necessary to protect the system against faults on this bus or loop so that a fault on it will be automatically disconnected without interrupting service. To accomplish this, the secondary loop should consist of a minimum of two three-phase circuits. These separate circuits should be bused at each point where power is supplied to the loop through a transformer and at each point where a radial load circuit is supplied to the loop through a transformer and at each point where a radial load circuit is served from the loop. Each individual loop circuit should be connected to these bus points through limiters.

A limiter is a device for disconnecting a faulted cable from a distribution system and for protecting the unfaulted portions of that cable against serious thermal damage. Although fusible, they are rated by the size of the conductors they protect and not a specified current in amperes. They function by means of a circuit-opening member which is heated and

destroyed by the current passing through it. The fusible circuit-opening member is completely enclosed so that there is no visible flame or smoke when the limiter operates. Limiters for building networks are suitable for use on circuits of 600 V and below and have an interrupting rating of 200,000 A. Limiters are designed for use with various sizes of cable and are rated in cable size. The largest limiter is rated at 1000 kcmil. The minimum fusing current of a limiter is about 3 to 3½ times the NEC continuous-current rating of the cable with which it is designed to be used. This value of fusing current is necessary to ensure positive selectivity among the limiters in the secondary loop. If limiters having appreciably lower values of fusing current were used, those on both the good conductors and the faulted conductor would function on the minimum definite time portion of other time-current curves for high fault currents. This means that not only the limiters in the faulted loop conductor but a number of those in the good conductors would blow almost instantly and in some cases cause unnecessary interruptions of service. In addition to preventing unnecessary limiter blowings, the high fusing-current value of limiters also has the advantage of keeping the normal temperature of the limiter terminals relatively low so that the associated cable can safely carry its rated current.

If loads are to be supplied from the secondary loop at points other than those at which the network transformers are connected to the loop, the current rating of the loop should be equal to the full-load current of one of the transformers supplying the loop. The current rating of the loop can be safely reduced to 67 percent of the above value if loads are supplied from the loop only at transformer locations. If more than 1 kVA rating of network transformer is used, the current rating of the loop should be based on the full-load current of the largest network transformer connected to the loop. When loads are served from the loop at points other than transformer locations, the maximum amount of load which should be supplied from the loop between any two adjacent transformers should not exceed the full-load rating of the loop of the two transformers.

To obtain satisfactory selectivity between limiters under all fault conditions, a minimum of two similar single-conductor cables per phase should be used in the secondary loop. The size and number of conductors used in any case should be selected to give the lowest installed loop cost. However, the conductors used should not be larger than about 600,000-cmil cable.

Loads are served from the secondary loop at conveniently located load buses over relatively short radial circuits. These load circuits are taken off the load buses through air circuit breakers. The breakers should provide adequate overload protection for their associated circuits and should be capable of interrupting the fault current available at that point on the system. The average interrupting duty on the load breakers in a network system will often be higher than the duty on the load breakers in a radial system having the same connected transformer capacity.

The optimum size and number of primary feeders can be used in the secondary network system because the loss of any primary feeder and its associated transformers does not result in the loss of any loads. In spite of the spare capacity required in primary feeders, this will often result in a saving in primary-feeder and switchgear cost when compared with a radial system. This saving is due to the fact that in many radial systems more and smaller feeders are often used to keep down the extent of the outage when a primary-feeder fault occurs.

When a fault occurs on a primary feeder or in a transformer, the fault is isolated from the system through the automatic tripping of the primary feeder circuit breaker and all the network protectors associated with that feeder circuit. This operation does not interrupt service to any loads. When the necessary repairs have been made, the system is restored to normal operating conditions by closing the feeder circuit breaker. All network protectors associated with that feeder will close automatically.

The simple network system sometimes takes a form commonly known as a *spot-network system*. With this system, emergency capacity to prevent a service interruption

when a primary-feeder or transformer fault occurs is provided by making a spare primary cable and transformer available at each load center instead of tying the load areas together by a secondary loop, as in the usual simple network.

The simple spot-network system resembles the secondary-selective radial system in that each load area is supplied over two or more primary feeders through two or more transformers. In this system, however, the transformers are connected through network protectors to a single load bus, as shown in Fig. 9.327. Since the transformers at each load bus operate in parallel, a primary-feeder or transformer fault does not cause any service interruption. The transformers supplying each load bus will normally carry equal loads, whereas equal loading of the two transformers supplying a load center in the secondary-selective radial system is difficult to obtain. The interrupting duty imposed on the load circuit breakers will be greater with the simple spot-network system than with the secondary-selective radial system.

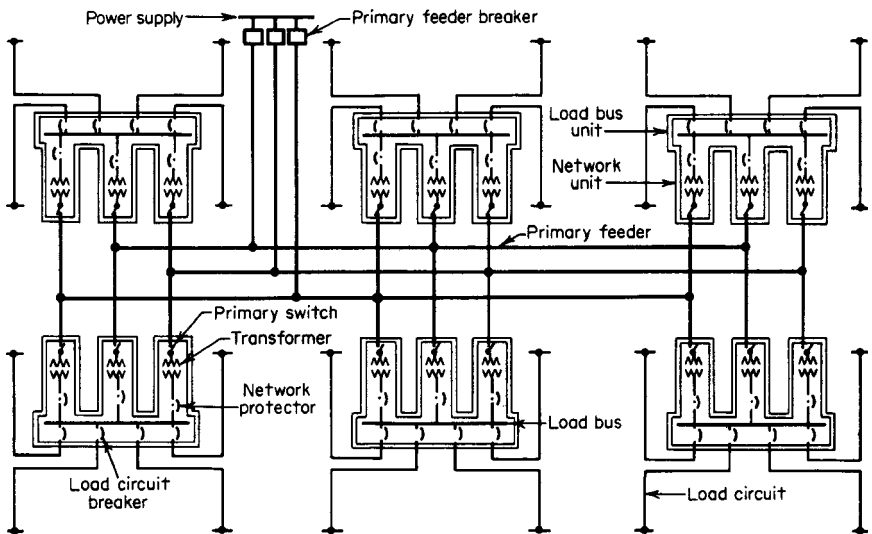

FIGURE 9.327 Simple spot-network system.

Simple spot-network systems are more economical than the other forms of network systems for buildings in which there are heavy concentrations of load covering small areas, with considerable distances between these concentrations and very little load in the areas between them. The chief disadvantage of spot-network systems is that they are not nearly so flexible for growing and shifting loads as are the other forms of network systems. Simple spot-network systems are used when a high degree of service continuity is required, flexibility is of minor importance, and their cost is less than that of the network systems using a secondary loop. The simple spot-network system is most economical when three or more primary feeders are required. This is true because supplying each load bus through three or more transformers greatly reduces the spare cable and transformer capacity that is required.

519. Primary-selective network. This is the most generally applicable and widely used form of industrial secondary network system. It is similar in principle to the simple network system, offers almost all its advantages, and is the lowest-cost network system for

buildings or load areas requiring only two or three primary feeders. Saving in first cost when compared with the simple network system is accomplished by using the principle of duplicate or alternate feed to each transformer, as with the primary-selective radial system. This procedure practically eliminates the necessity for spare transformer capacity and reduces the interrupting duty imposed on the load circuit breakers but not the spare primary-feeder capacity required.

Each transformer in the primary-selective network system is equipped with a primary selector switch. Two primary feeders are run to each transformer, as shown in Fig. 9.328. In a building requiring two primary feeders, each feeder must be capable of supplying the entire load in the building. Each transformer is connected to a load bus through a network protector. The radial circuits serving the loads are connected to the load bus through circuit breakers. A secondary loop, as is used in the banked-secondary radial and the simple network systems, connects each load bus to the two adjacent load buses. One-half of the network transformers are normally connected to each primary feeder.

FIGURE 9.328 Primary-selective network system.

A primary-feeder fault causes the faulty feeder and its transformers to be disconnected from the system by the automatic operation of the primary-feeder breaker and associated network protectors. The entire building load is then carried over the remaining primary feeder and one-half of the network transformers. The transformers associated with the faulty feeder can be connected to the good feeder by manually operating their selector switches. This relieves the overload on the transformers normally associated with the good feeder.

A transformer fault is isolated from the system by the operation of the primary-feeder breaker and the network protectors associated with the primary feeder. The defective transformer can be disconnected from the primary feeder by opening its selector switch. The feeder and its good transformers can be immediately returned to service. A primary-feeder or transformer fault will not cause any interruption of service to the load.

Cost of the primary-selective network system compares very favorably with that of the secondary-selective radial system. In buildings in which the load is quite uniform and there is little diversity among load centers, the secondary-selective radial system usually will be lower in initial investment than the network system. However, in buildings in which the load is nonuniform and there is appreciable diversity among load centers, the primary-selective network system often will be lower in first cost than the secondary-selective radial system.

It is a common practice to supply the radial circuits only from the load buses to which the network transformers are connected. At times a reduction in system cost can be made by serving loads from the loop at points between transformers. When this is done, the loop cables should preferably be paralleled and the loads taken off through load-bus units. Each load-bus unit should be similar to those used when network transformers connect to the loop; it consists of a load bus, two limiter buses with load-break switches and limiters, and load circuit breakers. Connecting loads to the secondary loop in this manner reduces the average length of the secondary load circuits.

By tapping all loads from the secondary loop at the nearest point, the amount of secondary load circuit conductors can be reduced to a minimum. This cannot be done practically when using a cable secondary loop if limiters are installed in the loop conductors at each load takeoff point. Such a form of network system is practical, however, if two or more parallel runs of plug-in bus duct are used for the secondary loop.

In this system, the transformers connect to a bus through network protectors, as in Fig. 9.328, except that there usually will be no load circuit breakers in the bus units. All loads usually are supplied through the load-break switches to the limiter buses and then through the limiters into the bus ducts that tie the adjacent bus units together.

This form of network system requires larger conductors in the secondary loop than those using the cable loop previously described. It also sacrifices something in service continuity when compared with network systems in which the loads are fed from load-bus units connected in a cable loop. This is true because a fault in a section of the bus-duct loop will cause an outage to the loads served from that section.

As with the simple network system, the primary-selective network may also take the form of a spot-network system. Each transformer in the primary-selective spot-network system is equipped with a primary selector switch and arranged for connection to either of two primary feeders, as shown in Fig. 9.329. This largely eliminates the necessity for spare transformer capacity, and the system is ordinarily designed without providing for such capacity.

Primary-feeder and transformer faults on this system are cleared without any interruption of service to the loads as in the simple spot-network system. When a primary feeder is deenergized because of a feeder fault, the transformers associated with the good feeder will carry as high as 160 to 200 percent of their rated kVA until the transformers normally associated with the defective feeder are switched to the good feeder by operation of their primary selector switches. After this switching operation has been completed, all the overloads on the system are relieved.

When a spot-network system of this design is used, a transformer failure requires a reduction in the load served from its load bus to prevent serious overloading of the remaining transformer connected to that bus. A transformer failure will occur so infrequently, however, that the cost of providing spare transformer capacity throughout the system cannot be justified to eliminate the remote probability of having to reduce load on one bus. If the possibility of having to reduce load is objectionable, it will cost less to use the simple spot-network system than to provide the necessary spare capacity in the primary-selective spot-network system. The primary-selective spot-network system, when designed without spare transformer capacity, will cost less than the simple spot-network system if two primary feeders and two transformers per load bus are used. If three or more primary feeders

FIGURE 9.329 Primary-selective spot-network system.

are required, the simple spot-network system will be lower in cost than the primary-selective spot-network system.

520. Influence of buildings on design. Building distribution systems are too often selected on the basis of using the system having the lowest initial investment. This practice usually results in the installation of a system which is neither the best nor the most economical for the building when all the factors are considered and properly evaluated.

All the major characteristics of the different types of distribution systems should be evaluated in the light of the building load requirements, in order to select the best system. The six major characteristics are initial investment, flexibility, service continuity, voltage regulation, efficiency, and cost of operation and maintenance.

The best system is that which gives the greatest value per dollar of investment and provides adequate electric service. This is rarely the system with the lowest *initial investment*.

Flexibility is the system's ability to be adapted to changing load conditions with the minimum of service interruptions and minimum cost of necessary changes.

Service continuity is measured in terms of the amount of load dropped with faults at different locations in the system, taking into account the likelihood of faults in the various locations.

Under *voltage regulation*, the change in voltage with load variations, the uniformity of this change at the various load points throughout the system, and the change in voltage resulting from suddenly applied loads should be considered.

The overall *efficiency* of the system from the power supply point or points to the utilization devices should be taken into account for both light-load and heavy-load conditions of operation.

Operating and maintenance costs are influenced by the nature and amount of equipment in the system and the ability to inspect, test, and maintain the equipment with minimum interruption of service.

The general arrangement and choice of the type of system depend upon the type and purpose of the building. In this discussion buildings shall be considered as belonging to one of these five classifications:

1. Large vertical buildings less than about 12 stories high
2. Tall (high-rise) commercial buildings
3. Large horizontal buildings such as shopping centers and large one-floor offices
4. Groups of small buildings such as hospitals and educational institutions
5. Industrial plants

The quality of service required by the loads varies somewhat within each of these classifications, depending upon the purposes of the buildings and the activities carried on within them.

521. Large vertical buildings. Large vertical buildings, such as office buildings, stores, apartments, hospitals, and hotels, require a high quality of electric service because the operation of essential equipment in the buildings depends directly on a reliable supply of electric power. Network systems are recognized as the best means of assuring satisfactory electric service in large buildings. However, in some cases, such as warehouses, interruptions of service for inspection and maintenance or as a result of faults may not interfere with the function of the building or cause hazards. In these cases, simple radial, primary-selective radial, or secondary-selective radial systems are used, depending upon the extent and duration of interruptions that can be tolerated and the importance of small savings in initial cost.

The network system is generally accepted as the most desirable form of distribution system for large buildings because it is the most economical method of providing reliability and good voltage characteristics. It is essential to have these characteristics in the distribution system for most large buildings because the activities in the buildings usually depend on a continuous supply of electric power with good voltage characteristics. Reliability is important because a failure of power that may stop elevators, pumps, and ventilating systems not only halts the activities in the buildings but may endanger the occupants. Obviously, good voltage regulation is essential to obtain the most effective output from lamps and other utilization devices. Good voltage regulation becomes particularly important when the same system supplies both the lighting and the power loads.

The relatively high load demands in large buildings encourage the use of large undesirable concentrations of transformer capacity in secondary substations with the result that very high fault currents are available in many cases. This requires expensive switchgear equipment to give adequate protection to the system against all possible faults in low-voltage circuits within the system. The power supply in buildings should be carefully designed to limit the fault currents to reasonable values so that less expensive equipment can be used. Several small substations instead of a few big substations can be used to reduce interrupting duties.

The interrupting duty on the low-voltage breakers in the substations directly affects the cost of the distribution system. High-interrupting-capacity breakers are more expensive than low-interrupting-capacity breakers. In general, the cost of the distribution system will materially increase if the interrupting duty exceeds 50,000 A. Therefore, it is desirable to plan the distribution system so that the interrupting duty does not exceed this value. In buildings in which the total load is not more than a few hundred kVA, it is not difficult to keep the interrupting duty below this value, and frequently it is possible to limit the interrupting duty below this value, and frequently it is possible to limit the interrupting duty to 25,000 A. The difference in cost between a substation using 25,000-A breakers and one using 50,000-A breakers is a relatively small part of the total cost of the substation.

Therefore, it is not economical to make extensive special arrangements to reduce the interrupting duty when it is between 25,000 and 50,000 A. On the other hand, when it is necessary to install switchgear having an interrupting capacity higher than 50,000 A, the switchgear may become a large part of the total cost, and considerable expenditures to reduce the interrupting duty to 50,000 A may be justified. Relatively small substations distributed throughout the building generally mean that the low-voltage feeders will be short and that the voltage regulation will be better. Furthermore, the small substations can be installed in smaller spaces. Frequently, it will be easier to find several small spaces for substations than to find or provide one large space in the building for one substation. Another advantage of using a number of small substations is that it is easier to find space to carry the low-voltage feeder conduits away from the substation.

The form of the network system most frequently used in large buildings is the simple spot-network system. However, a simple network system having several interconnected secondary substations is used in some cases.

When the distribution system in a building is continuously supervised by capable operators, the total transformer capacity sometimes can be reduced by using high-voltage selector switches instead of disconnecting switches on the network transformers. When four or more primary feeders are available, it is generally as economical to use disconnect switches and provide the necessary reserve transformer capacity as to use the more expensive selector switches. Selector switches should not be used whenever it is likely that they may not be operated promptly in an emergency.

The distributed type of simple network system is primarily applicable to very large buildings in which the low-voltage feeders can be materially shorter with this type of network than if a spot network were used. In such applications, the extra cost of the secondary ties may be more than offset by savings in low-voltage feeder circuits because the substations are located closer to the load centers. This form of network system may also provide better voltage conditions at the load centers than could be provided by a spot network and relatively long low-voltage feeder circuits.

The spot network is particularly applicable to medium-size buildings having only a few floors. In these cases, the savings in low-voltage feeders that could be obtained by using two or more small substations in a distributed form of network usually do not justify the expense of the secondary ties and their protective equipment. The spot network, of course, gives the same degree of reliability as does the distributed form of network. Obviously, two or more spot networks can be used in larger buildings with the same resulting savings in low-voltage feeder circuits. However, this means that there would be a greater number of smaller transformers and a correspondingly greater number of network protectors. The smaller units generally have a higher cost per kVA than the larger units, so that a number of small spot networks may cost more than a distributed network in an extensive system.

522. Tall buildings. Tall buildings are generally built in the densely loaded areas of cities. Almost without exception, the loads in these areas are served by secondary network systems. This makes it practical and economical to use some form of network system in a tall building. The nature of such a building practically requires a network system. Access to the major part of the building is accomplished almost entirely by elevators. Hence, it is imperative that power be continuously available for the operation of the elevators to avoid the hazard of panic or serious inconvenience resulting from a power outage. Furthermore, fire protection, water supply, heating, and ventilating depend for their operation on the availability, at all times, of an electric power supply. These considerations practically limit the choice of a distribution system to some form of secondary network. Usually three or more primary feeders are available within the area to supply the building, so that either a simple spot-network system or a simple network system is feasible. Various arrangements

of these two systems are used, depending on the height of the building, the location of the major loads within the building, and the total load demand.

In most modern tall commercial buildings there is likely to be a large air-conditioning load. When this load and the other power loads such as elevators, ventilating and heating equipment, fire pumps, water pumps, and related auxiliaries are taken into account, the power demand is likely to be more than the lighting load and may be as much as 3 or 4 times the lighting load. This proportion of power and lighting loads should be considered in the choice of utilization voltage. The power load will usually be the principal factor in the choice of locations for the distribution equipment.

Generally speaking, the practical maximum height that 208Y/120-V circuits can be carried in a tall building is about 12 stories. This limitation depends to a considerable extent on the relative cost of space for the distribution equipment in various parts of the building. The limitation of about 12 stories is based on including in the cost of the distribution system a charge for all the space used above the basements equal to the value of the same amount of commercially usable space. On this basis there is a thumb rule that major distribution centers will occur about every 25 floors in a tall office building. This is a very general rule, and the locations of the elevator equipment and major air-conditioning loads and other power loads in the building may make other locations of the distribution equipment more economical. The locations of the secondary substations involved in the distribution system in the building should be very carefully considered. Some specific comparisons have indicated that a much closer spacing of the secondary substations than 25 stories is economical. A closer spacing of the units improves the voltage conditions within the building and reduces losses in the system.

The simplest form of network system for a tall building is the simple spot-network system. In this system, a spot-network substation comprising the necessary number of network transformers and the associated low-voltage switchgear equipment is located at or near the major loads in the building. Therefore, the spot-network substation in the basement is generally the biggest of the various secondary substations. The locations of the power loads in the basement area or a logical segregation of the load may make two or more spot-network substations feasible. In this form of the network system, several primary-feeder circuits are carried up through the building to the various spot-network substation locations where the corresponding network transformers are connected to the primary feeders.

In many locations where tall buildings are built, it is practical to operate the building distribution system as part of the low-voltage secondary network in the area around the building. This involves the use of a simple network system within the building with secondary-tie circuits between the various network substations and the secondary-main system in the area around the building. The ties between the secondary mains of the utility network system and the building distribution system permit interchange of power between the two systems. This augments the reliability of the network system within the building and to some extent may improve the voltage conditions within the building. Since the same primary feeders that supply the building may also supply network units in the area around the building, there is some advantage in interconnecting the two systems to make sure that all the network equipment functions in the same manner. The desirability of interconnecting the building network system with a surrounding local network system may offset some of the advantages of a 460-V system within the building. The network system in the area around the building will be a 208Y/120-V system in most cases.

The simple network system involves some variations of the secondary ties between the network substations within the building. In their simplest form, these ties are purely tie circuits and do not supply loads at any time except by interchange of power from one substation to another. When this form of secondary tie is used, it generally will have only about two-thirds as much carrying capacity as the rated current of the largest of the associated network transformers. This provides enough capacity to make up for the outage of one

transformer at one of the network substations. Generally, the carrying capacity of the tie circuits is practically independent of the number of network units at any load bus. The secondary ties between the building system and the surrounding network system usually have about the same capacity as the ties between network substations within the building.

The capacity of the secondary ties can be increased to provide for tapping loads directly from the secondary ties between network substations. Basically, such a tie can be treated in two general ways. One way is to form load buses at every point along the tie where loads are tapped, as indicated in Fig. 9.330. If this is done, the capacity of the tie circuit will depend on the amount of load tapped off the circuit and the size of the network units associated with the tie. The capacity should be enough to carry all the loads tapped from the circuit, from one end of the circuit, as well as a reasonable amount of

FIGURE 9.330 Three arrangements of secondary-tie circuits between network substations in tall commercial buildings.

power interchanged between the network substations. In a simple case in which single-transformer network substations are interconnected by a tie circuit of this type, the total capacity of the circuit should be about equal to the rated current of one of the associated network transformers.

If load buses are not established in the tie circuit and the loads are tapped from one or another of the parallel branches of the tie circuit, the total carrying capacity of the tie circuit should be correspondingly increased. The reason for this is that it is unlikely that the load can be equally divided among the parallel branches of the tie circuit. Even if an equal division of connected load were possible, the diversity among the loads would mean that the load on one branch would not always be the same as that on another. Therefore, in this type of circuit the total carrying capacity should be at least $1\frac{1}{3}$ times the rated current of one of the associated transformers when there is only one transformer in each of the interconnected network substations.

The forms of the secondary-tie circuit illustrated in Fig. 9.330 consider only the use of paralleled three-phase circuits to form the tie circuit. This is because practical and convenient sizes of conductors can be used and overcurrent protection for the circuits can be economically provided. It is possible, of course, to use a single conductor per phase, such as a heavy bus, to form the tie circuit. To get the necessary carrying capacity in this way is likely to be expensive, and providing overcurrent protection for such a circuit is expensive and requires heavy protective equipment.

Another form of tie circuit that has been used is a secondary bus running the full height of the building. This form of tie circuit in effect is an extended spot network with the spot-network bus extending from the basement of the building to the uppermost network unit. In this arrangement the load circuits at the various floors are connected directly to the riser bus through protective devices or through a switchboard connected to the riser bus through a suitable protective device. The major disadvantage of this arrangement is the length of the spot-network bus. It is necessary to install this bus in such a way that there is practically no possibility of a fault on it. This can be accomplished by segregating the phases by barriers between the buses. However, such an installation is expensive. The capacity of such a bus should be somewhat more than the total load connected to the bus between adjacent network transformers. Some excess above this total load value would be required for the interchange of power between network units when one of the primary-feeder circuits is out of service.

The distribution of power within a tall building necessarily involves the use of transformers within the building. It is very important to choose transformers that minimize the possibility of fire or other damage to the building or injury to people in the building resulting from a transformer failure. For this reason, ventilated or sealed dry-type transformers are used in buildings. These types of transformers eliminate the hazard of fire and explosion damage resulting from a transformer failure.

523. Large horizontal buildings. Under the classification of large horizontal buildings, probably the most important with respect to numbers, size, and magnitude of load are shopping centers.

Shopping centers may be classified into three types with regard to size. They are the neighborhood shopping center that is designed to serve 5000 to 20,000 people, the district shopping center that serves 20,000 to 100,000 people, and the regional shopping center that serves a market of over 100,000 people.

Shopping centers will usually take one of five general physical arrangements. The simplest type, usually associated with the neighborhood shopping center, is the strip layout. A common variation of this simple layout is the L-shape layout. The mall, the

court, and the ring are three layouts that are used mostly in the district shopping center. The fifth type, the group or cluster of buildings, is generally used for large regional shopping centers.

The physical layout of a shopping center will influence the design of the electric distribution system. For instance, a system utilizing a loop-secondary circuit can be used to advantage in the mall-, ring-, or group-type shopping centers but may not be economical for the strip or court arrangement. The large loads in a shopping center will usually dictate where the power-center transformers must be located. If power centers must be located at these large loads, the loads in between them may be served over radial circuits from the power centers. However, if the distance between the power centers becomes great, using a system that permits the tapping of services off a secondary circuit running between power centers would be advantageous.

The selection of the utilization voltage or voltages to be used in shopping centers should not be limited to the choice of 120/240 V single-phase, 480 V three-phase, or 208Y/120 V three-phase. The magnitude, locations, and characteristics of the loads in shopping centers make it appear that the use of a three-phase, four-wire, grounded-Y, 480Y/277-V system would prove to be more economical in many cases.

Table 524 compares the distribution systems discussed previously for several magnitudes of load in each of the five types of shopping centers. The comparisons are made on a column basis, and it is not intended that the ratings in different columns should be compared.

The ratings take into account initial investment, service continuity, flexibility to handle new or changing loads, operation and maintenance costs, voltage regulation, and efficiency. Each of these factors has been weighted in proportion to its relative importance for each load magnitude and type of shopping center. The A ratings indicate that analysis of the system has shown it to rate at the top of the 12 systems compared in each column. The other quality ratings are given in terms of percentage of value of the A system:

Rating	Percent
B	81–90
C	71–80
D	61–70
E	51–60
F	41–50

525. Methods of supplying power to individual motor loads. The layout of the last stage of a motor distribution system will depend upon the type of building, construction characteristics of the building, motor size, types of motors to be served, and the flexibility desired in order to take care of changing location of loads. In one type of layout the branch circuit to each motor is run from a power panel. In another type the branch circuits to individual motors are tapped from a feeder. The features of the different types of motor distribution layouts are shown in Fig. 9.331.

The following discussion of the application of these methods is reproduced from *Electrical Systems Design*, by Joseph F. McPartland.

Miscellaneous motor loads in most commercial and institutional buildings and in many industrial buildings are usually circuited from power panels to which feeders deliver power. This type of distribution is a standard method of motor circuiting, generally limited to handling a number of motors of small integral-horsepower or fractional-horsepower sizes, located in a relatively small area such as a fan room or a pump room. The feeder to a power panel may be a riser in a multistory commercial or institutional building, run from a basement switchboard. In a one-level industrial area, the feeder to a power panel may be run from a main or load-center switchboard or from a load-center substation in a high-voltage distribution system. In commercial and industrial buildings, motor feeders may be run from a main switchboard or a load-center substation to a motor-control center serving a large group of motors in a machine room or in any compact area where the motors are relatively

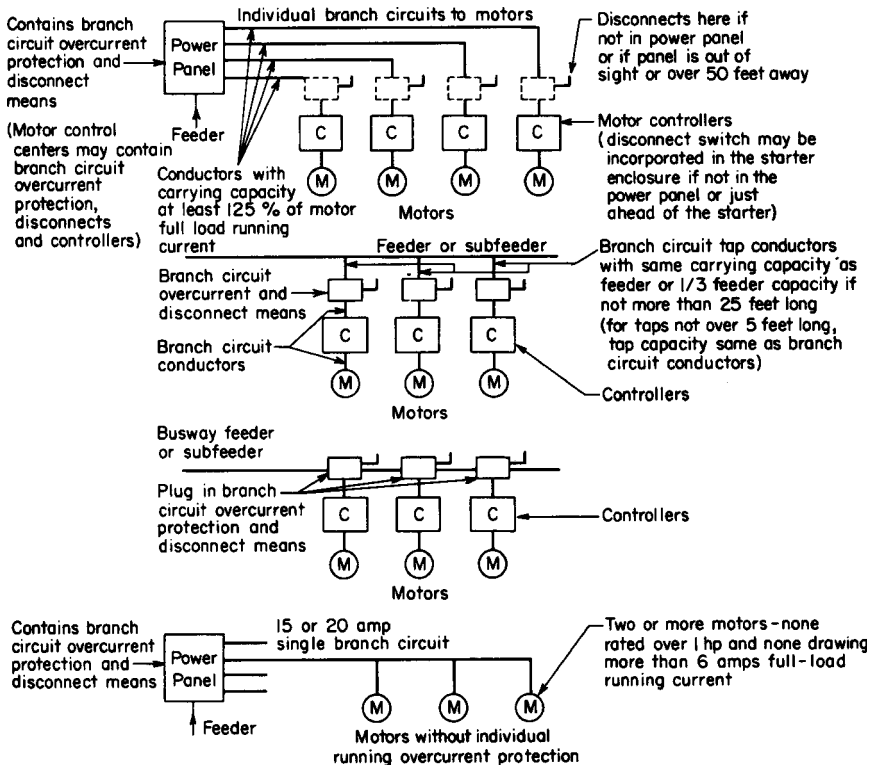

FIGURE 9.331 Methods of power distribution to individual motors. [*Electrical Systems Design*]

close together and close to the control-center assembly. The motor-control center contains all the control, protection, and disconnecting means for the motor circuits supplied.

In industrial buildings, in which a large number of motors are used over a large area, distribution of power to the individual motor loads generally follows the method of tapping motor branch circuits from the feeder. Such circuits may be tapped in several ways, with various combinations of branch-circuit overcurrent protection and motor control and disconnect means. The feeder in such an arrangement may originate from a main switchboard or from a load-center substation. In multistory buildings, such as office buildings or institutions, taps to motor branch circuits on a particular floor may be taken from a subfeeder originating in a load-center switchboard which is fed by a riser from the main switchboard in the basement. The feeder-tap method of supplying motor branch circuits is, of course, the basis for plug-in busway distribution to spread-out motor loads. In the system, the plug-in busway may be a feeder or a subfeeder, depending upon its origin. From a main switchboard, it would be a feeder; from a load-center switchboard, it would be a subfeeder. However, from a load-center substation, the plug-in busway would be a feeder—a secondary feeder derived from the transformation down from the primary feeder to the substation.

526. Adequate wiring for lighting and convenience outlets in commercial, public, and industrial structures.

It is very important in designing the interior wiring for a building to make adequate provision not only for present demands but also for probable future demands. The levels of illumination demanded by industry and commerce are being constantly increased. In order that a building may keep pace with this advancement without excessive expense in the reconstruction of its wiring, the wiring must be more than adequate to provide merely for present needs. Double carrying capacity can be provided in the original wiring installation for less than 25 percent additional cost. To provide a guide for adequate wiring, the following recommendations from the *Handbook of Interior Wiring Design* are given:

1. OUTLET LOCATION: COMMERCIAL AND PUBLIC OCCUPANCIES

a. Ceiling outlets for general illumination. Whenever possible, ceiling outlets should be uniformly spaced and located so that the spacing will be approximately the same in both directions. In *offices* and *schoolrooms*, the spacing between adjacent outlets shall not exceed the distance from floor to ceiling. In other interiors, the space may be extended to 1¹/₄ times the ceiling height. The space between an outlet and a wall should not exceed one-half of the average distance between outlets. In *halls* and *corridors*, spacing should not exceed 20 ft (6.1 m).

In locating outlets on any floor plan, construction features should be considered, especially ceiling beams. These are not always shown on the floor plans, yet they may seriously affect a lighting layout. This is particularly true for indirect lighting.

b. Stores: convenience outlets. There shall be installed at least one convenience outlet for each 400 ft² (37.2 m²) of floor area or major part thereof; these outlets need to be uniformly distributed over the entire area. Preference shall be given to the placing of these outlets in supporting columns and sidewalls, but no part of the floor area shall be more than 15 ft (4.6 m) from an outlet.

c. Stores: outlets for window illumination. Provision for show-window illumination shall be made by (1) a junction box on a wall or column at a suitable height above the transom bar or possible false ceiling to which all circuits of show-window reflectors or spotlights can be connected or (2) individual outlets spaced as recommended below. The NEC now requires receptacle outlets for every 3.7 linear m (12 linear ft) or major fraction of show window, located not more than 450 mm (18 in.) below the top.

For medium-base lampholders, outlets for show-window reflectors should be located 12 to 18 in. (304.8 to 457.2 mm) apart. For mogul-base lampholders, outlets

for show-window reflectors should be located 15 to 24 in. (381 to 609.6 mm) apart; for fluorescent lamps, as required by the lighting layout. The specific layout is to be governed by the standard loads of Sec. 527. Whenever more than one circuit per window is necessary, adjacent outlets should be on different circuits.

For spot or floodlights, at least two outlets per window shall be symmetrically placed, with an additional outlet for every 8 ft (2.4 m) or major fraction in excess of 16 ft (4.9 m).

- d. *Stores: convenience outlets in show windows.* In or near the floor of each window, there shall be installed at least one convenience outlet for each 50 ft² (4.6 m²) of platform or floor area used for window display, but in no case shall there be fewer than two convenience outlets per window.
- e. *Stores: outlets for case lighting.* Outlets shall be provided in the floor or wall for termination of the circuits for showcase and wall-case lighting. Such outlets shall be suitably located for connection to the lighting equipment and shall be governed by the standard loads as listed in Table 527.
- f. *Offices and schools: convenience outlets.* In each separate office room with 400 ft² (37.2 m²) or less of floor area, there shall be installed at least one convenience outlet for each 20 ft (6.1 m) of wall space. In each separate office with more than 400 ft² of floor area, there shall be installed at least four convenience outlets for the first 400 ft² of floor area and at least two outlets for each additional 400 ft² or major fraction thereof. Outlets should be placed at suitable locations to serve all parts of the office space. Certain offices, for example, professional and display offices, require many more outlets than are specified above, and the wiring needs must be individually studied if such probable occupancy is known.

For typical schoolrooms at least one convenience outlet shall be placed along the front wall and at least one along the rear wall.

- g. *Offices and stores: fans.* Unless made unnecessary by provision for complete air conditioning, outlets for fans shall be installed on the basis of at least two for each 400 ft² (37.2 m²) or major portion thereof. Such outlets shall be placed approximately 7 ft (2.1 m) above the floor and shall be of a type from which the fan may be mechanically suspended.
- h. *Stores: signs.* If no other equivalent provision is made for sign lighting, a rigid metal conduit or electrical metallic tubing, not smaller than 1 in., shall be run to the front face of the building for each intended or probable individual store occupancy. Such a raceway shall terminate outside the building at a point suitable for connection to the sign and shall terminate inside the building at a cabinet. Feeder capacity to this cabinet and service capacity shall be based upon a sign load of not less than 50 W/ft of store frontage, only the frontage on the principal street being considered if the store faces more than one street. Space provision shall be allowed for the connection and placement of a time switch to the sign circuit.

2. OUTLET LOCATION: INDUSTRIAL OCCUPANCIES

- a. *Ceiling outlets for general illumination.* The many special considerations of industrial lighting make it necessary to develop the outlet locations around the lighting layout. Local lighting units frequently supplement general illumination; special directional overhead sources are often necessary. In planning outlet locations, these must be considered as part of the complete installation. In halls and corridors lighted from a single row of outlets, the spacing between outlets shall not exceed 20 ft (6.1 m).
- b. *Convenience outlets.* There should be at least one convenience outlet in each bay in both manufacturing and storage spaces.

- 3. **STANDARD LOADS FOR GENERAL ILLUMINATION** The number of branch circuits and the capacities of the feeders and service shall be based upon the loads specified in Tables 527 and 528 as a minimum. If a known load that will exceed the loading here specified is to be supplied, the circuits, feeders, and service shall be based upon such known load.

The tabulated values represent the present acceptable standards of Illuminating Engineering Society foot-candle values. From these, the watts per square foot for each occupancy were determined by considering average conditions found in such occupancy, together with the accepted methods and equipment used in providing such illumination levels. In certain cases the standard loads include allowance for convenience outlets as well as for general illumination. The calculated wattage standards were based on the use of fluorescent and mercury-vapor equipment for large areas and incandescent equipment for local and supplementary lighting.

4. **BRANCH CIRCUITS*** The minimum number of branch circuits shall be based on the present connected load as follows:
- a. For two-wire 15-A circuits, the load per circuit shall not exceed 1000 W.
 - b. For multiwire 15-A circuits, the load shall not exceed 1000 W between each outside wire and the neutral.
 - c. For circuits designed for heavy-duty lampholders, the load per circuit shall not exceed 1500 W for No. 10 wire, 2500 W for No. 8, and 3000 W for No. 6.

The following considerations of wire size and circuit runs shall apply:

- d. No wire smaller than No. 12 shall be used for any circuit.
- e. When the run from a panelboard to the first outlet of a lighting branch circuit exceeds 50 ft (15.2 m), the size of wire used shall be at least one size larger than that determined by any of the above considerations. The calculated size may be used between outlets.
- f. When the run from a panelboard to the first outlet of a convenience-outlet circuit exceeds 100 ft (30.5 m), No. 10 wire or larger shall be used for such run.
- g. No runs longer than 100 ft (30.5 m) between the panelboard and the first outlet of a lighting branch circuit shall be made unless the intended load is so small that the voltage drop can be restricted to 2 percent between the panelboard and any outlet on that circuit. To avoid this condition, panelboards should be relocated or additional panelboards installed.

The following considerations in regard to combinations of outlets shall apply:

- h. No convenience outlet shall be supplied by the same branch circuit that supplies ceiling or show-window lighting outlets.
- i. Outlets for show-window spotlights shall be on separate circuits from general show-window outlets.
- j. The number of convenience outlets included on one circuit shall be based on the listing in the following table.

Outlets per Circuit

Location	Maximum number
Barbershops, beauty parlors, etc.	2
Medical, dental, and similar offices	2
Store show windows (for spotlights)	3
Store show windows (at floor)	6
Display areas in retail stores	6
School classrooms	6
Manufacturing spaces	6
Office spaces	8
Storage spaces	10

*These standards are based upon 15-A protection of branch circuits. If local regulations limit the load on branch circuits to less than these requirements, the wattage and area limits herein specified must be proportionately reduced.

- 5. CIRCUIT CONTROL** Suitable provision shall be made for the control of all circuits except those supplying convenience outlets only, and control of the latter circuits is recommended. Circuits may be controlled individually, in groups, or by a combination of both methods.

In a retail store, individual control at the panelboards by means of circuit switches or circuit breakers is usually preferable. In most other occupancies, control should be provided by means of local switches or circuit breakers. Frequently it is necessary to provide two or more switches for the local control of outlets supplied by a single branch circuit.

Provision shall be made for control of all circuits supplying a single sign by means of an external manually operable switch or circuit breaker, and in each case a suitable time switch shall also be provided to effect the same control.

In a retail store, each circuit supplying outlets in one or more show windows shall be individually controlled, and provision shall be made for the installation of a time switch for group control of all such circuits.

Group control of circuits for general illumination or for special decorative effects, by means of remote-control switches, is desirable in certain large spaces such as large offices, large reading rooms, museums, art galleries, and ballrooms.

- 6. PANELBOARDS** The number and location of panelboards shall be based on the number of branch circuits and the distance or runs as specified in Par. 4 of these adequacy standards.

On each panelboard one spare circuit shall be provided for each five circuits utilized in the initial installation. When flush-type cabinets are used, provision shall be made for bringing a corresponding number of circuit conductors to the ceiling of the story served, the ceiling of the story immediately below, or both points. Such provision may consist of circuit conductors or of empty raceways terminating in boxes suitably located for future extensions.

Provision shall be made for control of show-window lighting by such grouping of circuits to a panelboard as to enable a time switch to be suitably installed.

7. FEEDERS

a. Carrying capacity. The carrying capacity of each feeder or subfeeder shall be based on the number of separate circuits which it supplies, computed as follows:

- (1) *Overhead lighting circuits.* These are assumed as having 1000 W for each 15-A circuit and 1500 W for each 20-A circuit.
- (2) *Convenience-outlet circuits.* The assumed load is 1000 W per circuit.
- (3) *Spare panelboard circuits.* The assumed load is 500 W.
- (4) *Nonitemized and heavy-duty additional circuits.* The capacity is based on the specific load for which they are designed.

To the total of these four, such demand factors as permitted by the NEC may be applied. Refer to Div. 3 for additional information.

b. Provision for the future. In all determinations of feeder size, consideration should be given to increasing the capacity of the initial system by 50 percent to provide for future growth at a minimum of unwarranted expense. If an ultimate feeder size does not exceed No. 4 wire, the excess capacity should be installed immediately. In other cases, one of the following methods should be made a part of the original layout:

- (1) The installation of oversize raceways, so that the conductors installed can be withdrawn at any time and replaced by conductors of a suitable larger size
- (2) The installation or arrangement of the installed equipment so that additional feeders can be installed later at minimum expense to furnish the ultimate capacity
- (3) The installation of feeders of excess size

c. *Voltage drop.* Feeders and subfeeders shall be of such size that the total voltage drop from any panelboard to the point where connection is made to the lines of the utility supplying services shall not exceed 1 percent (see Div. 3 for method of calculation). To compute such a drop, the ultimate demand as calculated above shall be used whenever the wire size based on such demand is installed immediately. If provision for the future is made in some other way (oversize raceways, etc.), the voltage drop shall be computed on the basis of the carrying capacity of the wire used.

- 8. **FEEDER DISTRIBUTION CENTER** A feeder distribution center in the form of a panelboard, switchboard, or group of enclosed switches or circuit breakers shall be provided for the control and protection of each feeder.

Except when oversize feeders are provided in the original installation as recommended in the preceding section, provision shall be made at the feeder distribution center for the connection and suitable protection of feeders of increased size or of supplemental feeders. This can be accomplished by providing additional protective devices as part of the original installation, or by so designing the original equipment that space, bus capacity, and facilities for making connections will be available.

9. **SERVICE-ENTRANCE ADEQUACY STANDARDS (75°C RATED COPPER CONDUCTORS)**

Initial load, A	Service switch, A	Conductor size, gage No. or cir mils	Initial load, A	Service switch, A	Conductor size, gage No. or cir mils
1-23	60	8	118-133	200	4/0
24-33	60	6	134-150	400	4/0
34-47	100	4			
48-60	100	2	151-167	400	250,000
61-67	100	1	168-183	400	300,000
			184-200	400	350,000
68-83	200	1/0	201-217	400	400,000
84-100	200	2/0	218-267	400	500,000
101-117	200	3/0			

- 10. **SERVICE CONDUCTORS AND EQUIPMENT** The minimum capacity of the service required for the initial load depends on the total number of feeders supplied by it, whose individual loads are determined as specified in Par. 7. When applicable, demand factors as permitted by the NEC may be used (see Sec. 44 of Div. 3). To determine the probable required ultimate capacity of the service conductors and equipment, 50 percent should be added to the calculated initial load.

When the calculated initial load does not exceed 267 A, service conductors and equipment having the capacity needed for the ultimate load should be included as part of the original installation. The recommended equipment for various initial loads is tabulated in Par. 9. When the initial load exceeds 267 A, a study should be made of each individual case to determine what provision should be made for a future increase in the load.

These values should be understood in terms of relative load densities and not absolute design criteria. Current building codes generally impose energy conservation standards that substantially reduce these numbers in absolute terms.

527. Standard Loads for Lighting in Commercial Buildings

Occupancy	VA/sq-ft	Occupancy	VA/sq-ft
Armories: drill sheds and exhibition halls. (This does not include lighting circuits for demonstration booths, special exhibit spaces, etc.)	5	Looker rooms	2
Art galleries:		Fencing, boxing, etc.	5
General	3	Handball, squash, etc.	5
On paintings—50 W per running foot of usable wall area		Halls and interior passageways—20 W per running foot	
Auditoriums	4	Hospitals:	
Automobile showrooms	6	Lobby, reception room	3
Banks:		Corridors—20 W per running foot	
Lobby	4	Wards, including allowance for convenience outlets for local illumination	3
Counters—50 W per running foot including service for signs and small motor applications, etc.		Private rooms, including allowance for convenience outlets for local illumination	5
Offices and cages	5	Operating room	5
Barber shop and beauty parlors. (This does not include circuits for special equipment.)	5	Operating tables or chairs:	
Billiards:		Major surgeries—3,000 W per area	
General	3	Minor surgeries—1,500 W per area	
Tables—450 W per table		This and the above figure include allowance for directional control. Special wiring for emergency systems must also be considered.	
Bowling:		Laboratories	5
Alley runway and seats	5	Hotels:	
Pins—300 W per set of pins		Lobby, not including provision for conventions, exhibits	5
Churches:		Dining room	5
Auditoriums	2	Kitchen	4
Sunday-school rooms	5	Bedrooms, including allowance for convenience outlets	5
Pulpit or rostrum	5	Corridors—20 W per running foot	
Club rooms:		Writing room, including allowance for convenience outlets	3
Lounge	2	Library:	5
Reading rooms	5	Reading rooms. This includes allowance for convenience outlets.	
The above two uses are so often combined that the higher figure is advisable. It includes provision for convenience outlets.		Stack room—12 W per running foot of facing stacks	6
Courtrrooms	5	Motion-picture houses and theaters:	
Dance halls (No allowance has been included for spectacular lighting, spots etc.)	2	Auditoriums	2
Drafting rooms	7	Foyer	3
Fire-engine houses	2	Lobby	
Gymnasiums:			
Main floor	5		
Shower rooms	2

File room, vault, etc.	5	Sight-saving classes	5
Reception room	7	Showcases—25 W per running foot	7
Post office:	3	Show windows:	7
Lobby	2	Large cities:*	
Sorting, mailing, etc.		Brightly lighted district—700 W per running foot of glass	
Sorting, file room etc.	3	Secondary business locations—500 W per running foot of glass	
Professional offices:	3	Neighborhood stores—250 W per running foot of glass	
Waiting rooms	3	Medium cities:*	
Consultation rooms		Brightly lighted district—500 W per running foot of glass	
Operation offices	3	Neighborhood stores—250 W per running foot of glass frontage	
Dental chains—600 W per chair	5	Small cities and towns—300 W per running foot of glass frontage*	
Railway:	7	Lighting to reduce daylight window reflections—1,000 W per running foot of glass	
Depot-waiting room		Stores, large department, and specialty:	
Ticket offices—general		Main floor	6
On counters 50 W per running foot	3	Other floors	6
Rest room, smoking room		Stores in outlying districts	5
Baggage, checking office	5	Wall oases—25 W per running foot	
Baggage storage	3		
Concourse	3		
Train platform	2		
Restaurants, lunchrooms, and cafeterias:	2		
Dining areas	2		
Food displays—50 W per running foot of counter (including service aide)			

NOTE Figures based on use of fluorescent equipment for large-area application, incandescent for local or supplementary lighting.

*Wattages shown are for white light with incandescent filament lamps. Where color is to be used, wattages should be doubled.

528. Standard Loads for General Lighting in Industrial Occupancies

(Refer to the note in Table 527, which also applies to these values.)

Occupancy	VA/sq-ft	Occupancy	VA/sq-ft
Aisles, stairways, passageways 10 W per running foot		Foundries:	
Assembly:		Charging floor, tumbling, cleaning, pouring, shaking out	2.0
Rough	3.0	Rough molding and core making	2.0
Medium	4.5	Fine molding and core making	4.0
Fine	*4.5	Garages:	
Extra fine	*4.5	Storage	2.0
Automobile manufacturing:		Repair and washing	*3.0
Assembly line	*4.5	Glassworks:	
Frame assembly	3.0	Mixing and furnace rooms, pressing and Lehr glass—blowing machines	3.0
Body assembly	4.5	Grinding, cutting glass to size, silvering	4.5
Body finishing and inspecting	*4.5	Fine grinding, polishing, beveling, etching, inspecting, etc.	*4.5
Bakeries	4.0	Glove manufacturing:	
Book binding:		Light goods:	
Folding, assembling, pasting	3.0	Cutting, pressing, knitting, sorting	4.5
Cutting, punching, stitching, embossing	4.0	Stitching, trimming, inspecting	4.5
Breweries:		Dark goods:	
Brewhouse	3.0	Cutting, pressing, etc.	*4.5
Boiling, keg washing, etc.	3.0	Stitching, trimming, etc.	*4.5
Bottling	4.0	Hangars—aeroplane:	
Candy making	4.0	Storage—live	2.0
Canning and preserving	4.0	Repair department	*3.0
Chemical works:		Hat manufacturing:	
Hand furnaces, stationary driers, and crystallizers	2.0	Dyeing, stiffening, braiding, cleaning, and refining:	
Mechanical driers and crystallizers, filtrations, evaporators, bleaching	2.0	Light	2.0
Tanks for cooking, extractors, percolators, nitrators, electrolytic cells	3.0	Dark	4.5
Clay products and cements:		Forming, sizing, pouncing, flanging, finishing, and ironing:	
Grinding, filter presses, kiln rooms	2.0	Light	3.0
Moldings, pressing, cleaning, trimming	2.0	Dark	6.0
Enameling	3.0	Sewing:

		Fine bench- and machine work, fine sanding, and finishing	6.0

The figures given in this table are average design loads for general lighting. In those cases marked with an asterisk (*), the load values provide only for large-area lighting applications. Local lighting must then be provided as an additional load.

The figures given are based on the use of fluorescent and mercury-vapor equipment of standard design. Adjustments can be made for use of higher or lower efficiency equipment. For equal lighting intensities from incandescent units, the figures must be at least doubled.

Use of these figures in computing number and loading of circuits and feeders should always be checked against the conditions and requirements of the particular area. The figures are not substitutes for lighting design.

In any case, need for particular color quality of light, special intensities, or control of light must be determined as part of the lighting design, and wattages and circuit requirements must be provided accordingly.

529. Allowance for growth in feeders (*Electrical Systems Design*) should begin with the spare capacity designed into the branch circuits. For all circuits loaded to 50 percent of capacity, it can be assumed that there is an allowance for growth of each circuit load by an amount equal to 30 percent of the circuit capacity. This allowance is based on Code limitation of 80 percent load on circuits which are in operation for 3 h or longer or on circuits which supply motor-operated appliances in addition to other appliances and/or lighting. The 30 percent growth allowance in each circuit should be converted to a total watts figure and added to the total load on the feeder as calculated above. This grand total then represents the required feeder capacity to handle the full circuit load on the panelboard. The next step is to provide capacity in the feeder for anticipated load growth (plus some amount for possible unforeseen future requirements).

From experience, modern design practice dictates the sizing of feeders to allow an increase of at least 50 percent in load on a feeder when analysis reveals any load-growth possibilities. Such an analysis depends upon the type of building, the work performed, the plans or expectations of management with respect to expansion of facilities or growth of business, the type of distribution system used, locations of centers of loads, permanence of various load conditions, and particular economic conditions. Depending upon a thorough study of all these factors, the advisability of spare capacity can be determined for each feeder in a distribution system. But if study demands extra capacity in a feeder, substantial growth allowance (50 percent) is generally essential to realize the sought-after economy of future electrical expansion. Skimping upsizing of feeder conductors or raceways has proved a major shortcoming of past electrical design work. This is particularly true in tall office buildings, apartment houses, and other commercial buildings in which the elimination of riser bottlenecks represents a large part of the total modernization cost.

Spare capacity in feeders may be provided in one or more of several ways. If the anticipated increase in feeder load is to be made in the near future, the extra capacity should usually be included in the conductor size and installed as part of the initial electrical system. In many small office or commercial buildings and apartment houses, extra capacity should automatically be included in the initial size of the feeder conductors, provided the size is not greater than No. 2 after adding the 50 percent of extra capacity. Other methods of providing for growth in feeder load are as follows:

1. Selection of raceways larger than required by the initial size and number of feeder conductors. With this provision, the conductors can be replaced with larger sizes if required at a later date. The advisability of this step should be carefully determined in the case of risers or underground or concealed feeder raceway runs. In some cases, a compromise can be made between providing spare capacity in the feeder conductor size and upsizing the feeder raceway.
2. Including spare raceways in which conductors can be installed at a later date to obtain capacity for load growth. Such arrangements of multiple raceways must be carefully laid out and related to the existing overall system. The types of feeder-distribution centers or main switchboards and the layouts of local branch-circuit panelboards must be able to accommodate future expansion of distribution capacity based on the use of spare raceways, with modification and regrouping of feeder loads.

530. Control of groups of receivers (other than hall or night lights) from the main switchboard. If it is desirable to control a group of receivers from the main switchboard in the basement, a separate feeder must be carried from it to each group to be so controlled. Usually the feeder system can be laid out without regard to the control of the room lights, because, as a rule, they need not be controlled from the switchboard. It is usually advisable to have each of the lower floors, up to and including the ground floor, on a separate switch, as these floors often require light when the others do not. Special lighting

appliances such as sign, clock-dial, and outside dome lights require separate feeders from the switchboard, because they are turned on and off at set times from the switchboard. Certain motors may require similar control. In hotels the feeder switches are never opened except in case of accident, so from a control standpoint only it is not necessary to subdivide hotel feeders. When tenants of portions of buildings pay for the light they use, it is often desirable to carry a separate feeder from the switchboard to each tenant's suite so that all meters can be located together at the switchboard. Suites can be metered separately by cutting meters in the mains at the suites, but this may be undesirable.

531. The control of hall lights from the main switchboard is an important consideration. In private dwellings it does not usually pay to install a separate feeder for the hall lights, and it may not be necessary in a hotel, where attendants are constantly passing in the halls. In a majority of public buildings, however, separate control of the hall lights is very desirable, if not necessary. The usual problem, then, is whether there shall be one or two sets of hall-light feeders. With two sets of feeders for hall lights, local switches can be eliminated and control effected entirely from the main switchboard. Two sets of hall feeders increase the cost of installation, but the saving in energy usually justifies them. By arranging two sets of feeders, one set serving, say, one-third of the hall lights and the other the remaining two-thirds, the smaller group can be used for dark days and for an all-night circuit, and a saving in energy will result. When there are two sets of hall lights thus controlled, the wiring of outlets should be such that there will be a uniform distribution of light whichever set is lighted. When tenants pay for the energy used in their suites, a separate feeder for the hall lights is indispensable.

FARM WIRING

532. Wiring. The use of electric power on the farm is continually increasing. So that the farm electrical system may be adequate and give the best results in expenditure of money and satisfactory service, it is essential that the system be properly and wisely planned, that good materials and equipment be employed throughout, and that good workmanship be employed in its installation. In most cases the best installation will be achieved by the use of a power pole, as shown in Fig. 9.332. The power pole will be the central distribution point of the electrical system, which is why the NEC defines it as the "distribution point" and it will be so described in the remainder of this discussion. The power company will run its supply lines from its main pole line to the distribution point of the farm and down the pole to its meter. From the distribution point, the consumer will distribute the electric power by overhead or underground lines to the different buildings. In rare instances, it may not be possible to erect a distribution point. In such cases the power lines from the public utility will terminate at a building, probably the farmhouse. The meter will then be installed at this point. This method introduces some complications and is recommended only when the erection of the distribution point is very difficult or impossible.

The first step in planning the farm electric system is to determine the power demands for each building. The diversity of farm work makes it impossible to set down definite load requirements to fit all farms. Every kind of farming has its own needs insofar as power, machinery, and appliances are concerned. However, a number of wiring requirements are fundamental to the various farm buildings. No matter where the farm is located or how the buildings are constructed, certain minimum standards of wiring must be followed to obtain satisfactory electrical service. The following sections specify proper wiring for average conditions. They take into consideration the correct number of outlets, the proper switching, modern lighting, and adequate wire sizes for the machinery and appliances that are normally used in specific farm buildings. They are intended as a basic guide. If more equipment is to

FIGURE 9.332 Power pole (defined as a “distribution point” in the current NEC) for farm-building distribution feeders. [General Electric Co.]

be installed than is included in these specifications or if the farming operations are of a special nature, the specifications must be varied to suit the special needs.

533. Typical Computed Loads and Probable Maximum Demands

Building	Computed load	Probable demand
Farm residence	19 kW	13 kW
Dairy barn, medium size, including milk house and one 5-hp motor	20 kW	12 kW
Dairy barn, large size, including milk house and one 7½-hp motor	27 kW	15 kW
Same, two 7½-hp motors	36 kW	24 kW
Milk house barn with milk house	7.5 kW	5.8 kW
Milk house only	6.0 kW	4.8 kW
Beef-cattle, horse, sheep, and hog barns, medium size, with 5-hp motor	14 kW	10 kW
Same, large size, with 7½-hp motor	20 kW	15 kW
Poultry laying house:		
1,000 sq-ft	1.8 kW	1.8 kW
4,000 sq-ft	8.7 kW	6.4 kW
8,000 sq-ft	15.2 kW	11.7 kW
Brooder house, per brooder:		
Infrared	2.25 kW	2 kW
Standard brooder	1.25 kW	1 kW
Farm shop, with welder	17 kW	10 kW
Sweet-potato curing and storage	1.5 W/cu-ft	1.5 W/cu-ft
	or	or
	4 W/bu	4 W/bu
Machinery sheds, stock shelters, and miscellaneous buildings	1 W/sq-ft floor area	1 W/sq-ft floor area

SOURCE: “Farmstead Wiring Handbook.”

534. Other loads (*Design Manual on Steel Electrical Raceways*, published by American Iron and Steel Institute). Over and beyond the electrical requirements of individual buildings are a number of other loads for which provision must be made. These include such diverse items as water pumps (water system and irrigation), immersion heaters, water warmers, hay dryers and hoists, forage handlers, silo unloaders, and other miscellaneous equipment. Some idea of typical loads encountered is given by the following selected examples:

Forage handling:

Blower type	20-hp motor
Inclined elevator	2- to 3-hp motor
Silo unloaders	30- to 5-hp motor
Bulk-milk coolers	Varies with size and type; 1 to 5 hp for one or more motors

Such additional loads should be kept in mind when surveying a farm operation for initial wiring or rewiring, and provisions made in the system design to handle such equipment.

535. Specifications for dairy barn

Lights. In back of cows there should be one lighting outlet every 12 ft (3.7 m), and in front of cows one approximately every 20 ft (6.1 m). There should be one or two lights on top of the silo, so installed that they will light the silo and chute. Only general illumination is needed in the haymow. Floodlights above the hay line on opposite walls of the barn will therefore give the required lighting.

Convenience Outlets. Outlets should be placed approximately 15 ft (4.6 m) apart in a row in back of the cows. If the cows face in, outlets should be on the wall, up high enough so that cattle cannot come in contact with them. If the cows face out, outlets should be suspended from the ceiling on heavy-duty cords. They must be hung so that they can be reached easily yet high enough not to obstruct traffic.

In open spaces a convenience outlet should be installed for each 600-ft² (55.7-m²) area.

Switches. It is best to install separate switches for each row of lights in the barn. In small barns, however, all lights in back of the cows may be on one switch. When two or more entrances are used frequently, at least one row of lights should be controlled by three-way switches. The switch for the lights in the haymow should be mounted at a convenient location on the barn floor and also be equipped with a pilot light. To have a visible indication when the light is burning in the silo, a switch with a pilot light mounted at the entrance of the silo chute is recommended.

Circuits. The service-entrance panel for the barn must be adequate to take care of the load. Since some of the equipment needs special circuits, it is important to have an entrance panel of the proper capacity. The following number of circuits is recommended as a minimum. However, additional equipment or a change in the barn layout may make it necessary to deviate from this recommendation.

Lights	2 circuits (depending on size of barn)
Milking machine	1 circuit (230 V)
Feed grinder	1 circuit (230 V)
Utility motor	1 circuit (230 V)

Convenience outlets	1 circuit (depending on size of barn)
Fans	1 or more (depending on size of barn)
Hay dryer	1 circuit (230 V)

536. Specifications for milk house

Lights. In most cases a center light will be sufficient unless the milk house is unusually large. Then additional lights will be necessary over the work areas, especially where the utensils are washed.

Convenience Outlets. At least one convenience outlet for general use should be installed at a convenient location in the milk house. It is advisable to put this outlet on a heavy-duty 20-A circuit.

Switches. All lights should be controlled by a switch at the entrance.

Circuits. When the milk house is connected to the barn, its circuits may be included in the barn entrance panel. When the milk house is separate, a special entrance panel must be installed.

The following circuits are recommended as a minimum:

Lights and outlets	1 circuit
Milk cooler	1 circuit
Water heater	1 circuit (230 V)
Sterilizer	1 circuit (230 V)
Ventilating fan	1 circuit (if fan is small, it may be connected to light and outlet circuit)

537. Specifications for workshop, garage, and machine shed. Frequently the workshop, garage, and machine shed are one building, subdivided to serve all three purposes. The wiring for this building must therefore be arranged to suit this special condition.

Lights

Workshop. A well-lighted workshop is absolutely necessary for doing good work. Two types of lighting are needed: general lighting for the entire workshop and localized lighting over the workbench and near permanently located equipment.

For this reason, a ceiling light must be installed for every 200 ft² (18.6 m²) of floor area, at least one and possibly two lights over the workbench, and conveniently located lights over the stationary tools such as the drill press, plane, forge, or saw.

Garage. One light over the front of the cars and another one at the rear will permit making minor repairs to the car and other equipment.

Machine shed. One or two ceiling lights, depending on the size of the shed, give sufficient general illumination. Lights must be properly placed for best results.

Convenience Outlets

Workshop. Convenience outlets in the workshop must serve many different purposes. There must be a sufficient number, properly located, to facilitate the work. Install at least two convenience outlets over the workbench and other outlets throughout the workshop for

the connection of the electric tools. A heavy-duty outlet must be installed for the portable welder.

Garage. A convenience outlet at the rear wall of the garage permits the use of portable tools, a battery charger, and extension lights.

Machine shed. Since the welder may frequently be used in the machine shed, a heavy-duty outlet should be provided. Other convenience outlets should be considered for the connection of portable tools such as drills and soldering irons.

Switches

Workshop. The ceiling lights in the workshop should be controlled by a single-pole switch near the entrance. The lights over the workbench and fixed equipment can be controlled by pull-chain switches inside the fixture.

Garage. A single-pole switch near the entrance of the garage is needed for the control of the ceiling lights.

Machine shed. The same type of switch control should be used here as in the garage.

Circuits. As in the barn and milk house, the service-entrance panel for the workshop must have the correct capacity for the load. Since all the equipment will never be used at the same time, a reasonable diversity factor may be taken into consideration.

The number of circuits depends, of course, on the equipment and machinery installed. However, the following minimum should be carefully considered:

Lights	1 circuit
Convenience outlet	1 circuit
Wood saw and planer	1 circuit (No. 12 wire)
Portable welder	1 circuit (230 V)

538. Specifications for poultry house

Lights. Lighting in the poultry house serves to increase egg production in addition to providing light for seeing. One light should be installed for each 200 ft² (18.6 m²) of floor area, but if pens are smaller than 200 ft², at least one light per pen must be provided for. The same general-lighting arrangement should also be kept in the poultry-house workroom with additional local lighting for egg cleaning, grading, poultry scalding, waxing, etc.

Since ultraviolet light promotes healthier, stronger birds, sunlamps should be installed over feeding troughs. Full spectrum fluorescent tubes that closely match outdoor light should be used. With a color rendering index of 96 (outdoor light 100) and color temperature of 5500 K matching natural outdoor light, poultry and other livestock confined to a building can benefit from the ultraviolet and visible spectrum of the lighting. It is also recommended that at least one germicidal fixture for each 100 ft² (9.3 m²) of floor area of laying pens be installed. These lamps should be on a separate switch so that they can be turned off when someone is working in the pen.

Convenience Outlets. To connect the water warmer in the laying pens, at least one convenience outlet should be installed for every 200 ft² (18.6 m²) of floor area. The outlets are best located at the ceiling and should be equipped with the locking type of receptacle.

In the brooder house, the same arrangement of receptacles is recommended to serve brooders and water warmers. In the workroom, convenience outlets must be installed for the egg cleaner, candler, grader, poultry scalding, and waxer.

The feed-grinder and feed-mixer motors must have special heavy-duty outlets on a 230-V circuit.

Switches. Lights for all the laying pens should be connected to a regular switch as well as to an automatic time switch. The time switch will make morning lights to control egg production possible.

The ceiling lights in the workroom should be on a separate switch from the lights in the laying pens. The local lighting over the work areas can be controlled by wall switches or by pull-chain switches in the fixtures. Germicidal lamps, being on at all times, do not need a switch.

Circuits. The following circuits are recommended for the poultry house as a minimum:

Lights	1 circuit (depending on size of poultry house)
Ultraviolet lamps	1 circuit (depending on size of poultry house)
Germicidal lamps	1 circuit (depending on size of poultry house)
Convenience outlets	1 circuit
Brooder outlets	1 circuit each brooder
Feed mixer	1 circuit (230 V)
Feed grinder	1 circuit (230 V)

539. Specifications for hog house or sheep shed. For general illumination, a lighting outlet every 20 ft (6.1 m) along the passageways should be sufficient. These lights should be controlled by a single-pole switch near the entrance. Convenience outlets are needed in the farrowing pen for the connection of the pig brooders. This outlet should be about 3 ft (0.9 m) above the floor and in a corner of the pen.

540. Specifications for granary and corncrib. Lights over the center of the drive spaced 20 ft (6.1 m) apart are needed in the granary and corncrib. These lights should be controlled with a switch at the entrance. Upstairs, a light is needed for approximately every 200 ft² (18.6 m²) of storage area with a switch and pilot light installed downstairs near the stairs. At least one power outlet is needed downstairs for the connection of the grain elevator.

541. Specifications for farmyard. In the farmyard, electricity serves many important functions. Lights properly switched help in performing the evening chores. Outlets are needed throughout the yard for connection of the portable utility motor. Therefore, a plan for the wiring of a farm should include proper lighting and outlets outdoors. In general, the following simple rules will be sufficient:

Lights. Install at least three lights in the yard: one at the house, one at the barn, and one at the workshop or garage. They should be at least 15 ft (4.6 m) above the ground to allow a wide spread of light.

Outlets. Heavy-duty weatherproof outlets are needed for the connection of the utility motor. One should be mounted at the barn near the silo, and others at all places where farm chores will employ the utility motor. If the pump house is located adjacent to the yard, a separate circuit to the pump motor should be provided.

Switches. To make it possible to turn the lights on or off from several different points, three- and four-way switches must be installed. A switch at the house, one at the barn, and a third one at another convenient place are recommended for maximum efficiency.

542. Planning the farm wiring system. After the required loads have been determined, the wiring system can be planned. The system will be considered in three parts: (1) the distribution point, (2) distribution feeders, and (3) interior wiring of each building.

543. Distribution point. (Secs. 543 to 545; adapted from *Practical Electrical Wiring*, 20th ed., © Park Publishing, 2008, all rights reserved) Locate the pole as near as practical to the buildings that use the greatest amount of power; on modern farms, the house rarely has the greatest load. By locating the pole so the largest wires will be the shortest wires, you will find it relatively simple to solve the problem of excessive voltage drop without using wires larger than would otherwise be necessary for the current to be carried. Total cost is kept down when the large expensive wires to the buildings with the big loads are the shorter wires, and the smaller less expensive wires to buildings with the smaller loads are the longer wires.

Figure 9.333 shows a modern farm distribution point. The disconnecting means may be provided by the utility or by the owner, depending on local practice. The switch has no overload protective devices within it, thereby varying from the normal rule for services in NEC 230.91. The NEC classifies this device as a “site isolating device” to distinguish it from a service disconnect. Even if supplied and maintained by the utility, and therefore beyond the scope of the NEC, the NEC avoids needless duplication by recognizing it as a disconnecting means, provided it meets the requirements in NEC 547.9(A). Since it is not an actual service disconnect, it follows that the wiring that leaves this device still has the status of service conductors and must meet the wiring method and clearance requirements in Article 230. Although nothing technically prevents a farm from establishing a conventional service at the distribution pole, and then routing conventional overcurrent-protected feeders to each building, the arrangement shown here is widely used for overall cost effectiveness. Note that although the switch is at the top of the pole, it can be operated from a readily accessible point through the permanently installed linkage shown in Fig. 9.333. In addition, a grounding electrode conductor must be installed at this point and run it from the neutral block of the switch to a suitable electrode at the pole base.

If there are two or more distribution points located closer together than 500 ft (measured in a straight line), each location must have reciprocal labeling setting out the location of the other point(s) and the buildings or structures served by each.

544. Equipotential planes. Due to the sensitivity of livestock to very small “tingle” voltages, the NEC now requires an equipotential plane in livestock (does not include poultry) confinement areas, both indoors and out, if they are concrete floored and contain metallic equipment accessible to animals and likely to become energized. These areas must include wire mesh or other conductive elements embedded in (or placed under) the concrete floor, and those elements must be bonded to metal structures and fixed electrical equipment that might become energized, as well as to the grounding electrode system in the building. In the case of dirt confinement areas, the equipotential plane may be omitted. For outdoor areas the plane must encompass the area in which the livestock will be standing while accessing equipment likely to become energized.

Remember that the grounding system to which equipotential planes should be connected is usually (refer to the distribution feeder discussion of this topic) electrically separated from neutral return currents. The idea is to minimize voltage gradients. Due to the well-grounded environment, the NEC also requires all general purpose 15- and 20-A, 125-V receptacles in the area of an equipotential plane to have GFCI protection. This GFCI protection requirement also applies to similar receptacles in all damp or wet locations, including outdoors, and for dirt confinement areas whether indoors or out. Receptacles for

FIGURE 9.333 Site isolation switch as contemplated by the 2008 NEC for overhead farm distribution. The meter in this drawing happens to be connected to instrument transformers in the pole top enclosure.

specified (not general purpose) loads are not covered by this requirement, but where GFCI protection is omitted, a GFCI-protected receptacle must be installed within 3 ft of the unprotected receptacle.

545. Distribution feeders. From the pole top, go to the buildings that need to be supplied from this point. Review the discussion in Sec. 357 Par. 3 about regrounded neutrals. As a general rule the farmhouse can be supplied by a three-wire service, with its neutral regrounded at the house just as if the utility had made a direct termination. The farmhouse must not, however, share a common grounding return path with the barn. If it does, as in the case of a common metallic water piping system, the house (1) has to be supplied with

a four-wire service and (2) have all instances of electrical contact between the neutral and the local equipment grounding system removed.

Although the barn, arguably, could also be wired like the house (three-wire), a three-wire hookup would mean that the neutral and the equipment grounding system in the barn would be bonded together at the barn disconnect. That in turn would mean the neutral, in the process of carrying current across its own resistance, would constantly elevate the voltage to ground of all barn equipment by some finite amount relative to local ground, especially from the perspective of farm animals where they stand. The feet of livestock, being in close contact with moisture, urine, and other farm chemicals, are conductively rather well coupled to local earth. Most livestock are much more sensitive to voltage gradients than are people. A potential difference in the range of a fraction of a volt can take a cow out of milk production, which no farmer can afford.

The NEC addresses this in two ways. First, it establishes the unique rules on farm distributions being covered here. Second, it establishes an equipotential plane for these environments, discussed later in this chapter. The service to the barn is normally wired four-wire, and that is (1) customary because of the reasoning discussed in the previous paragraph, and (2) mandatory unless there are no parallel grounding return paths over water systems, etc., a necessary condition to comply with NEC 250.32(B) Exception. There is an additional condition attached to the four-wire scheme that is unique to agricultural buildings. The separate equipment grounding conductor must be fully sized. That is, if the run to the barn is 3/0 AWG copper for a 200-A disconnect, and the neutral is 1/0 AWG copper (both sized on the basis of load), the equipment grounding conductor is not 6 AWG as normally required by NEC Table 250.122; nor is it 4 AWG, the size for a grounding conductor on the supply side of a service using 3/0 AWG wires; nor is it 1/0 AWG, the size of the neutral. It must not be smaller than the largest ungrounded line conductor, or 3/0 AWG. When this wire arrives at the barn, it must arrive at a local distribution with the neutral completely divorced from any local electrodes or equipment surfaces requiring grounding.

546. Wiring of buildings. Normally the power-distribution feeder for the distribution point to a building is secured to the building with an insulator bracket (see Div. 8). Brackets should be mounted high enough so that the power feeders are never suspended lower than 5.5 m (18 ft) over driveways, for clearance of loaded wagons, and 3 m (10 ft) over footwalks.

From the insulator bracket service-entrance conductors are run down the side of the building to a point where they enter the building and connect to the service-entrance panel. Copper service-entrance cable is recommended for this purpose. This cable with its tough nonmetallic outer covering protects cattle from coming in contact with metallic parts of the wiring system. The table in Sec. 547 will give an idea of the size of service-entrance panels required (refer to Secs. 376 to 385 for information on service entrances).

It is recommended that Types UF, NMC, Copper SE, jacketed Type MC, rigid non-metallic conduit (either PVC or RTRC), liquidtight flexible nonmetallic conduit, or other cables or raceways suitable for the location be employed for the interior wiring of the buildings (refer to preceding sections of this division for information on wiring, and refer to Secs. 535 to 541 of this division for information on requirements for lights, convenience outlets, switches, and circuits).

At each building the wiring system must be grounded. This provision is in addition to the ground at the distribution point. Grounds must be established at each point of entrance to each building, and, if possible, all these grounds should be tied together on driven grounds. Also, for added safety, the farm water system should be tied at each building to the driven ground for that building. This is important. A well-grounded wiring system adds to the safety of the entire installation.

547. Service-Entrance Requirements

Type of building	Installation	Service-entrance conductors, A (All services are 9-wire, 115/230-V, unless otherwise specified)
Dairy barn (complete barn, including milk room) up to 2,500 sq-ft	Normal amount of lighting, ventilation, milker, milk cooler, water pump, dairy water heater, milk house heater, gutter cleaner (3 hp), hay drier, or utility motor (5 hp)	100
Same, above 2,500 sq-ft	Normal amount of lighting, ventilation, milker, milk cooler, water pump, dairy water heater, milk house heater, gutter cleaner (8 hp), hay drier, or utility motor (7 hp)	125
Same, above 2,500 sq-ft	Same as above, but two 7½-hp motors	195
Milking barn or "milking parlor"—includes milk room—(cows not housed)	Normal amount of lighting, milker, milk cooler, dairy water heater, milk house heater, ventilation	55
Milk house (when separate from barn)	Normal amount of lighting, milk cooler, dairy water heater, milk house heater	55
Horse, beef-cattle, sheep, and hog barn up to 2,500 sq-ft	Normal amount of lighting, ventilation, pig or lamb brooders, water pump, antifreezing protection on plumbing, utility motor (5 hp)	70
Same, above 2,500 sq-ft	Normal amount of lighting, ventilation, pig or lamb brooders, water pump, antifreezing protection on plumbing, utility motor (7½ hp)	100
Poultry laying house (including feed room) up to 4,000 sq-ft pen floor area	Normal amount of lighting, ventilation, water warmers, antifreezing protection on plumbing, automatic feeders, feed grinder (up to 1 hp)	55
Same, above 4,000 sq-ft pen floor area	Normal amount of lighting, ventilation, water warmers, antifreezing protection on plumbing, automatic feeders, feed grinder (up to 2 hp)	70
Poultry brooder house, portable type	Light and outlet for single brooder and water warmer	20 (2-wire, 115-V)
Poultry brooder house, permanent type, up to six pens	Normal amount of lighting, ventilation, brooders, water warmers, antifreezing protection on plumbing	55
Poultry brooder house, permanent type, above six pens	Normal amount of lighting, ventilation, brooders, water warmers, antifreezing protection on plumbing	70 minimum; estimate 2,000 W per pen
Poultry-cleaning and -dressing house	Normal amount of lighting, poultry scalding, waxer, wax reclaiming, picker, and refrigeration	55
Farm shop	Normal amount of lighting, bench tools (tool grinder, drill, soldering iron, etc.), farm welder, air compressor, saw, and battery charger	70

547. Service-Entrance Requirements (Continued)

Type of building	Installation	Service-entrance conductors, A (All services are 9-wire, 115/230-V, unless otherwise specified)
General farm buildings	Minimum capacity where lighting, motors, and miscellaneous 116- and 230-V equipment will be used	50
Storage sheds, stock shelters	Lighting and small portable equipment—not over two 2-wire bench circuits	40* (2-wire, 115-V)

*Ordinarily such buildings are supplied by a feeder or circuit from another building. In such cases, this is not a service as defined by the National Electrical Code. If a brooder house or similar structure is supplied directly from the power source, the minimum permissible size of service-entrance conductors would be No. 8 for two 2-wire branch circuits.

If the building is served by a feeder from another building the minimum size of service-entrance conductors would be No. 10 for two 2-wire branch circuits. For a single branch-circuit source, the minimum permissible size of service-entrance conductors would be No. 8 for two 2-wire branch circuits.

NOTE All the capacities listed assume service for the individual building only. If other buildings are supplied from any of these services, the capacity of the service would have to be increased accordingly.

SOLAR PHOTOVOLTAIC SYSTEMS

548. Solar photovoltaic systems (Secs. 548 to 554; adapted from *Practical Electrical Wiring*, 20th ed., © Park Publishing, 2008, all rights reserved) are becoming increasingly common, given favorable tax incentives and increasing energy costs. These systems are covered in NEC Article 690. They are very complex, and this handbook section will only cover the most common application in which a limited array provides power that offsets some of the power that would otherwise have come from the utility. It is important to keep in mind that the power produced by these systems is direct current (dc), frequently at voltages approaching 600 V. Special considerations must be made in order to harness this power safely. PV systems have another significant difference from conventional systems in that the amount of current is inherently limited by the capacity of the array.

549. The array captures the solar energy. Solar cells are grouped into modules that comprise the basic unit of solar generating hardware. The panels are then field connected to make a functioning array that provides dc power for the owner's use. A new change in the 2008 NEC requires that each array framework or supporting structure be connected to a grounding electrode located as near as practicable to the array. The power system electrode can be substituted if its location is within 6 ft of where the array electrode would normally be provided. If a separate electrode is used, whether or not it must be bonded to the power system electrodes depends on whether the inspector views them as "auxiliary" electrodes as covered in 250.54. The proposal for this change clearly intended that they be so classified; the panel removed the reference, but failed to substantiate its actions. Ask the inspector, but be prepared to make the bonding connection.

The NEC requires modules to be listed, and they will be marked by their manufacturer with the information specified in NEC 690.51. This information (short-circuit current, maximum power, operating current and voltage, open circuit voltage, and maximum system

voltage) forms the basis for calculations that are essential to system layout and conductor selection. These values will be in terms of standardized test conditions, and it is known that actual conditions can result in substantially exceeding the ratings. For example, extreme cold can result in voltage levels as much as 125 percent of rated output voltage [see NEC 690.7(A)]. In addition, some solar installations substantially exceed the standardized irradiance levels in the time period around solar noon, resulting in current production as much as 125 percent of the rated amount. In addition, the current produced by PV systems is, almost by definition, continuous. This generally adds another 25 percent to sizing overcurrent devices (refer to the extensive coverage of this topic in Div. 3, Sec. 94).

550. Special wiring rules apply at the modules. Effective with the 2008 NEC, unless conventional multiconductor wiring methods are used, module and panel interconnections must use either single-conductor Type USE-2 cable or the new Type PV (photovoltaic) single conductor wire; the previous allowance for Types UF, SE, and USE is discontinued. Do not use welding cable. Note that USE-2 wire must not be used inside a building unless it is dual rated as building wire, as shown by an additional marking of XHHW-2 or RHW-2 or comparable. These wires have 90°C temperature ratings and tolerate sunlight and wet-location exposure, and they can be connected to the positive and negative leads coming from the modules. However, if the array is readily accessible to passersby, the conductors must usually run within a raceway. Single-conductor entries into a pull box must have strain relief provided, such as through listed gland-type connectors that maintain the wet-location integrity of the box. Leave enough slack in the module leads so the module can be removed for servicing or replacement. When selecting wires, try to avoid wire stranded more finely than Class C concentric (19 strands up to 2 AWG, then 37 strands on larger wires). Wire more finely stranded than this must have both its stranding class and the numbers of strands marked on the connector, and such lugs are very difficult to find. Note also that the new Type PV conductors have a thicker than usual insulation, and as such require special raceway fill calculations if pulled into conduit or tubing.

Generally each string of modules connected in series should have a fuse in its ungrounded (usually the positive) lead based on 125 percent of 125 percent (net = 156 percent) of the rated short-circuit current of each of the series-connected modules. Remember that voltages add in series circuits, but current is everywhere the same. For example, the short-circuit current rating of four modules, each rated at 5.4 A short-circuit current and connected in series, is 5.4 A, but the voltage produced by this string will be four times the voltage of any single module. To size the fuse, multiply the current by 1.25 to get 6.75 A, and then multiply that by 1.25 for continuous loading for a result of 8.4 A, and choose the next higher standard size fuse. Choose a 9-A fuse, because the NEC specifies that PV source circuit overcurrent devices be in increments of a single ampere for all ratings below or equal to 15 A.

Figure 9.334 shows an array of six parallel strings of modules, four in each. The combiner box to the left provides terminals for the paralleled strings, and facilitates connections to the home run conductors. Wiring leaving the array can be multiconductor cable such as Type UF if it is identified as sunlight resistant and suitable for the temperature, or it can be a raceway-type wiring method suitable for the location. All wiring terminating on or running with a PV array should be assumed to be operating in a 70°C ambient or higher due to solar heating. This means that the wiring (and any nonmetallic raceway if used) must have a minimum temperature rating of 90°C as a practical matter, and that the effects of temperature on final conductor ampacity will be pronounced. For example, 12 AWG THWN-2, a 90°C conductor with a Table 310.16 ampacity of 30 A would end up with (using a 0.58 derating factor) a final ampacity of 17.4 A or even 12.3 A if a higher temperature were assumed.

FIGURE 9.334 The major elements of a utility-interactive PV supply.

551. DC feeder wiring connects the array with the inverter. The wiring between the PV source and the inverter is a feeder for a separately derived system and follows normal rules for sizing, although, depending on how it is routed, temperature may have an important impact. As we have seen, each of the six strings generates 6.75 A, resulting in a total array load of 41 A. Since these wires will be connected to an overcurrent device and switch terminals, and transmit continuous loads, we need to add 25 percent of this number to determine conductor sizes. The minimum ampacity of the feeder conductors would be 125 percent of 41 or 51 A. This corresponds to 6 AWG copper conductors, evaluated under the 75°C column of Table 310.16. If these feeder conductors were routed along the array the evaluation would change, because ambient temperature would become a major factor. In such a case (assuming 70°C conditions) the derating factor to be applied to THWN-2 conductors is 0.58. $41 \text{ A} / 0.58 = 71 \text{ A}$. Since this is less than the ampacity (in the 90°C column) of these conductors, the 6 AWG conductors can still be used, but the result is far closer to the table limits. Refer to Div. 3, Secs. 89 to 111 for a comprehensive explanation of these considerations.

552. Equipment grounding must not be forgotten. Although equipment grounding conductors are normally sized per Table 250.122 based on the rating of the line-side overcurrent device, in cases like this the NEC requires that the short-circuit current be used to enter that table, or in this case, 51 A. A 10 AWG conductor would be the correct size. Take care in terminating these conductors at an array. Listed modules will provide for grounding connections and they must be used. Other modules, typically aluminum bodied, will require field terminations. Look for a copper-bodied lug that has a tin coating and is listed for direct burial. These lugs are compatible with an aluminum surface and their stainless steel hardware will survive outdoor conditions. To attach these to the module, drill a small pilot hole, then seat the lug with a 10-32 thread-forming sheet metal screw treated with an antioxidant compound rated for aluminum connections. This is not a “teck” screw with sheet-metal threads; it is an actual machine screw, and the compound will assure that no oxygen reaches the raw aluminum surface during the thread-making process. This prevents the formation of aluminum oxide and assures a low-impedance, long-lasting connection.

553. Disconnects must be located upon entry unless a metal raceway is used. When the wiring enters the building, there must be a disconnect provided unless the wiring runs in a metal raceway. The metal raceway may be difficult to install, but the owner may prefer it to the appearance of wiring running down the outside of the building. On new construction the metal raceway can be preinstalled easily and avoids a disconnect at an inconvenient location. Note that NEC 690.15 requires the inverter (and comparable equipment) that could be energized from two sources to have a disconnecting means from each source, and also requires those disconnects to be grouped and identified. It follows that the PV disconnect shown in Fig. 9.334 would be required whether or not a disconnect were provided in the attic.

554. Disconnects must be applied within their ratings. A typical open-circuit voltage for the array in Fig. 9.334 might be 64 V (open circuit); with four modules in series the voltage would be 256 V, and after applying the 125 percent multiplier as noted the required rating becomes 320 V. As a practical matter, look for 600 V dc rated equipment when you are considering these components. The NEC also requires a label to be placed as shown in Fig. 9.334 showing system parameters. If the system includes storage batteries (the one shown does not) the maximum output current of the charge controller must be shown on the same label,

because a short-circuited battery bank adds many thousands of amperes of available fault current to the dc side of the system and the components need to be rated accordingly.

555. Inverters provide the interface with the ac side. The next step is to convert the dc output to ac, which is the principal function of the inverter. Inverters are selected based on the generally expected power capability of the system. This is far from the worst-case voltage (expected on the coldest morning) times the worst case current (expected at solar noon during the warm season), or about 10 kW in this example. Consult the manufacturers' recommendations; in this case a 5-kW inverter would be a typical size. Note that the inverter output conductors are sized to the continuous output current rating of the inverter, even if the capacity of the modules on the roof is smaller than what the controller can deliver. Most inverters listed for this application include a mechanism to interrupt the ground-fault current path, as required by NEC 690.5 for all dwellings, and all other locations using a grounded PV system unless the equipment grounding conductor is double the size of the circuit conductors after upsizing for conduit fill and ambient temperature. Both the ac and the dc sides of the inverter have grounding electrode requirements, and therefore both sides require a grounding electrode conductor to be in place. The ac side is already taken care of by the normal grounding connections in the building, but the dc side has to be added, sized in accordance with NEC 250.166. This means equal in size to the ungrounded conductor unless the electrode is a ground rod, or ring or concrete-encased electrode. Just as for ac system conductors, those conductors need not exceed 6 AWG, or the size of the ring conductor, or 4 AWG, respectively. Since this electrode must be bonded to the normal power system electrode, and can actually be the same electrode, many inverters include a ground bus common to both sides that facilitates this connection.

It should also be noted that there must be one, and never more than one, connection between the grounded dc circuit conductors and the grounding electrode. Since the interruption of the ground-fault current path is a required feature of a NEC 690.5 device, having this connection in the inverter allows for the proper application of these requirements. In addition, the PV disconnect must not open the grounded conductor; the switch in Fig. 9.334 will only have one of its poles (if more than one are present) in use.

556. Connection point to the normal power system are restricted. Most panelboards have busbars with ratings equal to the rating of the main overcurrent protective device ahead of them in the panel. Figure 9.334 shows a common 200-A panelboard. The NEC now requires that the input breaker from the inverter be at the opposite end of the bus from the normal main. In this way, no configuration of branch circuit or feeder loads could draw more than the current the busbars were designed to carry. In addition, the panel must be marked with a warning label advising against repositioning this breaker. There is, however, still a 20 percent limitation on the size of the interconnecting breaker. This is because, although the busbars could not be overloaded, the panel would still be delivering more power than the conditions under which it was tested. The 20 percent is a reasonable limit until more testing is carried out.

Note that the interconnecting breaker must be suitable for backfeeding. Most breakers are tested in both directions. The ones that are not are marked "line" and "load" and if so marked they can only be used in the direction indicated. In this example, a 5-kW inverter operating on a continuous basis on a 240-V system would calculate as a $(5000 \text{ kW}/240 \text{ V}) \times 1.25 = 26\text{-A}$ load for termination purposes, and a 30-A circuit breaker would be used. Note that this would be OK for a 150-A or larger panel, but too large for a smaller panel.

PRINCIPLES AND UNITS

1. Explanation of light. For the principal purposes of illumination design, light (*Standard Handbook for Electrical Engineers*) is defined as visually evaluated radiant energy. The visible energy radiated by light source is found in a narrow band in the electromagnetic spectrum, approximately from 380 to 770 nanometers (nm). Figure 10.1 shows the complete radiant-energy spectrum of electromagnetic waves, which travel through space at the velocity of approximately 3.0×10^8 m/s (186,000 mi/s). The longer waves are the ones used in radio communications; the shortest ones are the x-rays and cosmic rays. An enlarged section of the visible light portion of the spectrum is shown in the figure.

The effect of light upon the eye gives us the sensation of sight. The impression of color depends upon the wavelength of the light falling upon the eye. There are three primary colors of light: red, green, and violet. Violet light has the shortest wavelength of the radiant energy to which the eye is sensitive, red the longest, and green an intermediate wavelength between those of violet and red. These three colors are called the primary colors, because light of any one of them cannot be produced by combining light of any other colors. Light of any other color than these three can be produced by combining in the proper proportions light of two or all three of the primary colors.

By extension, the art and science of illumination also include the applications of ultraviolet and infrared radiation. The principles of measurement, methods of control, and fundamentals of lighting system and equipment design in these fields are closely parallel to those long established in lighting practice.

FIGURE 10.1 The electromagnetic spectrum.

2. Propagation of light. Rays of light travel in straight lines unless interfered by some medium that absorbs or deflects them. Whenever a light wave strikes a different medium from that through which it has been passing, there are three fundamental phenomena that may occur: absorption, reflection, or refraction. Whenever light waves strike any object, a portion of their energy is absorbed, the amount depending upon the nature of the substance. This absorbed energy is dissipated in the form of heat. The remaining portion of the light may be all transmitted through the substance, all reflected back from the surface, or part transmitted and part reflected, depending upon the nature of the substance and the angle at which the light impinges upon the surface of the object. If the light strikes the object perpendicularly to the surface, it is either transmitted in a straight line through the substance or reflected back from its surface in the same direction in which it impinged upon the surface. If light strikes an object at an angle other than 90° to its surface, then either the light is transmitted through the object but in an altered direction (refraction) or the light is reflected back from the object but in a different direction from that in which it impinged upon the object (reflection). With most objects all three of the phenomena occur, some of the light impinging upon them being absorbed, some transmitted through (refracted), and some reflected back from the surface.

3. Absorption. Although some of the energy of a ray of light is always absorbed whenever a light ray impinges upon an object, the amount absorbed varies over wide limits, depending upon the nature of the object, the molecular construction, the wavelength or color of the incident light, and the angle at which the light strikes the surface. All objects do not absorb light of different wavelengths in the same proportion. It is this phenomenon which accounts for the characteristic color of objects (see Sec. 13). Since objects do not absorb the same proportion of the incident light of different colors, the amount of light absorbed by an object depends upon the color or wavelength of the light impinging upon the object. Tables 4 and 12 give the percentage of incident white light that is absorbed by various types of surfaces.

4. Coefficients (Percent) of Absorption of Lighting Materials

Material	Absorption, percent
Clear glass globes	5–12
Light sandblasted globes	10–20
Alabaster globes	10–20
Canary-colored globes	15–20
Light-blue alabaster globes	15–25
Heavy blue alabaster globes	15–30
Ribbed glass globes	15–30
Clear plastic globes	20–40
Opaline glass globes	15–40
Ground-glass globes	20–30
Medium opalescent globes	25–40
Amber glass	40–60
Heavy opalescent globes	30–60
Flame-glass globes	30–60
Enameled glass	60–70
White diffuse plastic	65–90
Signal-green globes	80–90
Ruby-glass globes	85–90
Cobalt-blue globes	90–95

5. Absorptance. (*Standard Handbook for Electrical Engineers*) given the alpha symbol " α " in engineering work, is the ratio of the flux absorbed by a medium to the incident flux. Transmittance, given the tau symbol " τ " in engineering work, is the ratio of the transmitted flux to the incident flux. Measured values of transmittance depend upon the angle of incidence, the method of measurement of the transmitted flux, and the spectral character of the incident flux. Because of this dependence, complete information of the technique and conditions of measurement should be specified. The sum of reflectance (Sec. 8), transmittance, and absorptance is one.

6. Reflection of light. (Fig. 10.2) is the redirecting of light rays by a reflecting surface. Whenever light energy strikes an opaque object or surface, part is absorbed by the surface and part is reflected. Light-colored surfaces reflect (Table 9) a larger part of the light thrown on them than do dark-colored surfaces, whereas dark surfaces absorb a larger part of the light and black surfaces absorb nearly all the light which reaches them.

NOTE Consider first a smooth surface AB (Fig. 10.2, I), on which a ray of light L falls. This ray will be so reflected in the direction R that the angle i is exactly equal to the angle r .

FIGURE 10.2 The reflection of light. Note that the angle of incidence i always equals the angle of reflection r .

Consider now the effect of a number of rays falling on a smooth surface CD (Fig. 10.2, II). Each ray will be reflected in such a way that it leaves the surface at the same angle at which it strikes. The eye if held as shown would perceive only the light reflected into it. Consider now a broken surface such as FG (Fig. 10.2, III). Each ray of light is reflected from that portion of the surface on which it falls, just as though that point were on a smooth surface. The result is that the light is scattered, and if the surface is irregular enough, the eye placed at any point will receive reflections from many points of the surface. All opaque surfaces except polished surfaces have innumerable minute irregularities like the surface in Fig. 10.2, III. This alone enables them to be seen.

7. The different kinds of reflection will now be considered. *Regular reflection* is that (Fig. 10.3A, I, and 10.3B, I) in which the angle of incidence i is equal to the angle of reflection r . This kind of reflection is obtained from mirrored glass, prismatic glass, and polished metal surfaces. *Spread reflection* (Fig. 10.3A, II, and 10.3B, II) is that in which the maximum intensity of the reflected light follows the law of regular reflection, except that a part of the light is scattered slightly out of this line. Spread reflection is obtained from etched prismatic glass and from rough metallic surfaces. *Diffuse reflection* (Fig. 10.3A, III) is that in which the maximum intensity of the reflected light is normal to the reflecting surface. This holds over a large range of the angle of incidence. This kind of reflection is usually caused by reflection from particles beneath the surface (see Fig. 10.3B, III). Diffuse reflection may be obtained from opal glass, porcelain enamel, paint enamel, and paint finishes commonly used for interior decoration of walls and ceilings.

FIGURE 10.3A Classifications of reflection.

FIGURE 10.3B Magnified view of Fig. 10.3A.

8. Reflecting power of surfaces. (*Standard Handbook for Electrical Engineers*)

Different surfaces reflect different percentages of the light falling upon them. Reflectance, given the rho symbol " ρ " in engineering work, is the ratio of reflected flux to incident flux. Measured values of reflectance depend upon the angles of incidence and view, and on the spectral character of the incident flux. Because of the dependence, the angles of incidence

and view and this spectral characteristics of the source should be specified. The illumination of a small room having poorly reflecting walls may sometimes be improved by changing the wall coverings. If the room is large or if reflectors are used to throw the light downward so that not much light reaches the walls, a change in the wall covering will have little effect on the general illumination.

9. The following table of reflection coefficients is useful in showing the relative value of wall coverings in rooms.

10. Refraction. Whenever a light ray passes from one medium into another of greater or less density, the direction of the ray is altered. This is called refraction. Refraction may be one of three types: regular, irregular or spread, or diffuse, depending upon the nature of the construction of the substance and the character of its surfaces.

Regular refraction occurs with plain glass or glass prisms, as shown in Fig. 10.4. Light in passing through a substance goes through two refractions, one upon entering the substance and one upon leaving the substance. If the surfaces of the object are parallel, as in a piece of glass (Fig. 10.4, I), the direction of the light leaving the object is parallel to the direction of the light impinging upon the object. If the

II. Prisms.

FIGURE 10.4 Regular refraction.

surfaces of the object are not parallel, as in the prism of Fig. 10.4, II, the light leaving the object will not be in a direction parallel to the incident light. A prism can be constructed to refract the light from its different surfaces so that light is not transmitted through the prism but is reflected back as shown in Fig. 10.5.

Irregular, or spread, refraction occurs with light transmitted through glass with a rough surface such as etched or frosted glass, as shown in Fig. 10.6. Such a surface can be considered as consisting of a great number of very small smooth surfaces making slight angles with each other. The individual rays of light being emitted from such a surface are refracted at slightly different angles but all in the same general direction. Thus the light transmitted through a substance with such a surface is refracted in the same general direction but with the beam spread somewhat from what would be for regular refraction.

FIGURE 10.5 Total reflection with prism. [General Electric Co.]

FIGURE 10.6 Spread refraction with etched glass. [General Electric Co.]

The composition of opal glass is such that it contains a number of minute opaque particles throughout its structure. Light striking such an object travels through the glass until it strikes one of these opaque particles, from which it is either reflected back or transmitted through the glass to the other surface. The total beam of light striking the object is thus split up by the innumerable small opaque particles, part being reflected back in all directions, and part being refracted through the glass in all directions. The portion that is transmitted (refracted) through the glass is *diffusely refracted*. An idea of how diffuse refraction takes place can be gained from Fig. 10.7. In Fig. 10.8 the diffuse reflection and refraction of a ray of light impinging upon a piece of opal glass are indicated.

13. Color of objects. Our impression of the color of objects is due to the color of the light that the object reflects or transmits to our eyes. In Sec. 2 it was stated that all objects absorb a certain portion of the light that falls upon them but that all objects do not absorb the same proportion of light of the different wavelengths. It is through this different absorption that different objects have unlike colors. If all objects absorbed light in exactly the same manner, all objects would appear to have the same color. In order that things may appear in their true colors, they must be observed under white light, that is, light containing all three primary colors in the right proportion. An article which absorbs no light or which absorbs light of the three primary colors in the same proportion as they are combined to produce white light will transmit from its surface light in a condition unchanged from that in which the light fell upon the object. Such an object would appear white in color. An object which absorbs all or nearly all the light which falls upon it will have no color or, in other words, will be black. An object which absorbs all the green and violet rays will be red in color, since it will transmit to our eyes only red light. In order that an object may appear in its true color, the light falling upon it must contain light of the wavelength that the object reflects or transmits. Thus, light falling upon a red object must contain red light if the object is to appear in its true color. A red object viewed under a light which contains only green and violet rays will appear black, since the object is capable of reflecting only red rays.

14. Light-source color. The color of light sources has two basic characteristics: *chromaticity* and *color rendering*. Chromaticity, or color temperature, defines its “whiteness,” its blueness or yellowness, its warmth or coolness. It does not describe how colors will appear when lighted by the source. Chromaticity (color temperature) is a term sometimes used to describe the color of the light from a source by comparing it with the color of a *blackbody*, a theoretical *complete radiator* which absorbs all radiation that falls on it and in turn radiates a maximum amount of energy in all parts of the spectrum. A blackbody, like any other incandescent body, changes color as its temperature is raised. The light from a warm white fluorescent lamp is similar in color to the light from a blackbody at a temperature of approximately 3000 K,* and the lamp is accordingly said to have a color temperature of 3000 K. The light from a cool white fluorescent lamp is bluer, and the blackbody must be raised to 4200 K to match it. Hence the cool white lamp has a color temperature of 4200 K. A daylight fluorescent lamp has a color temperature of 6200 K.

Color temperature is not a measure of the *actual temperature* of an object. It defines *color only*. Some light sources, such as a sodium-vapor lamp or a green or pink fluorescent lamp, will not match the color of a blackbody at any temperature, and therefore no color temperatures can be assigned to them.

*Kelvin is a temperature scale which has its zero point at -273°C .

Color Temperatures, K

(Approximate values)

Blue sky	10,000–30,000
Overcast sky	7000
Noon sunlight	5250
Fluorescent lamps	
Daylight	6200
Cool white	4200
White	3500
Warm white	3000
Clear mercury lamps	5700
Deluxe mercury lamps	3900
Clear metal halide lamps	4100
High-pressure sodium lamps	2100
General-service incandescent lamps	2500–3050
Candle flame	1800

The other characteristic, the color-rendering index (CRI), attempts to describe how colors will appear when illuminated by a light source of specified chromaticity. The CRI rating system is an international system that mathematically compares how a light source causes eight selected colors to appear compared with a reference source. However, there are limitations to its use which should be recognized. Although the system provides for ratings up to 100, it can only be used to compare sources of approximately the same chromaticity. Comparison of the CRI of light sources with widely different color temperatures such as a cool light source and a warm light source can be misleading. Light sources with the same CRI may render some colors differently, and light sources with CRIs as much as 5 points different may cause colors to look the same. Owing to their spectral distribution, HID sources may actually look better than their CRIs would indicate.

The CRI system is the best presently available to describe the relative appearance of colors under different sources, and it can be useful when applied within the limits of the system.

15. Luminous flux (which, as is explained later, is measured in lumens) is a flow of light, that is, light energy or light waves. Luminous flux always originates from some source of light, such as the sun, a candle, or an incandescent lamp. But luminous flux can be redirected by reflecting surfaces. The luminous flux which emanates directly or is reflected from objects to the human eye is the medium whereby the objects are seen. Although there is no actual flow of anything material in a flux of light, there is a flow of light waves. The formal definition (*Standard Handbook for Electrical Engineers*) is that luminous flux φ is the integrated product of the energy per unit wavelength emitted by the source $P(\lambda)$, referred to as the source's spectral power distribution, and the spectral luminous efficacy $V(\lambda)$ as follows:

$$\varphi = 683 \int_{\lambda=360}^{800} P(\lambda)V(\lambda)d\lambda$$

From this it can be seen that the maximum possible output of a light source is 683 lm/W.

16. A true point source of light is a luminous mathematical point which emits luminous flux uniformly in all directions. It is a theoretical concept which cannot actually exist. It is, however, used (and is necessary) for the development of the quantities and units employed in lighting computations.

NOTE An actual light source may be considered a point source without prohibitive error if the distance between the source and the location at which the source is viewed or examined is at least 10 times the greatest dimension of the source.

FIGURE 10.9 A steradian illustrated. It is, in effect, the flare angle of a cone that, when striking the surface of a sphere at any distance, cuts off an area (shown cross-hatched in the figure) equal to the square of the distance. In the case of a projected beam of light, the number of steradians equals the projected area divided by the distance squared. A steradian covers about one-twelfth of the area of the entire sphere.

17. The luminous intensity (candlepower) of a given source of light in a certain specified direction is a measure of the ability of the source to project light in that direction. Luminous intensity is measured in a unit which is called the candela, formerly the candle. Fig. 10.9 (*Practical Electrical Wiring*, 20th edition, © Park Publishing, 2008, all rights reserved) illustrates the term “steradian” which is necessary to the definition of this and other fundamental lighting terms. If a light source emits 1 lumen of light, and that light is directed within 1 steradian of solid angle, that light source has a luminous intensity of 1 candlepower.

NOTE The luminous intensity of actual light sources is generally greater in certain directions than in others. Thus, in Fig. 10.10, the luminous intensity of the lamp is greatest in the horizontal direction.

FIGURE 10.10 Luminous intensities in different directions around an incandescent lamp.

18. The candela (cd) was formerly defined as the luminous intensity or light-producing power in the horizontal direction of a standard lamp which is made and used in accordance with U.S. Bureau of Standards specifications.

NOTE The luminous intensity of an ordinary sperm candle (Fig. 10.11) in the horizontal direction is about 1 candle (cd). Thus was derived the name of the unit, candela.

FIGURE 10.11 An intensity of illumination of 1 fc (10.76 lx).

19. The true luminous intensity or candlepower of a light source can be obtained only when the source is a true point source (Sec. 16). But a true point source does not exist. It is merely a mathematical concept. Now, the luminous intensity of an actual light source, in a certain direction (Fig. 10.12), is due to the combined effects of a number of point sources in the surface of the actual light source. Hence, the luminous intensity of an actual light source, in a given direction, as determined with a photometer (Sec. 27), is not the true candlepower (luminous intensity) but is the apparent luminous intensity (apparent candlepower) in that direction.

FIGURE 10.12 The illumination at point S is due to the combined effects of an infinite number of point sources P_1, P_2, P_3 , etc.

20. Illuminance is measured in footcandles (fc) or lux (lx). The footcandle is defined as that illumination which is produced (Fig. 10.11) by a 1-cd point source (or its equivalent) on a surface which is exactly 1 ft (0.3048 m) distant from the point source. The lux is the illumination produced by a 1 cd point source at a distance of 1.0 m from the source.

EXPLANATION If, in Fig. 10.11, the light source S is assumed to be a point source of luminous flux, then the illumination at point A , which is exactly 1 ft from S , is (by definition) 1 fc. Since the illuminated surface $MNOP$ is a plane, point A is the only point on the surface which has an illumination of 1 fc. The illumination at any other point on the surface, such as B or C , is less than 1 fc because it is farther away from S than is A . If, however, the

sphere of Fig. 10.9 has an internal radius of 1 ft and the true point source (Sec. 16) has a luminous intensity of 1 cd, then every point on the interior surface of the sphere will have an illumination of 1 fc (10.76 lx).

21. Illuminance is really the density of the luminous flux which impinges on the surface of an illuminated object. The average density of anything on a surface may be numerically represented by the number of things on the whole surface divided by the number of unit areas in the surface. Thus, as will be further explained in Sec. 25, if the luminous flux, in lumens, which impinges on a surface, is divided by the area of that surface in square feet, the average illumination over the surface will be the result.

22. Luminous flux is measured in lumens (lm). A lumen is defined as that quantity of incident luminous flux which will, when uniformly distributed over a surface having an area of 1 ft² (0.0929 m²), produce an illumination of 1 fc on every point of the surface. It will also illuminate a surface of 1 m² to a level of 1 lux.

NOTE When luminous flux impinges nonuniformly on a surface, then a lumen is the quantity of luminous flux which will, on a 1-ft² area of the surface, produce an average illumination of 1 fc.

23. A point source of light of 1-cd luminous intensity emits 12.57 lm. It has been shown (Sec. 20 and Fig. 10.9) that a 1-cd point source of light located at the center of a hollow sphere of 1-ft radius will produce an illumination of 1 fc on every point of the interior surface of the sphere. Now the superficial area of a sphere = $4\pi r^2 = 4 \times 3.1416 \times r^2$. Hence, this 1-ft-radius sphere will have an area of

$$4 \times 3.1416 \times 1 \times 1 = 12.57 \text{ ft}^2$$

Since every point on the surface of this sphere has an illumination of 1 fc, there must, to satisfy the definition of the lumen (Sec. 22), be as many lumens emitted by the 1-cd point source as there are square feet in the surface of the sphere. The sphere has an area of 12.57 ft². Therefore every 1-cd point source of light emits 12.57 lm.

24. To obtain the output of a light source in lumens when its mean spherical candlepower is known, substitute in the following formula. This formula is strictly accurate only for a true point source (Sec. 16) of light, but it gives results sufficiently accurate for all practical purposes if the mean spherical candlepower (Sec. 29) is substituted for I .

$$F = 12.57 \times I \text{ lm} \quad (2)$$

where F = total luminous flux emitted by the light source, in lumens, and I = luminous intensity or candlepower of a point source, in candelas, or, with sufficient accuracy for most practical purposes, the mean spherical candlepower of an actual light source.

EXAMPLE The mean spherical candlepower of a light source is 68.8. What quantity of luminous flux is emitted in lumens?

SOLUTION By For. (2), luminous flux $F = 12.57 \times I = 12.57 \times 68.8 = 865 \text{ lm}$.

25. Illuminance in footcandles is really lumens per square foot. From the definition of the lumen in Sec. 22, 1 lm of flux spread out over an area of 1 ft^2 produces 1 fc average illuminance over that surface; 2 lm would produce 2 fc, etc.

Similarly, 10 lm spread out over an area of 5 ft^2 would produce an average illuminance of $10 \div 5 = 2 \text{ fc}$. Likewise, 1 lm spread out over an area of 2 ft^2 would produce an illuminance of $1 \div 2 = 0.5 \text{ fc}$. Thus, it is evident that $\text{lumens} \div \text{ft}^2 \text{ area} = \text{average footcandles illuminance}$.

EXAMPLE A room which has an area of 600 ft^2 has 3300 lm of luminous flux impinging on the working plane. What is the average illuminance, in footcandles, on the working plane?

SOLUTION By the equation given above, average footcandles illumination = $\text{lumens} \div \text{ft}^2 \text{ area} = 3300 \div 600 = 5.5 \text{ fc}$.

26. The illuminance, in footcandles, which from a light source impinges on a surface, varies inversely as the square of the distance from the source. This is true absolutely for a true point source (Sec. 16). It is approximately true if the distance is at least 10 times the largest dimension of the light source.

EXPLANATION Assume (Fig. 10.13) that the 1-cd point source P is placed at the center of a hollow spherical shell which has an internal radius D of 1 ft. Then, a section A of the shell, having an area of 1 ft^2 , will have on its inner surface an illumination of 1 fc. This follows from the preceding discussions. Furthermore, from the definition of the lumen (Sec. 22), just 1 lm of flux is lighting this surface. Now, if the 1-ft-radius sphere is removed and the 1-cd source be placed at the center of a 2-ft-radius sphere, i.e., one of double the radius, then the same luminous flux will be spread out over an area B of 4 ft^2 . (This follows because of the geometric fact that similar areas vary directly as the square of similar dimensions.) The illumination on B will be $1 \text{ lm} \div 4 \text{ ft}^2 = 0.25 \text{ fc}$. Thus by doubling the distance from the source, the illumination has been quartered. Similarly, it can be shown for C that with the distance D increased 3 times the illumination provided by 1 lm of flux is one-ninth of what it was with the distance of 1 ft. Thus, illumination varies inversely as the square of the distance from the source.

FIGURE 10.13 The inverse-square law.

27. The photometer is an instrument which is used for determining the luminous intensity of a light source. Any determination made with a photometer gives apparent candlepower. However (Sec. 26), if the location at which the intensity is measured is at a sufficient distance from the source, then the source may for all practical purposes be considered a point source, and the value obtained for the unknown candlepower will be accurate well within the limits of error of experimental observation.

Photometric measurements are obtained from visual comparison of an unknown light source compared with a known source or with direct-reading photoelectric instruments which have been calibrated from a known source. The latter method is the most widely used today in the measurement of lamps and lighting fixtures.

28. Mean horizontal candlepower is the average of the candlepowers of a lamp in all directions in a horizontal plane. This term is now applied only to special lamps for laboratory test work.

29. Mean spherical candlepower is the average of the candlepowers of a lamp in all directions. It is measured by putting the lamp in the center of a sphere photometer (Fig. 10.14). The sphere has a small window of milk glass which is shielded from the direct rays of the lamp by a small opaque screen. The inner surface of the sphere is painted flat white for good reflection of the light. The candlepower of the window is compared with the horizontal candlepower of a standard lamp. This candlepower must be multiplied by a constant for the particular sphere to take account of the loss of light absorbed on the inner surface of the sphere and in the glass window. The mean spherical candlepower is used principally with the equation of Sec. 24 to obtain the lumen output in which the lamp is rated.

FIGURE 10.14 Sphere photometer. [General Electric Co.]

30. The luminous efficacy (also referred to as efficiency) of an electric-light source is stated in *lumens per watt*. This term is obtained by dividing the lumen output of the source by the watts input. It is (*Standard Handbook for Electrical Engineers*) the ratio

of the total luminous flux (lumens) to the total power input (watts). The maximum luminous efficacy of an ideal white source, defined as a radiator with constant output over the visible spectrum, is approximately 200 lm/W.

31. Candlepower distribution curves. Since the common light-giving sources either alone or in conjunction with the reflecting equipment used with them do not have the same light-giving power or candlepower in all directions, photometric graphs are employed to indicate the candlepower of the source in all directions. Curves giving this information for a light source are called candlepower distribution curves or simply distribution curves. These curves are obtained from a photometer which measures the luminous intensity of a light source in all directions (Fig. 10.15).

FIGURE 10.15 Mirror photometer used to measure the luminous intensity of a light source or luminaire in all directions. [General Electric Co.]

Many lamps or lamps with their reflectors have the same candlepower in all directions in any one horizontal plane. This fact enables the candlepower in any direction from such a source to be determined from a single distribution curve which gives the candlepowers in all directions in a vertical plane through the center of the light source.

32. How to read a photometric graph. In the photometric graph of Fig. 10.16, I, the candlepower directly downward is indicated by measuring it off on the vertical to a given scale. Thus, XA represents the candlepower directly below the light. Similarly, the distances XB , XC , XD , XE , XF , and XG represent to scale candle-powers around the light at angles above the vertical of 15, 30, 45, 60, 75, and 90°. Similarly, the candlepowers above 90° can be measured off to the given scale along lines at their respective angles. These points are then joined by a continuous line $GFED$, etc., and this line, completed for 360°, is called the *photometric distribution graph* of the light source. Figure 10.16, I, shows such a completed photometric curve, but in practice it is customary to use circular lines, as indicated on Fig. 10.16, II, to show the scale to which the candlepowers are

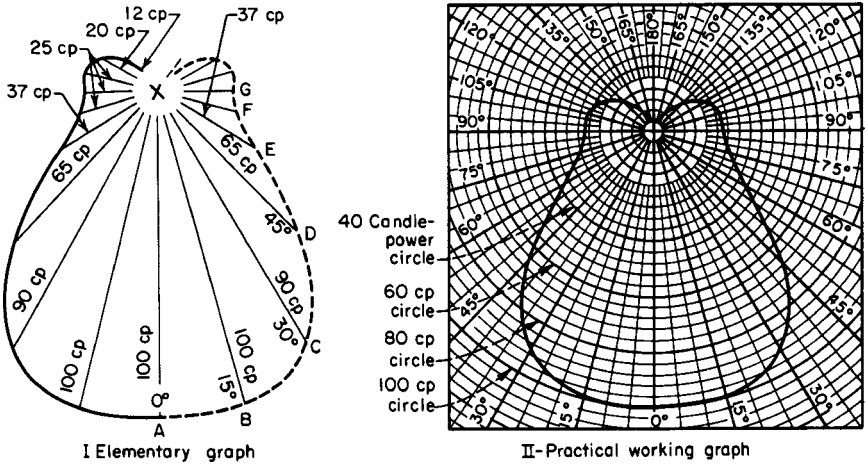

FIGURE 10.16 Photometric graphs.

plotted. The candlepower of the light unit can be measured at as few or as many angles as necessary, the accuracy of the resultant graph being largely determined by the number of angles taken.

33. The area of the distribution graph is not proportional to the amount of light given off. *B* (Fig. 10.78) represents a smaller total flux, by an amount equal to the absorption in the reflector, than does Graph *A*, though it has a larger area. Such a graph as *B* is useful for determining the intensity of light at any given angle and for determining the total luminous output, as explained in Sec. 34. These data may be required for any one of a number of practical operations.

34. The method of computing from its distribution graph the total flux, in lumens, emitted by a symmetrical light source is this: From the distribution graph of any light unit, as Fig. 10.16, take the candlepower at 5° and multiply it by the 0-10 factor as given in Table 36. This gives the lumens in the 0-10° zone. Similarly, to obtain the lumens in the 10-20° zone, take the candlepower at 15° and multiply it by the 10-20° factor as given in Table 36. The total lumen emitted in any large zone is obtained by adding the lumens of all the 10° zones contained in the large zone. If the sum total of the lumens is thus obtained for the 0-180° zone, the result is the total flux, in lumens, emitted by the source.

EXAMPLE What is the total flux emitted by a light source having a distribution graph as shown in Fig. 10.16?

SOLUTION

Degrees (1)	Candlepower (2)	Zone factor (3)	Lumens (4)
5	100	0.095	9.50

145	12	0.628	7.54
155	8	0.463	3.70
165	4	0.283	1.13
175	4	0.095	0.38
Total =			436.12

Total flux emitted = 436.12 lm.

Column 2 is obtained from the graph (Fig. 10.16). Column 3 is obtained from Table 36. Column 4 is obtained by multiplying the values in col. 2 by the corresponding values of col. 3.

NOTE The total flux in lumens emitted by a light source can be computed graphically as follows. On the candlepower distribution graph (Fig. 10.16) measure the horizontal distance between the vertical axis (0–180° line) and the point where the candlepower graph crosses the 5° line. Then lay off this distance on the candlepower scale to which the distribution graph is plotted. Multiply the value thus obtained by 1.1, and the result is the quantity of luminous flux, in lumens, emitted by the light source in the 0–10° zone. To determine the flux in any 10° zone, it is only necessary to measure the horizontal distance between the vertical axis and the point where the candlepower graph crosses the center of the 10° zone under consideration and then proceed as above. To obtain the total lumens emitted in any large zone lay off the horizontal distances between the vertical axis and the point where the candlepower graph cuts the center of each 10° zone contained within the large zone successively along the edge of a strip of paper. Then lay off the total length on the candlepower scale and multiply the result by 1.1.

For the determination of the lumen output of nonsymmetric or asymmetric luminaires, such as conventional fluorescent units, readings of candlepower must be taken in a number of planes. From these readings a weighted average candlepower is obtained for each zone.

For fluorescent lighting units, candlepower readings often are taken in five planes, at 0, 22½, 45, 67½, and 90° from a plane through the luminaire axis. Candlepower values are measured in each of these planes at 10° intervals (5, 15, 25°, etc.). If the candlepower readings in the five planes (0, 22½, 45, 67½, and 90°) for any one zone are designated, respectively, as *A*, *B*, *C*, *D*, and *E*, then their weighted average for that zone is obtained by the formula

$$cd = \frac{A + 2B + 2C + 2D + E}{8}$$

In some laboratories for similar tests, candlepower readings are taken in three planes only (0, 45, and 90°), as in Fig. 10.17. The candlepower values in *A* (crosswise) and *B* (lengthwise) plus twice the values in *C* (45°) are added. The sum divided by 4 equals the average candlepower.

Similarly, nonsymmetric or asymmetric luminaires for filament lamps have such wide variations in candlepower at a given angle about the vertical that an average reading from which to compute zonal lumens cannot be obtained by rotating the unit. Candlepower distribution curves for such equipment are prepared from data obtained in specific planes, and in interpreting such curves one must be careful to observe the planes they represent (see Fig. 10.18).

FIGURE 10.17 The average candlepower multiplied by the zone constant gives the zone lumens. Candlepower values at a given angle in curves *A* and *B* are added to twice the value in curve *C* at the same angle. This sum is divided by 4 to get the weighted average candlepower.

FIGURE 10.18 Candlepower distribution curves of nonsymmetrical sources such as show-window reflectors vary widely, and their interpretation depends on the specific planes in which they are taken.

35. The mean spherical candlepower (Sec. 29) of a light source can be determined (1) directly, by means of the sphere photometer (Sec. 29 and Fig. 10.14), and (2) indirectly, by computing the total lumens from the distribution graph, as explained in the preceding paragraph, and dividing the result by 12.57.

EXAMPLE What is the mean spherical candlepower of the light source of which the distribution graph is shown in Fig. 10.16?

SOLUTION By the example in Sec. 34, the total flux of the source = 436.12 lm. The mean spherical candlepower = $436.12 \div 12.57 = 34.6$.

36. Factors to obtain the lumens in the 10° zones around a light source. To obtain the lumens in any zone, multiply the candlepower at the center of the zone by the factor for that zone.

Degree zones		Factor
0–10	170–180	0.095
10–20	160–170	0.283
20–30	150–160	0.463
30–40	140–150	0.628
40–50	130–140	0.774
50–60	120–130	0.897
60–70	110–120	0.992
70–80	100–110	1.068
80–90	90–100	1.091

37. The footcandle meter (also called the light meter or luminance meter) is an instrument for measuring illumination directly in footcandles. It consists of one or two photovoltaic cells connected to a microammeter. When light falls on the photovoltaic cells, a voltage is generated as current flow through the meter approximately in proportion to the footcandle illumination on the cell. The small pocket type of footcandle meter is commonly referred to as a light meter (Fig. 10.19). It has a single photovoltaic cell and is calibrated in footcandles. The meter is placed with the window of the photovoltaic cell parallel to the plane in which it is desired to measure the illumination. Higher levels of illumination (such as those of daylight intensity) are measured via multiple scales on the same meter which are chosen through a selector switch.

Larger and more accurate meters (Fig. 10.20) have additional cells connected in parallel and utilize solid-state electronic circuits to amplify the output of the photovoltaic cells and maintain excellent accuracy through a wide range of footcandle levels.

FIGURE 10.19 The light meter. [General Electric Co.]

FIGURE 10.20 Light meter for more accurate readings. [Minolta Corporation]

Since the spectral response of photovoltaic cells is not the same as that of the human eye, it is necessary to incorporate filters into the light meter for the meter to read lighting levels properly under all different light sources. Another factor that requires correction within the meter is the proper measurement of light from various angles. If no correction is included, light at high incident angles will be reflected off the photovoltaic-cell surfaces with a resulting low reading of lighting level. Most footcandle meters today include a means of correcting the meter response to include light from all angles. This is referred to as *cosine correction*.

38. Glare (Fig. 10.21) is defined as any brightness within the field of vision of such a character as to cause discomfort, annoyance, interference with vision, or eye fatigue.

NOTE Glare may be subdivided into three different classes: (1) Direct glare (Fig. 10.21, II), which results when one looks directly at a brilliant light source. (2) Contrast glare, which is caused by brightness contrast. An example of this is the visual discomfort produced by a brilliant automobile headlight shining in the eyes on a dark night. The same headlight would cause no discomfort in the daytime. The annoyance experienced at night is due solely to the contrast between the bright headlight and the dark surroundings. (3) Reflected glare (Fig. 10.21, I), which is produced by light being reflected directly into the eyes from a polished, a white, or a light-colored surface. Glass desk plates, highly polished furniture, glazed paper, and mirrors may occasion reflected glare.

FIGURE 10.21 Methods of causing glare.

39. Brightness is the property of lighted objects which enables them to be seen by virtue of the light issuing from them. Technically, brightness is the density of luminous flux issuing or projected from a light source or from some illuminated surface.

NOTE The relation between brightness and illuminance: Illuminance is the density of the luminous flux impinging on an illuminated surface. Just as illuminance measures incident-luminous-flux density, so brightness measures issuing-luminous-flux density. It is due solely to the light issuing or reflected from things that we see. There might be great illumination (incident-luminous-flux density) on a dead-black object in a room with dead-black walls, and yet that object would be invisible, because the black would absorb (see Table 9) all the light which impinged on it and would reflect none to the eye.

40. The units of brightness are the *lambert*, the *millilambert*, the *footlambert*, and the *candela per unit of area*. The lambert (L) is by definition the brightness of a perfectly diffusing surface which radiates or reflects 1 lm/cm², while the millilambert (mL) is 0.001 of this value. The footlambert (fL) is the brightness of a surface which radiates or reflects 1 lm/ft². As its name implies, the candela per square inch is the brightness of a surface which radiates 1 cd/in². The lambert and the candela per square inch are commonly used for high brightness such as light sources, while the millilambert and the footlambert are used for designating ordinary illuminated surfaces.

41. The working equations for brightness computations are

$$b = 2.05 L \quad (3)$$

$$F = 6.45 SL \quad (4)$$

where b = brightness in candelas per square inch, L = brightness in lamberts, F = total luminous flux in lumens, and S = area of the surface in square inches.

EXAMPLE A light source has a brightness of 500 cd/in². What is its brightness expressed in lamberts?

SOLUTION By transposing terms in Formula (3) above:

$$L = \frac{b}{2.05} = \frac{500}{2.05} = 243.5 L$$

EXAMPLE An incandescent-lamp filament has a surface area of 0.4 in² and emits 1580 lm. What is its brightness in lamberts?

SOLUTION By transposing terms in Formula (4) above:

$$L = \frac{b}{6.45S} = \frac{1580}{6.45 \times 0.4} = 612 L$$

42. The relation between the illumination incident on and the brightness reflected from an illuminated surface can be understood from a consideration of the following facts. No surface, however smooth, is a perfect reflector, since some of the luminous flux impinging on the surface will be absorbed thereby. Therefore, when the surface brightness resulting from the reflection of the impinging light rays or illumination is computed, the coefficient of reflection (Table 9) of the material must be considered. The brightness equals the illumination times the coefficient of reflection.

$$mL = 1.076 \times E \times m = mL \quad (5)$$

where mL = average surface brightness over the surface under consideration in millilamberts; E = the incident illumination on the surface in footcandles; and m = the absolute coefficient of reflection (Table 9) of the surface material.

EXAMPLE A surface of white plaster has illumination of 5 fc. What is its brightness?

SOLUTION The coefficient of reflection of white plaster (Table 9) is 0.90. By Formula (5),

$$\text{Brightness} = 1.076 \times E \times m = 1.076 \times 5 \times 0.90 = 4.84 \text{ mL}$$

43. Conversion Factors for Various Units of Brightness

Values in units in this column \times
conversion factor = values in units
at top of column

	Candelas/in ²	Lamberts	Millilamberts	Footlamberts
Candelas/in ²	1	0.487	487	452
Lamberts	2.054	1	1000	929
Millilambert	0.00205	0.001	1	0.929
Footlambert	0.00221	0.00108	1.076	1

44. The maximum brightness beyond which glare will result (see Sec. 38) from a lighting unit usually should not exceed from 1 to 1.56 (2 to 3 cd/in² of projected area) in the central portion of the visual field. Higher values of brightness will produce a sensation of glare. The value depends on the size of the source, the position in the line of vision, and the contrast between the source and its surrounding. If the eyes are not to be fatigued when the unit is viewed continually, the brightness should not exceed 0.25 L. It should be noted that the maximum permissible brightness is somewhat influenced by the darkness of the surroundings (see Sec. 38).

44A. Brightness of Light Sources

Source	Approximate lamberts
Incandescent lamp with opal globe	0.24–1.46
Incandescent lamp, inside-frosted globe	7–15
Fluorescent lamp, white and daylight	1.2–2.6
Fluorescent lamp, green	2.4–3.6
Fluorescent lamp, red	0.12–0.23
Fluorescent lamp, pink, blue, or gold	0.83–1.8
Candle flame	1.46–1.95
Acetylene-burner flame	29–50
Vacuum-incandescent-lamp filament	460–700
Gas-filled-incandescent-lamp filament	3,000–4,000
Neon tube, red	0.24
Neon-mercury tube, green or blue	0.05–0.1
Mercury arc (quartz tube)	290–490
Metal halide arc	1,100–1,700
High-pressure sodium arc	1,100–1,900
Sky	0.7–2.0
Sun, on horizon	1,000
Sun, 30° above horizon	243,000
Sun, at noon	450,000
Ceiling over indirect-lighting fixture	0.01–0.1
Walls when lighted by diffused daylight	0.001–0.05

45. Brightness (or luminance) is usually measured by portable meters which operate on the same basic principle as the footcandle meter. Brightness meters use a photoreceptor such as a photomultiplier tube or photovoltaic cell which creates an electrical signal in proportion to the brightness of an object or surface. Some form of optical system is designed into the meter to permit the operator to focus on the meter or the object or surface being measured. The electrical signal is sent through an amplification circuit to the meter, which may be either analog or digital. With proper calibration, a direct reading of brightness is obtained. A typical portable brightness meter is shown in Fig. 10.22.

FIGURE 10.22 Portable brightness meter. [Minolta Corporation]

46. Fiber optics is a relatively new optical technology that refers to optical systems consisting of thin cylindrical glass or plastic fibers with excellent optical properties. Light enters one end of a fiber and is transmitted along the fiber core to the other end by internal reflections off the clad or fiber wall (Fig. 10.23). Large quantities of fibers are placed together to form a bundle. Each fiber is insulated with a special glass coating to prevent light from transforming one fiber to another. The bundle has external tubing to protect the fibers, and the ends of the bundle are bonded and polished. Initial use of fiber optics was in medical applications to observe conditions inside the human body. The most significant application has been in optical communications where voice signals are encoded and transmitted at high speed over the fibers. Fiber-optic systems have two advantages over conventional cable transmission systems: they are free from cross talk, and they are unaffected by random electrical disturbances such as lightning. Refer to Div. 11 for detailed coverage of this topic.

FIGURE 10.23 Light transmission through optical fibers.

In lighting applications, fiber optics are being used in some automobile models to monitor information on signal-light operation on the dashboard as well as in optical sensors in varying applications. They have also been used in signs and other advertising and decorative applications to create unique effects of colors and/or motion.

ELECTRIC-LIGHT SOURCES

47. Electric-light sources may be classified as follows:

- A. Visible-light sources
 1. Incandescent (filament)
 2. Fluorescent
 3. High-intensity-discharge (mercury, metal halide, and high-pressure sodium)
 4. Other gaseous-discharge
 - a. Low-pressure sodium
 - b. Neon
 - c. Glow (argon and neon)

- B. Ultraviolet-light sources
 - 1. Sunlight lamps
 - 2. Black-light lamps
 - 3. Germ-killing lamps
 - 4. Photochemical lamps
- C. Infrared heating lamps

INCANDESCENT (FILAMENT) LAMPS

48. The incandescent lamp consists of a filament which is a highly refractory conductor mounted in a transparent or translucent glass bulb and provided with a suitable electrically connecting base. The filament is heated by the passage of an electric current through it to such a high temperature that it becomes incandescent and emits light. In incandescent lamps of the older types the air was, insofar as practicable, exhausted from the space within the bulb and surrounding the conductor (filament), forming a partial vacuum. But in many of the modern lamps this space is filled with an inert transparent gas such as nitrogen. The conductor must have a high melting point or a high vaporizing temperature and a high resistance; it must be hard and not become plastic when heated. In vacuum-type lamps the vacuum must be good, not only to prevent the oxidation of the filament but also to prevent the loss of heat, which would reduce the efficiency. In non-vacuum-type lamps (gas-filled lamps) the gas used must be inert so as not to combine chemically with the filament material. The bulb must be transparent or translucent to permit the passage of light, not porous, so that it will retain the vacuum or inert gas, and strong to withstand handling and use.

49. Classification of incandescent lamps. Incandescent lamps may be classified in six different ways, according to:

1. The class of lamp
2. The shape of the bulb
3. The finish of the bulb
4. The type of the base
5. The type of filament
6. The type of service

50. Class of lamp. Incandescent lamps are classified as Type B or Type C. The Type B lamp is one in which the filament operates in a vacuum. The type C lamp is one which is gas-filled. Gas-filled lamps are the most widely used types. The gas reduces the rate of sublimation of the heated filament. Inert gases such as nitrogen, argon, and krypton are in common use today, with krypton used where its increased cost is justified by increased efficacy or increased lamp life. For example, the 90-W krypton "energy-saving" lamp produces 4% less light, but one-third longer rated life compared with the standard 100-W lamp.

51. Classification according to shape of bulb (Fig. 10.24). The standard-line shape is employed for general-lighting-service lamps up to and including the 100-W size.

FIGURE 10.24 Typical bulb shapes and designations (not to scale). Most high-intensity discharge (HID) lamps are BT-, E-, ED-, PAR-, and R-shape bulbs.

Lamps of 150 W and larger for general lighting service are made in the pear shape. The other shapes are utilized for lamps designed for special classes of service. Lumiline lamps are included in the tubular classification.

Shape of bulb	Designating letter
Standard-line	A
Bulb-tubular	BT
Cone-shaped	C
Flame-shaped	F
Globular	G
Parabolic	PAR
Pear-shaped	P or PS
Reflector	R
Straight-side	S
Tubular	T

Lamps are designated by a letter and figure such as PS-30. The letter indicates the shape of bulb and the figure the greatest diameter of the bulb in eighths of an inch. Thus, a PS-30 lamp is a lamp with a pear-shaped bulb with a diameter of $30/8$, or $3\frac{3}{4}$ in.

52. Classification according to finish of bulb

1. Clear
2. Inside-frosted
3. Silvered-bowl
4. White
5. Daylight
6. Inside-colored
7. Outside-colored
8. Colored-glass
9. Outside-coating

FIGURE 10.25 Silvered-bowl incandescent lamp.

53. Finish of bulbs. Incandescent lamps can be obtained with the bulbs finished in several different ways as listed in Sec. 52. With the clear lamps the bulb is made of clear glass which leaves the filament exposed to view. Clear-bulb lamps are used with reflecting equipment which completely conceals the lamp from view. They are employed with open-bottom types of reflecting equipment in some cases when the units are mounted so high that the lamps are not in the line of vision. Inside-frosted lamps have the entire inside surface of the bulb coated with a frosting which leaves the exterior surface perfectly smooth. This finish conceals the bright filament and diffuses the light emitted from the lamp. Inside-frosted lamps are used with open-bottom types of reflecting equipment and in places where no reflecting equipment is employed. Silvered-bowl lamps (Fig. 10.25) have a coating of mirror silver on the lower half of the bowl, which shields the brilliant filament and forms a highly efficient reflecting surface for indirect lighting. The upper part of the bulb is inside-frosted to eliminate streaks and shadows of fixture supports. Silvered-bowl lamps should be used only in fixtures designed for them, because the silvering directs the heat toward the socket assembly, which will therefore tend to operate at a higher temperature

than with clear lamps. White lamps have the entire interior surface of the lamp covered with a fine coating of silica. This coating gives a high degree of diffusion which softens shadows and reduces shiny reflections. Since bulb blackening is not apparent through the diffusing coating, the lamps appear clean and white throughout their life.

54. Daylight lamps have a blue bulb made of a special blue-green glass to approximate noon sunlight. The ordinary incandescent lamp produces light in which the red rays predominate. The blue-green glass of the bulb of daylight lamps absorbs part of the reddish

rays emitted by the filament of the lamp, giving a light which approaches the whiteness of noon sunlight. The glass absorbs about one-third of the total light emitted by the filament.

55. Colored bulbs. Colored light is obtained from filament lamps by the subtractive method, that is, by means of a separate filter or a bulb so processed that light of colors other than that desired is largely absorbed. Colored bulbs used in lamp manufacture are of natural-colored glass or of clear glass having a coating applied to either the inner or the outer surface of the bulb by one of several different processes. Natural-colored bulbs, wherein chemicals are added to the ingredients of the glass to produce the desired color, are regularly available in daylight blue, blue, amber, green, and ruby. Natural-colored bulbs produce light of purer colors than coated bulbs and are often used in preference to the latter for theatrical and photographic lighting.

Coated colored lamps are made by spraying either the inside or the outside of the bulb or by applying a fused enamel (ceramic) or acrylic coating to the outside of the bulb. The colors in most common use are red, blue, green, yellow, orange, and white.

When decorative or display lighting is involved, coated colored lamps are to be preferred to natural-colored lamps because of their lower cost. Enameled, acrylic-coated, and inside-sprayed bulbs are satisfactory for either indoor or outdoor use.

56. Tungsten-halogen lamps are incandescent (filament) lamps but are significantly different from conventional lamps in size and design. They represent the practical application of the halogen regenerative cycle in filament lamps. All tungsten-halogen lamps are filled with a gas of the halogen family. Iodine and bromine are the most commonly used. As the lamp burns, the halogen gas combines with the tungsten that is sublimated from the filament. As the gas circulates inside the bulb, the tungsten is deposited back on the filament rather than on the inside bulb wall. This keeps the bulb wall clean and allows the lamp to deliver essentially its initial light output throughout life. Owing to the lamp temperatures, quartz or a special high-silica "glass" are used for the lamp bulb or filament tube.

Four types of tungsten-halogen lamps are available (Fig. 10.26). The most widely used designs are the small tubular double-ended lamps. A coiled filament extends from one end of the lamp to the other. Lamp wattages range from 200 to 1500 W. A second type utilizes

FIGURE 10.26 Tungsten-halogen lamps. The PAR design is cut away to show the internal filament tube.

a base at only one end of the quartz bulb. In the third type, the quartz filament tubes are sealed into outer bulbs such as PAR lamps for good optical control.

The last type of tungsten-halogen lamp for lighting is an adaptation of the small photographic halogen projection lamp. Small 12-V quartz filament tubes are mounted in small multifaceted glass ellipsoidal reflectors with infrared transmitting reflectors which reflect light but transmit much of the infrared heat out the back of the lamp. These lamps are extensively used in display-lighting applications.

The average life of most general-lighting tungsten-halogen lamps is about twice the life of regular general-service incandescent lamps, or 2000 h. Although for the same wattage the initial light output of these lamps is about the same, at the end of 1000 h the tungsten-halogen lamp produces about 13 percent more light than the standard general-service lamp.

These lamps offer high light output from compact lighting equipment. For example, the reflector for the 1500-W T-3 tungsten-halogen lamp is only 1 ft (0.3 m) long and 6 to 7 in (152 to 177 mm) wide.

Tungsten-halogen PAR lamps combine the excellent efficiency and long life of quartz lamps with the light control of a PAR bulb. The quartz tube is mounted at the focal point of the PAR bulb's reflector for accurate beam control. At the end of life (4000 h), 500-W tungsten-halogen PAR lamps provide 40 percent more light than standard 500-W PAR lamps rated at 2000 h. Special infrared reflecting films are utilized on the inner surface of the bulb or filament tube of some halogen lamp designs. This film transmits visible light but reflects infrared energy back to the filament, thus reducing the input power required to achieve the desired filament temperature and increasing lamp efficiency by as much as 50 percent.

Tungsten-halogen lamps are widely used in general lighting and floodlighting. Special tungsten-halogen designs are also used in specialty applications such as stage, film, and TV lighting, copying machines, and optical devices.

56A. Classification According to Type of Base (Fig. 10.27)

Bayonet	Medium prefocus	Extended mogul end-prong
Candelabra	Mogul prefocus	Medium two-pin
Intermediate	Medium bipost	Medium side-prong
Medium	Mogul bipost	Candelabra prefocus
Three-contact medium	Medium skirted	Screw terminal
Admedium	Minicandelabra	Lug sleeve
Mogul	Recessed single-contact	Two-pin
Three-contact mogul	Mogul end-prong	Double-contact medium
Disc		

57. Lamp bases. A number of different types of bases for incandescent lamps (Fig. 10.27) are in use. Of these, the bayonet, candelabra, and intermediate base are used on small-size (miniature) lamps. The medium base, used on general-service lamps of 300 W and less, is the most common type. The mogul base is used on sizes of 300 W and up. The admedium is slightly larger in diameter than the medium and is used on some mercury lamps. The three-contact base is used with a three-lite type of lamp. The disc base is used on Lumiline lamps.

The medium and mogul prefocused bases are used on certain types of concentrated-filament lamps, such as those for picture projection and aviation service, for which it is desirable to have the light source accurately located. The medium bipin base is for fluorescent lamps. The medium bipost base is made in 500-, 750-, and 1000-W lamp sizes for use principally with indirect fixtures, for which it allows a better design of fixture and better radiation of heat than are obtainable with the mogul-base type. For the very large-size lamps of 1500 W and up for floodlighting service the mogul bipost is the standard.

FIGURE 10.27 Bases for incandescent lamps. [General Electric Co.]

58. Classification according to type of filament. Several different types of filament structures are used. The filament structure is designated by a letter or letters to indicate whether the wire is straight or coiled and by an arbitrary number sometimes followed by a letter to indicate the arrangement of the filament on the supports. Prefix letters include S (straight; wire is straight or slightly corrugated), C (coil; wire is wound into a helical coil, or it may be deeply fluted), and CC (coiled coils; wire is wound into a helical coil, and this coiled wire is again wound into a helical coil).

59. Classification of incandescent lamps according to type of service:

1. General lighting service
 - a. Clear bulb
 - b. Inside-frosted bulb
 - c. Silvered-bowl bulb
 - d. White bulb

2. Special lighting service
 - a. Daylight lamps
 - b. Decorative lamps
 - c. Rough-service lamps
 - d. Three-lite lamps
 - e. Tubular lamps
 - f. Vibration lamps
3. Miscellaneous lighting service
 - a. Appliance- and indicator-service lamps
 - b. Aviation-service lamps
 - c. High-voltage lamps
 - d. Low-voltage lamps
 - e. Marine-service lamps
 - f. Mine-service lamps
 - g. Optical-service lamps
 - h. Photographic lamps
 - i. Photoservice lamps
 - j. Projection lamps
 - k. Projector and reflector lamps
 - l. Sign lamps
 - m. Spotlight- and floodlight-service lamps
 - n. Street-lighting-service lamps
 - o. Traffic-signal lamps
 - p. Train- and locomotive-service lamps

60. General-lighting-service lamps are those of 120- or 130-V rating for ordinary uses in homes, stores, offices, schools, factories, etc.

61. Special-lighting-service lamps are for use in similar locations, but they have a special design feature, such as shape or color of bulb, or other special features.

For an explanation of daylight lamps refer to Sec. 54.

Decorative lamps for general and special lighting are colored lamps that are available in a number of different types (see Sec. 55). They can be used to provide special effects in homes, theaters, shops, restaurants, and lobbies and foyers of public buildings.

Special yellow enameled lamps, which often are called "bug" lamps, are available. Although these lamps are excellent for decorative lighting, they are designed primarily for outdoor lighting during the season of night-flying insects. They have less attraction for insects than lamps of other colors. These lamps are used in open porches, outdoor recreation areas, filling stations, camps, roadside stands, and any other place where people enjoy outside activities under lights.

Rough-service lamps are specially constructed so that the filament can withstand sudden bumps and other forms of rough treatment. They are used principally in extension-cord service in garages, industrial plants, and similar applications in which they will be subjected to excessive shock in service.

For an explanation of three-light lamps refer to Sec. 62.

Tubular incandescent lamps for special general-lighting service are available in the Lumiline type and the showcase type.

The Lumiline lamps with their long bulb, 1 in (25.4 mm) in diameter, give a continuous line of light which is well suited to places where space is limited, as in displays, niches, small coves, signs, mirrors, paintings, and luminous panels. These lamps have contact caps of the disk-base type at each end of the bulb. Specially designed sockets or lampholders are

required. Lumiline lamps are available with clear, inside-frosted, white, or colored-glass tubes.

Showcase lamps (Fig. 10.28) are tubular lamps with conventional screw bases, which are designed primarily for the lighting of showcases but which also are used for the lighting of shallow-depth displays and other special applications requiring small trough-type reflectors. These lamps are available in clear, inside-frosted, and special showcase-reflector types. The showcase-reflector type is made with a tubular bulb with the upper half inside-aluminized so that it can be used in showcases, shelves, speakers' stands, and the like, in an ordinary socket without any reflector. A spring contact on the base allows the lamp to be adjusted in the socket to throw the light rays in any desired direction.

FIGURE 10.28 Showcase lamps. [General Electric Co.]

Vibration lamps are designed particularly for use on or near rotating machinery and other places where relatively high-frequency vibration exists. Certain of these lamps are equipped with a special type of filament wire designed to operate suitably under vibration conditions.

62. The three-light lamp has two separate filaments in one bulb (Fig. 10.29). One filament consumes twice the wattage of the other, and the filaments can be lighted separately or together to produce three different levels of illumination, such as 50/100/150 W or 100/200/300 W. These lamps are particularly applicable to study lamps, reading lamps, and indirect floor lamps so that the user, with a single lamp, can adjust the illumination from that for decorative and casual use to full brilliancy for close seeing. They can also be used in stores so that daylight can be supplemented with an economical use of electric light and the illumination can be varied to suit different occasions.

FIGURE 10.29 Three-lite lamp. [General Electric Co.]

63. Appliance- and indicator-service lamps are specially designed for use with appliances and equipment for home and commercial use. These lamps, when properly used, provide effective illumination of equipment exteriors and interiors and also give clear indications of operations in progress.

64. Aviation-service (airport) lamps are designed to suite the special conditions encountered in the vital lighting for safety at airport landing fields. Several types are required to provide satisfactory approach, beacon, running, taxiway, and the like, lighting.

65. High-voltage-service lamps, rated at 230 and 250 V, are available for use in locations where only the higher voltage is available. These lamps are less rugged and less efficient than the general-lighting-service type. The reason for this is that the filament must be of longer and finer wire to have sufficient resistance to limit the current to approximately one-half the value for the same-wattage general-service lamp. For this reason use in any new installation in which the lower voltage could be made available is not encouraged. There are also general-service incandescent lamps of 277-V circuits. One manufacturer cautions that such lamps be enclosed if used on high-capacity, low-impedance electrical distribution systems.

66. Low-voltage-service lamps, rated at 6, 12, 30, 32, 60, and 64 V, respectively, are available for use on electrical systems such as those of automobiles, boats, garden lighting, miniature interior fixtures or desk lamps, underwater swimming-pool fixtures, battery-generator sets, and trains. In contradistinction to the high-voltage lamps, the filaments are much thicker, providing inherent resistance to vibration and shock. The practical lower limit of lamp voltages is about 1.5 V, because below that point the current required to heat the filament begins to excessively heat the support wires.

67. Marine lamps are specially designed to take care of the special maritime illumination requirements. These lamps are used on shipboard to outline and identify vessels for seaway safety and to signal between ships. On land, they provide a source for lighthouse beacons. Underwater, they illuminate areas where divers must work.

68. Mine lamps are specially designed to meet the conditions encountered in the general illumination of mines and mine equipment.

69. Lamps for optical devices are available in a great variety of types to meet the special requirements of devices used in the optical field of science, industry, and education.

70. Photographic lamps are spotlight lamps designed with concentrated filaments for maximum light output in the controlled beams of spotlights used in theaters, television studios, and motion-picture and other photographic studies. For best lighting results, the filaments of these lamps must be accurately positioned, and the lamps should include mounting characteristics that will properly locate the filament in relation to the spotlight optical system. These lamps operate at a higher color temperature and have a shorter life than lamps for general service.

71. Photoservice lamps are made in two types:

1. Photoflash lamps
2. Photoflood lamps

The *photoflash lamp* is used to illuminate scenes for the taking of photographs. The photoflash lamp (Fig. 10.30) consists of a bulb containing flammable material such as zirconium in an atmosphere of oxygen. When the lamp is connected to a source of voltage, the foil burns with a single brilliant flash lasting about 1/50 s. Photoflash lamps are generally used with older cameras. Most cameras today utilize small electronically ignited xenon flash tubes which can be flashed repeatedly.

FIGURE 10.30 Photoflash lamps. [General Electric Co.]

The *photoflood lamp* is used for continuous illumination in the taking of moving pictures, by commercial photographers for studio portrait work and by amateur photographers for interior photographs. The photoflood lamp is similar to the regular inside-frosted incandescent lamp except that the filament is designed to operate at a higher temperature. This lamp emits much more light than the general-service lamp for the same wattage, but its life is much shorter, for example, 2 h for the smallest size to 10 h for the largest size.

72. Projection lamps (Fig. 10.31) are used in slide and motion-picture projections. The lamps utilize carefully positioned concentrated filaments and a base type permitting accurate positioning of the filaments in the projectors. The filaments operate at high temperatures, resulting in higher efficiency and thus shorter life, usually from 25 to 50 h.

FIGURE 10.31 Projection lamps. [General Electric Co.]

73. Reflector and projector lamps (Fig. 10.32) are made with a parabolic-shaped bulb having a mirrored surface on the inside of the neck and a fixed-focus filament. They can be used with a plain socket to form a highly efficient spotlight. The projector type has a lens built into the face of the lamp for better control in the light. This lamp is made of heat-resisting glass so that it can be used either indoors or in locations exposed to the weather. The reflector type has an inside-frosted glass bulb which is not weatherproof and does not provide so accurate a control of the light but costs only about two-thirds as much as the projector type. Both types can be obtained in either a concentrating-spotlight or a wide-floodlight version. These bulbs are available with integral quartz-halogen lamps. The Energy Policy Act of 1992 established minimum efficacy standards for medium-base, 40–205-W, general service reflector and projector (R and PAR) lamps. As a result, many previously popular R and PAR lamps are no longer manufactured for sale in the United States. They have been replaced with more efficient halogen and halogen infrared PAR lamps and krypton filled R lamps.

FIGURE 10.32 Reflector and projector lamps. [General Electric Co.]

(*Standard Handbook for Electrical Engineers*) A number of projector lamps are available with dichroic filters (interference films) to control the spectral quality of the radiation in such a manner as to separate the heat from the light in the beam or to produce colored light without the usual losses due to absorption by filters. From 75% to 80% of the heat can be removed from the beam at a sacrifice of only 15% to 20% of the light. These "cool beam" lamps must be used in luminaires that are capable of dissipating the additional heat that remains within the luminaire. Colored dichroic lamps produce more deeply saturated colors with higher efficacy than is obtainable with color filters.

74. Sign and decorative lamps are lamps designed especially for outdoor signs, Christmas and other decorations, carnivals, fairs, and festoon lighting. They are used also for many interior applications. While many standard gas-filled lamps are used in enclosed and other types of electric signs, those designated particularly as sign lamps are mostly of the vacuum type. Lamps of this type are best adapted for exposed sign and festoon service because the lower bulb temperature of vacuum lamps minimizes thermal cracks due to the contact of rain and snow. Some low-wattage sign lamps, however, are gas-filled for use in flashing signs. This causes more rapid cooling of the filament and reduces the trailing effect which slow-cooling vacuum lamps might produce. Bulb temperatures of these low-wattage gas-filled lamps are sufficiently low to permit exposed outdoor use.

75. Spotlight and floodlight lamps have concentrated filaments, accurately positioned with respect to the base. They are used in equipment which produces accurately controlled beams of light. There are several companion listings of spotlight and floodlight lamps having the same dimensions but differing in life design. Floodlight lamps are used when burning hours are long, as in building floodlighting and show-window lighting. Spotlight lamps are used for applications in which burning hours are short and higher light output is needed, particularly in the blue and green portions of the visible spectrum. The T-12 and T-14 lamps are for use in ellipsoidal projectors when employed for show windows and interior displays. The floodlight lamps are used also for underwater units. A typical lamp is shown in Fig. 10.33.

76. Street-lighting-service lamps are lamps made specifically for use in street-lighting luminaires. They are made for series or multiple operation. A typical lamp is shown in Fig. 10.34. The series lamps are for operation on constant-current series circuits. They are made for 6.6- and 20-A circuits. Series-connected street lighting systems are rare today, but they are still used for airport runway lighting.

FIGURE 10.33 Floodlight lamp. [General Electric Co.]

FIGURE 10.34 Street-lighting-service lamp. [General Electric Co.]

FIGURE 10.35 Traffic-signal lamp. [General Electric Co.]

77. Traffic-signal lamps (Fig. 10.35) are clear lamps which are designed with a short light-center length for focusing the rays to give a signal indication of required brightness for traffic-signal use.

78. Train and locomotive lamps are specially designed to withstand the intense vibrations and shocks encountered in this service. They are available in voltages from 30 to 75 V for regular train-lighting service and for locomotive-cab and headlighting service.

79. Burning position. With a few exceptions general-lighting-service lamps can be burned in any position. However, the lumen maintenance of Type C lamps is best when they are burned base up. This is because the tungsten blackening is conducted upward by the gas and is always

deposited above the filament. When the lamp is burned base up, the blackening collects in the area of the bulb adjacent to the base, where the light is already partially intercepted by the base, socket, and luminaire husk. If the lamp is burned base down, the blackening collects in the bowl of the bulb, where it causes a much greater reduction in light output. Lamps burned in a horizontal position are affected similarly.

Certain types of lamps, particularly projection, spotlight, floodlight, and some street series lamps, are not designed for universal burning and should always be used in the position designated by the manufacturer's published data. The reason for this may be the construction of the filament, which would be likely to sag or short-circuit if burned in a position other than that for which it is designed. Operation in an incorrect position sometimes places the filament directly under a glass part which might be softened by the heat. If a lamp containing a collector grid is burned in any other position than with the grid directly above the filament, the special construction will not be effective in controlling blackening.

80. Lamp temperatures. Operation of lamps under conditions which cause excessive bulb and base temperatures may result in melting of the bulb, softening of the base cement, and loosening of the base or, in extreme cases, damage to the socket and adjacent wiring. Most fixtures are properly designed to dissipate the heat generated by the lamps, but severe conditions such as might be induced by over-voltage operation or the use of lamps of higher wattage than the manufacturer's rating may give rise to difficulty. If metal parts of shades, reflectors, or fixtures are allowed to come in contact with the bulb of a gas-filled lamp, the local cooling effect may result in glass cracks which will cause lamp failure (sometimes violent). Maximum safe operating temperatures for best lamp performance are shown in the following table.

Maximum Safe Operating Temperatures
(Approximate figures)

Soft-glass bulb	370°C
Hard-glass bulb	450–510°C
Cemented base	
Regular	170°C
Special Hi-Temp	200°C
Mechanical base	210°C
Bipost base	285°C

Gas-filled lamps, because of the convection currents within the bulb, have higher bulb temperatures than vacuum lamps. Therefore vacuum lamps are preferable for use in exposed outdoor locations where snow or rain may strike the hot bulb. Gas-filled lamps exposed to the elements should have hard or heat-resisting glass bulbs.

81. Vibration and shock. Tungsten wire heated to incandescence becomes somewhat soft and pliable, and filament coils may be distorted or broken if the lamp is subjected to shock or vibration while burning. Vibration, especially of the low-amplitude high-frequency variety, is an insidious enemy of satisfactory lamp performance and should be guarded against whenever possible. There are available a number of commercial sockets and fixtures designed to protect the lamps by absorbing vibration.

If vibration cannot be eliminated by these means, special *vibration-service lamps*, provided with extra filament supports, should be used. The construction of vibration-service lamps is such that they will give most satisfactory performance if burned in a vertical position, either base up or base down. They should never be used where they are likely to receive extreme shocks.

For use on extension cords and in any service where excessive shocks may be encountered, there are available *rough-service lamps* with a special type of shock-resisting filament construction. Rough-service lamps are designed to operate in any burning position and can be used in place of vibration-service lamps when it is necessary to burn lamps horizontally. Both vibration- and rough-service lamps sacrifice some efficiency to strength of construction and are more expensive than standard lamps; they should, therefore, be used only where required by service conditions.

82. The life of incandescent lamps is defined as the average life of a large group of lamps burned under specified conditions. The range of typical mortality curves for incandescent lamps is shown in Fig. 10.36.

FIGURE 10.36 Incandescent-lamp mortality curves. [General Electric Co.]

FIGURE 10.37 Variation in characteristics of incandescent lamps with voltage. [General Electric Co.]

much poorer. Figure 10.37 shows percentage variation in characteristics of lamps with variation from normal voltage. Consider a 120-V lamp operating at 114 V. The voltage impressed on the lamp is 95 percent of rated voltage. From Fig. 10.37 the lumens emitted by the lamp will be reduced to 84 percent of the rated value. Thus a 5 percent reduction in voltage results in a 16 percent reduction in light output.

Lamp Package Labeling. The Energy Policy Act of 1992 mandated package labeling requirements for most 120-V, medium-base, general service incandescent lamps under 200 W, 40–205-W, medium-base, general service incandescent reflector lamps, widely used 2'-U, 4' and 8' linear fluorescent lamps and integral-ballasted compact fluorescent lamps. The requirements became effective during 1995.

Packages for general service incandescent and incandescent reflector lamps and integral-ballasted compact fluorescent lamps must show light output, wattage, and life in equal size on the package together with a statement on using the lowest wattage lamp with the proper light output. In addition, general service incandescent reflector lamps must show with an explanation that the lamp meets minimum federal efficiency standards. Specialty incandescent and incandescent reflector lamps are exempt from the labeling requirements.

General service fluorescent lamps covered by the legislation must show a on the lamp or enclosing sleeve. Similar information must also be included in manufacturers' catalogues. On point-of-sale materials, the assumptions in any comparisons must be stated. Current legislative activities related to energy policy have raised the bar again on incandescent lamps in general, and over time this venerable light source may be relegated to specialty applications.

FLUORESCENT LAMPS

83. The fluorescent lamp (*Standard Handbook for Electrical Engineers*) is a low-pressure mercury electric-discharge lamp in which a phosphor coating transforms the ultraviolet energy generated by the discharge arc into light. The major parts of a fluorescent lamp (hot-cathode type) are the bulb (tube), electrodes, fill gas, phosphor coating, and bases, as shown in Fig. 10.38. When the proper voltage is applied across the ends of the lamp, an arc is produced by current flowing between the electrodes through the fill gas (mercury vapor mixed with argon or other inert gas). This discharge generates some visible radiation, but mostly ultraviolet at 253.7 nm, which in turn excites the phosphor coating to

The average life of standard lamps for general lighting purposes varies from 750 h for some lamps and 1000 h for others to 2500 h for certain sizes and types. Approximate hours of life are specified by the manufacturer. The life of a lamp is materially affected by the voltage impressed upon it. Operating a lamp at less than its rated voltage will prolong the life of the lamp while operating at higher than its rated voltage will shorten its life. This does not mean that it is good practice to operate lamps at less than their rated voltage. Decreasing the voltage on a lamp decreases the light given out by the lamp, but the percentage of decrease in light is much greater than the percentage of decrease in voltage, so that the efficiency of operation is

FIGURE 10.38 Fluorescent-lamp construction. [General Electric Co.]

emit light. Fluorescent lamps are available commercially principally in four distinct types, depending upon their operating circuits: (1) hot-cathode, preheat-starting; (2) hot-cathode, instant-starting; (3) hot-cathode rapid-start; and (4) cold-cathode.

84. Fluorescent lamp bulbs (*Standard Handbook for Electrical Engineers*) are basically tubular of small cross-sectional diameter. The bulb is available in straight, U-shaped, and circular configurations in bulb diameters from 1/4 to 2 1/8 in. In straight lengths, they range from 6 to 96 in (nominal). Shorter lamps, such as the 22-, 34-, and 46-in T-5 lamps, can simplify the design of luminaires for 600- and 1200-mm module ceiling systems. Circular (Circline) lamps have nominal overall diameters from 6 1/2 to 16 in. U-shaped lamps are 24 and 45 in. in nominal overall length. Fluorescent lamps are designated by a letter indicating the tube cross section shape and a number indicating the diameter in eighths of an inch. A T-8 lamp has a tubular bulb of 1 in. diameter. Smaller diameter lamps and lower height ballasts can result in "thinner" luminaires. Generally speaking, the thinner tubes offer increases in efficiency because the wall of the tube is closer to the internal arc path. They are also somewhat more temperamental because they want to run hotter for this reason, and are more sensitive to cold air or drafts.

85. Compact Fluorescent Lamps. The newest types of fluorescent lamps are compact lamps ranging in wattage from 5 to 50 W (Fig. 10.39). Utilizing T-4 or T-5 tubing, the basic lamp is formed in a biaxial or twin-tube shape with a single-end base. Other types have been added which employ double, triple, or quad twin-tube designs resulting in a more compact lamp design for a given lamp wattage.

The lower wattage twin-tube lamps are preheat designs with internal starters in the lamp base. The higher lumen twin-tube lamps are a rapid-start design with 4-pin bases. The double and triple twin-tube types have both preheat designs with internal starters and two-pin bases, and rapid start designs with 4-pin bases for external starters. Dimming systems are available for rapid-start designs.

Double, triple, and quad twin-tube lamps with integral ballasts in the lamp base in addition to twin-tube and double twin-tube lamps utilizing plug-in adapters with built-in ballasts are available for replacement in medium-base incandescent fixtures where general service incandescent lamps ranging in size from 25 to 100 W are installed. When replacing incandescent lamps with compact fluorescent lamps, care must be taken to ensure that the optical and thermal characteristics of the fixture will result in satisfactory compact fluorescent lamp performance.

The newer corkscrew configurations offer improvements in lamp life and stability and, like other fluorescent lamps, they save significant energy. An approximate rule of thumb is to take the incandescent wattage and divide by four to get the replacement CFL wattage. Fig. 10.40 shows a 14 W lamp, rated as equivalent to a 60 W lamp in output while increasing the relamping interval by a factor of eight. When a cold lamp is first turned on, the

FIGURE 10.39 Compact fluorescent lamps. [General Electric Co.]

brightness is about 80% of full, and full brightness is reached in about a minute. Different color temperatures are available, allowing the owner to select a warmer or cooler white. There are even multistage CFLs available to replace multiwattage incandescent lamps (e.g., 50 W-100 W-150 W incandescent lamps in three-way sockets; see Fig. 10.62) widely used in floor and table lamps. Be careful to read and observe any limitations placed on these lamps by their manufacturer. Some are limited to dry locations; others need only be protected from direct exposure to water; and most (but not all) must not be used with a dimmer.

Higher wattage compact fluorescent lamps provide the opportunity for efficient and smaller fluorescent luminaires for general lighting applications. A new type of compact

FIGURE 10.40 A new, twisted-tube CFL. As can be seen to the left, this one has a double-contact base, so it can operate at three different wattages.

fluorescent lamp utilizes the glass tube formed in the shape of a square (similar to two D's back to back). Identified as a 2D lamp, they are available in several sizes from 10 to 38 W. They provide the opportunity for shallow luminaire designs for ceiling or wall mounting. The 10 $\frac{1}{2}$ - and 22 $\frac{1}{2}$ -in-long straight sizes are useful in 1- and 2-ft luminaires, and a three-lamp, 2 by 2 ft recessed luminaire with 40-W twin-tube lamps can achieve so-called "nondirectional" layouts without significant reduction in total luminaire output compared with 2 \times 4 ft units. Designers should check with lamp manufacturers about suitability for dimming.

86. Electrodes. (*Standard Handbook for Electrical Engineers*) There are two electrodes in each fluorescent lamp, one at each end, designed to operate as either "hot" or "cold" electrodes (or cathodes). Figure 10.41 shows both types.

Hot-cathode lamps contain electrodes which are usually coiled-coil (or triple-coiled) tungsten filaments coated with one or more of the alkaline-earth oxides. By suitable circuit arrangements these cathodes can be heated to an electron-emitting temperature before the arc strikes, or they may be required to act momentarily as cold cathodes until they are heated by bombardment after the lamps have started. Lamps using these cathodes may be designed to carry currents of 1 to 2 A with low voltage drop (10 to 12 V) at the electrodes. Some energy-saving types of rapid-start ballasts have disconnect elements to discontinue cathode heating after the lamp starts. The power saved is approximately 3 W per lamp. Metal shields can be used to minimize end darkening, improving lamp lumen maintenance.

FIGURE 10.41 Cathodes for fluorescent lamps.

Cold-cathode lamps are those that use electrodes of tubular form of iron or nickel which may be coated on their inside surfaces with electron-emitting materials. These cathodes operate at temperatures which limit the lamps to low-current densities. The electrode drop in these lamps is relatively high (over 50 V), but they are not subject to short life as a result of frequent instant starting.

87. Fill Gas. (*Standard Handbook for Electrical Engineers*) Droplets of liquid mercury are present in the fluorescent lamp and vaporize to a very low pressure during lamp operation. Argon is added to assist ignition of the discharge in standard lamps, while energy-saving types have an argon-krypton mixture. Certain other types use a combination of argon and neon or argon, neon, and xenon.

88. Phosphors. (*Standard Handbook for Electrical Engineers*) The chemical composition of the phosphor coating on the bulb interior surface determines the color of the light produced and, in part, lamp efficacy. Those lamps with phosphors producing good overall color rendering are generally of higher efficacy.

The bulbs of some fluorescent lamps have a single, thick inner coat of conventional "halophosphor." Adding a thin coat of more expensive, rare-earth triphosphors can provide an improved color rendering index (CRI) and increase the efficacy. When a double coat of the triphosphors is used, CRIs are 80 to 90, while retaining the higher levels of lumens per watt. Triphosphor coatings are standard on certain families of fluorescent lamps—check manufacturers' technical literature for current information, and for designations employed with superior-color lamps. Special phosphors are also used in fluorescent lamps designed for plant growth and for black-light effects.

89. Data on Fluorescent Phosphors^a

(In addition to the phosphor, manganese is usually present as an activator.)

Phosphor	Lamp color	Wavelength, nm			
		Exciting range	Sensitivity peak	Emitted range	Emitted peak
Barium silicate	Black light	180–280	200–240	310–400	346
Barium-strontium-magnesium silicate	Black light	180–280	200–250	310–450	360
Cadmium borate	Pink	220–360	250	520–750	615
Calcium halophosphate	White	180–320	250	350–750	580
Calcium tungstate	Blue	220–300	272	310–700	440
Magnesium tungstate	Blue-white	220–320	285	360–720	480
Strontium halophosphate	Greenish blue	180–300	230	400–700	500
Strontium ortho phosphate	Orange	180–320	210	450–750	610
Yttrium oxide	Orange	180–300	220–280	550–650	611
Zinc silicate	Green	220–296	253.7	460–640	525

^aAll values are given in nanometers. The nanometer, used to measure wavelength of visible radiation, is 1/1,000,000,000 m (1.0×10^{-9} m) in length.

90. Fluorescent-lamp colors. Fluorescent lamps are available in a range of strong colors and in several different whites. The saturated colors—red, pink, gold, green, and blue—are used for decorative effects, while the whites serve for both decorative and general lighting purposes. All fluorescent lamps except gold and red are white when unlighted. Different phosphors produce the different colors when lamps are lighted.

White fluorescent lamps are designed to combine three elements important in lighting effects: (1) efficacy (efficiency)—most light per dollar, (2) color-rendering properties—the ability to bring out the beauty of colored materials and objects, and (3) whiteness—their appearance in relation to either natural outdoor daylight or the traditional artificial illumination such as filament lamps.

The choice among fluorescent whites frequently involves compromise among these three elements. Obtaining the best color-rendering properties can result in a reduction in efficiency. Choice of whiteness may affect both efficiency and color-rendering properties. The descriptions below outline the effects obtained from the most popular whites.

Cool white combines high efficiency with reasonably good color rendition. It is the most widely used fluorescent-lamp color in factories, offices, and schools. It blends well with natural daylight.

Warm white provides high efficiency with a warm tone. It emphasizes orange, yellow, and yellow green at the expense of other colors. It is generally used where a warm tone is more important than color rendition.

Deluxe cool white closely simulates the appearance and color-rendering properties of natural daylight. It has been widely used in stores such as florist shops, menswear shops, and other places where excellent color rendition of natural daylight is needed. It is also used in factory and office applications in which best appearance of colors is important. It has about 25 percent lower light output than cool white.

Deluxe warm white simulates the warm, effects of filament lighting in both whiteness and color rendering. It has been used in residences, restaurants, beauty parlors, department stores, bakeries, and other places where homelike lighting effects are wanted. For types used in the home, deluxe warm white is also called soft white. Deluxe warm lamps provide almost 30 percent less light than regular cool and warm white lamps. New rare earth phosphors have been developed which provide excellent color rendition in several warm and

cool tones with no loss in light output compared with cool and warm lamps. The industry designation for these colors is RE followed by a number which indicates color rendition and color temperature. For example: RE730 has a color rendition index between 70 and 79 and a color temperature of 3000 K; RE835 has a color rendition index between 80 and 89 and a color temperature of 3500 K.

Special fluorescent-lamp colors have been developed for applications such as outdoor plastic signs, color checking and matching in the textile and printing industries, the lighting of aquariums, and the growing of indoor plants.

Daylight, soft white, and white are still available for replacement purposes in existing installations and for new installations in which their appearance or color-rendering properties are particularly suitable.

The Energy Policy Act of 1992 established minimum efficiency and color rendering index standards for the widely used linear and U-shaped fluorescent types. As a result, cool white, warm white, white, daylight, and deluxe warm white are no longer manufactured in several of the previously available lamp types for sale in the United States. The rare earth colors with comparable color temperature provide increased light output and efficiency together with greatly improved color rendition. The older colors are still available as replacements in the nonregulated lamp types.

91. Color Temperature and Color Rendering Index of Some Common Light Sources* (*Standard Handbook for Electrical Engineers*)

Light source	Correlated color temperature, K	Color rendering index
"Cool" fluorescent		
Standard cool white ES [†]	4150	62
Cool white, ES, RE741 phosphor	4100	72
Lite white, ES	4200	49
RE841 phosphor	4100	80

Blue sky	11,000–25,000	
Sun, outside of earth's atmosphere	6500	

*Check manufacturer's technical literature for current data.

[†]"ES" = Energy-saving models

92. Bases. (*Standard Handbook for Electrical Engineers*) Lamps designed for instant-start operation generally have a base at each end with a single pin connection. (In some cases instant-start lamps may have two pins at each end electrically connected.) Lamps for preheat or rapid-start operation also have a base at each end, but with two pins (connections) in each. Some manufacturers use a green base finish or print to identify fluorescent lamps which have less mercury and/or pass the toxicity characteristic leaching procedure (TCLP), and therefore are classified as nonhazardous waste in many states. Rapid-start high-output lamps have recessed double-contact bases, and T-2 subminiature fluorescent lamps have axial bases. The Circline lamp has a single four-pin connector. Compact fluorescent lamps may have single two-pin or four-pin bases. Four-pin bases are required if the lamps are to be dimmed. See Fig. 10.42 for images of the available fluorescent lamp base types. Cold-cathode lamps are also instant-start lamps and have a single contact at each end, usually in the form of a cap base.

93. Operation and starting of fluorescent-lamps. Fluorescent lamps are best adapted to operate on ac circuits with reactance ballasts. The simplest operating circuit is shown in Fig 10.43. When the luminaire is energized, current passes through the ballast, creating magnetic flux, and also preheats the electrodes at each end which makes them capable of thermionic emission. In the case of a luminaire with a starter, the starter (Fig. 10.44) opens, which opens the flow of current through the ballast. Some luminaires are simpler yet, and simply wait for someone holding their finger on the start button to release it, causing the circuit to open in the same way. In either case the collapsing magnetic field in the ballast induces a relatively high voltage across the lamp, igniting it. Once the arc is struck, the impedance of the lamp decreases to the point where, if connected directly across the line, the resulting large current might destroy the lamp. However, the ballast remains in series with the current passing through the lamp, the ballast reactance opposes the flow of current, and the luminaire functions as intended.

Ballasts increase in complexity in instances where multiple lamps are being started and where power factor must be corrected, but all fluorescent luminaires share a key performance attribute, namely: a fluorescent lamp has much lower impedance when lit than when not lit. Therefore, all fluorescent luminaires have some method of striking the arc, and controlling the passage of current after the arc has been struck.

Electronic ballasts (Sec. 106) take this to an entirely new level, because they are classified as either *rapid-start*, or *instant-start*, or *programmed start*. The latter designation is used for ballasts that contain a microprocessor programmed to preheat the cathodes and increase the starting voltage at an optimum temperature, shut off the cathodes when the arc is established, and to sense end-of-lamp life and disconnect the ballast until the lamp is replaced.

Electronic instant-start ballasts may give shorter lamp life due to harder starting that puts more burden on the electrodes than do rapid-start and programmed-start ballasts, but are lower in input wattage because there is no standby electrode heating. The savings in kilowatt-hours often makes instant-start electronic ballasts the economic choice, unless occupancy sensors (or other causes of frequent lamp cycling) turn the lighting off and on 7 or more times each day. Users should also check with electronic ballast manufacturers about level of line inrush current on starting.

94. General-line lamps. The 4-, 6-, 8-, and 13-W T-5 fluorescent lamps are generally used when space for lamps is limited and where the inherent cool light and color quality of fluorescent lamps are desired. These are preheat lamps requiring a starter, and are rapidly disappearing from new installations, but a great many are still in operation.

FIGURE 10.42 Bases used for common types of fluorescent lamps: (a) regular fluorescent lamps, and (b) compact fluorescent lamps.

FIGURE 10.43 Circuit for fluorescent lamp and simple reactor.

FIGURE 10.44 Fluorescent-lamp starter switch and socket. They are also available with an internal normally closed switch that opens in the event that the lamp will not restart after repeated tries. If this occurs, a little button pops out on the top of the starter, preventing a continuing annoyance and possible damage. The starter is easily reset when the luminaire is relamped.

The 14-W T-8, 14-W T-12, 15-W T-8 and 15-W T-12 lamps are used in homes for kitchens and mirror lighting. They are also used in stores for showcases, niches, and signs, in industrial plants for local lighting at work stations, and in portable lamps.

The 20-W T-12 lamp was one of the most widely used fluorescent lamps. It was employed in home fixtures for lighting in kitchens, bathrooms, basements, and recreation rooms. It is used in window valances and under shelving and cupboards for decorative and utilitarian lighting.

Several sizes of T-8 and T-12 lamps are available in lengths from 22 to 33 in (559 to 838 mm) for use in appliance and home applications. The 33-in 25-W T-12 is the longest lamp which can be generated from 120 V ac with a simple reactor ballast.

The 25-W T-8 [36 in (914 mm) long] is used in stores for showcase, wall-case, and perimeter lighting where its small diameter provides opportunity for good light control. Modern T-8 lamps, often with electronic ballasts, are available in sizes that make most of the preheat applications above obsolete.

The 32-W T-8 rapid-start lamp is used today in place of the former 40-W T-12 preheat lamp and its successor, the 34-W T-12. The 40-W T-12 and the 40-W T-17 instant-start lamp and 90-W T-17 preheat lamp are used only for replacement in older installations. Newer fluorescent systems provide lower lighting costs in applications for these lamps.

95. High-output rapid-start lamps. The high-output line of T-12 lamps (24- to 96-in, or 610- to 2438-mm) operates at 800 to 1000 mA. Since the lamps are of rapid-start design, two electrical contacts are required at each base. The recessed double-contact base was developed to meet this requirement and, at the same time, to eliminate any hazard from electrical shock.

A high-output rapid-start lamp gives about 40 percent more light than a conventional lamp of comparable size. Because of the higher current load and thus higher bulb-wall temperature, this lamp performs best in ventilated fixtures. Typical open-top fixtures that allow substantial amounts of upward light provide excellent ventilation. Efficient surface-mounted and recessed fixtures have also been developed.

Because of the higher bulb-wall temperature, high-output lamps perform better in low-temperature applications than 430-mA lamps. They are widely used in outdoor plastic-sign applications.

The highest-output fluorescent lamps operate at 1500 mA. These lamps are available in T-10, T-12, and a noncircular PG-17 bulb (Fig. 10.45). The PG-17 is one of the most efficient 1500-mA lamps for indoor applications. This lamp has a U- or crescent-shaped cross section. The exciting ultraviolet radiation produced within the bulb has a shorter distance to travel before striking the fluorescent material or phosphor than it would have from the center of a corresponding bulb of circular cross section. The full benefit of the greater amount of ultraviolet radiation generated is obtained with the U-shaped construction. Less opportunity is provided for reabsorption of this radiation by the mercury vapor before it strikes the phosphor. The rails along the grooves serve to keep the mercury pressure inside the bulb near the optimum value by providing cool spots, which condense out excessive mercury vapor. The bridges between the grooves assure adequate bulb strength.

FIGURE 10.45 1500-mA fluorescent lamps. [General Electric Co.]

The distribution of light from this lamp differs from that of conventional sources. The total light in the 0 to 90° zone is equal to the total in the 90 to 180° zone, but in the 0 to 30° and 150 to 180° zones for the relative light output is approximately 12 percent more than that from a tubular cross section of equal total light output. In most fixture designs this directional effect can be used to advantage.

Like the high-output lamp, 1500-mA lamps maintain their light output well at low temperatures. Again, enclosed fixtures will provide maximum output in most low-temperature applications.

For exposed lamp, outdoor applications, or indoor applications such as refrigerated rooms for meat storage, jacketed T-10 and T-12 1500-mA lamps are available.

For exposed lamp, outdoor applications, or indoor applications such as refrigerated rooms for meat storage, jacketed T-10 and T-12 1500-mA lamps are available.

96. Slimline lamps are a family of fluorescent lamps which are instant-starting, with single-pin bases. In general, they have advantages in wiring installation and maintenance over other fluorescent lamps. The rugged single-pin base combined with push-pull insertion in sockets was very popular for some time, but their single-pin base reduces the design options ballast manufacturers have to work with in terms of the latest energy saving possibilities. Slimline lamps are still available in a range of lengths and diameters to fit general and supplementary lighting needs in most fields of application. These lamps have different lengths than most of their bipin sisters, running almost 2 in. shorter. For example, a F48T12 slimline lamp is 46 in. long overall, instead of 47.78 in. for a comparable F32T8 or F34T12 bipin lamp. Do not make the assumption that you can rewire an existing slimline luminaire to a conventional rapid start luminaire by simply changing the ballast and lampholders; the luminaire will likely prove too short.

The 96T12 is the most prominent slimline lamp for general-lighting service. The maintenance advantages of the 8-ft (2.4-m) lamp result from fewer parts in the lighting systems than preheat types require for the same amount of light—lamps, sockets, ballasts, starters, and the like, being considered.

The 72T12 and 48T12 are 6- and 4-ft (1.8- and 1.2-m) companions, respectively, of the 96T12 which permit finishing out the ends of continuous rows in which the 8-ft lamp is used. These lamps are also used for general lighting when shorter fixture lengths are desired

for scale or to fit an architectural module. The 24-, 36-, 42-, 60-, 64-, and 84-in (585-, 914-, 1067-, 1524-, 1626-, and 2134-mm) T-12 lamps are used primarily in outdoor plastic-sign applications.

The 96T8 and 72T8 are available as replacements in existing installations. The smaller diameter of these lamps makes them suited for use in coves or other restricted areas. New 96T8 lamps have been introduced with high efficiency, good color rendering rare earth phosphors for use on electronic ballast systems.

The 42T6 and 64T6 are designed to fit standard 4- and 6-ft (1.2- and 1.8-m) store show-cases. Their $\frac{3}{4}$ -in diameter means minimum visual obstruction for all types of displays. The smaller diameter also permits accurate control with polished, concentrating reflectors for wall-case, show-window, cove, wall, or mural lighting and many other specialized applications.

97. Reduced-wattage fluorescent lamps in most of the widely used types and sizes have been introduced to minimize energy consumption. Depending on the lamp type, lamp wattage is reduced by 13 to 20 percent with minimal loss in light output. These lamps use krypton in place of argon as the fill gas, which reduces the voltage across the lamps. Reduced-wattage lamps are used on the same ballasts as standard lamps. They are available for use in lighting fixtures intended for 30-W and 40-W rapid-start, 90-W T-17 preheat, 96-in (2438-mm) T-8 slimline, 48-in (1219-mm) and 96-in T-12 slimline, 48-in and 96-in high-output, and 48-in and 96-in 1500-mA fluorescent lamps.

Reduced-wattage lamps are intended for use where lamp ambient temperatures are 60°F (16°C) or higher. Lamp flickering may occur where the lamp ambient temperature is below 60°F or where strong air drafts blow directly on bare bulbs.

The 40-W rapid-start lamps are available with an internal switch which removes the cathode-heating current during lamp operation after the lamp has started to reduce energy use further. Although these approaches are better than doing nothing, converting to modern T-8 or T-5 systems is preferable because of the inherent improvement in the lamp geometry relative to the internal arc.

FIGURE 10.46 Circline fluorescent lamp. Cases for fluorescent-lamp ballasts. [General Electric Co.]

98. Circline lamps. Fluorescent lamps are also made in the form of a circle. These are known as Circline lamps. Circline fluorescent lamps (Fig. 10.46) are now available in four diameters, 6, 8, 12, and 16 in. They are used in home lighting fixtures and portable lamps. They are also used for decorative lighting in restaurants, theaters, lobbies, lounges, and other commercial areas. They are adapted for some inspection processes in industry. The 6-, 8-, and 12-in-diameter lamps have a preheat type of cathode and can be operated on trigger-start ballasts. The 16-in-diameter lamp is a rapid-start lamp.

Adapters or Circline lamps, including a ballast, which permit their installation in incandescent medium-base lampholders are available. They are used in portable lamps as well as ceiling sockets for incandescent lamps.

99. Ballast life and temperatures. The conventional ballast is enclosed in a container filled with a heavy impregnating compound which congeals around the choke coils

and condenser. This serves to radiate heat and, by its compactness, to eliminate or minimize noise or hum. Since the wattage loss in the ballast creates heat, suitable ventilation must be provided in fixture design or in places where ballasts are installed to keep the temperature within safe limits. If the temperature rises too high, the capacitor will fail and cause excessive heating and eventual failure of the internal windings.

Excessive ballast temperatures may be the result of one of the following:

1. Shorted starter in preheat circuits.
2. Burned-out lamp.
3. Rectifying lamp (near the end of lamp life).
4. Line-voltage fluctuation. Certain types of ballasts are sensitive to line-voltage fluctuation and therefore overheat at higher line voltages.
5. Improper design of fixture so that ballast heat cannot be dissipated efficiently.
6. Improper location of fixture which prevents proper heat dissipation.
7. Improper selection of ballast for the type of lamps used.

At a maximum temperature of 105°C (221°F) *within the winding* or 90°C (194°F) *measured on the case* and a maximum capacitor temperature of 70°C (158°F), the expected ballast life is about 12 to 15 years, depending on the operating hours each year. An increase of 10°C (18°F) beyond these limits will cut ballast life by as much as 50 percent.

The NEC requires that all fluorescent fixtures used indoors incorporate ballast protection other than that for simple reactor ballasts, as shown in Figs. 10.48 and 10.49. In response to this Code rule Underwriters Laboratories has a standard that requires the use of Class P (protected) ballasts for indoor fixtures. Class P ballasts contain inherent (thermal devices or thermal fuses, or both, which open automatically if the maximum temperature of the ballast is exceeded. Only Class P ballasts should be used as replacements in fixtures where ballasts other than reactor types are installed.

Although external fusing of a ballast (consisting of small quick-blow glass-tube fuses rated close to the normal ballast current rating) provides some degree of ballast protection, such fuses respond only to line current and not to temperatures inside the ballast. Since some internal ballast faults will cause excessive temperatures without an increase in line current, the fuse will not sense such faults. Accordingly, all present Class P ballasts contain internal thermal devices or fuses which respond to internal temperatures. External fusing will, however, provide a backup protection for Class P ballasts, and they will afford a high degree of protection for other types of ballasts if sized according to the recommendations of fuse and ballast manufacturers.

100. Radio interference. The performance of the mercury arc of a fluorescent lamp at the electrodes is associated with an electrical instability that sets up a continuous series of radio waves. There are three ways in which these waves may reach the radio and interfere with reception:

1. Direct radiation from the bulb to the radio aerial circuit
2. Direct radiation from the electric supply line to the aerial circuit
3. Line feedback from the lamp through the power line to the radio

The direct radiation from the bulb diminishes rapidly as the radio is separated from a lamp, and this effect can be controlled by proper positioning of the radio and its aerial. The

following table shows the recommended distance of popular fluorescent lamps from an AM radio antenna to minimize the effect of direct bulb radiation. This issue is much less of a factor with FM radio, and may not arise at all depending on the listening habits of the occupants. In addition, the new electronic ballasts, operating in the 40–50 kHz range, don't impact media reception the way magnetic ballasts once did.

Recommended Distance from Lamp to AM Radio Antenna

Lamp size	Distance, ft
14-, 15-, and 20-W	4
32-W Circline	5
30-W	6
40-W	8
90-W, 72- and 96-in slimline	10

If the radio must remain within the bulb-radiation range, it will be necessary to take the following precautions.

1. Connect the aerial to the radio by means of a shielded lead-in wire with the shield grounded, or install a doublet type of aerial with twisted pair leads.
2. Provide a good ground for the radio.
3. The aerial proper must be out of bulb- and line-radiation range. The use of a correct antenna system will usually help reduce radio interference by providing a better station-signal strength.

The use of fixture-shielding material such as electrically conductive glass or special louver materials can aid in reducing radiated interference.

Interference from line radiation and line feedback can best be minimized by the proper application of line filters at each lamp or fixture. A simple form of filter is a three-section capacitor unit. One such unit per fixture, or for each 8 ft (2.4 m) of lamps in a cove, will reduce line noise by approximately 75 percent. If it is desirable to eliminate line noise completely, the inductive-capacitor type is recommended. This filter has a current-carrying capacity of 2 A, which is, for example, about the load of four 40-W lamps.

When only one or two radios are located near a fluorescent installation and the aerial circuit has been properly shielded from bulb and line radiation, a single line filter located at the radio power outlet will suffice.

When radios located in buildings adjoining the fluorescent installation are receiving line-feedback type of interference, it is practical to install a single filter such as the three-section capacitor unit at each panel box feeding fluorescent-lamp circuits.

When it is necessary to filter each lamp or fixture, the filter should be located as close to the lamps as possible. This precaution should be taken because of line radiation between lamp and filter.

The improper spacing of lampholders, resulting in poor contact with lamp base pins, can also generate interference, as can improperly grounded fluorescent fixtures. Failure to ground the neutral of branch circuits (as required in the National Electrical Code) is an additional cause. If the service lines are not properly grounded, filters will be much less effective.

Fluorescent equipment destined for homes or other places where radios are likely to be present should have the proper radio-interference filter in each fixture.

101. The temperature of the bulb has a decided effect on the efficiency of a fluorescent lamp (Fig. 10.47). The best efficiency occurs at 100 to 120°F (38 to 49°C), which is the operating temperature corresponding to an ambient room temperature of 70 to 80°F (21 to 27°C). Efficiency decreases slowly as the temperature is increased above normal but decreases very rapidly as the temperature is decreased below normal. For this reason the fluorescent lamp is not satisfactory for locations where it will be subject to wide variations in temperature. This reduction in efficiency with low surrounding air temperature can be minimized by enclosing the lamp within a clear-glass tube or by using higher-current special fluorescent lamps designed for exposed low-temperature application (Sec. 95) so that the lamp will operate at more nearly its desirable temperature (Fig. 10.48). Some CFLs apply a mercury amalgam that provides more stable lumen output over a wider range of temperatures and operating positions.

FIGURE 10.47 Effect of bulb-wall temperature on the efficiency of the fluorescent lamp.

FIGURE 10.48 Effect of surrounding air temperature on the efficiency of the fluorescent lamp.

102. The life of a fluorescent lamp is affected not only by the voltage and current supplied to it but also by the number of times it is started. Electron emission material is sputtered off from the electrodes continuously during the operation of the lamp and in larger quantities each time the lamp starts. Since life normally ends when the emission material is completely consumed from one of the electrodes, the greater the number of burning hours per start, the longer the life of the lamp. Depreciation of light output is caused principally by tube blackening and is rapid (as much as 10%) during the first 100 h but very gradual from that point on. For this reason lamps are rated commercially on the basis of the lumen output after 100 h of operation. When the emission material is exhausted, lamps on a preheat type of circuit will blink on and off as the electrodes heat but the arc fails to strike. Lamps designed for instant or rapid start will simply fail to operate. Blinking lamps should be removed from the circuit promptly to protect both the starter and the ballast from overheating.

The rated average life of a fluorescent lamp in burning hours is based upon the average life of large representative groups of lamps measured in the laboratory under specified test conditions. Many fluorescent lamps have a rated average life of 12,000 to 20,000 h at 3 burning hours per start.

With the proper ballast operating voltage within the line-voltage limits shown on the ballast label, rated lamp life should be obtained.

103. Power factor. (*Standard Handbook for Electrical Engineers*) A fluorescent lamp, by itself, is inherently a high-power-factor circuit, but the reactive ballast normally used to stabilize the arc is inherently low power factor. Since in the usual circuit the voltage drop across the ballast is approximately equal to that across the lamp arc, the resulting power factor of a single-lamp reactive-ballast circuit is on the order of 50%. For many applications this low power factor is objectionable. In single-lamp ballasts, power factor correction may be obtained by means of a capacitor shunted across the line connections or, where the lamp requires a higher voltage, by a capacitor across the transformer secondary. The two-lamp ballast, through phase displacement of the lamp currents, or series capacitors, offers a ready means of power factor correction and is usually designed to give a circuit power factor greater than 90%. Fig. 10.44 shows a representative example of this principle at work.

104. Variations in line voltage produce less effect on fluorescent lamps than on incandescent lamps, the phase relationship among line voltage, lamp voltage, and auxiliary voltage being such that lamp voltage varies inversely as the square root of the line voltage. For this reason, most fluorescent lamp ballasts are rated for a nominal circuit voltage of 120 V with an acceptable range of 110 to 125 V. Line voltage less than 110 may make starting of the arc uncertain; a voltage over 125 may overheat the ballast. Line voltage less than 110 or greater than 125 can decrease the life of the lamp. Ballasts are also available for widely employed lamp types for use on 277-V systems with an acceptable range of 254 to 289 V. In addition, ballasts are available for some lamp types for 208-, 240-, and 480-V systems. Modern electronic ballasts are often available in configurations that automatically detect and operate successfully on a full range of line voltages (see Sec. 106) from 120 to 277 V.

Fluorescent lamps generally should be operated at voltages within $\pm 10\%$ of their designed operating points for best performance. Decreased life and uncertain starting may result from operation at lower voltages, and at higher voltages there is danger of overheating of the ballast as well as decreased lamp life. One exception to this is found in the series operation of cold-cathode lamps where an adjustable voltage supply makes possible operation over a wide range of illumination levels, that is, dimmer operation such as that used in stage lighting.

105. Noise ratings of ballasts. (*Standard Handbook for Electrical Engineers*) All inductive fluorescent ballasts emit a certain amount of noise; the noise increases with the lamp current. Ballasts are noise-rated according to laboratory standards. Such a rating is only a guide for installation practice and does not attempt to specify one ballast type over another for specific installations of fluorescent lamps.

Noise ratings are designated by letter, from A, the quietest, through F. The A rating is best, for example, for home applications, in which the surrounding and competitive noise level may be at a minimum. In an industrial plant with attendant operation noises, ballast hum may be of no importance. Not all ballasts, regardless of their general noise rating, produce annoying hum or noise. Chances are that the noise potential of different ballast designs is significant only in exceptionally quiet places. Individual ballasts of any noise rating may by some chance become offensive. Likewise, the ballast hum or noise vibration may be induced into the wiring channel or fixture and may be minimized or emphasized by the method used in mounting and clamping the ballast within the fixture. Electronic ballasts are generally much quieter than magnetic ballasts and provide an "A" rating.

106. Electronic ballasts. While 60 Hz is the standard frequency for ac distribution, higher frequencies have a number of advantages in the operation of fluorescent lamps. As the

frequency increases, lamp efficacy is increased. The increase in efficacy depends on the lamp type and the frequency of power delivered to the lamp. The gain in efficacy for 40-W T-12 rapid-start lamps is shown in Fig. 10.49. In addition, ballast losses are reduced, further improving system efficiency, and ballasts can be smaller and lighter-weight since they do not require the impregnating compound used in magnetic ballasts.

FIGURE 10.49 Effect of frequency on 40-W T-12 fluorescent-lamp efficacy. [General Electric Co.]

The use of solid-state electronic elements instead of magnetic components has made all this a practical reality. (*Standard Handbook for Electrical Engineers*) It has made electronic ballasts the standard for today's fluorescent lighting systems. Some use a control chip that results in constant light output and energy consumption over a significant range of line voltages. Electronic ballasts are lighter in weight, operate cooler, and can be designed for rapid- and instant-start lamps to meet federal efficacy and FCC EMI/RFI standards. Some models permit dimming of fluorescent lamps, and can be used with appropriate sensors to compensate for changes in daylight illuminance levels. Electronic ballasts cost more than electromechanical types, but often provide swift payback for the lighting-hours usage and kilowatt-hour rates typical of commercial, institutional, and industrial applications. These ballasts operate on standard 60-Hz power systems but operate these lamps at approximately 25,000–50,000 Hz.

These systems have far surpassed their predecessors. Earlier high-frequency systems utilized central rotary or static inverters providing 360- to 400-Hz power with small capacitance- and inductance-type ballasts. These systems required separate electrical distribution systems for lighting. High-frequency systems have been used on aircraft to reduce weight with 400-Hz generators and small capacitive ballasts. In motor vehicles, lamps are operated at variable frequencies up to 500 Hz.

Many electronic components are employed in assembling electronic ballasts. Their specific designs are considered proprietary, but Fig. 10.50 gives the block diagram for basic electronic ballasts for fluorescent lamps.

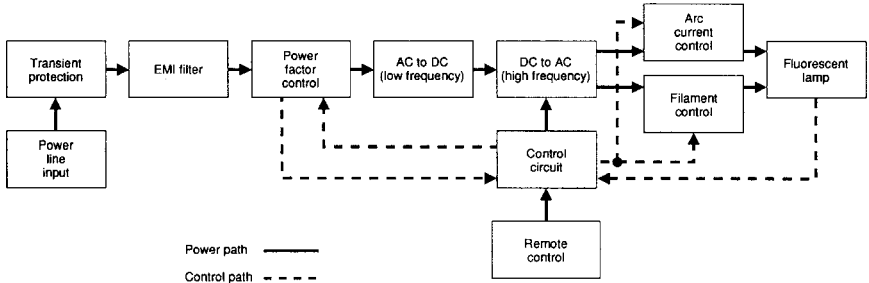

FIGURE 10.50 Basic block diagram for electronic fluorescent lamp ballast (Courtesy of Osram/Sylvania Inc.).

Most ballasts for T-2, T-4, and T-5 fluorescent lamps sense deactivated-cathode “end-of lamp life” conditions when one or more of the cathodes are depleted. This avoids a potentially hazardous situation when those small-diameter lamps are used with electronic ballasts, which could continue operating a bad-cathode lamp, perhaps causing the glass at that end to melt or crack. Some electronic ballasts for T-8 rapid-start lamps are expected to also incorporate end-of-life shutdown circuits.

107. Dimming. (*Standard Handbook for Electrical Engineers*) For dimming hot-cathode fluorescent lamps, a number of different arrangements are available. For smooth operation, the lamps on any circuit should be made by the same manufacturer, at the same time, in the same color, and of the same age in use. Group replacement is the most satisfactory procedure. Lamps should be operated free from drafts at 50 to 80°F and should be seasoned 100 h at full brightness prior to dimming. Certain energy-saving lamps are not recommended for dimming applications. Special dimming ballasts are typically required.

Dimming ballasts are available to reduce light output of T-8 and T-12 rapid-start lamps to 1%, 5%, or 10% of full lighting output. Most dimming ballasts are electronic ballasts. Standard T5 lamps can only be dimmed to 5% while T5HO can be dimmed to 1%. Compact fluorescent lamps can be dimmed to either 1% or 5%. Dimming ballasts offer slightly lower lumens per watt than non-dimming electronic ballasts. One manufacturer states that dimming from 100% to 1% and to 10% is perceived as 10% and 32% of full brightness, respectively. Various sliding and other types of wall box and wireless dimmer controls are available for dimming control, or in connection with occupant and daylight sensors for automatic energy-conservation systems. Ballasts can be controlled via analog or digital signals, and the controller must be configured to operate the type of ballasts being used. Compatibility with emergency-lighting ballasts should also be explored.

108. Harmonic loading issues. (*Standard Handbook for Electrical Engineers*) Due to the significant savings provided by electronic ballasts, most fluorescent ballasts used today in commercial luminaires are electronic. The escalation of electronic data-processing equipment and variable-speed motors increased attention given to the harmonic content of electric power systems. Fluorescent-lamp ballasts are known to contribute to total harmonic distortion (THD). Harmonics raise the current in the neutral conductor of 3-phase, 4-wire, wye-connected power distribution systems, even though the phase loads may be reasonably balanced. Some older circuits exist where reduced neutrals are used for fluorescent lighting loads. However, full 100% capacity neutral conductors have long been recommended for branch circuits consisting of more than one-half fluorescent

lighting. Indeed, some electrical engineers specify cables with single, oversized neutral conductors, cables providing a separate neutral for each phase, transformers designed to handle harmonic loading, etc.

Both electronic and magnetic ballasts generate harmonics in the line current. For electronic types, most modern fluorescent ballasts limit the total harmonic distortion to under 20% or in some cases under 10%, neither of which should create problematic current in the neutral conductor. Reported measurements of compact fluorescent lamps and diode devices for use in incandescent-lamp sockets showed power factors in the 47% to 67% range, and total harmonic distortion (THD) greater than 100%. Although electronic ballasts generally have lower THDs than do magnetic ballasts, check compliance with the requirement of most electric utilities that the THD of electronic ballasts be less than 20%.

109. Where direct current is available (*Standard Handbook for Electrical Engineers*) at circuit voltages comparable with the open-circuit voltages of the usual ac ballast circuits, fluorescent lamps may be operated from these sources. For such operation, resistance must be added to the usual series reactance ballast (transformer ballasts are not applicable) to limit the operating current to the designed value. This causes a marked reduction in the overall efficacy of the lamp and circuit combination over that obtained in ac operation. Under dc operation, lamps more than a few feet in length will promptly develop a concentration of the mercury vapor at the negative end of the lamps, with the result that only a fraction of the bulb will give off light. This condition can be overcome through a periodic (about once in 4 h) reversal of the polarity of the lines feeding the lamps. The life of lamps is likely to be shorter on dc.

110. Operating suggestions (General Electric Co.). To secure the best performance of fluorescent lamps, it is important that users understand how to maintain their fluorescent installations properly. Many factors that affect the performance of these lamps were never encountered with incandescent filament lamps, and users must realize that some of these elements of satisfactory service are within their control.

For example, if a filament lamp does not light when current is applied, the one single, positive conclusion is that the lamp is burned out or defective. No such conclusion should be made in the case of the fluorescent lamp. This lamp, though perfect in all respects, may not start or operate properly through no fault of the design or manufacture of the lamp.

Average Life. Since mortality laws apply to fluorescent as well as to filament lamps, it is not unusual for some fluorescent lamps to fail before rated life when life will last for a longer period than their rated average life to balance out the normal early failures.

Normal Failure. The electroemissive material on fluorescent-lamp electrodes is used up during the life of the lamp, the sputtering off being more rapid during starting. Therefore, a longer life will be obtained if lamps are allowed to operate continuously instead of being turned on and off frequently. Average rated life should be obtained if lamps are operated for normal periods of 3 or 4 h with each start.

When the active material on the electrodes is used up, the lamp will no longer operate. On preheat circuits, it may continue to blink on and off as the starter attempts to start the lamp. On instant-start circuits, the lamp may spiral at the end of normal life.

Swirling and spiraling. This phrase refers to all conditions in which the lighted lamp appears to fluctuate in brightness from end to end. The cause is principally particles of materials loosened from the cathode and floating in the arc stream. Such particles usually settle to the bulb when the current is turned off for a few minutes. This temporary swirling may occur in new lamps and is not serious. If swirling persists, some operating condition may be the cause of the particles being cast into the arc stream. High-impact

starting voltage may jar loose such material; this high-voltage starting may be due to (1) a ballast of inadequate design, (2) a lack of proper starting aids in trigger-start and rapid-start systems, (3) a starter in a preheat circuit that is not working properly to give adequate preheat, or (4) any other circuit condition such as low supply voltage in which neither starter nor ballast functions normally yet in which lamps may occasionally start by high-voltage impact alone without preheat.

Instant-start lamps have cathodes designed to withstand high-voltage starting. When new lamps of this type swirl persistently, the lamp may be at fault and should be replaced. At the end of normal lamp life, when no electron-emissive material remains on the cathode, the high starting voltage disintegrates even the metallic parts of the cathode, which then invade the arc stream. This is the cause of the excessive swirling that characterizes the end-of-life period of instant-start lamps.

Normal Depreciation. The lighted output at 100 h is used for rating purposes because the loss during this period may amount to as much as 10 percent. The average light output during life is approximately 90 percent of the 100-h rating value.

Blackening. A fluorescent lamp darkens rather uniformly throughout the length of the tube during life, though this is not noticed unless an old lamp is compared with a new one in front of a light source. At the end of life, the lamp usually shows a dense blackening either at one end or at both. Also, there may be dark rings, slightly brownish in color, at one end or both. On the average, there should be little indication of either blackening or rings during the first 500 h of operation. If the lamp has not given a proper length of service when this occurs, this may be due to improper starting, frequent starting with short operating periods, improper ballast equipment, unusually high or low voltage, improper wiring, or a defect in the lamp.

End blackening should not be confused with a mercury deposit which sometimes condenses around the bulb at the ends. This mercury condensation appears to be more common with the 1-in- (25.4-mm-) diameter lamps than with the 1½-in (38.1-mm) sizes. It is occasionally visible on new lamps but should evaporate after the lamp has been in operation for some time. However, it may reappear later when the lamp cools. Frequently, dark streaks appear lengthwise of the tube as small globules of mercury cool on the lower (cooler) part of the lamp. Mercury condensation is quite common on lamps in louvered units owing to the cooling effects of air circulation around the louvers.

Mercury may condense at any place on the tube if a cold object is allowed to lie against it for a short period. Such spots near the center section may not again evaporate. When condensation occurs in this manner, rotating the lamp 180° in the lampholder may give a more favorable position for evaporation or may place the spot in a less conspicuous place from an appearance standpoint.

Near the end of life, some lamps may develop a very dense spot about ½ in (12.7 mm) wide and extending almost halfway around the bulb, centering about 1 in (25.4 mm) from the base. This is quite normal, but a spot developing early in life is an indication of excessive starting or operating current. This may be due to a ballast off-rating or to an unusually high circuit voltage.

Occasionally a lamp may develop a ring or gray band at one end or at both. Such rings are usually located about 2 in (50.8 mm) from either base. These rings have no effect on the lamp performance and are no indication that a lamp is near failure and must soon be replaced.

Circuit Voltage. The circuit voltage should be within the ballast rating, although 110- to 125-V ballasts *may in some cases* give satisfactory lamp performance on circuits as low as 105 V or as high as 130 V. Ballasts designed for 265 to 277 V may sometimes give satisfactory results on line voltages as low as 260 V and as high as 285 V. Excessive undervoltage or over voltage is injurious to the lamp.

Ballast Hum. Characteristic transformer hum is inherent in lamp ballast equipment, although the noise may come and go, varying considerably with individual ballasts. If ballasts are mounted on soft rubber, neoprene, or similar nonrigid mountings, the vibrations due to the magnetic action in the chokes will not be transferred to supporting members, and disconcerting auxiliary hum will be reduced to a minimum. Such vibration insulation, however, will inhibit heat radiation and transfer to such a point that ballast ambient-temperature limits will be exceeded.

Low-Temperature Operation. In most cases, satisfactory starting and performance can be expected at temperatures considerably below 50°F (10°C) by (1) keeping the voltage in the upper half of the ballast rating, (2) conserving lamp heat by enclosure or by other suitable means, and (3) using thermal starting switches.

Starting Difficulty. Starting difficulties may be due to a number of causes other than the starter itself. In general, any difficulty in starting may result in premature end blackening and short lamp life.

A Lamp That Makes No Effort to Start. First the lamp should be checked to make sure that it is properly seated in the sockets. If this fails to correct the trouble, the lamp should be checked in another circuit, and, if necessary, the voltage can be checked at the sockets. If no indication of power is found at the sockets, the circuit connections are incorrect or the ballast is probably defective. In a preheat circuit, the starter should be checked. It may have reached the end of life and should be replaced.

A Lamp That Is Slow in Starting. Low line voltage, low ballast rating, or in preheat circuits a sluggish starter can also result in slow starting.

A Lamp the Ends of Which Remain Lighted. This condition indicates a short circuit in the starter, which should be replaced. Starters that have been in service for some time frequently fail in this manner. If the ends of a lamp in a new installation remain lighted, it is possible that the wiring is incorrect. Of course, if short-circuiting types of No-Blink or Watch-Dog (Fig. 10.44) starters are used, the lamp ends will remain lighted in a normally failed lamp; this condition automatically corrects itself when the failed lamp is replaced with a new lamp.

A Lamp That Blinks On and Off in Preheat Circuits. Blinking is the usual indication of a normal failure of a lamp. It will usually be found more convenient to put in a new starter first and then, if blinking continues, to renew the lamp. Low circuit voltage, low ballast rating, low temperature, and cold drafts may individually cause difficulties of this nature, or several of these may be contributing factors. It is also possible for improper circuit connections to cause such blinking. The annoyance of blinking lamps can be avoided by using No-Blink starters in installations employing lamps for which such special types of starters are available.

If the ends of a lamp remain lighted or the lamp blinks on and off, either the trouble should immediately be corrected or the lamp or starter should be removed from the circuit. A blinking lamp can shortly ruin both lamp and starter. Ordinary starters can be replaced with No-Blink starters (where these starters are available), which remove the starter element from the circuit if lamps fail to light after a reasonable number of attempts have been made.

Early End Blackening. Heavy end blackening early in life indicates that the active material on the electrodes is being sputtered off too rapidly. It may be due to

1. High or low voltage. For best results, the circuit voltage should be within ballast rating.
2. Loose contacts (most likely at the lampholder). Remedy: lampholders should be rigidly mounted and properly spaced. See that lamps are securely seated in lampholders.

3. Improperly designed ballasts or ballasts outside specification limits. Remedy: the use of ballasts approved by the Electrical Testing Laboratories will usually eliminate trouble of this nature.
4. In preheat circuits a defective or worn-out starter, causing the lamp to blink on and off, prolonged flashing of the lamp at each start, or the ends of the lamps remaining lighted over a period of time. Remedy: replace with a new starter.
5. Improper wiring of units.

111. Induction fluorescent luminaires. (Adapted from *Practical Electrical Wiring*, 20th edition, © Park Publishing, 2008, all rights reserved) A new form of fluorescent lighting offers a major breakthrough in terms of lower maintenance expense. The fluorescent lighting covered so far relies on electrodes within the lamp to initiate the arc discharge that creates the energy to produce what is ultimately useful light. With few exceptions, electrodes have an electron-emitting coating, and when that wears off, the lamp is burned out and must be replaced. What if there are no electrodes to burn out? Photographs of Nikola Tesla in his laboratory, taken more than a century ago, show him holding long, thin, sealed glass tubes coated internally with phosphors that produced light as he held them in the air near a high-frequency source of power, of his invention, known today as a tesla coil. Today the same process is being used to generate light, particularly in places for which the maintenance expenses associated with relamping are high, such as street lighting.

Figure 10.51 shows a streetlight that works on this principle. The base contains provisions to mount a photocell with the ballast out of sight behind it. The ballast is an induction

FIGURE 10.51 A decorative induction fluorescent streetlight. The lamp at the right, which has no electrodes, should last 25 years. The inside contour of the glass envelope of the lamp, not visible in this photo, is cylindrical in shape, extending vertically from its base almost to the top of the globe. It fits perfectly over the exciter coil wound around the outside of the vertical section of the luminaire. An attractive glass globe (not shown) completes the assembly.

generator operating at about 2.6 MHz. The generator is connected via coaxial cable to the axially located power coupler that serves as an antenna coil extending vertically out of the top of the base. A special fluorescent lamp is at the right. It is in the shape of an incandescent lamp, but it contains a small amount of mercury and internal phosphors similar to conventional fluorescent lamps, giving 3000 or 4000 K white light, and it has a comparable efficacy. The lamp has no electrodes to wear out. The light output from this 85-watt system is initially 6000 lumens, falling to a mean of 4800 lumens, with a CRI above 80. The lamp life is rated at 100,000 hours, which translates to about 25 years of evening streetlight duty. Since relamping streetlights typically involves work from a bucket truck, this reduction in maintenance overhead results in substantial savings.

This technology is available in other forms, with other lamp shapes and optics. For example, there are doughnut-shaped lamps that fit into high-bay-style downlighting suitable for industrial and warehouse applications. These directly compete with comparable HID luminaires. The principle of induction-coupled fluorescent light remains the same. For these applications, there is another benefit. In addition to the lower maintenance expense, there is no restrike time, so the lights can turn on and off at the flick of a snap switch, just like fluorescent lighting in an office.

HIGH-INTENSITY-DISCHARGE LAMPS

112. High-intensity discharge lighting covers (*Standard Handbook for Electrical Engineers*) a general group of lamps consisting of mercury, metal halide, and high-pressure sodium lamps. A mercury lamp is an electric discharge lamp in which the major portion of the radiation is produced by the excitation of mercury atoms. A metal halide lamp is an electric discharge lamp in which the light is produced by the radiation from an excited mixture of a metallic vapor (mercury) and the products of the dissociation of halides (e.g., halides of thallium, indium, sodium). A high-pressure sodium lamp is an electric discharge lamp in which the radiation is produced by the excitation of sodium vapor in which the partial pressure of the vapor during operation is of the order of 10^6 N/m², or about 10 atm.

A lamp designation system developed by the American National standards Institute (ANSI) is currently in use. It consists of five groups of letters or numbers: first a letter indicating the type of lamp (H, mercury; M, metal halide; S, high-pressure sodium), followed by an arbitrary number designating electrical characteristics (which relates to the type of ballast required), followed by two arbitrary letters which describe the physical characteristics, then the lamp nominal wattage, and finally letters indicating the phosphor color. An example for a 175-W metal halide lamp would be M57/C/175/U/MED.

113. High-intensity-discharge (HID) lamps (*Standard Handbook for Electrical Engineers*) consist of a cylindrical transparent or translucent arc tube which confines the electric discharge and the associated gases. That tube is further enclosed in a glass bulb or outer jacket to exclude air to prevent oxidation of the metal parts and to stabilize operating temperatures and significantly reduce ultraviolet radiation emitted by the excitation of the vapors. The mount structure of many HID lamps is anchored to the “dimple top” of the outer glass bulb, ensuring greater structural integrity and more accurate alignment of the arc tube. The construction of a typical mercury lamp is shown in Fig. 10.52. The basic elements are the arc tube, fabricated from fused silica and filled with a drop of mercury and a rare gas at low pressure; the electrodes; and the outer envelope, which may or may not have a phosphor coating on the interior for improved color rendering. Mercury lamps, due to their

FIGURE 10.52 Mercury lamp.

relative inefficiency and generally poor color rendering, are rarely, if ever, applied in today's lighting designs. They will be covered here because many are still in service. Refer to Fig. 10.24 and the caption thereto for the usual shape designations that apply to HID lamps.

114. The high-pressure mercury lamp consists of a quartz arc tube sealed within an outer glass jacket or bulb. The inner arc tube is made of quartz to withstand the high temperatures resulting when the lamp builds up to normal wattage. Two main electron-emissive electrodes are located at opposite ends of the tube; these are made of coiled tungsten wire. Near the upper main electrode is a third, or starting, electrode in series with a ballasting resistor and connected to the lower main-electrode lead wire.

The arc tube in the mercury lamp contains a small amount of pure argon gas which is used as a conducting medium to facilitate the starting of the arc before the mercury is vaporized. When voltage is applied, an electric field is set up between the starting electrode and the adjacent main electrode. This ionizing potential causes current to flow, and as the main arc strikes, the heat generated gradually vaporizes the mercury. When the arc tube is filled with mercury vapor, it creates a low-resistance path for current to flow between the main electrodes. When this takes place, the starting electrode and its high-resistance path become automatically inactive.

Once the discharge begins, the enclosed arc becomes a light source with one electrode acting as a cathode and the other as an anode. The electrodes will exchange functions as the ac supply changes polarity.

The quantity of mercury in the arc tube is very carefully measured to maintain quite an exact vapor pressure under design conditions of operation. This pressure differs with wattage sizes, depending on arc-tube dimensions, voltage-current relationships, and various other design factors.

Efficient operation requires the maintenance of a high temperature of the arc tube. For this reason the arc tube is enclosed in an outer bulb made of heat-resistant glass, which makes the arc tube less subject to surrounding temperature or cooling by air circulation. About half an atmosphere of nitrogen is introduced in the space between the arc tube and the outer bulb. The operating pressure for most mercury lamps is in the range of 2 to 4 times atmospheric pressure. Lamps can operate in any position. However, light output is reduced when burned in position other than vertical. Mercury lamps for lighting applications range in wattage from 40 to 1000 W. The 175- and 400-W types are the most popular. Mercury lamps are used in street lighting, industrial lighting, and outdoor area lighting. In new installations today, mercury lamps are being replaced with more efficient metal halide or high-pressure sodium systems. A typical clear mercury lamp is shown in Fig. 10.52. Some special mercury lamps are available for use in ultraviolet applications.

115. Phosphor-coated mercury lamps are the most widely used mercury lamps. Within the visible region the mercury-lamp spectrum, or energy radiated, consists of principal wavelengths. The lack of radiation in the red end results in a greenish-blue light.

When one looks at a lighted mercury lamp, the source itself appears to emit a daylight white. The absence of red radiation causes most colored objects to appear distorted in color value. Blue, green, and yellow colors of objects are emphasized, while orange and red objects appear brownish or black.

Color improvement has been incorporated in the design of mercury lamps by the use of special phosphors on the inside of the outer bulb (Fig. 10.53). The function of the phosphor is to convert the invisible ultraviolet energy into visible light in the same manner as light is produced in fluorescent lamps. The phosphor produces light principally in the red region, where the light from the arc tube is deficient.

The original color-improved phosphors provided better color appearance with a small loss in lamp efficacy. Present phosphor-coated mercury lamps utilize a vanadate phosphor which not only significantly improves color appearance but increases lamp efficacy over clear mercury lamps by 7 to 11 percent. Most phosphor-coated mercury lamps provide a cool tone of light output somewhat similar to cool-white fluorescent lamps. Lamps are also available with a phosphor that creates a warmer tone of light output close to that of incandescent lamps.

FIGURE 10.53 Phosphor-coated mercury lamp. [General Electric Co.]

116. Metal halide lamps are similar to mercury lamps in construction, in that the lamp consists basically of a quartz arc tube mounted within an outer glass bulb. However, in addition to mercury, the arc tubes contain halide salts, usually sodium and scandium iodide. During lamp operation, the heat from the arc discharge evaporates the iodides along with the mercury. The result is an increase in efficacy approximately 50 percent higher than that of a mercury lamp of the same wattage together with excellent color quality from the arc.

The amount of the iodides vaporized determines lamp efficacy and color and is temperature-dependent. Metal halide arc tubes have carefully controlled seal shapes to maintain temperature consistency between lamps. In addition, one or both ends of the arc tube are coated to maintain the desired arc-tube temperature. There is some color variation between individual metal halide lamps owing to differences in the characteristics of each lamp.

(*Standard Handbook for Electrical Engineers*) Metal halide lamps have historically been susceptible to color maintenance problems due to shifts in their color over time. Recent developments aimed to minimize the occurrence of this problem include special rounded-shape arc tubes, pulse start ignitor technology, and the use of ceramic arc tubes. Another relatively new technology is that of ceramic arc-tube metal-halide lamps. These lamps are generally available in the lower wattages, some in PAR shapes, and provide improved color consistency and very good color rendering. The clear arc tube is replaced with a short translucent ceramic arc tube of similar material to that used in a high-pressure sodium lamp.

Metal halide lamps utilize a starting electrode at one end of the arc tube which operates in the same manner as the starting electrode in a mercury lamp. A bimetal shorting switch is placed between the starting electrode and the adjacent main electrode. This switch closes during lamp operation and prevents a small voltage from developing between the two electrodes, which in the presence of the halides could cause arc-tube seal failure. A typical metal halide lamp is shown in Fig. 10.54, and Fig. 10.55 is a drawing with the parts identified.

Metal halide lamps are available in 32-, 50-, 70-, 100-, 175-, 250-, 400-, 1000-, and 1500-W sizes. There are also special halide lamps with limitations in burning positions which have higher lamp efficacy. While many metal halide lamps can be operated in any

FIGURE 10.54 Metal halide lamp. [General Electric Co.]

FIGURE 10.55 Construction of a standard metal halide lamp. (Courtesy of Osram Sylvania.)

burning position, initial light output, lumen maintenance, and life ratings change with burning position. There are also 175-W and 400-W metal halide lamps designed for special metal halide regulator type ballasts which provide higher lamp efficacy and longer life.

Although metal halide ballasts are designed to the specific starting and operating requirements for these lamps, there are several metal halide lamps which are designed to operate on certain 400- or 1000-W mercury-lamp ballasts. They provide substantially higher light output over life than the mercury lamps they have replaced. Special 250-W and 400-W metal halide lamps are available to operate on comparable wattage high pressure sodium ballasts. These lamps are intended for use in applications where the color of HPS lamps is not desired. Light output and life of the metal halide lamps is lower than with the HPS lamps.

Phosphor-coated metal halide lamps have the same external appearance as phosphor-coated mercury lamps. They are available in 175-, 250-, 400-, and 1000-W types. Although the light from the metal halide arc tube provides good color rendition, the phosphor, similarly to phosphors used in mercury lamps, adds further to the color rendition. It also provides a diffuse light source for lighting fixtures when optical characteristics are better suited to this type of lamp. Special metal halide lamps, with aluminized reflective coatings on the top of the bulb, can reduce glare and help minimize light trespass. There are PAR- and R-bulb mercury and metal halide lamps, xenon metal halide for fiber optic systems, and iodine metal halide to simulate natural daylight.

117. The ultraviolet energy produced by mercury and metal halide arc tubes is absorbed by the outer bulb in normal operations. However, in the event that the outer bulb is broken by being struck by an external object such as a basketball in a gymnasium, the arc tube, if not damaged, may continue to operate for many hours. With sufficient exposure, the ultraviolet energy from an arc tube operating without the protection of the outer bulb can cause temporary sunburn of the skin or eyes, similar to an excess exposure to the sun.

For lighting applications in open fixtures where lamps may be subject to accidental or intentional breakage, special self-extinguishing lamps are available. These lamps are designed with an internal fuse in series with the arc tube, which opens within 15 min when exposed to air, causing the arc to be extinguished.

The NEC requires that in such facilities the luminaires installed be equipped with a solid glass or plastic lens to provide containment. In addition, metal-halide lamps are known to occasionally undergo what the industry euphemistically describes as “nonpassive end-of-life failures.” For this reason the NEC requires, regardless of location, that metal halide luminaires using lamps other than thick-glass parabolic reflector (PAR) lamps must be either contained or provided with a rejection feature so they can only be relamped with a special type of lamp. These lamps, designated “Type O,” (for “open”), have been tested to contain an inner arc-tube rupture and have a longer-than usual screw-shell. They mate with a Type O lampholder, which is deep enough that any other metal-halide lamp will not be able to be screwed in far enough to meet with the center contact, preventing energization.

118. The high-pressure sodium (commonly referred to as HPS) lamp has the highest light-producing efficacy of any commercial source of white light (Fig. 10.56), with a drawing showing its internal parts in Fig. 10.57. Like most other high-intensity-discharge lamps, high-pressure sodium lamps consist of an arc tube enclosed within an outer glass bulb. The arc operates in a sodium vapor at a temperature and pressure which provide a warm color with light in all portions of the visible spectrum at a high efficacy. Owing to the chemical activity of hot sodium, quartz cannot be used as the arc-tube material. Instead, high-pressure sodium arc tubes are made of an alumina ceramic (polycrystalline alumina oxide) which can withstand the corrosive effects of hot sodium vapor.

There are coated-tungsten electrodes sealed at each end of the arc tube. The sodium is placed in the arc tube in the form of a sodium-mercury amalgam which is chemically inactive. The arc tube is filled with xenon gas to aid in starting.

High-pressure sodium lamps are available in sizes from 35 to 1000 W. They can be operated in any burning position and have the best lumen-maintenance characteristic of the three types of HID lamps. Except for the 35-W lamp, most high-pressure sodium lamps have rated lives of more than 24,000 h. The 35-W lamp has a rated life of 16,000 h. The 50-, 70-, 100-, and 150-W sizes are available in both a mogul-base and a medium-base design.

Diffuse-coated high-pressure sodium lamps are available in several wattages for use in lighting fixtures where a larger effective light-source size is desired, such as units for low

FIGURE 10.56 High-pressure sodium lamp. [General Electric Co.]

FIGURE 10.57 Construction of a typical high-pressure sodium lamp. (Courtesy of Osram/Sylvania.)

mounting height and decorative applications. The coating does not change the lamp color and reduces lamp efficacy by 5 to 7 percent.

Improved-color high-pressure sodium lamps are available in a few types with significantly better color appearance. This is achieved through a change in arc-tube pressure. The light output and life of improved-color HPS lamps are less than with the standard high-pressure sodium lamp.

Special high-pressure sodium lamps have been designed to operate on specified mercury ballasts. Lamp design is similar to that of standard high-pressure sodium lamps except that a neon-argon starting gas is used and an internal starting aid is located in the lamp to permit starting on approved mercury ballasts. These lamps can only be used on reactor or autotransformer lag-type mercury ballasts. Lamp life and efficacy are reduced for these special HPS lamps.

119. HID spectral-distribution mercury, metal halide, and high-pressure sodium lamps have significantly different color characteristics in the light produced by each type. All HID lamps produce light in definite lines or bands rather than the continuous spectrum of an incandescent lamp. The typical spectral-power-distribution curves for HID lamps are shown in Fig. 10.58.

FIGURE 10.58 Spectral characteristics of high-intensity-discharge lamps. [General Electric Co.]

IV. Phosphor-coated metal halide.

V. High-pressure sodium.

FIGURE 10.58 (Continued)

120. Application of HID lamps for general lighting. HID lamps are widely used in flood-lighting and roadway, industrial, and sports lighting and to an increasing extent in indoor commercial applications. Owing to their greater efficacy, metal halide and high-pressure sodium lamps have replaced mercury lamps in new HID installations. In addition, many mercury installations are being changed to metal halide or HPS systems. Mercury lamps are used today primarily for replacement purposes.

HPS lamps are used predominantly in applications where efficacy and lowest lighting-system operating costs are the primary factors affecting system choice. Metal halide systems are used primarily in installations where color appearance together with high efficiency are important, such as store applications or sports lighting for television.

121. Reflector-type mercury lamps are available in several wattages for use in applications where it is desirable to provide optical control of the light within the lamp. As in the case of incandescent reflector-type lamps, the sealed-in reflecting surface does not

deteriorate during the life of the lamp. Reflector-type lamps are available in 100-, 175-, 250-, 400-, and 1000-W sizes. They are used primarily in floodlighting applications. Typical types are shown in Fig. 10.59.

FIGURE 10.59 Reflector-type mercury lamps. [General Electric Co.]

122. Self-ballasted mercury lamps. All mercury lamps require a ballast to provide proper starting voltage and control the current in the lamp. Self-ballasted mercury lamps are lamps which will start with the available line voltage and contain an internal tungsten filament in series with the arc tube to limit the lamp current. The filament ballast increases the losses in the lamp. Thus, the lamp efficacy of self-ballasted mercury lamps is much lower than that of other mercury lamps. Since there is no ballast in the circuit, self-ballasted mercury lamps, like incandescent lamps, must be matched to the voltage at the socket.

123. High-intensity-discharge lamp ballasts. (*Standard Handbook for Electrical Engineers*) The practical limit of an HID lamp's current-carrying capacity is how high a temperature its enclosing tube can withstand without rupturing. By connecting an impedance in series with the lamp, the current is controlled. In most lamps about one-half the supply voltage is absorbed by a series ballasting device. As a result, unless a current-limiting device is used, the lamp current will increase until the lamp is destroyed. Ballasts for HID lamps provide three basic functions: to control lamp current to the proper value, to provide sufficient voltage to start the lamp, and to match the lamp voltage to the line voltage. Ballasts are designed to provide proper electrical characteristics to the lamp over the range of primary voltage stated for each ballast design. Most HID ballasts are designed into the luminaire. Typical ballasts are shown in Fig. 10.60.

FIGURE 10.60 Ballasts for high-intensity-discharge lamps. [General Electric Co.]

Ballasts are classified into three major categories depending on the basic circuit involved: nonregulating, lead-type regulating, and lag-type regulating. Each type has different operating characteristics.

Circuits for mercury-lamp ballasts are shown in Fig. 10.61. Reactor ballasts can be used if sufficient line voltage is available to start and operate the mercury lamp, approximately twice the lamp voltage. These ballasts have a low power factor unless corrected by a capacitor. The lag ballast consists of an autotransformer plus a reactor combined in a single structure. Performance is similar to that of a reactor, and the ballast is used where normal line voltage is lower than the required lamp-starting voltage. This ballast also has a low power factor unless corrected by a capacitor. Lag and reactor ballasts should only be used when line-voltage regulation is good, not over ± 5 percent since lamp wattage will vary ± 10 percent with a ± 5 percent change in line voltage.

The regulator ballast, also referred to as the constant-wattage (CW) or stabilized ballast, has primary and secondary windings electrically isolated from each other. A capacitor is used together with the magnetic portion of the ballast to control the lamp current. Owing to the capacitor, regulator ballasts have a high power factor. The basic advantage of regulator ballasts is their excellent regulation of lamp wattage with changes in line voltage. Lamp watts vary only ± 2 to 3 percent with line-voltage changes of ± 13 percent.

Autoregulator ballasts combine an autotransformer with the regulator circuit. As a result, these ballasts are smaller and less costly than the regulator design and have lower losses. They are also called constant-wattage-autotransformer (CWA) ballasts. The regulation of lamp wattage with line voltage is very good although somewhat less than with the regulator design: approximately a ± 5 percent change in lamp wattage with a ± 10 percent change in line voltage. Autoregulator ballasts have a high power factor. Multiple primary-voltage ratings are available by using a series of taps in the transformer. Ballasts designed for 120/208/240/277 V are available.

Two-lamp mercury-lamp ballasts are available. The circuit is basically the same as that of the single-lamp regulator ballasts except that two lamps are operated in series.

Metal halide ballasts use the same circuit as mercury autoregulator ballasts. The magnetic design is different to provide the required peaked open-circuit voltage for satisfactory

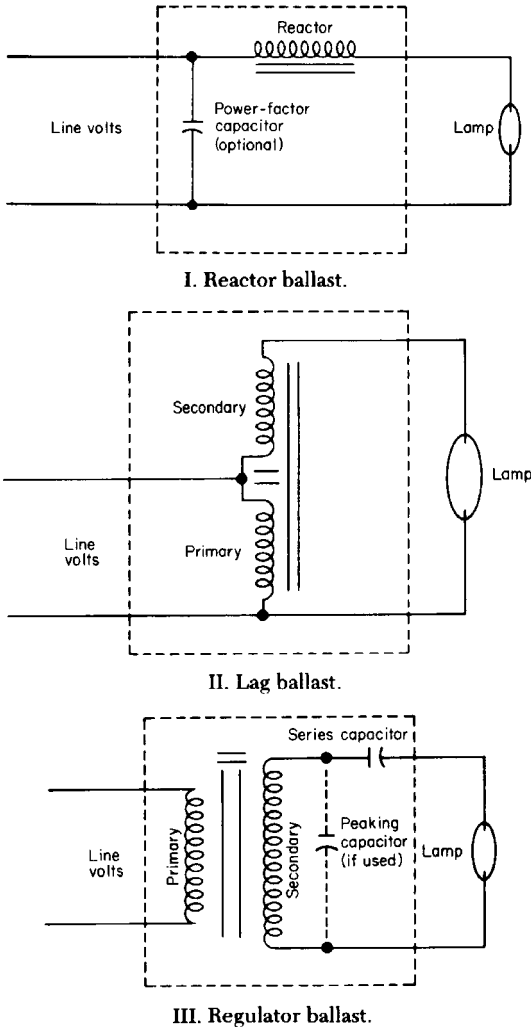

FIGURE 10.61 Mercury-lamp ballast circuits. [General Electric Co.]

lamp starting and operation. Metal halide ballasts provide a regulation of lamp wattage between those of an autoregulator and a reactor or lag ballast. With a 10 percent change in low voltage, lamp wattage will vary by about 10 percent. All-metal-halide ballasts have a high power factor.

Ballasts for high-pressure sodium lamps, in addition to providing the basic functions of all ballasts, have an additional requirement. In contrast to mercury and metal halide lamps, the voltage of high-pressure sodium lamps increases significantly during lamp life. The ballast must be able to handle this change and operate the lamp within specified limits. The voltage required to start HPS lamps is much greater than that required for mercury and

metal halide types. This necessitates an auxiliary starting circuit which supplies a low-energy, high-voltage pulse of several thousand volts. This starting aid is a separate device from the magnetic and capacitor portions of the ballast. As the result of the high-voltage starting pulse required by high-pressure sodium lamps, the lampholder for these lamps must be rated to handle this voltage.

The circuits of high-pressure sodium ballasts are shown in Fig. 10.62.

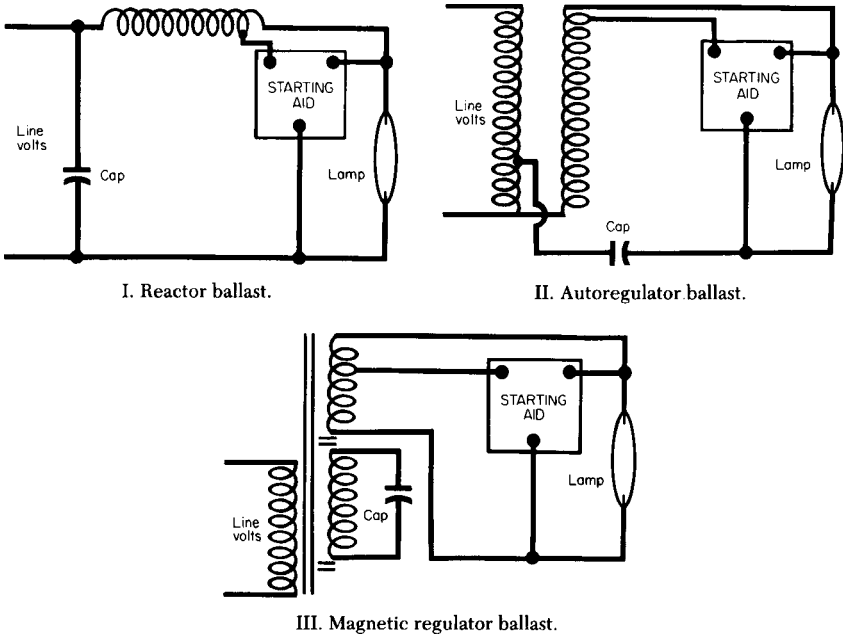

FIGURE 10.62 Circuits of high-pressure sodium lamp ballasts. [General Electric Co.]

As with mercury reactor ballasts, reactor ballasts for high-pressure sodium lamps can be used only when there is sufficient line voltage for proper lamp operation. They have a low power factor, unless corrected, and have poor regulation of lamp wattage with line-voltage variation. The required starting aid is part of the circuit.

Autoregulator and magnetic-regulator HPS ballasts are similar to mercury autoregulator and regulator ballasts, respectively, with the magnetic design changed to provide the proper lamp characteristics and the addition of the starting aid. They have regulation characteristics similar to those of mercury ballasts and have a high power factor.

As indicated with the various ballast designs, the ability of the ballast to control lamp wattage and thus light output as the line voltage changes is referred to as lamp-wattage regulation. The effect of line-voltage variation on lamp wattage for the various HID ballast designs is shown in Fig. 10.63.

Data on HID ballasts can be obtained from ballast manufacturers.

FIGURE 10.63 Effect of line-voltage variation on HID lamps. [General Electric Co.]

124. HID lamp warm-up and restrike. All high-intensity lamps require time for the arc to stabilize as its operating value and achieve full light output. This requires several minutes and is controlled by the ballast type. During the warm-up period, ballast line current and wattage will change continuously until they reach the stable operating point. Figure 10.64 shows the characteristics for a typical lag autotransformer or reactor ballast and a regulator ballast.

125. Low voltage-dip tolerance. The ability of an HID lamp to tolerate a dip in line voltage depends on ballast design. Ballasts are usually rated on their ability to tolerate dips of up to 4 s while keeping a lamp operating. Generally, nonregulating ballasts will tolerate dips of only 10 to 20 percent, while regulating ballasts will sustain lamp operation during dips in line voltage of as much as 30 to 50 percent for lag-type regulator ballasts and 20 to 40 percent for lead-type regulator ballasts. However, in HPS systems ballast dip tolerance changes over time owing to the increase in lamp voltage. After midlife of the lamp, regulating and lead types of regulator ballasts become susceptible to lamp dropout with more than 10 to 15 percent dips in line voltage. Dip tolerance of lag-type regulator HPS ballasts also changes but remains above the tolerance for lead-type regulator ballasts.

When HID lamps are extinguished owing to a voltage dip or turning the fixture off, there is a delay in restrike time until the arc tube can cool and internal pressure can drop to the level where the arc will restrike with the available voltage from the ballast. This time varies with different HID lamps. Mercury lamps will restrike in 3 to 7 min depending on the type. Metal halide lamps can take as long as 15 min to restrike, while high-pressure sodium lamps will restrike in the shortest time, usually within 1 min.

FIGURE 10.64 HID-lamp light output, lamp wattage, and line current during the lamp warm-up period.

(*Standard Handbook for Electrical Engineers*) Tungsten-halogen auxiliaries are available for HID industrial luminaires to provide standby illumination in the event of momentary power failure. For indoor and outdoor sports lighting, and other applications where instant restrike is preferable, special ignitors are available, as are special instant-restrike high-pressure sodium lamps. Metal halide lamps with a wire lead (at the end opposite the base) are used with auxiliary ignitors to achieve instant restrike. For aisle lighting in warehouses and other interior and exterior situations where illumination levels for accurate seeing are not needed all of the time, high/low electrical components, combined with occupancy detectors, transmitters, and luminaire-mounted receivers can provide major energy saving by reducing input wattage 50% to 70% during intervals when the spaces are unoccupied.

126. Line fusing of HID ballasts. There are times when line fusing of an HID ballast may be desirable, as in high-bay or other relatively inaccessible installations. The principal reason for fusing is to remove a faulty luminaire from a circuit before it causes a branch-circuit outage. A fused ballast aids in troubleshooting when a faulty ballast is encountered. Fuse ratings should meet ballast manufacturers' recommendations. Slow-blow types are desirable when available to minimize nonfault opening.

127. Remote installation of HID ballasts. Although most HID lighting fixtures have the ballast installed in the fixture, in occasional applications it is desirable to install the ballast remote from the fixture. With mercury and metal halide systems, correctly sized wire is required to maintain proper ballast voltage at the lamp socket as the primary design factor. In HPS systems, the maximum distance is limited by the characteristics of the starting aid which provides the low-energy starting pulse. The ballast manufacturer should be consulted for the remote-mounting distance limitation of HPS ballasts.

128. Effect of temperature. Excessive temperatures can result in lamp failure or unsatisfactory performance. Most HID lamps have a maximum bulb-temperature limit of 400°C (752°F) and a maximum base-temperature limit of 210°C (410°F) for mogul-base types and 190°C (374°F) for medium-base designs.

Most HID ballasts have sufficient voltage to start lamps at -29°C (-20°F). HID ballasts have maximum operating-temperature limits for reliable life performance. Ballasts designed for mounting within fixtures have a coil-temperature limit of 165°C (329°F). Enclosed ballasts are generally designed for ambient temperatures of 40°C (104°F) or less. Special high-temperature enclosed-ballast designs are available for some lamp types for ambient temperatures as high as 60°C (140°F).

129. High-intensity-discharge system troubleshooting. HID lighting systems include the power supply system (wiring, circuit breakers, and switches), lighting fixture (socket, reflector, refractor or lens, and housing), ballast, lamp, and, in outdoor fixtures, frequently a photoelectric cell to turn on the fixture at dusk. When an HID system does not operate as expected, the source of the problem can be in any part of the total system.

It is important to understand normal lamp-failure characteristics to determine whether or not operation is abnormal. All HID lamps have expected lamp-failure patterns over life; these are published by lamp manufacturers. Rated life represents the expected failure point for one-third to one-half of the lamps, depending on the lamp type and the lamp manufacturer's rating.

End-of-life characteristics vary for the different HID lamp types.

1. *Mercury.* Normal end of life is a nonstart condition or very low light output resulting from blackening of the arc tube owing to electrode deterioration during life.
2. *Metal halide.* Normal end of life is a nonstart condition resulting from a change in the electrical characteristic so that the ballast can no longer sustain the lamp. Lamp color at the end of life will usually be warmer (pinker) than that of a new lamp owing to arc-tube blackening during life that changes thermal balance in the arc tube. Metal halide lamps can have a nonpassive failure mode at the end of life. This varies with lamp type and burning position. The lamp manufacturer's recommendations regarding metal-halide lamp enclosure should be reviewed.
3. *High-pressure sodium.* Normal end of life is on-off cycling. This results when an aging lamp requires more voltage to stabilize and operate than the ballast is able to provide.

When the lamp's normally rising voltage exceeds the ballast output voltage, the lamp is extinguished. Then, after a cool-down period of about 1 min, the arc will restrike and the cycle is repeated. This cycle starts slowly at first and increases in frequency, if the lamp is not replaced, until ultimately the lamp fails owing to overheating of the arc-tube seal.

There are four basic visual variations in the lamp of an HID lighting system which indicate that a problem may exist: (1) the lamp does not start, (2) the lamp cycle is on and off or is unstable, (3) the lamp is extra bright, or (4) the lamp is dim. The following table indicates the most likely possible causes for each of these system conditions.

HID-system conditions	Possible causes	
	Other than lamp	Lamp
Lamp does not start.	Ballast failure Incorrect or loose wiring Low supply voltage Low ambient temperature broken Circuit breakers tripped Inoperative photocell Starting-aid failure (HPS)	Lamp loose in socket Incorrect lamp Normal end of life Lamp internal structure broken
Lamp cycle is on and off or is unstable.	Low supply voltage Incorrect ballast High supply voltage (HPS) Ballast voltage low System voltage dipping Fixture concentrating energy on lamp (HPS)	Normal end of life or or (HPS) Lamp operating voltage too high (HPS) Lamp arc tube unstable
Lamp is extra bright.	Shorted or partially shorted ballast or capacitor Overwattage operation	Incorrect lamp High lamp voltage
Lamp is dim.	Low supply voltage Incorrect ballast Low ballast voltage to lamp Dirt accumulation Ballast capacitor shorted Corroded connection in fixture	Incorrect lamp Low lamp voltage Lamp a hard starter

130. Low-pressure sodium lamps (Fig. 10.65) utilize sodium vapor to conduct the arc. They provide very high efficacy with light that is almost totally yellow in color. The lamps are constructed with two glass envelopes. The inner arc tube is usually U-shaped and is made of a special sodium-resistant glass. Glass can be used in low-pressure sodium lamps because the sodium vapor operates at temperatures and pressures substantially lower than those of a high-pressure sodium lamp. Electrodes are sealed into the ends of the arc tube. The arc tube is filled with a starting gas of neon with a small amount of argon. Sodium metal is placed in the arc tube. To reduce heat loss, the outer jacket is evacuated and the inside of the outer bulb is coated with an indium oxide coating that transmits light but reflects infrared energy. Low-pressure sodium lamps are available in wattages from 18 through 185 W. As with any other discharge lamp, low-pressure sodium lamps must be operated on a ballast designed to meet the lamp-starting and -operating requirements. Owing to the monochromatic yellow color of the light (consisting of a double line in the yellow region of the spectrum at 589 and 589.6 nm) from low-pressure sodium lamps, they are generally used in applications where the appearance

FIGURE 10.65 Low-pressure sodium lamp. [General Electric Co.]

of people and colors is not important. The major application of these lamps is for area lighting and streetlighting where monochromatic yellow light is acceptable and a high luminous efficacy is required. Low-pressure sodium lamps are often applied in the vicinity of astronomical observatories, since the monochromatic light can be filtered out of telescope images.

LIGHT-EMITTING DIODES (LEDS)

131. Light-emitting diodes (LEDs) represent a major new area of development in the evolution of artificial illumination. Formerly reserved for low-power signaling, they are steadily gaining power and whiteness to take their place as a source of conventional lighting. An LED is a semiconductor diode that gives off light when voltage is applied so as to electrically bias the p-n junction (refer to Div. 6, Sec. 6 and Sec. 11 for details of how this works) in the forward direction. Conventional diodes, such as those made from silicon or germanium, do not radiate in this process, but some materials such as gallium arsenide do emit visible light. LEDs inherently radiate incoherently but in a narrow spectrum, and as such are useful as indicators. Recently, however, methods have been found to produce white light from this process. One approach is to sandwich an indium gallium nitride (InGaN) semiconductor in a cladding layer of gallium nitride (GaN). The InGaN radiates at about 460 nm (dark blue) and the GaN emits in the green range. If this combination is covered with a phosphor in the yellow range (typically yttrium aluminum garnet crystals doped with trivalent cerium (Ce^{+++} :YAG) the blue light combines with the yellow from the phosphor. Since yellow is a combination of red and green, the eye perceives the resulting mix as red, green, and blue, which makes a very passable approximation of white. There are other approaches under active investigation, including the use of nanotechnology to apply special coatings to blue LEDs.

The efficacy of white LED light sources has been steadily moving forward as well. The highest efficacy commercially available is somewhat over 100 lm/W, which equals or exceeds a very good fluorescent source and approaches the best high-pressure sodium sources. This is a fast-moving target, and values even higher than this have been claimed in a number of research facilities. The absolute theoretical maximum for any source is 683 lm/W; this is the coefficient of the definite integral that defines luminous flux (see Sec. 15.)

NEON LAMPS

132. High-voltage neon lamps (Fig. 10.66) consist of two terminals or electrodes set into the opposite ends of a glass tube which contains neon, helium, or argon gas, with or without mercury, at low vapor pressure. Refer to Div. 9, Sec. 460 for NEC requirements that pertain to this work. Refer to Sec. 141 for information on low-voltage neon lamps, referred to as glow-lamps.

FIGURE 10.66 Schematic diagram of gas-filled tube and transformer. [S. C. Miller and D. G. Fink, *Neon Signs*.]

As in all gaseous-discharge lamps a higher voltage is required to start the arc than is required for continuous operation. These lamps are supplied from a high-reactance transformer in which the secondary voltage falls rapidly as the current drain is increased. This feature provides the higher voltage required to start the lamp and tends to make the arc circuit stable. Even if the secondary terminals should become short-circuited, no more than full-load current will flow, so that the transformer will not be damaged. A high voltage, 2000 to 15,000 V depending on the length and diameter of the tubing and the gas used, is applied to the electrodes at the ends of the tubing by means of this transformer. Refer to Div. 9, Sec. 459 and related sections for NEC requirements that apply to this transformer.

The tubing can be made to produce a number of different colors, depending on the gas used, the color of the glass tubing, and whether or not mercury is added. Table 133 gives the colors available.

133. Colors Obtainable from Neon Tubes

(From S. C. Miller and D. G. Fink, *Neon Signs*)

Color produced	Gas used	Mercury used	Color of glass tubing used	Gas pressure, mm of mercury
Standard colors				
Red	Neon	No	Clear	10 and over
Dark red	Neon	No	Soft red	10 and over
Gold	Helium	No	Soft yellow (noviol)	3
White	Helium	No	Clear	3
Light green	Argon	Yes	Soft canary (uranium oxide)	8
Medium green	Argon	Yes	Soft yellow (noviol)	8
Light blue	Argon	Yes	Clear	8
Dark blue	Argon	Yes	Soft blue	8
Colors available but not widely used				
Soft red	Neon	No	Soft opal	10 and over
Orange	Neon	No	Soft yellow (noviol)	10 and over
Soft white	Helium	No	Soft opal	3
Dark green	Argon	Yes	Soft medium amber	8
Red lavender	Neon	No	Soft dark purple	10 and over

134. The gas pressure as given in Table 135 must be determined quite accurately during manufacture. If the pressure is too low, the resistance of the tubing and the cathode voltage drop will be high and the tendency to sputter will be great. Sputtering means that the metal of the electrode evaporates and deposits on the tube, causing the ends of the tube to blacken. This process lowers the gas pressure still further until the tube flickers and finally fails to light. If the pressure is too high, the light will not be brilliant. The gas pressure can be tested by holding a special type of spark coil (Fig. 10.67) against either the glass or the electrode wire.

FIGURE 10.67 A high-tension spark coil for testing the vacuum system. The knob at the end is used to control the intensity of the spark which appears at the metal tip of the device. [S. G. Miller and D. G. Fink, *Neon Signs*]

135. Gas Pressure Determined by Color, Using Spark-Coil Tester
(S. C. Miller and D. G. Fink, *Neon Signs*)

Coil held against	Color observed	Gas pressure, mm of mercury	Remarks
Electrode wire	Purple	200	Color visible only at edge of electrode shell
Electrode wire	Purple	150	Faint glow in tube
Electrode wire	Purple	50	Fair glow in tube
Electrode wire	Blue purple	15	Dark glow
Electrode wire	Red purple	4	
Electrode wire	Lavender	2	
Electrode wire	Light lavender	1	
Glass	Dark blue	0.25	
Glass	Light blue	0.10	
Glass	Very light blue	0.01	
Glass	Blue disappears	0.005	No glow in tube, blue haze near glass wall

136. The principal application of neon lamps is for sign lighting. They are particularly adapted for this class of illumination owing to their bright colors and the fact that the tubes lend themselves readily to the forming of letters and figures. The brilliant single-color red, blue, or green light has an eye appeal in outdoor advertising which white light cannot offer. The orange-red light of the neon tube penetrates great distances, making neon signs stand out with brilliance and sparkle even on rainy nights. The flexibility of these thin glass tubes in the forming of trademarks, special figures, and animated designs also adds to their desirability to the advertiser. Finally, the relatively low wattage (about 4 to 6 W/ft of tubing) makes the operating cost relatively low.

137. The diameter of tubing used is from 7 to 15 mm (9/32 to 19/32 in). These sizes are convenient to work with and thoroughly practical for almost all applications. The voltage required per foot of tubing varies with the diameter of the tubing, as given in Fig. 10.68. The smaller-size tubes give more brilliant light but require the greatest voltage per foot of tube.

FIGURE 10.68 The voltage per foot required to operate tubing of various diameters filled with neon gas. [S. C. Miller and D. G. Fink, *Neon Signs*]

138. The transformers are rated according to secondary voltage and short-circuit current in milliamperes. Table 140 gives a list of standard transformers with the length of tubing in feet which can be supplied by each. This length varies with the diameter of the tubing and the gas used. When it is desired to combine two different sizes and colors of tubing in series on one transformer, the chart of Fig. 10.69 can be used. Any combination of lengths which are side by side in one column in the chart can be used on the transformer whose rating is given above the chart.

For example, a 9000-V, 30-mA transformer may supply (in the first column of the chart) 20 ft (6.1 m) of 15-mm blue tubing and 16 ft (4.9 m) of 15-mm red or (in the third column) 20 ft of 15-mm red and 11 ft (3.4 m) of 12-mm blue, making a total of 36 ft (11 m) in the first case of the larger tubing and 31 ft (9.4 m) in the second case of the combination of the larger and the medium-size tubing. Note that as the diameter of the tubing is decreased, the number of feet which can be supplied decreases on account of the rise in the voltage per foot, as shown in Fig. 10.73.

139. In the makeup of signs one section of tubing usually forms two or three letters. The different sections of tubes are then connected in series with wire jumpers until as many feet of tubing have been assembled as can be handled by the transformer to be used, as determined from Table 140. In large signs several transformers, each connected to its own section of tubing, can be used. The crossovers of tubing between letters can be blocked out by winding the tubing with tape and covering it with a waterproof varnish, or the tubes can be painted with a nonmetallic opaque paint. The glass should be made perfectly clean before painting by rubbing it with a wet cloth and drying. Metallic paint (with a lead or copper base) should never be used on the tubing, as it will conduct electricity and may cause a corona discharge between the tube and the housing which will attack the glass.

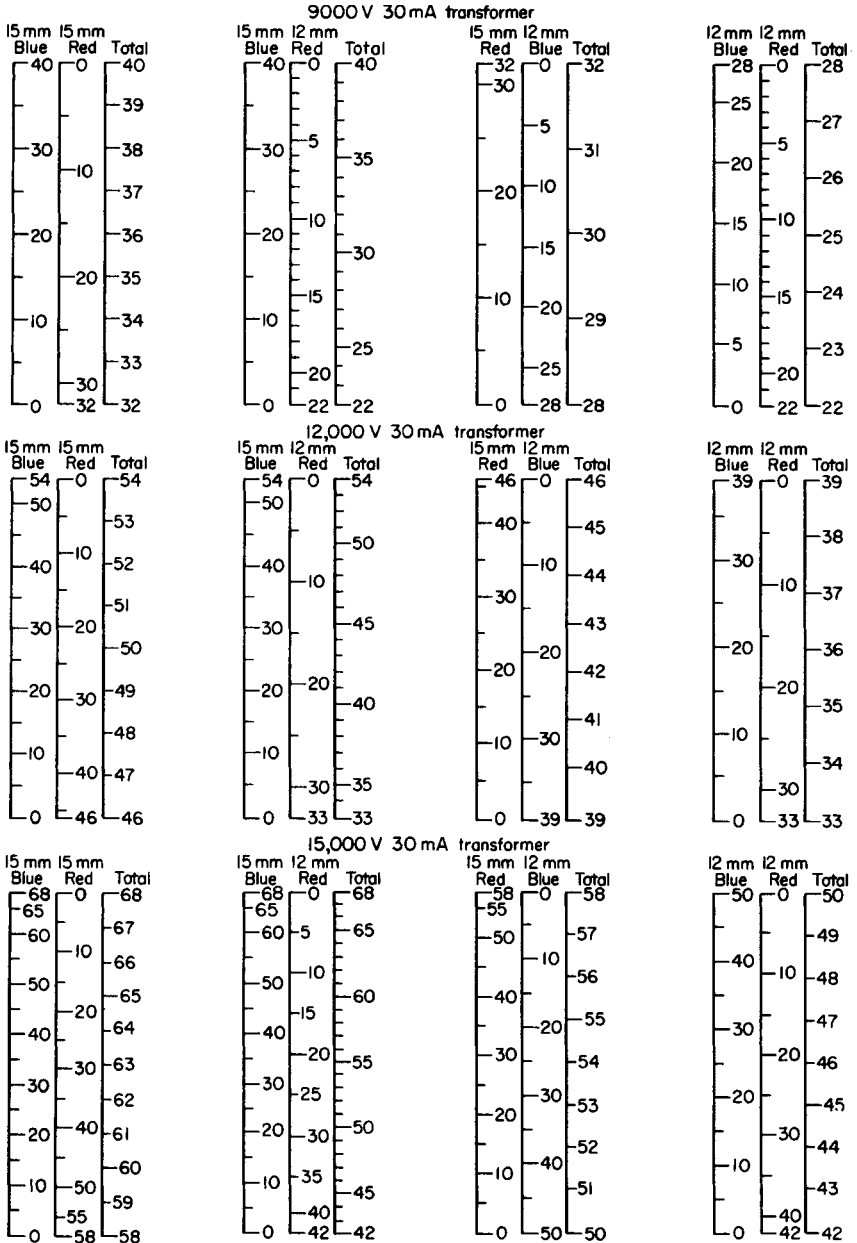

FIGURE 10.69 Chart for determining the footage of combinations of red and mercury tubing which may be run from a single transformer. [S. C. Miller and D. G. Fink, *Neon Signs*.]

^aThis chart was compiled from an average taken from various charts listed by leading transformer companies in the United States. Values given are conservative, to allow for variations in glass diameters.

141. Low-voltage neon-glow lamps (Fig. 10.70) are operated on 105- to 125-V dc or ac systems. They contain two plates to form electrodes spaced with their abutting edges about 1/16 to 1/8 in (1.6 to 3.2 mm) apart. The bulb is filled with neon gas. A high-resistance coil in the base or external is connected in series with the electrodes and serves to limit the current, no auxiliary devices being necessary. When the circuit is closed, the 110 to 125 V causes the small air space between the plates to become ionized. A glow

FIGURE 10.70 Low-voltage neon-glow lamps. [General Electric Co.]

discharge takes place between the plates and then spreads so as virtually to cover the surface of the plates. The plates are very rugged and long-lived, failure usually being due to the burning out of the series resistance. When these lamps are used on direct current, only one electrode glows, whereas on alternating current both electrodes glow. They can therefore be used as an ac, dc detector device. They may be used as pilot and indicator lamps in industry, for stroboscopic lamps in the laboratory, and as all-night lights in homes. Their low wattage, long life, and dependability make them ideal for such uses. Other glow-lamp applications in electronic circuitry include oscillators, pulse generators, voltage regulators, and coupling networks. The characteristics of neon-glow lamps are given in Table 142.

Their useful life varies approximately as the inverse of the cube of the current. A glow lamp has a negative volt ampere characteristic; hence a limiting resistance is used in series with it. In conventional screw-base types, the resistor is concealed in the base. Average lamp life ranges between 7500 and 25,000 h.

143. Argon-glow lamps, which consist of a mixture of gases, radiate mainly blue and violet and in the near-ultraviolet region. The negative glow appears blue violet. The fact that there is strong radiation in the near-ultraviolet region can be demonstrated by the fluorescent effects produced on uranium glass and many phosphorescent and fluorescent substances. Commercially, therefore, argon-glow lamps are used to some extent as convenient ultraviolet sources.

ULTRAVIOLET-LIGHT SOURCES

144. Ultraviolet-light sources are lamps which are designed primarily to produce light of wavelengths in the ultraviolet part of the spectrum (see Fig. 10.1). It should be understood that not all ultraviolet light is the same. There are at present four recognized bands of ultraviolet light. The band in which the light from any source falls depends upon the wavelength of the light emitted. Each of the recognized bands differs widely from the others in its characteristics, usefulness, and field of application. The four bands are as follows: the near-ultraviolet or fluorescent region, the erythemic region, the abiotic or bactericidal region, and the Schumann region. They are listed in order of decreasing wavelength of the light, the wavelength of the near-ultraviolet being closest to that of visible light. The light from the ordinary fluorescent lamp originates as its source as light in the near-ultraviolet band. This nonvisible light is transformed into visible light by the fluorescence of the coating on the lamp tube under the influence of the near-ultraviolet light. The light output from the lamp therefore becomes visible light, so that the ordinary fluorescent lamp is not an ultraviolet-light source. However, by the use of special phosphors for the coating of fluorescent lamps, fluorescent lamps can be made to be sources of ultraviolet light.

The common methods of producing ultraviolet radiation are (1) by carbon and tungsten arcs, (2) by tungsten filaments operated at higher temperatures than in ordinary lamps, and (3) by gaseous-discharge lamps of proper design. Ultraviolet light can be used for healthful radiation as in the case of the sunlight lamps, for photographic printing, for illuminating fluorescent materials for analysis or for theatrical effects, or for the killing of germs as in the case of the germicidal lamps.

145. Black light (General Electric Co.) is the popular name for near-ultraviolet radiant energy in the 320- to 380-m μ range. The label is not a very precise one. Whether or not this energy *looks* black is debatable. Certainly it is *not* light, because the human eye is insensitive to it.

The interesting thing about black light is that when it falls on certain materials, it makes them fluoresce, that is, emit visible light. What actually occurs is a conversion of energy: the black light that falls upon the fluorescent surface is absorbed and then reradiated at longer wavelengths—wavelengths to which the eye is sensitive. So surfaces that contain or are treated with fluorescent chemicals glow, white or in color, when irradiated by black light. If the surroundings are kept dark, as they often are, the effect is that of self-luminous elements floating in space.

The weirdly beautiful and dramatic effects that black light makes possible account for its popularity in decoration, display, and advertising. In its many and rapidly expanding workaday uses, black light makes it possible to see things that otherwise could not be seen.

The most important artificial sources of black light are black-light fluorescent and mercury lamps. All mercury lamps used for black-light applications require external filters. Filament lamps are weak and inefficient sources of black light, and argon-glow lamps produce it in only very small quantities. Carbon arcs produce useful amounts of black light. Radiant energy from the sun and sky contains a strong black-light component.

Fluorescent black-light lamps are used in insect control. Many night-flying insects are particularly sensitive to near-ultraviolet and blue light. Black-light lamps are used in insect traps to attract the insects into the trap to be exterminated by an electric grid or trapped.

Tubular sources designated as BLB lamps, such as 4-, 6-, and 8-W T-5, 15-W T-8, and 20- and 40-W T-12 lamps, have integral filters and may be operated with the same ballasts as corresponding fluorescent lamps. The luminance of an irradiated fluorescent material is between 1 and 5 fL with printing inks and between 0.25 and 2.5 fL with interior paints, depending on the color. The apparent brightness increases considerably as the eyes become

dark-adapted. Conversely, the effectiveness of black light is greatly reduced or entirely negated by a small amount of visible light.

Data for black-light lamps are given in Table 146.

^aLength of fluorescent lamps includes standard lampholders. Length of mercury lamps is the maximum overall length.

^bRated average life for fluorescent lamps is the life when operated at 3 h per start on ballasts meeting published specifications. Rated average life for mercury lamps is the life when operated at 10 or more h per start on ballasts meeting published specifications.

^cRelative value of 100 = 8100 fluorers.

^dIntegral-filter lamp.

147. Filters (General Electric Co.). Most sources of black light produce visible light along with the ultraviolet. In the great majority of applications this visible light is undesirable. If it is not screened out by filters, it illuminates not only the luminous areas but also their surroundings. This, of course, reduces brightness contrasts and robs the display (or whatever the application may be) of its effectiveness. So almost always some sort of light-absorbing filter

is placed between the black-light source and the irradiated surface. In the case of the BLB fluorescent lamps, the filter is an integral part of the lamp.

Filters having a wide range of characteristics are used for black-light applications. At one extreme are filters that pass virtually no visible light and not very much ultraviolet; at the other extreme are deep-blue sheet glasses that transmit appreciable visible light and a great deal of near-ultraviolet. Scientifically designed black-light filters are regularly supplied in molded squares or roundels or in sheet glass. They are used in all black-light applications that require a high degree of absorption of the visible light. Some of the deep-blue sheet glasses being used as black-light filters were not originally intended for this service. But since their near-ultraviolet transmission is high, their cost is low, and they are easily cut to any desired size, they are used in many applications in which some visible light can be tolerated.

148. Applications of black light

1. Decorative purposes in the lighting of murals and show-window displays
2. Insect control
3. Advertising: producing effects in outdoor signboards
4. Inspection of cast and machined parts
5. Detection of leaks in hydraulic systems
6. Diagnostic use in medicine and biology
7. Inspection of food
8. Inspection of textiles
9. Sorting of laundry via invisible markings
10. Checking cleanliness in restaurants, dairies, etc.
11. Photoproduative processes
12. Location of mineral deposits

149. Germ-killing or bactericidal lamps, called germicidal lamps (Fig. 10.71), have been developed for use in many places for sterilizing and prevention of mold. The germ-killing lamp is a gaseous-discharge lamp consisting of a long tube containing mercury vapor and inert gases. It gives out ultraviolet radiation in the bactericidal band which kills bacteria of many kinds. Germicidal lamps are discharge lamps similar in operation to fluorescent lamps and thus require the correct ballast for proper operation. Many germicidal lamps are designed to operate on standard fluorescent-lamp ballasts.

FIGURE 10.71 Germicidal lamps. [General Electric Co.]

150. The uses for germicidal lamps

1. Storage and aging of meat. The meat when exposed to ultraviolet radiation can be kept in a warm, high-humidity atmosphere where it will age and become tender much more rapidly with no formation of mold or slime and with no loss of weight due to drying out.
2. Water sterilization.
3. Irradiation of air to prevent the spread of disease.
4. Sterilizing drinking glasses, hospital instruments, toilet seats, etc., to prevent the spread of disease.

151. Photochemical lamps (General Electric Co.) are a family of mercury lamps designed for specialized applications of ultraviolet radiation. The lamps with tubular quartz bulbs transmit the full range of generated radiation. Since these emit shortwave germicidal radiation, they must be used with utmost caution. Bare tubes must not be exposed to the eyes or skin. When lamps are used exposed, shortwave-absorbing glass filters should surround the lamp.

Ultraviolet radiation from quartz lamps is extremely useful as a catalyst in many industrial chemical processes such as polymerization, halogenation, chlorination, and oxidation. Similarly, the lamps are highly effective for ultraviolet therapy.

Quartz lamps are used by manufacturers for weathering tests on paints, dyes, and other finishes. Since a high concentration of energy from lamps is possible, a few hours' exposure may be equivalent to many days' exposure to natural sunlight. These lamps have also found widespread use in the sterilization of water. This method is particularly desirable when the taste and odor from chemical sterilization are objectionable.

Photochemical lamps are used for black-and-white printing, blueprinting, copyboard lighting, diazo printing, and vacuum-frame printing. Some lamps use an ultraviolet-transmitting glass which does not transmit far ultraviolet. These are excellent photographic lamps, since many of their strongest emission lines lie close to the maximum sensitivity of most photosensitive materials.

INFRARED HEATING LAMPS

152. Heating or drying lamps are incandescent lamps with filaments which operate at a lower color temperature (2500 instead of about 3000 K) so that most of the radiation occurs in the infrared part of the spectrum with wavelengths longer than those of visible light.

Infrared lamps (Fig. 10.72) have many uses in commercial and industrial applications for heating and drying and on farms for brooding of poultry and other animals. Important features of these lamps include rapid heat transfer, efficient operation, simple oven construction, low oven first cost, adaptability to conveyor-line production, cleanliness, and low maintenance cost. The several wattages in each bulb size permit a wide range of temperatures.

The T-3 infrared quartz lamps are capable of delivering several times the energy concentration provided by the R-40 or G-30 types of lamps. They can be used in compact trough reflectors for concentrated radiation.

153. Lamp Disposal. Fluorescent and other discharge lamps contain a relatively small amount of mercury. For example, standard 4-ft fluorescent lamps contain about 20–30 mg of mercury. The amount in high intensity discharge (HID) lamps depends on the lamp wattage. Mercury release into the environment is a concern. Small quantities of these

FIGURE 10.72 Infrared heating lamps. [General Electric Co.]

fluorescent or HID lamps placed in ordinary trash may not appreciably effect the nature or method of disposal of the trash. However, under most circumstances disposal of large quantities of lamps may be regulated.

There are varying requirements regarding lamp disposal in different areas of the country, and they may change.

Contractors and users disposing of quantities of fluorescent and HID lamps should be familiar with the regulations relating to lamp disposal in the geographic areas where they are working.

LUMINAIRES

154. Purpose of luminaires. A luminaire is a device which directs, diffuses, or modifies the light given out by the illuminating source in such a manner as to make its use more economical, effective, and safe to the eye. The luminaire includes the reflector, lamp sockets, enclosing materials, ballasts in fluorescent and HID units, and stems and canopies where used. Since the light from a bare lamp is given off approximately equally in all directions, to use the light economically some accessory is required to direct the light to the desired areas. As most lamps have a high brightness, it is desirable in producing satisfactory illumination that the eye be shielded from the source in order to reduce direct glare. In many cases the appearance of the illuminating system is of great importance, so that the luminaire must possess decorative features as well as those necessary for satisfactory illumination.

155. Distribution graphs of luminaires. The effect of a luminaire in changing the direction and distribution of the light given out by a light source is best expressed by a distribution graph. Figure 10.73 shows such a graph for a bare lamp and for the same lamp with a reflector. The graph represents the light in a single vertical plane through the center of the light unit, and it is assumed that the light in all similar vertical planes are similarly distributed. See Sec. 32, "How to Read a Photometric Graph."

FIGURE 10.73 Comparison between the distribution curve of a bare incandescent lamp and that of the same lamp equipped with a suitable reflector.

Figure 10.74 shows a sample photometric test report for a 400-W HPS luminaire. A report of this type is used in comparing luminaire with one another as to relative distribution of light, type of illumination, lumen-output efficiency, and brightness.

156. Classification of luminaires. Luminaires can be classified by several methods:

1. According to system of illumination produced
 - a. Direct
 - b. Semidirect
 - c. General diffuse or direct-indirect
 - d. Semi-indirect
 - e. Indirect
2. According to the amount that the luminaire encloses the lamp
 - a. Open
 - b. Enclosed
3. According to class of service
 - a. Industrial
 - b. Commercial and institutional
 - c. Residential
 - d. Street lighting
 - e. Floodlighting
4. According to the material used for reflection or transmission of the light
 - a. Steel
 - b. Aluminum
 - c. Opal glass
 - d. Prismatic glass
 - e. Glass and metal
 - f. Plastic
 - g. Plastic and metal
5. According to method of mounting
 - a. Suspended
 - b. Surface-mounted
 - c. Recessed or built-in
6. According to light source
 - a. Incandescent lamp
 - b. High-intensity-discharge lamp
 - c. Fluorescent lamp

PHOTOMETRIC DATA

GENERAL ELECTRIC

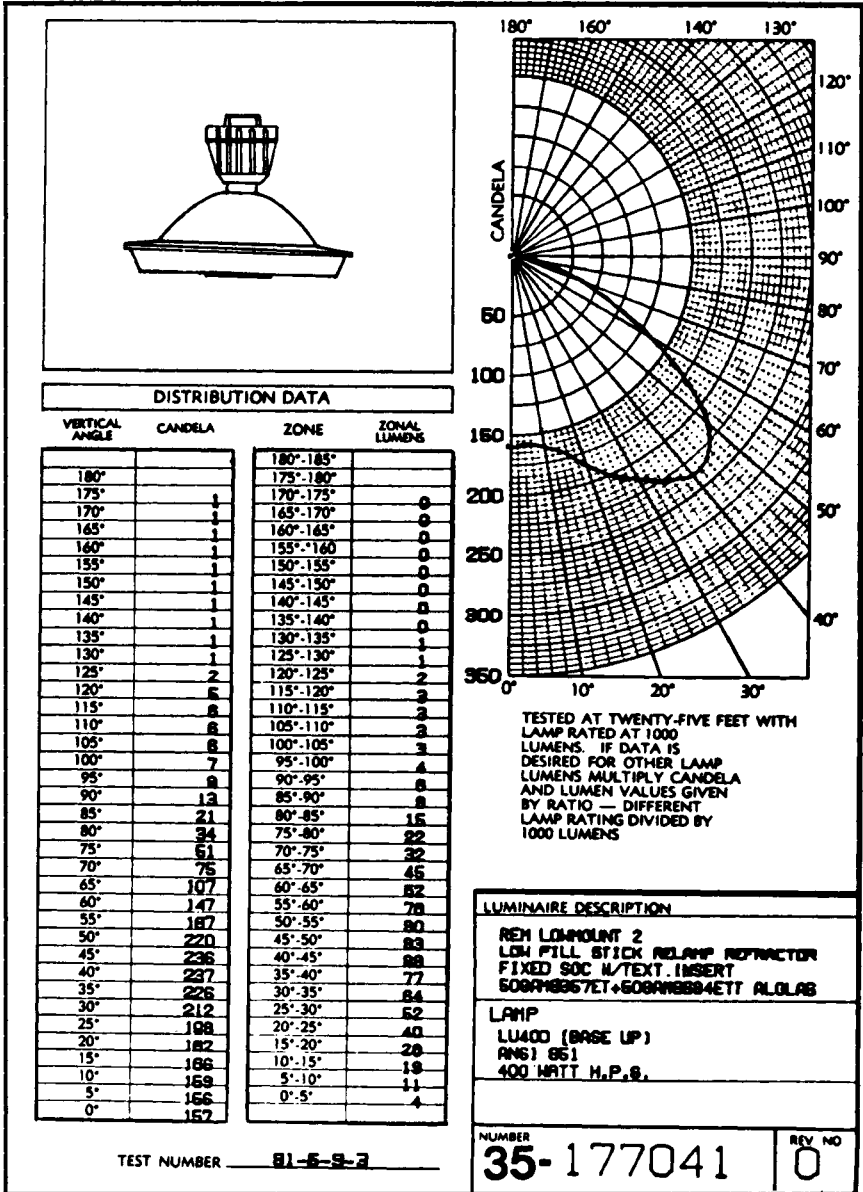

FIGURE 10.74 Photometric test report. [General Electric Co.]

157. Direct lighting is defined as a lighting system in which practically all (90 to 100 percent) of the light of the luminaires is directed in angles below the horizontal directly toward the usual working areas (Fig. 10.75, VI). This type of lighting is produced by luminaires, which range from industrial-type steel or aluminum reflectors to fixtures mounted above large light-source areas such as glass or plastic panels and skylights. Although, in general, such a system provides illumination on working surfaces most efficiently, this achievement may be at the expense of other factors such as excessive contrasts of the light source with the surroundings, troublesome shadows, or direct and reflected glare.

(*Standard Handbook for Electrical Engineers*) The distribution may vary from wide-spread to highly concentrating, depending on the reflector material, finish, and contour, and on the shielding or control media employed. Troffers and downlights are two forms of direct luminaires. Direct lighting units can have the highest utilization of all types, but this utilization may be reduced in varying degrees by brightness-control media required to minimize direct glare. Veiling reflections and shadows may be excessive unless the distribution and location of luminaires are designed to reduce these effects. Large-area units are generally also advantageous since they soften shadows. Luminous ceilings, louvered ceilings, and large-area modular lighting elements are forms of direct lighting having characteristics similar to those of indirect lighting discussed in paragraphs below. Luminous ceilings may be difficult to apply at low power densities.

158. Indirect lighting. From 90 to 100 percent of the light output of the luminaire is directed toward the ceiling at angles above the horizontal (Fig. 10.75, I). Practically all the light effective at the working plane is redirected downward by the ceiling and to a lesser extent by the sidewalls. Since the ceiling is in effect of the light source, the illumination produced is quite diffuse in character. While indirect lighting is not as efficient as some of the other systems on a purely quantitative basis, the even distribution and absence of shadows and reflected glare frequently make it the most desirable type of installation for offices, schools, and similar applications. Because room finishes play such an important part in redirecting the light, it is particularly important that they be as light in color as possible and carefully maintained in good condition. The ceilings should always have a matte finish if reflected images of the light source are to be avoided.

Glass or plastic luminaires in this classification are known as *luminous indirect*, while metal luminaires which transmit no light are *totally indirect*. The translucent type is sometimes more desirable than the totally indirect because a luminous fixture is less sharply silhouetted against the relatively bright ceiling. Indirect illumination may also be provided by means of architectural coves. Luminaire suspension length, or cove proportions, must be carefully selected to provide uniform ceiling coverage, where desired, and to prevent excessive ceiling brightness.

159. Semi-indirect lighting. From 60 to 90 percent of the light output of the luminaire is directed toward the ceiling at angles above the horizontal (Fig. 10.75, II), while the balance is directed downward. Semi-indirect lighting has most of the advantages of the indirect system but is slightly more efficient and is sometimes preferred to achieve a desirable brightness ratio between ceiling and luminaire in high-level installations. The diffusing medium employed in these luminaires is glass or plastic of a lower density than that employed in indirect equipment.

I. Indirect.

II. Semi-indirect.

III. General diffuse.

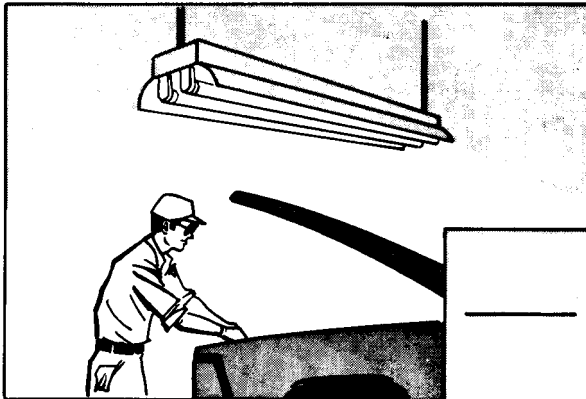

FIGURE 10.75 Systems of illumination.

IV. Direct-indirect.

V. Semidirect.

VI. Direct.

FIGURE 10.75 (Continued)

160. General diffuse or direct-indirect lighting. From 40 to 60 percent of the light is directed downward at angles below the horizontal. The major portion of the illumination produced on ordinary working planes is a result of the light coming directly from the luminaire. However, a substantial portion of the light is directed to the ceiling and side-walls. If these are light in color, the upward light provides a brighter background against which to view the luminaire, in addition to supplying a substantial indirect component which adds materially to the diffuse character of the illumination. The difference between the *general diffuse* (Fig. 10.75, III) and *direct-indirect* (Fig. 10.75, IV) classifications is in the amount of light produced in a horizontal direction. The general diffuse type is exemplified by the enclosing globe which distributes light nearly uniformly in all directions, while the direct-indirect luminaire produces very little light in a horizontal direction, owing to the density of its side panels. Glass, plastic, or louvered bottoms are commonly used with the latter type of luminaire to provide lamp shielding.

161. Semidirect lighting. From 60 to 90 percent of the light is directed downward at angles below the horizontal (Fig. 10.75, V). The footcandles effective under this system at normal working planes are primarily a result of the light coming directly from the luminaire. The portion of the light directed to the ceiling results in a relatively small indirect component, the greatest value of which is that it brightens the ceiling area around the luminaire, with a resultant lowering of brightness contrasts. Equipment of this type is exemplified by the suspended plastic-sided fluorescent luminaire or the open-bottom glass shade for incandescent lamps.

162. An open luminaire is one which only partially encloses the lamp. Open direct-lighting luminaires have the lamp exposed to view from at least one direction. The luminaires of Figs. 10.78, 10.79, 10.81, I, and 10.82 III are open-type direct-lighting units.

163. An enclosed luminaire completely encloses the lamp from view from any direction. The ones shown in Figs. 10.82, I, II, and IV, and 10.83 are enclosed direct-lighting luminaires.

164. Classification of luminaires according to class of service. Industrial service refers to use in factories and manufacturing establishments. *Commercial service* refers to use in offices, stores, and public buildings. *Residential use* means use in houses and apartments; *street lighting* means the illumination of streets, roads, and highways; and *floodlighting* means the illumination of outdoor areas such as painted signs, recreational grounds, automobile parking spaces, and building exteriors.

165. Steel reflectors have a sheet-steel base coated with porcelain enamel, paint enamel, or aluminum paint to form the reflecting surface. The best types of steel reflectors are those coated with porcelain enamel, since their reflecting surface is very efficient, durable, and easily cleaned. Paint-enamel reflectors when new are quite efficient, but the reflecting surface deteriorates very rapidly. Aluminum-painted reflectors are slightly better than paint-enamel ones but not so durable as porcelain-enamel ones.

Steel reflectors are used in the manufacture of many luminaires of the direct and indirect types.

166. Aluminum reflectors are used in many different types of luminaires. The reflecting surface is usually given an electrochemical treatment called Alzak which removes the impurities from the aluminum and endows it with a hard, durable surface which has a high reflection efficiency of approximately 90 percent. Like steel reflectors, aluminum reflectors are used in luminaires for both direct and indirect lighting.

167. Opal glass is a white diffusing glass (Sec. 10) which transmits light with a loss of only about 15 to 35 percent, the amount depending on the density of the glass. It breaks up the light rays so that the lamp is not visible and glare is kept at a minimum. Opal glass is used for enclosed diffusing luminaires for incandescent and HID lamps and for side-panel shields in some commercial fluorescent luminaires.

168. Prismatic glass consists of clear glass which is molded into scientifically designed prisms. Each prism is designed with reference to the position of the light source. By proper design, distribution curves of the extensive, intensive, or focusing types are obtained. The extensive reflector or globe refractor distributes the light over a wide angle below the horizontal (Fig. 10.76, I), the maximum intensity being at an angle of about 45° with the vertical.

Intensive reflectors, globes, and lenses (Fig. 10.76, II) throw the light directly downward, the maximum intensity occurring between 0 and 25° with the vertical.

FIGURE 10.76 Distribution characteristic curves for direct prismatic-glass luminaires. [Manville Special Products Group, Holophane Division]

Focusing globes, lenses, and reflectors (Fig. 10.76, III) concentrate the light to a small area, producing the greatest intensity of illumination along the axis of the reflector. Focusing units give an end-on candlepower approximately $3\frac{1}{2}$ times as great as the rated horizontal candlepower of the lamp. The area intensely illuminated is a circle, the diameter of which should be one-half the height of the lamp above the plane of illumination; outside this limit the intensity falls rapidly but not so abruptly as to give the effect of a spot of light. Generally focusing units give their maximum candlepowers at about 10° from the vertical.

Prismatic-glass units are used in many direct, semidirect, and semi-indirect luminaires. The different types of prismatic units employed are reflectors, globes, and lenses. Some luminaires employ only a single type of unit, and others employ a combination of types of units. Luminaires employing prismatic-glass units are available for incandescent, fluorescent, and HID lamps.

169. Combination glass-and-metal luminaires are used principally for enclosed direct-lighting units. The metal part of the unit usually direct the light, while the glass is used for diffusing purposes or simply for the enclosure of the unit so that it will be dusttight or vaportight.

170. Plastics are used to some extent in luminaires for incandescent lamps and HID lamps and to quite a great extent for fluorescent lamps. The incandescent luminaires employing plastics are of the semi-indirect type (very close to indirect). With fluorescent units plastic is used in many direct and direct-indirect luminaires for side-panel shielding. It is also used quite extensively for bottom and side enclosures of direct and semidirect fluorescent units.

171. A combination of plastic and metal is used in some fluorescent luminaires. In some units the plastic is used for side-panel shielding. In others it is used to enclose the bottom of the unit for diffusing purposes or for making the unit dusttight and vaportight.

172. Method of mounting. *Suspended mounting* refers to hanging the luminaire from the ceiling with a chain, tube, conduit, or cord-pendant suspension. *Surface mounting* refers to placing the body of the luminaire directly against the ceiling. *Recessed or built-in mounting* refers to placing the luminaire in recesses in the ceiling or on the walls or structural members, so that it forms a part of the architectural treatment of the building interior.

173. Luminaires for use with incandescent lamps are available for all classes of service. For a discussion of street-lighting and floodlighting equipment refer to Secs. 233 and 241. Incandescent luminaires for residential use are available in a great variety of types, which are too numerous to be discussed here.

174. Industrial luminaires for incandescent lamps are of either the metal or the glass-metal type. The more common types are discussed in the following sections.

175. Enameled-steel-reflector luminaires for incandescent lamps are made in several different types of assemblies. One type has a reflector and hood pressed in one piece. When the nut is loosened at the top, the reflector will slide up on the stem, exposing the socket for wiring. This is a weatherproof type for use outdoors and for indoor installations where interchangeability of reflectors and ease of cleaning are not the important considerations. With the turn-lock type of reflector, the entire reflector and socket can be removed from the supporting cap by a quarter turn and taken down for cleaning. The prongs of the turnlocking device, in addition to supporting the reflector and socket, provide the electrical connection from the socket to the circuit terminated in the cap. This type is especially advantageous in locations where the cleaning of reflectors in position is going to be difficult. The threaded-reflector type has a reflector which can be removed from the socket and hood by unscrewing. Several shapes of reflectors will fit the same hoods. Hoods are available with a threaded connection for fixture-stem suspension or with a flange having holes for mounting as the cover of a 4-in (102-mm) outlet box. With the threaded type the

reflectors can be taken down for cleaning, and different reflectors inserted in the same hood, depending on the distribution curve of light desired. The snap-on type is designed so that it can be fastened on pendant sockets. The reflector holder snaps on the reflector, and then the whole assembly screws onto the threads on the outside of an ordinary brass socket. The vaportight type (Fig. 10.77) is for interior use in wet atmospheres. It requires a cast outlet box with a threaded opening. The reflector is bolted to a ring which threads on the outside of the box opening. A threaded glass globe screws into the inside of the box opening against a gasket, which seals the box against entrance of moisture. A metal guard is used for low mounting heights or other locations where it is necessary to protect the globe from mechanical injury. The guard screws on the outside of the box opening.

III. For outlet-box mounting

FIGURE 10.77 Vaportight units. [Miller Lighting, Hubbell Lighting Division]

These enameled-steel-reflector assemblies are all available in several shapes for specific purposes as shown in Figs. 10.78 and 10.79. The flat cone (Fig. 10.78, I) and the shallow bowl (Fig. 10.78, II) are used for yard and aisle lighting for wide distribution of light when the quality of the light is unimportant and glare from the partially exposed lamp is not objectionable. The RLM dome (Fig. 10.78, III) is a standard dome reflector which must comply with standard specifications of the Reflector and Lamp Manufacturers as regards contour and quality of the porcelain reflecting surface. This type of reflector is commonly used for general interior industrial lighting. The deep-bowl type (Fig. 10.78, IV) is used frequently when units must be hung very low, as over workbenches. Angle reflectors (Fig. 10.79) are used in industrial lighting to supplement overhead units in very high interiors and for special types of service which require very good illumination on vertical planes. They are used also for the lighting of billboards and painted signs.

Specifically designed deep-bowl units also are available for high-bay mounting.

FIGURE 10.78 Contour outlines of typical enameled-steel reflectors with their characteristic distribution curves.

I - Reflector

II - Craneway using angle reflectors

FIGURE 10.79 Elliptical-angle steel reflector. [Benjamin Division, Thomas Industries, Inc.]

The use of silvered-bowl lamps in steel reflectors will provide well-diffused illumination.

Glass covers are available for enclosing the bottom of steel reflectors to make them dusttight.

FIGURE 10.80 Glassteel diffuser.

176. The Glassteel diffuser luminaire for incandescent light is a combination glass-and-steel direct-lighting unit which is employed for high-quality industrial lighting. It consists of a completely enclosing opal-glass globe (Fig. 10.80) mounted inside a dome-shaped, porcelain-enameled reflector. The porcelain reflector has the same general construction as the standard RLM dome reflector. Small openings in the top of the dome allow a small portion of the light to be directed to the ceiling.

This illumination of the ceiling produces natural and cheerful working conditions, whereas with the RLM dome reflectors the ceiling is left in darkness. The enclosing globe of the Glassteel diffuser shields the lamp from view and diffuses the light, reducing the glare effect. The Glassteel diffuser is made in all the types of assemblies explained above under the discussion of enameled-steel luminaires.

177. Aluminum luminaires for incandescent lamps are chiefly of the high-bay type (Fig. 10.81). They provide more accurate control of light than is obtainable with the enameled-steel reflectors and are recommended when the mounting height is high compared with the width of the area to be lighted. A concentrating type is used when the units are sufficiently high so that it is best to locate them closer together than the mounting height and for high-mounted units in narrow interiors. A spread type gives better illumination on vertical surfaces and can be used when the spacing is up to $1\frac{1}{2}$ times the mounting height. These luminaires are made in the one-piece and turn-lock types as described in Sec. 175.

Steel-clad units, which consist of an Alzak aluminum reflector protected by a porcelain-enamel steel housing, are available for severe service conditions. These units may be provided with glass covers for protection against moisture and noncombustible dust.

I. Open type.

II. Vaportight type.

FIGURE 10.81 Aluminum high-bay luminaires. [Miller Lighting, Hubbell Lighting Division]

178. Prismatic-glass luminaires for industrial use with incandescent and HID lamps are available in low-bay (Fig. 10.82, I, II, and IV) and high-bay (Fig. 10.82, III) types. The basic unit is provided with an open-bottom prismatic-glass reflector which produces semidirect illumination. When upward light is not required but protection against moisture (condensate, leakage, etc.) from the ceiling is desirable, an aluminum cover can be used over the prismatic reflector without materially affecting the downward distribution of light. Guards of either wire- or louver-type construction are available for protection of the lamp. These units, in addition to their industrial applications, are widely used in certain commercial types of buildings, such as gymnasiums and supermarkets.

Another prismatic-glass luminaire for industrial use with incandescent lamps is an all-purpose vaportight and dusttight unit. This luminaire consists of a prismatic-glass reflector-refractor and a cast-metal filter with stainless-steel supporting bails assembled to normally closed-type cam latches. This unit is shown in Fig. 10.82, II. It is used in chemical, petroleum, ordnance, generating-station, textile, woodworking, food-processing, and similar industries.

I. Low-bay enclosed industrial luminaire suitable for damp locations.

II. Low-bay general-area lighting or hazardous-area lighting; high-pressure sodium, metal halide, or mercury lamp unit.

III. High-bay metal halide, mercury, or high-pressure sodium lamp unit.

IV. Low-bay high-pressure sodium, metal halide, or mercury lamp unit.

FIGURE 10.82 Industrial-type prismatic-glass HID luminaires. [Manville Special Products Group, Holophane Division]

179. Luminaires for high-intensity-discharge lamps are generally intended for high-bay mounting in industrial interiors. Luminaires are available in enameled steel, Alzak aluminum, and prismatic-glass types. The metal units are of the same general type of construction as similar luminaires used for lighting with incandescent lamps. Refer to Secs. 175 and 177.

Prismatic-glass units are available for both high-bay and low-bay mounting (refer to Fig. 10.82). Both the high-bay and the low-bay units consist of a prismatic-glass reflector with the outside of the reflector protected by a sealed and permanently spun-on metal cover.

Other high-bay luminaires utilize reflectors with a coated-glass surface for high efficiency and easy maintenance. Enclosed high-bay fixtures are also available with internal filter systems which greatly reduce light-output depreciation due to dirt. Low-bay units are available with acrylic and polycarbonate plastic refractors. (See Fig. 10.83).

Hazardous location.

High bay.

Low bay.

FIGURE 10.83 HID industrial luminaires. [GE Lighting Systems]

180. Industrial luminaries for fluorescent lamps generally employ porcelain-enamel steel reflectors. They provide direct illumination. Both open and enclosed units are available for two- to four-lamp assemblies. The open units may be of the open- or closed-end type of construction. The tops of the reflectors may be solid or be provided with apertures (refer to Figs. 10.84, 10.85, and 10.86.) These open units may have a plain reflector, or the reflector may be fitted with a longitudinal shield or with louvers (refer to Fig. 10.87). The shield is positioned between the lamps and provides a crosswise shielding angle of approximately 27° from the horizontal. Closed units are provided with glass or plastic covers across the bottom of the luminaire. Closed units with sealed covers are available for hazardous locations (see Fig. 10.88).

Different mounting methods are shown in Fig. 10.89.

FIGURE 10.84 Partially open-end type of steel fluorescent luminaire. [Miller Lighting, Hubbell Lighting Division]

FIGURE 10.88 Closed-type fluorescent luminaire for hazardous locations. [Benjamin Division, Thomas Industries, Inc.]

FIGURE 10.89 Methods of suspension for industrial fluorescent luminaires. [Miller Lighting, Hubbell Lighting Division]

181. The ballast for fluorescent lamps is mounted in the supporting channel or base of the luminaire. The construction to accommodate the ballast for one type of luminaire is shown in Fig. 10.90.

FIGURE 10.90 Construction of a fluorescent luminaire.

182. Fluorescent luminaires for commercial lighting are made in a great variety of types. They can be obtained to produce illumination of any one of the different systems of illumination listed in Sec. 156, item 1. All the materials listed in Sec. 156, item 4, are employed for the reflection and diffusion of the light in fluorescent luminaires of the different constructions available. Probably the best method of obtaining an appreciation of the various types available is through a study of the latest catalogs of fixture manufacturers.

Commercial fluorescent luminaires may be classified as follows:

1. Large-area ceiling units
2. Troffers
3. Conventional suspended or surface units

Large-area ceiling units (refer to Figs. 10.91, 10.92, and 10.93) are available in 2- by 2-, 2- by 4-, and 4- by 4-ft (0.6- by 0.6-, 0.6- by 1.2-, and 1.2- by 1.1-m) panels which can be mounted to achieve almost any geometrical design. The luminous surface of the panels may be made of glass or plastic. Units are available for surface or recess mounting.

Translucent wall-to-wall lighting (Fig. 10.94) is illumination by means of one large luminous area. It does not employ luminaires unless the whole luminous ceiling is considered one large luminaire. The diffusing panels for wall-to-wall lighting may be of plastic or louver construction.

Troffers are fluorescent luminaires which are mounted in recesses in the ceiling so that the surface of the unit is practically flush with the ceiling. A typical troffer luminaire is shown in Fig. 10.95, and the method of installing troffers in a suspended plaster ceiling in Fig. 10.96. Troffers are available for installation in almost any type of ceiling. Troffers (Fig. 10.97) may be of the open type, louvered, or covered with a glass, prismatic-glass, or plastic cover.

Conventional suspended or surface luminaires (Figs. 10.98 and 10.99) are available in units for producing illumination of any one of the systems.

183. The size of luminaire for an incandescent lamp should be such that its wattage rating will correspond to the wattage rating of the lamp to be used with it. This is necessary for the proper distribution of light, for adequate dissipation of the heat produced by the lamp, and for prevention of excessive brightness of the unit. An exception is the use of a smaller-size lamp if an adapter is employed in the socket to bring the lamp bowl into the proper position in the luminaire. When replacing lamps, always use the same size that was used previously unless careful investigation has shown a different size to be satisfactory.

PRINCIPLES OF LIGHTING-INSTALLATION DESIGN

184. The general purpose of artificial lighting is to enable things to be seen readily. Since things are seen by the light which is reflected from them (see "Brightness," Sec. 39) into the eye, in an effective lighting installation it is necessary that the number and arrangement of lighting units render most easily seen those things which it is desired to see. To accomplish this, recognition must be made of the effect of light on the human eye.

FIGURE 10.100 Essential parts of the eye shown in section.

185. Physiological features of artificial lighting. To appreciate properly the principles of scientific lighting, it is necessary to understand the mechanism of the eye. Figure 10.100 (from *Primer of Illumination*, copyright by the Illuminating Engineering Society) shows the parts of the eye as they would appear if it were cut through from back to front vertically. In the process of seeing, the light passes through the cornea, pupil, and lens of the eye to the retina, just as in a camera

light passes through the lens to the sensitized film. The picture is formed on the retina, which is a layer made up of the ends of nerve fibers that gather into the optic nerve and go directly to the brain.

186. The optic nerve sends the picture to the brain. The lens of the eye, unlike that of the camera, automatically changes in thickness to focus or make a clear image on the retina for seeing at different distances. This focusing action is called the accommodation of the eye, and when the light is dim or bad, the focusing muscle vainly hunts for some focus which may make objects look clear and gets tired in trying to do it. The muscles

which move the eye about also get tired in the same way, and the result is eyestrain, which stirs up pain and headache just as any other overtired muscles of the body may set up an ache.

187. The iris, which gives the eye its color, serves to regulate the amount of light that reaches the eye. In very dim light it opens out, making the pupil big, as shown in Fig. 10.101, and in very bright light it shuts up as shown and thus keeps out a flood of brilliant light which might hurt the retina. The protective action of the pupil is fairly good but by no means complete, for it seldom becomes smaller than shown in the illustration, however bright the light. From a study of Fig. 10.101 we may deduce:

FIGURE 10.101 Expansion and contraction of the pupil of the eye.

1. When trying to see any object, do not allow a light to shine into the eyes, and do not face a brightly lighted area. In addition to tiring the retina, the superfluous light causes the pupil to contract, so that less light from the lighted object reaches the retina. An object which would seem well lighted in a room with dark walls and with no light shining in the eyes will appear poorly lighted in a bright room with light walls or when a light is shining in the eyes, simply because the pupil is smaller. This also explains why a higher light intensity is necessary in the daytime than at night. It is generally easier to read with the same light source in a room having dark walls than if the walls are light in color, though the total illumination on the page will probably be less. Reflected light from glossy paper produces the same effect as light surroundings. The effect produced by a light shining directly into the eyes is termed *glare* (see Sec. 38).
2. A fluctuating light causes the pupil to be constantly changing. This is very tiring to the muscles controlling the iris and if long continued may cause a permanent injury.
3. The lens of the eye is not corrected, as is a photographic lens, for color variations. It cannot focus sharply red and blue light from the same object simultaneously, although ordinarily this is not noticed. As white light is composed of all colors, it follows that we can see more clearly (i.e., objects appear sharper and more distinct) by a monochromatic light (light of only one color) than even by daylight. The light from mercury-vapor lamps closely approximates this condition.
4. Illumination should be uniform; otherwise the eye, in continually attempting to adapt itself to the unequal conditions, becomes tired as with a fluctuating light.

Correct lighting enables one to see clearly with minimum tiring of the eyes. To secure this, all the above conditions must be satisfied.

188. The requirements of a satisfactory lighting installation (Ward Harrison, *Electric Lighting*) are (1) sufficient light of unvarying intensity on all principal surfaces, whether horizontal, vertical, or oblique planes; (2) a comparable intensity of light on adjacent areas and on the walls; (3) light of a color and spectral character suited to the purpose for which it is employed; (4) freedom from glare and from glaring reflections; (5) light so directed and diffused as to prevent objectionable shadows or contrasts of intensity; (6) a lighting effect appropriate for the location and lighting units which are in harmony with

their surroundings, whether lighted or unlighted; and (7) a system which is simple, reliable, easy to maintain, and in initial and operating cost not out of proportion to the results attained. Neglect of any of these may result in an unsatisfactory installation.

189. Intensity of illumination. Although the eye is capable of adjusting itself to perceive objects over a wide range of intensities, the speed of this perception and the ability to distinguish fineness of detail are improved as the intensity increases, until the intensity becomes so great that a blinding effect is produced. An intensity of illumination that will be so high as to produce a blinding effect is, however, far above the range of intensities utilized in artificial illumination. The effect of the intensity of illumination upon the length of time required for the perception of objects is shown in Fig. 10.102A. The effect of the intensity of illumination upon the length of time required for the discrimination of detail is shown in Fig. 10.102B. From a study of the curve of Fig. 10.107A it is seen that the speed of perception increases approximately proportionally to the intensity of illumination, until an illuminatin of 5 fc (53.8 lx) is reached. Above this point the increase in speed of perception for a given increase in intensity gradually decreases. From these facts it was at one time erroneously considered that intensities of illumination above 5 fc were of little practical value in making things more clearly seen. That this is not true has been definitely proved not only by laboratory tests but also by practical tests in actual working areas. High levels of illumination have been found to result in an actual saving in dollars and cents owing to the increased production and decrease in spoilage produced by their use. Recommended values of intensities are given in Table 220.

FIGURE 10.102A Effect of intensity of illumination upon time for perception. [General Electric Co.]

FIGURE 10.102B Effect of intensity of illumination upon time required for discrimination of detail. [General Electric Co.]

190. Blink test. To have some definite and scientific way of measuring eyestrain and fatigue, the General Electric Co. devised the *blink test*. In this test the number of blinks per minute which the eye makes involuntarily are counted. This is done when the eyes are in a rested condition and then again after an hour of work at the various usual tasks of the individual under different levels of illumination. The rate of increase in blinking is taken as a measure of eye and nerve fatigue. The rate of blinking always increases somewhat with working or reading, but the higher the illumination intensity, up to at least 75 or 100 fc (807.3 or 1076.4 lx), the lower the rate of blinking, especially when attention to detail is required.

191. Elimination of glare. In designing a lighting installation the greatest care should be exercised to avoid the presence of any one of the three types of glare described in Sec. 38. So that a lighting unit in the central portion of the visual field may not produce glare, its brightness should not exceed from 2 to 3 cd/in² of apparent area. The maximum permissible brightness is, of course, influenced by the darkness of the surroundings.

No less important than the elimination of direct glare is the avoidance of reflected glare of specular reflection. Its effects are often more harmful than those due to direct glare. The use of highly polished furniture, plate-glass desktops, and glossy finishes on walls should be avoided. A large expanse of too-light-finished wall surface will cause harmful glare in offices, schoolrooms, and other locations where the occupants of the room must sit facing the wall for long periods of time. Although it is always desirable to have walls finished in light colors such as cream or buff in order to utilize as effectively as possible the light emitted by the source, the reflection factor of the lower walls should not be so high as to cause eye fatigue. For rooms in which occupants must face the walls for long periods, the reflection factor of the wall below eye level should not exceed 50 percent.

192. Production of shadows. The character of the shadow cast by an object depends upon the uniformity of the illumination in the area and upon the direction of the light falling upon the object. If the light falling upon an object is coming from one direction only, a sharp, dense shadow will be cast. As the number of directions in which light is impinging upon an object is increased, the sharpness and denseness of the shadow cast will be reduced. A shadow will still be cast even if the object is illuminated from all directions unless the intensity of the illumination is the same in all directions. Therefore, to eliminate shadows completely the illumination must be uniform and completely diffused; that is, illumination of any point will be produced by light from all directions. The less uniform the illumination is or the fewer the directions of light falling upon an object, the more dense and sharp will be the shadows cast.

The desirability of shadows in an illuminated area depends upon the nature of the installation. In no installation is it desirable to have complete uniformity of illumination, that is, illumination with no shadows or contrast in the intensity of illumination. Such illumination would produce a cold and flat effect tiresome to the eye. Nor could the shape and contour of objects be discerned. On the other hand, it is equally bad to have illumination which results in very dark, dense shadows and excessive contrasts in the intensity of illumination of different areas. Such illumination would be very hard on the eyes, owing to the continual change in the size of the pupil as the field of vision varies. When shadows are too dark, an object cannot be distinguished from its shadow; the shape of object is discernible from its shadow and without great contrast in intensity of illumination.

Shadows of the proper quality are of great value in observing objects in their three dimensions, in determining the shape of an object, and in determining irregularities in surfaces. They are of no value in the observation of plane surfaces. Shadows should never be dark and dense. If shadows are essential, they should be soft and luminous so that the object is clearly discernible from its shadow and so that there is no great marked contrast in intensity of illumination.

193. Uniformity of illumination is usually expressed as a maximum deviation from the average or mean intensity of illumination. It is not necessary to have the illumination of an area exactly uniform in order that the contrasts in the illumination of different portions will be unobservable by the eye or that the shadows will be too dense or sharp. The degree of uniformity of illumination obtained depends on the ratio of the spacing distance of the lighting units to their mounting height that should not be exceeded if satisfactory uniformity of

FIGURE 10.103 Effect of spacing of outlets on uniformity of illumination.

illumination is to be obtained. The effect of the spacing of the units upon the uniformity of illumination is illustrated in Fig. 10.103. Although this maximum spacing distance varies somewhat for reflectors distributing differently the light emitted by them, it is a good general rule to make the spacing distance equal to the mounting height. A greater spacing distance is likely to result in sharp and too dense shadows. One need not hesitate to use a closer spacing distance than that equal to the mounting height if desired, since the closer the spacing, the more uniform will be the illumination of the area. For the average installation it is best to keep the spacing distance of the units within the values recommended for specific luminaires. If the ceiling is unusually high, closer spacing distances may be advisable to reduce the density of the shadows. In the illumination of certain areas such as storage spaces, it is permissible to space the units slightly farther apart.

194. Methods of illumination. With respect to the arrangement of the light sources the methods of illumination may be divided into four classes as follows:

1. Localized
2. General
3. Group or localized general
4. Combination of general and localized

In the localized method an individual lighting unit of small wattage is supplied for each worker, machine, or workbench; the units are supported at a low level to bring the light close to the work. There is no attempt to produce uniform illumination over the total area.

With the general illumination method the lighting units are supported fairly close to the ceiling or at least at a considerable distance above the working plane. They are spaced uniformly throughout the area without special regard to the location of machinery, furniture, and the like, and at such a distance from one another as to give nearly uniform illumination.

The group method is somewhat of a compromise between the localized and general methods. The lighting units are mounted close to the ceiling or at a considerable distance above the working plane. The units are not spaced uniformly but are located with respect to the machinery, position of operators, etc., so as to give sufficient illumination for work at each machine. The illumination of the area is not uniform.

In the combination of general and localized methods uniform illumination is supplied over the complete area by means of units located according to the general method. This illumination is supplemented with local lights for certain operations that require a higher intensity than that required for the main area.

195. Comparison of methods of illumination. The localized arrangement of lighting units in industrial and most commercial applications should be a thing of the past

and should never be tolerated. It produces very dense shadows and such low intensities in the general area that it is likely to cause very serious accidents. Such a method will prove to be very harmful to the occupants of the room, owing to direct glare from the low-hung lamps, and may so blind the operators of machines that they can be severely injured.

For the great majority of installations the general method of arranging light sources is the most satisfactory. It is the method most commonly employed. For some classes of work which require a very high intensity of illumination at the working point, it would not be economical to light the whole area to this high intensity. These conditions can be satisfactorily met by means of the combination of the general and localized methods, provided the local lamps are well shielded to prevent the possibility of glare. With the combination method the ratio of local to general illumination intensity should not be greater than 10:1. In other words, if some operations require 75 fc (807.3 lx), the general illumination should be not less than $7\frac{1}{2}$ fc (80.7 lx).

In places where there are machines with large overhanging parts and in rooms with high obstructions, the group method will direct the light upon the working parts better than the general arrangement. The group method is frequently a good arrangement for rooms containing a number of similar machines arranged in rows.

196. Effect of proportions of a room. Of the light which strikes the walls of a room, only part is reflected back into the room to become useful upon the working plane. Consequently, the greater the proportion of the total light that is directed to the walls, the lower the intensity of illumination on the working plane, or, stated in another way, the greater the proportion of the total light that is directed to the walls, the larger must the lamps be to produce a given intensity on the working plane. The proportion of the light that strikes the walls depends upon the size of the room and the height at which the units are mounted. In a large room the ratio between the wall area and the floor area is less than for a small room. Thus, for the same mounting height a smaller proportion of the total light will strike the walls than in a small room. In large rooms, therefore, less light is absorbed by the walls than in small rooms.

In a room of given dimensions, if the mounting height of the units is increased, more light will fall upon the walls. One should be careful not to get the impression that it is best to mount the units as low as possible. Although less light is absorbed by the walls with low-hung units, there are other more important factors that are affected by the mounting height. As the mounting height of the units is reduced, the spacing between them must also be reduced so that uniform illumination is produced and the shadows are not too dense. The cost of installing a large number of small units is greater than that of installing a smaller number of larger units. Also, the larger-size lamps are much more efficient with respect to the number of lumens produced per watt. As a result, the saving from the use of large units mounted high more than offsets the increased absorption of light by the walls. For practically all installations it is best to mount the units as high as possible. There is less probability of glare with high-mounted units than with low-hung ones, since the units are not so likely to be in the field of view.

197. Room cavity ratios. A room cavity ratio is used as the measure of the effect of room proportions upon the useful utilization of the light given out by the luminaire. Values of room cavity ratios are given in Table 212. The room cavity ratio serves as a reference index for use with Tables 217, 218, and 219 in determining the coefficient of utilization.

198. Effect of character of finish of walls. Of the light that falls upon the walls or ceiling of a room, the percentage that is reflected back into the room depends upon the color of the wall and ceilings and the type of paint employed. The lighter the color, the greater the coefficient

of reflection. The reflection factor of two freshly painted walls of practically the same color may differ, however, by several percent, depending upon the grade of paint employed. The reflection factor of a surface decreases as time elapses after painting. The amount of this depreciation in reflecting power varies widely with different grades of paint. It is important to have the walls and ceiling light in color and to employ a good grade of paint which will have a high initial reflection factor that does not depreciate an excessive amount with age. The walls, however, should not be made so bright as to be a source of glare (see Sec. 191).

199. Location of lighting equipment. The lighting units for general illumination should be located symmetrically throughout the area to be illuminated. When the room is divided into bays by means of columns, roof trusses, or girders or when the ceiling is divided into panels, the units should be arranged symmetrically, for the sake of appearance, with respect to such architectural divisions, provided the arrangement will not interfere with the uniformity of illumination. Fluorescent luminaires generally are arranged in rows or in some other symmetrical pattern which will fit in with the architectural arrangement of the area and the utilization of the space. Incandescent and mercury-vapor units generally are arranged in the form of squares or rectangles. Typical layouts are shown in Fig. 10.104.

It is important that the units be placed at the centers of squares and not at the corners. Figure 10.105 shows a method of locating outlets which is undesirable because it gives a very low intensity of illumination near the walls compared with that at the center of the room. Figure 10.106 shows the correct method of locating outlets in the centers of the squares. In certain cases, notably in office lighting and in rooms with benches located along the walls, it may, to minimize shadows, be desirable to place the outer rows of outlets somewhat nearer the sidewalls of the room than they would be if symmetrically arranged as shown in Fig. 10.106.

In laying out a lighting installation the maximum permissible spacing distance for the production of uniform illumination and satisfactory density of shadows should be determined first. The maximum permissible spacing for direct, semidirect, or general diffusing luminaires depends upon the candlepower-distribution characteristics of the luminaire.

After the maximum spacing has been determined, locate the units on a plan of the area so that they will be positioned symmetrically with respect to architectural conditions and at the same time will not exceed the maximum permissible spacing distance.

When the outlets are located above traveling cranes, the staggered system (Fig. 10.104e) is preferable so that as the crane moves along, it cuts off the light from only one unit at a time. If it is not desired to use the staggered system, additional lighting outlets, with special shock-absorbing sockets, should be located on the underside of the crane truss so that as the crane moves along, the light from those units replaces the light from the regular outlets which are cut off by the crane.

In buildings of mill-type construction the units are usually supported on the lower chord of the roof truss or suspended from the roof purlins. When the units are mounted on the lower chord of the roof truss, the illumination near the walls at each end of the building is low. When work must be carried on in these areas, it is better to support the units from the purlins or to locate a row of angle units along each end wall.

High mounting is desirable because then the lamps are out of the way of cranes and are less apt to be broken, glare is reduced to a minimum, and in the case of a light ceiling there is more reflection and better diffusion of light. The lamps should be lowered in locations where there is horizontal overhead belting, to the level of the bottom of the belting; otherwise, a portion of the light is ineffective. It may be necessary, for the same reason, to install two or three units in an area where conditions would otherwise warrant only one unit.

(a)

Four units per bay – This is the most common system for the square bay of usual dimensions.

(b)

Four-two system – This is equivalent to three units per bay and is an alternative to four per bay where spacing allows.

(c)

Two units per bay – Usually applicable only in narrow bays where the width is less than two-thirds the length.

(d)

One unit per bay – A very common practice, but satisfactory only where bay size is no greater than the maximum permissible spacing – an unusual condition.

(e)

Staggered system – A recourse where one unit per bay is unsatisfactory and where four per bay is unnecessary. Less favorable appearance, and certain areas near walls may be inadequately lighted. Often expensive to wire.

(f)

Interspaced system – Applicable in rectangular bays where one unit per bay would exceed the permissible spacing in one direction, and where center row will not interfere with future structural arrangements, such as added office partitions.

FIGURE 10.104 Layouts of lighting units for symmetrical spacing. [General Electric Co.]

FIGURE 10.105 Incorrect arrangement of lighting units.

FIGURE 10.106 Correct arrangement of lighting units.

200. Reflection factor is the percentage of light reflected from a surface, such as a wall or ceiling, to the total light falling on the surface. The difference between the reflection factor and 100 percent represents the percentage of light which is absorbed by the surface and lost. Reflection factors for some of the common colors are given in Table 215. The reflection factor varies with the roughness of the surface as well as with the darkness of the color.

201. The coefficient of utilization is the overall efficiency of the lighting installation: the ratio of the useful lumens which get down to the working plane to the total lumens generated by the lamp. Tables 217, 218, and 219 give values for the coefficient of utilization for different types of luminaires, subdivided according to room cavity ratios and reflection factors for walls and for the ceiling. For more complete data refer to the *IES Lighting Handbook*.

202. Maintenance of lighting equipment. The intensity of illumination produced by a lighting installation will be somewhat less after the system has been in use for some time than it was when the system was first installed. This depreciation in the lighting system with time is due to the decrease in efficiency of the lamp in use and to the decrease in reflecting efficiency of the reflecting equipment, walls, and ceiling, which is the result of the natural deterioration of the surface with age and of the collection of dust and dirt.

In the design of lighting installations, a maintenance factor is used to take into account this depreciation. It has values less than unity, so that when the initial illumination is multiplied by the maintenance factor, the actual illumination after a period of several months' use will be obtained.

The amount of depreciation will vary from 25 to 45 percent, corresponding to a maintenance factor of 0.75 to 0.55, depending upon the type and material of the reflecting equipment, the system of illumination employed, the local conditions of dust and dirt, and the frequency of cleaning of equipment and repainting of walls. All lighting units should be adequately cleaned at regular intervals to prevent a waste of energy and low intensity of illumination. The frequency of the cleaning periods depends upon the degree of prevalence of dust and dirt and upon the type of luminaire.

203. Four principal methods are used in calculating illumination:

1. Point-by-point method
2. Lumen-per-foot method
3. Zonal-cavity method (general lighting)
4. Beam-lumens method (floodlighting)

204. The point-by-point method is based on the inverse-square law that the intensity of light flux varies inversely as the square of the distance from the light source to the point of measurement (see Sec. 26 and Fig. 10.107). The illumination on any plane perpendicular to the light rays is given by the following formula:

$$\text{Footcandles (on perpendicular plane)} = \frac{cd}{D^2} \quad (6)$$

where cd = the candlepower of the light source in the direction in which the distance D is taken and D = the perpendicular distance from the light source to the illuminated plane in feet.

Since the illumination of the horizontal plane is the value usually desired, the formula must be multiplied by the ratio H/D (see Fig. 10.107), or

$$\text{Footcandles (on horizontal plane)} = \frac{cd \times H}{D^3} \quad (7)$$

If the illumination on a vertical plane is desired, the basic formula (6) must be multiplied by the ratio X/D (see Fig. 10.112), or

$$\text{Footcandles (on vertical plane)} = \frac{cd \times X}{D^3} \quad (8)$$

The illumination at any point is obtained by adding the footcandles due to each light source which is sending rays of light to the point.

It is obvious that the point-by-point method is practical for use only with the direct type of lighting, for with any other system of illumination the number of light sources which would have to be considered would make the calculations prohibitively tedious. Even with the direct system it is usually necessary to calculate the footcandles from several different light sources. This method is especially applicable to calculating localized lighting when only a single light source needs to be considered.

FIGURE 10.107 Point-by-point method of lighting calculations.

205. Lumen-per-foot method (General Electric Co.). The predetermining of lighting levels for supplementary lighting systems in which continuous linear sources are used can be accomplished from empirical data based on the lumens per foot of the source. These data are adaptable for relatively short distances between the light source and the work or

display to which the inverse-square law obviously does not apply. The lumen-per-foot method employs the following formulas:

Where the lamp and reflector have been selected,

$$\text{Footcandles} = K \times \text{lumens per foot of source} \tag{9}$$

Where a footcandle level is desired,

$$\text{Necessary lumens per foot} = \frac{\text{footcandles desired}}{K} \tag{10}$$

In formulas (9) and (10) the constant K refers, respectively, to either one of two constants K_H and K_V as given in Tables 206, 207, 208, and 209 for horizontal and vertical illumination.

Two types of luminaires are specified: broad distribution as from a unit with a mat-finish reflector and narrow distribution as from a polished metal reflector. The beam in both cases is presumed to be aimed at a plane 4 ft (1.2 m) from the source through point A.

The importance of the reflector is evident from a comparison of Tables 208 and 209. The average K value at 4 ft in 208 is 0.009; in 209, 0.021. This difference is 133 percent.

The actual values from which the tables were compiled are readings taken at the midpoint of luminaires 12 ft (3.7 m) in length. For conventional lighting systems, the footcandle levels would normally drop at the end of rows unless additional lamps or lamps of higher output were provided.

206. Horizontal Illumination

(Horizontal fc = $K_H \times$ lamp lumens per foot)

^aFor lumens per foot of other colors use the following multiplying factors: deluxe cool white, 0.71; deluxe warm white, 0.71; daylight, 0.93; soft white, 0.68; green, 1.2; gold, 0.6; blue, 0.45; and pink, 0.45.

211. The zonal-cavity method. The lumen method of calculating illumination, which has been in use for many years, is based on the theory that average illumination is equal to lumens divided by the work area over which they are distributed. Newer methods of analysis of lighting distributions, taking into account the concept of interreflection of light, have led to more accurate coefficient-of-utilization data and have been adopted in the Illuminating Engineering Society (IES) approved method of lighting calculations called the *zonal-cavity method*. This method provides increased flexibility in lighting calculations, including greater accuracy, but still adheres to the basic concept that footcandles are equal to light flux over an area (the lumen method).

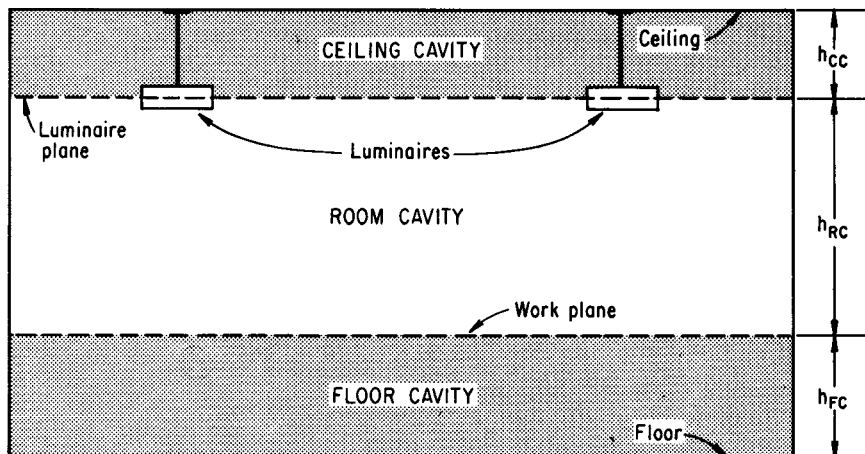

FIGURE 10.108 Basic cavity dimensions of space.

The zonal-cavity method assumes that an area to be lighted will be made up of a series of cavities which have effective reflectances with respect to one another and to the work plane. Basically, the area is divided into three spaces, or cavities, a *ceiling cavity*, a *room cavity*, and a *floor cavity*. These are shown graphically in Fig. 10.108.

In using the zonal-cavity method, there are four basic steps to be followed in making a calculation: (1) determine cavity ratios, (2) determine effective cavity reflectances, (3) select coefficient of utilization, and (4) compute average footcandle level.

Step 1. Determine Cavity Ratios. Cavity ratios may be determined by calculation, using formulas (15), (16), and (17) in Sec. 216, which is the basic and most accurate method; or the values may be found in Table 212 for typical-size cavities which cover a wide range of room dimensions. For a more complete table of cavity ratios, see the *IES Lighting Handbook*.

Step 2. Determine Effective Cavity Reflectances. Table 213 provides a means of converting the combination of actual wall and ceiling or actual wall and floor reflectances into a single effective ceiling cavity reflectance ρ_{cc} and a single effective floor cavity reflectance ρ_{fc} . Note that if the luminaire is recessed or surface-mounted or if the floor is the work plane, the ceiling cavity ratio or floor cavity ratio will be 0, and then the actual reflectance of the ceiling or floor will also be the effective reflectance. When using reflectance values of room surfaces, the expected maintained values should be used for calculation of maintained footcandles, or if initial footcandle values are desired, the initial reflectance values should be used.

Step 3. Select Coefficient of Utilization (CU). Using the ρ_{cc} , ρ_{fc} , and ρ_w (wall reflectance) determined in step 2 and knowing the room cavity ratio previously calculated in step 1, formula (16), in Sec. 216, refer to the coefficient of utilization in the CU table for the luminaire under consideration. Tables showing CU values for currently typical, popular types of luminaires are given in Tables 217, 218, and 219. For more complete data, see the *IES Lighting Handbook*. Manufacturers of lighting equipment will supply CU data for their own luminaires upon request. Note that since the CU tables are linear, linear interpolations can be made for exact cavity ratios or

reflectance combinations. Most CU tables are based on an effective floor cavity reflectance of 20 percent. Table 214 can be used to revise the CU for other effective floor cavity reflectances.

In determining the coefficient of utilization for a fluorescent luminaire, it is important that the specific lamp and ballast combination planned for an installation be identified and checked with the fixture manufacturer for any effect on the published CU. Fluorescent-lamp rated light output is established at 25°C (77°F). The light output from all fluorescent lamps varies with temperature (see Sec. 104). Different lamp designs, such as energy-saving types, do not operate at the same temperature in a specific luminaire, thus will differ in relative light output. Different ballast designs operate at different wattages and vary in losses, both of which affect the temperature in the luminaire and thus the light output.

Fluorescent-lamp ballasts usually do not operate lamps at rated wattage and light output. The ratio of lamp light output on a ballast compared with rated light output is called the *ballast factor*. Published coefficients of utilization assume rated lamp light output. Thus the CU for fluorescent luminaires must be multiplied by the ballast factor for the lamp-ballast combination being used in order to obtain accurate design calculations. The lamp type and ballast type must be identified to establish the specific ballast factor. Ballast factors can be obtained from ballast manufacturers.

Step 4. Compute Average Footcandle Level. Use the standard lumen method [formula (13) in Sec. 216] to compute the footcandle level that will be obtained. When maintained illumination levels are to be calculated, the maintenance factor (MF) should include lamp lumen depreciation (LLD) and luminaire dirt depreciation (LDD). Light source manufacturers can supply the LLD factor for any type of lamps; the factor should be based upon the luminaire's dirt attraction or dirt retention characteristics and the degree of dirtiness of the areas where it is to be used. Procedures for making these calculations are given in the *IES Lighting Handbook*.

212. Cavity Ratios(From *IES Lighting Handbook*, 4th ed.)

In making lighting calculations for proposed projects, lighting designers should have all the facts required for use in their calculations. Included would be the end-use application of the space; the physical dimensions; the color and reflectance values of the ceiling, walls, and floor; the layout of furniture or machinery, including colors of the various furnishings, etc.; and a knowledge of the degree of cleanliness (or dirtiness) of the area which will affect maintenance of the lighting levels. The degree of accuracy of the lighting calculations is influenced directly by the degree of accuracy involved in these various factors. The zonal-cavity method of making lighting calculations offers a high degree of accuracy in the calculated results, but these results cannot be any more accurate than the data used to make the calculations, including estimates of maintenance factors.

213. Percent Effective Ceiling or Floor Cavity Reflectance for Various Reflectance Combinations

(From *IES Lighting Handbook*, 4th ed.)

214. Factors for Effective Floor Cavity Reflectance Other than 20 Percent^a

(From *IES Lighting Handbook*, 4th ed.)

Room cavity ratio	% effective ceiling cavity reflectance, ρ_{cc}							
	80		70		50		10	
	% wall reflectance, ρ_w							
	50	30	50	30	50	30	50	30
1	1.08	1.08	1.07	1.06	1.05	1.04	1.01	1.01
3	1.05	1.04	1.05	1.04	1.03	1.03	1.01	1.01
5	1.04	1.03	1.03	1.02	1.02	1.02	1.01	1.01
6	1.03	1.02	1.03	1.02	1.02	1.02	1.01	1.01
8	1.03	1.02	1.02	1.02	1.02	1.01	1.01	1.01
10	1.02	1.01	1.02	1.01	1.02	1.01	1.01	1.01

^aFor 30% effective floor cavity reflectance, multiply by appropriate factor above. For 10% effective floor cavity reflectance, divide by appropriate factor above.

215. Reflection Factors of Colored Surfaces

Color	Reflection factor, %
Flat white	75–85
Ivory	70–75
Buff	60–70
Yellow	55–65
Light tan	45–55
Light green	40–50
Gray	30–50
Blue	25–35
Red	15–20
Dark brown	10–15

216. Lighting design formulas**Lumen Method*

$$\text{Footcandles} = \frac{\text{lumens}}{\text{area, ft}^2} \quad (11)$$

$$\text{Initial fc} = \frac{\text{LL} \times \text{CU}}{\text{area, ft}^2} \quad (12)$$

$$\text{Maintained fc} = \frac{\text{LL} \times \text{CU} \times \text{MF}}{\text{area, ft}^2} \quad (13)$$

$$\text{MF} = \text{LLD} \times \text{LDD} \quad (14)$$

where fc = footcandles
 LL = lamp lumens
 CU = coefficient of utilization
 MF = maintenance factor
 LLD = lamp lumen depreciation factor
 LDD = luminaire dirt depreciation factor

IES Zonal-Cavity Method

Ceiling cavity ratio:

$$\text{CCR} = \frac{5h_{cc}(L + W)}{L \times W} \quad (15)$$

Room cavity ratio:

$$\text{RCR} = \frac{5h_{rc}(L + W)}{L \times W} \quad (16)$$

Floor cavity ratio:

$$\text{FCR} = \frac{5h_{fc}(L + W)}{L \times W} \quad (17)$$

where h_{cc} = distance in feet from luminaire to ceiling
 h_{rc} = distance in feet from luminaire to work plane
 h_{fc} = distance in feet from work plane to floor
 L = length of room in feet
 W = width of room in feet

220. Levels of illumination. The present *Recommended Levels of Illumination*, RP-15, utilizes a sophisticated approach to lighting. It provides flexibility in establishing lighting levels so that lighting systems can be set to meet specific needs. The procedure is fully described in the *IES Lighting Handbook: Application Volume*. Because this approach is the current state of the art, the prescriptive footcandle tables that appeared at this location for many editions up through the 11th edition (published in 1987) were subsequently deleted. However, this editor has been made very aware that a great many electricians still value the old tables, to the point of retaining the older editions of this *Handbook*.

Therefore, the old tables follow this commentary. The current IES protocol is still the best way to do these calculations, however, for those who want a prescriptive footcandle list as a starting point, they are now returned to this volume. *Inspection quickly shows that some of this information, which was last fully updated over twenty years ago, is plainly dated. Use the list with this caveat firmly in mind.*

While for convenience of use this table sometimes lists locations rather than tasks, the recommended footcandle values have been arrived at for specific visual tasks. The tasks selected for this purpose have been the more difficult ones which commonly occur in the various areas. To assure these values at all times, higher initial levels should be provided as required by maintenance conditions.

When tasks are located near the perimeter of a room, special consideration should be given to the arrangement of the luminaires to provide the recommended level of illumination on the tasks. The illumination levels shown in the table are intended to be the minimum on a task irrespective of the plane in which it is located. The commonly used lumen method of illumination calculation gives results for only a horizontal work plane. The ratio of vertical to horizontal illumination will generally vary from 1:3 for luminaires having a narrow

distribution to 1:2 for luminaires of wide distribution. When the levels thus achieved are inadequate, special luminaire arrangements must be used or supplemental lighting equipment employed.

Supplementary luminaires may be used in combination with general lighting to achieve these levels. The general lighting should not be less than 20 fc (21.5 dalx) and should contribute at least one-tenth of the total illumination level.

^uObtained with a combination of general lighting plus specialized supplementary lighting. Care should be taken to keep within the recommended brightness ratios. These seeing tasks generally involve the discrimination of fine detail for long periods of time and under conditions of poor contrast. To provide the required illumination, a combination of the general lighting indicated and specialized supplementary lighting is necessary. The design and installation of the combination system must provide not only a sufficient amount of light but also the proper direction of light, diffusion, and eye protection. As far as possible it should eliminate direct and reflected glare as well as objectionable shadows.

^vDark paintings with fine detail should have 2 to 3 times higher illumination.

^wIn some cases, much more than 100 fc (108 dalx) is necessary to bring out the beauty of the statuary.

^xReduced or dimmed during sermon, prelude, or meditation.

^yTwo-thirds of this value if interior finishes are dark (less than 10 percent reflectance) to avoid high brightness ratios, such as between hymn book pages and the surroundings. Careful brightness planning is essential for good design.

^zSpecial lighting such that (1) the luminous area is large enough to cover the surface which is being inspected and (2) the brightness is within the limits necessary to obtain comfortable contrast conditions. This involves the use of

sources of large area and relatively low brightness in which the source brightness is the principal factor rather than the footcandles produced at a given point.

⁸For close inspection, 50 fc (54 dalx).

⁹Pencil handwriting and reading of reproductions and poor copies require 70 fc (75 dalx).

¹⁰For close inspection, 50 fc (54 dalx). This may be done in the bathroom, but if a dressing table is furnished, local lighting should provide the level recommended.

¹¹The specular surface of the material may necessitate special consideration in selection and placement of lighting equipment or orientation of the work.

¹²Or not less than one-fifth of the level in adjacent areas.

¹³Brightness of visual task must be related to background brightness.

¹⁴General lighting for these areas need not be uniform in character.

¹⁵Including street and nearby establishments.

¹⁶(1) Values are illumination on the merchandise on display or being appraised. The plane in which lighting is important may vary from horizontal to vertical. (2) Specific appraisal areas involving difficult seeing may be lighted to substantially higher levels. (3) Color rendition of fluorescent lamps is important. Incandescent and fluorescent usually are combined for best appearance of merchandise. (4) Illumination may often be made nonuniform to fit merchandising layout.

¹⁷Values based on a 25 percent reflectance, which is average for vegetation and typical outdoor surfaces. These figures must be adjusted to specific reflectances of materials lighted for equivalent brightnesses. Levels give satisfactory brightness patterns when viewed from dimly lighted terraces or interiors. When viewed from dark areas, they may be reduced by at least one-half, or they may be doubled when a high key is desired.

¹⁸See Sec. 232.

¹⁹Vertical.

²⁰60 lamp lumens per square foot of surface.

²¹100 lamp lumens per square foot of surface.

²²Supplementary lighting should be provided in this space to produce the higher levels of lighting required for specific seeing tasks involved.

²³The installation should be such that the level of illumination can be increased to at least 40 fc (43 dalx) for daytime embarkation.

²⁴In public areas such as lounges, ballrooms, bars, smoking rooms, and dining rooms, the footcandle values may vary widely, depending upon the atmosphere desired, the decorative scheme, and the use made of the room.

²⁵See footnotes *u* and *w*.

²⁶Also underwater lights and sunlamps.

INTERIOR-LIGHTING SUGGESTIONS

221. Residence lighting. In the lighting of the home, the decorative element should predominate. The lighting must, however, comply with the general rules of lighting (Sec. 188) concerning color, shadows, glare, and illumination. A room in which yellow or red is the predominant color gives a warm, cheerful impression, whereas a room furnished in blue tends to produce the opposite sensation. Shade and softened shadows are preferable to sharp shadows or to no shadows. It is especially important that any glare be minimized. Luminous ceilings can be installed in such rooms as kitchens and bathrooms.

Detailed recommendations for residence lighting are given in a booklet prepared by the Committee on Residence Lighting of the Illuminating Engineering Society and titled *Design Criteria for Lighting Interior Spaces*.

Kitchen. The kitchen requires plenty of well-diffused light for timely preparation of food without accidents. In most kitchens, general lighting from two 40-W fluorescent lamps or two 150-W to four 100-W incandescent lamps will provide satisfactory general illumination. For very large kitchens, 80 to 120 W of fluorescent lighting or two 100-W incandescent lamps per 60 ft² will be needed. Unless the room is very small with light-colored walls and ceilings, the general illumination should be augmented by additional localized ceiling or bracket units. A single light in the center of the kitchen usually compels the cook to work entirely in his or her own shadow, whether at the range, the sink, or the kitchen cabinet or table. A single fluorescent ceiling unit over the center of the sink or a bracket at each side of the sink is nearly always necessary to eliminate

shadows and provide adequate illumination at the sink. Often it is advisable to locate similar units at the range and counter work areas.

Bedroom. The illumination requirements of the bedroom are somewhat similar to those of the kitchen. General illumination should be provided by means of a centrally located ceiling unit of low brightness so that it will not be uncomfortable to the eyes of one lying in bed. Additional illumination should be provided at the dresser or bureau by means of either brackets or a portable lamp on each side of the mirror. A bracket or wall-mounted fluorescent unit should be provided at the head of each bed unless localized table luminaires are used for providing illumination for reading at these locations. Better illumination for this purpose is generally obtained by a wall-mounted bracket or fluorescent units.

Living Room. Although ceiling fixtures have been eliminated in many living rooms, an attractive, properly shielded fixture is a very effective method of obtaining the general level of illumination needed for festive occasions. For a quiet evening at home a lower level of general illumination can be obtained by means of the indirect type of floor and table lamps. With their high efficiency and good color characteristics, compact fluorescent lamps with integral ballasts or ballast adapters should be considered for use in floor and table lamps. The chief function of bracket lamps is ornamentation, and they should not be relied upon to provide necessary light for useful purposes.

Dining Room. There are several satisfactory methods of illuminating the dining room, the selection depending upon personal taste. General illumination may be provided by means of a centrally located chandelier. It should be mounted 30 in (762 mm) above the table in an 8-ft- (2.4-m-) ceiling room. In rooms with higher ceilings, the chandelier should be raised 3 in (76 mm) for each foot. Recessed downlights can be used with chandeliers for dramatic lighting of table settings. Cove lighting by means of fluorescent lamps concealed in a trough a few inches down from the ceiling may be used. Wall brackets for decorative effects are also common.

Bathroom. In the bathroom illumination of the mirror requires the greatest consideration. For the best illumination of the mirror three luminaires, one at each side of the mirror and one mounted overhead, are needed. Fairly good results can be obtained with only two units located one at each side of the mirror. If only one unit is used, it should be mounted overhead and centered with respect to the mirror. For small bathrooms the mirror wall brackets will supply sufficient general illumination for the rest of the room. In rooms of any appreciable size a central enclosing unit should be used in addition to the bracket lamps. A ceiling-mounted heat lamp will provide added comfort for the winter months.

222. Store lighting. The object of lighting in a store is twofold. Primarily, sufficient illumination must be provided to enable articles for sale to be seen plainly, but of almost equal importance is the advertising value. The lighting units should be so selected as to give a pleasing and cheerful appearance to the store as a whole, without glare. Stores may be divided into three classes: (1) the small store, in which efficiency is of first importance; (2) the large store, such as a department store, in which efficiency is necessary on account of the large areas to be lighted but in which it must be balanced by artistic appearance, the result being a compromise between the two; and (3) shops, large or small, in which the articles for sale are of a special type and the profits large enough so that even the most inefficient system can be afforded if it is sufficiently attractive to appeal to customers. The general requirements which must be satisfied are outlined separately in the following sections.

General Features of Store Lighting. General lighting best meets the requirements for the lighting of stores. The lamps should be arranged symmetrically with respect to bays or pillars. Direct glare must be very carefully avoided. The position of the counters need

not be considered in spacing the lamps. Local accurate-color-matching units are advisable at certain points in the store, such as counters for the sale of ribbon and dress goods.

The intensity of illumination must be varied with the articles which are to be sold. Furniture requires well-diffused lighting of relatively low intensity. Colored dress goods, men's clothing, rugs and carpets, and so on, require a high intensity. In many installations, side light is necessary and should be given special attention in selecting types of units and reflectors. Crystal and jewelry should be so lighted as to sparkle and glitter. Bare lamps and mirrored reflectors may be used in ornamental-type luminaires for this purpose. In this case glare is to a certain extent unavoidable, but light units can usually be so located as to be out of the range of vision of customers when they are inspecting the wares on display.

Pictures require a high intensity, with the light units at such an angle that light will not be reflected from the surface of the painting or from the glass directly into the observer's eyes. Individual units or mirrored-trough reflectors, with fluorescent or tubular tungsten lamps, are ordinarily used.

High-color-rendition fluorescent lamps should be used to illuminate all items in which color is important, such as women's dresses, coats, and furs, men's suits and coats, draperies and curtains, tapestries, and neckties. Concealed fluorescent units may also be used in wall valances or coves for decorative effects.

Showcases. A showcase interior should have more illumination than the top of the case but not more than about twice as much. If the illumination on top is in the 30- to 75-fc (323- to 807-lx) range, T-6 or T-8 slimlines inside the case, operated at 200 mA, provide sufficient light; for higher footcandles on the top, an operating current of 300 mA is sometimes recommended. Too great a differential between the illumination inside the case and that on the top, where the merchandise is normally inspected more closely prior to purchase, is not advisable. Many products examined under an illumination level significantly lower than that under which they were displayed lose some of their attraction. This is not a consideration with feature displays, since they are seldom removed for inspection.

The plot in Fig. 10.109 indicates the approximate initial footcandles perpendicular to the source at various angles for each 100 rated lamp lm/ft of case length. The figures above the arcs represent footcandles obtained with a fluorescent lamp in a specular showcase

FIGURE 10.109 Initial footcandles for each 100 rated lamp lm/ft of showcase length.

reflector. The figures below the arcs represent footcandles obtained with standard filament reflector showcase lamps and differ from the fluorescent values because of beam control.

Wall Cases. Wall cases generally should be illuminated to approximately the same level as counter display areas. However, higher levels are desirable when the brightness of the wall case and the adjoining sales space is to be used partly to pull traffic into the area. One of the most important features of the lighting of wall cases for wearing apparel is that it be designed to light the entire case from top to bottom rather than just the shoulders of the garments. The illumination at the bottom should be at least one-tenth of that at the top.

The accompanying table lists the approximate illumination in footcandles produced by fluorescent lamps on a vertical surface for each 100 rated lamp lm/ft of case length. The specular symmetrical reflector was so adjusted that its maximum candlepower was directed at a point 42 in (1067 mm) below the lamp. When no reflector was used, the entire inner surface of the valance was painted white.

		Horizontal distance— <i>H</i> , in							
	Vertical distance— <i>V</i> , in	Values with symmetrical reflector, fc				Values without reflector, fc			
		6	12	18	24	6	12	18	24

	60	0.6	1.2	1.9	2.6	0.3	0.8	1.0	1.4

223. Show-window lighting. Since the primary object of a show window is to attract attention, it should be illuminated to a sufficient intensity so that it will stand out from its surroundings. Several factors need to be considered in designing show-window lighting systems such as type of merchandise, location of the store, time-of-day usage, enclosed or open back design, and the size and shape of the show window. Great care should be exercised in designing show-window lighting so that the lamps will be concealed from view. The lighting equipment should be concealed either by recessing it in the ceiling or by employing a valance between the reflector and the front glass of the window. A good way to blind prospective customers so that they cannot see the goods on display in your window is to put exposed lamps around the window borders, suspend them from chandeliers, or so install them in the top of the window that their eyes cannot escape them.

Shadows are necessary in window lighting to produce the desired effects, but they should not be too sharply defined. The light should come from in front of the goods. If the lamps are placed in the middle of the show-window ceiling, the front of the goods displayed in the front of the window will be in darkness because of shadows they cast.

If the back of the display window is not boxed in or if the window back is of glass, a valance or a curtain should be provided to screen the window lamps from the store and to prevent back reflection to an observer on the sidewalk.

Customers' attention should be attracted by illuminating selected articles with spotlights. If decorative effects are desired, colored spotlights may be used, and motor-operated

dimmers can add motion and dramatic effects. Fluorescent units bring out the beauty of floral displays and emit very little heat. Daylight lamps bring out the beauty of polished aluminum and chromium-plated articles.

224. Show-window lighting equipment. Incandescent lamps are extensively used in show-window applications owing to the wide variety of wattages, sizes, reflectorized types, and colored lamps. Lighting units with special reflectors for show-window lighting are available in many shapes to meet the varied requirements of different types and sizes of windows. Reflectorized (reflector and projector) lamps are widely used owing to the built-in light control within the lamp. Low-voltage PAR and MR-16 reflector lamps provide excellent beam control for lighting special areas of a show window to a higher intensity. Colored reflector and PAR lamps or the use of colored gelatin screen or glass roundels can provide desired effects with color. No general rules for shadows and color of light to be used can be given. An infinite number of effects can be obtained. By experiment, the display manager should determine the best effect for each display to be lighted.

225. School and office lighting. As school and office work is usually performed during daylight hours, any artificial illumination is usually in conjunction with available daylight. Since practically all the work done in an office or school is on plane surfaces such as papers and books, shadows not only are unnecessary but are objectionable. Also, since the persons must use artificial illumination for long periods of time, the glare should be minimal. These requirements render indirect and semi-indirect units especially suitable for office and school illumination. The units should, as a general rule, be more closely spaced than for other classes of service. This spacing will produce a more gradual shading of any shadows and will also afford a greater flexibility in desk and partition arrangement. The extensive use of video-display units in offices and classrooms has established the need to design lighting systems to avoid reflected brightness in VDU screens.

226. Lighting Codes and Legislation. Codes and regulations relating to lighting generally fall within two categories: energy saving codes and safety and construction codes. Energy saving codes are concerned with methods to conserve energy through the efficient use of electric lighting. The codes establish maximum limits for power density values (watts per square foot) for lighting used in various applications. In addition there may also be codes which set minimum efficiency standards for lighting equipment.

The safety and construction codes involve the safety and construction requirements which must be complied with in the construction, installation, and maintenance of lighting systems.

Contractors involved with lighting should be familiar with the codes and regulations which are applicable in the geographic areas of their work.

HEAT WITH LIGHT FOR BUILDING SPACES

227. Luminaires for environmental control. Not too many years ago architects designed buildings primarily as space enclosures. The end use for which the space enclosures were intended usually dictated the type and design of the buildings and the division and arrangement of the space. Comfort conditioning of the space for people normally consisted of a heating system for use in cold weather and a ventilating or air-conditioning system for warm weather.

Progress in building design and construction and in technological developments in space conditioning has changed the architects' objective in the design of buildings. Present

emphasis is not only on space enclosure tailored to the needs of occupants but also on environment and environmental control of lighting, heating, cooling, acoustics, space flexibility, and appearance (pleasing colors, etc.).

Visual and thermal conditions have become two of the most important considerations in planned interior environment. Visual comfort is controlled primarily by quality and quantity of illumination. And adequate illumination of proper quality for high visual performance and high visual comfort increases electric-energy loads, which also means higher heat gain. Thus, lighting systems that provide adequate quality illumination may have a considerable effect on thermal conditions within buildings. Thermal comfort is controlled through a proper balance in temperature, relative humidity, and air motion. Accordingly, light- and heat-producing characteristics of the lighting system have become dominant factors in the thermal equation.

This expanded use of lighting heat heralds a new era in environmental design. It provides the opportunity to supply all or a substantial part of a building's heating requirements from lighting systems with accompanying benefits, and control of lighting heat is necessary for the most effective utilization of this energy.

228. Integrated lighting-heating-cooling systems. There has been a growing coordinated activity between electrical and mechanical engineers since 1958, when the Illuminating Engineering Society adopted new and higher recommended levels of illumination for most seeing tasks. This activity has resulted in many new techniques for handling lighting heat loads, which are based on the integration and correlation of lighting, heating, and cooling systems. Although many approaches to this problem are possible, the basic one is to divert all possible lighting heat gain from the occupied spaces in buildings to keep the capacity of the (cooling) system as low as possible. Another objective is to recapture some or all of this lighting heat gain to keep the capacity of the heating system as low as possible. This heat may be removed from interior areas of the building which need cooling, for example, and redirected to perimeter areas which need heating at the same time.

229. Air-handling troffers. In the typical integrated system, heat from the lighting system is removed by passing return air from the air-conditioned space through vents integral with the luminaires over the warm surfaces of lamps, ballasts, and luminaires, into the plenum or return air duct, and back through the return side of the air-conditioning system. After tempering, the supply air is redistributed, entering the conditioned spaces through a different set of vents, which are also integral with the luminaires. Luminaires designed for this purpose are called *air-handling troffers*. There is also available an *air-water luminaire*, in which circulating water through the luminaire removes the lighting heat.

By combining lighting, heating, and cooling services in a single outlet element (the luminaire), the conflict for space both above and on the ceiling is reduced. This integration forces coordinated design and produces as its visual result an architecturally clean, uncluttered ceiling.

Many lighting manufacturers now have available air-handling troffers in a range of sizes and for a variety of air-handling requirements: (1) static (non-air-handling), (2) air supply, (3) air return, and (4) a combination of air supply and air return. These luminaires may be integrated with either cooling systems or heating systems, or both. Installation methods conform generally to those for standard fluorescent troffers.

Also available are several complete ceiling systems combining both air-supply and air-return provisions, some of which use conventional fluorescent luminaires and some of which incorporate special air-handling luminaires that are an integral part of the ceiling system. Typical examples are shown in Figs. 10.110, 10.111, and 10.112. The air-handling troffer in Fig. 10.110 supplies cool air to the occupied space below the ceiling and returns

FIGURE 10.110 Air-handling troffer. [Day-Brite Lighting Division, Emerson Electric Co., *Electrical Construction and Maintenance*]

FIGURE 10.111 Unified ceiling system. [Day-Brite Lighting Division, Emerson Electric Co.]

FIGURE 10.112 Recessed incandescent downlights integrated with heating and cooling systems.

warm air from the occupied space through the troffer to the open plenum above. Heat from lamps and ballasts is also removed. Warm plenum air may be discarded or mixed with fresh air and recirculated for heating specific occupied spaces.

The unified ceiling system in Fig. 10.111 provides complete environmental control through a modular-size integrated package. Each module combines lighting, heating, cooling, sound control, partition tracks for flexibility, shielding of the lighted portion of a luminaire in the line of vision, and good appearance.

The recessed incandescent downlight (Fig. 10.112) is integrated with heating and cooling systems to the extent that lighting heat may be exhausted to the plenum space and discharged as waste or reused.

STREET LIGHTING

230. General requirements for street lighting. Good roadway lighting, often termed *traffic safety lighting*, not only promotes safer conditions for drivers but provides greater safety for pedestrians as well. It enhances the community value of a street by its attractive appearance, which is usually reflected in higher property values. Well-lighted streets also act as a deterrent to criminal activity.

To achieve truly effective street lighting it is essential that the installation be well planned. Planned street lighting should follow the American Standard Practice for Roadway Lighting of the Illuminating Engineering Society and will involve the following considerations:

1. Traffic classification of the street.
2. Determination of the proper lighting intensity for the street classification.
3. Selection of luminaires according to the light distribution needed for the street.
4. Determination of the mounting height of the luminaire above the road surface and the proper linear spacing between luminaires.

Each step follows the preceding one in logical order, and the following information will assist in the planning of an installation. Manufacturers of roadway lighting equipment have computerized programs to assist in detailed planning of an installation.

231. Roadway classification. A traffic classification relating to use should be made of all streets so that the lighting-system design will be in keeping with the particular needs of each street or highway. It is also recommended that roadways be classified by the area of location to establish the volume of pedestrian traffic to be considered. Typical roadway and area classifications are defined here (General Electric Co.).

Roadway Class

1. *Freeway.* A divided major roadway with full control of access and with no crossings at grade. This definition applies to toll as well as to nontoll roads.
2. *Expressway.* A divided major roadway for through traffic with partial control of access and generally with interchanges at major crossroads. Expressways for noncommercial traffic within parks and parklike areas are generally known as parkways.
3. *Major roadways.* The part of the roadway system that serves as the principal network for through-traffic flow. The routes connect areas of principal traffic generation and important rural highways entering the city.
4. *Collector roadways.* The distributor and collector roadways serving traffic between major and local roadways. These are roadways used mainly for traffic movements within residential, commercial, and industrial areas.
5. *Local roadways.* Roadways used primarily for direct access to residential, commercial, industrial, or other abutting property. They do not include roadways carrying through traffic. Long local roadways will generally be divided into short sections by collector roadway systems.

Area Class

1. *Commercial.* That portion of a municipality in a business development where ordinarily there are large numbers of pedestrians and heavy demand for parking space during periods of peak traffic or sustained high pedestrian volume and continuously heavy demand for off-street parking during business hours. This definition applies

to densely developed business areas outside, as well as those that are within, the central part of a municipality.

2. *Intermediate.* That portion of a municipality which is outside a downtown area but generally within the zone of influence of a business or industrial development, characterized often by moderately heavy nighttime pedestrian traffic and somewhat lower parking turnover than is found in a commercial area. This definition includes densely developed apartment areas, hospitals, public libraries, and neighborhood recreational centers.
3. *Residential.* A residential development, or a mixture of residential and commercial establishments, characterized by few pedestrians and lower parking demand or turnover at night. This definition includes areas with single-family homes, townhouses, and/or small apartments. Regional parks, cemeteries, and vacant lands are also included.

232. Lighting intensity. The recommended illumination level is dependent both on the area and on the roadway classification. Recommended minimum average maintained levels and recommended average-to-minimum uniformity ratios for several classifications are shown in the following table.

ANSI-IES Recommendations

Roadway classification	Minimum average maintained footcandles	Uniformity, average footcandles/minimum footcandles
Residential areas		
Local	0.4	6:1
Collector	0.6	3:1
Major	1.0	3:1
Intermediate areas		
Local	0.6	3:1
Collector	0.9	3:1
Major	1.4	3:1
Commercial areas		
Collector	1.2	3:1
Major	2.0	3:1

233. Selection of luminaire. Luminaires should be selected according to their pattern of light distribution so as to conform not only to the light intensity required but to the physical characteristics of the street to be lighted. Typical lateral candlepower distribution curves for several types of luminaires are shown. Lateral beam width is measured to half maximum candlepower.

Type I Luminaire. Type I is a two-way lateral distribution having a preferred lateral width of 15° on each side of the reference line (total, 30°), with an acceptable range of from 10 to less than 20°. It projects two beams in opposite directions along the roadway parallel to the curbline. The candlepower distribution is similar on both sides of the

vertical plane of maximum candlepower. Luminaires with this type of distribution are generally applicable to locations near the center of a roadway where the mounting height is approximately equal to the roadway width.

Four-Way Type I Luminaire. Four-way Type I is a distribution having four principal concentrations at lateral angles of approximately 90° to one another, each with a width of from 20° to less than 40° as in Type I. This distribution is generally applicable to luminaires located over or near the center of a right-angle intersection.

Type II Luminaire. Type II distributions have a preferred lateral width of 25° with an acceptable range of from 20° to less than 30° . This distribution is generally applicable to luminaires located at or near the side of relatively narrow roadways when the width of the roadway does not exceed 1.6 times the mounting height.

Four-Way Type II Luminaire. Four-way Type II distributions have four principal light concentrations, each with a width of from 20° to less than 30° as in Type II. This distribution is generally applicable to luminaire locations near one corner of a right-angle intersection.

Type III Luminaire. Type III distributions have a preferred lateral width of 40° with an acceptable range of from 30° to less than 50°. This type of distribution is intended for luminaires mounted at or near the side of medium-width roadways when the width of the roadway does not exceed 2.7 times the mounting height.

Type IV Luminaire. Type IV distributions have a preferred lateral width of 60° with an acceptable width of 50° or more. This type of distribution is intended for side-of-road mounting and is generally used on wide roadways (width up to 3.7 times the mounting height).

Type V Luminaire. Type V distribution is essentially circular, with equal candlepower at all lateral angles. This type of distribution is intended for luminaire mounting at or near the center of a roadway, in the center islands of parkways, and at intersections.

234. Mounting height and spacing of luminaires. Two considerations are of paramount importance in determining optimum mounting height: the desirability of minimizing direct glare from the luminaire and the need for a reasonably uniform distribution of illumination on the street surface. The higher the luminaire is mounted, the farther it is above the normal line of vision and the less glare it creates. However, the attainment of uniform illumination requires a certain relationship between mounting height, luminaire spacing, and the vertical angle of maximum candlepower for the specific luminaire (usually between 70° and 80°).

For a given luminaire the ratio of pole spacing to mounting height should be low enough so that the light at the angle of maximum vertical candlepower will strike the street at least halfway to the adjacent pole. To provide greater uniformity on busy streets the spacing is often reduced by as much as 50 percent, which provides a 100 percent overlap of vertical beams.

The mounting heights recommended by the Illuminating Engineering Society's Roadway Lighting Committee take into account both the objective of minimum glare and that of maximum uniformity. Greater mounting heights may often be preferable, but heights less than those recommended should be avoided.

FLOODLIGHTING

235. Modern floodlighting meets many utilitarian requirements as well as many applications concerned with decoration, aesthetics, or advertising values. Protecting property after nightfall, completing a construction job within the time allotted, illuminating a dangerous traffic intersection, and prolonging the hours of play in recreational areas are only a few of the almost infinite applications of utilitarian floodlighting.

As an advertising medium that compels attention without detracting from the beauty or dignity of a building, floodlighting offers its best proof by the many excellent examples to be found in almost every city. The natural beauty of churches, civic buildings, monuments, and gardens is often enhanced by skillfully applied floodlighting.

236. Floodlighting design. The type of area to be lighted, the possible location of equipment, and the variation in surrounding conditions impose problems in design which tend to make floodlighting-design standardization difficult. Manufacturers of floodlighting equipment can be consulted for detailed design information. There are, however, certain basic rules which may be followed in installation design.

237. Step 1: Determine the level of illumination. In Table 220 are listed the illumination levels for many floodlighting applications. These levels are designated as *foot-candles in service*, and allowance must be made for reasonable depreciation in the original design.

In lighting buildings, monuments, etc., the reflection factor of the object and the brightness of the surroundings must be considered to determine the amount of light necessary (Table 238).

238. Recommended Illumination Levels for Floodlighting
(*IES Lighting Handbook*)

Surface material	Reflectance, %	Surround	
		Bright	Dark
		Recommended level, fc	
Light marble, white or cream terracotta, white plaster	70–85	15	5
Concrete, tinted stucco, light gray and buff limestone, buff face brick	45–70	20	10
Medium gray limestone, common tan brick, sandstone	20–45	30	15
Common red brick, brownstone, stained wood shingles, dark gray brick	10–20 ^a	50	20

^aBuildings or areas of materials having a reflectance of less than 20% usually cannot be floodlighted economically unless they carry a large amount of high-reflectance trim.

* Vertical.

240. Step 2: Determine the type and location of floodlights. Floodlighting equipment may be of either the *general-purpose* or the *heavy-duty* class. The general-purpose floodlight is one in which the inner surface of the housing serves as the reflecting surface. The heavy-duty floodlight is more rugged, since its aluminum or glass reflector is protected by a metal housing.

The finish of the reflector has an important influence on the beam spread. Most enclosed units are available with either a narrow-beam (specular-finish) or a wide-beam (diffuse-finish) reflector. Essentially all floodlighting equipment is enclosed today for improved maintenance.

241. Data on Typical Floodlight Equipment

Description	Advantages	Lamp types	Beam-spread NEMA type ^a
Group A Heavy-duty or general-purpose	Good light control for distance Weathertight Useful in a variety of applications, mostly sports lighting	1000- to 1500-W metal halide 400- to 1000-W high pressure sodium	1-5
			
Group B Heavy-duty high-wattage HID	Good light control Weathertight Easily serviced High fixture efficiency	250-, 400-, and 1000-W metal halide 250-, 400-, and 1000-W high-pressure sodium	6 × 2 6 × 5 6 × 6 6 × 7
			
Group C Heavy-duty low-wattage HID	Good light control Weathertight Easily serviced High fixture efficiency Use at lower mounting or where lower lighting levels are satisfactory	175-W metal halide 35- through 250-W high-pressure sodium	6 × 6 7 × 6 7 × 7
			
Group D Heavy-duty tungsten-halogen	Good light control Weathertight Easily serviced Low cost	300-, 500-, 1000-W, and 1500-W, tungsten halogen	6 × 4 6 × 5
			

^aAsymmetrical beam spreads have a horizontal and a vertical designation. The horizontal is stated first; i.e., a 6 × 2 beam spread is a NEMA Type 6 in the horizontal dimension and a NEMA Type 2 in the vertical dimension.

242. To simplify the specification of equipment the National Electrical Manufacturers Association has introduced a series of type numbers specifying beam spread and group letters specifying floodlight construction. To meet NEMA standards a floodlight must conform to certain construction requirements as well as have a certain minimum efficiency for a given beam spread.

Although the choice of beam spread for a particular application depends upon individual circumstances, the following general principles apply;

1. The greater the distance from the floodlight to the area to be lighted, the narrower the beam spread desired.
2. Since by definition the candlepower at the edge of a floodlight beam is 10 percent of the candlepower near the center of the beam, the illumination level at the edge of the beam is one-tenth or less of that at the center. To obtain reasonable uniformity of illumination the beams of individual floodlights must overlap each other as well as the edge of the surface to be lighted.
3. The percentage of beam lumens falling outside the area to be lighted is usually lower with narrow-beam units than with wide-beam units. Thus narrow-beam floodlights are preferable when they will provide the necessary degree of uniformity of illumination and the proper footcandle level.

Outdoor Floodlighting Designations

Beam spread, °	NEMA type
10–18	1
18–29	2
29–46	3
46–70	4
70–100	5
100–130	6
130 and up	7

243. Typical Floodlighting Applications

Application	Location of equipment	Class of equipment
	At edge of area and mounted as high as possible. Spacing not to exceed 4 times mounting height.	General-purpose enclosed or heavy-duty Type 4, 5, or 6
	Immediately inside and below concealing parapet—maximum distance from face of building to be lighted.	Heavy-duty or general-purpose Type 3, 4, or 5
	In banks at suitable location. One bank normally should cover an area whose height and length are not greater than the distance from the units to the face of the building.	Heavy-duty or general purpose Type 1, 2, 3, or 4
	At edge of area where they will not hinder traffic. Minimum mounting height 20 ft.	Heavy-duty Type 5 or 6
	On ground 5 to 25 ft from vertical surface, concealed by hedge, low structure, or natural elevation.	Heavy-duty or general purpose Type 3, 4, 5, or 6

The location of floodlighting equipment is usually dictated by the type of application and the physical surroundings. If the area is large, individual towers or poles spaced at regular intervals may be required to light it evenly; smaller areas may require only one tower with all equipment concentrated on it, or adjacent buildings may be utilized as floodlight locations. The accompanying chart will aid in the selection of the right equipment and its proper location for a number of typical floodlighting applications.

In planning any floodlighting system it is important that the light be properly controlled. Strong light directed parallel to a highway or a railroad track can be a dangerous source of glare to oncoming traffic, and light thrown indiscriminately on adjacent property may be a serious nuisance.

244. Step 3: Determine the coefficient of beam utilization. To determine the number of floodlights that will be required to produce a specified level of illumination in a given situation, it is necessary to know the number of lumens in the beam of the floodlights and the percentage of the beam lumens striking the area to be lighted. The beam lumens can be obtained from the manufacturer's catalog. The ratio of the lumens striking the floodlighted surface to the beam lumens is called the *coefficient of beam utilization*. (CBU). If an area is uniformly lighted, the average CBU of the floodlights in the installation is always less than 1.0.

The coefficient of beam utilization for any individual floodlight will depend on its location, the point at which it is aimed, and the distribution of light within its beam. In general, it may be said that the average CBU of all the floodlights in an installation should fall within the range of 0.60 to 0.90. Utilization of less than 60 percent of the beam lumens is a definite indication that a more economical lighting plan should be possible by using different locations or narrower-beam floodlights. On the other hand, if the CBU is over 0.90, the beam spread selected probably is too narrow and the resultant illumination will be spotty. Accurate determination of the CBU is possible only after the aiming points have

If: EO = OL = 25
 AL = FL = 40
 LD = 80

Then: angle LFO = 32°
 EFO = 19°
 BFE = 32°
 GFO = 41°
 AFL = 45°
 CFE = 51°
 HFO = 60°
 DFL = 64°

The CBU of the floodlight at F is about .81

been selected. However, an estimated CBU can be determined by experience or by making calculations for several potential aiming points and using the average figure thus obtained.

To make such calculations the floodlighted area is superimposed on the photometric grid and the ratio of the lumens inside this area to the total beam lumens is determined. All horizontal lines on a building (or straight lines on a ground area which are parallel to a line perpendicular to the beam axis) appear as straight horizontal lines on the grid if the floodlight is so aimed that its beam axis is perpendicular to a horizontal line on the face of the building. All vertical lines except the one through the beam axis appear slightly curved.

245. Step 4: Estimate the maintenance factor. Lighting efficiency is seriously impaired by blackened lamps and by dirt on the reflecting and transmitting surfaces of the equipment. To compensate for the gradual depreciation of illumination on the floodlighted area, a maintenance factor must be applied in the calculations to make allowance for the following:

1. Loss of light output due to dirt on the lamp, reflector, and cover glass.
2. Loss in light output of the lamp with life. Because some of the light must pass through the bulb more than once before finally leaving the floodlight, bulb blackening also lowers floodlight efficiency, the reduction in beam lumens being about double the reduction in bare-lamp output.

A maintenance factor of 0.75 has been widely used for floodlights.

However, if the atmosphere is not clean, if the floodlights are cleaned infrequently, or if lamps are replaced only on burnout, a realistic appraisal of in-service conditions will require the use of considerably lower maintenance factors. Differences in lumen maintenance among lamp types and sizes should also be considered. With incandescent lamps the higher the wattage for a given bulb size or the smaller the bulb for a given wattage, the denser the bulb blackening and the greater the depreciation in light output.

Approximate Average Lamp Lumens throughout Life

Lamp type	% of Initial lumens
Standard incandescent	83
Tungsten-halogen incandescent	98
Mercury	60
Metal halide	80
High-pressure sodium	90

With narrow-beam floodlights, dirt on the reflector and cover glass tends to widen the beam spread, reducing the maximum candlepower more than the total light output. Thus for a small lighted area utilizing only the central part of a beam (e.g., a 4-ft, or 1.2-m) archery target at 100 yd, or 91.4 m), a smaller percentage of the beam lumens will strike the target after the floodlight has become dirty. Therefore the depreciation in footcandle intensity will be greater than the depreciation in total light output, and it will be necessary to consider this in selecting a maintenance factor.

246. Step 5: Determine the number of floodlights required.

$$\text{Number of floodlights} = \frac{\text{area} \times \text{footcandles}}{\text{beam lumens} \times \text{CBU} \times \text{MF}} \quad (18)$$

where area is the surface area to be lighted in square feet and footcandles are as selected from Table 238. For beam lumens, refer to the manufacturer's catalog for the equipment under consideration. If the lamps are to be burned at other than rated voltage, the beam lumens, and hence the number of floodlights required, is altered. The increase in lumen output for 5 and 10 percent overvoltage operation is indicated in Sec. 249. For the CBU (coefficient of beam utilization), refer to step 3; and for the MF (maintenance factor), to step 4.

247. Step 6: Check for coverage and uniformity. After a tentative layout has been made (steps 1 to 5), uniformity can be checked by calculating the intensity of illumination at a few points on the floodlighted surface. This may be done by the point-by-point method described in Sec. 204, using either a candlepower-distribution curve or an isocandle diagram. If uniformity is found to be unsatisfactory, a larger number of units may have to be used.

248. Application notes

Type of Light Source. Most floodlighting installations today utilize high-intensity-discharge lamps owing to their higher efficacy and long lamp life. Where incandescent lamps are used, they are generally the tungsten-halogen types.

Buildings and Monuments. The floodlighting of a building or a monument is primarily a problem in aesthetics, and each installation must be studied individually. Under some circumstances, particularly with small utilitarian buildings or larger buildings which lack special architectural features, uniform illumination is desirable. To create an appearance of uniform brightness over the entire facade of a building, it is usually necessary to increase the actual brightness appreciably toward the top. Higher brightness at the top of a building also increases its apparent height.

With buildings of classical design or special architectural character uniform illumination often defeats the purpose of the lighting, which should aim to preserve and emphasize the architectural form. Buildings are designed primarily for daytime appearance, when the light comes from above. This effect is almost impossible to duplicate with floodlights, which must be mounted in nearby locations and usually at a height no greater than the elevation of the building. However, it is often possible to achieve a result that is interesting and pleasing, although quite different from the daytime appearance. Shadows are essential to relief, and contrasts in brightness levels or sometimes in color can be used advantageously to bring out important details and to suppress others. Sculpture or architectural details require particularly careful treatment to avoid flatness or grotesque shadows that may entirely distort the appearance as it has been conceived by the artist or architect.

Excavation and Construction. Approximately one 1500-W tungsten-halogen, one 400-W metal halide or HPS, or two 250-W metal halide or HPS units will be required for each 5000 ft² (465 m²) of excavation area or for each 1000 to 2000 ft² (93 to 186 m²) of construction area. It is usually most satisfactory to mount floodlights in groups of two or more on wood poles or towers 40 to 70 ft (12.2 to 21.3 m) above ground. A minimum of two poles should be used, with enough poles on larger jobs to provide coverage at

any working point from two or three floodlight banks. Fixed-pole spacing may be from $1\frac{1}{2}$ to 3 times mounting height and as much as 5 times mounting height on large projects. Occasionally it is practical to provide one or two portable poles mounted on timber-sled bases. If a mechanical shovel or crane is used, it is advisable to mount an automatic leveling floodlight on the boom.

Directional Application Such as Railway Yards and Freight Terminals. There are two general types of railway-yard lighting, the unidirectional system and the parallel opposing system. The first is applicable only to tracks on which the traffic is all in one direction, the light being directed with the traffic flow. Glare is entirely eliminated, but seeing is entirely by direct light without the advantages of silhouette effect. The parallel opposing system is used when the traffic flows in both directions. Here seeing is accomplished by direct light from the tower behind the observer and by the silhouette of cars and glint from the rails produced by light from the tower ahead of the observer.

Tower locations are determined by track layouts and operating methods, but in general spacings should not exceed 1000 to 2000 ft (305 to 610 m) for the parallel opposing system or 800 to 1000 ft (245 to 305 m) for the unidirectional system. The first tower in the classification yard should be near the ladder tracks but on the approach side of the hump, so that spill light or a separate floodlight, if necessary, illuminates the hump area. Narrow yards can be lighted by single towers located in the center. Wide yards should have pairs of towers opposite each other, each about one-fourth of the yard width from the edge. Except for spacings well below the values noted above, 90 ft (36 m) should be considered a minimum mounting height.

The lighting of outdoor freight terminals without covered platforms is similar to that of railroad yards except that the intensities must be much higher. Poles must be placed at the ends of the platforms to prevent interference with vehicular traffic and in line with the platforms to avoid shadows thrown by cars standing on the tracks. Mounting heights of from 60 to 80 ft (18 to 24 m), depending on the average length of throw, are required. Heavy-duty floodlights are recommended for all railroad service.

Color. Color is provided in floodlight installations usually by colored cover glass, which is generally available for enclosed floodlights to replace regular lenses. When smaller amounts of colored light are needed, colored R or PAR incandescent lamps may be used. Any color of filter absorbs a large amount of light, and this loss must be considered in designing the installation. The following approximate transmission values are found in typical commercial color filters: amber, 40 to 60 percent; red, 10 to 20 percent; green, 5 to 20 percent; and blue, 3 to 10 percent. Although less colored light than white light is usually required for equal advertising or decorative effectiveness, it is desirable to determine by experiment the exact amount of colored light necessary for any particular application.

The color of light from high-intensity-discharge light sources is particularly desirable in specific decorative floodlighting applications. Metal halide and phosphor-coated mercury lamps are used where a cooler color of light is preferred, while high-pressure sodium lamps are applied in installations better suited to a warmer tone. Clear mercury lamps are very effective in floodlighting trees and landscaping owing to the greenish-blue character of the light from these lamps.

249. Sports Lighting. The level of illumination required depends upon several factors, among which are the speed of the game, the skill of the players, and the number of spectators and their distance from the field of play. If television coverage is involved, this also affects the lighting level. Economic considerations also are important. High intensities of illumination are desirable in almost all sports, but since lower levels are acceptable, a variety of layouts are suggested.

HID lighting systems with metal halide and high-pressure sodium lamps are extensively used in sports lighting owing to their high efficacy and longer lamp life. The warm-up and restrike characteristics of these light sources should be recognized in designing the lighting system. A standby incandescent system may be desired in spectator areas.

Incandescent lighting systems are still used in sports-lighting applications owing to the lower system cost when the annual hours of usage are limited. In sports installations in which the lighting is operated during fewer than about 500 h per year, it may be economical to use short-life incandescent lamps or to burn standard lamps at higher than rated voltages. This reduces the power cost and the required number of floodlights. For fewer than 200 h per season, general-service incandescent lamps at 10 percent overvoltage are generally used. If the system is used between 200 and 500 h per year, operation of general-service lamps at 5 percent overvoltage is preferable. The following table shows the effect of overvoltage operation on the life, wattage, and light output of 1000- and 1500-W incandescent lamps.

Approximate Performance of 1000- and 1500-W Incandescent Lamps

Voltage	Light, %	Watts, %	Lamp life, %
Rated	100	100	100
5% over rated	117	108	50
10% over rated	135	116	30

The layouts that follow are guidelines to obtain the recommended levels of illumination if high-quality floodlights are mounted and operated as indicated. Some latitude in beam-spread requirements is acceptable when several floodlights are mounted on a single pole, provided the resulting average beam spread is approximately the same as that specified.

NOTE For current recommended practice on sports lighting, consult Illuminating Engineering Society, *IES Sports Lighting*, RP-6.

250. Archery

The floodlight provides visibility of the arrow throughout flight.

Floodlights	Per target One Type 2, Group A
Lamps	One Type 6 × 5, Group B For enclosed floodlight Distance up to 30 yd: 175-W metal halide 30 to 50 yd: 250-W metal halide 50 to 100 yd: 400-W metal halide
Mounting height	Enclosed floodlight 15 ft above ground Flood on same pole 12 ft above ground
Poles	One per target

251. Badminton

Indoor courts may be lighted with industrial diffusing units along the sidelines.

Floodlights						
Class	Type	Group	No. per		Lamp watts	Total load, kW
			Group	pole		
Recreational	6 × 5	D	2	4	500	2
Lamps			500-W tungsten-halogen			
Mounting height			20 to 25 ft above court			
Poles			Two per court			

252. Baseball

Floodlights								Minimum mounting height, ft

			A's	B's	C's			
Major league	2	A	120
AAA and AA	2, 3	A	12	24	18	144	235	110
A and B	2, 3	A	10	16	8	84	137	90
C and D	3, 5	A	6	8	6	52	85	70
Semipro and municipal	5	A	4	6	4	36	59	60

^aLuminaire quantities based on field and stadium dimensions.

Lamps 1500-W metal halide

253. Basketball: Indoor

If ceiling is lower than 20 ft, more units on closer spacing should be used and recessed in the ceiling if possible. Luminaires should be rigidly mounted, and lamps should be protected from the ball.

Class	Fixture	Lamp watts	Spacing, ft	
			A	B
Metal halide				
College or pro	High-bay industrial	250	14.2	16.8
High school	High-bay industrial	175	15.9	21.0
Recreational	High-bay industrial	175	26.0	28.0
High-pressure sodium				
College or pro	High-bay industrial	250	17.0	16.0
High school	High-bay industrial	150	17.0	16.0
Recreational	High-bay industrial	70	17.5	19.2

Mounting height On ceiling

254. Basketball: Outdoor

Wide-beam floodlights are required to illuminate the ball when it is a considerable distance above the court.

Class	Floodlights			Total no.	Total load, kW	Lamp type
	Type	Group	No. per pole			
Recreational	6 × 5	B	2	8	3.6	400-W metal halide
	6 × 5	B	2	8	2.5	250-W HPS

Mounting height 30 ft above court
Poles Four per court

255. Billiards

In large commercial parlors where a number of tables are installed, general illumination of high intensity proves more satisfactory than individual luminaires over each table.

Equipment	Tournament: two two-lamp fluorescent fixtures with louvers
Lamps	Recreational: one two-lamp fluorescent fixture with louvers 40-WT-12 fluorescent
Load	200 or 100 W
Mounting height	7 ft above floor

256. Bowling

Luminaires should be shielded by false ceiling beams or baffles unless they are of the asymmetric type. They should be positioned so as to provide even illumination along the alley with higher intensity on the pins. Behind the foul line any type of general area-lighting equipment may be employed.

Equipment	Four two-lamp 40-W direct fluorescent fixtures per pair of alleys One 20-W fluorescent unit per alley over the pins
Lamp	40-W T-12 fluorescent 20-W T-12 fluorescent
Mounting height	9 ft minimum

257. Boxing

The class of bout will determine the level of illumination.

Floodlights

Class	Type	Group	No. per pole	Total no.	Lamp watts	Total load, kW
Championship	5	A	2	8	1000	8.7
Professional	5	A	1	4	1000	4.3
Amateur	6	A	2	8	400	3.6

Four per court

259. Football

The distance between the farthest row of spectators and the nearest sideline (see table) determines the lighting requirements, but the seating capacity should also be considered. Either of the pole plans shown or any intermediate longitudinal spacing is considered good practice. Local conditions determine the exact pole locations.

Class	Recommended footcandles	Distance—poles to sideline, ft	No. of poles	Floodlights			Total no.	Total load, kW
				Type	Group	No. per pole		
I	100	Over 140	6	2	A	24	144	234
		100-140	6	2	A	22	132	222
II	50	75-100	6	2	A	12	72	117
		50-75	6	3	A	10	60	98
III	30	30-50	6	3, 4, 5	A	6A, 8B	40	65
IV	20	15-30	8	4	A	3	24	39

Class	Distance farthest spectators to field, ft	Seating capacity	Lamps	1500-W metal halide
I	Over 100	Over 30,000		
II	50-100	10,000-30,000		
III	30-50	5,000-10,000		
IV	Under 30	5,000		

260. Golf Driving Range

The floodlights should be directed so as to provide illumination on the ball throughout its flight.

Floodlights

Aiming point	Type	Group	No. per pole	Lamp	Load per pole, kW
X	5	B	1	1000-W metal halide	1.1
Y	2	A	2	1000-W metal halide	2.2
Z	2	A	1	1000-W metal halide	1.1

Mounting height 25 to 30 ft above tees
 Poles One for every 50 ft of range width; minimum: two poles

261. Handball: Outdoor

Glare is largely eliminated by locating the floodlights behind the players.

Floodlights

Class	Type	Group	No. per pole		Total no.	Lamp watts	Total load, kW
			X	Y			
Club	6 × 5	D	1	1	3	1500	4.5
Recreational	6 × 5	D	...	1	2	1500	3.0

Lamps 1500-W tungsten-halogen
 Mounting height At least 25 ft above court
 Poles For club play, three per pair of courts
 For recreational play, two per pair of courts

262. Horseshoe Pitching

Floodlights should be directed across courts to prevent direct glare.

Floodlights

Class	No. of courts	Type	Group	No. per pole		Total no.	Lamp watts	Total load, kW	Lamp type
				X	Y				
Tournament	4-6	6 × 5	B	1	1	4	400	1.84	Metal halide
	1-3	6 × 5	B	...	1	2	400	0.92	Metal halide
Recreational	4-6	6 × 5	B	1	1	4	250	1.24	HPS
	1-3	6 × 5	B	...	1	2	250	0.62	HPS

Lamps Metal halide or high-pressure sodium
 Mounting height At least 20 ft above court
 Poles Four for 4-6 court layout, two for 1-3 court layout

263. Ice Skating: Outdoor

The design suggested produces satisfactory illumination for recreational skating.

Floodlights

Area	Type	Group	W/ft ²	Lamp type
Rink	6 × 5	B	0.10	HPS
	6 × 5	B	0.16	Metal halide
Pond	6 × 5	B	0.02	HPS
	6 × 5	B	0.03	Metal halide

The size of the area determines the number and wattage of the floodlights.
 Lamps High-pressure sodium or metal halide
 Mounting height At least 20 ft above ice
 Pole spacing Not to exceed 4 times mounting height

264. Racetracks

The lighting equipment should be so positioned and directed as to keep glare and shadows at a minimum.

Floodlights		Types A and B
Lamps	Metal halide	
Load	Varies with track size	
Mounting data	50 to 80 ft high and 50 ft inside inner edge of track	

265. Shuffleboard

Floodlights should be directed across the court to prevent glare.

Floodlights

Class	No. of courts	Type	Group	No. per pole		Total no.	Lamp watts	Total load, kW	Lamp type
				X	Y

270. Swimming Pool: Underwater Floodlights

Especially designed equipment is mounted in niches in the walls of the pool.

Location of pool	W/ft ²	
	Good practice	Minimum
Outdoors	0.5	0.3
Indoors	2.0	1.6

Lamp watts	<i>B</i> maximum ft, where <i>D</i> is over 5 ft	<i>B'</i> maximum ft, where <i>D</i> is less than 5 ft	<i>E</i> in below waterline
250–400	4	5	18–24

Lamps Metal halide
 Consult fixture manufacturer if 12.
 V units are to be used.

271. Swimming Pool: Overhead Floodlights

The number of floodlights and the lamp size are determined by the size of the area and the type of equipment.

Floodlights	Type 6 × 5, Group B
Lamps	Metal halide or high-pressure sodium
Load	0.32 W/ft ² for metal halide, 0.20 W/ft ² for HPS (Both pool and surrounding area to be lighted)
Mounting height	At least 20 ft above water
Pole spacing	Not to exceed 4 times mounting height

272. Tennis: Single Court

Floodlights must be directed sufficiently high to provide even illumination on the ball during flight.

Floodlights

Class	No. of poles	Type	Group	No. per pole		Total no.	Lamp watts	Total load, kW
				X	Y			
Tournament	6	5	A	2	2	12	1000	13.1
Club	6	5	A	2	1	8	1000	8.7
Recreational	4	5	A	...	1	4	1000	4.4

Lamps 1000-W metal halide
 Mounting height 30 ft above court

273. Tennis: Two Courts

Floodlights must be directed sufficiently high to provide even illumination on the ball during flight.

Floodlights

Class	No. of poles	Type	Group	No. per Pole		Total no.	Total load, kW
				X	Y		
Club	6	5	A	2	2	12	13
Recreational	6	6 × 5	B	1	1	6	6.5

Lamps 1000-W metal halide
 Mounting height 35 to 40 ft above the court

274. Table Tennis

When louvered fluorescent luminaires are used, they may be mounted either lengthwise or crosswise of the table.

Recreational

Class	Fixtures		Lamp watts	Total load, kW
	No.	Type		
Recreational	2	Fluorescent	40	0.16
	2 or 4 ^a	Deep-bowl ^b	150	0.3 or 0.6

^aFor skilled play four luminaires mounted 4½ to 6 ft above the table should be used.

^bLouvered fluorescent luminaires for two 40-W lamps may also be used.

Lamps 40-W T-12 fluorescent
 150-W incandescent

275. Trapshooting

Uniform illumination will prevent apparent variation in bird speed.

Floodlights	Four 6 × 5, Group B
Lamps	1000-W metal halide
Load	4.3 kW
Mounting height	20 ft above ground
Poles	Two

276. Volleyball: Outdoor

Wide-beam floodlights are necessary to provide uniform illumination.

Floodlights

DIVISION 11

OPTICAL FIBER

The Advantages of Fiber Optics	11.1
Applications	11.2
The Nature of Light	11.3
Invisible Light	11.3
Transmitting Light Through Fibers	11.4

1. General. Optical fibers are hair-thin strands of ultra-pure glass (or slightly larger strands of plastic), and are used for the transmission of signals. Unlike most signaling methods, optical fiber transmits light, rather than electricity.

Pulses or waves of light can be used in the same ways as pulses or waves of electricity and magnetism to transfer data from one place to another. Because of the transmission characteristics of light through optical fiber, it is in many ways superior to using electricity through conductors, offering less loss, less signal distortion, and allowing higher bandwidth transmission over longer distances than other media.

The current importance of optical fiber data transmission is difficult to overestimate. Not only has optical fiber become essential to long-distance telephone transmissions, but it is becoming increasingly important for all other forms of data transmission, such as CATV distribution, connecting cell phone towers, municipal traffic networks, security systems in buildings, airports, and the backbones of local area networks (LANs).

Use of optical fiber for the transmission of cable television signals is gaining quickly, and is in fact the standard distribution means for almost everything except the coaxial cable drops into businesses and residences, and, of course, interior wiring.

Computer networks are quickly exceeding the capacity of copper conductors, and are beginning to change over from copper to fiber. The newest computer networks are specifying optical fiber transmission, simply because the standards groups are uncertain that there will be a workable copper transmission method. [Desktop (horizontal) connections may transition from copper to wireless for mobility.]

THE ADVANTAGES OF FIBER OPTICS

A well-designed system of fiber optics as a communications medium offers four primary advantages over traditional electrical systems:

2. Performance. Optical fiber cables have a much greater bandwidth capacity than wire. This allows for high-volume, high-speed data transfer. Data transmission of optical fiber can easily reach speeds of hundreds of gigabits per second, far higher than copper communications cables.

NOTE: The terms “bits per second” and “hertz” can be confusing. One bit per second and one Hertz are rough equivalents, and are sometimes used interchangeably.

The term *Hertz* comes from the electrical and electronics industry. *Bit* comes from the digital computer industry. Because of this, electrical and electronic manufacturers, such as cable makers, will more often use *Hertz*, while computer industry people will use *bits per second*. When applied to the transmission characteristics of copper cables, *Hertz* is a fine term; but when discussion signals are transmitted from place to place, *bits per second* is better.

Because of the intricacies of computer technology, there is a slight technical difference between bits per second and Hertz; but again, the terms are so close to equivalent that there is little reason to “nit-pick” over interchangeable use.

3. Electrical immunity. Optical fiber cable is nonmetallic. Because of this, it can neither emit nor pick up electromagnetic interference (EMI) or radio frequency interference (RFI); both being problematic with metal wires. Cross talk between cables does not exist. Additionally, fiber optics (the term *fiber optics* has long been applied to the use of optical fiber in general) have no grounding or shorting problems. This is also an important feature when installing communications wiring in hazardous environments. Optical fiber cabling causes no sparking or excessive heat, even when broken.

4. Small size and low weight. Optical fiber cable weighs approximately one ninth the weight of coaxial cable and is also physically smaller. In order to carry 24 telephone conversations, telephone companies must use two pairs of copper wire. By using optical fiber cable rather than copper, one pair of cables can carry hundreds of thousands of conversations.

5. Security. Electronic *bugging* generally depends on electromagnetic monitoring. Because optical fibers carry light rather than electricity, they are immune to bugging. In order for bugs to be used on optical fiber cables, the cables must be physically tapped; this is easily detectable as the signal is diminished and error rates increase.

APPLICATIONS

Because of the advantages mentioned above, optical fiber is slowly becoming the standard method of data transfer. It is commonly found in the following applications:

- All long distance telephone lines
- All trans-oceanic telephone lines
- All Internet backbones, long-haul and trans-oceanic
- Local telephone lines
- Connections to cell phone towers
- Local Internet lines
- Cable television distribution
- Computer network backbones
- Computer network horizontal runs
- Closed-circuit television
- Electronic newsgathering

- Military communications
- Industrial signals and controls
- Miscellaneous signaling and control applications

THE NATURE OF LIGHT

To understand the use of optical fibers, it is first necessary to understand the nature of light itself. Light is to optical fiber what electricity is to conductors.

Light is essentially a series of electromagnetic waves, with a few properties of particles added. When being described as a particle, light is often referred to as a stream of photons, moving from one place to another. A photon is considered to be very similar to an electron, and can be abstractly described as a primary particle of light, just as an electron may be described as a basic particle of electricity. As applied to optical fiber transmission, the particle characteristics of light are generally of lesser importance than the wave characteristics. Nonetheless, you should be aware of this dual nature (wave and particle) of light. A precise explanation of these characteristics would enter the realms of quantum physics, and is beyond the scope of this text.

The first characteristic of light that presents itself to us is color. Some light is red, some blue, some other colors. After years of research, it was discovered that each color of light has its own *wavelength*; or in other words, its own frequency (measured in cycles per second, or Hertz). For instance, waves of red light have a lower frequency than blue light, and green is in-between. Our eyes perceive different frequencies of light waves much like radios tune into different frequencies of radio waves. But rather than specifying light by its frequency, we signify the color by the wavelength of the light. So, a certain *wavelength* of light means a certain *color* of light. We measure wavelengths in nanometers (billionths of a meter). For example, a deep red light would have a wavelength of about 600 nm.

Wavelength and frequency really signify the same thing, and can be interchanged by using a mathematic formula. As wavelength decreases, the frequency increases. We specify wavelength for this work rather than frequency, since it is generally easier to use, and it is used in virtually all of scientific literature.

INVISIBLE LIGHT

Our eyes are perfectly tuned for the light of our sun. The sun puts out certain wavelengths of light, which our eyes pick up very well. There are, however, other wavelengths of light, and some of those are beyond our visual range. In other words, our eyes have limits, and beyond those limits we are blind. This is like a radio that can pick up the AM and FM bands, but not the shortwave bands. The shortwave signals are out there waiting, but your receiver cannot tune in to them.

You have no doubt heard of infrared light; it is the type of light that television remote control units use. These light waves are useful, but we cannot see them. It is this type of light that we use for optical signals.

It would be handy if we could use visible light in optical fibers, but it simply doesn't work well. The characteristics of the glass used in optical fibers are such that they transmit certain wavelengths (colors) of light better than others. In particular, the wavelengths of 850 nm, 1300 nm, and 1550 nm are transmitted with a minimum of loss. These wavelengths are just outside of our visual spectrum, in the infrared range.

TRANSMITTING LIGHT THROUGH FIBERS

Some of the more common terms used to describe optical fiber are a “light tube” or a “conduit for light.” These terms have led a lot of people to think that there is some type of hole in the middle of an optical fiber. This is not the case.

None the less, optical fiber does function as a “tube” or “conduit” for light. Light does flow down the center of a fiber (the core) like water flows through a pipe. As you can see in Fig. 11.1, there are three concentric layers to an optical fiber.

FIGURE 11.1 Layers of an optical fiber.

1. Light pulses only through the glass *core* of the fiber.
2. The *cladding* (which is a different type of glass) serves as a barrier to keep the light within the core, functioning much like a mirrored surface.
3. The *coating* has nothing to do with light transmission, and is used only for mechanical strength and protection.

Light is kept to the core of the fiber, and flows through the core as water would flow through a tube. We could even say that the fiber is a “virtual” tube. The light stays in the center of the fiber, not because there is a physical opening there, but because the cladding glass reflects any escaping light back to the core.

These “light tubes” are very thin strands of ultra-pure glass. The dimensions of typical fibers are as follow:

Core	8–62.5 μm (a micron is one millionth of a meter)
Cladding	125 μm (outer diameter, so the cladding thickness over a 62.5 μm core would be $(125 - 62.5) \div 2 = 31.25 \mu\text{m}$)
Coating	250 μm (also the outer diameter)

The dimensions shown above are diameters. The core is one density of glass, the cladding is a second grade of glass, and the coating is an acrylate plastic.

6. Cabling. In order to suitably protect our glass fibers, we package them in cabling. It is a misconception that fiber cables are fragile.

Actual fiber itself (not the *cable*, but only the thin *fiber*) is a concern; but this concern is more from twisting than from bending and pulling. Optical fiber is surprisingly flexible, and will not break easily like sheet glass. It actually has several times the sheering strength of steel; but, being so thin, it can be broken. Torsion is a concern. When optical fibers are both twisted and pulled, they tend to develop microcracks, which inhibit light transmission and distort the light signal.

FIGURE 11.2 Fiber cable with several layers of protection for the glass fiber.

Fiber *cables*, however, are not at all fragile. In fact they are often more durable than copper communication cables. Optical cables encase the glass fibers in several layers of protection, as is shown in Fig. 11.2.

The first protective layer is the coating that we mentioned earlier. The next layer of protection is a *buffer* layer. The buffer is typically extruded over the coating to further increase the strength of the single fibers. This buffer can be of either a *loose tube* or *tight tube* design. Most datacom cables are made using either one of these two constructions. A third type, the ribbon cable, is frequently used in the telecommunications work, and may be used for datacom applications in the future; it uses a modified type of tight buffering.

A tight tube, or tight buffer, is a layer of plastic extruded directly on to the bare fiber. This is nearly identical to the way plastic insulation is extruded over copper conductors to make insulated building wire; but this is obviously much thinner.

A loose tube is simply a paper or plastic tube—like a thin drinking straw—into which are inserted several optical fibers. Each of these fibers will have a very thin layer of plastic extruded over them, primarily for color-coding and to add a little bit of strength. If you think of threads inside of a drinking straw, you will have a reasonable understanding of how the loose tube protection scheme works. The tubes isolate the fibers from the outside world. They are free to move around inside of the tubes, which bear the external stresses.

After the buffer layer, the cable contains a *strength member*. Most commonly, the strength member is Kevlar fabric, the material that bulletproof vests are made from. The strength member not only protects the fiber, but also is used to carry the tensions of pulling the cable. (You can never ever pull the fibers themselves.)

After the strength member finally comes the outer jacket of the cable, which is typically some type of polyethylene or PVC. The exact type of nonmetallic jacketing will determine which suffix will apply to the cable designation, as covered in Sec. 40. In many cases, however, there will be additional *stiffening members* which also increase the cable's strength and durability.

7. Fiber connectors. As the fiber optic field began to develop, one of the biggest mechanical problem that existed was permanently fixing the fibers at their ends. Since they have such a small diameter, they must be held rigidly in place and accurately aligned, in order to mate with other fibers, light sources, or light detectors. The first fiber connectors were difficult to install. They used a variety of glues, ovens, and long, difficult polishing methods.

Terminating fibers (termination involves installing a connector and polishing the face of the fiber) can now be done within half the previous time, and the process continues to improve.

8. Splices. While fiber connectors are used to make nonpermanent connections at the ends of fibers, splices are used to join ends of fiber to each other permanently. There are two primary ways this is done: by *fusion*, that is, by melting the pieces of glass together; and by *mechanical* means. The critical factors in splicing are the following:

1. That the fiber joint passes light without loss.
2. That the joint is mechanically secure; that is, that it will not be easily broken.

9. Testing. When installing a fiber system (the whole system of optical fibers is often called a *cable plant*, an old telephone industry term), it must be tested, to ensure that it will properly perform. The purpose of testing is to make sure that light will pass through the system properly. The main types of optical testing used in the field are the following:

Continuity testing. This is a simple visible light test. Its purpose is to make sure that the fibers in your cables are continuous; that is, that they are not broken. This is done with a modified type of flashlight device and the naked eye, and takes only a few minutes to perform.

Power testing. This is to accurately measure the quality of optical fiber links. A calibrated light source puts infrared light into one end of the fiber, and a calibrated meter measures the light arriving at the other end of the fiber. The loss of light in the fiber is measured in *decibels*.

OTDR testing. The OTDR is a piece of equipment properly called an *optical time domain reflectometer*. This device uses light backscattering to analyze fibers. In essence, the OTDR takes a snapshot of the fiber's optical characteristics. It sends a high powered pulses into the fiber and measures the light scattered back toward the instrument. The OTDR can be used to locate fiber breaks, splices and connectors, as well as to measure loss. However, the OTDR method of loss measurement may not give the same value for loss as a source and power meter, due to the different methods of measuring loss. In addition, the OTDR gives a graphic display of the status of the fiber being tested. Another advantage is that it requires access to only one end of the fiber.

As useful as the OTDR is, however, it is not necessary in the majority of situations. A power meter and source are used to test the loss of fiber optic cable, simulating the way the fibers are used, and measuring the light lost from one end of the cable to the other. In addition, OTDRs are quite expensive. Even when they are necessary, many installers prefer to rent them, rather than to purchase them.

10. Basic optical terminology

Attenuation. Attenuation is the weakening of an optical signal as it passes through a fiber. Attenuation is signal loss. Attenuation in an optical fiber is a result of two factors, *absorption* and *scattering*.

Absorption is caused by the absorption of the light and its conversion to heat by molecules in the glass. Primary absorbers are residual deposits of chemicals that are used in the manufacturing process to modify the characteristics of the glass. This absorption occurs at definite *wavelengths* (the wavelength of light signifies its color and its place in the electromagnetic spectrum). This absorption is determined by the elements in the glass, and is most pronounced at the wavelengths around 1000 nm (nanometers), 1400 nm, and above 1600 nm.

Scattering occurs when light collides with individual atoms in the glass, and is knocked off its original course. This is the primary cause of attenuation.

Fiber optic systems transmit in the “windows” created between the absorption bands at 850 nm, 1300 nm, and 1550 nm wavelengths, for which lasers and detectors can be easily made.

Networks. To communicate between several pieces of equipment (for example, between 20 different computers in an office), they must all be connected together. To do this, we must do two things:

1. Develop a logical method of connecting them. Should we tie them all to a central point? Should we connect them in a loop? Or just a direct link?
2. Provide a definite protocol for communicating. If the machines do not “talk to each other” in some type of order, the whole system will collapse in a jumble of signals that the machines can neither separate nor interpret.

There have been many types of networks developed, each with their own strengths and weaknesses. The many network names you have probably heard, such as Ethernet, 10base T, FDDI, ATM, and Token Ring are simply different methods of connecting computers together.

Bandwidth. Bandwidth is the range of signal frequencies or bit rate at which a fiber system can operate. In essence, it is a measure of the amount of signal that can be put through a fiber. Higher bandwidth means more data per second; lower bandwidth means less signal.

Dispersion. There are two especially confusing terms that you will come across in optical fiber literature. They are *chromatic dispersion* and *modal dispersion*. In both of these terms, *dispersion* refers to the spreading of light pulses until they overlap one another, and the data signal is distorted and lost. *Chromatic* refers to color, and *modal* primarily refers to the light’s path. Thus we can state in simple terms that:

Chromatic dispersion = Signal distortion due to color

Modal dispersion = Signal distortion due to path

Note that dispersion is not a *loss* of light; it is a *distortion* of the signal. Thus, dispersion and attenuation are two different and unrelated problems: Attenuation is a loss of light; dispersion is a distortion of the light signals.

11. Total internal reflection. Optical fibers function well for signal transmission because of the principle of *total internal reflection*.

When light goes from one material to another of a different density (in scientific terms, this difference in density is called *index of refraction*), the light’s path will bend. This is what causes the illusion of a stick bending when it is stuck into water. When the light bends at a certain angle (and this angle is different for different types and densities of materials), all of it is reflected, and none passes through the boundary between the two materials.

This phenomenon is used to bend the light at the core/cladding boundary of the fiber, and trap the light in the core. By choosing the material differences between the core and cladding, one can select the angle of light at which total internal reflection occurs.

This angle defines a primary fiber specification, the *numerical aperture* of a fiber, which is also abbreviated as NA.

12. Numerical aperture. The numerical aperture (NA) designates the angle called *the angle of acceptance*—the angle beyond which the light rays injected into an optical fiber are no longer guided, and will pass through the core/clad boundary and be lost.

Fibers with higher NAs will accept a wider range of light paths (the technical term for paths is *modes*). Because there are so many modes, the signal will be distorted. So, a fiber with a higher NA will cause increased signal distortion, and will be able to carry less signal. We may then say that high-NA fibers have less bandwidth, and that low-NA fibers have greater bandwidth.

13. Index of refraction. The index of refraction of a material is the ratio of the speed of light in vacuum to that in the material. In other words, the index of refraction is a measure of how much light slows down after it enters the material. Since light has its highest speed in a vacuum (approximately 300,000 kilometers per second), and since light slows down whenever it enters any medium, (water, plastic, glass, crystal, oil, etc.), the index of refraction of any material is greater than one.

For example, the index of refraction in a vacuum is 1, that of glass and plastic optical fibers is around 1.5, and water has an index of refraction of around 1.3 You can see from this that the light signals sent through an optical fiber travel at considerably less than the “speed of light” as most people think of it. The much-stated speed of light (again, 300,000 kilometers per second) is the speed of light in a vacuum—not the speed of light in all materials.

14. Pulse spreading (dispersion). We have previously discussed signal distortion, saying that it comes from two primary causes—the colors of light sent through the fiber (chromatic dispersion), and the paths that light takes as it moves through the fiber (modal dispersion). Both of these reasons for distortion have the same final effect—to distort the signal by *pulse spreading*.

Pulse spreading is illustrated in Fig. 11.3. Notice that the digital signal sent into the fiber is square. As the signal travels down the fiber, it is distorted, and begins to spread.

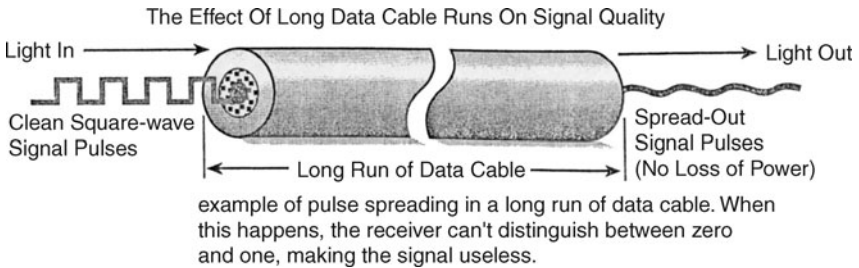

FIGURE 11.3 Chromatic pulse spreading of the digital signal.

Pulse spreading is not a loss of light—just as much light is leaving the fiber as entered it. The light signals, however, are distorted. If the pulses spread too much, they will be unintelligible to the receiver, and the communication will be ineffective.

One at a time, we will now explain why both color and path cause this pulse spreading.

15. Chromatic dispersion. Chromatic dispersion (pulse spreading due to the colors of light sent through the fiber), occurs because of one fact: Different colors of light (which we also call different wavelengths of light) travel at different speeds in an optical fiber.

For example, if two different wavelengths (colors) of light are sent into a long fiber at the same time, one of them will reach the far end before the other will—they will not reach the end at the same time.

You can see from this example that the time difference between the two different wavelengths arriving at the end of the long fiber would tend to spread a data pulse. This causes the pulse spreading that is shown in Fig. 11.3.

Because of chromatic dispersion, it is important to use light sources that put out a very narrow range of colors. Unfortunately, a technology of building affordable, single-color light sources has not yet been developed. Our current light sources put out a range of wavelengths (colors), not a single wavelength.

The newer lasers are the best of our light sources, and put out a reasonably small range of wavelengths. Even though these lasers are more expensive than light emitting diode (LED) light sources, they are often used because they cause far less chromatic dispersion. The LED sources are used only for shorter runs where higher chromatic dispersion is manageable.

Good laser sources are said to have a *narrow spectral bandwidth*, putting out light within a 1 nm range. So, the light output from a 1550 nm laser will be within a range of 1549.5 and 1550.5 nm.

LED sources, on the other hand, are said to have a *broad spectral bandwidth*. Many LEDs have a spectral bandwidth of 20 nm. So, the light output from an 850 nm LED would be between 840 and 860 nm.

16. Modal dispersion. (A factor in multimode fiber only.) Modal dispersion (pulse spreading due to the paths of light sent through the fiber), occurs because some paths through a fiber are more direct than others. Look at Fig. 11.4, and you will see this illustrated.

FIGURE 11.4 Modal dispersion of the paths of light through a fiber.

In Fig. 11.4, one of the light rays go right down the middle of the fiber, another enters the fiber at a rather severe angle, and must bounce from side to side, all the way through the fiber.

You can see how the light ray that goes down the middle of the fiber has a significantly shorter path, and will reach the far end considerably sooner than the other ray of light will. Notice how different paths of light traveling through a fiber will reach the end at different times, and will cause a data pulse to spread.

Modal dispersion has been a major factor in determining the design of optical networks, and even in the design of fibers themselves.

17. Types of optical fibers. The three main types of optical fibers that are commonly used today are the following:

Single-mode fibers. A single-mode fiber allows only one light wave ray to be transmitted down the core. The core is extremely small, usually between 8 and 9 μm . Because of quantum mechanical effects, the light traveling in the very narrow core stays together in packets, rather than bouncing around the core of the fiber.

This tendency of the light in a narrow core to travel in packets is not because the core is small enough to allow only one photon at a time to pass through. Photons are many orders of magnitude smaller than the core. Rather, this effect is due to a relationship between the wavelength of the light and the core size. As stated above, this is a quantum mechanical effect, and a detailed explanation is beyond our scope in this text.

Thus single-mode fiber has an advantage over all other types in that it can handle far more signal, and over far greater distances.

Multimode, graded-index fibers. Graded-index fibers contain many layers of glass, each with a lower index of refraction as it moves outward from the center. Since light travels faster in the glass with lower indexes of refraction, the light waves refracted to the outside of the fiber are speeded up to match those traveling in the center. The result is that this type of fiber allows for high speed data to be transmitted over a reasonably long distance. Multimode fibers are used with LED light sources, which are less expensive than the laser light sources which are used for single-mode. Graded index fibers come in core diameters of 50, 62.5, 85, and 100 μm . For a long time, 62.5 μm was the standard size, although 50 μm fiber is now being specified for Gigabit Ethernet networks.

Multimode, step-index fibers. Step-index fibers are used far less than the other types, having a far lower capacity. They have a relatively wide core, like multimode, graded-index fibers, but since they are not graded, the light put through them bounces wildly through the fiber, and exhibits high levels of modal dispersion (signal distortion due to path).

All three types of fiber are shown in Fig. 11.5.

FIGURE 11.5 Multimode step-index fibers.

18. Fiber sizing. The size of an optical fiber is referred to by the outer diameter of its core and cladding. For example, a size given as 62.5/125 indicates a fiber which has a core of 62.5 μm and a cladding of 125 μm . The coating is not typically mentioned in the size, because it has no effect on the light-carrying characteristics of the fiber.

The *core* is the part of the fiber that actually carries the light pulses that are used for transferring data. This core may be made of either plastic or glass. The size of the core is important, as core sizes of joined fibers must match. Larger cores have greater total light-carrying capacity than smaller cores, but have less signal-carrying capacity than the smaller cores because they lead to far greater signal distortion. We may say that more photons can travel through a larger core, but they are not effective for transferring signals.

The *cladding* sets a boundary around the fiber so that light running into this boundary is reflected back into the cable. This keeps the light moving down the cable, keeping it from escaping. Claddings can be made of either glass or plastic, and always have a different density than that of the core. (If they did not have a different density [index of refraction], they could not reflect escaping light back into the core.)

As an example of this, imagine that you are standing next to a calm mountain lake. As you look across the lake, you can see a reflection of the mountains and trees on the far side. The lake works as a large mirror. As you move your eyes closer, eventually the reflection stops, and you can see through the surface of the water. Just in front of your feet, you can see fish swimming in the water. In this example, the water's surface acts like the cladding of an optical fiber, with the air acting as the core. When the light reaching your eyes is of a shallow enough angle, the surface of the lake reflects all of it. But when the angle between your eyes and the water's surface becomes too steep, the light passes through the surface, and is not reflected.

Coatings are typically multiple layers of ultraviolet curable acrylate plastic. This is necessary to add strength to the fiber, to protect it, and to absorb shock. These coatings are between 25 and 100 μm thick. (One micron is equal to one millionth of a meter. For comparison purposes, a sheet of paper has a thickness of approximately 25 μm .) Coatings can be stripped from the fiber (and must be for terminating) either mechanically or chemically, depending on what type of plastic is used.

19. Manufacturing fiber. Manufacturing optical fiber is a very difficult and complex process. In general, the process entails three parts:

- 1. The manufacture of a preform,** which is a cylinder of glass that the optical fiber will be made from. They are generally about three feet long and an inch wide. The preform has a physical make up identical to the final fiber, including both core and cladding, except that it is much wider and shorter.
- 2. Pulling the fiber.** The preform is heated very precisely, and a thin strand of glass is pulled off of one end. The diameter of this strand is controlled very carefully through variances in heating and pulling tension. This strand is the optical fiber, containing both the core and cladding.
- 3. Cooling, coating, winding.** Once the fiber is pulled off the preform, it must be carefully and slowly cooled, covered with the final coating, and wound on to reels.

There are three methods currently used to fabricate moderate to low loss waveguide fibers: modified chemical vapor deposition (MCVD), outside vapor deposition (OVD), and vapor axial deposition (VAD).

Modified chemical vapor deposition. MCVD begins with a hollow glass preform, approximately 3 ft long and 1 in. in diameter, and is placed in a horizontal or vertical lathe and spun rapidly. A computer-controlled mixture of gases is passed through the inside of the tube. On the outside of the tube, a heat source (oxygen/hydrogen torch) passes up and down.

Each pass of the heat source fuses a small amount of the precipitated gas mixture to the surface of the tube. Most of the gas is vaporized silicon dioxide (glass), but there are carefully controlled remnants of impurities (dopants) which cause changes in the index of refraction of the glass. As the torch moves and the preform spins, a layer of glass is formed inside the hollow preform. The dopant (mixture of gases) can be changed for each layer so that the index may be varied across the diameter.

After sufficient layers are built up, the tube is collapsed into a solid glass rod, which is the preform. It is now a scale model of the desired fiber, but much shorter and thicker.

The preform is then taken to the drawing tower, where it is pulled into a length of fiber up to 10 kilometers long.

Outside vapor deposition. This method utilizes a glass target rod which is placed in a chamber and spun rapidly on a lathe. A computer-controlled mixture of gases is then passed between the target rod and the heat source. On each pass of the heat source, a small amount of the gas reacts and fuses to the outer surface of the rod, resulting in what is referred to as “soot” on the preform, although it is certainly nothing like creosote and charcoal on the inside of a chimney. After enough layers are built up, the target rod is removed and the remaining soot preform is collapsed into a solid rod. The preform is then taken to the tower and pulled into fiber.

Vapor axial deposition. This process utilizes a very short glass target rod which is suspended by one end. A computer-controlled mixture of gases is applied between the end of the rod and the heat source. The heat source is slowly backed off as the preform lengthens due to the soot build-up caused by gases reacting to the heat and fusing to the end of the rod. After sufficient length is formed, the target rod is removed from the end, leaving the soot preform.

The preform is then taken to the drawing tower to be heated and pulled into the required fiber length.

20. Fiber coatings. After the fiber is pulled, a protective coating is applied very quickly after the formation of the hair-thin fiber. The coating is necessary to provide mechanical protection and prevent the ingress of water into any fiber surface cracks. The coating typically is made up of two parts: a soft inner coating, and a harder outer coating. The overall coating thickness varies between 62.5 and 187.5 μm , depending on fiber applications.

These coatings are typically strippable by mechanical means, and must be removed before fibers can be spliced or fitted with connectors.

TABLE 11.1 Fiber Types and Typical Specifications

Fiber type	Core/cladding diameter (m)	Attenuation (dB-km)			Bandwidth (MHz-km)
		850 nm	1300 nm	1550 nm	
Step index	200/240	6			50
Multimode	50/125	3	1		600
Graded index	62.5/125	3	1		500
	85/125	3	1		500
	100/140	3	1		300
Single-mode	8–9/125		0.5	0.3	Very high
Plastic 1 mm	(1 dB/m 665 nm)			Low	

21. A brief history of optical fiber. The idea of the optical fiber dates back to the nineteenth century in England, where a man named Tyndall developed a “light fountain” based on the phenomenon of internal reflection.

In 1881 William Wheeler, a Concord, Massachusetts engineer, applied for a patent that illustrates the transport of light by means of a light conductor. This patent describes an indoor lighting system intended to substitute for the incandescent bulbs which Edison had just invented. The system uses light emitted by a powerful electrical arc that is distributed to each of the rooms in a building by means of optical conductors.

In 1934, AT&T engineer Norman R. French devised the first optical transmission system, followed by RCA’s Kell and Sziklai. The RCA patent described today’s photonic transmission systems in some detail.

The principle of an optical fiber was described in 1957, first in England by Hopkins and Kapany, who described the first fibroscope in a paper published in the journal *Nature*, then in the United States by American Optical Corp.’s R&D Manager, Brian O’Brien, who patented a bundle of optical fibers used for image transport.

The invention of the laser revived the researchers interest in optical communications and Charles K. Kao and George Hockham, of STL (Standard Telecommunications Laboratories), were the first to demonstrate that long distance transmissions via optical fibers were possible.

In 1970, three Corning Glass Works researchers, R. Maurer, D. Keck, and P. Schultz, made practical long distance transmission possible by producing an optical fiber with 20 dB/km attenuation.

The key dates in the history of optical fiber signal transmission are the following:

- 1880 A. G. Bell’s Photophone
- 1881 W. Wheeler’s patent for a light conducting guide
- 1934 N. R. French’s patent for a partly optical transmission system
- 1950 R. D. Kell & G. C. Sziklai’s patent for an optical transmission system
- 1957 B. O’Brien’s patent for a fiber bundle
- 1957 Articles in the journal *Nature* on fiber bundles and a fibroscope
- 1961 Invention of the laser
- 1966 C. Kao & G. A. Hockham: long distance optical transmissions
- 1970 R. D. Maurer, D. B. Keck, & P. C. Schultz: first 20 dB/km fiber

22. Data transmission. Optical data transmission (the method of sending data through optical fiber cables) is illustrated in Fig. 11.6. This drawing shows a telephone conversation traveling over optical fiber cabling. The voice is first transformed by the telephone into an electrical signal. This signal is then scanned by a digital encoder, which reduces the signal into *binary code* (a series of offs and ons). The driver, which activates

FIGURE 11.6 Optical data transmission.

the LED or laser light source, transmits the ons as bursts of light and the offs as the absence of a light pulse. The light travels through the optical fiber cable until it is received at its destination, amplified, and fed into a digital decoder. The decoder translates the digital signal back into the original electrical signal. And finally, the telephone changes the electrical signal back into sound.

Transmitters and *decoders* are the devices which change electricity into light pulses, and change light pulses back into electrical pulses.

23. Simplex and duplex transmission. Optical transmissions are called *simplex*, *half-duplex*, or *full-duplex* based on their method of transmission. Both simplex and half-duplex systems use only one fiber to communicate, and are less expensive to build.

The simplex method transmits in only one direction, while the half-duplex system can send signals in both directions, but not both directions at the same time. Half-duplex is similar to a two-way radio in its operation. The terminal electronics must act as both a receiver and transmitter and are, appropriately, called transceivers.

The full-duplex system, on the other hand, uses two fibers to communicate. This way one fiber is always available to transmit from point A to point B while the other fiber is transmitting from B to A. Therefore, both ends of a full-duplex system have both transmitters and receivers. Because of this, you must be careful not to mix them up during installation by reversing the transmit and receive fibers. Sometimes the fibers are color coded, or they may have some other identifying feature such as a ridge marking one fiber on duplex cables. In any case, be careful to not reverse the two fibers when installing connectors on the ends.

24. Units of measurements. The magnitudes involved in transmission through optical fibers lead to submultiples and multiples of units to be widely used: decibel, micrometer, megabit, and so on.

Generally, all dimensions of an optical fiber are expressed in micrometers (μm), which is one millionth of a meter. Of course, millimeter (mm) is used for large diameter fibers.

The wavelengths of light are also expressed in micrometers, or nanometers (nm), which are billionths of a meter.

Transmission parameters such as rates (bit/s) or bandwidth (Hz-km) are expressed in multiples such as kilo, mega, or giga. And the terabit (trillions of bits per second) may soon be the reference for transmission rates in telecommunication networks.

Energy losses and attenuations are only expressed in decibel.

25. Frequency and wavelength. Wavelength (an inverse function of frequency) is just one way of describing the speed of vibration of these photons emitted from a light source. The speed of any wave phenomenon is always the wavelength (λ) multiplied by the frequency (f). Light as a form of electromagnetic radiation has a speed (usually stated as “c”) of 3.0×10^8 m/sec in a vacuum, very nearly that speed in air and perhaps $1/3$ less in a glass fiber. Thus, for light $c = \lambda f$. For example, 10,000,000,000,000,000 Hz (1.0×10^{16} Hz) would correspond to a wavelength of about 3.0×10^{-8} m or 30 nanometers (nm) in air, which is in the ultraviolet range. Our eyes recognize wavelengths from about 390 nm to 770 nm as different colors running from violet to red. There are thousands of other wavelengths we do not see. Our eyes and brains are not tuned to receive them.

Different frequencies of light have different characteristics of loss (attenuation) through glass. Because of these loss characteristics, engineers have chosen 850, 1310, and 1550 nm as the first, second, and third windows of fiber transmission. Since we can't see these three wavelengths, we can't tell, with the naked eye, if their transmitters are operating.

26. Decibel-watt conversion. In optics, all energy and power levels, and all losses or attenuations, are expressed in decibels rather than in Watts. The reason is simple: all transmission calculations and measurements on a fiber are almost always made as comparisons against a reference: received power compared to emitted power, energy in versus energy out (energy lost in a connection), and so on.

Generally, energy levels (emission, reception, etc.) are expressed in *dBm*. This signifies that the reference level of 0 dBm corresponds to 1 milliwatt (mW) of power.

Generally, power losses or gains (attenuation in a fiber, loss in a connector, etc.) are expressed in dBm.

The unit $\text{dB}\mu$ is used for very low levels, in the microwatt level.

A decibel is simply one tenth of a Bel (the name given in honor of Alexander Graham Bell), which is a difference of an order of magnitude (10 times) in the intensity of any event. That number is inconveniently large, so we use decibels instead. It is important to bear in mind that this is a logarithmic relationship. One half of a Bel increase is not half again the original number ($1.5\times$); it is $10^{1/2}$ times the original number or about $3.2\times$. Using decibels, a half Bel increase is a 5 dB increase, thus a positive 5 dB change reflects a multiplier of 3.2. Because the logarithm of 2 (using base 10) is about 0.3, decibel measurement works as follows: a difference of 3 dB equals a doubling or halving of power.

A 3 dB gain in power means that the optical power has been doubled. A 6 dB ($3 + 3$) gain means that the power has been doubled, and then squared, equaling four times the original power. A 9 dB gain ($3 + 3 + 3$ dB) is an eightfold (the original doubling cubed) increase in power, and a 12 dB [$(3 + 3) + (3 + 3)$] gain is about 16 times the original power level. This is the original squared result squared again, or restated as the original doubling raised to the fourth power of the original power level. The resulting number makes sense when you consider that $10 \text{ dB} = 1.0 \text{ Bel}$, defined in terms of a tenfold change. A 3 dB loss of power means that the power has been cut in half. A 6 dB loss means that the power has been cut in half, then cut in half again, equaling one-fourth of the original power. If you have a scientific calculator (or the one built into most computer operating systems) simply hit the inversion (usually "INV") key (or set the check box), type in the increase or decrease in Bels ($\text{dB} \times 0.1$) and hit the "log" button, and the result will be the multiplying factor from the original power level.

A loss of 3 dB in optical power is equivalent to a 50% loss. For example, 1 milliwatt of power in, and 0.5 milliwatt of power out.

A 6 dB loss would equally a 75% loss. (1 milliwatt in, 0.25 milliwatt out.)

27. Active and passive components. The two primary classifications of optical components are *active* components and *passive* components.

Active components are elements in an optical transmission line that somehow convert electrical energy into optical energy or optical energy to electrical energy. Typical active components include light sources (light emitting diodes, laser diodes) and detectors (photodiodes, phototransistors.). Optical components whose operation also requires electrical energy, such as active couplers or optical amplifiers, also belong to this category.

Passive components are elements whose function in an optical link is not to convert electricity into light and vice versa. Passive components would include all the components used in a link, except the active components (optical emitters, receivers, and amplifiers), such as connectors, splices, terminal blocks, couplers, and the like. Mechanical elements such as the protective casings of joints or cable heads are also classified as passive components.

28. Materials used for active components. Silicon, germanium, gallium arsenide, indium phosphide are semiconductor materials used in active optical components.

Silicon and germanium are used for photodiodes only. Gallium arsenide and gallium aluminum arsenide are reserved for emitters. InGaAs and InGaAsP (indium gallium arsenide and indium gallium arsenide phosphide) are general purpose materials with very good emission and reception characteristics.

The abbreviations we use for these materials are the following:

Silicon	Si
Germanium	Ge
Gallium	Ga
Aluminum	Al
Arsenide	As
Indium	In
Phosphide	P

29. LED light sources. LEDs are the most widespread emitters. Their operating principle is simple: a voltage is applied to a semiconductor made of two electrically opposed regions, generating a current flow through the diode. The P region (the positively biased semiconductor region) is doped so that it lacks electrons with respect to the basic material, thus creating what are called “holes”—places where electrons are missing. The N region (the negatively biased semiconductor region) is inversely doped, thus creating free electrons. When a voltage is applied to the diode, the electrons and the holes move toward the junction between the two regions where they combine by emitting photons, the essential particles of light.

30. Types of LEDs. There are three types of LEDs that are commonly used for optical fiber work. The first two are the *surface emission* diodes and *transverse emission* diodes. The fundamental difference between these two types of diodes lies in the emission surface, which is much smaller in transverse emission diodes. The photons generated by current flowing between the two P and N regions are confined in the junction, which has a very small thickness. Therefore, light is emitted on one side of the diode.

The third LED type is the Burrus diode (after the name of Charles A. Burrus, of AT&T Bell Laboratories), in which an optical fiber gathers the emitted light. Therefore, the characteristics of this diode are directivity and a high coupling rate.

Following are several commonly used LEDs:

- GaAs, GaAlAs LEDs: 820–850 nm transmission systems on multimode fibers
- GaAsP LED: plastic optical fibers, visible infrared (665 nm)
- InGaAsP LED: 1330 nm transmission systems on multimode fibers

31. Semiconductor lasers. Semiconductor lasers provide a higher power and a better directivity than LEDs. These characteristics are inherent to their different design although they use the same principle of photon emission by electron excitation. When an electron moves from one energy level to a lower level, it emits a photon. This is called “spontaneous emission,” and can be controlled and triggered by a photon hitting the electron, which then emits a photon with the same wavelength as the first one. This

is **Light Amplification by Stimulated Emission of Radiation**, which is the Laser effect. Vertical-cavity, surface-emitting lasers (VCSELs) are used a great deal in optical fiber systems.

The Laser effect (defined as an “emission of a strong light energy with a high directivity”) is obtained when several conditions are met:

1. The number of high energy level particles must be greater than that of lower level particles. If it is not so, lower level particles absorb the light energy emitted by the photons.
2. These photons must remain confined in a *resonator* so that amplification can be ensured. A resonant cavity is therefore made of two mirrors, one reflecting the light and the other one letting the beam thus created through.

Laser diodes are made of a semiconductor crystal, one side of which is coated by a reflective layer (to form the reflecting mirror) while the emission side is left bare.

Most of the semiconductor materials used for LEDs cannot be used for lasers, such as LEDs emitting in the visible range. In contrast, the materials used for lasers can also be used for LEDs. (A laser diode is capable of operating as an LED.)

The laser effect in a semiconductor is triggered above a given threshold, when the initial stimulation has produced enough photons for the process to be maintained and amplified. Below this threshold, the laser diode functions as a light emitting diode. Beyond this value, a small increase in the control current will generate a very high increase in the emitted power.

At the end of the manufacturing line, all the laser diodes that do not meet the qualification criteria for lasers are regarded as LEDs and used as such.

32. Typical laser diodes.

Here are some commonly used lasers:

- Multimode Lasers: Classical Laser Diodes (LDs), called *Perot-Fabry*, for 1300 nm transmission systems on conventional single-mode fibers, and 1550 nm transmission systems on dispersion-shifted single-mode fibers.
- Single-mode Lasers: Monochromatic LDs, called *DFB* for 1550 nm transmission systems on conventional single-mode fibers.

33. Emission spectrums. The first criterion of choice of an optical emitter (LED or laser) is its wavelength, which influences the attenuation in the link. The second criterion is its *spectral bandwidth*, which influences signal distortion (chromatic dispersion). The emitter is not monochromatic; it scatters a light energy centered around its nominal wavelength (the wavelength for which is specified). The spectrum of emission of laser diodes is much narrower than that of light emitting diodes. Chromatic dispersion is therefore much lower with a laser than with an LED.

The emission wavelength is dependent the materials used to manufacture the light source. The spectral bandwidth is dependent on the structure of the emitter.

34. Configurations of emissions. When an optical emitter, LED or laser, is driven by an analog signal, the light energy which it generates varies continuously depending on the variations of this signal. In the case of a digital signal, the energy is modulated according to the pulses.

In other words, whatever configuration of signal goes in will be the signal configuration that goes out.

TABLE 11.2 Optical Power Levels of Fiber Optic Communication Systems

Network type	Wavelength, nm	Power range, dBm	Power range, W
Telecom	1300, 1550	+3 to -45 dBm	50 nanowatts to 2 milliwatts
Datacom	665, 790, 850, 1300	-10 to -30 dBm	1 to 100 microwatts
CATV	1300, 1550	+10 to -6 dBm	250 microwatts to 10 milliwatts

35. Photodiodes. The light detectors used for optical transmission are semiconductor photodiodes. The operation of these photodetectors is the opposite of LEDs. When a voltage is applied across the diode, the electrons and the holes migrate out of the junction zone between the P and N regions. The empty zone thus created blocks the current flowing through the diode. When the diode is illuminated, electron-hole pairs are formed and current flows again in proportion to the light energy received.

The detector sensitivity at a determined wavelength is dependent on the selected materials.

36. Characteristics of optical receivers. Phototransistors are not used in optical communication systems because their pulse response time is too great for today's transmission rates. The detectors most frequently used are *PIN* devices and avalanche photodiodes (APD). "PIN" refers to *P-intrinsic-N*, the empty zone between the P and N regions of a semiconductor that is doped so that current flow is faster when it is illuminated.

Here are common optical receivers along with their common uses:

- PIN-FET diodes (combining a PIN photodiode and a field effect transistor): used in numerous applications due to their low cost (integrated electronics)
- PN photodiodes: used for low rate transmission systems
- PIN photodiodes: used for high rate transmission systems, low reception levels
- Phototransistors: used for low cost sensors, economical data transmission systems
- Photodarlington: used for low cost sensors, economical low rate applications
- Avalanche photodiodes (APD): used for very low reception levels
- Photoreceivers with built-in photodiode and preamplifier (Pin-FET): used for medium rate applications

37. Coupling the source to the fiber. The injection of the light energy into the fiber is one of the essential points in optical transmission.

The source power varies from about 10 μ W for LEDs to a few tens of milliwatts for semiconductor lasers. The emitted energy is not integrally injected into the fiber; rather, it is dependent on the emission angle of the source (10 to 20° for lasers, much wider for LEDs). The alignment of the source and of the fiber and of the emitting area is also important.

Therefore, the coupling of the emitter and of the fiber, also called *injection*, must be performed with the utmost care.

38. Passive components. Following are descriptions of the most common passive optical components:

Couplers. Today, couplers are widely used in optical transmission systems. Couplers are essentially T connections, which split a branch off of a continuous fiber.

Local area networks are one typical application, where each piece of equipment (computer, printer, etc.) is connected to the network via a coupler, which is an optical T branch, functioning the same as those used to send electronic signals used with coaxial cables.

Typical coupler topologies. The typical configurations of passive couplers are the *star* and the *tee*.

Tee couplers are made of two fibers, one main fiber which passes through it, and one branch fiber. The energy carried by the first fiber is divided at the branching point into two portions that are not necessarily equal: 50/50 couplers are available, but 25/75, 10/90 couplers, and other configurations are available as well.

The star coupler has more than 3 input/outputs (sometimes abbreviated as *I/Os*). The light entering through one or several fibers is mixed in the coupler and exits via the other fibers.

Tee or star couplers are available in numerous models and applications, including:

- Star couplers (2-way to 2-way, 4-way-to-4-way, etc.). These are used in local area networks, dispatching networks, sensors, instrumentation.
- T or X couplers, used in local area networks, dispatching networks, sensors, and for instrumentation.
- *Mux-Demux* (Multiplexer-Demultiplexer) couplers. These are used in telecommunications, videocommunications, instrumentation, and for sensors.

Splitters. The splitter, or directional coupler, is so called because it can separate the energy only in one transmission direction. In the other direction, it can become a multiplexer (putting light sources together).

The two-directional coupler is used to divide the energy in both directions.

39. Wavelength division multiplexing. Wavelength division multiplexing (WDM) is the process of sending several signals with different wavelengths in both directions through the same fiber. This can be done as long as there is a gap between each wavelength that is sufficient to prevent any mixing of the pulses. This gap need not be large; in fact, gaps in the range of tenths of a nanometer are common.

Wavelength division multiplexing systems use couplers to group the signals on the same fiber. On the other end of the line, when the signals are received, couplers are used to dispatch the signals to their respective devices.

The same coupler may be a *multiplexer* (which puts several light sources together) or a *demultiplexer* (which divides one light source into many) according to the fibers used at the input and at the output.

40. Types of optical cables, by cable composition; by NEC classification. The physical construction of optical cables for system functions is not governed by any agency. On the other hand, optical cables possess (assuming they are listed) NEC designations that are essential to understand in terms of fire resistance and in the context of a

building electrical system. This section covers both concepts, beginning with system functions and concluding with the NEC classifications. The final cable selection specification will combine both. It is up to the designer of the system to make sure that the cable selected will meet the application requirements. Five basic cable types have however emerged as de facto standards for a variety of applications:

Simplex and zipcord. One or two fibers, tight-buffered, Kevlar reinforced and jacketed. Used mostly for patch cord and backplane applications. See Fig. 11.7.

FIGURE 11.7 Simplex and zip-cord optical cable.

Tightpack cables. Also known as distribution style cables. Up to several tight-buffered fibers bundled under the same jacket with Kevlar reinforcement. Used for short, dry conduit runs, and riser and plenum applications. These cables are small in size, but because their fibers are not individually reinforced, these cables need to be terminated inside a patch panel or junction box. See Fig. 11.8.

Breakout cables. These cables are made of several simplex units, cabled together. This is a strong, rugged design, and is larger and more expensive than the tightpack cables. It is suitable for conduit runs, and riser and plenum applications. Because each fiber is

FIGURE 11.8 Tightpack optical cable.

individually reinforced, this design allows for a strong termination to connectors and can be brought directly to a computer backplane. See Fig. 11.9.

Loose-tube cables. These are composed of several fibers cabled together, providing a small, high fiber count cable. This type of cable is ideal for outside plant trunking applications. Depending on the actual construction, it can be used in conduits, strung overhead, or buried directly into the ground. See Fig. 11.10.

FIGURE 11.9 Breakout optical cable.

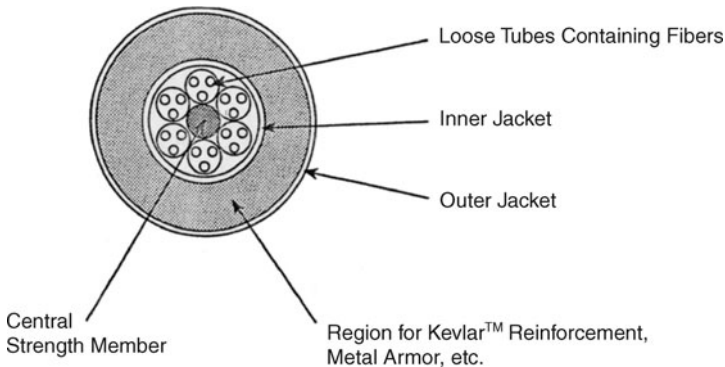

FIGURE 11.10 Loose-tube optical cable.

Hybrid or composite cables. There is a lot of confusion over these terms, especially since effective with the 1993 edition, the NEC switched its terminology from *hybrid* to *composite*.

Under the new terminology, a *composite* cable is one that contains a number of copper conductors properly jacketed and sheathed depending on the application, and in the same cable assembly as the optical fibers.

This situation is made all the more confusing since there is another type of cable that was formerly called composite. This type of cable contains only optical fibers, but which have two different types of fibers: multimode and single-mode.

Remember that there is confusion over these terms, with some people using them interchangeably. At this point the proper terminology is the following:

- A *composite* cable is a fiber/copper cable.
- A *hybrid* cable is a fiber/fiber cable.

Conductive and nonconductive cables. The NEC adds definitions for optical fiber cable types for its own purposes, which have nothing to do with cable performance in terms of signal transmission, and everything to do with how the cables interface with the electrical system. For example, a tightpack cable assembly, defined above, might be a conductive or nonconductive cable depending on internal construction, or theoretically even a composite cable if made up with copper in addition to the fiber. Since the NEC permits some optical fiber cables but not others to run in industrial cable trays next to medium-voltage (over 600V) power conductors, the importance of these distinctions to the installing electrician is clear. Specifically:

- A *conductive* cable is one with noncurrent-carrying conductive members such as metallic strength members, metallic vapor barriers, or metallic armor or sheath.
- A *nonconductive* cable is one with no metallic members and no electrically conductive materials.

Fire resistance of optical fiber cables. The NEC has an additional classification system for optical fiber cables, which also has nothing to do with signal transmission but has everything to do with how the cables will perform under fire conditions, particularly with respect to the likelihood that they will add a dangerous amount of fuel and transmit fire from one place to another. As in the case of other power-limited circuits (see Div. 9 Sec. 485) a hierarchy has been created as evidenced by a required cable marking, although in this case it only has three instead of four layers because residential occupancies have no special allowances. Specifically, optical fiber cables must be listed as compliant with one of the following designations:

- *General purpose cable* with no suffix, or a suffix “G” is generally suitable for all locations except as covered below whether concealed or exposed. The marking will begin with “OF” for optical fiber, then add a conductive element designation (either “C” for conductive or “N” for nonconductive) and conclude with no suffix or a “G” depending on which test protocol it was tested to. A “no suffix” cable may not have been tested to a certain Canadian standard and could be restricted in certain applications within the Canadian market.
- *Riser cable* is the next better grade of cable, and it can be used in risers from floor to floor. The marking also begins “OF,” followed by “C” or “N” and finish with an “R.”
- *Plenum cable* is the highest grade, and it can be used in plenum cavities used for environmental air such as above a suspended ceiling that connects to the intake of a large air handler. It will have the same markings as for riser cable except the final marking will be a “P.”

Better cables in this hierarchy can always substitute for poorer cables, and nonconductive cables can always substitute for conductive cables within the same location rating, as shown in NEC Table 770.154(E). For example, OFNP can substitute for OFNR, which can

substitute for OFCR or it could substitute for OFNG or OFN, and the like. Any listed cable is also permitted in a more restricted location than its nominal marking would indicate if it is pulled into another wiring method that would be permitted for the location. For example, the interior of a plenum-cavity suspended ceiling normally requires OFNP or OFCP grade fiber, but even OFN or OFC can be pulled into a steel raceway system in that location, such as EMT and steel boxes in accordance with NEC 300.22(C).

Unlisted cables cannot be used in buildings generally, but they can be used for outside plant. They are limited to the first 15 m (50 ft) from their “point of entrance,” and they cannot be used in a riser or plenum cavity. The point of entrance can, if necessary, be artificially extended into the building through the use of appropriately grounded rigid or intermediate metal conduit; if these wiring methods extend from the point where the outside plant enters the facility to an enclosure, then the point of entrance will be the downstream enclosure.

Optical fiber Raceways are commonly referred to as “innerduct” because they will often be pulled into large underground conduits to segment groups of fiber optic cables and provide them with a low-friction surface for insertion. They are also widely used as a raceway within buildings that is easily installed because it comes in coils that can be bent by hand. They are closely related to electrical nonmetallic tubing, a power wiring method covered in Div. 9, Sec. 27. They must be listed, and their allowable locations are the same as for optical fiber cables with comparable markings.

41. Connectors and splices. Connecting and splicing optical fibers is one of the more labor-intensive part of the installation process. Pulling the cables into place is relatively easy, and other parts of the installation are comparably simple. But connecting these glass fibers correctly requires time, special tools, and specific skills.

All fiber joints must meet two criteria. They must be:

1. *Mechanically strong:* Fiber connections must be capable of withstanding moderate to severe pulling and bending tests.
2. *Optically sound with low loss:* Since the purpose of fiber is to transmit light, the fiber joint must transmit as much light power as possible with as little loss and back reflection as can be designed into the joint.

Fiber connections fall generally into two categories: the permanent or fixed joint which uses a fiber *splice*, and the nonfixed joint which uses a fiber optic *connector*.

Splices are used as a permanent connection. Typical uses include reel ends, for pigtail vault splices and at distribution breakouts. The criteria for good fiber splices are low loss and high mechanical strength. Additional considerations are expense per splice and possible reusability of the splice itself.

Fiber optic connectors are used as a termination for inside cables, outside cables as they terminate in a central office, for interfaces between terminals on LANs, for patch panels, and for terminations into transmitters and receivers.

Whether one joins fibers using splices or connectors, one negative aspect is always common to both methods—signal loss. This loss of light power at fiber connections is called *attenuation*, and is measured in decibels.

42. Attenuation. Attenuation is the loss of signal or light intensity as it travels through an optical fiber transmission system. Some losses occur in the fiber itself and others at fiber joints. Measurement of attenuation (loss) is made in decibels (dB).

Attenuation in the optical fiber itself usually occurs as a result of absorption, reflection, diffusion, scattering, or dispersion of the photon packets within the fiber. However, losses also occur at splices and connections.

The factors which cause attenuation in an optical fiber system can be broken into two categories: those being *intrinsic* losses (losses coming from built-in characteristics) and *extrinsic* losses (losses from external factors).

Intrinsic losses occur from factors over which the installer has very little control and are generally caused by engineering design or manufacturing flaws. The following is a list of the more prominent intrinsic losses:

1. Core eccentricity (core off-center, as compared with the total fiber)
2. Core ellipticity (an oval-shaped core)
3. Numerical aperture (NA) mismatch
4. Core diameter mismatch

Core eccentricity (meaning that the center of the core center and the center of the cladding are not precisely the same center) causes an overlap or underlap of fiber cores at a splice point.

Ellipticity (or ovality) is a departure from circularity. A very small variation in the roundness of a fiber core can affect the total system loss.

Intrinsic loss, while no fault of the installer, can be minimized by butting the fibers as closely as possible.

When splicing fibers having cores of different diameters, testing will show a significant loss when testing from the large core into the small core, and will show a supposed “gain” when testing from the small core into the large core.

Extrinsic losses on the other hand are caused by the mechanics of the connection itself. Frequent causes of extrinsic loss attenuation at splicing points include:

1. Misalignment of fiber ends caused by improper insertion techniques into splices and connectors
2. Bad cleaves and poor polishing techniques resulting in poor end face quality
3. Inadvertent air spaces between fibers at a splice or connection which has not been corrected with index matching gel or liquid
4. Contamination caused by dirt, wiping tissue, cotton swabs, shirt sleeves, or airborne dust particles

TABLE 11.3 Mismatched Fiber Connection Losses (Excess Loss in dB)

Receiving fiber	62.5/125	Transmitting fiber 85/125	100/140
50/125	1.6–1.6	3.0–4.6	4.7–9
62.5/125	—	0.9	2.1–4.1
85/125	—	—	0.9–1.4

43. Back reflection. Another type of loss is back reflection (or reflectance) and is measured as return loss. As the light travels through the fiber, passing through splices and connections, finally arriving at the end point, some of that light is reflected back by fiber end faces at those points. This is shown in Fig. 11.11.

Typical allowable splice losses for single-mode fiber are 0.0 to 0.25 dB, and with a return loss or back reflectance of less than -50 dB. In multimode fiber splices, typical losses are 0.0 to 0.25 dB, with an average of 0.20 dB, and return loss of less than -50 dB. In the case of fiber connectors, single-mode allowable connector losses range from 0.05 to 0.5 dB per connector (0.1 to 1.0 dB per connection), and return loss typically is less than -30 dB. Multimode connectors have a nominal connector loss of 0.06 to 0.7 dB per connector (0.12 to 1.4 dB per connection) with a return loss less than -25 dB being typical.

FIGURE 11.11 Signal loss due to back reflection.

44. Connectors. Remember that connectors are used as terminating fixtures for temporary nonfixed joints. As such, they are made to be “plugged-in” and disconnected several or many times. Since no one connector is ideal for every possible situation, a wide variety of connector styles and types have been developed over the short life of fiber communications. We can classify connectors by assigning them into five major categories:

1. Resilient ferrule
2. Rigid ferrule
3. Grooved plate hybrids
4. Expanded beam
5. Rotary

Examples of these types of connectors can be seen in Figs. 11.12 and 11.13. Connector compatibility exists between the same types from different manufacturers. Adapters are generally available in either sleeve connectors or patch cords to allow coupling of different types of connectors. Although no single connector is best for every application, listed below are the currently popular connectors found in many different types for various applications.

FIGURE 11.12 Optical fiber connectors.

FIGURE 11.13 LC Connector (top); SC Connector (upper middle), ST Connector (lower middle), Biconic (bottom).

TABLE 11.4 Connectors and Applications

Datacommunications (mostly multimode)	Telecommunications (mostly single-mode)
LC, SMA (now obsolete)	LC, FC/PC (now obsolete)
ST (most commonly used)	ST (occasionally used)
SC (specified for newer systems)	SC (growing)
FDDI (obsolete)	D4 (decreasing)
ESCON (obsolete)	Biconic (obsolete)

Although not compatible with all other connectors, most ferrule types that use a 2.5 mm ferrule allow a loose fit for temporary testing. For example, by lightly inserting the ferrule of an ST into an FC coupler, a fast (but not always recommended) test can be made for continuity.

45. Cable termination and connector installation. Before the installation of connectors onto a fiber cable, a breakout kit may have to be installed. This procedure will not be necessary on breakout cables having 2 mm buffered fibers, but will be required on 250, 500, or 900 μm tight buffer cables. The break out kit consists of 2 mm buffer tubing over 900 μm inner tubing. The bare fibers are inserted into these buffer tubes to provide handling protection and strength when mounted onto connectors.

Installing a fiber connector onto a pigtail or unbuffered fiber is a widely varied process. The four most common ways of accomplishing this task are:

1. Epoxy glue with oven cure then polish
2. Hot melt preglued then polish
3. Cleave and crimp, no polish
4. Prepolished splice

The epoxy glue method is the oldest, and is still widely used today. This process involves filling the connector with a mixed two-part epoxy. The prepared and cleaned fiber is then inserted into the connector. After curing the epoxy in an oven for the proper time (10 to 40 minutes) the fiber is scribed and cleaved nearly flush with the end of the connector, and polished with a succession of finer and finer lapping papers. Typical polish papers start at 3 μm and go as fine as 0.3 μm grit.

The Hot Melt (trademark of 3M Co.) uses a preloaded connector. The connector is placed into an oven to soften the glue and allow insertion of the prepared fiber. After cooling, the scribe and polish process is the same as the previously described polish process.

Cleave and crimp connectors, on the other hand, do not need a polish procedure. The connector already has a polished ferrule tip and requires only the insertion of a properly cleaved fiber to butt against the internal fiber "stub." Once in place, the fiber connector is crimped to hold the fiber in place.

Each mounting method has its advantages and disadvantages, varying from ease of installation to cost per connector to performance qualities.

46. Choosing a fiber connector. With all of the myriad selections of connector types, styles, and physical characteristics available on the market, choosing the specific connector for your job is often a mystifying task. One important criteria is connector

performance. When selecting a connector, comparisons of performance are generally based on the following criteria:

- Insertion loss: Usually 0.10 to 1.0 dB per connection.
- Return loss (back reflection, reflectance): Varies from -20 (air gap like a SMA) to -60 dB (the best APC angle polished connectors)
- Repeatability of connection: Usually specified at thousands of times.

Also, your choice of fiber connector may also depend upon such things as single-mode or multimode fiber, and the type of mounting.

The accessibility of the fiber to casual users may cause you to anticipate rough handling. In this case, gripping strength of the connector becomes important to avoid pull-outs by users. Gripping points of the connector may include the fiber itself, the primary plastic buffer coating (tight buffer), the loose tube buffer, the cable strength members (Kevlar), and/or the cable jacket itself.

Another additional reason for choosing a particular type of connector is the type of equipment already purchased or currently in use. If, for instance, you are adding to an existing system already equipped with ST connectors, one should continue to use ST connectors to ensure compatibility system-wide. If you are using previously purchased electronics with Biconic connectors installed, then that will be your choice, unless you wish to change all of the connections in the equipment.

47. Terminating single-mode fibers. Terminating single-mode cables generally uses a combination of connector installation and splicing. Since the single-mode connector has very fine tolerances, they are generally terminated in a manufacturing lab. (The critical factors are loss and reflectance.) In a laboratory setting, fiber insertion and physical contact polishing can be controlled precisely. Complete cable assemblies with connectors on both ends are made and tested, since testing a cable with two ends is easier than with bare fiber on one end.

In the field, the assemblies are cut in half and spliced onto the installed backbone cables. Although the splice adds some additional loss and cost, the overall method provides a higher yield and better connection at lower cost than trying to control the termination process in the field.

48. Breakout kits. Breakout kits are a simple box (into which a cable enters), fitted with semirigid tubes, through which the individual fibers exit. The tubes provide mechanical protection for the unprotected fibers, which will usually run from the breakout point to individual connectors or splices.

This procedure is not necessary on “breakout cables” having 2 mm buffered fibers, but will be required on 250, 500, or 900 μm tight buffer cables. The breakout kit consists of 2 mm buffer tubing over 900 μm inner tubing. The bare fibers are inserted into these buffer tubes to provide handling protection and strength when mounted onto connectors. These tubes are frequently referred to as *furcation tubing*.

49. Splices. The two basic categories of splices are *fusion* and *mechanical*. Generally speaking, splices offer a lower return loss, lower attenuation, and are physically stronger than connectors. Also, splices are usually less expensive than connectors (two connectors being required to equal one splice), they require less labor, constitute a smaller joint for

inclusion into splice closures, offer a better hermetic seal than connectors, and allow either individual or mass splicing.

The type of splice chosen is usually determined by:

Type of fiber. Most single-mode fiber is fusion-spliced because of its lower loss and better return loss performance. Multimode fiber, with its complicated core structure, does not always fusion splice easily, so mechanical splices can give equal performance at a lower overall cost. (Some experienced installers, however, regularly fusion-splice graded index fibers with good results.)

Attenuation including return loss. New fusion splicers give incredibly low loss when used properly, while a properly terminated connector can approach the loss of a mechanical splice.

Physical durability. The “welding” process used in the fusion splice gives higher strength and greater durability.

Ease of installation. A fully automated fusion splicer is very expensive, but makes the splicing a one-button process. Partly automated fusion splicers are less expensive, but require more effort to use. Mechanical splicing types vary, but are usually easier to use than connector kits.

Cost per splice. In the case of fusion splicing, the most common type of splicing for single-mode fiber in new work, the initial capital investment is generally much greater than the cost for mechanical splicing. A fusion splicing machine is a several thousand dollar investment. However, very low loss can be achieved (sometimes 0 dB), and fusion splices show almost no back reflection at all. An additional benefit of fusion splicing is that the mechanical tensile strength of the fiber remains near that of the original fiber (50 to 75,000 psi).

50. Fusion splicing. Fusion splicing uses an electric arc to ionize the space between prepared fibers to eliminate air, and to heat the fibers to proper temperature (2000°F). The fibers are then fed in as semiliquids, and meld together. The previously removed plastic coating is replaced with a plastic sleeve or other protective device. The perfect fusion splice results in a single fiber rather than two fibers having been joined. One drawback to fusion splicing is that it generally must be performed in a controlled environment, such as a splicing van or trailer, and should not be done in open spaces because of dust and other contamination.

Fusion splicing in manholes is prohibited because of the explosive gases which are frequently found in such locations, and because of the electric arc generated during this process.

Due to the “welding” process, it is sometimes necessary to modify the fusion parameters to suit particular types of fibers, especially if it is necessary to fuse two different fibers (fibers from two different manufacturers, or fibers with different core/cladding structures).

A fusion splicer is shown in Fig. 11.14.

51. Mechanical splicing. Mechanical splicing is quick and easy for restoration, its major use, and is sometimes used for new construction. It does not require a controlled environment other than a reasonable level of dust control. The strength of a mechanical splice is better than most connectors, although fusion splices are stronger. Back reflection and loss vary dramatically from one type of splice to another.

Equipment investment for specific splicing kits are far less expensive than for fusion splicers. Splices are either glued, crimped, or faced. Mechanical splices all must use some type of index matching gel or liquid which is subject to contamination and aging. Those splices which require adhesive glue can become outdated as the glue ages.

FIGURE 11.14 Fusion splicer. [Aurora]

Mechanical splices use either a V groove or tube type design to obtain fiber alignment. The V groove is probably the oldest and still most popular method especially for multifiber splicing of ribbon cable. This type of splice is either crimped or snapped to hold the fibers in place.

Tubular splices on the other hand may rely on glue or crimping to hold the fibers together, while a small tube inside which the fibers are inserted causes alignment to occur.

Faced type of splices are very much like miniaturized connectors using ferrules and a polishing process.

Completed splices, whether fusion or mechanical, are placed into splicing trays that are designed to accommodate the particular type of splice in use. Splicing trays then fit into splice organizers, and in turn into a splice closure.

A mechanical splice is shown in Fig. 11.15.

52. Hand tools and supplies. No job can be completed without the correct tools, and fiber splicing and connectorizing are no exception. Hand tools can be purchased as a prepackaged tool kit or on an individual basis as needed. At a minimum, to complete most fiber optic operations, the following will be needed:

Cleaning fluid and rags (or an approved cable cleaner).

Buffer tube cutter.

Reagent grade, isopropyl alcohol in nonspill bottle or presoaked pads.

FIGURE 11.15 Mechanical splices. [3M Fiberlok]

Canned air.

Tape: masking and “Scotch” invisible.

Coating stripper

Cleaver or scribe.

Microscope or cleave checker.

Splicing method (fusion or mechanical) determines specific tooling needs.

Connectorization method determines specific tool kit (if required).

Fusion splicer (optional).

OTDR (optional, rentable).

Splicing van or trailer (nice to have an organized workplace, especially for outside plant work).

Power meter (for measuring optical power or loss).

LED or laser light source (to inject a test signal for loss).

Visible light source (for tracing cables).

Fiberoptic talkset to communicate over the fiber. Alternatives are walkie-talkies and cellular phones.

Termination kits (these may be made by purchasing tools individually rather than in a kit form). Sometimes the splicing or connectorization kits will contain too many small insignificant tools which you may already own. Once you determine the needed tools, you can purchase only those tools.

53. Fiber optic safety. Optical fibers are generally considered safe, due to the fact they carry no electricity, and therefore cannot cause fires like electrical wiring. Nonetheless, fiber is not entirely safe, and does pose certain risks to installers.

The first, though less serious, type of fiber danger is due to the light the fiber transmits; in particular, light put out by the lasers that drive some of these systems (CATV, Dense Wavelength Division Multiplexing). The various types of light sources used by common fiber systems was shown in Sec. 31, along with the wavelength of light used and power level. This table shows that while the power levels of all these systems are relatively low, the highest go up to about 10 milliwatts. While this may not sound like a lot of wattage (especially compared to several-hundred watt lamps), bear in mind that all of this light may be pumped through a fiber that is only 9 millionths of a meter (μm) in diameter. Even at these low

levels, that can be a fairly high level of watts per square centimeter. Remember the trick of starting a fire with a magnifying glass, and bear in mind that light is able to do damage.

You will also notice from this that almost all of these wavelengths are at 800 nm (nanometers, or billionths of meters) or higher. These are all infrared light, which our eyes do not see. Hazardous situations can arise when untrained people pick up a live fiber, and look directly into it. They see no light, and therefore assume no danger. In these situations, damage can be done to an unsuspecting person's retina. This is especially hazardous when inspecting fiber ends with a microscope, since the microscope will focus nearly all of the light directly into the eye. Serious damage can result from this.

Do not, however, confuse looking into a live fiber with performing continuity checks. One of the better fiber testing tools is called a *visual tracer*. Essentially, a visual tracer is a visible light that you shine down the fiber. You then use your eye to trace the fiber through its course to its end.

The tracer itself can be a flashlight, a specially modified flashlight, or even a microscope that will hold the fiber in place steadily, and couple an adequate amount of power into the fiber. The better tracers are special test sources that use a bright red LED source. The power levels of all visual tracers are too low to cause eye damage, so you do not have to be concerned with them. Besides, they are visible, and you can tell that you are looking at a light source.

For single-mode cables, a more powerful tool is sometimes used, called a *visual fault locator* (VFL). These use red lasers with enough power to actually show breaks in the fiber through the jacket of the fiber. They are stronger than simple fiber tracers, but still not powerful enough to do bodily damage.

There is a special film card that can be used to identify live fibers by eye. This small card converts the infrared light to visual light. By using it, you can tell quickly and easily whether a fiber is live or not.

All this being said, the odds of going blind by looking into the broken end of an optical fiber are virtually nil. It is possible for someone to be injured by mishandling optical fibers, but only under certain circumstances. Those circumstances are usually the following:

1. The light source must be high-powered. Only the more powerful lasers are strong enough to cause injury.
2. The beam of light exiting the fiber must be narrow. Do you remember the old trick of starting a fire with sunlight and a magnifying glass? Just as in that case, the light from a fiber must be very tightly focused to cause harm. This is why broken fibers do not cause harm. Broken ends of glass fiber are erratic, and scatter the light that passes through them. This light is nowhere near focused enough to cause damage to the eye.

All of this is not to say that looking into the end of a properly polished fiber cannot be a problem. Since a polished fiber end will not diffuse the light that flows through it, the potential for injury with such fibers exists.

A far more serious safety concern is the fibers themselves. Fibers are pieces of glass. And like all glass, they can cut and injure us.

Because of this, handling fiber requires considerable care. First of all, you must be very careful when handling *open* fibers, that is, fibers that are not contained in a cable. (Modern optical fiber cables are very safe, and pose no danger to the installer. It is when the cables are opened up that hazards like these start.) If you were to accidentally jab yourself with one of these open fibers, you could easily end up with a painful sliver. But what is worse is that this sliver may not be visible! Remember that these slivers are made of transparent glass, and can be very difficult to see.

Jabbing yourself with a fiber is not, however, the biggest glass hazard. The really dangerous situation is when fibers are stripped, trimmed, and cut. These operations result in short, nearly microscopic pieces of glass lying around a work area. These are short, thin,

invisible needles. If they are left lying around in a busy work area, it is almost inevitable that someone will end up touching or handling them. As sharp and thin as these glass shards are, they will easily penetrate the skin. And unlike a wood sliver, these glass slivers will not degrade inside the skin.

These cut pieces of fiber are dangerous. In order to avoid this hazard, a technician working with fibers should make generous use of masking tape (or any other type of tape) to catch the fiber pieces. Some technicians wrap the tape around a few fingers, sticky side out. This catches the fibers as soon as they are cut. Plenty of sticky side out tape should be kept at the work area, and the entire area should be blotted frequently with tape to pick up stray pieces. Also, this tape must be handled carefully. When the pickup operation is complete, the tape should be folded upon itself and carefully disposed of. This tape should never be left lying open, or wadded up and thrown on the floor. Remember, fibers are insidious, since they are very difficult to see, especially when you are not expecting them to be present. If you sit on some of these cut pieces, you won't forget ever again.

Pieces of fiber should be placed in bottles with screw lids (or other type of secure container) as soon as they are trimmed from cables, typically during the terminating procedure.

As mentioned earlier, one of fiber's better-known characteristics is that it carries no electricity, and is therefore not a fire hazard. That does not, however, mean that optical fiber cables cannot be a fire hazard in a building.

Optical cables must be installed according to their fire safety characteristics, if they are to result in a safe installation, as covered in Sec. 40. In addition, proper fire stops must be used when they (like any cable) pass through any fire-rated partition, such that the required fire separation of the partition is maintained. In addition, any abandoned optical fiber cables (defined as not terminated at equipment other than a connector and not identified for future use with a tag) must be removed. The tag must have sufficient durability for the use at its location.

Regardless of the overall safety of optical fiber, optical cable installations carry many of the same risks as copper cables.

Installers need to pay special attention to long outdoor runs of cables with metal components. (Many outdoor cables have metal strength members or other metal components.) These long pieces of metal can have significant voltages induced into them from lightning strikes in the area. Contact with these pieces can be dangerous. While these metal cable components are required to be grounded in all buildings, this may not always be done out of doors. You should ground any metal cable components before handling them.

Working near power conductors is often required in fiber optic installations. This, as always, is a serious hazard. There are three types of optical cables (see Sec. 40 for NEC definitions of cable types), each with their own system separation rules, as follows:

- a.** *Composite optical fiber cables* containing nonpower-limited control or power circuits are only permitted to be used where the optical fiber and the nonpower-limited components are functionally associated. However, once a composite cable qualifies for use under this criterion, it may be used in the same raceway or cable tray as nonpower-limited wiring conductors, and these cables may enter other wiring enclosures for termination or other purposes. In industrial occupancies only, with qualified maintenance and supervision, composite cables are even permitted with the power conductor operating at medium voltage (over 600V).
- b.** *Conductive optical fiber cables* are not permitted in the same raceway or cable tray as nonpower-limited wiring of any kind.
- c.** *Nonconductive optical fiber cables* are permitted within a common raceway or the same cable tray as nonpower-limited wiring of any kind operating at 600V or less. If the nonconductive fiber cables are functionally associated with the nonpower-limited wiring, the cables are permitted in nonpower-limited wiring enclosures. Nonconductive optical fiber cables are also permitted in common wiring enclosures where installed in

a factory- or field-assembled control center. In industrial occupancies only, with qualified maintenance and supervision, nonconductive optical fiber cables are also permitted with the power conductors operating at medium voltage (over 600V).

- d. With power-limited circuits.** Optical fiber cables are permitted without limitation as to being either conductive or nonconductive, and are permitted to be part of a composite cable with, and to run in the same wiring raceways, cable trays, and other enclosures with copper wiring that is part of a power-limited system. Specifically, optical fiber cabling is permitted with a Class 2 or Class 3 system per NEC Article 725 (See Div. 9 Sec. 481 to 489.), or a power-limited fire alarm system per NEC Article 760, or a communications system as covered in NEC Article 800, or a CATV system covered in NEC Article 820, or a network-powered broadband communications system having a low-power source as defined by the applicable parameters in NEC Table 830.15.

Where these requirements specify a separation between optical fiber cabling of any type and electrical power or control circuits of any type, those separation requirements can be met by providing a permanent or listed barrier between the systems. This can be accomplished in cable tray or surface raceway systems by using barriers compatible with the tray or surface raceway, and in an enclosure by either arranging a fixed and grounded permanent barrier or by enclosing the optical fiber cables in a grounded raceway as required. For example, flexible metal conduit is often used within a nonpower-limited enclosure to extend either the nonpower-limited source wiring or the power-limited or optical fiber cabling from the entry point to a termination point where system separation no longer needed to be maintained.

54. Testing. Testing fiber optic components and systems requires making several basic measurements. The most common measurement parameters are shown in the following table. Optical power, required for measuring source power, receiver power and loss or attenuation, is the most important parameter, and is required for almost every optical link. Backscatter and wavelength measurements are the next most important, and bandwidth or dispersion are very rarely performed in the field. Measurement or inspection of geometrical parameters of fiber are essential for fiber manufacturers only.

TABLE 11.5 Fiber Optic Testing Requirements

Test parameter	Instrument
Optical Power (Source Output, Receiver Signal Level)	Fiber Optic Power Meter
Attenuation or Loss of Fibers, Cables, and Connectors	FO Power Meter and Source, Test Kit or OLTS (optical loss test set)
Source Wavelength	FO Spectrum Analyzer
Backscatter (Loss, Length, Fault Location)	Optical Time Domain Reflectometer (OTDR)
Fault Location	OTDR, Visual Cable Fault Locator
Bandwidth/Dispersion (Modal & Chromatic)	Bandwidth Tester or Simulation Software

55. Power meter testing. Fiber optic power meters measure the average optical power emanating from an optical fiber and are used for measuring power levels and, when used with a compatible source, for loss testing. They typically consist of a solid state detector, signal conditioning circuitry, and a digital display of power. To interface to the large variety of fiber optic connectors in use, some form of removable connector adapter is usually provided.

Power meters are calibrated to read in milliwatts, microwatts and/or *dBm* (this references the decibel to one milliwatt; thus a *dBm* reading refers to how many *dBs* the power level is from one milliwatt). Some meters offer a relative *dB* scale also, useful for laboratory loss measurements.

Although most fiber optic power and loss measurements are made in the range of 0 *dBm* to -50 *dBm*, some power meters offer much wider ranges. For testing analog CATV systems or fiber amplifiers, special meters with extended high power ranges are used. Optical power meters have a typical measurement uncertainty of $+/-5\%$.

56. Visual cable tracers and fault locators. The most common fault with fiber optic systems is poor connections. Since the light used in systems is not visible, visual inspections will not tell you whether or not the transmitter is operating. This problem can be overcome by injecting the light from a visible source, such as a LED or incandescent light bulb. By doing so, you can visually trace the fiber from transmitter to receiver, and verify that the light is traveling the correct course. The test instruments that are used to inject visible light are called *visual fault locators*.

If a powerful enough visible light, such as a HeNe (Helium-Neon) or visible diode laser is injected into the fiber, high loss points can be made visible. This method will work on buffered fiber and even jacketed single fiber cable if the jacket is not opaque to the visible light. The yellow jacket of single-mode fiber and the orange of multimode fiber will usually pass the visible light. Most other cable colors, especially black and gray, will not work with this technique, nor will most multifiber cables. However, many cable breaks, macrobending losses caused by kinks in the fiber, bad splices, and the like can be detected visually.

Since the loss in the fiber is quite high at visible wavelengths, on the order of 9 to 15 *dB/km*, this instrument has a short range, typically 3 to 5 km, which is more than enough for virtually all indoor installations.

57. Microscopes. Generally the first test performed once the fibers are pulled into place is a visual inspection with a microscope. This is done when preparing fiber ends for termination.

The microscopes used for testing fibers have stages which are modified to hold the fiber or connector in the field of view. Fiber optic inspection microscopes vary in magnification from 30 to 800 power, with 30 to 100 power being the most widely used range. Cleaved fibers are usually viewed from the side, to see breakover and lip. Connectors are viewed end-on, or at a small angle, to find polishing defects such as scratches.

Photos showing fiber ends in various stages of polishing are shown in Fig. 11.16. A well-made connector will have a smooth, polished, scratch free finish, and the fiber will not show any signs of cracks or pistoning (where the fiber is either protruding from the end of the ferrule or pulling back into it).

The proper magnification for viewing connectors is generally accepted to be 30 to 100 power. Lower magnification, typical with a jeweler's loupe or pocket magnifier, will not provide adequate resolution for judging the finish on the connector. Too high a magnification tends to make small, ignorable faults look worse than they really are. A better solution is to use medium magnification, but inspect the connector three ways:

1. By viewing directly at the end of the polished surface with side lighting
2. By viewing directly with side lighting and light transmitted through the core
3. By viewing at an angle with lighting from the opposite angle

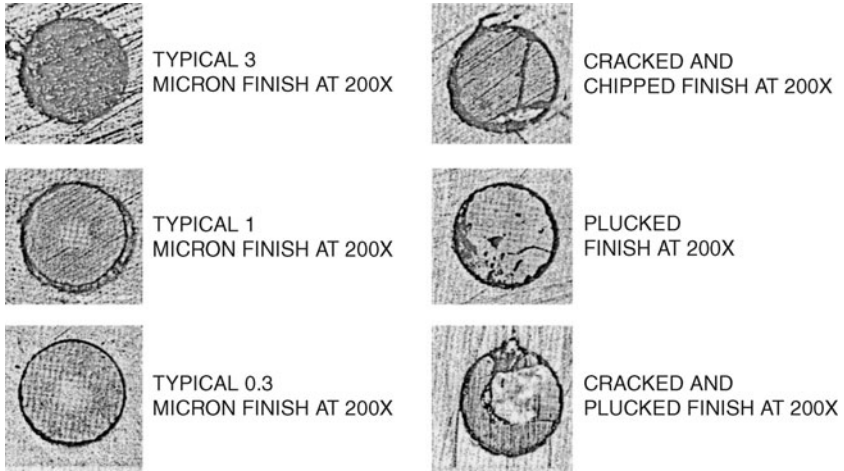

FIGURE 11.16 Fiber ends at various stages of polishing. (Courtesy of Buehler)

Viewing directly with side lighting allows determining if the ferrule hole is of the proper size, the fiber is centered in the hole, and a proper amount of adhesive has been applied. Only the largest scratches will be visible this way, however. Adding light transmitted through the core will make cracks in the end of the fiber, caused by pressure or heat during the polish process, visible.

Viewing the end of the connector at an angle, while lighting it from the opposite side at approximately the same angle, will allow the best inspection for the quality of polish and possible scratches. The shadowing effect of angular viewing enhances the contrast of scratches against the mirror smooth polished surface of the glass.

One needs to be careful in inspecting connectors, however. The tendency is to be overly critical, especially at high magnification. Only defects over the fiber core are a problem. Chipping of the glass around the outside of the cladding is not unusual and will have no effect on the ability of the connector to couple light in the core. Likewise, scratches only on the cladding will not cause any loss problems.

58. Continuity testing. Continuity testing is the most fundamental fiber optic test. It is usually performed when the cable is delivered to the job site (and certainly before installation) to ensure that no damage has been done to the cable during shipment to the work site.

This testing is commonly done with a visible light source, which can be an incandescent lamp, HeNe laser at 633 nm or a LED or diode laser at 650 nm, a wavelength (that is, color) which can be seen by the eye. HeNe laser instruments are usually tuned to an output power level of just less than 1 mW, making them Class II lasers which do not have enough power to harm the eye, but do have enough power to be easily seen over about 4 km of fiber, and to even find fiber microbends or breaks by viewing the light shining from the break through the yellow or orange jacket used on most single fiber cables. In most cases, a high quality flashlight, shined directly into a good fiber end, works quite well.

59. Insertion loss testing. The most basic (and most commonly performed) fiber optic test is called an *Insertion Loss* test. Insertion loss is the loss caused by the insertion of a component such as a splice or connector in an optical fiber. Figures 11.17 and 11.18 display the basic method of insertion loss testing. These drawings show a single cable being tested. But in the field each fiber, from one end of the system to the other, is commonly tested this way. Since the power meter test set consists of two parts (the light source and the meter), one piece can be used at one end of the system, and another at the far end. The process usually includes the following parts:

1. The test set is referenced. This is done by connecting the two parts with a known good jumper, and setting the zero level on the meter.
2. The source is taken to one end of the links, the meter to the other.
3. Some type of communication link is established between the two ends (walkie-talkies, cell phones, talk sets, etc.).

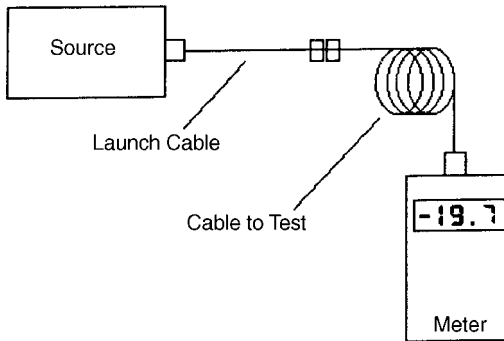

FIGURE 11.17 Single-end insertion loss test.

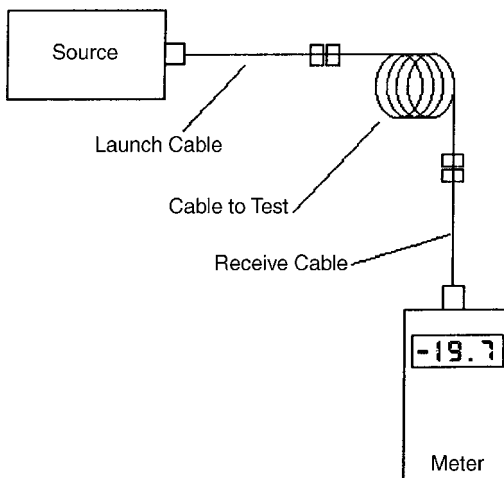

FIGURE 11.18 Double-end insertion loss test.

4. Each fiber is tested, one after another, and the results are carefully recorded.
5. When required, each fiber segment of fiber (for example, from one patch panel to another) is tested separately.
6. Some systems may be tested in either directions. (Source at A, meter at B or Source at B, meter at A.)

Virtually all optical fiber systems are tested for end-to-end insertion loss to confirm that the required signal will be permitted to pass.

Loss is typically measured at 850 and 1300 nm wavelengths for multimode links. Single-mode fiber is always tested at 1300 nm, and may also be tested at 1550 nm.

60. Testing the installed fiber system. To thoroughly test the cable system, one needs to test it three times: before installation, each installed segment, and complete end-to-end loss.

One should test the cable on the reel for continuity before installing it, to insure no damage was done in shipment from the manufacturer to the job site. Since the cost of installation usually is high, often higher than the cost of materials, it only makes sense to ensure that one does not install bad cable. It is generally sufficient to just test continuity, since most fiber is installed without connectors and then terminated in place, and connectors are the most likely problem to be uncovered by testing for loss. After installation and termination, each segment of the cable plant should be tested individually as it is installed, to ensure each connector and cable is good. Finally, each end-to-end run (from equipment placed on the cable plant to equipment) should be tested as a final check.

For multimode fibers, testing is now usually done at both 850 and 1300 nm wavelengths (colors) using LED sources. This will prove the performance of the cable for every datacom system, and will meet the requirements of all network vendors. For single-mode fiber cables, testing is usually done at 1300 nm, but 1550 is sometimes required also. The 1550 nm testing will show that the cable can support wavelength division multiplexing (WDM) at 1300 and 1550 nm for future service expansion.

If cable system end-to-end loss exceeds total allowable loss, the best solution is to retest each segment of the cable plant separately, checking suspect cables each way, since the most likely problem is a single bad connector or splice. Bad connectors must then be repolished or replaced to bring the loss within acceptable ranges.

61. Optical time domain reflectometers. The optical time domain reflectometer (OTDR) is one of the most powerful types of optical fiber testers. It uses the phenomena of backscattered light to analyze fibers, find faults, and optimize splices. Any time light is sent through a fiber, a small amount of light is scattered backward to the source. If there is some type of fault or obstruction in the fiber, an unusually high amount of light will be scattered back. The OTDR operates by sending into the fiber a high powered pulse and then measuring the light scattered back toward the instrument.

If one assumes that the average amount of backscatter (called the *backscatter coefficient*) is constant, the OTDR can be used to measure loss as well as locate fiber breaks, splices, and connectors. In addition, the OTDR gives a graphic display of the status of the fiber being tested. And it offers another major advantage over the source/power meter in that it requires access to only one end of the fiber.

OTDR measurement is heavily dependent on the backscatter coefficient, which is a function of fiber scattering characteristics, core diameter, and numerical aperture. OTDRs must also be matched to the fibers being tested in both wavelength and fiber core diameter

to provide accurate measurements. Thus many OTDRs have modular sources to allow substituting a proper source for the application.

While most OTDR applications involve finding faults in installed cables or checking splices, they are also very useful in inspecting fibers for manufacturing faults.

If a fiber has a splice or connector, an OTDR's signal will be diminished as the pulse passes it, so the OTDR sees a reduction in power, indicating the light loss of the joined fibers. If the splice or connector reflects light, the OTDR will show the reflection as a spike above the backscattered signal. The OTDR can be calibrated to use this spike to measure optical return loss.

The end of the fiber will show as a deterioration of the backscatter signal into noise, if it is within the dynamic range of the OTDR. If the end of the fiber is cleaved or polished, one will also see a spike above the backscatter trace. This allows one to measure the total length of the fiber being tested.

Figure 11.19 shows a typical OTDR trace.

FIGURE 11.19 Optical time domain reflectometer optical fiber ODTR trace test.

62. The limitations of OTDR use. With the OTDR, one can measure loss and distance. To use them effectively, it is necessary to understand their measurement limitations. The OTDR's distance resolution is limited by the transmitted pulse width. As the OTDR sends out its pulse, crosstalk in the coupler inside the instrument and reflections from the first connector will saturate the receiver. The receiver will take some time to recover, causing a

nonlinearity in the baseline of the display. It may take the time equivalent to 100 meters before the receiver recovers. It is common to use a long fiber cable called a *pulse suppressor* between the OTDR and the cables being tested to allow the receiver to recover completely.

The OTDR also is limited by the pulse width in its ability to resolve two closely spaced features. Long distance OTDRs may have a minimum resolution of a few hundred meters, while short range OTDRs can resolve features several meters apart.

When measuring distance, the OTDR has two major sources of error not associated with the instrument itself: the velocity of the light pulse in the fiber, and the amount of fiber in the cable. The velocity of the pulse down the fiber is a function of the average index of refraction of the glass. While this is fairly constant for most fiber types, it can vary by a few percent. When making cable, it is necessary to have some excess fiber in the cable, to allow the cable to stretch when pulled without stressing the fiber. This excess fiber is usually 1 to 2%. Since the OTDR measures the length of the fiber, not the cable, it is necessary to subtract 1 to 2% from the measured length to get the likely cable length. This is very important if one is using the OTDR to find a fault in an installed cable, to keep from looking too far away from the OTDR to find the problem. This variable adds up to 10 to 20 meters per kilometer, therefore it is not ignorable.

Accurate OTDR attenuation measurements depend on having a constant backscatter coefficient. Unfortunately, this is often not the case. Fibers which have tapers in core size are common, or variations in diameter are a result of variations in pulling speed as the fiber is being made. A small change in diameter (1%) causes a larger change in cross sectional area which directly affects the scattering coefficient, and can cause a large change in attenuation (on the order of 0.1 dB). Thus fiber attenuation measured by OTDRs may not be uniform along the fiber, and can produce significantly different losses in opposite directions.

The first indication of OTDR problems for most users occurs when looking at a splice and a “gain” is seen at the splice. Since passive fibers and splices cannot create light, another phenomenon is obviously the cause. A “gainer” is an indication of the difference of backscatter coefficients in the two fibers being spliced.

If an OTDR is used to measure the loss of a splice and the two fibers are identical, the loss will be correct, since the scattering coefficient is the same for both fibers. This is exactly what you see when breaking and splicing the same fiber, the normal way OTDRs are demonstrated.

If the receiving fiber has a lower backscatter coefficient than the fiber before the splice, the amount of light sent back to the OTDR will decrease after the splice, causing the OTDR to indicate a larger splice loss than actual.

If one looks at this splice in the opposite direction, the effect will be reversed. The amount of backscattered light will be larger after the splice and the loss shown on the OTDR will be less than the actual splice loss. If this increase is larger than the loss in the splice, the OTDR will show a gain at the splice, an obvious error. As many as one-third of all splices will show a gain in one direction. The usual recommendation is to test with the OTDR in both directions and average the reading, which has been shown to give measurements accurate to about 0.01 dB.

63. Noncommunication applications of optical fiber. The optical fiber has first been devised as a simple means to carry light from one point to another. A patent registered by William Wheeler in 1881 describes a home lighting system using light conducting tubes. A more recent patent describes a bundle of optical fibers used to carry images. Today, light guide fibers are used in every technical and scientific sector, including surgery, industry, fundamental research, avionics, automotive, and consumer.

The most common of these noncommunication applications are the following:

Light guides

Medical lasers

Public lighting and displays

Home lamps and Christmas tree lighting

Transmission of images

Medical imaging (endoscopy, etc.)

Sensors

Passage detectors for objects or people

Gyroscopes

Pressure sensors

Audio detectors

Fibrosopes are increasingly used in medicine and surgery, both in the detection and the eradication of abnormal formations. Fiber gyroscopes are found in modern aircraft. Optical sensors are legion, and are used in all industries. Lighting uses for optical fibers are increasing steadily. Image guide (faceplate), sensor, and lighting/indication are three major applications of fibers as light guides.

DIVISION 12

WIRING AND DESIGN TABLES

TABLE No.	TABLE TITLE	
1	Standard Sizes of Lamps for General Illumination, in Watts	12.3
2 to 6	Demand Factors and Data for Determining Minimum Loads	12.4
7 to 10	Full-Load Currents of Motors	12.10
11	Capacitor Ratings for Use with Three-Phase 60-Hz Motors	12.13
12 to 23	Ampacities of Conductors	12.14
24	Ampacity of Flexible Cords and Cables	12.28
25	Ampacity of Fixture Wires	12.30
26	Ampacity of Aluminum Cable, Steel-Reinforced	12.31

*Reprinted with permission from NFPA 70-2008 National Electrical Code®. Copyright © 2007, National Fire Protection Association, Quincy, Massachusetts, 02269. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

NOTE 1 *Over-12- to 27-kW ranges all of the same rating.* For ranges individually rated more than 12 kW but not more than 27 kW, the maximum demand in col. C shall be increased by 5 percent for each additional kilowatt of rating or major fraction thereof by which the rating of individual ranges exceeds 12 kW.

NOTE 2 *Over-8³/₄- to 27-kW ranges of unequal ratings.* For ranges individually rated more than 8³/₄ kW and of different ratings but none exceeding 27 kW, an average value of rating shall be calculated by adding together the ratings of all ranges to obtain the total connected load (using 12 kW for any range rated less than 12 kW) and dividing by the total number of ranges. Then the maximum demand in col. C shall be increased by 5 percent for each kilowatt or major fraction thereof by which this average value exceeds 12 kW.

NOTE 3 *Over 1³/₄ kW through 8³/₄ kW.* In lieu of the method provided in col. C, it shall be permissible to add the nameplate ratings of all household cooking appliances rated more than 1³/₄ kW but not more than 8³/₄ kW and to multiply the sum by the demand factors specified in col. A or B for the given number of appliances. Where the rating of cooking appliances falls under both Column A and Column B, the demand factors for each column shall be applied to the appliances for that column, and the results added together.

NOTE 4 *Branch-circuit load.* It shall be permissible to compute the branch-circuit load for one range in accordance with Table 220.55. The branch-circuit load for one wall-mounted oven or one counter-mounted cooking unit shall be the nameplate rating of the appliance. The branch-circuit load for a counter-mounted cooking unit and not more than two wall-mounted ovens, all supplied from a single branch circuit and located in the same room, shall be computed by adding the nameplate rating of the individual appliances and treating this total as equivalent to one range.

NOTE 5 This table also applies to household cooking appliances rated over 1³/₄ kW and used in instructional programs.

3. Demand Factors for Household Electric Clothes Dryers^a

(Table 220.54, 2008 NEC)

Number of dryers	Demand factors, percent
1	100
2	100
3	100
4	100
5	80
6	70
7	65
8	60
9	55
10	50
11	47
12–23	47% minus 1% for each dryer exceeding 11
24–42	35% minus 0.5% for each dryer exceeding 23
43 and over	25%

4. Demand Factors for General Lighting Loads^a

(Table 220.12, 2008 NEC)

Type of occupancy	Unit load volt-amperes per square meter	Unit load per Ft ² , volt-amperes
Armories and auditoriums	11	1
Banks	39 ^c	3½ ^c
Barbershops and beauty parlors	33	3
Churches	11	1
Clubs	22	2
Courtrooms	22	2
Dwelling units ^b	33	3
Garages, Commercial (storage)	6	½
Hospitals	22	2
Hotels and motels, including apartment houses without provisions for cooking by tenants ^b	22	
Industrial commercial (loft) buildings	22	2
Lodge rooms	17	1½
Office buildings	39	3½ ^b
Restaurants	22	2
Schools	33	3
Stores	33	3
Warehouses (storage)	3	¼
In any of the above occupancies except one-family dwellings and individual dwelling units of multifamily dwellings:		
Assembly halls and auditoriums	11	1
Halls, corridors, and closets	6	½
Storage spaces	3	¼

5. Data for determining National Electrical Code minimum allowable lighting and appliance loads: calculation of feeder loads. The computed load of a feeder shall be not less than the sum of all branch-circuit loads supplied by the feeder, subject to the following provisions:

- 1. GENERAL LIGHTING** The demand factors listed in Table A shall apply to that portion of the total branch-circuit load computed for general illumination. They shall not be applied in determining the number of branch circuits for general illumination. See Pars. 7 and 8.

A. Lighting-Load Feeder Demand Factors

Type of occupancy	Portion of lighting load to which demand factor applies (volt-amperes)	Demand factor, percent
Dwelling units	First 3000 or less at	100
	From 3001 to 120,000 at	35
Hospitals ^a	Remainder over 120,000 at	25
	First 50,000 or less at	40
Hotels and motels including apartment houses without provision for cooking by tenants ^a	Remainder over 50,000 at	20
	First 20,000 or less at	50
Warehouses (storage)	From 20,001 to 100,000 at	40
	Remainder over 100,000 at	30
All others	First 12,500 or less at	100
	Remainder over 12,500 at	50
	Total volt-amperes	100

^aThe demand factors of this table shall not apply to the computed load of feeders or services to areas in hospitals, hotels, and motels where the entire lighting is likely to be used at one time, as in operating rooms, ballrooms, or dining rooms.

These demand factors are based on minimum load conditions and 100 percent power factor and in specific instances may not provide sufficient capacity for the installation contemplated. In view of the trend toward higher-intensity lighting systems and increased loads because of the more general use of fixed and portable appliances, each installation should be considered with regard to the load likely to be imposed and the capacity increased to ensure safe operation. When electric discharge lighting systems are to be installed, a high-power-factor type should be used; otherwise the conductor capacity may need to be increased.

- 2. SHOW-WINDOW LIGHTING** For show-window lighting a load of not less than 600 volt-amperes/linear meter or 200 volt-amperes/linear foot shall be included for each linear foot of show window, measured horizontally along its base.
- 3. TRACK LIGHTING** For track lighting in other than dwelling units or guest suites of hotels and motels, an additional load of 150 volt-amperes shall be included for every 600 mm (2 ft) of track or fraction thereof. Where multicircuit track is installed, the load shall be considered to be divided equally between track circuits.
- 4. MOTORS** For motors, a load computed according to the provisions of Secs. 6 to 13 shall be included.
- 5. NEUTRAL FEEDER LOAD** The neutral feeder or service load shall be the maximum imbalance of the load determined by NEC Article 220 and as summarized Sec. 4 and this section. The maximum unbalanced load shall be the maximum net calculated load

between the neutral and any one ungrounded conductor, except that the load thus obtained shall be multiplied by 140 percent for three-wire two-phase or five-wire two-phase systems. For a feeder or service supplying household electric ranges, wall-mounted ovens, and counter-mounted cooking units, and electric dryers, the maximum unbalanced load shall be considered to be 70 percent of the load on the ungrounded conductors, as determined in accordance with Table 220.55 for ranges and Table 220.54 for dryers. For three-wire dc or single-phase ac, four-wire three-phase, three-wire two-phase, or five-wire two-phase systems, a further demand factor of 70 percent may be applied to that portion of the unbalanced load in excess of 200 A. There shall be no reduction of the neutral capacity for that portion of the load which consists of nonlinear loads supplied from a 4-wire, wye-connected, 3-phase system nor the grounded conductor of a 3-wire circuit consisting of two phase wires and the neutral of a 4-wire, 3-phase, wye-connected system.

- 6. FIXED ELECTRICAL SPACE HEATING** The computed load of a feeder supplying fixed electrical space-heating equipment shall be 100 percent of the total connected load on all branch circuits.

Exception. Where reduced loading of the conductors results from units operating on duty cycle, intermittently, or from all units not operating at one time, the authority enforcing the Code may grant permission for feeder or service conductors to be of a capacity less than 100 percent, provided the conductors are of sufficient capacity for the load so determined.

- 7. NONCOINCIDENT LOAD** In adding the branch-circuit loads to determine the feeder or service load, the smaller of two noncoincident loads may be omitted from the total if it is unlikely that both loads will be served simultaneously.
- 8. SMALL APPLIANCES** The computed branch-circuit load for receptacle outlets in other than dwelling occupancies, for which the allowance is not more than 180 VA per single or multiple receptacle mounted on a single yoke, may be included with the general-lighting load and subject to the demand factors in Par. 1, or may be computed at 100% for the first 10 kVA and the remainder at 50% demand factor.
- 9. KITCHEN EQUIPMENT** It is permitted to calculate the load for commercial electric cooking equipment, dishwasher booster heaters, water heaters, and other kitchen equipment in accordance with the following table, with the proviso that in no case shall the calculated load be less than the sum of the largest two kitchen equipment loads: (Table 220.56, 2008 NEC)^a

Number of units of equipment	Demand factors, percent
1	100
2	100
3	90
4	80
5	70
6 and over	65

^aReprinted with permission from NFPA 70-2008, National Electrical Code®, Copyright © 2007, National Fire Protection Association, Quincy, Massachusetts 02269. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

DWELLING UNITS A dwelling unit is defined as one or more rooms for the use of one or more persons as a housekeeping unit with complete and independent living facilities, including permanent provisions for living, sleeping, cooking, and sanitation. The requirements in Pars. 10 to 13 apply to dwelling-type occupancies and are supplemental to Pars. 1 to 9. For example, where a dwelling unit has both, electrically powered heat and air conditioning, the smaller of the two loads may be omitted under the noncoincident load principle in Par. 7 above.

10. SMALL APPLIANCES

- a. Dwelling units.* In dwelling units a feeder load of not less than 1500 VA for each two-wire circuit shall be included for small appliances (portable appliances supplied from receptacles of 15- or 20-A rating) in pantry and breakfast room, dining room, and kitchen. Where the load is subdivided through two or more feeders, the computed load for each shall include not less than 1500 VA for each two-wire circuit for small appliances. These loads may be included with the general-lighting load and subject to the demand factors in Par. 1. The 15-A individual branch circuit for refrigeration equipment that is permitted, but not required under the provisions of NEC 210.52(B)(1) Exception No. 2, need not be included as an additional small-appliance branch circuit if it is installed.
- b. Laundry circuit.* A feeder load of not less than 1500 VA shall be included for each two-wire laundry circuit. This load may be included with the general-lighting load and subject to the demand factors in Par. 1.

11. ELECTRIC RANGES The feeder load for household electric ranges and other cooking appliances, individually rated more than $1\frac{3}{4}$ kW, may be calculated in accordance with Table 2. To provide for possible future installations of ranges or higher ratings, it is recommended that when ranges of less than $8\frac{3}{4}$ -kW ratings or wall-mounted ovens and counter-mounted cooking units are to be installed, the feeder capacity may be not less than the maximum demand value specified in col. A of Table 2.

Where a number of single-phase ranges are supplied by a three-phase four-wire feeder, the current shall be computed on the basis of the demand of twice the maximum number of ranges connected between any two-phase wires. See example in Sec. 50 of Div. 3. The same procedure applies to multiple clothes dryers connected to a wye distribution, as covered in Par. 12.

12. ELECTRIC CLOTHES DRYERS The load for household electric clothes dryers in dwelling units shall be either 5000 watts (volt-amperes) or the nameplate rating, whichever is larger, for each dryer served. The use of the demand factors in Table 3 is permitted.

13. FASTENED-IN-PLACE APPLIANCES (OTHER THAN RANGES, CLOTHES DRYERS, AIR-CONDITIONING EQUIPMENT, OR SPACE-HEATING EQUIPMENT) When four or more fastened-in-place appliances other than electric ranges, clothes dryers, space heating or air-conditioning equipment, or space-heating equipment are connected to the same feeder or service in a one-family, two-family, or multifamily dwelling unit, a demand factor of 75 percent may be applied to the appliance load.

14. FARM BUILDINGS Feeders supplying farm buildings (excluding dwellings) or loads consisting of two or more branch circuits shall have minimum capacity computed in accordance with Table B.

B. Method of Computing Farm Loads for Other Than Dwelling Units

Load in amperes at 240 V	Percent of connected load
Loads expected to operate without diversity, but not less than 125 percent full-load current of the largest motor and not less than first 60 A of load	100
Next 60 A of all other loads	50
Remainder of other load	25

NOTE 1 For services to farm dwellings, see Pars. 10 to 13.

NOTE 2 For service at the main point of delivery to the farmstead, see Par. 15.

15. FARM SERVICES

- a. Service-equipment and service-entrance conductors for individual farm buildings (excluding dwellings) shall have a minimum capacity computed in accordance with Par. 14.
- b. Minimum capacity of service conductors and service equipment, if any, at the main point of delivery to farms (including dwellings) shall be determined in accordance with the following formula:

- 100 percent of the largest demand computed in accordance with Par. 14
- 75 percent of the second largest demand computed in accordance with Par. 14
- 65 percent of the third largest demand computed in accordance with Par. 14
- 50 percent of the demands of remaining loads computed in accordance with Par. 14

NOTE 1 Consider as a single computed demand the total of the computed demands of all buildings or loads having the same function.

NOTE 2 The demand of the farm dwelling, if included in the demands of this formula, should be computed in accordance with Note 1 of Table B.

6. Average Demand Factors for Motor Loads^a

Number of motors	Character of load	Demand factor
1–5	Individual drives—tools, etc.	1.00
6–10	Individual drives—tools, etc.	0.75
10–15	Individual drives—tools, etc.	0.70
15–20	Individual drives—tools, etc.	0.65
20–30	Individual drives—tools, etc.	0.60
30–50	Individual drives—tools, etc.	0.50
50–75	Individual drives—tools, etc.	0.45
75–100	Individual drives—tools, etc.	0.40
Above 100	Individual drives—tools, etc.	0.40
6–10	Group drives	0.85
Above 10	Group drives	0.70–0.45
	Fans, compressors, pumps, etc.	1.00–0.85

^aPermission for the use of a demand factor should be obtained from the authority enforcing the National Electrical Code.

7. Full-Load Current in Amperes, Direct-Current Motors^a

(Table 430.247, 2008 NEC)

The following values of full-load currents^b are for motors running at base speed.

hp	Armature voltage rating ^b					
	90 V	120 V	180 V	240 V	500 V	550 V
1/4	4.0	3.1	2.0	1.6		
1/3	5.2	4.1	2.6	2.0		
1/2	6.8	5.4	3.4	2.7

This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

These values of full-load currents are for motors running at usual speeds and motors with normal torque characteristics.

The voltages listed are rated motor voltages. The currents listed shall be permitted for system voltage ranges of 110 to 120 and 220 to 240.

9. Average Full-Load Currents of Two-Phase Four-Wire Motors^a

(Table 430.249, 2008 NEC)

hp	Induction-type squirrel-cage and wound-rotor, A				
	115 V	230 V	460 V	575 V	2,300 V

These values of full-load current are for motors running at speeds usual for belted motors and motors with normal torque characteristics. Current in common conductor of two-phase three-wire system will be 1.41 times value given.

The voltages listed are rated motor voltages. Corresponding nominal system voltages are 110 to 120, 220 to 240, 440 to 480, and 550 to 600 V.

10. Full-Load-Current Three-Phase Alternating-Current Motors^a

(Table 430.250, 2008 NEC)

^aReprinted with permission from NFPA 70-2008, National Electrical Code®, Copyright © 2007, National Fire Protection Association, Quincy, Massachusetts 02269. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

These values of full-load currents are typical for motors running at speeds usual for belted motors and motors with normal torque characteristics.

^bFor 90 and 80 percent power factor, the above figures shall be multiplied by 1.1 and 1.25, respectively.

The voltages listed are rated motor voltages. The currents listed shall be permitted for system-voltage ranges of 110 to 120, 220 to 240, 440 to 480, and 550 to 600 V.

11. Capacitor Ratings for Use with Three-Phase 60-Hz Motors^a

Induction motor horsepower rating	Nominal motor speed, rpm											
	3,600		1,800		1,200		900		720		600

^aFor 5 to 8 simultaneously energized power conductors in raceway or cable, the ampacity of each power conductor shall be reduced to a value of 80 percent of that shown in the table.

^bFor 4 to 6 simultaneously energized 125°C (257°F) ac power conductors in raceway or cable, the ampacity of each power conductor shall be reduced to a value of 80 percent of that shown in the table.

NOTE Other insulations shown in Table 310.13(A) and approved for the temperature and location shall be permitted to be substituted for those shown in Table 14. The allowable ampacities of conductors used with 15-min motors shall be the 30-min ratings increased by 12 percent. Reprinted with permission from NFPA 70-2008, National Electrical Code®, Copyright © 2007, National Fire Protection Association, Quincy, Massachusetts 02269. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

CONTACT CONDUCTORS The size of contact wires shall be not less than the following:

<i>Distance between End Strain Insulators or Clamp-Type</i>	<i>Size of Intermediate Supports Wire</i>
Less than 9.0 m (30 ft)	No. 6
9.10–18 m (30–60 ft)	No. 4
Over 18 m (60 ft)	No. 2

15. Curve for Determining Ampacities at 60 Hz of Bare Concentric-Stranded Copper Conductors for 30°C Rise over 40°C Ambient

For outdoor service, a 25 percent increase in ampacities is permissible.

16. Curve for Determining Ampacities for Weatherproof-Covered Concentric-Stranded Copper Conductors Installed outside Buildings

17. National Electrical Code allowable ampacities of conductors for all interior wiring (Tables 18 to 22, inclusive)

1. EXPLANATION OF TABLES For an explanation of type letters and for the recognized size of conductors for the various conductor insulations, see Sec. 310.13(A) in the NEC. For installation requirements, see Sec. 310.1 through 310.12 and the various articles of NEC.
2. 120/240-VOLT, 3-WIRE, SINGLE-PHASE DWELLING SERVICES AND FEEDERS For individual dwelling units of one-family, two-family, and multifamily dwellings, conductors, as listed below, shall be permitted to be utilized as 120/240-volt, 3-wire, single-phase service-entrance conductors, service lateral conductors, and feeder conductors that

serve as the main power feeder to each dwelling unit and are installed in raceway or cable with or without an equipment grounding conductor. For applications of this section, the main power feeder shall be the feeder between the main disconnect and the panelboard that supplies, either by branch circuits, feeders, or both, all loads that are part of or associated with the dwelling unit. The feeder conductors to a dwelling unit shall not be required to have an allowable ampacity rating greater than their service-entrance conductors. The grounded conductor shall be permitted to be smaller than the ungrounded conductors, provided the requirements of Secs. 215.2, 220.61, and 230.42 of the NEC are met.

Conductor Types and Sizes RHH, RHW, RHW-2, THHN, THHW, THW, THW-2, THWN, THWN-2, THHN, XHHW, XHHW-2, SE, USE, USE-2

Copper	Aluminum and copper-clad aluminum	Service or feeder rating, A
AWG	AWG	...
4	2	100
3	1	110
2	1/0	125
1	2/0	150
1/0	3/0	175
2/0	4/0	200
3/0	250 kcmil	225
4/0	300 kcmil	250
250 kcmil	350 kcmil	300
350 kcmil	500 kcmil	350
400 kcmil	600 kcmil	400

3. **BARE OR COVERED CONDUCTORS** Where bare or covered conductors are used with insulated conductors, their allowable ampacities shall be limited to that permitted for the lowest temperature rating of the adjacent insulated conductors.
4. **MINERAL-INSULATED METAL-SHEATHED CABLE** The conductor temperature at the end seal fitting shall not exceed the temperature rating of the listed end seal fitting, and the installation shall not exceed the temperature ratings of terminations or equipment.
5. **MORE THAN THREE CONDUCTORS IN A RACEWAY OR CABLE** When the number of current-carrying conductors in a raceway or cable exceeds three, the ampacities given in Tables 18 and 21 shall be reduced as shown in the following table:

Number of current-carrying conductors	Percent of values in tables as adjusted for ambient temperature if necessary
4 through 6	80
7 through 9	70
10 through 20	50
21 through 30	45
31 through 40	40
41 and above	35

Where single conductors or multiconductor cables are installed without maintaining spacing for a continuous length longer than 600 mm (24 in.) and are not installed in raceways, the ampacity of each conductor shall be reduced as shown in the above table. Each current-carrying conductor of a paralleled set of conductors shall be counted as a current-carrying conductor.

Exception No. 1. When conductors of different systems, as provided in Sec. 300.3 of the NEC, are installed in a common raceway or cable, the derating factors shown above shall apply to the number of power and lighting (Articles 210, 215, 220, and 230 of the NEC) conductors only.

Exception No. 2. For conductors installed in cable trays, the provisions of Sec. 392.11 of the NEC shall apply.

Exception No. 3. Derating factors shall not apply to conductors in nipples having a length not exceeding 600 mm (24 in).

Exception No. 4. Derating factors shall not apply to underground conductors entering or leaving an outdoor trench if those conductors have physical protection in the form of rigid metal conduit, intermediate metal conduit, or rigid nonmetallic conduit having a length not exceeding 3.05 m (10 ft) above grade and the number of conductors does not exceed four.

Exception No. 5. Adjustment factors shall not apply to Type AC or to Type MC cable without an overall outer jacket where having 3 current-carrying conductors, the conductors are 12 AWG copper, there are not more than 20 current-carrying conductors bundled, stacked or supported on "bridle rings." A 60 percent adjustment factor shall be applied where the current-carrying conductors in these cables that are stacked or bundled longer than 600 mm (24 in) without maintaining spacing exceeds 20.

6. NEUTRAL CONDUCTOR

- a. A neutral conductor which carries only the unbalanced current from other conductors of the same circuit need not be counted in determining ampacities as provided for in Par. 5.
- b. In a three-wire circuit consisting of two-phase wires and the neutral of a four-wire, three-phase Y-connected system, a common conductor carries approximately the same current as the line-to-neutral load currents of the other conductors and shall be counted in determining ampacities as provided in Par. 5.
- c. On a four wire, three-phase Y circuit where the major portion of the load consists of nonlinear loads, there are harmonic currents present in the neutral conductor, and the neutral conductor shall be considered a current-carrying conductor.

7. GROUNDING CONDUCTOR

A grounding conductor shall not be counted when applying the provisions of Par. 5.

18. Ampacities of Insulated Conductors Rated 0–2000 V, 60 to 90°C (140°F through 194°F)^a

(Table 310.16, 2008 NEC)

Not more than three current-carrying conductors in raceway or cable or earth (directly buried), based on ambient temperature of 30°C (86°F).

Temperature rating of conductor (see Table 310.13(A) of NEC)

^aThe overcurrent shall not exceed 15 A for 12 AWG and 25 A for 10 AWG after any correction factors for ambient temperatures and number of conductors have been applied.

NOTE 60°C conductors: TW, UF; 75°C conductors: RHW, THHW, THW, THWN, XHHW, USE; 90°C conductors: RHH, THHN, THHW, XHHW, THW-2, THWN-2, RHW-2, USE-2, XHH, XHHW-2, ZW-2.

24. Ampacities for Flexible Cords and Cables. Table 400.5(A) of the NEC provides the allowable ampacities for flexible cords and cables for general application, and Table 400.5(B) of the NEC provides the ampacities for flexible cords and cables of specialized construction, both tables being applicable to not more than three current-carrying conductors. These tables shall be used in conjunction with applicable end-use product standards to ensure selection of the proper size and type. If the number of current-carrying conductors exceeds three, the allowable ampacity or the ampacity of each conductor shall be reduced from the three-conductor rating as shown in the following table:

Number of conductors	Percent of value in Tables 400.5(A) and 400.5(B) of the NEC
4 through 6	80
7 through 9	70
10 through 20	50
21 through 30	45
31 through 40	40
41 and above	35

Ultimate Insulation Temperature. In no case shall conductors be associated together in such a way with respect to the kind of circuit, the wiring method used, or the number of conductors such that the limiting temperature of the conductors is exceeded.

A neutral conductor that carries only the unbalanced current from other conductors of the same circuit need not be considered as a current-carrying conductor.

In a 3-wire circuit consisting of two phase conductors and the neutral conductor of a 4-wire, 3-phase wye-connected system, a common conductor carries approximately the same current as the line-to-neutral currents of the other conductors and shall be considered to be a current-carrying conductor.

On a 4-wire, 3-phase wye circuit where more than 50 percent of the load consists of non-linear loads such as electric-discharge lighting, electronic computer/data processing, or similar equipment, there are harmonic currents present in the neutral conductor, and the neutral conductor shall be considered to be a current-carrying conductor.

An equipment grounding conductor shall not be considered a current-carrying conductor.

Where a single conductor is used for both equipment grounding and to carry unbalanced current from other conductors, as provided for in Sec. 250.140 of the NEC for electric ranges and electric clothes dryers, it shall not be considered as a current-carrying conductor.

Exception: For other loading conditions, adjustment factors shall be permitted to be calculated under Sec. 310.15(C) of the NEC.

Amcapacity of Flexible Cords and Cables^a

(Table 400.5(A), 2008 NEC)

Based on ambient temperature of 30°C (86°F). See Sec. 400.13 and Table 400.4 in the NEC.

NOTE *Ultimate insulation temperature.* In no case shall conductors be associated together in such a way with respect to the kind of circuit, wiring method used, or number of conductors that the limiting temperature of the conductors will be exceeded.

^b7 amperes for elevator cables only; 2 amperes for other types.

^cThe allowable currents under subheading A apply to three-conductor cords and other multiconductor cords connected to utilization equipment so that only three conductors are current-carrying. The allowable currents under subheading B apply to two-conductor cords and other multiconductor cords connected to utilization equipment so that only two conductors are current-carrying.

^dTinsel cord.

^eElevator cables only.

Ampacity of Cables Types SC, SCE, SCT, PPE, W, and G-GC
(Table 400.5(B), 2008 NEC)

Based on ambient temperature of 30°C (86°F). See Table 400.4 in the NEC.

Size, AWG, kcmil	Temperature rating of cable								
	60°C(140°F)			75°C(167°F)			90°C(194°F)		
	D	E	F	D	E	F	D	E	F

400	455	392	343	545	469	410	615	535	468
500	515	448	392	620	537	470	700	613	536

The ampacities under subheading D shall be permitted for single-conductor Types SC, SCE, SCT, PPE, and W cable only where the individual conductors are not installed in raceways and are not in physical contact with each other except in lengths not to exceed 600 mm (24 in) where passing through the wall of an enclosure.

The ampacities under subheading E apply to two-conductor cables and other multiconductor cables connected to utilization equipment so that only two conductors are carrying current. The ampacities under subheading F apply to three-conductor cables and other multiconductor cables connected to utilization equipment so that only three conductors are carrying current.

25. Allowable ampacity of fixture wires (Table 402.5, 2008 NEC)^a. The ampacity of fixture wire shall not exceed the following:

Size, AWG	Ampacity
18	6
16	8
14	17
12	23
10	28

^aReprinted with permission from NFPA 70-2008, National Electrical Code®, Copyright © 2007, National Fire Protection Association, Quincy, Massachusetts 02269. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

NOTE No conductor shall be used under such conditions that its operating temperature will exceed the temperature specified in Table 402.3 of the NEC for the type of insulation involved.

26. Curves for Determining Ampacity of Aluminum Cable, Steel-Reinforced
(Aluminum Co. of America)

27. Ampacity of Parkway Cables Buried Directly in Ground^a

Conductor size, AWG or 1000 cmil	Maximum allowable ampacity per conductor (copper)		Conductor size, AWG or 1000 cmil	Maximum allowable ampacity per conductor (copper)	
	Single-conductor cable, A	Three conductor cable, A		Single-conductor cable, A	Three conductor cable, A
8 AWG	85	60	3/0 AWG	335	225

1	220	150	350	515	345
1/0	255	170	400	555	375
2/0	295	195	500	635	425

^aTable based on earth temperature of 20°C (68°F). Rubber-insulated conductors in accordance with ICEA specification. Average soil condition: sandy loam, 10 percent moisture. Average depth of burial 18 in. Other cables sufficiently far away to prevent mutual heating. Rated voltages up to 5 kV, grounded neutral.

28. Notes to NEC Tubular Raceway and Wire Dimension Tables (Chap. 9, Tables) The notes apply to coverage of subjects addressed in Sec. 29 through 32 following.

NOTE 1 See Annex C of the NEC for the maximum number of conductors and fixture wires, all of the same size (total cross-sectional area including insulation), permitted in trade sizes of the applicable conduit or tubing.

NOTE 2 Table 1 applies only to complete conduit or tubing systems and is not intended to apply to sections of conduit or tubing used to protect exposed wiring from physical damage.

NOTE 3 Equipment grounding or bonding conductors, where installed, shall be included when calculating conduit or tubing fill. The actual dimensions of the equipment grounding or bonding conductor (insulated or bare) shall be used in the calculation.

NOTE 4 Where conduit or tubing nipples having a maximum length not to exceed 600 mm (24 in) are installed between boxes, cabinets, and similar enclosures, the nipples shall be permitted to be filled to 60 percent of their total cross-sectional area, and 310.15(B)(2)(a) adjustment factors need not apply to this condition.

NOTE 5 For conductors not included in Chap. 9 of the NEC, such as multiconductor cables, the actual dimensions shall be used.

NOTE 6 For combinations of conductors of different sizes, use Tables 5 and 5A in Chap. 9 of the NEC for dimensions of conductors and Table 4 in Chap. 9 of the NEC for the applicable conduit or tubing dimensions.

NOTE 7 When calculating the maximum number of conductors permitted in a conduit or tubing, all of the same size (total cross-sectional area including insulation), the next higher whole number shall be used to determine the maximum number of conductors permitted when the calculation results in a decimal of 0.8 or larger.

NOTE 8 Where bare conductors are permitted by other sections of the Code, the dimensions for bare conductors in Table 8 of Chap. 9 of the NEC shall be permitted.

NOTE 9 A multiconductor cable or flexible cord of two or more conductors shall be treated as a single conductor for calculating percentage conduit fill area. For cables that have elliptical cross sections, the cross-sectional area calculation shall be based on using the major diameter of the ellipse as a circle diameter.

29. Percent of Cross Section of Conduit and Tubing for Conductors (Table 1, Chap. 9, 2008 NEC)

Number of conductors	1	2	Over 2
All conductor types	53	31	40

NOTE 1 Table 1 is based on common conditions of proper cabling and alignment of conductors where the length of the pull and the number of bends are within reasonable limits. It should be recognized that, for certain conditions, a larger size conduit or a lesser conduit fill should be considered.

NOTE 2 When pulling three conductors or cables into a raceway, if the ratio of the raceway (inside diameter) to the conductor or cable (outside diameter) is between 2.8 and 3.2, jamming can occur. While jamming can occur when pulling four or more conductors or cables into a raceway, the probability is very low.

30. Dimensions and Percent Area of Conduit and Tubing (Areas of Conduit or Tubing for the Combinations of Wires Permitted in Table 1, Chap. 9 of the NEC). Refer to Table 4, Chap. 9 in the NEC for these dimensions, which are different for each of the various tubular wiring methods recognized by the NEC.

31. Dimensions of Insulated Conductors and Fixture Wires. Refer to Table 5, Chap. 9 in the NEC for these dimensions.

32. Compact Aluminum Building Wire Nominal Dimensions and Areas. Refer to Table 5A, Chap. 9 in the NEC for these dimensions.

33. Minimum Wire-Bending Space at Terminals in Inches (mm) for conductors *not* entering or leaving through the wall opposite the terminal, from NEC Table 312.6(A).

Minimum bending space, in. (mm) at terminals ^a

NOTES

1. Bending space at terminals shall be measured in a straight line from the end of the lug or wire connector in a direction perpendicular to the enclosure wall.

2. For removable and lay-in wire terminals intended for only one wire, bending space shall be permitted to be reduced by the following number of millimeters (inches).

^a12.7 mm (1/2 in.)

^b25.4 mm (1 in.)

^c38.1 mm (3/4 in.)

^d50.8 mm (2 in.)

^e76.2 mm (3 in.)

3. This column shall be permitted to determine the required wire bending space for compact stranded aluminum conductors in sizes up to 1000 kcmil and manufactured using AA-8000 series electrical grade aluminum alloy conductor material in accordance with 310.14.

35. Enclosed Switch Wiring Space^a (Enclosed and Dead-front Switches—UL98)

^aClass H, J, or K fuses. Class G fuses are 15, 20, 25, 30, 40, 45, 50, and 60 A.

^bNonadjustable thermal-magnetic breakers.

39. Nonrenewable Cartridge Fuses (Underwriters Laboratories Inc.)

UL listing covers cartridge-enclosed fuses of the nonrenewable type, rated 0–600 amp, 250 V, 0–1200 amp, 300 V, 0–6000 amp, 600 V. These fuses are intended for use on ac circuits only unless also marked with a dc voltage rating. These fuses are suitable for branch circuit and service overcurrent protection in accordance with the requirements of the National Electrical Code.

Fuses designated as Class K1, K5, K9 (0–600 amp, 250 V, ac, or 600 V, ac) are classified as to interrupting capacity and in terms of maximum clearing ampere squared seconds and maximum peak let-through current. They incorporate dimensional features equivalent to, and are interchangeable with Class H Fuses. They are not marked “Current Limiting.”

Fuses designated as Class RK1 and RK5 (0–600 amps, 250 V, ac or 600 V, ac) are high interrupting capacity types and are marked “Current Limiting.” They are classified in terms of maximum clearing ampere squared seconds and maximum peak let-through current at 50, 100, and 200 thousand rms symmetrical amperes. They incorporate features which permit their insertion into Class H and K fuse-holders. Also, they are provided with a feature which allows their insertion into rejection type fuseholders designed to accept only Class RK1 or RK5 fuses.

Fuses designated as Class CC (0–30 amp, 600 V, ac) are high interrupting capacity types and are marked “Current Limiting.”

Fuses designated as Class G (0–60 amp, 480 V, ac) are high interrupting capacity types and are marked “Current Limiting.”

Fuses designated as Class J (0–600 amp, 600 V, ac) or Class L (601–6000 amp, 600 V, ac) are high interrupting capacity types and are marked “Current Limiting.”

Fuses designated as Class T (0–1200 amp, 300 V and 0–800 amp, 600 V, ac) are high interrupting capacity types and are marked “Current Limiting.”

The term “Current Limiting” indicates that a fuse, when tested on a circuit capable of delivering a specific short circuit current (rms amperes symmetrical) at rated voltage, will start to melt within 90 electrical degrees and will clear the circuit within 180 electrical degrees ($1/2$ cycle).

Because the time required for a fuse to melt is dependent on the available current of the circuit, a fuse which may be “Current Limiting” when subjected to a specific short circuit current (rms amperes symmetrical) may not be current limiting on a circuit of lower maximum available current.

The following tables indicate the maximum permissible let-through values which are obtained when the fuse is connected to a circuit having an available current tabulated in the following tables.

Maximum Peak Let-Through Current (I_p Amperes) and Clearing I^2t (ampere squared seconds)

Class CC fuses						
Rating amps	Between threshold and 50 KA		100 KA		200 KA

401-600	10000	65	10000	80	12000	100

Class K-1, K-5, K-9 fuses are marked, in addition to their regular voltage and current ratings, with an interrupting rating of 200,000, 100,000, or 50,000 amp (rms symmetrical).

Class CC, RK1, RK5, J, L, and T fuses are marked, in addition to their regular voltage and current ratings, with an interrupting rating of 200,000 amp (rms symmetrical).

Class G fuses are marked, in addition to their regular voltage and current ratings, with an interrupting rating of 100,000 amp (rms symmetrical).

Class H fuses have an interrupting rating of 10,000 amp (rms symmetrical).

When a fuse has a dc rating, it is marked with the dc voltage and interrupting rating.

A Class CC, G, J, K, or R fuse and a Class T fuse rated 600 A or less may have an interrupting rating of 10,000, 20,000, 50,000, or 100,000 amp dc. A Class T fuse rated 601-1200 A and a Class L fuse may have an interrupting rating of 20,000, 50,000, or 100,000 amp, dc. A Class H fuse may have an interrupting rating of 10,000 amp, dc.

Class K and R fuses which have been investigated for use in protecting trailing cables in dc circuits in mines are marked "Mine Duty" and have an interrupting rating of 20,000 amp, dc.

Equipment (a switch, motor starter, panelboard, etc.) which has been investigated and found suitable for use with these fuses is marked with the class of fuse intended to be used in the equipment and available current rating applicable to that piece of equipment. The equipment with these fuses installed, is suitable for use on circuits having a maximum available fault current up to the short circuit rating of the equipment, or the interrupting rating of the fuse, whichever is lower.

An interrupting rating on a fuse included in a piece of equipment does not automatically qualify the equipment in which the fuses are installed for use on circuits with higher available currents than the rating of the equipment itself.

Classes CC, G, H, J, K, L, R, and T fuses may be marked as having a time delay characteristic, such as "Time Delay," "Dual Element," or some equivalent designation.

The basic standards used to investigate products in this category are UL198B, "Class H Fuses," UL198C, "High-Interrupting-Capacity Fuses, Current-Limiting Types," UL198D, "Class K Fuses," UL198L, "DC Fuses for Industrial Use," UL198M, "Mine-Duty Fuses," UL24801, "Low-Voltage Fuses—General Requirements," UL248-4, "Class CC Fuses," UL248-8, "Class J Fuses," UL248-10, "Class L Fuses," UL248-12, "Class R Fuses," and UL248-15, "Class T Fuses."

DEFINITIONS

Case size. Fuses of all ratings for which the size of the cartridge is the same; for example, 31–60 A, 61–100 A.

Clearing time. The total time measured from the beginning of the specified overcurrent condition until the interruption of the circuit, at rated voltage. It is equal to the sum of the melting time and the arcing time.

Current-limiting fuse. A fuse which safely interrupts all available currents within its interrupting rating and, within its current-limiting range, limits the clearing time at rated voltage to an interval equal to or less than the first major or symmetrical current-loop duration and limits peak let-through current to a value less than the peak current that would be possible if the fuse were replaced by a solid conductor of the same impedance.

Current-limiting range. The range of rms symmetrical available currents equal to or less than the interrupting rating in which the total clearing time at rated voltage and frequency is less than $1/2$ cycle.

Interrupting rating. The rating specifying the highest rms symmetrical, alternating current which the fuse is required to interrupt under the conditions of these requirements.

I^2t (amperes squared–seconds). An expression of the energy available as a result of current flow. The term is normally applied during the melting, arcing, or total clearing time of the fuse under which, in the latter instance, it is often designated as “clearing I^2t .”

Maximum energy. The test condition under which in a specified maximum time ($1/2$ cycle), the maximum amount of heat possible is generated in the fuse before clearing.

Melting time. The time required for the current to melt the current-responsive element.

Normal-frequency recovery voltage. The normal-frequency rms voltage impressed upon the fuse after the circuit has been interrupted and after high-frequency transients have subsided.

Peak let-through current (I_p). The maximum instantaneous current through the fuse during the total clearing time.

Rating tests. Carrying-capacity, temperature, and clearing-time–current tests.

Recovery voltage. The voltage impressed upon the fuse after a circuit has been interrupted.

Threshold current. The rms symmetrical available current at the threshold of the current-limiting range, when melting of the current-responsive element has occurred at approximately 90° on the symmetrical current wave and total clearing time is less than $1/2$ cycle at rated voltage and rated frequency and with a circuit power factor of 20 percent or less.

Threshold ratio. The ratio obtained by dividing the threshold current by the continuous-current rating of the fuse.

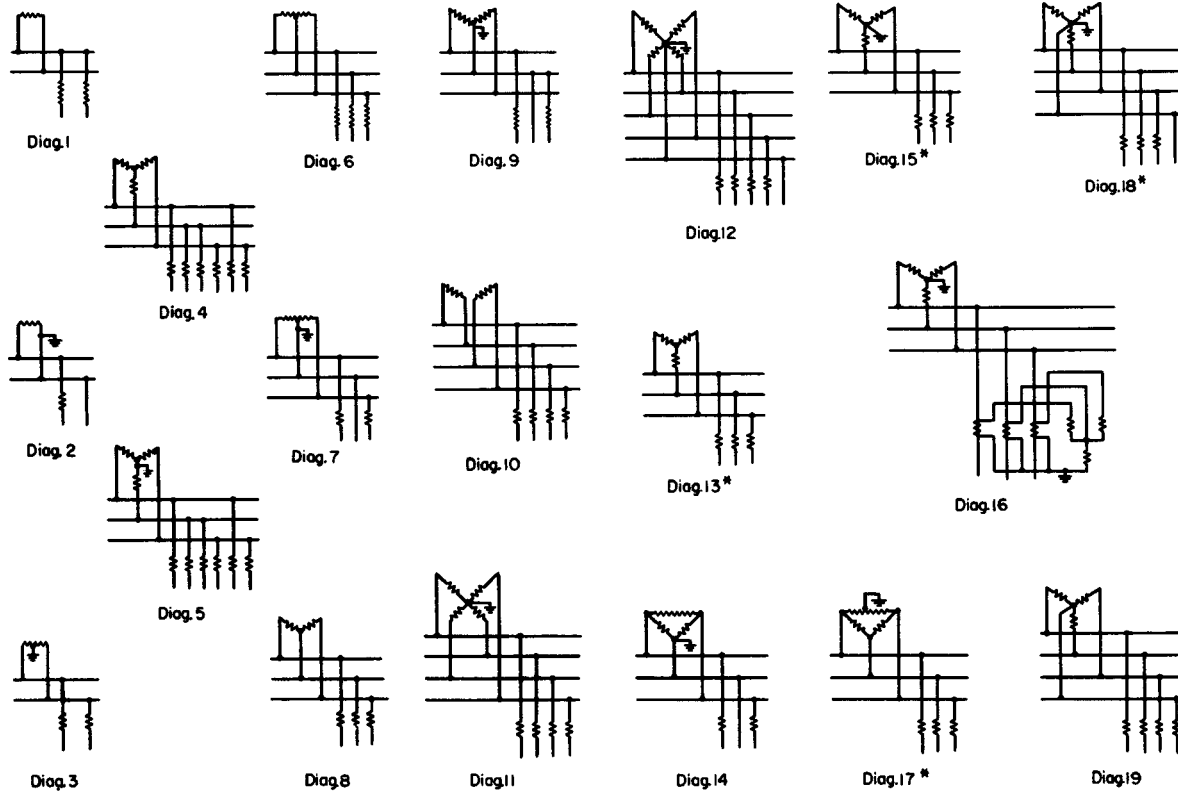

40. Number of Overcurrent Units, Such as Trip Coils or Relays, for Protection of Circuits^a

Systems	Number and location of overcurrent units ^b
Two-wire single-phase ac or dc, ungrounded	Two (one in each conductor). Diagram 1 of Fig. 12.1.
Two-wire single-phase ac or dc, one wire grounded	One (in ungrounded conductor). Diagram 2 of Fig. 12.1.
Two-wire single-phase ac or dc, midpoint grounded	Two (one in each conductor). Diagram 3 of Fig. 12.1.
Two-wire single-phase ac derived from three-phase, with ungrounded neutral	Two (one in each conductor). Diagram 4 of Fig. 12.1.
Two-wire single-phase derived from three-phase, grounded neutral system by using outside wires of three-phase circuit	Two (one in each conductor). Diagram 5 of Fig. 12.1.
Three-wire single-phase ac or dc, ungrounded neutral	Three (one in each conductor). Diagram 6 of Fig. 12.1.
Three-wire single-phase ac or dc, grounded neutral	Two (one in each conductor except neutral conductor). Diagram 7 of Fig. 12.1.
Three-wire two-phase, ac, common wire, ungrounded	Three (one in each conductor). Diagram 8 of Fig. 12.1.
Three-wire two-phase, ac, common wire, grounded	Two (one in each conductor except common conductor). Diagram 9 of Fig. 12.1.
Four-wire two-phase, ungrounded, phases separate	Four (one in each conductor). Diagram 10 of Fig. 12.1.
Four-wire two-phase, grounded neutral or five-wire two-phase, grounded neutral	Four (one in each conductor except neutral conductor). Diagrams 11 and 12 of Fig. 12.1.
Three-wire three-phase, ungrounded	Three (one in each conductor). Diagram 13 of Fig. 12.1. ^c
Three-wire three-phase, one wire grounded	Two (one in each ungrounded conductor). Diagram 14 of Fig. 12.1.
Three-wire three-phase, grounded neutral	Three (one in each conductor). Diagram 15 of Fig. 12.1. ^c
Three-wire three-phase, midpoint of one phase grounded	Three (one in each conductor). Diagram 17 of Fig. 12.1. ^c
Four-wire three-phase, grounded neutral	Three (one in each ungrounded conductor). Diagram 18 of Fig. 12.1. ^c
Four-wire three-phase, ungrounded neutral	Four (one in each conductor). Diagram 19 of Fig. 12.1.

^aRefer to Sec. 319 of Div. 9 and Fig. 12.1. When standard devices are not available with three or four overcurrent units as required in the table, it is permissible to substitute two overcurrent units and one fuse when three overcurrent units are called for and two overcurrent units and two fuses when four overcurrent units are called for. The fuse or fuses are to be placed in the conductors not containing an overcurrent unit. However, this practice of substituting fuses for overcurrent units is to be discouraged for obvious reasons.

^bAn overcurrent unit may consist of a series overcurrent tripping device or the combination of a current transformer and a secondary overcurrent tripping device. Either two or three secondary overcurrent tripping devices may be used with three current transformers on a three-phase system similar to those shown in Diagrams 15 and 18 in Fig. 12.1.

^cWhen three current transformers are used instead of three series overcurrent tripping devices shown in Diagrams 13, 15, 17, and 18 in Fig. 12.1, the secondary tripping devices may consist of three secondary overcurrent tripping devices or two secondary overcurrent tripping devices with a residual current tripping device of a lower range. See Diagram 16 of Fig. 12.1.

*See Note c of Table 40.

FIGURE 12.1 Required number of overcurrent units.

41. Number and Location of Overload Units Other Than Fuses for Protection of Motors^a

(Table 430.37, 2008 NEC)

Kind of motor	Supply system	Number and location of overload units such as trip coils, relays, or thermal cutouts
One-phase, ac or dc	Two-wire, one-phase, ac or dc, ungrounded	One in either conductor
One-phase, ac or dc	Two-wire, one-phase, ac or dc, one conductor grounded	One in ungrounded conductor
One-phase, ac or dc	Three-wire, one-phase, ac or dc, grounded neutral conductor	One in either ungrounded conductor
One-phase ac	Any three-phase	One in ungrounded conductor
Two-phase ac	Three-wire, two-phase, ac, ungrounded	Two, one in each phase
Two-phase ac	Three-wire, two-phase, ac, one conductor grounded	Two in ungrounded conductors
Two-phase ac	Four-wire, two-phase ac, grounded or ungrounded	Two, one per phase in ungrounded conductors
Two-phase ac	Grounded neutral or five-wire, two-phase ac, ungrounded	Two, one per phase in any ungrounded phase wire
Three-phase ac	Any three-phase	Three, one in each phase ^b

This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

^bException. An overload unit in each phase shall not be required where overload protection is provided by other approved means.

42. Motor code letters and locked-rotor kilovolt-amperes. The National Electrical Manufacturers Association has adopted a standard of identifying code letters that may be marked by the manufacturer on motor nameplates to show the motor kilovolt-ampere input with a locked rotor. The meaning of the code letters is as follows:

Letter designation	kVA per hp with locked rotor	Letter designation	kVA per hp with locked rotor
A	0–3.14	K	8.0–8.99
B	3.15–3.54	L	9.0–9.99
C	3.55–3.99	M	10.0–11.19
D	4.0–4.49	N	11.2–12.49
E	4.5–4.99	P	12.5–13.99
F	5.0–5.59	R	14.0–15.99
G	5.6–6.29	S	16.0–17.99
H	6.3–7.09	T	18.0–19.99
J	7.1–7.99	U	20.0–22.39
		V	22.4 and up

43. Maximum Rating or Setting of Motor Branch-Circuit, Short-Circuit, and Ground-Fault Protective Devices^a

(Table 430.52, 2008 NEC)

Type of motor	Percent of full-load current			
	Nontime delay fuse ^c	Dual element (time-delay) fuse ^c	Instantaneous trip breaker	Inverse time breaker ^b
Single-phase motors	300	175	800	250
AC polyphase motors other than wound-rotor	300	175	800	250
Squirrel Cage:				
Other than Design B energy efficient	300	175	800	250
Design B energy-efficient	300	175	1100	250
Synchronous	300	175	800	250
Wound rotor	150	150	800	150
Direct-current (constant voltage)	150	150	250	150

NOTE For certain exceptions to the values specified, see 430.54 of the NEC.

Synchronous motors of the low-torque, low-speed type (usually 450 rpm or lower), such as are used to drive reciprocating compressors, pumps, etc., that start unloaded, do not require a fuse rating or circuit-breaker setting in excess of 200 percent of full-load current.

This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

^bThe values given in the last column also cover the ratings of nonadjustable inverse-time types of circuit breakers that may be modified as in Sec. 430.52(C)(1), Exception No. 1 and No. 2.

^cThe values in the Nontime Delay Fuse column apply to Time-Delay Class CC fuses.

44. Conversion Table of Single-Phase Locked Rotor Currents for Selection of Disconnecting Means and Controllers as Determined from Horsepower and Voltages Rating

(Table 430.251(A), 2008 NEC)

For use only with Secs. 430.110, 440.12, 440.41, and 455.8(C) of the NEC.

Rated HP	Maximum locked-rotor current amperes single phase		
	115 volts	208 volts	230 volts
1/2	58.8	32.5	29.4
3/4	82.8	45.8	41.4

51. Effective Spacings of Wires to Use for Different Systems

System	Arrangement of wires	Effective spacing that should be used with Mershon diagram or table of ratio of reactance to resistance
Single-phase three-wire	Any	Use spacing between outside wires
Two-phase, any number of wires	Any	Use a spacing equal to average distance between centers of wires of the same phase
Three-phase		Effective spacing = $\sqrt[3]{ABC}$ when wires are transposed so that each wire occupies each position for approximately one-third of the length of the line
		Effective spacing = $\sqrt[3]{ABC}$ when wires are transposed so that each wire occupies each position for approximately one-third of the length of the line
	 A = B	Effective spacing = 1.26A when wires are transposed so that each wire occupies each position for approximately one-third of the length of the line The position of the neutral in a four-wire system does not affect the spacing

52. Approximate Power Factors of Apparatus

Type of apparatus	Power factor
Incandescent lamps and heaters.....	1.0
Fluorescent lamps and mercury-vapor lamps ^a	0.5–0.95
Induction motors: ^b	
1 hp.....	0.67
2 hp.....	0.73
3 hp.....	0.80
5 hp.....	0.83
7 1/2–25 hp.....	0.86
30–50 hp.....	0.89
60–125 hp.....	0.92
150–200 hp.....	0.93
Synchronous motors.....	0.8 to 1.0 leading

NOTE All power factors less than unity are lagging except for synchronous motors.

^aFor more accurate information refer to Div. 10.

^bThe values of power factor for induction motors are average values when the motors are operating at 75 percent of rated load.

53. 60-Hz Ratios: Reactance to Resistance**54. 25-Hz Ratios: Reactance to Resistance****55. Alternating-Current Drop Factors**

Ratio of reactance to resistance	Power factor

This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

These resistance values are valid *only* for the parameters as given. Using conductors having coated strands, different stranding type, and, especially, other temperatures, changes the resistance.

Formula for temperature change: $R_2 = R_1[1 + \alpha(T_2 - 75)]$ where $\alpha_{cu} = 0.00323$ and $\alpha_{AL} = 0.00330$ at 75°C.

Class B stranding is listed as well as solid for some sizes. Its overall diameter and area are those of its circumscribing circle.

Conductors with compact and compressed stranding have about 9% and 3%, respectively, smaller bare conductor diameters than those shown.

IACS conductivities used: bare copper = 100%; aluminum = 61%.

See Table 5A, NEC for actual compact cable dimensions.

58. Metric practice (ANSI/IEEE 268-1982). The International System of Units, developed and maintained by the General Conference on Weights and Measures (abbreviated CGPM from the official French name *Conférence Générale des Poids et Mesures*), is intended as a basis for worldwide standardization of measurement units. The name International System of Units and the international abbreviation SI were adopted by the Eleventh CGPM in 1960.

CLASSES OF SI UNITS SI units are divided into three classes: base units, supplementary units, and derived units

BASE UNITS SI is based on seven well-defined units which by convention are regarded as dimensionally independent:

Quantity	Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	Cd

SUPPLEMENTARY UNITS The units listed below are called *supplementary units* and may be regarded either as base units or as derived units:

Quantity	Unit	Symbol
Plane angle	radian	rad
Solid angle	steradian	Sr

DERIVED UNITS Derived units are formed by combining base units, supplementary units, and other derived units according to the algebraic relations linking the corresponding quantities. The symbols for derived units are obtained by means of the mathematical signs for multiplication, division, and use of exponents. For example, the SI unit for velocity is the meter per second (m/s or $\text{m}\cdot\text{s}^{-1}$), and that for angular velocity is the radian per second (rad/s or $\text{rad}\cdot\text{s}^{-1}$). Derived SI units which have special names and symbols approved by the CGPM are listed below:

Quantity	Unit	Symbol	Formula
Frequency (of a periodic phenomenon)	hertz	Hz	1/s
Force	newton	N	$(\text{kg}\cdot\text{m})/\text{s}^2$
Pressure, stress	pascal	Pa	N/m^2
Energy, work, quantity of heat	joule	J	$\text{N}\cdot\text{m}$
Power, radiant flux	watt	W	J/s
Quantity of electricity, electric charge	coulomb	C	$\text{A}\cdot\text{s}$
Electric potential, potential difference, electromotive force	volt	V	W/A
Capacitance	farad	F	C/V
Electric resistance	ohm	Ω	V/A
Conductance	Siemens	S	A/V
Magnetic flux	weber	Wb	$\text{V}\cdot\text{s}$
Magnetic flux density	tesla	T	Wb/m^2
Inductance	henry	H	Wb/A
Luminous flux	lumen	lm	$\text{cd}\cdot\text{sr}$
Illuminance	lux	lx	lm/m^2
Activity (of radionuclides)	becquerel ^a	Bq	1/s
Absorbed dose	gray ^a	Gy	J/kg

^aAdopted by the CGPM in 1975.

59. Some Common Derived Units of SI

Quantity	Unit	Symbol
Acceleration	meter per second squared	m/s^2
Angular acceleration	radian per second squared	rad/s^2
Angular velocity	radian per second	rad/s
Area	square meter	m^2
Concentration (of amount of substance)	mole per cubic meter	mol/m^3
Current density	ampere per square meter	A/m^2
Density, mass	kilogram per cubic meter	kg/m^3
Electric charge density	coulomb per cubic meter	C/m^3
Electric field strength	volt per meter	V/m
Electric flux density	coulomb per square meter	C/m^2
Energy density	joule per cubic meter	J/m^3
Entropy	joule per kelvin	J/K
Heat capacity	joule per kelvin	J/K
Heat Flux density	watt per square meter	W/m^2
Irradiance		
Luminance	candela per square meter	cd/m^2
Magnetic field strength	ampere per meter	A/m
Molar energy	joule per mole	J/mol
Molar entropy	joule per mole kelvin	$J/(mol \cdot K)$
Molar heat capacity	joule per mole kelvin	$J/(mol \cdot K)$
Moment of force	newton meter	$N \cdot m$
Permeability	henry per meter	H/m
Permittivity	farad per meter	F/m
Radiance	watt per square meter steradian	$W/(m^2 \cdot sr)$
Radiant intensity	watt per steradian	W/sr
Specific heat capacity	joule per kilogram kelvin	$J/(kg \cdot K)$
Specific energy	joule per kilogram	J/kg
Specific entropy	joule per kilogram kelvin	$J/(kg \cdot K)$
Specific volume	cubic meter per kilogram	m^3/kg
Surface tension	newton per meter	N/m
Thermal conductivity	watt per meter kelvin	$W/(m \cdot K)$
Velocity	meter per second	m/s
Viscosity, dynamic	pascal second	$Pa \cdot s$
Viscosity, kinematic	square meter per second	m^2/s
Volume	cubic meter	m^3
Wave number	1 per meter	$1/m$

60. Recommended Pronunciations

Prefix	Pronunciation (United States) ^a
Exa	ex' a (<i>a</i> as in <i>about</i>)
Peta	pet' a (<i>e</i> as in <i>pet</i> , <i>a</i> as in <i>about</i>)
Tera	as in <i>terrace</i>
Giga	jig' a (<i>i</i> as in <i>jig</i> , <i>a</i> as in <i>about</i>)
Mega	as in <i>megaphone</i>
Kilo	kill' oh
Hecto	heck' toe
Deka	deck' a (<i>a</i> as in <i>about</i>)
Deci	as in <i>decimal</i>
Centi	as in <i>centipede</i>
Milli	as in <i>military</i>
Micro	as in <i>microphone</i>
Nano	nan' oh (<i>an</i> as in <i>ant</i>)
Pico	peek' oh
Femto	fem' toe (<i>fem</i> as in <i>feminine</i>)
Atto	as in <i>anatomy</i>
Selected units	Pronunciation
Candela	can dell' a
Joule	rhyme with <i>tool</i>
Kilometer	kill' oh meter
Pascal	rhyme with <i>rascal</i>
Siemens	same as <i>seamen's</i>

^aExact.

63. Definitions of Derived Units of the International System Having Special Names

Physical quantity	Unit and definition
Absorbed dose	The <i>gray</i> is the energy imparted by ionizing radiation to a mass of matter corresponding to one joule per kilogram.
Activity	The <i>becquerel</i> is the activity of a radionuclide having one spontaneous nuclear transition per second.
Electric capacitance	The <i>farad</i> is the capacitance of a capacitor between the plates of which there appears a difference of potential of one volt when it is charged by a quantity of electricity equal to one coulomb.
Electric conductance	The <i>Siemens</i> is the electric conductance of a conductor in which a current of one ampere is produced by an electric potential difference of one volt.
Electric inductance	The <i>henry</i> is the inductance of a closed circuit in which an electromotive force of one volt is produced when the electric current in the circuit varies uniformly at a rate of one ampere per second.
Electric potential difference, electromotive force	The <i>volt</i> (unit of electric potential difference and electromotive force) is the difference of electric potential between two points of a conductor carrying a constant current of one ampere when the power dissipated between these points is equal to one watt.

(Continued)

Electric resistance	The <i>ohm</i> is the electric resistance between two points of a conductor when a constant difference of potential of one volt, applied between these two points, produces in this conductor a current of one ampere, this conductor not being the source of any electromotive force.
Energy	The <i>joule</i> is the work done when the point of application of a force of one newton is displaced by a distance of one meter in the direction of the force.
Force	The <i>newton</i> is that force which, when applied to a body having a mass of one kilogram, gives it an acceleration of one meter per second squared.
Frequency	The <i>hertz</i> is the frequency of a periodic phenomenon of which the period is one second.
Illuminance	The <i>lux</i> is the illuminance produced by a luminous flux of one lumen uniformly distributed over a surface of one square meter.
Luminous flux	The <i>lumen</i> is the luminous flux emitted in a solid angle of one steradian by a point source having a uniform intensity of one candela.
Magnetic flux	The <i>weber</i> is the magnetic flux which, linking a circuit of one turn, produces in it an electromotive force of one volt as it is reduced to zero at a uniform rate in one second.
Magnetic flux density	The <i>tesla</i> is the magnetic flux density given by a magnetic flux of one weber per square meter.
Power	The <i>watt</i> is the power which gives rise to the production of energy at the rate of one joule per second.
Pressure or stress	The <i>pascal</i> is the pressure or stress of one newton per square meter.
Quantity of electricity	The <i>coulomb</i> is the quantity of electricity transported in one second by a current of one ampere.

^aSince 1893 the United States basis of length measurement has been derived from metric standards. In 1959 a small refinement was made in the definition of the yard to resolve discrepancies both in the United States and other countries; this changed its length from 3600/3937 m to 0.9144 m exactly. The change resulted in the new value being shorter by 2 parts in 1 million. At the same time it was decided that any data in feet derived from and published as a result of geodetic surveys within the United States would remain with the old standard (1 ft = 1200/3937 m) until further decision. This foot is named the United States survey foot. As a result all United States land measurements in United States customary units will relate to the meter by the old standard. All the conversion factors in these tables for units referenced to this footnote are based on the United States survey foot rather than on the international foot. Conversion factors for the land measure given below may be determined from the following relationships:

1 league = 3 mi (exactly)
 1 rod = 16½ ft (exactly)
 1 section = 1 mi² (exactly)
 1 township = 36 mi² (exactly)

^bThis value conflicts with the value printed in NBS 330 (17). The value requires updating in NBS 330.

^cThis value was adopted in 1956. Some of the older international tables use the value 1.055 04 E+03. The exact conversion factor is 1.055 055 852 62*E+03.

^dThis is sometimes called the moment of inertia of a plane section about a specified axis.

^eThe exact conversion factor is 1.638 706 4*E-05.

^fIn 1964 the General Conference on Weights and Measures adopted the name *liter* as a special n for the cubic decimeter. Prior to this decision the liter differed slightly (previous value, 1.000 028 dm³), and in expression of precision volume measurement this fact must be kept in mind.

^gThe exact conversion factor is 4.535 923 7*E-01.

^hThe exact conversion factor is 4.448 221 615 260 5*E+00.

ⁱDefined (not measured) value.

INDEX

The numbers referenced in the Index represent the *division and section number*, not the page number. For example, an Index reference to 10-57 means Div. 10, Sec. 57. Since within each division all section numbers are placed in numerical order, there should be no difficulty in locating any section number.

At the beginning of each division is a table of contents which describes the various topics within the division. These are listed by page numbers.

Absorption:

- coefficients of, 10-3
- definition of, 10-5

Absorption characteristics of materials, 10-4

Acceleration, motor, control of, 7-259 to 7-278

Acid, sulfuric, 4-157

Admedium lamp base, 10-57

Admittance, definition of, 1-52

Aerial cable, 2-61

Air conditioning, sizing, 7-407, 9-445

Aircraft cable and wire, 2-79

Airport lamps, 10-64

Alignment, motor, 7-369

Alley arms, 8-62

Alternating current:

- average value of, 1-119
- conversion to direct current, 7-206 to 7-213
- definition of, 1-34
- effective value of, 1-120
- generation of (*see* Generators, alternating-current)
- maximum value of, 1-118
- standard voltages and applications of, 3-26
- waveform of, 1-112

Alternating-current circuits [*see* Circuit(s), alternating-current]

Alternating-current drop factors, 12-55

Alternating-current generators (*see* Generators, alternating-current)

Alternating-current motors [*see* Motor(s), alternating-current]

Alternators (*see* Generators, alternating-current)

Altitude, effect on motors, 7-351

Aluminum, conductivity and weight of, 2-19

Aluminum cables, 2-21, 2-86

- ampacity of, 12-19, 12-21
- resistance of, 12-57

Aluminum conductors, 2-19

- ampacity of, 12-19, 12-21
- steel-reinforced, 2-19

Ambient temperature, ampacity derating for, 3-101

American screw gage, 4-234

American wire gage, 2-3, 2-85

Ammeters:

- for compound generators, 7-22
- use of, rules for, 1-170

Ampacity, 3-31, 3-89 to 3-106, 12-12 to 12-23

- AC cable, type, special ampacity rules, 9-193
- ambient temperature derating, 3-101
- conductor selection for, 3-103
- control wires, when counted for derating, 3-99

- definition of, 3-90, 9-3
- derating procedure, 3-100
- effects of thermal insulation on, 9-242
- middle of the wire concept, 3-96
- mutual conductor heating effect, 3-97

NEC Annex B, Sec. B.310.11 calculations, 3-112 to 3-114

neutrals, special sizing for short-circuits, 3-107

neutrals, when counted for derating, 3-98

NM cable, type, special ampacity rules, 9-228

- Ampacity (*Cont.*):
 partial runs, differences, 3-102
 tables, explanation of function, 3-91
- Amperes:
 definition of, 1-37
 distinction from volts, 1-82
 relation to coulombs, 1-36
- Amplidyne, 7-44, 7-143
- Anchor rods:
 attachment of, 8-88
 guy, 8-54
- Anchors:
 expansion, 4-242 to 4-247
 guy, 8-83 to 8-100
- Angle of lag, 1-127
- Angle of lead, 1-130
- Angular displacement in transformer connections, 5-91
- Antenna, lightning protection of, 4-74
- Apartment houses, wiring for, 9-508 to 9-510
- Appliance loads, minimum allowable, 12-5
- Appliances:
 circuits required for, 9-499
 disconnecting means for, 9-427
 grounding, 9-428
 protection of, 9-425
 ratings allowed on circuits for, 9-497
 signals for, 9-429
 wiring for, 9-425, 9-430
- Approved (standard of acceptance, per NEC), 9-3
- Arc-fault circuit-interrupter, 4-77
- Argon-glow lamps, 10-143
- Armature troubles, synchronous motors, 7-231
- Armature windings:
 baking of, 7-244
 of direct-current generators, 7-3
- Armatures, direct-current: causes of heating of, 7-71
 grounded, locating, 7-68
 reversed, 7-70
 short circuits in, 7-231
 testing, 7-65, 7-66
- Armor:
 cable, 2-38, 2-49, 2-50, 2-52
 tape, 2-49
 wire, 2-51
- Armor rods, 8-77
- Armored cable, 2-56
- Armored-cable wiring, 9-5, 9-182 to 9-192
- Arms:
 alley, 8-62
 buck, 8-63
 double, 8-61
 reverse, 8-63
- Arresters, lightning, 4-74 to 4-76
- Assemblies:
 cable, 2-21
 multioutlet, 9-303 to 9-309

- disconnects for, 3-13
 - floodlighting of, 10-220, 10-235
 - rewiring of, 9-492, 9-493
 - service equipment for, 3-18
- Bulbs, lamp: colored, 10-55
- finish of, 10-52
 - mercury, 10-115
 - shape of, 10-51
- Busbars, copper: data for, 2-94
- sections of, 2-86
 - spacing for, 4-83
- Bushings:
- antishort insulating, 9-186
 - conduit, 9-83, 9-88
 - insulating socket, 4-132
- Busways:
- feeder, 9-268
 - layout, 9-271
 - lighting, 9-278, 9-280
 - mounting of, 9-274
 - plug-in, 9-273
 - plugs for, 9-277
 - trolley, 9-278, 9-279, 9-280
- BX cable (*see* AC cable)
- Cable(s):
- AC cable, 9-5
 - aerial, 2-61
 - aircraft, 2-79
 - aluminum, 2-19, 2-86
 - current-carrying capacity of, 12-19, 12-21
 - application of, 2-13 to 2-84
 - armored, 2-56
 - bends in, radius of, 9-196
 - connectors for, 9-187
 - cutting of, 9-185
 - installation of, 9-183
 - protection at ends of, 9-186
 - support for, 9-190
 - types of, 9-182
 - wiring with, 9-5, 9-182 to 9-192
 - arrangement of, in manholes, 8-128
 - Cable(s) (*Cont.*):
 - automotive, 2-79
 - bare, 2-10
 - binder tapes for, 2-24
 - borehole, 2-66
 - breaking strength of (*see* Breaking strength of wire and cable)
 - bronze, 2-13, 2-86
 - building, 2-25 to 2-29
 - buried in ground, 8-129
 - BX (*see* AC cable)
 - cellulose-acetate-insulated, 2-35
 - classification of: by covering, 2-10, 2-38 to 2-52
 - by insulation, 2-25 to 2-36
 - by material, 2-13 to 2-19
 - concentric-lay, 2-2
 - conductors in, number of, 2-2, 2-20
 - copper vs. aluminum
 - data for, 2-88
 - grades of, 2-14
 - makeup of, 2-13, 2-86
 - resistance of, 2-88
 - stranded, 2-90, 2-97
 - copper-clad aluminum, 2-86, 2-95 to 2-98
 - copper-steel, 2-17, 2-86
 - cotton-yarn-insulated, 2-33
 - covered, 2-11, 2-12
 - coverings for, protective, 2-37 to 2-52
 - current-carrying capacities for, 3-31, 12-14 to 12-27
 - dead-ending of, 9-48
 - definitions of, 2-2
 - dimensions of, 12-28 to 12-29
 - for direct burial in earth, 2-60
 - drive-in-theater, 2-73
 - duplex, 2-2
 - for electric transportation equipment, 2-70
 - elevator, 2-101
 - enamel-insulated, 2-34
 - fibrous-glass-insulated, 2-36
 - fire-alarm, 2-69
 - flat cable assemblies, Type FC, 9-6
 - flat conductor, Type FCC, 9-7
 - flexible-cord, 2-101
 - gage table for, 2-85
 - gas-filled, 2-30
 - general-purpose power, 2-53
 - glass-insulated, 2-36
 - heat-resisting, 2-10, 2-99
 - heating, 9-440, 9-446
 - clearance for, 9-440
 - installation of, 9-440, 9-446
 - marking of, 9-440
 - installation of, in conduit, 9-122 to 9-148
 - insulated: definition of, 2-10
 - dimensions of, 12-28 to 12-29
 - safe temperatures of, 3-31

Cable(s) (*Cont.*):

insulation for, 2-25 to 2-36
 approved types of, 2-99
 thickness of, 2-99
 integrated gas spacer, Type IGS, 9-8
 iron, 2-16, 2-87
 jacket coverings for, 2-43
 lead-covered, 2-2
 lead sheath for, 2-38 to 2-46
 locating faults in, 1-192
 magnet [*see* Wire(s), magnet]
 makeup of, 2-13, 2-86
 materials for, 2-13, 2-86, 2-87
 MC cable, 1-57, 9-10, 9-190 to 9-192
 connectors, 9-195
 equipment grounding, 9-197
 mine-shaft, 2-66
 mineral-insulated, 2-54
 data for, 2-100
 description of, 2-54, 9-229
 installation of, 9-231
 termination of, 9-232 to 9-235
 wiring with, 9-10, 9-229 to 9-235
 multiconductor, 2-2, 2-20
 MV cable, 9-236 to 9-239
 National Electrical Code for, 2-99
 network, 2-63
 nonmetallic-sheathed, 2-55
 wiring with, 9-12, 9-215 to 9-228
 number allowed: in conduit, 12-28 to 12-32
 in ducts, 8-127
 oil-burner ignition, 2-71
 oil-filled, 2-30
 paper-insulated, 2-30
 parkway, current-carrying capacity of, 12-27
 patching jackets of, 2-143
 plastic-insulated, 2-27
 data for, 2-99
 dimensions of, 12-31
 pole and bracket, 2-65
 portable, joints for, 2-133 to 2-137
 portable power, 2-74
 power and control tray, Type TC, 9-13
 pulling in, 8-124
 radio, 2-78
 range, 2-101
 resistance of (*see* Resistance)
 rope-lay, 2-2
 rubber-insulated: data for, 2-99
 description of, 2-26
 dimensions of, 12-31
 saturants for covering, 2-45
 sector, 2-2
 series lighting, 2-64
 service, 2-60
 description of, 2-60, 3-18
 service-drop, 2-60, 3-18
 service-entrance, 2-60, 3-18

Cable(s) (*Cont.*):

servicing of, 2-2
 shielded-conductor, 2-2
 shielded-type, 2-2
 shielding of, 2-22
 shipboard, 2-81
 signal, 2-69
 for signs, gas-tube, 2-71
 silk-insulated, 2-35
 size for circuits: economical, 3-82 to 3-88
 selecting, 3-30 to 3-36, 3-76
 soldering of, 2-148 to 2-154
 splicing of, 2-103 to 2-170
 steel, 2-16
 steel-copper (*see* copper-steel)
 steel guy, 8-59
 stranded: data for, 2-89 to 2-94
 makeup of, 2-86
 street-lighting, series, 2-64
 submarine, 2-67
 support for, 9-45 to 9-58, 9-111
 telephone and telegraph, 2-16, 2-80
 terminology for, 2-2
 testing insulation resistance of, 1-181, 9-335
 thermoplastic-insulated (*see* plastic-insulated)
 traffic-control, 2-69
 triplex, 2-2
 trolley, sections of, 2-86
 twin, 2-2
 twisted pair, 2-2
 underground, 2-60, 2-62
 underground-feeder, wiring with, 9-15, 9-240
 varnished-cambric-insulated: data for, 2-99
 description of, 2-31
 weatherproof, 2-11, 2-12
 x-ray, 2-72
 [*see also* Conductors; Wire(s)]
 Cable armor, 2-38, 2-49, 2-50
 Cable braids, 2-39
 Cable clamps, use of, 4-112

- Circline fluorescent lamps, 10-98
- Circuit(s), 3-1 to 3-88
 allowance for growth in, 3-36, 9-526, 9-529
 alternating-current, 3-19 to 3-23
 advantages of, 3-24
 characteristics of, 1-121
 measuring power in, 1-182 to 1-185
 single-phase, 1-144, 3-19
 three-phase, 1-152 to 1-156, 3-19
 two-phase, 1-148, 3-19
 voltage drop in, 3-61
 for apartment houses, 9-508 to 9-510
 appliance, 9-425, 9-499
 calculating load on: branch, 3-37, 3-38
 main, 3-45 to 3-51
 branch: air-conditioning, 9-445
 appliance, 9-425, 9-499
 busways for, 9-278
 calculating load on: lighting and appliance, 3-37, 3-38
 motor, 3-53
 range, 3-39
 for commercial, public, and industrial structures, 9-526
 defined, 3-15
 lighting, 9-526
 rating of, 9-497
 protection of, 9-502
 voltage of, 9-503
 calculation of, 3-30 to 3-88
 capacitive, angle of lead in, 1-130
 capacitor, 4-138
 Class 2 and 3, 9-469
 comparison of, 3-23
 current-carrying capacity of, 3-31, 9-319 to 9-321, 9-495 to 9-497, 12-12 to 12-27

Circuit(s) (*Cont.*):

- design of, 3-30 to 3-88
- direct-current, 1-109, 3-19 to 3-25
 - measuring power in, 1-182
 - polarity of, test for, 1-209
 - power in, 1-110
 - three-wire, 3-20 to 3-23
 - two-wire, 3-19
 - voltage drop in, 3-58 to 3-60
- divided, 3-7
- for farm buildings, 9-532 to 9-547
- faults in, testing for, 1-192, 1-205
- feeder, 3-11
 - calculating load on, 3-40 to 3-54
 - for commercial, public, and industrial structures, 9-527
 - lighting and appliance, 3-40 to 3-52
 - motor, 3-53 to 3-55
 - grounding of, 9-354
 - grounds in, testing for, 1-194 to 1-199
 - high-voltage, 9-404 to 9-409
 - inductive, angle of lag in, 1-127
 - insulation resistance of, 1-175 to 1-177, 9-335
 - lighting: calculating load on: branch, 3-37, 3-38
 - main, 3-40 to 3-52
 - minimum allowable loads on, 3-52
 - rating of, 9-497
 - load on, calculation of, 3-37 to 3-55, 3-80
 - load center of, 3-57
 - location of, on poles, 8-69
 - low-energy power, 9-463 to 9-486
 - low-voltage, 9-410
 - low-voltage power, 9-463 to 9-486
 - main, 3-13
 - calculating load on, 3-40 to 3-55
 - motor, 7-370 to 7-395
 - branch: parts of, 7-377
 - protection of, 7-385, 12-43, 12-47
 - requirements for, 7-377
 - types of, 7-372 to 7-376
 - calculating load on, 3-53 to 3-55
 - demand factors for, 3-53 to 3-55
 - feeder, protection of, 7-260
 - remote control, 7-388, 7-393
 - switches for, 4-23, 7-383, 7-384, 7-386
 - wiring tables for, 7-391
 - multiple, 3-2, 3-9, 9-326
 - multiple-series, 3-5
 - nomenclature of, 3-1 to 3-17
 - outdoor residential wiring, 9-505 to 9-507
 - overload protection of, 12-40
 - parallel, 3-2, 9-326
 - resistance of, 3-8
 - parallel-series, 3-5
 - phasing out of, 7-108
 - power loss in, 1-157, 3-81 to 3-87
 - protection of, 4-46, 7-385, 9-318 to 9-320

Circuit(s) (*Cont.*):

- range, calculating load on, 3-39, 3-52
 - rectifier, 6-4
 - remote-control, 9-463 to 9-486
 - resistance of, to alternating currents, 1-122
 - series, 3-1
 - for street lighting, 5-71
 - series-multiple, 3-6
 - series-parallel, 3-6
 - shunt, 3-2
 - signal, 9-449 to 9-463
 - single-phase, 1-144, 3-19 to 3-23, 3-29
 - size of wire for, 3-30 to 3-36, 3-38 to 3-87, 7-387, 9-318
 - tap, 3-16
 - testing for faults in, 1-192 to 1-208
 - three-phase, 1-152 to 1-156, 3-19, 3-23
 - two-phase, 1-148, 3-19, 3-23
 - types of, 3-1 to 3-17
 - underground residential, 9-507
 - voltage drop in: allowable, 3-35, 12-48, 12-49
 - calculations for, 3-58 to 3-76
 - voltages for, 3-29
- Circuit breakers, 4-59 to 4-73
- arc-fault circuit-interrupters, 4-77
 - auxiliary, 4-59
 - Class CTL, 4-62
 - current-limiting, 4-61
 - delta breakers prohibited, 4-86
 - description of, 4-47, 4-59
 - enclosed, 7-308
 - fused, 4-60
 - high-voltage, 9-405
 - magnetic, 4-59
 - motor-starting, 7-308
 - in panelboards, 4-62, 4-85, 4-90
 - primary, 4-59
 - protection of motor circuits with, 7-385
 - ratings of, standard, 12-38, 12-39
 - secondary, 4-59
 - sizes of, for circuit protection, 9-320
 - solid-state, 4-59
 - thermal, 4-59
 - thermal-magnetic, 4-59
- Circuit diagrams, symbols for, 1-18 to 1-20
- Circuit directories, panelboards, and switchboards, 4-85
- Circular mil:
- definition of, 1-91
 - equivalents, 1-9, 1-92
- Circular mil-foot, 1-94
- Clamps:
- cable, 4-112
 - conduit, 9-104 to 9-111
 - elbow, 9-166
 - flexible-conduit, 9-166
 - ground, 9-372

- Clamps (*Cont.*):
 guy, 8-57, 8-87
 Newberry, 2-136
 wiring box, 4-112
- Class CTL overcurrent devices, 4-62
- Cleaning motor, 7-250
- Clearance:
 for equipment, 9-337, 12-37
 in high-voltage wiring, 9-407 to 9-409, 12-37
 for wires on pole lines, 8-69, 8-70
- Cleats:
 dead-ending on, 9-48
 wiring, 4-91, 4-92
- Clevises, 8-49, 8-53
- Code, National Electrical, wiring, 9-1
- Color:
 in floodlighting, 10-248
 of grounded conductors, 9-373 to 9-374
 of light, 10-1
 of lighted objects, 10-13
 from neon tubes, 10-132
 of ungrounded conductors, 9-375
- Color temperature of light, 10-14
- Commercial buildings:
 lighting loads for, 9-527, 9-528
 wiring for, 9-511 to 9-531
- Commercial repair garages, 9-422
 major repair facilities, 9-422
 minor repair facilities, 9-422
 wiring methods in, 9-422
- Commutating-pole, direct-current generator,
 7-26 to 7-31, 7-38
- Commutation, 7-74
- Commutators:
 blackening of, 7-79
 care of, 7-50, 7-73
 correcting roughness on, 7-88
 glowing of, 7-74
 grinding of, 7-80
 heating of, 7-76
 high mica on, 7-87, 7-88
 inspection of, 7-249
 loose rings on, 7-81
 loose segments on, 7-78
 lubrication of, 7-92
 pitting of, 7-74
 rough, 7-75
 slotting of, 7-82 to 7-86
 troubles with, 7-74 to 7-82, 7-88 to 7-93
- Compass:
 showing direction of current flow with, 1-89
 testing polarity of poles with, 7-56
- Compensating windings, 7-32
- Compensators:
 connections for, 5-117 to 5-119
 description of, 7-311
- Complementary metal-oxide-semiconductor
 logic (CMOS), 6-22
- Composite conductor, 2-2
- Compression joints, 2-162, 2-170, 2-171
- Compression lugs, 2-162, 2-171
- Compressors, motors for, 7-365
- Computer language, 6-28
- Concealed knob-and-tube wiring, 9-42,
 9-67 to 9-69
 impracticality of contemporary extensions,
 9-68
- Concentric-lay cable, 2-2
- Concentric-lay conductor, 2-2
- Concentric-strand, 2-2
- Concrete for underground conduit work, 8-109
- Concrete poles, 8-14, 8-15
- Condenser:
 control of acceleration with, 7-271, 7-275
 definition of, 1-48
 synchronous, 7-180
- Conductance, defined, 1-53
- Conductivity, 1-55
 of aluminum conductors, 2-19
 of copper, 2-88
 of copper conductors, 1-55
 percentage, 1-55
- Conductors:
 aluminum, 2-19
 ampacity of, 3-89 to 3-107, 12-19, 12-21
 applications and insulations, 2-99
 arranging in multiple, 9-326
 bare: definition of, 2-10
 classification of: by covering, 2-38 to 2-52
 by insulation, 2-25 to 2-29
 by materials and makeup, 2-13
 by service, 2-53 to 2-83
 composite, 2-2
 concentric-lay, 2-2
 continuous loading of, 3-94
 copper: ampacity of, 12-15, 12-16, 12-19,
 12-21, 12-22
 data for, 2-88 to 2-94
 makeup of, 2-15
 resistance of, 12-57
 solid, data for, 2-88
 stranded: ampacity of, 12-15, 12-16
 data for, 2-89
 copper-clad aluminum:
 conduit characteristics, 2-95
 makeup of, 2-86
 percent cladding, 2-97, 2-98
 wire guide, 2-96
 copper-steel, 2-17
 Copperweld, 2-17
 crane, 9-388, 12-14
 current-carrying capacity of, 12-15 to 12-24
 dead-ending of, 9-49
 definitions of, 1-40, 2-2, 6-1
 of different systems, 9-330
 dimensions of, 12-30, 12-31 to 12-32

Conductors (*Cont.*):

- drawing of, into conduit, 9-122 to 9-148
 - (*see* Cable pulling)
- high-voltage, 9-404, 12-24
- identification of grounded, 9-373 to 9-374
- insulated, dimensions of, 12-30, 12-31
- insulation for, 2-25 to 2-36
 - approved types of, 2-99
 - thickness of, 2-99
- iron, 2-16
- makeup of, 2-13, 2-15, 2-86
- materials for, 2-13 to 2-19, 2-86
- number allowed: in boxes, 9-345
 - in cables, 2-20
 - in conduit, 12-28 to 12-32
- parallel makeups, 3-108 to 3-111
 - conductors to be equal, 3-109
 - grounding conductor sizing rules, 3-111
 - raceways (and cables) in, 3-110
- resistance tables for, 12-57
- resistive, 2-2
- round, 2-2
- service, 9-376
 - for commercial, public, and industrial structures, 9-527
 - size of, 9-381
 - splicing of, 9-382
- signal wiring, 9-469
- size of, for interior wiring, 9-318
- small, overcurrent device sizing limits, 3-105
- splicing of, 9-325
- steel, 2-16
- stranded: data for, 2-90 to 2-93
 - definition of, 2-2
- support for, 9-52 to 9-58
 - temperature rise in, determination of, 1-100, 1-101
 - terminal connections for, 2-146 to 2-155, 9-224
 - terminology of, 2-2
 - vertical, 9-111
 - [*see also* Cable(s); Wire(s)]
- terminations, effects of continuous loading, 3-94
- terminations, temperature limitations of, 3-92
- ungrounded, permitted colors of, 9-375

Conduit:

- aluminum, 9-72, 9-79
- area of, 12-30
- bending of, 9-92, 9-93, 9-112 to 9-115
- clearances for, 9-84, 9-91
- concrete, 8-106
- continuity of, 9-338
- couplings, 9-77, 9-78
- cross-section fill, 12-28 to 12-32
- cutting of, 9-121
- diameter of, 12-30

Conduit (*Cont.*):

- dimensions, 9-77
- drawing conductors in, 9-122 to 9-148
 - (*see* Cable pulling)
- Electrical nonmetallic tubing, 9-27
- fiberglass, 9-23
- fill, 12-28 to 12-32
- fishing conductors in, 9-122 to 9-148
- flexible-metallic, 9-166
 - connectors for, 9-173
 - cutting of, 9-174
 - installation of, 9-168
 - reaming of, 9-175
 - sizes of, 9-167, 9-170
 - support for, 9-168
 - wiring with, 9-18, 9-166 to 9-178
- flexible-metallic-liquidtight, 9-179 to 9-181
- flexible metallic tubing, 9-26
- Greenfield, 9-167
- high density polyethylene, Type HDPE, 9-21
- intermediate metal conduit, Type IMC, 9-74
- liquidtight, flexible-metal, 9-179 to 9-181
- liquidtight, flexible nonmetallic, Type LFNC, 9-24
- nonmetallic underground with conductors, Type NUCC, 9-22
- number of conductors in, 12-28 to 12-32
- plastic-coated, 9-75
- reaming of, 9-120, 9-175
- reinforced thermosetting resin conduit, Type RTRC, 9-23
- rigid metal, 9-70 to 9-121
- rigid nonmetallic, 8-102, 9-20, 9-149 to 9-164
- rodding, 8-123
- runs of, 9-103
- size of, required, 9-94
- spacings for, 9-84, 9-91
- support for, 9-104 to 9-111
 - in concrete buildings, 9-110
 - threading of, 9-118
- Conduit benders, 9-112 to 9-115
- Conduit bends, 9-93
- Conduit bushings, 9-83, 9-88
- Conduit couplings, 9-77, 9-78
- Conduit elbows, 9-86
- Conduit fittings, 9-100
- Conduit hangers, 9-109
- Conduit hickies, 9-114
- Conduit locknuts, 9-84
- Conduit nipples, 9-87
- Conduit outlet boxes, 4-115, 9-96
- Conduit straps, 9-89 to 9-109
- Conduit supports, spacing of, 9-107
- Conduit threads, 9-82
- Conduit wrenches, 9-119
- Connections, cable (*see* Cable joints)

- Connectors:
- armored-cable, 9-187
 - box and cable, 9-173, 9-187, 9-221, 9-234, 9-236, 9-243
 - marking, 2-195
 - pressure, 2-158
 - solderless, 2-147, 2-156 to 2-163
- Conservator, 5-8
- Constant currents, 1-35
- Contact electromotive force, 1-79
- Contact resistance, 1-102, 4-6
- Contactors:
- counter-emf, 7-273
 - inductive-time-limit, 7-266 to 7-269
 - magnetic, 7-255
 - series, 7-256, 7-272
 - shunt, 7-255
- Contacts, switch, 4-6
- Continuity, test for, 1-206
- Continuous load:
- definition of, 3-94
 - effect on device terminations, 3-94
- Control:
- across-the-line: alternating current, 7-259, 7-297, 7-302 to 7-306
 - direct-current, 7-279
 - heating, 9-444
 - motor, 7-277 to 7-325
 - acceleration, 7-259 to 7-276
 - across-the-line, 7-259, 7-297, 7-302, 7-306
 - alternating-current, 7-297 to 7-325
 - autotransformer, 7-297 to 7-301
 - compensator, 7-297 to 7-300
 - condenser-charge, 7-271, 7-275
 - counter-emf, 7-259, 7-273
 - current-limit, 7-259, 7-271
 - direct-current, 7-277 to 7-296
 - electronic, 7-138 to 7-144
 - field-relay, 7-295
 - frequency, 7-259, 7-276
 - primary-resistor starting, 7-271
 - reactance-starting, 7-297 to 7-300
 - reduced-voltage starting:
 - autotransformer, 7-311
 - part-winding, 7-312
 - reactor, 7-310
 - star-delta, 7-313
 - resistance-starting, 7-297 to 7-301
 - solid-state, 7-275, 7-320
 - time-current acceleration, 7-271, 7-274
 - multiple-switch, in residences, 4-31, 4-36, 4-40
 - overload protection in, 7-257
 - and plugging, 7-268
 - position, 7-144
 - reduced-voltage, 7-297 to 7-301
 - synchro, 7-178
 - terminology of, 7-251
- Control (*Cont.*):
- time-current, 7-259, 7-274
 - time-limit, 7-259 to 7-271
- Control cables, 2-68
- Control generators, direct-current, 7-44, 7-143
- Controllers:
- autotransformers as, 7-311
 - classification of: by method of operation, 7-254
 - by service, 7-253
 - combination, 7-306
 - compensator, 7-311
 - condenser-charge, 7-271, 7-275
 - counter-emf, 7-273, 7-294
 - current-limit, 7-294
 - dial, 7-317
 - direct-current, 7-277 to 7-296
 - drum, 7-285, 7-287, 7-293, 7-318
 - enclosures for, 7-252
 - frequency, 7-276
 - inductive-time-limit, 7-266 to 7-270
 - magnetic: across-the-line, 7-305, 7-306
 - for alternating-current motors, 7-305 to 7-324
 - autotransformer, 7-297 to 7-301
 - compensator, 7-297 to 7-301
 - counter-emf, 7-273, 7-294
 - current-limit, 7-294
 - for direct-current motors, 7-294
 - frequency, 7-276
 - time-current, 7-259, 7-274
- manual: for alternating-current motors, 7-303, 7-304, 7-325
 - for direct-current motors, 7-278, 7-279
- multiple-switch, 7-286
- multispeed, 7-314, 7-315
- overload-protection, 7-285, 7-311
- polyphase induction motor, 7-305 to 7-322
- reduced-voltage, 7-311 to 7-319
- resistance, 7-309
- rheostat, 7-280, 7-281, 7-291
- saturable-reactor, 7-323
- SCR, 7-320
- semimagnetic, 7-254
- single-phase, 7-325
- solid-state, 7-275
- speed, for direct-current motors, 7-288 to 7-295
- starting, for direct-current motors, 7-277 to 7-295
- static stepless crane control, 7-275
- synchronous-motor, 7-323
- terminology of, 7-251
- time-current, 7-259
- time-limit, 7-259 to 7-271
- Convenience outlets:
- for cellular-metal-floor raceway, 9-286
 - with underfloor raceway, 9-258

- Conversion of current, 7-206 to 7-213
- Conversion factors, 1-8 to 1-16
- Converters, synchronous, 7-208 to 7-212
- Copper:
 - economics of, 3-23
 - grades of, 2-14
- Copper busbar, data for, 2-94
- Copper-clad aluminum, 2-86, 2-95 to 2-98
- Copper conductors:
 - bare, 2-88
 - grades of, 2-14
 - makeup of, 2-15, 2-86
 - stranded, 2-89 to 2-93
- Copper wire:
 - grades of, 2-14
 - makeup of, 2-15, 2-86
 - properties of, 2-88
 - sizes of, 2-88
 - tinned, 2-14
- Copperweld cables, 2-17, 2-86
- Copperweld ties, 8-78
- Cords:
 - ampacity, 12-24
 - definition of, 2-2
 - drop, supporting of, 9-64
 - fastening of, in sockets, 9-324
 - flexible, 2-77
 - application of, 9-324
 - current-carrying capacity of, 12-24
 - types of, 2-101
- Cores, transformer, 5-4
- Cotton insulation, 2-33
- Coulomb:
 - explanation of, 1-36
 - metric (SI units), 12-58 to 12-64
 - relation of, to ampere, 1-37
- Coverings:
 - cable, 2-9 to 2-12, 2-38, 2-52, 2-99
 - removing from cables, 2-108 to 2-110
- Covers:
 - box, 4-108, 4-114, 9-348
 - manhole, 8-116
- Crane-collector switches, 9-387
- Crane-wiring diagrams, 9-403
- Cranes:
 - cab switch for, 9-398
 - circuit breakers for, 9-387
 - conductors for, 9-388 to 9-397
 - size of, 9-397, 12-14
 - supporting, 9-392 to 9-395
 - termination of, 9-393
 - tracks as, 9-396
 - current collectors for, 9-390
 - insulators for, 4-91
 - motors for, 9-402
 - trolley rails for, 9-390
 - resistance of, 9-397
 - supporting, 9-395
- Cranes (*Cont.*):
 - trolley wire for, 9-389
 - wiring for, 9-386 to 9-403
- Crossarm bolts, 8-27
- Crossarms:
 - alley, 8-62
 - assembly of, 8-60 to 8-64
 - braces for, 8-40 to 8-43
 - buck, 8-63
 - double, 8-61
 - gains for, 8-64, 8-65
 - guying of, 8-97
 - reverse, 8-63
 - single, 8-60
 - steel, 8-38
 - supporting, 8-60 to 8-64
 - wooden, 8-36 to 8-37
- Crystals, production of voltage with, 1-80
- Current(s):
 - alternating (*see* Alternating current)
 - classes of, 1-32
 - conversion of, 7-206 to 7-213
 - direct (*see* Direct current)
 - direction of, 1-83, 1-87
 - effects of, 1-85
 - explanation of, 1-30
 - fusion, for wires, 4-48
 - induced, in metal enclosures, 9-327
 - limiting effect, 12-39
 - locked-rotor, 7-131
 - for series motors, 7-200
 - for squirrel-cage induction motors, 7-163
 - mean annual, 3-88
 - measurements of, 1-169 to 1-174
 - motor, full-load, 12-7 to 12-10
 - motor-starting, 3-53 to 3-55, 7-131, 7-132, 7-136
 - symbols for direction of, 1-84
 - unit of, 1-37
- Current-carrying capacity of conductors (*see* Ampacity)
- Current density:
 - conversion factors for, 1-15
 - safe, 1-104
- Current-limiting overcurrent devices:
 - circuit breakers, 4-61
 - fuses, 4-51, 12-39
- Cutout booster, 5-108
- oil-fuse, 4-58
- Cutting:
 - armored cable, 9-185
 - conduit, 9-192
 - flexible conduit, 9-174
- Cycle, alternating-current, 1-113
- Daniell's cells, 4-143
- Darlington circuit, 6-24
- Dashpots, 7-261 to 7-265

- Daylight lamps, 10-54, 10-55

 high-frequency operation of,
 10-106
 induction, 10-111
 instant-start, 10-93
 life of, 10-99
 luminaires for, 10-180 to 10-182
 operating suggestions for, 10-110
 operation of, 10-93
 phosphors, 10-88, 10-89
 power factors of, 10-103, 12-52
 power-groove, 10-95
 radio interference from, 10-100
 rapid-start, 10-93, 10-95, 10-98
 reduced wattage, 10-97
 sizes of, standard, 12-1
 slimline, 10-96
 starting of, 10-93
 temperatures of, 10-101
 troubles with, 10-110
 voltage effect on, 10-104
 wiring arrangements for, 10-93
- fluorescent mercury, 10-47
 gaseous-discharge, 10-112 to 10-143
 germ-killing, 10-149, 10-150
 heating, 9-408, 10-152
 high-intensity discharge, 10-120, 10-158 to
 10-165
 high-pressure sodium, 10-148, 10-123
 incandescent, 10-48 to 10-82
 appliance-service, 10-63
 aviation-service, 10-64
 bases for, 10-56
 bulbs for: finish of, 10-49 to 10-55
 shape of, 10-51
 burning position of, 10-79
 classification of, 10-49 to 10-78
 colored, 10-55
 daylight, 10-54

Lamp(s), incandescent (*Cont.*):

- decorative, 10-61
- designation of, 10-50
- filaments for, 10-58
- finish of bulbs for, 10-52, 10-53
- floodlight, 10-75
- floodlighting, 10-75
- general description of, 10-48
- general-lighting service, 10-60
- high-voltage, 10-65
- indicator-service, 10-63
- low-voltage, 10-66
- Lumiline, 10-61
- marine, 10-67
- optical-service, 10-69
- photographic, 10-70
- photo-service, 10-71
- picture projection, 10-72
- power factors of, 12-50
- projector, 10-73
- reflector, 10-73
- rough-service, 10-61, 10-81
- safe operating temperatures for, 10-80
- service classification of, 10-59
- shapes of bulbs for, 10-51
- showcase, 10-61
- sign, 10-74
- sizes of, standard, 12-1
- special-lighting-service, 10-61
- spotlight, 10-75
- street-lighting, 10-76
- three-lite, 10-62
- traffic-signal, 10-77
- train-lighting, 10-78
- vibration-service, 10-61, 10-81
- infrared, 9-408, 10-152, 10-154
- mercury-vapor, 10-113 to 10-129
 - applications of, 10-130
 - bulbs for, 10-114 to 10-122
 - efficiency of, 10-119
 - high-pressure, 10-114 to 10-130
 - lumen output of, 10-122
 - operation of, 10-114
 - power factors of, 12-52
 - sizes of, standard, 12-1
 - spectral data for, 10-123 to 10-130
- metal halide, 10-116
- neon, 10-132 to 10-143
 - application of, for signs, 10-136
 - colors of, 10-133
 - NEC requirements, 9-460
 - transformers for, 10-138
 - tubing for, 10-172, 10-140
- neon-glow, 10-141, 10-142
- photochemical, 10-151
- power factors for, 12-52
- sizes of, standard, 12-1
- three-lite, 10-62

Lamp(s) (*Cont.*):

- ultraviolet, 10-144 to 10-146
 - black-light, 10-145 to 10-148
 - filters for, 10-147
 - general description of, 10-144
 - germ-killing, 10-149, 10-150
 - photochemical, 10-151
 - voltages for, 3-29
- Lamp bases, incandescent, 10-57
- Lamp bulbs:
 - colored, 10-55
 - incandescent, 10-48 to 10-81
- Lamp filaments, incandescent, 10-58
- Lamp holders, 4-97 to 4-104
- Lap-type armature windings, 7-3
- Laterals, underground, 8-110
- Layout of interior wiring installations, 9-491 to 9-504
- Layouts, circuit, 9-512
 - banked-secondary radial, 9-515
 - loop-primary radial, 9-514
 - primary-selective network, 9-519
 - primary-selective radial, 9-516
 - secondary-selective radial, 9-517
 - simple network, 9-518
 - simple radial, 9-513
- Lead-acid batteries (*see* Batteries, lead-acid)
- Lead-covered cable, 2-2
- Lead sheath for cable, 2-38, 2-47, 2-48
- Length conversion factors, 1-8
- Light:
 - absorption of, 10-3, 10-12
 - brightness of, 10-39 to 10-45
 - candlepower of, 10-18
 - color of, 10-1
 - color of objects in, 10-13
 - color temperature of, 10-14
 - definition of, 10-1
 - distribution curves for, 10-31 to 10-34
 - explanation of, 10-1
 - footcandles of, 10-11, 10-20
 - glare of, 10-38 to 10-44
 - lumens of, 10-11, 10-22
 - luminous intensity of, 10-11, 10-17
 - measurement of, 10-15 to 10-37
 - meters for measuring, 10-27, 10-37, 10-46
 - point source of, 10-16, 10-19
 - primary colors of, 10-1
 - propagation of, 10-2
 - reflection of, 10-6, 10-7
 - by various materials, 10-12
 - refraction of, 10-2, 10-10
 - coefficients of, 10-9
 - sources of, 10-47
 - brightness of, 10-45
 - efficiency of, 10-30
 - transmission of, by various materials, 10-12 (*see also* Illumination; Lighting)

- Light emitting diodes (LEDs), 10-131
- Lighting:
- circuits for [*see* Circuit(s), lighting]
 - color rendering index (CRI), 10-91
 - color temperature table, 10-91
 - codes for, 10-226
 - depreciation of equipment in, 10-202
 - design of, 10-211
 - design tables for, 10-211 to 10-220
 - direct, 10-157
 - exterior, recommended levels of, 10-220, 10-239
 - flood (*see* Floodlighting)
 - general diffuse, 10-160
 - hospital, 10-220
 - indirect, 10-158
 - for industrial activities, 10-220
 - interior, recommended levels of, 10-220
 - laws governing, 10-226
 - light-emitting diodes (LEDs), 10-131
 - levels of, recommended, 10-220, 10-239
 - location of equipment for, 10-199
 - maintenance of equipment for, 10-202
 - maintenance of factors for, 10-202, 10-216 to 10-219
 - office, 10-220, 10-225
 - outline, wiring for, 9-452
 - physiological features of, 10-185
 - principles of design for, 10-184 to 10-219
 - reflectors for, 10-165 to 10-171
 - requirements for, 10-188
 - residential levels of, 10-220, 10-221
 - room cavity ratios for, 10-197
 - school, 10-220, 20-225
 - semidirect, 10-161
 - semi-direct, 10-159
 - series, 5-71
 - show-window, 10-220, 10-223 to 10-224
 - showcase, 10-222
 - sports: design of, 10-220, 10-249 to 10-276
 - recommended levels of, 10-220, 10-239
 - store, 10-220, 10-222 to 10-224
 - street, 10-230 to 10-234
 - classification of, 10-231
 - intensity of, 10-232
 - location of, 10-234
 - luminaires for, 10-233
 - transformers for, 5-70, 5-71
 - systems of, 10-157 to 10-161
 - transportation, recommended levels of, 10-220
 - units of, 10-11
 - voltages for, 3-29
- (*see also* Illumination; Light)
- Lighting circuits [*see* Circuit(s), lighting]
- Lighting loads for commercial buildings, 9-527
- demand factors for, 12-4
 - for industrial occupancies, 9-528
 - minimum allowable, 3-52, 12-5
- Lightning protection, 4-74 to 4-76
- Line drop, percentage, 3-34
- Line poles, 8-4 to 8-26
(*see also* Poles)
- Lines:
- pole (*see* Pole lines)
 - underground (*see* Wiring, underground)
- Liquidtight flexible-metal-conduit, wiring with, 9-19, 9-179 to 9-181
- Listed (standard of acceptance, per NEC), 9-3
- Live parts, protection of, 7-392, 9-337
- Load diagrams, 3-78
- Load factor effect on transformers, 5-26
- Loading of transformers, 5-23 to 5-29
- Loads:
- appliance, minimum allowable, 12-5
 - calculation of, 3-37 to 3-55, 3-80
 - division of: for alternating-current generators, 7-114
 - for direct-current generators, 7-18, 7-24
 - for transformers, 5-112 to 5-116
 - farm buildings, 9-533
 - lighting: demand factors for, 12-4
 - minimum allowable, 3-52, 12-5
 - minimum allowable, for circuits, 3-52
 - motor, demand factors for, 12-6
 - neutral, calculation example, 3-46
- Locked-rotor current [*see* Current(s)]
- Locknuts, conduit, 9-84, 9-90

 - enclosed, 10-163
 - filament lamp, 10-217
 - fluorescent lamp, 10-180 to 10-182, 10-219
 - general diffuse, 10-160

- Luminaires (*Cont.*):
 glass: opal, 10-167
 prismatic, 10-168, 10-179
 and steel, 10-180
 incandescent lamp, 10-217
 indirect-lighting, 10-158
 industrial, 10-174
 maintenance factors for, 10-202, 10-216 to 10-219
 mercury lamp, 10-218
 mounting of, 10-172
 opal glass, 10-167
 open, 10-162
 plastic, 10-170
 prismatic glass, 10-168, 10-178
 semidirect lighting, 10-161
 semi-indirect lighting, 10-159
 size of, 10-183
 spacing for, 10-211
 steel, 10-165, 10-175
 studs for, 9-344
 support for, 9-289, 9-344
 troffer, 10-182
 vaportight, 10-175
 Luminance, 10-11, 10-45
 Luminous flux, 10-11, 10-15, 10-22
 Luminous intensity, 10-11, 10-17
- Machine tools, speeds of, 7-362
 Macrocell arrays, 6-16
 Magnesium oxide cable insulation, 2-29
 Magnet wire [*see* Wire(s), magnet]
 Magnetic contactor, 7-255
 Magnetic controllers (*see* Controllers, magnetic)
 Magnetic field:
 explanation of, 1-22
 rule for direction of, 1-87
 Magnetic flux, 1-23
 Magnetic poles, 1-21
 Magnetic relays, 4-68
 Magnetic switches, 4-10, 4-36, 4-37, 4-64, 7-311
 Magnetic timing, 7-266
 Magnetism:
 definition of, 1-21
 residual, 7-7
 Magneto test set, 1-160
 Magnets:
 definition of, 1-21
 polarity of, 1-21
 types of, 1-21
 Main circuit, 3-13
 Mains, panelboard, 4-87
 Main service, 9-379
 Manholes, 8-111 to 8-121
 arrangement of cables in, 8-128
 cable support in, 8-127
 construction of, 8-112 to 8-116
 covers for, 8-116
- Manholes (*Cont.*):
 draining of, 8-117
 eyebolts for, 8-126
 heads for, 8-116
 hooks for, 8-119
 location of, 8-111
 NEC rules for sizing, 8-121
 size of, 8-112
 stirrup for, 8-126
 Marine lamps, 10-67
 Markup, how to figure, 1-5
 Materials:
 for cables and conductors, 2-13 to 2-19, 2-86
 coating of 9-339
 general construction, 4-232 to 4-254
 Matter
 conservation of, 1-28
 electrical structure of, 1-25
 Measurement:
 of current, 1-170 to 1-174
 of harmonics, 5-196
 of power, 1-182 to 1-185
 of power factor, 1-186
 of resistance, 1-175 to 1-181, 1-189 to 1-191
 of voltage, 1-170
 Medium-voltage (over 600 V) interior wiring,
 9-404 to 9-409
 isolating means, 9-406
 medium-voltage cable, Type MV, 9-9
 Megger, 1-181, 7-245, 9-335
 Mercury-vapor lamps (*see* Lamp, mercury-vapor)
 Mershon diagram, 3-72, 3-74, 12-56
 Messenger-supported wiring, 9-43
 Metal-clad cable, 1-57, 9-10
 Metal raceway (*see* Raceway, metal)
 Meter connections, 1-170 to 1-216
 Meters:
 bypass switches in, 4-27
 disconnect switches for, 4-27
 symbols for, 1-20
 (*see also* Instruments)
 Metric practice, 12-58 to 12-64
 alphabetical list of units, 12-64
 definitions, 12-63
 inch-millimeter equivalents, 12-61, 12-62
 pronunciations, 12-60
 SI common derived units, 12-59
 SI units and symbols, 12-58
 Mho, definition of, 1-53
 Micrometers, 2-7, 2-8
 Mil, equivalents, 1-8
 Mine-shaft cable, 2-66
 Mineral cable insulation, 2-29
 Mineral-insulated cable wiring, 9-11, 9-229 to 9-235
 Mold-type welding of connections, 2-155
 Molding, metal (*see* Raceways, metal)

Motor(s):

acceleration of, control of, 7-259 to 7-325
 adjustable-speed, 7-122
 adjustable varying-speed, 7-122
 alignment of, 7-369
 alternating-current, 7-146 to 7-205
 bearing trouble with, 7-217, 7-226, 7-234
 brush-shifting, 7-189
 capacitor, 7-193 to 7-196
 control of, 7-297 to 7-325
 controllers (*see* Controllers)
 vs. direct-current, 7-339
 hermetic-refrigerant motor compressors,
 7-399 to 7-403
 inductively split-phase, 7-192
 overload protection of, 7-309, 7-377 to
 7-382
 performance characteristics of, 7-356 to
 7-358
 starting compensation for, 5-117
 transformers for, 5-30
 polyphase induction, 7-146 to 7-177
 automatic start, 7-171
 breakdown torque for, 7-165, 7-176
 capacitors for, 12-11
 collector-ring troubles with, 7-225
 commutator brush-shifting, 7-177
 compensator troubles with, 7-224
 construction of, 7-146
 control of, 7-297 to 7-324
 controllers for, 7-311 to 7-323
 defects of, 7-214 to 7-227
 derating for harmonics, 7-170
 efficiencies of, 7-173, 7-175
 end play in, improper, 7-226
 faults of, 7-214 to 7-227
 full-load currents of, 12-9, 12-10
 locked-rotor current for, 7-163
 locked-rotor torque for, 7-164
 low maximum output for, 7-219
 low torque in, causes of, 7-218
 multispeed, 7-172
 oil leakage in, 7-227
 open circuits in, 7-221
 operation of, 7-147, 7-171, 7-172
 performance curves of, 7-151
 power factors of, 7-173, 7-175
 principle of, 7-147
 reduced-voltage start, 7-312
 reversing of, 7-202
 rotor troubles in, 7-222
 shutdown, causes for, 7-217
 slip of, 7-147, 7-148A
 speed control of, 7-154 to 7-162
 squirrel-cage, 7-146, 7-162 to 7-173
 starting of, 7-150
 starting characteristics of, 7-150, 7-209
 starting compensator troubles with, 7-224

Motor(s), alternating-current, polyphase
 induction (*Cont.*):

synchronous speed of, 7-148
 torque of, 7-148B to 7-153
 troubles with, 7-214 to 7-227
 voltages on, effect of unbalanced, 7-223
 winding faults in, 7-220
 wound-rotor, 7-146, 7-153, 7-174, 7-175
 repulsion, 7-187
 repulsion-induction, 7-198
 repulsion-start, induction-run, 7-197
 series, 7-199
 locked-rotor current for, 7-201
 locked-rotor torque for, 7-200
 shading-coil, 7-191
 single-phase, 7-187 to 7-202
 controllers for, 7-325
 full-load current of, 12-8
 protection of, 7-377 to 7-382
 single-phase induction, 7-190 to 7-202
 speed of, 7-100
 starting methods for, 7-297 to 7-325
 synchro, 7-178
 synchronous, 7-179 to 7-186
 armature troubles in, 7-231, 7-233
 bearing troubles in, 7-234
 brushes for, 7-235
 classification of, 7-181
 collector rings for, 7-235
 controllers for, 7-323
 full-load current of, 12-9, 12-10
 hunting of, 7-232
 open circuits in, 7-230
 reversing of, 7-202
 short circuits in, 7-231
 special-purpose, 7-186
 starting troubles of, 7-229
 torque requirements of, 7-184
 troubles with, 7-228 to 7-236
 voltage protection of, 7-323
 trouble with, 7-214 to 7-236
 altitude effect on, 7-351
 bearings for, 7-127
 selection of, 7-345
 troubles with, 7-217, 7-226, 7-234, 7-236
 blocked-rotor current of, 7-131
 blower, 7-364
 brake, 7-124
 braking of, 7-202A to 7-205
 brushes (*see* Brushes)
 care of, 7-237 to 7-250
 choice of, 7-338, 7-362 to 7-365
 cleaning of, 7-250
 code letters for, 7-385, 12-42
 commutators for (*see* Commutators)
 compressor, 7-365
 connection of, to circuits, 3-19 to 3-22
 constant-speed, 7-122

Motor(s) (*Cont.*):

control of (*see* Control, motor)
 controllers for (*see* Controllers)
 crane, 9-403
 current-carrying capacity of conductors for,
 12-12 to 12-14
 currents of: full-load, 12-7 to 12-10
 starting, 3-53, 3-54, 7-131, 7-132, 7-136
 direct-current, 7-134 to 7-145
 vs. alternating-current, 7-339
 armature of, 7-3
 open circuit in, 7-63
 short circuit in, 7-66
 testing, 7-61
 automatic drive control of, 7-141
 brushes for, care of, 7-49, 7-74, 7-75
 (*see also* Brushes)
 characteristics of, 7-134
 commutators for: care of, 7-49, 7-73
 grinding of, 7-80
 troubles with, 7-74 to 7-83
 compensating winding of, 7-32
 compound, 7-134
 controllers for (*see* Controllers)
 efficiencies of, 7-145
 electronic control of, 7-137 to 7-144
 excitation of, 7-134
 field in, open, 7-57
 full-load currents of, 12-7
 neutral point of, 7-29
 overload protection of, 7-284, 7-377 to
 7-382
 polarity testing of, 7-56
 reversing of, 7-202
 rheostats for, 7-280, 7-281, 7-291
 series, 7-134
 shunt, 7-134
 connections for, proper, 7-52
 speed of, low, 7-93
 speed control of, 7-136 to 7-144, 7-287 to
 7-295
 armature resistance, 7-138 to 7-140
 automatic drive, 7-141
 automatic electrodynamic drive, 7-143
 electronic, 7-137 to 7-144
 field-current, 7-139, 7-140
 starting of, 7-277 to 7-295
 starting controllers for, 7-277 to 7-294
 starting current of, 7-136
 starting methods for, 7-136
 torque characteristics of, 7-135
 troubles with, 7-51 to 7-95
 types of, 7-134
 undervoltage protection of, 7-281
 disconnecting devices for, 7-383, 7-384, 7-386
 dripproof, 7-128
 drives for (*see* Drives)
 drying out, 7-244

Motor(s) (*Cont.*):

dust-ignition-proof, 7-128
 duty-cycle service, 7-389
 enclosures for, 7-128
 explosionproof, 7-128
 externally, ventilated, 7-128
 fan, 7-364
 feeders, conductor sizing, 3-54, 7-389
 feeders, short-circuit and ground-fault
 protection, 7-390
 fields reversed in, 7-54
 foundations for, 7-366
 fractional-horsepower, 7-200
 gear, 7-125
 general, 7-121 to 7-133
 general-purpose, 7-123

- Plates:
 battery, 4-152
 flush switch, 4-116
- Plug-and-receptacle, instrument, 4-35
- Plugging of motors, 7-202A, 7-203, 7-268
- Plugmold metal raceway, 9-200, 9-203
- Plugs:
 fish, 9-176
 receptacle, 4-98
- p-n* junctions, 6-6
- Polarity:
 commutating pole, 7-30
 of electromagnets, 1-88
 field, testing of, 7-56
 of magnets, 1-21
 of solenoids, 1-88
 testing direct-current generator for, 7-40, 7-56
 tests for, 1-167, 1-209
 transformer, 5-74, 5-75
- Pole braces, 8-100
- Pole gains, 8-64, 8-65
- Pole guys (*see* Guys)
- Pole lines, 8-3
 accessories for, 8-27 to 8-58
 clearance of wires on, 8-69 to 8-71
 construction of, 8-60 to 8-71
 dead-ending of, 8-79
 guying practices on (*see* Guys)
 materials for, 8-27 to 8-58
 size of wire for, 8-81
 spacing of wires on, 8-69 to 8-71
 tree wiring for, 8-80
 wire on, tying in, 8-72 to 8-79
- Poles, 8-4 to 8-26
 buck-armed, 8-63
 commutating, 7-26 to 7-31, 7-38
 concrete, 8-14, 8-15
 crossarm mounting on, 8-60 to 8-64

- Poles (*Cont.*):
- depth to set, 8-16
 - gaining of, 8-64, 8-65
 - gin, 8-21
 - guy connections to, 8-55
 - holes for, 8-19
 - joint use of, 8-70
 - location of wires on, 8-69
 - magnetic, 1-21
 - self-supporting, 8-98
 - setting of, 8-20 to 8-23
 - size of, to use, 8-17
 - spacing of, 8-18
 - span between, 8-18
 - steel, 8-12, 8-26
 - step sockets for, 8-66
 - steps for, 8-66
 - switch, 4-4
 - types of, 8-4
 - wooden, 8-5 to 8-11
 - classification of, 8-4 to 8-6
 - dimensions of, 8-6
 - preservation of, 8-9
 - reinforcing, 8-24
 - seasoning of, 8-11
 - specifications for, 8-8
 - weight of, 8-7

- Sign wiring, 9-448 to 9-462
- Signal cable, 2-69

- Signal, power-limited circuits, 9-463 to 9-489
 abandoned cables, duty to remove, 9-488
 grounding, 9-487
 mechanical execution of work, 9-488
 separation from nonpower-limited circuits, 9-489
 transformers for, 5-63
- Signs:
 disconnects, 9-455
 flashing, 9-461
 gaseous-discharge: transformers for, 9-458
 wiring for, 9-454
 grounding and bonding, 9-462
 incandescent lamps for, 10-74
 neon lamps for, 10-136
 transformers for, 9-459, 10-138
 wiring for, 9-451
 types of, 9-440
- Silicon, 6-5
- Silicon-controlled rectifiers, 6-10, 7-320
- Silicon rectifiers, 6-10
- Silicone-asbestos cable insulation, 2-26
- Silk cable insulation, 2-35
- Simple network system, 9-518
- Simple radial system, 9-513
- Single-phase circuits [*see* Circuit(s), alternating-current, single-phase]
- Single-phase current, 1-144
- Size of wire, gages of, 2-3, 2-85
- Skin effect:
 general considerations of, 1-123
 in voltage-drop calculations, 3-61
- Sleeves:
 connecting, split-copper, 2-104, 2-112
 expansion, 4-242
 splicing, 2-104, 2-112, 2-170
- Slimline fluorescent lamps, 10-96
- Slip, induction motor, 7-147
- Snap switches, ac, ac-dc, mercury, 4-30
- Snow-melting systems, 9-443
- Sockets:
 fastening cords in, 9-324
 lamp, 4-124 to 4-133
 pole-step, 8-66
- Soil, chemical treatment of, for grounding, 8-145
- Solar photovoltaic wiring, 9-548 to 9-554
 array, modules, 9-549 to 9-550
 current and voltage calculations, 9-549
 fine-stranded wiring provisions, 9-550
 high ambient temperature considerations, 9-550
 ratings and listing provisions, 9-549
 Type PV single-conductor cable, 9-550
- DC system feeder calculations, 9-551
 disconnects, 9-553 to 9-554
 location, 9-553
 ratings, 9-554
- Solar photovoltaic wiring (*Cont.*):
 equipment grounding, 9-552
 interconnections to ac supply, 9-556
 inverters, 9-555
 system grounding connections, 9-555
 utility-interactive system, 9-548
- Soldering cable joints, 2-112, 2-148 to 2-153
- Soldering connections, 2-148, 2-153
- Soldering flux, 2-113
- Solderless connectors, 2-147, 2-155 to 2-164
- Solenoid, rule for polarity of, 1-88
- Solid-state technology:
 complementary metal-oxide-semiconductor logic (CMOS), 6-22
 computer language, 6-28
 binary, 6-28
 byte, 6-28
- Darlington circuit, 6-24
- differential amplifier, 6-24, 6-26
- discrete solid-state components, 6-3
 rectifiers, 6-4
 thyristors, 6-4
 transistors, 6-4
 zener diodes, 6-4
- electronic memories, Table 6-7
 memory capacity, 6-32
 random-access memory (RAM), 6-27, 6-33
 read-only memory (ROM), 6-27, 6-33
- electronic power supply circuit, 6-25
- electronic voltage regulators, 6-26
- emitter-coupled logic (ECL), 6-21
- field-effect transistors (FET), 6-9
 junction field-effect transistor (JFET), 6-9
 metal-oxide-semiconductor field-effect transistor (MOSFET), 6-9
- fundamentals of solid-state devices, 6-4
 crystal structure, 6-4
 electrons and holes, 6-4
 silicon atom, 6-4
- gate arrays, 6-16
- integrated circuits, 6-2, 6-14
 classification, Table 6-1
 digital, 6-14
 hybrid IC, 6-2, 6-14
 linear, 6-14
 monolithic IC, 6-3, 6-14
- logic gates, 6-18, 6-19
 saturated, 6-18
 unsaturated, 6-19
- macrocell arrays, 6-16
- microcomputer hierarchy, 6-29
- microcomputers:
 arithmetic-logic unit (ALU), 6-27
 central processing unit (CPU), 6-27
 input/output (I/O section), 6-27
 microprocessor units (MPUs), 6-27
 random-access memory (RAM), 6-27
 read-only memory (ROM), 6-27

Solid-state technology (*Cont.*):

- nonsaturated-logic gates, 6-20, 6-21, 6-22
 - operational amplifiers, 6-24
 - optoelectronic devices, 6-11
 - injection laser diodes (ILD), 6-11
 - light-emitting diodes (LED), 6-11
 - optocouplers, 6-11
 - photodetector, 6-11
 - photodiode, 6-11
 - phototransistor, 6-11
 - p-n* junctions, 6-6
 - capacitance effect, 6-6
 - forward-biased, 6-6
 - rectifier diodes, 6-7
 - reference diodes, 6-7
 - reverse-biased, 6-6
 - Schottky rectifier, 6-7
 - zener diodes, 6-7
 - read-only memories, 6-27, 6-33
 - erasable programmable read-only memory (EPROM), 6-33
 - programmable read-only memory (PROM), 6-33
 - read-only memory (ROM), 6-33
 - saturated-logic gates, 6-18
 - diode-transistor logic (DTL), 6-18
 - transistor-transistor logic (TTL), 6-18
 - Schottky TTL, 6-20
 - advanced low-power Schottky TTL family (ALSTTL), 6-20
 - fast Schottky TTL family (FAST), 6-20
 - low-power Schottky (LSTTL), 6-20
 - silicon, 6-5
 - n*-type materials, 6-4
 - p*-type materials, 6-4
 - thyristors, 6-10
 - gate-turnoff thyristors, 6-10
 - silicon-controlled rectifiers (SCR), 6-10
 - triacs, 6-10
 - trigger-circuit, 6-10
 - transducers, 6-13
 - transistor, 6-7, 6-8
 - bipolar, 6-7, 6-8
 - field-effect, 6-9
 - switching characteristics of, 6-17
 - unijunction, 6-10
 - unipolar (FETs), 6-7
 - trigger devices, 6-10
 - bilateral triggers (DIAC), 6-10
 - programmable unijunction transistors (PUTs), 6-10
 - silicon bidirectional switches, 6-10
 - sidacs, 6-10
 - unijunction transistor (UJT), 6-10
 - varactor diodes, 6-12
 - zener diodes, 6-3, 6-4, 6-26
- Space, working, 9-337
- Space heating, electrical, fixed, 9-431 to 9-447

Sparking:

- in direct-current machinery, 7-62
- Sparking distances for air gaps, 1-158
- Special occupancies, wiring for, 9-490
- Specific gravity, measuring, 4-156 to 4-172, 4-175, 4-193, 4-214
- Specific resistance:
 - definition of, 1-94
 - table of values of, 1-97
- Spectral data for mercury-vapor lamps, 10-129, 10-130
- Speed:
 - direct-current motor, control of, 7-137 to 7-143
 - motor, standard, 7-354
- Speed regulation, motor, 7-133
- Splices, termination rules for, 3-93
- Splicing:
 - aluminum basic installation techniques, 2-86, 2-95 to 2-98
 - of conductors, 9-325
 - gum for, 2-105
 - of service conductor, 9-382
 - sleeves for, 2-165 to 2-170 (*see also* Cable joints)
- Spool insulators, 8-50
- Sports lighting:
 - design of, 10-239, 10-249 to 10-276
 - recommended levels of, 10-220, 10-239
- Spot-network system, 9-518
- Spotlight lamps, 10-75
- Spray booths, 9-424
- Spread reflection, 10-7
- Spread refraction, 10-10
- Square mil:
 - definition of, 1-92
 - equivalents, 1-9, 1-93
- Squirrel-cage motors [*see* Motor(s), alternating-current]
- Star connections, 1-152 to 1-156
 - for transformers, 5-84 to 5-91
- Starters:
 - fluorescent lamp, 10-93
 - motor (*see* Control, motor)
- Starting for direct-current motors, 7-277, 7-295
- Steel cable, 2-16, 2-86
- Steel crossarms, 8-38
- Steel poles, 8-12, 8-26 (*see also* Poles)
- Steel-wire gage, 2-4, 2-85
- Steps, pole, 8-66
- Stirrups, manhole, 8-126
- Storage batteries (*see* Batteries)
- Stores:
 - level of illumination for, 10-220, 10-222 to 10-225
 - wiring for, 9-526, 9-527
- Strain insulators, 8-51

- Strand, concentric, 2-2
- Stranded conductors:
 - data for, 2-89 to 2-93
 - definition of, 2-2
 - makeup of, 2-86
- Stranded wire, 2-2
- Straps, conduit, 9-104
- Street lighting (*see* Lighting, street)
- Street-lighting lamps, 10-76
- Stub guys, 8-94
- Stud, fixture, 9-344
- Subfeeder, definition of, 3-12
- Submain, definition of, 3-14
- Submarine cables, 2-67
- Substation:
 - primary unit, 4-80
 - rectifier unit, 4-80
 - secondary unit, 4-80
- Support, universal insulator, 9-54, 9-55
- Support, wiring-box, 4-117, 4-120
- Surface conversion factors, 1-9
- Surface metal raceway wiring, 9-38, 9-198 to 9-205
- Surface nonmetallic raceway wiring, 9-39
- Surge arresters, 4-75
- Surge protection, 4-76
- Susceptance, definition of, 1-54
- Suspension insulators, 8-49
- Switch blades, 4-6
- Switch contacts, adjustment of, 4-18
- Switch enclosures, NEMA, types of, 4-12
- Switchboards, 4-78 to 4-84
 - classification of, 4-79, 4-80
 - clearances for, 4-82, 4-84
 - definition of, 4-78
 - location of, 4-82
 - low-voltage distribution, 4-80
 - materials for, 4-81
 - motor-control center, 4-80
 - safety enclosed, 4-80
 - spacing for, 4-82 to 4-84
 - types of, 4-79
- Switches, 4-2 to 4-42
 - adjustment of contacts, 4-18
 - appliance, 4-30
 - bolted pressure contact, 4-21
 - branch-circuit, 7-259
 - butt-contact, 4-6, 4-8
 - canopy, 4-30
 - classification of, 4-3
 - closet-door, 4-30
 - collector, crane, 9-387
 - connecting of, 4-32, 4-40
 - contact resistance of, 4-6
 - contacts for, 4-6
 - control, 4-34
 - cord, 4-30
 - crane-service, 9-387, 9-398
 - Switches (*Cont.*):
 - definition of, 4-2
 - dial, 4-10
 - disconnect, 4-22, 7-383
 - direct-current, 7-296
 - door, 4-30
 - double-break, 4-8
 - double-pole, 4-31
 - double-throw, 4-5
 - drum, 4-10
 - electronic, 6-58
 - enclosed, types of, 4-12
 - entrance, 4-26 to 4-29
 - in farm buildings, 9-535 to 9-541
 - field, 4-25
 - flush, 4-30
 - four-way, 4-31, 4-40
 - fused, 4-13
 - general-purpose, 4-12, 4-14
 - for hazardous locations, 4-12
 - heater, 4-31
 - high-capacity, 4-21
 - high-voltage, 9-405
 - installation of, 4-33, 4-39
 - instrument, 4-35
 - insulation of, 4-9
 - interchangeable, 4-30
 - interior-wiring, 4-30 to 4-37
 - isolating, 4-22, 7-383
 - knife-blade, 4-6, 4-8, 4-15
 - lighted handle, 4-31
 - low-voltage relay, 4-36
 - magnetic, 4-10, 4-36, 4-37, 4-64, 7-311
 - manual, 4-10, 4-65
 - master, 7-251, 7-254
 - mercury, 4-7, 4-30
 - meter bypass, 4-27
 - meter disconnect, 4-27
 - meter-service, 4-26 to 4-29
 - momentary-contact, 4-31
 - motor-circuit, 4-23, 7-383, 7-386, 12-46
 - motor-starting, 4-24, 7-303 to 7-311
 - mounting of, 4-41
 - multiple-throw, 4-3
 - open, 4-15
 - operating mechanism for, 4-10
 - pendant, 4-30
 - pilot handle, 4-31
 - plug-and-receptacle, 4-35
 - poles of, 4-4
 - protection of, overcurrent, 4-13
 - pull-chain, 4-30
 - pushbutton, 4-10
 - quick-break, 4-11
 - quick-make, 4-11
 - rating of, 4-16, 4-33
 - rotary, 4-10, 4-30, 4-35
 - safety enclosed, 4-17

Switches (*Cont.*):

- service, 4-26 to 4-29, 9-377
- single-break, 4-8
- single-pole, 4-31
- single-throw, 4-5
- sizes of, 4-20
- snap, 4-10
 - rating of, 4-33
 - types, 4-30
- solid neutral, 4-4, 4-13
- speed of operation of, 4-11
- standard wiring of, 4-30
- surface, 4-30
- switching-neutral, 4-13
- temperature rise of, 4-16
- testing of blade contacts of, 4-19
- three-way, 1-202, 4-31, 4-40
 - connecting, 4-32
- through-cord, 4-30
- toggle, 4-10
- tumbler, 4-10, 4-30
- two-pole, 4-31
- types of, 4-3
- voltage drop in, 4-16
- watertight, 4-12
- wiring, 4-30 to 4-42

Switchgear, 4-78 to 4-84

- for direction of current flow, 1-84
- graphical electrical, 1-18, 1-19
- high-voltage, 4-80
- lighting, 10-1
- low-voltage, 4-80
- safety enclosed, 4-80

Synchronizing alternating-current generators, 7-106 to 7-112

Synchronous motors [*see* Motor(s), alternating-current, synchronous]

Synchros, description of, 7-178

Synchroscope, 7-112

Systems, 3-19 to 3-29

- application of, 3-24
- comparison of, 3-23, 3-24
- complete, 3-10
- direct-current: vs. alternating-current, 3-23, 3-24
 - three-wire, 3-19 to 3-22
 - two-wire, 3-19
- distribution, 9-512
 - banked-secondary radial, 9-515
 - grounding of, 8-132 to 8-146
 - loop-primary radial, 9-514
 - overhead, types of, 8-3
 - primary-selective network, 9-519
 - primary-selective radial, 9-516
 - secondary-selective radial, 9-517
 - simple radial, 9-513
 - simple network, 9-518
- grounding, 9-336, 9-352

Systems (*Cont.*):

- insulation resistance of, 9-335
- interior wiring, design of, 9-491 to 9-503
- power supply, effect of motors on, 7-342
- single-phase, 3-19 to 3-22, 3-29
- synchro, 7-178
 - three-phase, 3-19, 3-29
- transmission, grounding of, 8-134
- two-phase, 3-19
- underground, 8-101
- voltages of, 3-25, 3-26
 - [*see also* Circuit(s)]

T connections for transformer, 5-95 to 5-97

Tap, definition of, 3-16

Tape:

- armor, 2-47
- binder, 2-24
- cable, 2-38, 2-40
- splicing, 2-105, 2-106, 2-115

Taping of cable joints, 2-117

Telegraph sounder for testing circuits, 1-163

Telephone cable and wire, 2-16, 2-80

Telephone receiver for testing circuits, 1-161

Temperature:

- ambient, 7-130
- for cable and wire, safe, 3-31
- effect of, on resistance, 1-99
- insulation, safe, 7-130
- for insulation, 7-130
- safe: for cable and wire, 3-31
- storage-battery, 4-165, 4-184
- transformer, 5-24, 5-25, 5-175

Temperature coefficients of resistance, 1-97, 1-99

Temperature conversion factors, 1-16

Temperature relay, 7-251

Temperature rise:

- in conductor, how to determine, 1-101
- of motors, 7-130

Terminal blocks, 2-161

Terminal connections (*see* Cable joints)

Terminals, cable, 2-146 to 2-164

Terminations:

- grounded conductor terminations, 3-95
- temperature limitations, 3-92

Terminations for power cables,

7-155 to 7-164

Test equipment, 1-160 to 1-218

Test lamp, 1-165

Tests:

- armature, 7-61
- cable-ground, 1-194 to 1-198
- for circuit polarity, 1-209
- of circuits for faults, 1-203 to 1-207
- excitation, direct-current motor, 7-52
- ground, direct-current machinery, 7-59
- ground-resistance, 8-139

Tests (*Cont.*):

- insulation-resistance, 1-193
 - of interior wiring, 9-335
 - of motors, 1-179, 7-245
- for motor horsepower, 1-218
- for polarity of direct-current generators, 7-40, 7-56
- of three-way switch connections, 1-202
- transformer, 5-75
- of transformer oil, 5-156

Thermal relays, 4-66

Thermal releases, 4-67

Thermocouples, 1-76

Thermoguard motors, 7-382

Thermoplastic insulation (*see* Insulation, plastic)

Thimble, guy, 8-55

Third-brush generators, 7-41

Thomson effect, 1-76

Threading for conduit, 9-118

Threads, conduit and pipe, 9-82

Three-lite lamps, 10-62

Three-phase circuits [*see* Circuit(s), three phase]

Three-phase current, 1-117, 1-152

Three-wire generators, 7-33 to 7-40

Threshold current, 12-39

Thyristors, 6-4, 6-10

Ties:

- insulator, 8-72 to 8-79
- wire, 8-72 to 8-79

Time value of money, 1-6

Timers, pneumatic, 7-264

Torch, blow, 2-153, 2-154

Torque:

- breakdown, for induction motors, 7-165, 7-176
- definition of, 1-67
- locked-rotor: for single-phase motors, 7-200, 7-201
 - for squirrel-cage induction motors, 7-164
- motor, 7-129
 - polyphase induction, 7-148 to 7-153, 7-164
 - required, 7-346
 - starting, direct-current, 7-135
 - relation to horsepower, 1-68
 - relations in mechanisms, 1-69

Towers, steel, 8-13

(*see also* Poles)

Traffic-control cable, 2-69

Traffic-signal lamps, 10-77

Train-lighting lamps, 10-78

Transducers, 6-13

Transfer switches, (*see* Automatic transfer switch)

Transformers:

- accessibility, NEC rules, 5-133
- accessories for, 5-40, 5-41
- air-blast-cooled, 5-6

Transformers (*Cont.*):

- air-cooled, 5-6
 - data for, 5-57
- askarel-insulated, NEC rules, 5-138
- autotransformer, 5-9, 5-32
 - applications of, 5-117 to 5-119
 - connections for, 5-117 to 5-119
 - NEC requirements, 5-124
- booster, 5-98 to 5-109
- bucking, 5-103, 5-109
- capacity of, 5-30, 5-31, 5-94
- care of, 5-120 to 5-177
- characteristics of, 5-43 to 5-57
- choke, 5-103
- classification of, 5-5
- connections for, 5-74 to 5-119
 - delta, 5-83 to 5-91
 - open-delta, 5-87 to 5-90
 - single-phase, 5-76, 5-77
 - for standard distribution, 5-76
 - star, 5-84 to 5-91
 - T, 5-95 to 5-97
 - for three-phase, 5-81 to 5-91
 - to two-phase, 5-92 to 5-95
 - for three-wire secondary, 5-77
 - for two-phase, 5-78
- conservator, 5-6
- constant-current, 5-14, 5-68 to 5-70
- constant-voltage, 5-2, 5-15 to 5-17, 5-33, 5-58 to 5-63
- control, 5-61
- cooling of, 5-6
- copper losses in, 5-20
- core losses in, 5-21
- cores of, 5-4
- current, 5-14, 5-65 to 5-67, 5-194, 5-195
- data for, 5-43 to 5-57
- definitions of, 5-1 to 5-3; NEC definition, 5-123
- delta-connected, 5-83 to 5-91
- distribution
 - characteristics of, 5-43 to 5-57
 - connections for, 5-76
 - description of, 5-35
 - mounting of, 5-183 to 5-192, 8-68
 - wiring for, 8-68
- drying of, 5-158 to 5-168
- dry-type, 5-6, 5-57 to 5-63, 5-134 to 5-135
- eddy-current losses in, 5-21, 5-194
- efficiencies of, 5-19, 5-43 to 5-57
- expansion tank, 5-6
- gaseous-discharge lamp, 5-62, 9-456, 10-138
- grounding autotransformers, NEC rules, 4-125
- grounding of, 5-130, 8-136
- guide for loading of, 5-23 to 5-29
- guarding, NEC rules, 5-128
- handling of, 5-153
- high-fire-point-liquid-insulated, 5-134

Transformers (*Cont.*):

- hysteresis losses in, 5-21
- impedance of, 5-43 to 5-57
- induction motors, for, 5-30, 5-31
- Inertiaire, 5-8
- inspection of, 5-154
- installation of, 5-120 to 5-192
- instrument, 5-64 to 5-66
- insulation of, 5-7 to 5-10
- insulation resistance of, 5-163
- iron losses in, 5-21
- K-factor ratings, 5-195
- less-flammable liquid-insulated, NEC rules, 5-136
- liquid-immersed, 5-6
- load division between, 5-112 to 5-116
- loading guide for, 5-23 to 5-29
- localized lighting, 5-59
- losses in, 5-19 to 5-22, 5-43 to 5-57, 5-194
- maintenance of, 5-167 to 5-177
- marking, NEC rules, 5-131
- mercury-vapor lamp, 10-122
- modification of insulating fluid, NEC rules, 5-141
- motors, for, 5-30, 5-31
- mounting of: methods of, 5-13, 5-183 to 5-192
 - pole, 5-184 to 5-192, 8-68
- mounting accessories for, 5-40, 5-41
- neon-sign, 5-62, 10-138
- network, 5-34
- noise, 5-178 to 5-183
- nonflammable fluid-insulated, NEC rules, 5-137
- nonsinusoidal currents, 5-194, 5-195
- oil for, 5-7, 5-8, 5-167
- oil-burner ignition, 5-59
- oil drying of, 5-168
- oil filling of, 5-168
- oil-immersed, 5-6 to 5-8, 5-23 to 5-29
 - data for, 5-43 to 5-57
- oil-insulated, indoors, NEC rules, 5-139
- oil-insulated, outdoors, NEC rules, 5-140
- oil leaks in, 5-173
- oil testing, 5-167
- open-delta-connected, 5-87 to 5-90
- operation of, 5-16, 5-23 to 5-29, 5-174 to 5-183
- overcurrent protection of, 5-123, 5-124
- overloads on, 5-27
- parallel operation of, 5-112 to 5-116, 5-127
- performance characteristics of, 5-43 to 5-57
- platform type, 5-13
- polarity of, 5-74, 5-75
- pole-mounting, 5-13
- polyphase, 5-11, 5-12
- power, 5-38
 - small, 5-58, 5-59

Transformers (*Cont.*):

- primary winding of, 5-3
- purpose of, 5-14
- ratings of, 5-22, 5-37 to 5-39, 5-94
- ratio of, 5-17
- regulation of, 5-18, 5-43 to 5-57
- regulator, 5-72, 5-73
- scale in, 5-171
- Scott connection of, 5-92 to 5-97
- secondary winding of, 5-3
- secondary ties, NEC rules, 5-126
- self-air-cooled, 5-6, 5-57 to 5-63, 5-130
- self-protected, 5-35
- series, 5-71
- sign-lighting, 5-60
- signal, 5-61
- single-phase: accessories for, 5-40
 - connections for, 5-76, 5-77
 - data for, 5-43 to 5-48
 - ratings of, 5-38
- Spirakore, 5-4
- star-connected, 5-84 to 5-91
- step-by-step regulator, 5-73
- step-down, 5-3
- step-up, 5-3
- storage of, 5-152
- subway, 5-13
- supports for, 5-184 to 5-192
- surge-protected, 5-35
- T-connected, 5-95 to 5-97
- taps on, 5-36
- temperature of, 5-24, 5-25, 5-175
- terminal wiring space, 5-132
- terminology for, 5-3
- tests of, 5-75
- theory of operation of, 5-16
- three-phase, 5-10, 5-92 to 5-97, 5-110 to 5-119
 - accessories for, 5-41
 - connections for, 5-81 to 5-97, 5-110, 5-111
 - data for, 5-49 to 5-56
 - ratings of, 5-39
 - types of, 5-5
 - variable voltage, 5-14
 - vault, 5-13
 - voltage taps for, 5-36
 - water-cooled, 5-6
 - windings for, 5-2
 - vaults for, 5-142 to 5-148
 - ventilation, NEC rules, 5-129
 - zigzag grounding autotransformers, 5-125
- Transient suppression, 6-39
- Transient voltage surge suppressors (TVSS), 4-76
- Transistors, 6-4, 6-7, 6-8
- Transmission characteristics of materials, 10-12
- Transmission systems (*see* Systems)

- Transportation lighting, recommended levels of, 10-220
- Trays, storage-battery, 4-224
- Tree guying, 8-95
- Tree wire, 2-61
- Trees, wiring through, 8-80
- Trench header duct, 9-259, 9-290, 9-298
- Trickle charge, 4-154
- Trigger devices, 6-10
- Trigonometric functions, table of, 1-1
- Triplex cable, 2-2
- Troffers, 10-182
- Trolley cables, 2-86
- Trolley rails, 9-390
- Trolley wire, crane, 9-389
- Troubles with direct current motors and generators, 7-51 to 7-95
- Tubes:
- porcelain, 4-96
 - wiring, 9-59, 9-60
- Tubing:
- area of, 12-30
 - diameter of, 12-30
 - electrical metallic, 9-25, 9-206 to 9-214
 - flexible, 9-61, 9-62
 - number of cables allowed in, 12-28, 12-29
- Tungsten-halogen lamps, 10-56
- Turnbuckles, use of, 9-49
- Twisted pair, 2-2
- Two-phase circuits [*see* Circuit(s), two-phase]
- Two-phase current, 1-117, 1-148
- Ultraviolet-light sources [*see* Lamp(s), ultraviolet]
- Underfloor-raceway wiring, 9-40, 9-245 to 9-262
- reinsulation of conductors prohibited, 9-253
- Underground cable, 2-60, 8-129, 9-15, 9-240
- Underground circuits, residential, 9-507
- Underground feeder cables in interior wiring, 9-15, 9-240
- Underground laterals, 8-110
- Underground wiring, emergence from grade, 9-165
- Undervoltage, motor, protective devices, 7-258, 7-281
- Unijunction transistor (UJT), 6-10
- Universal insulator support, 9-54, 9-55
- Varactor diodes, 6-12
- Varnished-cambric cable insulation, 2-31, 2-32
- Vaults, transformer, 5-142 to 5-148
- Voltage:
- alternating-current: average value of, 1-119
 - effective value of, 1-120
 - instantaneous values of, 1-112
 - maximum value of, 1-118
 - waveform of, 1-112
- Voltage (*Cont.*):
- branch circuit, 9-503
 - of generators, direct-current, 7-4
 - measurements of, 1-169 to 1-173
 - production of (*see* Electromotive force)
 - regulator, 6-26
 - selection of system, 3-29
 - standard, 3-25, 3-26
 - test for presence of (*see* Electromotive force)
 - unbalanced, effect of, on induction motors, 7-223
- Voltage breakdown in air, 1-158
- Voltage changes, effect of, 3-28
- Voltage drop:
- allowable, in circuits, 3-35, 12-48, 12-49
 - calculation of, 3-58 to 3-75
 - effect of inductance on, 12-50
 - effective spacings for calculation of, 12-51
- Voltage loss, percentage, 3-34
- Voltage protection of alternating-current motors, 7-310
- Voltage-protective devices, 7-258
- Voltage regulators, 5-72, 5-73
- Voltage taps, transformer, 5-36
- Voltaic cell, 4-140, 10-37
- Voltmeter:
- ground-detector, 1-214
 - measuring current with, 1-172
 - measuring resistance with, 1-175
 - rules for use of, 1-170
 - triplex, 1-217
- Volts:
- definition of, 1-38
 - distinction of, from amperes, 1-82
- Volume conversion factors, 1-10
- Vulcanizers, 2-170
- Vulcanizing cable and cable joints, 2-138 to 2-145
- Washers, 8-35
- Watt:
- equivalents for, 1-13
 - relation of, to horsepower, 1-64
- Wattour, equivalents for, 1-12
- Wattour meter, how to read, 1-188
- Wattmeter, 1-183 to 1-187
- Wave-type armature windings, 7-3
- Waveform of alternating-current voltages and current, 1-112
- Weatherproof cable and wire, 2-11, 2-12
- Weight, conversion factors for, 1-11
- Weighted average cost of capital, 1-6
- Wheatstone bridge, 1-189
- Windings:
- armature, for direct-current generator, 7-3
 - compensating field, 7-32
 - field, for direct-current generator, 7-2
 - transformer, 5-2

Wire(s):

- aircraft, 2-79
- aluminum, 2-19
 - resistance of, 12-57
- annunciator, 2-59
- automotive, 2-79
- bare, 2-10
- building, 2-99
- cablebus, 9-30, 9-310 to 9-313
- classification of, 2-9
 - by covering, 2-10 to 2-12
 - by insulation, 2-25 to 2-36
 - by material, 2-13
 - by service, 2-53 to 2-83
- cleaning ends of, 2-111
- clearance of, pole-line, 8-69 to 8-71
 - grades of, 2-14
 - makeup of, 2-13, 2-86
 - properties of, 2-88
 - resistance of, 12-57
 - tinned, 2-14
- copper-clad aluminum:
 - data for, 2-96
 - conductor characteristics of, 2-95
 - makeup of, 2-86
 - percent cladding of, 2-97, 2-98
 - wire guide for, 2-96
- Copperweld, 2-17
- cotton-covered, 2-33, 2-82
- covered, description of, 2-10 to 2-12
- crane trolley, 9-389
- current-carrying capacity of, 3-311, 2-12 to 12-27
- dead-ending of, 8-79
- definition of, 2-2
- drawing of, into conduit, 9-122 to 9-148
 - (*see* Cable pulling)
- enameled, 2-34, 2-82
- fine-stranded, limitations on use, 2-13
- fixture: ampacity of, 12-25
 - properties of, 2-76
 - splicing of, 2-155, 9-344
 - types of, 2-75, 2-76
- flexible-cord, 2-77, 2-101, 12-24
- fusion currents for, 4-48A
- ground, 8-137
- guy, 8-59
- insulated: definition of, 2-10
 - safe temperature of, 3-31
- insulation for, 2-25 to 2-36
 - approved types of, 2-99
- magnet: coverings for, 2-82
 - description of, 2-82
 - selection of, 2-82
 - types of, 2-82
- measuring gages for, 2-6
- Nichrome, 2-102
- number allowed in conduit, 12-28 to 12-32

Wire(s) (*Cont.*):

- office, dampproof, 2-59
- radio, 2-78
- resistance, 2-102
- size of: for circuits, 3-76 to 3-80
 - economical, 3-81 to 3-88
 - for interior wiring, 9-318
 - for pole lines, 8-81
 - selecting, 3-30 to 3-36
- skinning of, 2-109, 2-110, 2-149
- soldering of, 2-148 to 2-153
- spacing of effective, 12-51
 - pole-line, 8-69 to 8-71
- stranded, definition of, 2-2
- stranded, termination rules, 2-163
- stranding data, 2-89 to 2-93
- stranding, limitations on use, 2-13
- stringing of, 8-82
- telephone and telegraph, 2-80
- tree, 2-61
- twin, 2-2
- weatherproof, 2-11, 2-12
 - [*see also* Cable(s); Conductors]
- Wire armor, 2-51
- Wire connectors, 2-155
 - designation and marking of, 2-163
- Wire gages:
 - names and uses of, 2-3
 - table of, 2-85
- Wire holders, 8-50
- Wire nails, 4-230
- Wire racks, 9-57
- Wire sizes, gages of, 2-3, 2-85
- Wire mold metal raceway, 9-200 to 9-205
- Wireway wiring, 9-33, 9-264 to 9-266
- Wireways, nonmetallic, 9-34, 9-267
- Wiring:
 - AC cable, 9-5
 - apartment-house, 9-508 to 9-510
 - armored cable, 9-5, 9-182 to 9-192
 - branch circuits for, 9-493 to 9-504
 - busway, 9-29, 9-256 to 9-268
 - cable trays, 9-41, 9-314, 9-317
 - cellular-concrete-floor raceway, 9-31, 9-294 to 9-302
 - cellular-metal-floor raceway, 9-32, 9-282 to 9-293
 - clearances for, 9-337
 - of commercial buildings, 9-511 to 9-531
 - concealed knob-and-tube, 9-42, 9-67 to 9-69
 - impracticality of contemporary extensions, 9-68
 - conductors of different systems in, 9-330
 - crane, 9-386 to 9-403
 - definition of terms for, 9-3
 - design of, 9-491 to 9-504
 - for electric heating, 9-446
 - electric-range, 9-430

Wiring (*Cont.*):

electrical metallic tubing, 9-25, 9-206 to 9-214
 enclosures for protective devices for, 9-323
 farm, 9-532 to 9-547
 flat cable assemblies, Type FC, 9-6
 flat conductor cable, Type FCC, 9-7
 flexible cord for, 9-324
 flexible metallic conduit, 9-9, 9-166 to 9-181
 flexible metallic tubing, 9-26
 general requirements for, 9-318 to 9-385
 grounding of, 9-336, 9-352 to 9-374
 gutters for, 9-326
 hazardous locations in, 9-411 to 9-424
 classification and grouping, 9-411 to 9-415
 Class I, flammable gases and vapors, 9-412
 Class II, combustible dusts, 9-413
 Class III, ignitable fibers and flyings, 9-414
 dust-ignition-proof equipment, 9-416
 explosionproof equipment, 9-416
 groups, Class I and Class II, 9-415
 intrinsically-safe wiring, 9-417
 maintenance, 9-419
 nonincendive wiring, 9-417
 protective approaches to wiring, 9-417
 purged and pressurized enclosures, 9-417
 seals, 9-420
 specific occupancy requirements, 4-422 to 4-424
 threads, conduits, and enclosures, 9-419
 wiring methods, 9-421
 zone classification system, 9-418
 high-voltage interior, 9-404 to 9-409
 of industrial buildings, 9-511 to 9-531
 insulation: approved for, 2-99
 resistance of, 9-335
 interior: for air conditioning, 9-445
 appliance circuits for, 9-499
 intermediate metal conduit, 9-74
 lighting circuits for, 9-499
 liquidtight flexible metal conduit, 9-179 to 9-181
 loop system of, 9-189
 low-voltage, 9-410
 metal-clad cable, 1-57, 9-10
 methods of, 9-4
 mineral-insulated cable, 9-11, 9-229 to 9-235
 multioutlet-assembly, 9-35, 9-303 to 9-309
 National Electrical Code for, 9-1
 nonmetallic extension, 9-36
 nonmetallic sheathed cable, 9-12, 9-215 to 9-228
 open (on insulator), 9-44, 9-45 to 9-66
 outlet boxes in, 4-109, 4-124, 9-340 to 9-349

Wiring (*Cont.*):

outside, 8-3, 8-71
 protection of circuits in, 9-319, 9-320
 receptacle circuits for, 9-499
 regulations for, local, 9-2
 rigid metal conduit, 9-17, 9-70 to 9-121
 rigid nonmetallic conduit, 9-20, 9-149 to 9-164
 for schools, 9-526, 9-527
 selecting methods for, 9-492
 service-entrance cable in, 9-14, 9-241
 signs, 9-448 to 9-462
 (*see also* Signs)
 space for working around, 9-337
 for special occupancies, 9-490
 splicing conductors in, 9-325
 surface raceway, 9-38, 9-198 to 9-205
 underground, 8-101 to 8-131
 buried cable for, 8-129 to 8-131
 cable-in-duct, 8-108
 concrete ducts for, 8-106
 ducts for, 8-101 to 8-107
 installing ducts for, 8-107 to 8-109
 laterals for, 8-110
 layout of runs for, 8-127
 manholes for, 8-111 to 8-121
 plastic conduit, 8-103
 polyethylene conduit, 8-103
 pulling cable in, 8-124
 reinforced thermosetting resin conduit, Type RTRC, 8-103
 rodding ducts for, 8-123
 supporting cable in manholes in, 8-125
 systems for, 8-101
 underfloor raceway, 9-40, 9-245 to 9-263
 underground feeder cable for, 9-15, 9-240
 wire approved for, 2-99
 wireway, 9-33, 9-264
 Wiring boxes (*see* Boxes)
 Wiring materials, 4-91 to 4-136
 coating of, corrosion resistance for, 9-339
 Wooden crossarms, 8-36, 8-37
 Wooden poles, 8-6 to 8-11
 (*see also* Poles)
 Work defined, 1-56
 Wrenches, conduit, 9-119
 Wrought-iron conduit, dimensions, 9-77

 Y connections, three-phase, 1-153, 1-154

 Zener diode, 6-3, 6-4, 6-26
 Zonal cavity method for lighting calculations, 10-211
