

Fifteenth Edition

AMERICAN ELECTRICIANS' HANDBOOK

- 
- Detailed analysis of how to perform circuit load calculations to determine wire sizes
 - The latest updates on the National Electrical Code®
 - Up-to-date information on photovoltaics and induction lighting

Terrell Croft | Wilford I. Summers | Frederic P. Hartwell

**AMERICAN
ELECTRICIANS'
HANDBOOK**

ABOUT THE EDITORS

TERRELL CROFT is deceased.

WILFORD I. SUMMERS is an electrical consultant and former Executive Director of the International Association of Electrical Inspectors.

FREDERIC P. HARTWELL is president of Hartwell Electrical Services, Inc., and is a working electrician. He has over 30 years of experience in the field of electrical work, including 10 years as the senior editor and National Electrical Code® expert for *Electrical Construction and Maintenance* magazine. He is the senior member on Code Making Panel Nine of the National Electrical Code® Committee.

CONTENTS

Preface to the Fifteenth Edition ix

Division 1 Fundamentals 1.1

Useful Tables / 1.2
Conversion Factors / 1.10
Graphical Electrical Symbols / 1.13
Principles of Electricity and Magnetism: Units / 1.23
Measuring, Testing, and Instruments / 1.69
Harmonics / 1.96

Division 2 Properties and Splicing of Conductors 2.1

Electrical Conducting Wires and Cables / 2.1
Cable Joints and Terminal Connections / 2.61
Aluminum-Building-Wire Installation Practices / 2.100
Termination and Splice Kits / 2.144

Division 3 Circuits and Circuit Calculations 3.1

Types of Circuits / 3.1
Electrical Systems / 3.8
Circuit Calculations / 3.20
NEC Ampacity Rules for Conductors / 3.64

Division 4 General Electrical Equipment and Batteries 4.1

Introduction / 4.1
Switches / 4.1
Installation of Switches / 4.31
Protective Devices / 4.33
Switchboards and Switchgear / 4.70
Panelboards / 4.80
General Wiring Materials and Devices / 4.88
Power Capacitors / 4.132
Batteries: General / 4.138
Primary Batteries / 4.138
Storage Batteries: General / 4.143
Lead-Acid Storage Batteries / 4.147
Nickel-Iron-Alkaline Batteries / 4.159
Nickel-Cadmium Batteries / 4.170

Installation of Storage Batteries	/	4.182
General Construction Materials	/	4.185

Division 5 Transformers

5.1

Construction, Types, and Characteristics	/	5.1
Connections: Polarity	/	5.51
Single-Phase Connections	/	5.52
Two-Phase Connections	/	5.54
Three-Phase Connections	/	5.55
Special Transformer Connections	/	5.64
Connections for Three-Phase Transformers	/	5.73
Parallel Operation	/	5.73
Connections and Applications of Autotransformers	/	5.75
Installation, Care, and Operation	/	5.79
Provisions for Different Types of Transformers	/	5.86
Provisions for Transformer Vaults	/	5.88
The Noise Problem	/	5.100
Pole and Platform Mounting	/	5.102
Saturable-Core Reactor	/	5.109

Division 6 Solid-State Devices and Circuits

6.1

Fundamentals of Electronics	/	6.1
Discrete Solid-State Components	/	6.4
Integrated Circuits	/	6.39
Integrated-Circuit Logic Functions	/	6.46
Microcomputers	/	6.68
Electronic Memories	/	6.74
Product Reliability	/	6.85

Division 7 Generators and Motors

7.1

Principles, Characteristics, and Management of DC Generators (Dynamos)	/	7.1
Principles, Characteristics, and Management of AC Generators (Alternators)	/	7.41
Principles, Characteristics, and Management of Electric Motors	/	7.55
Direct-Current Motors	/	7.62
Alternating-Current Motors	/	7.72
Conversion Equipment	/	7.117
Troubles of AC Motors and Generators: Their Localization and Correction	/	7.120
Care of Motors	/	7.128
Control Equipment for Motors	/	7.136
Motor Drives and Application	/	7.201
Motor Circuits	/	7.222
Control Circuits	/	7.243
Industrial Control Panels	/	7.245
Air-Conditioning and Refrigerating Equipment	/	7.250
Engine- and Gas-Turbine Generators	/	7.257

Division 8 Outside Distribution

8.1

Pole Lines: General, Construction, and Equipment	/	8.1
Pole-Line Construction	/	8.32

Pole-Line Guying /	8.55
Underground Wiring /	8.67
Grounding of Systems /	8.84

Division 9 Interior Wiring

9.1

General /	9.2
Open Wiring on Insulators /	9.14
Concealed Knob-and-Tube Wiring /	9.24
Rigid-Metal-Conduit and Intermediate-Metal-Conduit Wiring /	9.25
Cable Pulling Calculations for Raceways /	9.58
Interior or Aboveground Wiring with Rigid Nonmetallic Conduit /	9.67
Flexible-Metal-Conduit Wiring /	9.73
Liquidtight Flexible-Metal-Conduit Wiring /	9.76
Metal-Clad-Cable Wiring: Types AC and MC /	9.77
Surface-Raceway Wiring /	9.83
Electrical-Metallic-Tubing Wiring /	9.91
Nonmetallic-Sheathed-Cable Wiring /	9.94
Mineral-Insulated Metal-Sheathed-Cable Wiring /	9.100
Medium-Voltage-Cable Wiring /	9.107
Underground-Feeder and Branch-Circuit-Cable Wiring /	9.109
Interior Wiring with Service-Entrance Cable /	9.109
Underfloor-Raceway Wiring /	9.112
Wireway Wiring /	9.128
Busway Wiring (NEMA) /	9.130
Cellular-Metal-Floor-Raceway Wiring /	9.162
Cellular-Concrete-Floor-Raceway Wiring /	9.173
Wiring with Multioutlet Assemblies /	9.181
Cablebus Wiring /	9.188
Cable Trays /	9.191
General Requirements for Wiring Installations /	9.197
Crane Wiring /	9.245
Wiring for Circuits of Over 600 Volts /	9.253
Wiring for Circuits of Less Than 50 Volts /	9.255
Wiring for Hazardous (Classified) Locations /	9.255
Installation of Appliances /	9.264
Electric Comfort Conditioning /	9.266
Wiring for Electric Signs and Outline Lighting /	9.289
Remote-Control, Signaling, and Power-Limited Circuits /	9.295
Wiring for Special Occupancies /	9.300
Design of Interior-Wiring Installations /	9.301
Wiring for Residential Outdoor Lighting /	9.308
Wiring for Commercial and Industrial Occupancies /	9.312
Farm Wiring /	9.347
Solar Photovoltaic Systems /	9.357

Division 10 Electric Lighting

10.1

Principles and Units /	10.1
Electric-Light Sources /	10.23
Incandescent (Filament) Lamps /	10.24
Fluorescent Lamps /	10.38
High-Intensity-Discharge Lamps /	10.59
Light-Emitting Diodes (LEDs) /	10.75
Neon Lamps /	10.75

Ultraviolet-Light Sources /	10.82
Infrared Heating Lamps /	10.85
Luminaires /	10.86
Principles of Lighting-Installation Design /	10.106
Tables for Interior Illumination Design /	10.124
Interior-Lighting Suggestions /	10.144
Heat with Light for Building Spaces /	10.148
Street Lighting /	10.151
Floodlighting /	10.155

Division 11 Optical Fiber

11.1

The Advantages of Fiber Optics /	11.1
Applications /	11.2
The Nature of Light /	11.3
Invisible Light /	11.3
Transmitting Light through Fibers /	11.4

Division 12 Wiring and Design Tables

12.1

Standard Sizes of Lamps for General Illumination, in Watts /	12.3
Demand Factors and Data for Determining Minimum Loads /	12.4
Full-Load Currents of Motors /	12.10
Capacitor Ratings for Use with Three-Phase 60-Hz Motors /	12.13
Ampacities of Conductors /	12.14
Ampacity of Flexible Cords and Cables /	12.28
Ampacity of Fixture Wires /	12.30
Ampacity of Aluminum Cable, Steel-Reinforced /	12.31
Ampacity of Parkway Cables Buried Directly in Ground /	12.31
Number of Conductors in Conduit and Dimensions /	12.32
Switches-Termination Space /	12.33
Switch-Gutter and Termination Space /	12.34
Enclosed Switch Wiring Space /	12.35
Elevation of Unguarded Parts above Working Space /	12.36
Ordinary Ratings of Overload Protective Devices, in Amperes /	12.37
Nonrenewable Cartridge Fuses /	12.39
Ratings and Number of Overload Protective Devices /	12.44
Motor Code Letters and Locked-Rotor Kilovolt-Amperes /	12.46
Maximum Ratings for Motor Branch-Circuit Protection /	12.47
Conversion Table of Single-Phase Locked Rotor Currents /	12.47
Conversion Table of Polyphase Design B, C, D, and E Maximum Locked-Rotor Currents /	12.48
Horsepower Ratings of Fused Switches /	12.49
Minimum Branch-Circuit Sizes for Motors /	12.50
Maximum Allowable Voltage Drop /	12.51
Graph for Computing Copper-Conductor Sizes according to Voltage Drop /	12.53
Data for Computing Voltage Drop /	12.54
Metric Practice /	12.58

Index follows Division 12

PREFACE TO THE FIFTEENTH EDITION

This marks a large transition, as the editorial responsibility for one of the great classics in the field of electrical publishing changes hands. I am both honored and humbled by the significance of the task. Wilford “Bill” Summers ably maintained the legacy of this unique and extraordinary publication for some 30 years, comprising most of my career as an electrician. To now have the solemn responsibility for this work calls forth all of my skills, both as a working electrician and as an editor and student of the language, as well as a member of the NEC® Committee.

The American Electricians’ Handbook has always been my intellectual attic as an electrician. If I really needed some information, no matter how off the beaten path, I have always been able to find the information in this book. This Fifteenth Edition has been entirely and carefully revised and expanded consistent with advances of the art and the latest good practice, and in accord with the latest requirements of the 2008 National Electrical Code®. The returning reader will find approximately 100 pages of entirely new material, including tables, illustrations, and photographs. To make room, some of the verbatim reprints of NEC® tables and sections have been discontinued. This editor believes that any user of this book has ready access to a current copy of the NEC®, but not so the added material.

This edition includes completely new material on net present value calculations, so you can evaluate and sell the benefits of electrical improvements today. It comprehensively covers ampacity calculations that are some of the most challenging for engineers and working electricians alike. It covers autotransformers in detail for the first time, along with industrial control panels with an emphasis on being able to continue to build this equipment in the field. For the first time the book covers all NEC® Chap. 3 wiring methods to at least a minimal degree. It also covers cable pulling calculations step by step, so any electrician can determine whether a pull is feasible and apply the suggested strategies to make it so if this is not the case. It covers high-impedance grounding systems and farm wiring distributions in accordance with the latest NEC® developments. Finally, it covers the most common aspects of the burgeoning field of solar photovoltaic wiring for the first time, along with LED and induction fluorescent lighting sources.

However, to quote from the preface to the Fourteenth Edition, the original purpose of the Handbook has been retained. This book continues to “provide a compilation of data and information on the various types of equipment and conductors presented without advanced mathematics so as to be as useful as possible to the average electrical person. In many cases much of the basic principles stated herein are widely utilized by apprenticeship and electrical inspector training classes.” This editor believes that “what the user

National Fire Protection Association, NFPA, National Electrical Code, NEC, NFPA 70, and NFPA 70E are registered trademarks of the National Fire Protection Association. All NFPA trademarks are the official property of the National Fire Protection Association.

wants is not an encyclopedia of the manufacturer product lines but an orderly and accessible collection of working tool information otherwise scattered throughout other technical literature.”

As with previous editions, this book has been produced with the kind assistance of many individuals, organizations, and associations. A handbook of this nature could not be written without such assistance and suggestions. Some, however, have gone beyond the call of duty and deserve special recognition here. Many thanks to Tim Croushore for his help with fundamentals, to Gil Moniz of NEMA for his timely assistance in Div. 7, to Dave Mercier for his help with the cable pulling calculations, to John Wiles for his review of the solar photovoltaic coverage, and to Paul Rosenberg for his work on optical fiber technology.

FREDERIC P. HARTWELL

NOTE: Minus (-) values indicate a net loss.

5. Net profits. In figuring the net profit of doing business, Table 6 will be found to be very useful. The table may be used in three ways, as explained below.

To Determine the Percentage of Net Profit on Sales That You Are Making. Locate, at the top of one of the vertical columns, your percentage overhead—your “cost of doing business” in percentage of gross sales. Locate, at the extreme left of one of the horizontal columns, your percentage markup. The value at the intersection of these two columns will be the percentage profit which you are making.

EXAMPLE If your cost of doing business is 18 percent of your gross sales and you mark your goods at 35 percent above cost, your net profit is 7.93 percent of gross sales, obtained by carrying down from the column headed 18 percent and across from the 35 percent markup.

To Determine the Percentage Overhead Cost of Doing Business That Would Yield a Certain Net Profit for a Given Markup Percentage. Locate in the extreme left-hand column the percentage that the selling price is marked above the cost price. Trace horizontally across from this value until the percentage net profit desired is located. At the top of the column in which the desired net profit is located will be found the percentage overhead cost of doing business that will allow this profit to be made.

EXAMPLE If the markup is 45 percent and the profit desired is 15 percent, an overhead cost of doing business of 16 percent can be allowed, obtained by carrying across from the 45 percent markup to the 15 percent profit and finding that this column is headed by 16 percent overhead.

To Determine the Percentage That Should Be Added to the Cost of Goods to Make a Certain Percentage Net Profit on Sales. Select the vertical column which shows the percentage cost of doing business at its top. Trace down the column until the desired percentage profit is found; from this value trace horizontally to the extreme left-hand column, in which will be found the markup percentage—the percentage to be added to the cost to afford the desired profit.

EXAMPLE It is desired to make a 12 percent net profit when the cost of doing business is 20 percent of gross sales. Select the vertical column with 20 percent at its top. Trace down the column to locate the net profit desired of 12 percent. This will be partway between 11.00 and 13.33. Carrying across to the left from these values gives a required markup between 45 and 50, or approximately 47 percent.

For values which do not appear in the table, approximate results can be obtained by estimation from the closest values in the table. If more accurate results are desired for these intermediate values, the following formulas may be used:

$$P = 100 - h - \frac{10,000}{100 + m} \tag{1}$$

or

$$m = \frac{100(P + h)}{100 - (P + h)} \tag{2}$$

or

$$h = 100 - P - \frac{10,000}{100 + m} \tag{3}$$

where m = percentage markup based on cost of goods, h = percentage overhead based on gross sales, and P = percentage net profit based on selling price.

If you sell your goods at the retail list prices set by the manufacturers, you can use the table by converting the trade discount which you receive to an equivalent percentage markup, according to the following table:

Manufacturer's discount	Equivalent percentage markup	Manufacturer's discount	Equivalent percentage markup
10	11	35	54
15	17 ¹ / ₂	40	66 ² / ₃
20	25	45	81 ³ / ₄
25	33 ¹ / ₃	50	100
30	43		

Intermediate values may be calculated from the following formula:

$$m = \frac{100Q}{100 - Q} \tag{4}$$

where m = percentage markup based on cost of goods and Q = manufacturer's discount.

6. Accounting for the time value of money. [Adapted with permission from the Jan. 1997 issue of *EC&M Magazine*, © 1997, Penton Business Media. All rights reserved.]

Many proposals purport to save money over the long term, such as energy management initiatives. Are they actually worthwhile to a customer? A good way to decide is to go into the future and bring the future benefits back to today's dollars, and compare that result with the project cost. An important tool for this purpose is *net present value*, because it accounts for the time value of money. To use the tool, you will need to know the project cost, how much money will be saved per year over the project lifetime, and how the customer views his or her financial rate of return.

EXAMPLE

Step 1: Determine the annual cash flow impact of the project

Suppose a group of variable speed drives would cost \$50,000 and generate a utility rebate upon completion of \$5000. The reduction in electrical expense is projected to be \$15,000 per year. Assume the effective rate of taxation is 40 percent and the project could be depreciated (for tax purposes) over five years. Assume no change in the costs of equipment maintenance.

Initial cash outlay:	\$50,000
(less utility rebate)	<u>(5,000)</u>
Net outflow	<u>\$45,000</u>

Annual cash inflow:

Increased sales or revenue	\$0
Reductions in operating expense	15,000
Increases in operating expense	0
Depreciation expense ($50,000 \div 5$)	(10,000)
Pretax savings	5,000
Taxes (40%)	(2,000)
Net Income	3,000
Depreciation	10,000
Annual cash inflow, first five years	\$13,000

Since there will never be an actual check written for depreciation (the calculation is done for tax impact only) and this is a cash flow analysis, the depreciation goes back in at the end. The result matches the common sense result; the net cash flow is the energy savings (\$15,000) reduced by the marginal increase in taxes (\$2000). After the first five years, the picture changes due to the fact that, for tax purposes, the equipment is fully depreciated. This means that the taxes go up by \$4000 (40 percent of \$10,000), reducing the annual positive cash flow to \$9000.

Step 2: Determine the hurdle rate

This is the rate of return that the firm needs to realize on the project in order to have it make sense in terms of their own accounting procedure. It consists of the firm's *weighted average cost of capital* (WACC) plus a factor reflecting the perceived risk of the proposed project. The point of this part of the analysis is to compare the blended rate of return from the proposed project with the rate of return from other sources of funds the firm may have, both in terms of stock sales and bank financing. Suppose the firm has a million dollar capitalization split 70-30 between shareholder equity (18 percent return expected) and long-term debt (for this example assumed to be 7 percent).

Long-term debt	\$300,000	@ 7%	\$21,000
Shareholders' equity	<u>700,000</u>	@ 18%	<u>126,000</u>
Total	\$1,000,000		\$147,000

The WACC is $\$147,000 \div \$1,000,000 = 14.7$ percent. If the risk factor assigned to the project (based on comparable experience and utility rate stability in other locations) were 3.3 percent, then the *hurdle rate*, the required rate of return, would be 14.7 percent + 3.3 percent = 18 percent. Note that this rate will vary from firm to firm and from time to time based on economic conditions.

Step 3: Determine the net present value of the project based on the hurdle rate

The final step is to calculate what future cash flows are worth in today’s dollars, so a comparison can be made with other projects competing for funding. Year by year, develop a discount rate for that year and multiply it by the expected cash flow. For example, the discount rate for year 3 is 0.6086 (based on an 18 percent return). To see that this comes out correctly, multiply this by 1.18 to get 0.7182 (year 2), and then by 1.18 to get 0.8475 (year 1), and then by 1.18 again to get 1.0000. This result for year 0, which is the present day, shows the calculations are being done correctly. For any future year (*t*), the discount factor is (where *r* is the hurdle rate):

$$\text{Discount factor} = \frac{1}{(1 + r)^t} \tag{5}$$

The *net present value* of all cash flows from the time of project origination onward is the sum of all calculations by year, expressed mathematically as follows where C_t is the cash flow for each future year used in the summation:

$$\text{NPV} = \sum_{t=0}^n \frac{C_t}{(1 + r)^t} \tag{6}$$

In this example the tabulated results are as follows:

Year	Cash flow	Discount factor (18%)	Discounted cash flow
0	(\$45,000)	1.0000	(\$45,000)
1	13,000	0.8475	11,018
2	13,000	0.7182	9,337
3	13,000	0.6086	7,912
4	13,000	0.5158	6,705
5	13,000	0.4371	5,682
6	9,000	0.3704	3,334
7	9,000	0.3139	2,825
8	9,000	0.2660	2,394
9	9,000	0.2255	2,030
10	9,000	0.1911	1,720
<i>Net Present Value</i>			\$8,007

These calculations are tedious to do by hand but there are many computer programs and financial calculators that do the job quickly. The fact that this result is positive shows that it compares well with alternative rates of return and should be strongly considered.

7. Other tools also account for the factor of time in financial management.

For example, the *payback time* simply divides project cost by marginal revenue. In the example in Step 3, this would be $\$45,000 \div \$13,000$, or 3.46. Be careful with this tool because it does not take into account ongoing future revenue after the break-even point.

A different project with a shorter payback period, but with a shorter useful life, may turn out to be less profitable. For example, suppose a project, also costing \$45,000, reduced expenses by \$15,000 per year (reducing the payback time from 3.46 years to 3.0 years) but had a useful life of only 4.0 years. The total return would be \$60,000, but the drive project financial return, although less at the end of the fourth year, would exceed \$60,000 during the fifth year and the profitability would continue to increase for the rest of the project life.

Another tool looks at the net present value, and instead of determining the discounted value of future savings, calculates the *internal rate of return* (IRR) for the project. In other words, at what percentage rate of return will the discounted value of all future cash flows just equal the project cost, and therefore make the net present value of the improvements equal zero? In the case of the variable speed drive project in Step. 3, the IRR is just under 24 percent. This is substantially higher than the hurdle rate in that example, but it may be misleading because it assumes reinvestment of all revenues at the same rate of return. Such a rate of return is generally unrealistically high, and the *net present value* metric is preferred, because it uses actual costs.

CONVERSION FACTORS

1 m ³	= 61,023 in ³ = 1001 L = 35.31 ft ³ = 1.308 yd ³

11. Weight

1 mg	= 0.01543 gr = 0.001 g
1 gr	= 64.80 mg = 0.002286 oz (avoirdupois)
1 g	= 15.43 gr = 0.03527 oz (avoirdupois) = 0.002205 lb
1 oz (avoirdupois)	= 437.5 gr = 28.35 g = 16 drams (avoirdupois) = 0.0625 lb
1 lb	= 7000 gr = 453.6 g = 256 drams = 16 oz = 0.4536 kg
1 kg	= 15,432 gr = 35.27 oz = 2.205 lb
1 ton (short)	= 2000 lb = 907.2 kg = 0.8928 ton (long)
1 ton (long)	= 2240 lb = 1.12 tons (short) = 1.016 tons (metric)

12. Energy Torque units should be distinguished from energy units; thus, foot-pound and kilogram-meter for energy, and pound-foot and meter-kilogram for torque (see Sec. 67 for further information on torque).

1 ft · lb	= 13,560,000 ergs = 1.356 J = 0.3239 g · cal = 0.1383 kg · m = 0.001285 Btu = 0.0003766 Wh = 0.0000005051 hp · h
1 kg · m	= 98,060,000 ergs = 9806 J = 7.233 ft · lb = 2.34 g · cal = 0.009296 Btu = 0.002724 Wh = 0.000003704 hp · h (metric)
1 Btu	= 1055 J = 778.1 ft · lb = 252 g · cal = 107.6 kg · m = 0.5555 lb Celsius heat unit = 0.2930 Wh = 0.252 kg · cal = 0.0003984 hp · h (metric) = 0.0003930 hp · h
1 Wh	= 3600 J = 2,655.4 ft · lb = 860 g · cal = 367.1 kg · m = 3.413 Btu = 0.001341 hp · h
1 hp · h	= 2,684,000 J = 1,980,000 ft · lb = 273,700 kg · cm = 745.6 Wh
1 kWh	= 2,655,000 ft · lb = 367,100 kg · m = 1.36 hp · h (metric) = 1.34 hp · h

13. Power

1 g · cm/s	= 0.00009806 W
1 ft · b/min	= 0.02260 W = 0.00003072 hp (metric) = 0.00000303 hp
1 W	= 44.26 ft · lb/min = 6.119 kg · m/min = 0.001341 hp

For values not appearing in the table use the following formulas:

$$^{\circ}\text{C} = \frac{5}{9} \times (^{\circ}\text{F} - 32) \quad (7)$$

$$^{\circ}\text{F} = (\frac{9}{5} \times ^{\circ}\text{C}) + 32) \quad (8)$$

17. Greek Alphabet

(Anaconda Wire and Cable Co.)

Greek letter	Greek name	English equivalent
A α	Alpha	a
B β	Beta	b
Γ γ	Gamma	g
Δ δ	Delta	d
E ϵ	Epsilon	e
Z ζ	Zeta	z
H η	Eta	é
Θ θ	Theta	th
I ι	Iota	i
K κ	Kappa	k
Λ λ	Lambda	l
M μ	Mu	m
N ν	Nu	n
Ξ ξ	Xi	x
O \omicron	Omicron	ö
Π π	Pi	p
P ρ	Rho	r
Σ σ	Sigma	s
T τ	Tau	t
Y υ	Upsilon	u
Φ ϕ	Phi	ph
X χ	Chi	ch
Ψ ψ	Psi	ps
Ω ω	Omega	ö

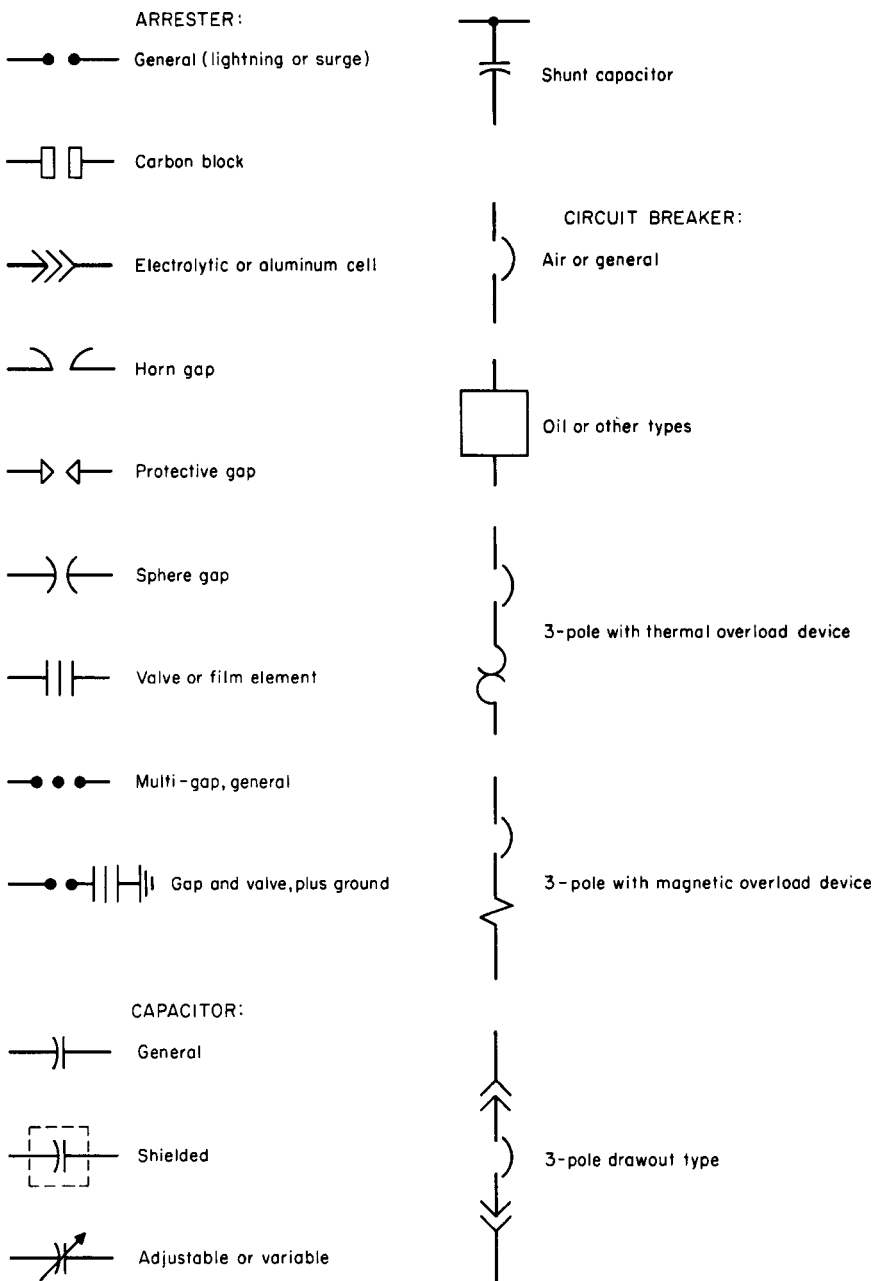

GRAPHICAL ELECTRICAL SYMBOLS

18. Standard graphical symbols for electrical diagrams were approved by the American National Standards Institute (ANSI) on October 31, 1975.

The complete list of the standardized symbols is given in the ANSI publication *Graphical Symbols for Electrical and Electronic Diagrams*, No. ANSI/IEEE 315-1975. A selected group of these symbols for use in one-line electrical diagrams is given in Secs. 19 and 20 through the courtesy of Rome Cable Corporation.

20. Graphical Symbols for Meters or Instruments and Identification Markings for Relays

(From American National Standards Institute ANSI/IEEE 315-1975)

NOTE: The asterisk is not a part of the symbol. Always replace the asterisk by one of the following letter combinations, depending on the function of the meter or instrument, unless some other identification is provided in the circle and explained on the diagram.

A	Ammeter
AH	Ampere-hour meter
CMA	Contact-making (or breaking) ammeter
CMC	Contact-making (or breaking) clock
CMV	Contact-making (or breaking) voltmeter
CRO	Oscilloscope or cathode-ray oscillograph
D	Demand meter
DB	DB (decibel) meter
DBM	DBM (decibels referred to 1 mW) meter
DTR	Demand-totalizing relay
F	Frequency meter
G	Galvanometer
GD	Ground detector
I	Indicating
M	Integrating
μ A or UA	Microammeter
MA	Milliammeter
N	Noise meter
OHM	Ohmmeter
OP	Oil pressure
OSCG	Oscillograph, string
PH	Phase meter
PI	Position indicator
PF	Power-factor meter
RD	Recording demand meter
REC	Recording
RF	Reactive-factor meter
S	Synchroscope
TLM	Telemeter
T	Temperature meter
TT	Total time
VH	Varhour meter
V	Voltmeter
VA	Volt-ammeter
VAR	Varmeter
VI	Volume indicator
VOM	Volt-ohm meter
VU	Standard volume indicator
W	Wattmeter
WH	Watt-hour meter

ANSI Device function numbers. [Reprinted with permission from the Jan. 1998 issue of EC&M Magazine, © 1998, Penton Business Media. All rights reserved.]

NOTE: If a device has two functions, both are shown. For example, a device 27/59 would be a combined undervoltage and overvoltage relay. See Fig. 1 for an example.

2. Time-delay starting or closing relay
3. Checking or interlock relay
6. Starting circuit breaker
8. Control power-disconnecting device
12. Overspeed device
14. Underspeed device
15. Speed- or frequency-matching device
18. Accelerating or decelerating device
19. Starting-to-running transition contactor
21. Distance relay
23. Temperature-control device
25. Synchronizing or synchronism-check device
27. Undervoltage relay
30. Annunciator relay
32. Directional power relay
36. Polarity device
37. Undercurrent or underpower relay
40. Loss of excitation (field) relay
41. Field circuit breaker
42. Running circuit breaker
43. Manual transfer or selector device
46. Reverse-phase or phase-balance current relay
47. Phase-sequence voltage relay
48. Incomplete-sequence relay
49. Machine or transformer thermal relay
50. Instantaneous overcurrent or rate-of-rise relay
51. AC time overcurrent relay
52. AC circuit breaker
55. Power-factor relay
56. Field-application relay
59. Overvoltage relay
60. Voltage- or current-balance relay
62. Time-delay stopping or opening relay
64. Ground-protective relay
67. AC directional overcurrent relay
68. Blocking relay
69. Permissive control device
72. DC circuit breaker
74. Alarm relay
76. DC overcurrent relay
78. Phase-angle measuring or out-of-step protective relay
79. AC reclosing relay
81. Frequency relay
82. DC reclosing relay
85. Carrier or pilot-wire receiver relay
86. Locking-out relay
87. Differential protective relay

- 91. Voltage directional relay
- 92. Voltage and power directional relay
- 94. Tripping or trip-free relay

PRINCIPLES OF ELECTRICITY AND MAGNETISM: UNITS

21. Magnets and magnetism. Any body which has the ability to attract iron or steel is called a *magnet*. The attractive ability of such a body is called *magnetism*. Certain specimens of iron ore sometimes possess the property when they are taken from the earth. Such natural specimens will attract and hold iron filings and are called *natural magnets* or *lode-stones*. The two ends of a magnetic specimen that have the greatest attraction for the iron filings are called the *poles* of the magnet. If a natural magnet is suspended by a string from its center so that it is free to turn, it will turn until the axis through its poles is lying north and south. The end or pole which is pointing north is called the *north pole* of the magnet, and the other end or pole, which is pointing south, is called the *south pole*.

It is possible by certain means discussed in Sec. 24 to produce artificial magnets, i.e., to magnetize a piece of iron or steel that did not originally in its natural state possess the property of magnetism. Artificial magnets are of two types, temporary and permanent. *Temporary magnets* are those which will hold their magnetism only as long as the magnetizing force is maintained. *Permanent magnets* are those which will hold their magnetism after the magnetizing force has been removed and will continue to be magnets for a long time unless they are demagnetized by some means such as by being jarred or heated.

Any material that can be magnetized or that is attracted by a magnet is called a *magnetic material*.

22. Magnetic field. The region around a magnet has peculiar properties that exist only as long as the magnet is present. A force exerted upon any piece of magnetic material will be placed in the space near to the magnet. This property or condition of the space around a magnet is called a *magnetic field*. If a magnet is covered with a sheet of paper sprinkled with iron filings, the filings will arrange themselves in definite curves extending from pole to pole, as shown in Fig. 1.2. The direction taken by the filings shows the direction of the magnetic field, i.e., the direction of the force exerted upon a magnetic material placed in the region around the magnet. The presence of this property (magnetic field) around a magnet can be demonstrated by means of a compass needle, a small, light magnet suspended so that it can turn freely. If a compass needle is placed in the region around a magnet, it will turn to a definite position, thereby demonstrating that there is a force acting upon a magnetic material placed in the region around a magnet. The magnitude or strength of the magnetic field (the magnitude of the force exerted upon a magnetic material in the space around a magnet) will differ at different points. The field will be strongest at the poles.

FIGURE 1.2 Arrangement of iron filings around a magnet.

The direction of a magnetic field at any point is the direction in which a force is exerted upon the north pole of a compass needle placed at that point in the field. It will be the direction in which the north-pole end of the axis of the compass needle points.

FIGURE 1.3 Lines of magnetic flux around a bar magnet.

23. Magnetic flux. The magnetic field of a magnet may be depicted by curved lines from the north to the south pole as shown in Fig. 1.3. Arrows placed on the lines, which picture the condition in the space, indicate the direction of the force that would be exerted upon the north pole of a compass needle at that point. The density with which the lines are drawn represents the magnitude of the field, i.e., the magnitude of the force that would be exerted upon a magnetic material placed at that point in the field. These lines, which picture the condition in the space around a magnet, are called *lines of magnetic flux* or simply *magnetic flux*.

24. Methods of producing artificial magnets. A magnetic material can be magnetized to a certain degree by stroking it with a permanent magnet or by placing it in the field of another magnet. Either of these means will normally produce only relatively weak magnets. The general method of magnetizing a material or of producing a magnetic field is to pass an electric current through a coil of wire (see Secs. 85 and 86).

25. Matter is anything which has weight and occupies space according to the laws of physics. The atomic theory states that all matter is made of atoms, which usually contain an equal number of positively and negatively charged particles. Thus, a normal atom exhibits no external sign of electrification. Most of the mass of an atom is found in the particles located in the small central portion called the *nucleus*, with much smaller particles, called *electrons*, in motion around the nucleus. By convention, the electrons are assigned a negative charge, the charge on each being equal to but opposite the charge on each of the charged particles in the nucleus, called *protons*. In addition, most atoms also contain particles in their nuclei that are neutral. These particles, called *neutrons*, are each approximately equal in mass to a proton. Atoms cannot be further reduced in size by any chemical process. Although there are very few elements, they can chemically combine into the millions of different compounds that comprise our physical and biological environment.

26. The different kinds of atoms (the atoms of the different elements) differ only in the number and arrangement of the electrons and in the numbers of protons and neutrons which compose them. Each element is characterized by its atomic number, which is defined as the number of protons in the nucleus. The lighter elements have few protons and electrons; the heavier elements, many. A normal atom of any given element always has the same number of electrons and a positive nucleus of the same magnitude. The arrangement of the electrons gives each element its chemical properties, and also determines whether the element is electrically conductive. The neutrons act to stabilize the atomic nucleus, but have no bearing on the basic chemical properties of the element or its conductivity. Only 117 or 118 elements are now known, and of those only 94 occur in nature, some only in very small quantities.

EXAMPLES Most atoms of hydrogen, the lightest element, consist of one electron and a corresponding positive nucleus of one proton. However, some atoms of hydrogen (called *deuterium*) have a nucleus of one proton and one neutron. Oxygen atoms contain eight protons and electrons, and usually eight neutrons, although as in the case of hydrogen other

numbers of neutrons are possible. An atom of the most common form of uranium, one of the heaviest elements, has 92 electrons and a nucleus of 92 protons and 146 neutrons.

27. Thus everything about us, all matter, is composed in significant part of electrically charged particles. The electrons can be, and often are, forced from the atoms. The positive nuclei, except under very special conditions (disruption of the atom), cannot be moved from the atom. Electrical phenomena usually occur when some of the electrons are moved or when the electrical balance which normally obtains within the atoms is disturbed. A single electron is unimaginably small, running about 1.27×10^{-13} in or 5×10^{-11} mm in diameter and 9.1×10^{-28} g. A single atom is very small indeed, and the electron is far smaller yet, weighing less than one eighteen-hundredth of the mass of an atom of hydrogen.

28. Matter is conserved and cannot be created or destroyed (except by thermonuclear reactions, which are not covered in this book). It is evident that there is in the universe a certain definite amount of electrically charged particles. Therefore electric charge, like matter, is conserved and can neither be created nor destroyed. It can, however, be forced to move and thus transmit power or produce electrical phenomena. Electrical energy (not electricity) can be generated (produced from energy of some other form) by forcing electrons to move in certain paths.

29. An electromotive force (emf) is the force or pressure, measured in *volts* (V), which makes electrons move or tends to make them move. Thus, if an emf is impressed across the two ends of a wire, it will force the electrons of the atoms which compose the wire to move from atom to atom, in the direction of the emf, through the wire, if we assume, of course, that a closed conducting path is provided. A lightning flash is merely a movement of electrons between the atoms of the atmosphere caused by an emf or voltage existing between the clouds and the earth.

30. An electric current, measured in *amperes* (A), consists of a movement or flow of electrically charged particles. In a wire, the normal application covered in this book, the only particles that move are the negatively charged electrons; however, in other places the current may involve positively charged ions (atoms lacking one or more electrons and thus with a net positive charge). For example, as a battery discharges both positively charged and negatively charged particles will be in motion (in opposite directions at any given instant) in the electrolyte.

Good conductors tend to be metals because each of the metallic atoms has some loosely bound electrons in its outer electron layers that are comparatively free to move in the presence of emf. This veritable sea of loose electrons is reflective to light and is partially responsible for the shiny appearance of untarnished metals.

31. Electric fields and the nature of electricity. You may be aware that electricity moves along a conductor at essentially the speed of light, which in a vacuum is 186,000 mi/s (300,000 km/s). In conventional conductors the speed is considerably slower, but still unimaginably fast. Thus, forgetting about losses in the wire for a moment, if you connected a load to the end of a wire that went around the earth seven times, and turned the

switch to ON, the load would receive the electric energy only a second or so later. This degree of speed occurs because closing the switch creates an electric field through and around the conductor, and that field is part of the same electromagnetic spectrum as radio, radar, infrared, visible light, ultraviolet, x-rays, and gamma radiation. By contrast, the electrons only move through a conductor at a speed in the neighborhood of 1 mm/s or less. How is this possible?

Picture a large load being elevated by a lever at the rate of 1 mm/s. The lever is like the pool of electrons that are free to move when an emf is applied. Just as the load end of the lever moves at the same instant as the other end when the required force is applied, so also do the electrons at the end of the conductor (and at all points in between) move when the emf is applied. The applied energy is transmitted through the electric and magnetic fields that surround the conductor, and that are guided to the loads by the conductor. Even though individual electrons move slowly, the electromagnetic field associated with their motion (current) transmits energy at the speed of light.

32. Electric currents may be divided into two general classes, direct currents and alternating currents.

33. A direct current is one which always flows in the same direction.

34. An alternating current is one the direction of which is reversed at regular intervals.

35. Direct currents may also be classified into (1) continuous currents, which are steady, nonpulsating direct currents; (2) constant currents, which continue to flow for a considerable time in the same direction and with unvarying intensity; and (3) pulsating currents, which are regularly varying continuous currents.

36. The coulomb (C) is the name given to the unit quantity of electrical charge. It is somewhat analogous to our common unit of quantity of water, the gallon (gal). A coulomb of electricity, so calculations show, is the quantity of charge represented by 6.02×10^{18} electrons (or protons). However, it is *rate of flow*, which is measured in amperes, that is of importance to the electrician rather than the total quantity of electricity that flows. Hence, the unit coulomb is almost never used directly in practical work.

37. Ampere is the name given to the practical unit of rate of flow of electricity; it is analogous to “gallons per minute” or “cubic meters per second” in hydraulics. The ampere represents a rate of flow of 1 C/s. That is, it is equivalent to a flow of 6.02×10^{18} electrons per second. It has been internationally agreed (recommended by the Chicago International Electrical Congress of 1893 and legalized by act of Congress in 1894) that the ampere be defined as “that unvarying current, which, when passed through a solution of nitrate of silver in water in accordance with standard specifications, deposits silver at the rate of one thousand one hundred and eighteen millionths (0.001118) of a gram per second.”

The ampere also is that unvarying current which when passed through two straight parallel conductors of infinite length and negligible cross section, located at a distance of 1 m from

each other in vacuum, will produce a force between the conductors of 2×10^{-7} newton (N) per meter of length. Current international agreements use this second definition as one of seven base quantities (the other six being length, mass, time, thermodynamic temperature, amount of substance, and luminous intensity) from which all other quantities are defined. Therefore, the present international definition of a coulomb is that quantity of electric charge that passes any cross section of a conductor in 1 sec when the current is maintained constant at 1 A.

EXAMPLES The current flowing in an ordinary 40-W incandescent lamp is about $\frac{1}{3}$ A. Series street-lighting lamps require from 6.6 to 20 A. The current in a telegraph wire is approximately 0.04 A.

38. Volt is the unit of emf; i.e., it is the unit whereby the tendency to establish and maintain electric currents may be measured. By international agreement it has been decided that 1 V shall be taken as the potential difference between two points on a conductor carrying a current of 1 A when the power dissipated between the two reference points is 1 W. As a practical matter, 1 V will force a current of 1 A through a resistance of 1 ohm (Ω).

39. Resistance (R or r) is the name given to the opposition which is offered by the internal structure of the different materials of the earth to the movement of electricity through them, i.e., to the maintenance of an electric current in them. This opposition results in the conversion of electrical energy into heat in accordance with the formula $W = I^2R$, where W = watts, I = intensity of current expressed in amperes, and R = ohms (Ω) of resistance. The electrons of some materials, such as the metals, can be moved from atom to atom within the material with relative ease, i.e., by the application of a small emf. All materials offer some opposition to the maintenance of a current through them, and there is no material in which some current cannot be produced, although it may be minute.

40. Conductor is the name given to a material through which it is relatively easy to maintain an electric current.

41. Insulator is the name given to a material through which it is very difficult to produce an electric current. Some examples of good insulating materials are glass, mica, and porcelain.

42. A resistor is an object having resistance; specifically, a resistor is a conductor inserted in a circuit to introduce resistance. A *rheostat* is a resistor so arranged that its effective resistance can be varied.

43. Ohm is the name given to the practical unit of electrical resistance. A resistance of 1 Ω is that opposition which will result in electrical energy being converted into heat at the rate of 1 W/A of effective current. In any circuit the rate at which electrical energy is converted into heat is given by the formula $W = I^2R$ of Sec. 39. The ohm is also used to describe the opposition to the passage of electric current due to impedance and capacitance. See Sec. 51 for more information.

It has been agreed that the international ohm shall be represented by the resistance offered to an unvarying electric current by a column of mercury, at the temperature of 0°C , which has a mass of 14.4521 g, a constant cross section, and a length of 106.3 cm.

44. Impedance (Z or z) is the name given to the total opposition of a circuit or part of a circuit to the passage of an electric current through it, caused by the combined effects of the characteristics of the circuit of resistance, inductance, and capacitance. Impedance is measured in ohms.

45. Self-inductance is the phenomenon whereby an emf is induced in a circuit by a change of current in the circuit itself. This emf is always in such a direction that it opposes the change of current which produces it.

Whenever current passes through a conductor, it tends to set up a magnetic field around the conductor. If the current through the conductor changes, the flux produced by it will change. The change in the flux will produce a voltage in the conductor. This voltage is the voltage of self-induction. Since inductance has an effect only when the current in the conductor is changing, inductance will have no effect on a closed dc circuit but will have an effect on ac circuits in which the current is always changing from instant to instant.

46. Inductance (L) is defined as the property of a circuit that causes a voltage to be induced in the circuit by a change of current in the circuit. The henry (H) is the unit of inductance. A circuit has an inductance of 1 H when if the current is changed at the rate of 1 A/s, 1 V will be induced in the circuit.

47. Inductive reactance (X_L) is the name given to the opposition to the flow of changing current due to inductance. It is measured in ohms as resistance is.

48. Capacitance (C) is the phenomenon whereby a circuit stores electrical energy. Whenever two conducting materials are separated by an insulating material, they have the ability of storing electrical energy. Such an arrangement of materials (two conductors separated by an insulator) is called a *capacitor* or *condenser*. If a source of dc voltage is connected between the two conducting materials of a capacitor, a current will flow for a certain length of time. The current initially will be relatively large but will rapidly diminish to zero. A certain amount of electrical energy will then be stored in the capacitor. If the source of voltage is removed and the conductors of the capacitor are connected to the two ends of a resistor, a current will flow from the capacitor through the resistor for a certain length of time. The current initially will be relatively large but will rapidly diminish to zero. The direction of the current will be opposite to the direction of the current when the capacitor was being charged by the dc source. When the current reaches zero, the capacitor will have dissipated the energy which was stored in it as heat energy in the resistor. The capacitor will then said to be discharged.

The two conducting materials, often called the plates of the capacitor, will be electrically charged when electrical energy is stored in the capacitor. One plate will have an excess of positive electricity and therefore will be positively charged with a certain number of coulombs of excess positive electricity. The other plate will have an excess of negative electricity and therefore will be negatively charged with an equal number of coulombs of excess

negative electricity. When in this state, the capacitor is said to be charged. When a capacitor is charged, a voltage is present between the two conductors, or plates, of the capacitor.

When a capacitor is in a discharged state, no electrical energy is stored in it, and there is no potential difference, no voltage, between its plates. Each plate contains just as much positive as negative electricity, and neither plate has any electric charge.

From the above discussion it is seen that a capacitor has a sustained current only as long as the voltage is changing. A capacitor connected to a dc supply will not have a sustained current. In an ac circuit, the voltage is continually changing from instant to instant. Therefore, when a capacitor is connected to an ac supply, an alternating current continues to flow. The current is first in one direction, charging the capacitor, and then in the opposite direction, discharging the capacitor.

49. Farad (F) The unit of capacitance. It is designated by the symbol F. A circuit or capacitor will have a capacitance of 1 F if when the voltage across it is increased by 1 V, its stored electricity is increased by 1 C. Another definition for a capacitance of 1 F, which results in the same effect, is given below. A circuit or capacitor will have a capacitance of 1 F when if the voltage impressed upon it is changed at the rate of 1 V/s, 1 A of charging current flows.

50. Capacitive reactance (X_c) is the name given to the opposition to the flow of alternating current due to capacitance. It is measured in ohms as resistance and inductive reactance are.

51. Ohm is the unit in which all opposition to the maintenance of an electric current is measured, not just resistance as covered in Sec. 43. A circuit or part of a circuit has an opposition of 1 Ω when an emf of 1 V will produce an effective current of 1 A. In any circuit or part of a circuit, the current is equal to the emf in volts divided by the total opposition in ohms. Thus,

$$I = \frac{E}{Z} \quad E = IZ \quad Z = \frac{E}{I} \quad (9)$$

Although all opposition to electric current is measured in ohms, the two types, resistive opposition and reactive opposition, are quite different. Resistance results in the loss of electrical energy from the circuit. Reactance results in the interchange of energy between electromagnetic fields and the circuit. It does not result in the loss of energy from the circuit. Capacitive reactance results in the interchange of energy between an electric field and a circuit. Current passing through any type of opposition results in the loss of voltage, or voltage drop.

52. Admittance (Y or y) is the name given to the quantity which is the reciprocal of impedance. It expresses the ease with which an emf can produce a current in an electric circuit. It is measured in a unit called the mho or siemens (S). A circuit or part of a circuit has an admittance of 1 mho when an emf of 1 V will produce an effective current of 1 A. In any circuit or part of a circuit the current is equal to the emf in volts multiplied by the total admittance in mhos. Thus,

$$I = EY \quad E = \frac{I}{Y} \quad Y = \frac{I}{E} \quad (10)$$

53. Conductance (G or g) is the component of the admittance which results in loss of power from the circuit in the form of heat. It is measured in mhos. For a dc circuit conductance becomes the reciprocal of the resistance.

54. Susceptance (B or b) is the component of the admittance which results in no loss of power from the circuit. It is measured in mhos. It does not exist for a dc circuit.

55. Conductivity. The relative ease with which an electric current can be passed through a material is called its *percentage conductivity*. The conductivity of pure annealed copper is taken as the base, so that pure annealed copper is said to have 100 percent conductivity. Copper of 100 percent conductivity has a resistance of $10.371 \Omega/\text{mil} \cdot \text{ft}$ at 20°C . The resistance per circular mil-foot of any material can be found by dividing 10.371 by the percentage conductivity of the material.

56. Work is the overcoming of mechanical resistance through a certain distance. Work is measured by the product of the mechanical resistance times the space through which it is overcome. It is measured by the product of the moving force times the distance through which the force acts in overcoming the resistance. Work is therefore measured in foot-pounds ($\text{ft} \cdot \text{lb}$). In the international system, work is measured by joules (J). A joule of work is performed when a newton of force is maintained over a distance of 1 m. It is also the amount of work expended when a watt of power is expended for a duration of 1 s.

EXAMPLE What work is done if a weight of 6 lb is lifted through a distance of 8 ft?

SOLUTION $\text{Work} = \text{ft} \times \text{lb} = 8 \times 6 = 48 \text{ ft} \cdot \text{lb}$

EXAMPLE If 20 gal of water is pumped to a vertical height of 32 ft, what work has been done?

SOLUTION A gallon of water weighs 8 lb. Therefore,

$$\text{Work} = \text{ft} \times \text{lb} = 32 \times (20 \times 8) = 5120 \text{ ft} \cdot \text{lb}$$

EXAMPLE If the piston in a steam engine travels $1\frac{1}{2}$ ft during a certain interval and the total pressure on the piston is 40,000 lb, what work is done during the interval?

SOLUTION $\text{Work} = \text{ft} \times \text{lb} = 1.5 \times 40,000 = 60,000 \text{ ft} \cdot \text{lb}$

57. Energy is capacity for doing work. Any body or medium which is of itself capable of doing work is said to possess energy. A coiled clock spring possesses energy because, in unwinding, it can do work. A moving projectile possesses energy because it can overcome the resistance offered by the air, by armor plate, etc., and thus do work. A charged storage battery possesses energy because it can furnish electrical energy to operate a motor. As in the case of work, energy can be expressed in foot-pounds, or joules in the international system.

58. Power is the time rate of doing work. The faster work is done, the greater the power that will be required to do it. For example, if a 10-hp motor can raise a loaded elevator a certain distance in 2 min, a motor of 20 hp (approximately) will be required to raise it the same distance in 1 min.

59. The horsepower (hp) is the unit of power and is about equal to the power of a strong horse to do work for a short interval. Numerically, 1 hp is $33,000 \text{ ft} \cdot \text{lb}/\text{min} = 550 \text{ ft} \cdot \text{lb}/\text{s} = 1,980,000 \text{ ft} \cdot \text{lb}/\text{h}$. Expressed as a formula,

$$\text{hp} = \frac{L \times W}{33,000 \times t} = \frac{\text{ft} \cdot \text{lb}/\text{min}}{33,000} \quad (11)$$

where hp = horsepower, L = distance in feet through which W is raised or overcome, W = weight in pounds of the thing lifted or the push or pull in pounds of the force overcome, and t = time in minutes required to move or overcome the weight W through the distance L . In the international system, the unit of power is the watt.

EXAMPLE What horsepower is required in raising the load and bucket weighing 200 lb shown in Fig. 1.4 from the bottom to the top of the shaft, a distance of 100 ft, in 2 min?

FIGURE 1.4 Bucket in shaft.

SOLUTION Substitute in the formula

$$\text{hp} = \frac{L \times W}{33,000 \times t} = \frac{100 \times 200}{33,000 \times 2} = 0.3 \text{ hp}$$

EXAMPLE What average horsepower is required while moving the box loaded with stone, in Fig. 1.5, from A to B, a distance of 650 ft, in 3 min? A total horizontal pull of 150 is required to move the box.

FIGURE 1.5 Moving loaded box.

SOLUTION Substitute in the formula

$$\text{hp} = \frac{L \times W}{33,000 \times t} = \frac{650 \times 150}{33,000 \times 3} = 0.98 \text{ hp}$$

60. Electric power is the rate of doing electrical work. The unit is the watt or the kilowatt. A kilowatt is 1000 W. Work is being done at the rate of 1 W when a constant current of 1 A is maintained through a resistance by an emf of 1 V. It is also the power required to do work at the rate of 1 J/s.

61. Energy of one sort may be transformed into energy of another sort. Heat energy in coal may be transformed (with a certain loss) with a boiler, a steam engine,

and a generator into electrical energy. The energy possessed by a stream of falling water may be transformed with a waterwheel and a generator into electrical energy. There is a definite numerical relation between different sorts of energy. Thus 1 British thermal unit, or Btu (the unit of heat energy), is equivalent to 778 ft · lb. In electrical units energy is expressed in watthours (Wh) or kilowatt hours (kWh).

62. A kilowatthour represents the energy expended if work is done for 1 h at the rate of 1 kW.

63. A horsepower-hour represents the energy expended if work is done for 1 h at the rate of 1 hp. Therefore, 1 hp · h = 60 × 33,000 = 1,980,000 ft · lb.

64. To reduce horsepower to watts and kilowatts and vice versa. Since 1 hp = 746 W,

$$\begin{aligned} \text{hp} &= \frac{W}{746} = W \times 0.00134 \\ W &= \text{hp} \times 746 \end{aligned} \quad (12)$$

$$\begin{aligned} \text{hp} &= \frac{\text{kW}}{0.746} = \text{kW} \times 1.34 \\ \text{kW} &= \text{hp} \times 0.746 \end{aligned} \quad (13)$$

EXAMPLE W = 2460; hp = ?

SOLUTION Substitute in the formula

$$\text{hp} = \frac{W}{746} = 2460 \div 746 = 3.3 \text{ hp}$$

EXAMPLE A motor takes 30 kW. What horsepower is it taking?

SOLUTION Substitute in the formula

$$\text{hp} = \frac{\text{kW}}{0.746} = 30 \div 0.746 = 40.24 \text{ hp}$$

Or instead, using the other formula,

$$\text{hp} = \text{kW} \times 1.34 = 30 \times 1.34 = 40.2 \text{ hp}$$

65. Efficiency is the name given to the ratio of output to input. No machine gives out as much useful energy or power as is put into it. There are some losses in even the most perfectly constructed machines.

$$\text{Efficiency} = \frac{\text{output}}{\text{input}} \quad (14)$$

Although efficiency is basically a decimal quantity and is so used in making calculations, it is usually expressed as a percentage. Percentage efficiency is equal to the decimal

expression of efficiency multiplied by 100. An efficiency of 0.80 expressed as a decimal is an efficiency of 80 percent expressed as a percentage.

Basically efficiency deals with energy. However, when the rate of energy conversion is constant, the values of output and input in terms of power may be used in dealing with efficiency:

$$\text{Input} = \frac{\text{output}}{\text{efficiency}} \tag{15}$$

and

$$\text{Output} = \text{input} \times \text{efficiency} \tag{16}$$

When the formulas are used, output and input must be expressed in the same units and efficiency as a decimal.

66. Output is the useful energy or power delivered by a machine, and input is the energy or power supplied to a machine.

EXAMPLE If 45 kW is supplied to a motor and its output is found to be 54.2 hp, what is its efficiency?

SOLUTION Since 1 hp = 0.746 kW, 54.2 hp = 54.2 × 0.75 = 40.6 kW. Then substituting in the formula,

$$\text{Efficiency} = \frac{\text{output}}{\text{input}} = \frac{40.6}{45} = 0.90 = 90 \text{ percent}$$

67. Torque is the measure of the tendency of a body to rotate. It is the measure of a turning or twisting effort and is usually expressed in pound-feet or in pounds-force at a given radius. Torque is expressed as the product of the force tending to produce rotation times the distance from the center of rotation to the point of application of the force. Thus in Fig. 1.6 there is a torque of 50 × 1 = 50 lb · ft, tending to turn the windlass owing to the weight attached to the rope. In the motor of Fig. 1.7 the group of conductors under the north pole produces a combined force of 10 lb. The torque produced by this group of conductors

FIGURE 1.6 Example of work and torque.

FIGURE 1.7 Torque produced by the force of the conductors of a motor.

will be $10 \times 9/12 = 7.5 \text{ lb} \cdot \text{ft}$. The group of conductors under the south pole will similarly produce $10 \times 9/12 = 7.5 \text{ lb} \cdot \text{ft}$. Both these torques tend to produce rotation in the same direction. Therefore, the total torque produced by the motor will be $7.5 + 7.5 = 15 \text{ lb} \cdot \text{ft}$.

Torque exists even if there is no motion. Thus, in Fig. 1.6 the torque exerted by the weight is $50 \text{ lb} \cdot \text{ft}$ as long as the weight is supported, whether the drum is moving or standing still. In the motor of Fig. 1.7 a torque of $15 \text{ lb} \cdot \text{ft}$ is exerted upon the armature, tending to produce rotation whether the motor is revolving or standing still. If there is no rotation, no work can be done; yet there is a torque tending to produce rotation.

68. Relation between horsepower and torque

$$\text{hp} = \frac{6.28 \times \text{rpm} \times T}{33,000} \quad (17)$$

or

$$T = \frac{33,000 \text{hp}}{6.28 \times \text{rpm}} \quad (18)$$

where $T =$ torque in $\text{lb} \cdot \text{ft}$.

EXAMPLE What is the torque of a 10-hp motor if it delivers a full load at 1150 rpm?

$$T = \frac{33,000 \times 10}{6.28 \times 1150} = 45.7 \text{ lb} \cdot \text{ft}$$

69. Torque and force relations in mechanisms. In any mechanism such as the windlass of Fig. 1.6 or a motor belted or geared to a load, if the losses are neglected so that the efficiency is 100 percent, the power output will be equal to the power input. For such a perfect mechanism, the following relations will hold true:

$$T_1 \times \text{rpm}_1 = T_2 \times \text{rpm}_2 \quad (19)$$

or

$$\frac{T_1}{T_2} = \frac{\text{rpm}_2}{\text{rpm}_1}$$

where $T_1 =$ torque at point 1 in the mechanism, $\text{rpm}_1 =$ rpm at point 1 in the mechanism, $T_2 =$ torque at point 2 in the mechanism, and $\text{rpm}_2 =$ rpm at point 2 in the mechanism.

In the windlass of Fig. 1.6 the rpm's for all points in the mechanism are the same. Therefore, the torque at any point is equal to the torque at any other point. The torque that must be exerted at the handle of the windlass to raise the weight at a uniform rate of speed would have to be equal to the torque exerted by the weight. (This formula neglects the weight of the rope and the friction.) The force exerted on the handle will be $50/2 = 25 \text{ lb}$.

The motor of Fig. 1.7 is equipped with a pulley on the shaft for driving a belt. The pulley has a diameter of 6 in. The force exerted upon the belt (the tension of the belt) is determined in the following manner. Since the rpm of the pulley is the same as the rpm of the motor armature, the torque produced by the conductors is the same as the torque exerted by the pulley. The force on the belt is therefore $15/0.5 = 30 \text{ lb}$.

70. EMFs may be produced in the following ways:

1. Electromagnetic induction
2. Thermal action
3. Chemical action
4. Changing electric fields
5. Contact between unlike substances
6. Vibration or heating of crystals

71. EMFs may be produced by electromagnetic induction in the following three ways:

1. By moving a conductor across a magnetic field. If the conductor of Fig. 1.8 is moved up or down so as to cut the lines of flux of the magnetic field between the poles of the magnet, an emf will be generated between the two ends of the conductor. This is the method employed for the production of voltage in dc generators (see Sec. 74).
2. By moving a magnetic field across a conductor. If in Fig. 1.8 the conductor is held stationary and the magnet is moved up or down so that the lines of flux of the magnetic field between the poles of the magnet will cut the conductor, an emf will be generated between the two ends of the conductor. This is the method employed for the production of voltage in most ac generators (see Sec. 144).
3. By changing the strength of the magnetic field linked with a conductor. If in Fig. 1.9 an alternating electric current is passed through winding A, it will set up a magnetic field through the iron ring. This magnetic field will be continually changing in strength, owing to the changing magnitude of the current. There will therefore be a continual change in the magnetic flux linked with winding B. This change will generate a voltage between the two ends of winding B. It is this phenomenon that makes possible the operation of transformers (see Div. 5, "Transformers").

FIGURE 1.8 EMF generated by magnetic flux.

Wherever large quantities of electrical energy are required, the necessary emf is produced by one of the means of electromagnetic induction.

72. A hand rule to determine the direction of an induced emf (see Fig. 1.10). Use the *right hand*. Extend the thumb in the direction of the motion or equivalent motion

FIGURE 1.9 Method of producing an emf by electromagnetic induction.

FIGURE 1.10 Application of right-hand rule.

of the conductor and extend the forefinger in the direction of the magnetic flux. Then the middle finger will point in the direction of the induced emf. (Magnetic flux flows from the north pole to the south pole outside a magnet and from south to north inside the magnet.) This rule can be remembered by associating the sounds of the following word groups: thumb-motion, forefinger-force, and middle finger-motive force. The rule is also known as Fleming's rule.

73. AC generator (alternator). A very simple elementary ac generator is shown in Fig. 1.11. As the conductors are revolved through the magnetic field, a voltage will be produced in each conductor. In view of the series circuit formed by the two conductors, the voltages produced by the conductors will act to send current through the circuit in the same direction. The total voltage between the terminals of the machine will be the sum of the voltages produced by the two conductors at that instant. As long as conductor *A* is under the north pole and conductor *B* under the south pole, there will be a terminal voltage which will send current through the external circuit from *C* to *D*. When the conductors are midway between poles, they will not cut any flux and no voltage will be produced. As conductor *A* moves under the south pole and conductor *B* under the north pole, the conductors will again cut flux and voltages will again be produced in the conductors. The direction of these voltages will, however, be just opposite to the direction of the voltages when *A* was under the north pole and *B* under the south pole. The terminal voltage of the machine therefore periodically reverses in direction, and the machine is an ac generator.

74. A dc generator (dynamo) is shown in Fig. 1.12. The production of voltage in the conductors is exactly the same as for the elementary ac generator of Sec. 73. As the conductors revolve, an alternating voltage is produced in them. In order that the terminal voltage can always act upon the external load in the same direction, some device must be inserted between the conductors and the terminals. This device must reverse the connections of the conductors to the external circuit at the instant when the voltage of the conductors is zero and is changing in direction. Such a device is called a *commutator*.

75. The magnitude of the voltage produced by electromagnetic induction depends upon the rate at which the lines of flux are cut by the conductor. Whenever 100 million lines of flux are cut per second, 1 V is produced. The voltage produced is therefore equal to the number of lines of flux cut per second divided by 100 million.

FIGURE 1.11 Elementary ac generator.

FIGURE 1.12 Elementary dc generator.

76. Thermal action produces emf's in the following ways:

1. *Seebeck effect.* In a closed circuit consisting of two different metals, an emf will be produced if the two junctions between the different metals are kept at different temperatures (see Fig. 1.13). Thermocouples function through this phenomenon. The magnitude of the emf produced will depend upon the material of the metals and the difference in temperature between the hot junction and the cold ends. Since only very small voltages can be produced in this way, the method is not applicable when electrical energy of any quantity is required. However, this method is of great practical value for application in temperature measurements.
2. *Peltier effect.* When current passes through the junction between two different metals, energy conversion takes place between energy in heat form and energy in electrical form. The action is reversible, and the direction of energy conversion depends upon the direction in which the current passes across the junction. This phenomenon is entirely different and distinct from the conversion of electrical energy into heat caused by the passage of a current through the resistance of the junction of the two materials.
3. *Thomson effect.* When the temperature along a metallic conductor varies in magnitude, a very small emf is produced.

77. EMFs produced by chemical action. Certain combinations of chemicals will generate emf's. For instance, if a piece of zinc (Fig. 1.14) and a piece of carbon are immersed in a solution of sal ammoniac, an emf will be produced between the zinc and the carbon. Such a combination is called a *battery*. If the key in Fig. 1.14 is closed, an electric current will flow and the bell will ring. The voltage of dry cells and storage batteries is produced in this way by chemical action.

78. EMFs produced by electric fields. Whenever there is a voltage between two conductors, certain conditions are produced in the space around and between the conductors. This condition in the surrounding space is called an *electric field*. The electromagnetic field surrounding an energized conductor (see Sec. 1-31) will influence a nearby conductor even if there is no direct connection between the two. Discussion and explanation of this

FIGURE 1.13 EMF generated by heat.

FIGURE 1.14 EMF generated by chemical action.

phenomenon are outside the scope of this book. However, emf's produced by changes in this electric field are of great practical importance, since these changes induce changing voltages in the neighboring conductors. Voltages produced by this means in telephone lines from neighboring electric power lines may cause serious interference with communication over the telephone lines. These induced voltages and currents are also the basis for transformer operation (see Sec. 5-16, etc.).

79. Contact emf. When any two different materials are brought into contact with each other, a very small emf is produced. However, voltages of considerable magnitude may be produced by this phenomenon by the rapid rubbing together of different materials. The rubbing results in rapid change of the contact points between the two materials and thus in an accumulation of the small individual contact emf's into a voltage of considerable magnitude. Practical illustrations of voltages produced by this means are voltages on belts produced by the motion of the belt over the pulleys between automobile bodies and the ground produced by the revolution of the rubber tires over the road. These voltages often are called *frictional voltages*.

80. EMFs produced by crystals. Certain crystals, such as quartz and Rochelle salt crystals, have the property of producing very small emf's between opposite faces of the crystals when subjected to pressure. Some crystals, such as tourmaline, when heated produce a very small emf between opposite faces. Although emf's produced by these means are of very small magnitude, they are of great practical value in microphones and instruments for the measurement of vibrations in machinery.

FIGURE 1.15 The effect of increasing voltage.

81. EMF, which is measured in volts, causes electricity to flow. A higher voltage is required to force a given current of electricity through a small wire than through a large one. If the voltage impressed on a circuit is increased, the current will be correspondingly increased (see Fig. 1.15).

82. The distinction between amperes and volts should be clearly understood.

The amperes represent the rate of electricity flow (see Secs. 30 and 37) through a circuit, while the volts represent the tendency causing the flow. There may be a tendency (voltage) and yet no current. If the path of electricity is blocked by an open switch (Fig. 1.16), there will be no current of electricity, though the tendency to produce (voltage) may be high. With a given voltage, a greater current of electricity will flow through a large wire than through a small one.

FIGURE 1.16 Electricity flow blocked by an open switch.

83. Direction of electric current. Although in most cases current consists of the actual motion of negative electricity in a certain direction, the conventional direction of a current is the direction in which positive electricity would move to cause the same effects as are produced by the actual motion of electricity. Therefore the direction of current, as it is usually considered, is in the opposite direction to the motion of the electrons.

84. Symbols for indicating the direction of an emf or currents into or out of the end of a conductor are shown in Fig. 1.17.

FIGURE 1.17 Symbols indicating direction of current flow.

85. Effects of an electric current. The two principal effects of an electric current are a heating effect and a magnetic effect.

Whenever an electric current passes through a material, there is a heating effect due to the current. This effect is indicated by the increase in temperature of the material. A certain portion of the electrical energy that is put into the circuit is transformed into heat energy owing to the opposition offered to the flow of current by the resistance of the material. This loss of electrical energy (transferred to heat energy) is associated with a drop in voltage. This drop in voltage is produced by the amount of voltage required to force the current through the resistance. The heating effect with its associated drop of voltage and temperature rise of the material always takes place whenever a current is passed through a circuit. These are also known as I^2R (watts) or IR (drop losses).

There is an association between electricity and magnetism because a magnetic field can be produced by an electric current. In fact, whenever an electric current is passed through a conductor, the current tends to set up a magnetic field around the conductor. The presence of this field can be demonstrated by holding a compass near a wire that is carrying a current (Fig. 1.23). The compass needle will be deflected in a definite direction with the direction of current flow.

86. Magnetic effect of electric current. The magnetic lines of flux (magnetic field) produced by a current passing through a straight wire can be determined by passing the wire through a sheet of paper upon which iron filings are sprinkled, as illustrated in Fig. 1.18. The direction of the lines of flux will be in concentric circles around the axis of the conductor. The field will be strongest close to the conductor.

FIGURE 1.18 Magnetic field around a conductor.

If the current is passed through a coil of wire wound around a piece of iron, as in Fig. 1.19, it will be found that the iron is magnetized in a definite direction. Such a magnet is called an *electromagnet*. This is the method always employed for producing strong magnets or

FIGURE 1.19 Elementary electromagnet.

FIGURE 1.20 Magnetic field from current flowing through a coil of wire.

setting up strong magnetic fields. A coil of wire carrying current will act like a magnet and will produce a magnetic north pole at one end and a magnetic south pole at the other (see Fig. 1.20). The direction of the magnetic field produced will be from the north-pole end around through the space outside of the coil to the south-pole end and then back through the interior of the coil to the north-pole end.

87. Hand rule for direction of magnetic field about a straight wire (see Fig. 1.21). If a wire through which electricity is flowing is so grasped with the *right hand* that the thumb points in the direction of electricity flow, the fingers will point in the direction of the magnetic field and vice versa.

FIGURE 1.21 Hand rule for direction of field.

FIGURE 1.22 Hand rule for determining polarity of a solenoid.

88. Hand rule for polarity of a solenoid or electromagnet (see Fig. 1.22). If a solenoid or an electromagnet is so grasped with the *right hand* that the fingers point in the direction of the current, the thumb will point in the direction of the magnetic field through the solenoid, i.e., toward the north pole of the solenoid.

89. Rule for determining direction of current flow with a compass (see Fig. 1.23). If a compass is placed under a conductor in which electricity is flowing from south end to north end, the north end of the needle will be deflected to the west. If the compass is placed over the conductor, the north end of the compass will be deflected to the east. If the direction of current flow in the conductor is reversed, the direction of deflection of the needle will be reversed correspondingly.

FIGURE 1.23 Performance of a compass needle near a conductor.

90. The resistances of different materials vary greatly. Some, such as the metals, conduct electricity very readily and hence are called *conductors*. Others, such as wood or slate, are, at least when moist, partial conductors. Still others, such as glass, porcelain, and paraffin, are called *insulators* because they are practically nonconducting. No material is a perfect conductor, and no material is a perfect insulator (see Sec. 39).

The resistance of a conductor depends not only upon the material of the conductor but also upon the conductor's dimensions and the distribution of the current throughout the cross section of the conductor. The resistance of a given conductor will have its minimum value when the current is uniformly distributed throughout the cross section of the conductor. Uniform current distribution exists in the conductors of most dc circuits. In the conductors of ac circuits the current is never exactly uniformly distributed. The resistance of a circuit to alternating current is always somewhat greater than it is to direct current (see Sec. 122). The amount by which the ac resistance exceeds the dc value depends upon several factors.

Unless otherwise stated, values of resistance should be taken as the resistance for uniform distribution of the current. They are the values to use for dc circuits.

The resistance of materials also depends upon the temperature of the material.

91. A circular mil is the area of a circle $\frac{1}{1000}$ in diameter. A mil is $\frac{1}{1000}$ of an inch (see Fig. 1.24). The areas of electric conductors are usually measured in circular mils. Since the area of any figure varies as the square of its similar dimensions, the area of any circle can be expressed in circular mils by squaring its diameter expressed in thousandths. Thus, since $\frac{3}{8} = \frac{375}{1000} = 0.375$, the area of a circle $\frac{3}{8}$ in in diameter would be $375 \times 375 = 140,625$ cmil. The area of a circle 0.005 in in diameter would be $5 \times 5 = 25$ cmil.

FIGURE 1.24 Circular mil and square mil.

92. A square mil is the area of a square having sides $\frac{1}{1000}$ in long (see Fig. 1.24). Areas of rectangular conductors are sometimes measured in square mils. Areas in square mils are obtained by multiplying the length and breadth of the rectangle expressed in thousandths of an inch. Thus, the area of a rectangle $\frac{1}{2}$ in wide and 2 in long would be $500 \times 2000 = 1$ million mils². In actual area, a circular mil is about $\frac{8}{10}$ as great as a square mil.

93. To reduce square mils or square inches to circular mils, or the reverse apply one of the following formulas.

$$\text{Mils}^2 = \text{cmil} \times 0.7854 \tag{20}$$

$$\text{cmil} = \frac{\text{mils}^2}{0.7854} \tag{21}$$

$$\text{cmil} = \frac{\text{in}^2}{0.0000007854} \tag{22}$$

$$\text{In}^2 = \text{cmil} \times 0.0000007854 \tag{23}$$

FIGURE 1.25 Conductor sections.

EXAMPLE The sectional area of the busbar in Fig. 1.25, I, in circular mils is

$$\begin{aligned} \text{cmil} &= (\text{in}^2)/0.0000007854 \\ &= (3 \times 1/4) \div 0.0000007854 \\ &= 0.75 \div 0.0000007854 \\ &= 955,000 \text{ cmil} \end{aligned}$$

EXAMPLE The sectional area of the steel T shown in Fig. 1.25, II, in circular mils is:

$$\text{cmil} = \text{in} \div 0.0000007854 = 0.53 \div 0.0000007854 = 674,800 \text{ cmil}$$

FIGURE 1.26 Curves showing resistance per circular mil-foot of pure copper at various temperatures and conductivities.

94. The circular mil-foot (cmil · ft) is the unit conductor. A wire having a sectional area of 1 cmil and a length of 1 ft is a circular mil-foot of conductor. The resistance of a circular mil-foot of a metal is sometimes called its *specific resistance* or its *resistivity*. The resistance of a circular mil-foot of copper under different conditions is given in Fig. 1.26. Resistances for other metals and alloys are given in Table 97.

95. To compute the resistance of a conductor of any common metal or alloy, use the value given for the resistance of a circular mil-foot of the material in Table 97 in the following formula:

$$R = \frac{p \times l}{\text{cmil}} \quad \text{or} \quad \frac{p \times l}{d^2} \quad (24)$$

where R = resistance of the conductor in ohms; p = resistance of 1 cmil · ft of the material composing the conductor, from Table 97; l = length of conductor in feet; d = diameter in mils; and d^2 = diameter in mils squared or, what is the same thing, the area of the conductor in circular mils.

The other forms of the formula are

$$\begin{aligned} p &= \frac{d^2 \times R}{l} \quad l \\ &= \frac{d^2 \times R}{p} \quad d = \sqrt{\frac{p \times l}{R}} \end{aligned} \quad (25)$$

EXAMPLE If we take from Table 97 the resistance of 1 cmil · ft of copper at 23°C (75°F) as 10.5 Ω, what is the resistance of 500 ft of copper wire 0.021 in in diameter?

SOLUTION Substituting in the formula,

$$R = \frac{pl}{d^2} = \frac{10.5 \times 500}{21 \times 21} = \frac{5250}{441} = 11.9 \Omega$$

96. An approximate rule for computing the resistance of round copper wire, in ohms per thousand feet, is to divide 10,500 by the size of the wire in circular mils. This rule should be used only for rough estimating computations.

EXAMPLE Thus, for a 4/0 wire (211,600 cmil), the resistance is approximately $R = 10,500/211,600 = 0.05 \Omega/1000 \text{ ft}$.

97. Approximate Specific Resistances and Temperature Coefficients of Metals and Alloys

98. The resistance of conductors that are not circular in section can be computed by first getting their areas in square inches and then reducing this square-inch value to circular mils as given in Sec. 93. Then proceed with the formula in the preceding paragraph.

99. Change of resistance with change of temperature. The resistance of all pure metals increases as they become hot. The resistance of certain alloys is not affected by the temperature. The resistance of a few materials, carbon for instance, decreases as their temperature increases. The proportion that resistance changes per degree rise in temperature is called the *temperature coefficient of resistance* (see Table 97 for values). Unless otherwise stated, the temperature coefficient is positive; i.e., the resistance increases with increase in temperature. For all pure metals, the coefficient is practically the same and is 0.004 for temperatures in degrees Celsius and 0.0023 in degrees Fahrenheit.

100. To find the resistance of a conductor at any ordinary temperature, use this formula:

$$R_h = R_c + [a \times R_c(T_h - T_c)] \quad \text{or} \quad T_h - T_c = \frac{R_h - R_c}{a \times R_c} \quad (26)$$

where R_h = resistance, in ohms, hot; R_c = resistance, in ohms, cold; T_h = temperature of conductor hot, in degrees; T_c = temperature of conductor cold, in degrees; and a = temperature coefficient of the material of the conductor from Table 97. (This is an approximate method, but it is sufficiently accurate for all ordinary work.)

EXAMPLE The resistance of 1 cmil · ft of annealed copper is 9.59Ω at 32°F . What will be its resistance at 75°F ?

SOLUTION From Table 97 the coefficient is 0.00223. Now substitute

$$\begin{aligned} R_h &= R_c + [a \times R_c(T_h - T_c)] = 9.59 + [0.00223 \times 9.59(75 - 32)] \\ &= 9.59 + [0.00223 \times 9.59 \times 43] = 9.59 + 0.92 = 10.51 \Omega, \text{ at } 75^\circ\text{F} \end{aligned}$$

101. The temperature rise in a conductor can be determined with the formula of Sec. 100 by measuring hot and cold resistance. The expression $T_h - T_c$ is the difference between hot and cold temperatures and is therefore the temperature rise or fall.

EXAMPLE The resistance of a set of copper coils measured 20Ω at a room temperature of 20°C . After carrying current for some time the resistance measured 20.78Ω . What was the temperature rise in the coil?

SOLUTION The temperature coefficient of copper per degree Celsius from Table 97 is 0.004. Substitute in the formula

$$T_h - T_c = \frac{R_h - R_c}{aR_c} = (20.78 - 20.0) \div (0.004 \times 20) = 0.78 \div 0.08 = 9.75^\circ\text{C}$$

Therefore, the average temperature rise in the coil was $9\frac{3}{4}^\circ\text{C}$.

102. Contact resistance is the resistance at the point of contact of two conductors. When current flows, heat is always developed at such a point. The greater the clamping pressure between the conductors in contact and the greater the area of contact, the less the contact resistance will be. The nature of the surfaces in contact must also be considered. Smooth surfaces have less contact resistance than rough surfaces. Contacts should always be so designed that, for a given current, the area of contact will be large enough to prevent the contact resistance from being so great as to cause excessive heating. Table 104 indicates safe values.

103. Ohm's law. From the preceding sections it is evident that a voltage is required to force a current through a circuit against the resistance caused by the material of the conductor. The relation between current, resistance, and voltage is known as *Ohm's law*. It is merely a restatement, as applied to electric circuits, of the general law which governs all physical phenomena; i.e., the result produced is directly proportional to the effort or cause and inversely proportional to the opposition. For the phenomenon dealing with current passing through resistance, the emf is the cause, the current is the result or effect, and the resistance is the opposition. Thus,

$$I = \frac{E}{R} = \left(\text{amperes} = \frac{\text{volts}}{\text{ohms}} \right) \quad (\text{amperes}) \quad (27)$$

$$R = \frac{E}{I} = \left(\text{ohms} = \frac{\text{volts}}{\text{amperes}} \right) \quad (\text{ohms}) \quad (28)$$

$$E = I \times R = \text{volts} = (\text{amperes} \times \text{ohms}) \quad (\text{ohms}) \quad (28)$$

where I = the effective current in amperes, which flows through the resistance in the circuit or in the portion of the circuit under consideration; R = the resistance in ohms of the circuit or the portion of the circuit under consideration; and E = the effective emf in volts required to force the current through the resistance of the circuit or the portion of the circuit under consideration.

104. Safe Current Densities for Electrical Contacts and for Cross Sections

Kind of contact or cross section	Material	Current density	
		Amp per sq in	Sq mils per amp
Sliding contact (brushes)	Copper brush	150-175	5,700-6,700
	Brass gauze brush	100-125	8,000-10,000
	Carbon brush	30-40	25,000-33,300
Spring contact (switch blades)	Copper on copper	60-80	12,500-16,700
	Composition on copper	50-60	16,700-20,000
	Brass on brass	40-50	20,000-25,000
Screwed contact	Copper to copper	150-200	5,000-6,700
	Composition to copper	125-150	6,700-8,000
	Composition to composition	100-125	8,000-10,000
Clamped contact	Copper to copper	100-125	8,000-10,000
	Composition to copper	75-100	10,000-13,000
	Composition to composition	70-90	11,000-14,000
Fitted contact (taper plugs)	Copper to copper	125-175	5,700-8,000
	Composition to copper	100-125	8,000-10,000
	Composition to composition	75-100	10,000-13,000
Fitted and screwed contact	Copper to copper	200-250	4,000-5,000
	Composition to copper	175-200	5,000-5,700
	Composition to composition	150-175	5,700-6,700
Cross section	Copper wire	1,200-2,000	500-800
	Copper wire cable	1,000-1,600	600-1,000
	Copper rod	800-1,200	800-1,200
	Composition casting	500-700	1,400-2,000
	Brass casting	300-400	2,500-3,300
	Brass rod	575-750	1,300-1,700

105. Application of Ohm's law. Great care must be exercised in the use of Ohm's law. The voltage given by Eq. (27) may or may not be the voltage that must be impressed on the circuit to force the given current through the circuit. When the circuit contains only resistance, the voltage given by Ohm's law is the voltage impressed on the circuit. Ohm's law holds true for all circuits, both direct and alternating, but the voltage obtained by its use is only the voltage required to overcome the resistance of the circuit. Ohm's law cannot be used for a complete motor circuit to determine the resistance of the circuit.

106. Use Ohm's law for:

1. Determination of the voltage required to provide a given current through only a resistance
2. Determination of the current which would be produced by a given voltage impressed upon only a resistance
3. Determination of the voltage drop caused by a current passing through a resistance
4. Calculations of complete dc circuits which do not contain any emf other than the impressed voltage
5. Any circuit or portion of a circuit which consists only of resistance

107. Do not use Ohm's law for:

1. AC circuits in general
2. Complete motor circuits
3. Complete circuits containing any emf other than the impressed voltage

Refer to Secs. 131 and 132 for calculation of ac circuits.

108. Examples of the application of Ohm's law

EXAMPLE What will be the current in the dc circuit of Fig. 1.27?

SOLUTION An entire circuit is shown. It is composed of a dynamo, line wires, and a resistance coil. The emf developed by the dynamo (do not confuse this with the emf impressed by the dynamo on the line) is 120 V. The resistance of the entire circuit is the sum of the resistances of dynamo, line wires, and resistance coil. Substituting in the formula,

$$I = \frac{E}{R} = \frac{120}{1 + 1 + 9 + 1} = \frac{120}{12} = 10 \text{ A}$$

EXAMPLE What current will flow in the circuit of Fig. 1.28?

SOLUTION This again is an entire circuit. Substituting in the formula,

$$I = \frac{E}{R} = \frac{1}{0.5 + 0.5 + 2 + 0.5} = \frac{1}{3.5} = 0.28 \text{ A}$$

Note that the internal resistance of the battery must be considered.

FIGURE 1.27 An entire dynamo circuit.

FIGURE 1.28 An entire battery circuit.

EXAMPLE With 10 A flowing, what will be the voltage drop in the line wires in Fig. 1.29?

SOLUTION Each has a resistance of 1.0 Ω; hence

$$E = I \times R = 10 \times 2 = 20 \text{ V}$$

FIGURE 1.29 Feeder to motors.

FIGURE 1.30 Portions of circuits.

EXAMPLE What is the resistance of the incandescent lamp of Fig. 1.30A? It is tapped to a 120-V circuit, and the ammeter reads 0.5 A. The branch wires are so short that their resistance can be neglected.

SOLUTION Substitute in the formula,

$$R = \frac{E}{I} = \frac{120}{0.5} = 240 \Omega$$

EXAMPLE The dc motor of Fig. 1.30B takes 20 A, and the drop in voltage in the branch wires should not exceed 5 V. What is the greatest resistance that can be permitted in the branch conductors?

SOLUTION Substitute in the formula,

$$R = \frac{E}{I} = \frac{5}{20} = 0.25 \Omega$$

This (0.25 Ω) is the resistance of both wires. Each would have a resistance of 0.125 Ω .

EXAMPLE The electric heater of Fig. 1.31 takes 5 A. The resistance of each branch wire is 0.1 Ω . What will be the drop in volts in each branch wire?

SOLUTION Substitute in the formula,

$$E = I \times R = 5 \times 0.1 = 0.5 \text{ V}$$

In both branch wires or in the branch circuit, the volts lost would be $2 \times 0.5 = 1 \text{ V}$.

FIGURE 1.31 Portion of a circuit.

EXAMPLE Three dc motors (Fig. 1.29) taking respectively 20, 25, and 5 A (these values are stamped on the nameplates of the motors) are located at the end of a feeder having a resistance of 1.0 Ω on each side. What will be the voltage drop in the feeder?

SOLUTION Substitute in the formula,

$$E = R \times I = (1 + 1) \times (20 + 25 + 5) = 2 \times 50 = 100 \text{ V}$$

109. DC circuits. A constant-current dc circuit has only one characteristic that affects the value of the current, i.e., the resistance offered by the material of which the circuit is made. Therefore, Ohm's law applies to a complete dc circuit or to any portions of the circuit which do not contain any emf other than the impressed voltage. For a motor circuit, therefore, Ohm's law will apply only to the line-conductor portion of the circuit. Ohm's law will give the voltage required to overcome the resistance of the line conductors, the voltage drop of the circuit. The total impressed voltage will be equal to the sum of the voltage at the motor terminals plus the IR voltage of the line conductors. The voltage impressed on the motor will be equal to the impressed line voltage minus the IR voltage drop in the line-conductors.

110. Power in dc circuits is equal to the product of volts and amperes. Expressing this as a formula,

$$W = I \times E \quad I = \frac{W}{E} \quad E = \frac{W}{I} \tag{30}$$

and also in circuits where all the energy is converted into heat energy,

$$W = I^2 \times R \quad W = \frac{E^2}{R} \quad I = \sqrt{\frac{W}{R}} \quad E = \sqrt{R \times W} \tag{31}$$

$$R = \frac{E^2}{W} \quad R = \frac{W}{I^2} \tag{32}$$

where I = current in amperes, E = voltage or emf in volts, R = resistance in ohms, and W = power in watts.

111. In applying the above equations be careful that the values of current, voltage, and resistance used in any one problem all apply to the same circuit or to the same portion of a circuit.

EXAMPLE How many watts are consumed by the incandescent lamp in Fig. 1.32?

SOLUTION Substitute in the formula,

$$W = I \times E = 1/2 \times 120 = 60 \text{ W}$$

EXAMPLE How many watts are taken by the motor of Fig. 1.33? How many kilowatts? How much horsepower?

FIGURE 1.32 Incandescent-lamp branch circuit.

FIGURE 1.33 Electric motor.

FIGURE 1.34 Feeder.

SOLUTION Substitute in the formula,

$$W = I \times E = 70 \times 220 = 15,400 \text{ W}$$

$$\text{kW} = \frac{W}{1000} = \frac{15,400}{1000} = 15.4 \text{ kW}$$

$$\text{hp} = \frac{W}{746} = \frac{15,400}{746} = 20.6 \text{ hp}$$

EXAMPLE In the feeder of Fig. 1.34, what power will be lost in the line wires to the motor?

SOLUTION Substitute in the formula,

$$W = I^2 \times R = (40 \times 40) \times (0.3 + 0.3) = 1600 \times 0.6 = 960 \text{ W}$$

112. Waveform of alternating currents and voltages. An alternating current or voltage is one which is reversed at regular intervals. The curve formed by plotting the instantaneous values of the voltage or current against time is called the *waveform of the voltage or current*. It is best to have the value of an alternating current or voltage vary with time according to what is known as the sine law. The instantaneous values of an alternating current varying according to this law are shown in Fig. 1.35. A voltage or current which varies in this manner is called a *sinusoidal voltage or current*. Most modern ac generators produce a voltage which is very nearly sinusoidal and is generally so considered. The current in some ac circuits is very nearly sinusoidal and in others may differ considerably from the sine law. In most cases, however, for practical work both alternating voltages and currents can be considered as following the sine law. If it is not satisfactory to do this, the calculations become complicated and discussion is outside the scope of this book.

FIGURE 1.35 Graph of a 60-Hz alternating current having a maximum value of 100 A.

113. A cycle is a complete set of values through which an *alternating current* (see Sec. 34 for an explanation of alternating current) repeatedly passes (see Fig. 1.35). The expression “60 hertz (Hz)” means that the current referred to makes 60 complete cycles in a second. It therefore requires $\frac{1}{60}$ s to complete 1 cycle (see Fig. 1.35). With a 25-Hz current, $\frac{1}{25}$ s is required to complete 1 cycle (see Fig. 1.36).

FIGURE 1.36 Curve of a 25-Hz alternating current.

114. The frequency of an alternating current is the number of cycles completed in a second. A frequency of 60 Hz is practically standard for lighting and power installations. Most electric power companies generate, transmit, and distribute their power at this frequency. For railroad electrification, 25 Hz is sometimes employed. If 25 Hz is used for lighting, lamps will flicker. Some of the older stations in the United States still generate at 50 Hz. In Europe 50 Hz has been used for light and power and $16\frac{2}{3}$ Hz for railroads.

115. Electrical degrees. The instantaneous values of an ac voltage can be studied in Fig. 1.37, which shows an elementary four-pole generator and the waveform of voltage for one complete revolution of the conductor. When the conductor is in the position marked A, halfway between adjacent poles, it will not cut any flux and therefore no voltage will be induced in the conductor. As the conductor moves from this position, it will start to cut flux and will do so at a greater and greater rate until the conductor is in the position B. At this point, flux will be cut at the maximum rate, and the voltage produced will be maximum. As the conductor moves from position B to position C, it will cut flux at a decreasing rate, until when position C is reached (halfway between poles), the conductor will not cut flux at all. As the conductor moves on from position C, it will start to cut flux, but the direction of the flux is reversed. The direction of the induced voltage will therefore reverse at the instant when the conductor passes through position C. If we pursue the same reasoning for the rest of the revolution, the voltage produced in the conductor will follow the waveform shown in Fig. 1.37. The arc that the

FIGURE 1.37 Elementary ac generator, illustrating electrical degrees and waveform.

conductor must pass through to generate one complete cycle of voltage is called *360 electrical degrees*. In any ac generator there are therefore 360 electrical degrees in the arc between the centerline of one pole and the centerline of the next pole of the same polarity. The number of electrical degrees in one complete revolution for any generator is equal to 360 times the number of pairs of poles for which the machine is wound. One electrical degree is equal to 1 (pair of poles) part of a mechanical degree.

If the elementary generator of Fig. 1.37 produced a 60-Hz voltage, the conductor would have to make 1800 rpm. This would mean that the conductor would make one revolution in $\frac{60}{1800}$ or $\frac{1}{30}$ s. Since the voltage goes through two cycles in one revolution (see Fig. 1.37), it takes $\frac{1}{60}$ s for one cycle. This means that in $\frac{1}{60}$ s the conductor moves from position *A* to position *E*.

Refer to Fig. 1.37 and take *A* position as zero instant of time and as zero electrical degrees. When the conductor has moved from position *A* to position *B*, it will have passed through $\frac{360}{4}$ or 90 electrical degrees, and the elapsed time will be $\frac{1}{4 \times 60}$ or $\frac{1}{240}$ s. Electrical degrees and time are therefore proportional. Instead of the instantaneous values of the voltage being plotted against time, they can be plotted against electrical degrees. These two methods of plotting such curves are shown in Figs. 1.35 and 1.36.

116. The word phase, which is used in ac terminology, refers basically to time. When two alternating currents are in phase, they reach their corresponding zero, maximum, and intermediate values at exactly the same instants. Two in-phase ac quantities are shown in Fig. 1.38. If currents or voltages are not in phase, they reach corresponding values at different instants of time, as shown in Fig. 1.39.

FIGURE 1.38 Two alternating currents in phase. **FIGURE 1.39** Two alternating currents out of phase.

Since electrical degrees are proportional to time, it is a standard practice to state the out-of-phase relation of two quantities in electrical degrees. In specifying the phase relation of two quantities, it is necessary to state whether the relationship is leading or lagging. For example, in Fig. 1.39, it is not complete to state that quantity *A* is 45 degrees out of phase with *B*. The correct statement is either “*A* leads *B* by 45 degrees” or “*B* lags *A* by 45 degrees.” The number of degrees that two quantities are out of phase is the number of electrical degrees that must elapse in the time between the occurrence of a certain instantaneous value of one quantity and the occurrence of the corresponding instantaneous value of the other quantity. For example, in Fig. 1.39 quantity *B* does not reach its maximum positive value until 45 degrees after quantity *A* has reached its maximum positive value. Quantity *B* therefore lags quantity *A* by 45 degrees. The number of electrical degrees that two quantities are out of phase is called the *phase angle*.

117. A three-phase current consists of three different alternating currents out of phase 120 degrees with each other. A two-phase current consists of two different alternating currents out of phase 90 degrees with each other.

118. The maximum value of an alternating current or voltage is the greatest value that it attains. This is an instantaneous value (see Fig. 1.40).

FIGURE 1.40 Alternating emf values.

119. The so-called average value of an alternating current or voltage is the average of the instantaneous values for $\frac{1}{2}$ cycle. Average values are not of much use to practical people.

120. Effective values of alternating current and voltage are the ones ordinarily referred to when we speak of alternating quantities. Alternating voltages and currents are constantly changing in value, within a certain range, from instant to instant even if the load is constant. It is not practicable to deal with or indicate with instruments these constantly changing values. The effective value of an alternating current or voltage is the value of a direct current or voltage that would have the same heating effect. A sinusoidal alternating current which has a maximum value of 14.14 A will have the same heating effect as a 10-A direct current. The effective value of the alternating current is therefore 10 A. Practical people deal almost exclusively with effective values. Alternating-current measuring instruments indicate effective values. The relation between effective and maximum values for sinusoidal quantities is given below and illustrated in Fig. 1.40. Effective value is also referred to as rms (root mean square) value.

$$\text{Effective value} = 0.707 \times \text{maximum value} \tag{33}$$

$$\text{Maximum value} = \frac{\text{effective value}}{0.707} \tag{34}$$

EXAMPLE What is the effective voltage of a circuit that has a maximum voltage of 156?

SOLUTION Substitute in the formula,

$$\text{Effective value} = 0.707 \times \text{maximum value} = 0.707 \times 156 = 110 \text{ V}$$

EXAMPLE If a voltmeter on an ac circuit reads 2200, what is the maximum instantaneous voltage?

SOLUTION Substitute in the formula,

$$\text{Effective value} = \frac{\text{effective value}}{0.707} = \frac{2200}{0.707} = 3110 \text{ V}$$

121. Characteristics of ac circuits. All three of the circuit characteristics, resistance, inductance, and capacitance, may affect the value of the current in an ac circuit.

122. Resistance of ac circuits. As mentioned in Sec. 90, the resistance of a circuit to alternating current may be considerably different from its resistance to direct current. This increase in the resistance may be due to two factors. One factor, which takes place inside the conductors, is called *skin effect* and is discussed in the following sections. The other factor is due to the proximity of magnetic and electrical conducting material to the circuit. The varying magnetic field produced by the alternating current results in electric and magnetic power losses in these neighboring materials. These power losses must be supplied by the power delivered to the electric circuit and therefore result in increasing the effective resistance of the circuit over what it was for direct current. Refer to Sec. 157 for examples of effective resistance to an alternating current.

123. Skin effect. When an alternating current flows through a conductor, there is an inductive action whereby the current in the conductor is forced toward its surface. The current density is greater at the surface than at the center, and under certain conditions practically no current may flow along the axis of the conductor. Although skin effect and self-induction both originate from the same magnetic field, they are not otherwise related. Since skin effect increases voltage drop and energy loss, it amounts to an increase in resistance and is so considered. Nonconducting cores are sometimes placed in the centers of large cables for alternating currents so that all the metal will be effectively used (see Div. 2 for such conductors).

124. Skin effect in conductors of magnetic materials is much greater than in those of nonmagnetic materials owing to the stronger magnetic field that a given current will set up in a magnetic metal.

125. The effect of inductance in an ac circuit is that it produces opposition to the flow of the current and tends to make the current lag behind the voltage in time or phase. If a pure inductive circuit (one with only inductance and no resistance) could be built, the current would lag 90 degrees, or $1/4$ cycle, behind the voltage. In actual circuits containing both resistance and inductance, the current will lag some angle between 0 and 90 degrees behind the voltage. The angle of lag will depend upon relative resistance and inductance.

126. The opposition to alternating current which is produced by inductance is called *inductive reactance* (see Sec. 47). For a sinusoidal current the value of the inductive reactance is

$$X_L = 2\pi fL \quad (35)$$

where X_L = inductive reactance in ohms, f = frequency in hertz, and L = inductance in henrys.

127. The angle of lag of a current in an inductive circuit can be calculated from the following equation:

$$\text{Tangent of angle of lag} = \frac{X_L}{R} \quad (36)$$

where X_L = inductive reactance in ohms and R = ac resistance (not dc resistance). Also see method of Sec. 133.

128. The effect of capacitance in an ac circuit is that it produces opposition to the flow of the current and tends to make the current lead the voltage. For a pure capacitive circuit (one with only capacitance and no resistance) the current will lead the voltage by 90 degrees, or $1/4$ cycle. For a circuit with both resistance and capacitance, the current will lead the voltage by some angle between 0 and 90 degrees, depending upon the relative value of the resistance and the capacitance.

129. The opposition to alternating current which is produced by capacitance is called *capacitive reactance* (see Sec. 50). For a circuit with sinusoidal relations the value of the capacitive reactance is

$$X_c = \frac{1}{2\pi fc} \quad (37)$$

where X_c = capacitive reactance in ohms, f = frequency in hertz, and c = capacity in farads.

130. The angle of lead of a current in a capacitive circuit can be calculated from the following equation:

$$\text{Tangent of angle of lead} = \frac{X_c}{R} \quad (38)$$

where X_c = capacitive reactance in ohms and R = ac resistance (not dc resistance). Also see method of Sec. 133.

131. Impedance is the name given to the total opposition to the flow of alternating current. It is the combined opposition of resistance, inductive reactance, and capacitive reactance. Impedance is measured in ohms and is expressed by the symbol Z . The impedance of a series circuit may be calculated by the following formulas:

For a circuit containing resistance, inductance, and capacitance

$$Z = \sqrt{R^2 + (X_L - X_c)^2} \quad (39)$$

For a circuit containing resistance and inductance

$$Z = \sqrt{R^2 + X_L^2} \quad (40)$$

For a circuit containing resistance and capacitance

$$Z = \sqrt{R^2 + X_c^2} \quad (41)$$

For a circuit containing only resistance

$$Z = R \quad (42)$$

For a circuit containing only inductance

$$Z = X_L \quad (43)$$

For a circuit containing only capacitance

$$Z = X_c \quad (44)$$

where Z = impedance in ohms, X_L = inductive reactance in ohms, and X_c = capacitive reactance in ohms.

132. Relations between voltage, current, and impedance are

$$E = IZ \quad (45)$$

$$I = \frac{E}{Z} \quad (46)$$

$$Z = \frac{E}{I} \quad (47)$$

where E = voltage impressed on circuit in volts, I = current in amperes, and Z = impedance in ohms.

The above equations apply to complete ac circuits or any portions of a circuit which do not contain any emf other than the impressed voltage. For a motor circuit, therefore, they will apply only to the line-conductor portion of the circuit. They will give the voltage required to overcome line impedance, the IZ voltage of the circuit.

It is noticed that Ohm's law (Sec. 105) can be used for a complete ac circuit only when the circuit contains only resistance.

133. The phase angle of a circuit containing only resistance, inductance, and capacitance can be found from the following formula:

$$\text{Cosine of phase angle} = \frac{R}{Z} \quad (48)$$

where Z = impedance in ohms and R = resistance in ohms.

134. Power in ac circuits. The power of an ac circuit is very seldom equal to the direct product of the volts and amperes. To calculate the power of a single-phase ac circuit, the product of the volts and amperes must be multiplied by the power factor (see Sec. 136).

135. Apparent power is the term applied to the product of voltage and current in an ac circuit. It is expressed in voltamperes (VA) or in kilovolt-amperes (kVA) or megavolt-amperes (MVA).

136. Power factor is the ratio of the true power or watts to the apparent power or voltamperes. The power factor is expressed as a decimal or in percentage. Thus power factors of 0.8 and of 80 percent are the same. In giving the power factor of a circuit, state whether it is leading or lagging. The current is always taken with respect to the voltage. A power factor of 0.75 lagging means that the current lags the voltage. The power factor may have a value anywhere between 0 and 1.0 but can never be greater than 1.0.

EXAMPLE In Fig. 1.41, which shows a single-phase circuit, the ammeter I reads 10 A, and the voltmeter E 220 V. The apparent power is the product of volts and amperes, or

FIGURE 1.41 Example of power factor.

$IE = 10 \times 220 = 2200$ VA. But the wattmeter W reads 1870 W. A wattmeter always indicates real or true power. Therefore, the power factor (for a single-phase circuit) is

$$\text{Power factor} = \frac{\text{true watts}}{\text{apparent power}} = \frac{1870}{2200} = 0.85 \text{ or } 85 \text{ percent}$$

137. The cosine of the angle of lag or lead is equal to the power factor. Cosines for different angles can be found in trigonometric tables in handbooks (see Sec. 1). The symbol θ , the Greek letter “theta,” is often used to designate the angle of lag or lead; hence power factor is sometimes referred to as $\cos \theta$ (cosine theta). This means the cosine of the angle θ .

138. The power factor in a noninductive circuit, one containing resistance only, is always 1, or 100 percent; i.e., the product of volts and amperes in such a circuit gives true power.

139. The power factor in a circuit containing inductance or capacitance may be anything between 0 and 1 (0 and 100 percent), depending on the amount of inductance or capacitance in the circuit.

140. Typical power factors of various kinds of central-station loads are as follows:

Incandescent Lighting. 1.0.

Incandescent Lighting with Small Step-Down Transformers. 0.95 to 0.98.

Incandescent Street-Lighting Series Circuits. 0.6 to 0.8.

Sodium-Vapor Street Lighting, Parallel Circuits. 0.8 to 0.85.

Sodium-Vapor Street Lighting, Series Circuits. 0.5 to 0.7.

Fluorescent Lighting. 0.5 to 0.95, depending on type of auxiliary used.

Mercury-Vapor Lighting. 0.5 to 0.95, depending on type of auxiliary used.

Single-Phase Induction Motors; Squirrel-Cage Rotor. $\frac{1}{20}$ to 1 hp, power factor, 0.55 to 0.75, average 0.68 at rated load; 1 to 10 hp, power factor, 0.75 to 0.86, average 0.82 at rated load.

Polyphase Induction Motors; Squirrel-Cage Rotor. 1 to 10 hp, power factor, 0.75 to 0.91, average 0.85 at rated load; 10 to 50 hp, power factor, 0.85 to 0.92, average 0.89 at rated load.

Polyphase Induction Motors; Phase-Wound Rotors. 5 to 20 hp, power factor, 0.80 to 0.89, average 0.86 at rated load; 20 to 100 hp, power factor, 0.82 to 0.90, average 0.87 at rated load.

Induction-Motor Loads in General. Power factor, 0.60 to 0.85, depending on whether motors are carrying their rated loads.

Rotary Converters, Compound-Wound. Power factor at full load can be adjusted to practically 100 percent. At light loads it will be lagging and at overloads slightly leading.

Rotary Converters, Shunt-Wound. Power factor can be adjusted to any desired value and will be fairly constant at all loads with the same field rheostat adjustment. Rotary converters, however, should not be operated below 0.95 power factor leading or lagging at full load or overload.

Small Heating Apparatus. This load has the same characteristics as an incandescent-lighting load. The power factor of the load unit is practically 1, but the distributing transformers will lower it to some extent.

Arc Furnaces. Power factor, 0.80 to 0.90.

Induction Furnaces. Power factor, 0.60 to 0.70.

Electric-Welding Transformers. Power factor, 0.50 to 0.70.

Synchronous Motors. Adjustment between 0.80 power factor leading to a power factor of 1. (1) Operating power factors above 0.95 will be obtained only when practically all the load consists of synchronous motors or converters which can be operated at practically a power factor of 1. (2) Power factors of 0.90 to 0.95 can be safely predicted only when the load is entirely incandescent lighting or heating or when a large noninductive load, such as synchronous motors or converters, is used with a smaller proportion of inductive motor load. (3) For the average central-station load, consisting of lighting and motor service, a power factor of 0.80 should be assumed. (4) A power factor of 0.70 should be assumed for a plant having a large proportion of induction motors, fluorescent lighting, electric furnaces, or electric-welding load.

141. Kilowatts and kilovolt-amperes (General Electric Company). The term *kilowatt* (kW) indicates the measure of power which is all available for work. Kilovolt-amperes (kVA) indicate the measure of apparent electric power made up of two components, an energy component and a wattless or induction component. Kilowatts indicate real power and kilovolt-amperes apparent power. They are identical only when current and voltage are in phase, i.e., when the power factor is 1. Ammeters and voltmeters indicate total effective current and voltage regardless of the power factor, while a wattmeter indicates the effective product of the instantaneous values of emf and current. A wattmeter, then, indicates real power.

Standard guarantees on ac generators are made on the basis of loads at 80 percent power factor. However, it must not be inferred that a given generator will deliver its rated power output at all power factors. The generator rating in kilowatts will be reduced in proportion to the power factor and probably in a greater ratio if the power factor is very low. The method of rating ac generators by kilovolt-amperes instead of by kilowatts is now in general use.

In discussing an ac load, it is well to state it in terms of kilowatts, power factor, and kilovolt-amperes; thus: 200 kW, 80 percent power factor (250 kVA). This shows that the current in the circuit corresponds to 250 kVA and heats the generator and conductors to that extent but that only 200 kW is available for doing work. An illustration of the distinction between kilowatts and kilovolt-amperes is given in Fig. 1.42.

FIGURE 1.42 Distinction between kilowatts and kilovolt-amperes.

142. Effects of low power factor. It is sometimes considered that the wattless component of a current at low power factor is circulated without an increase of mechanical input over that necessary for actual power requirements. This is inaccurate because internal work or losses due to this extra current are produced and must be supplied by the prime mover. Since these extra losses manifest themselves in heat, the capacity of the machine is reduced. Moreover, wattless components of current heat the line conductors, just as do energy components, and cause losses in them. The loss in any conductor (see Sec. 39) is always

$$W = I^2 R \tag{49}$$

where W = the loss in watts, I = the current in amperes in the conductor, and R = the resistance in ohms. It requires much larger equipment and conductors to deliver a certain amount of power at a low power factor than at a power factor close to 1.

143. Correction of low power factor. In industrial plants, excessively low power factor is usually due to underloaded induction motors because the power factor of motors is much less at partial loads than at full load. If motors are underloaded, new motors of smaller capacity should be substituted. Power factor can be corrected (1) by installing synchronous motors which, when overexcited, have the property of neutralizing the wattless or reactive components of currents or (2) by connecting static capacitors across the line.

144. A single-phase alternating emf will be induced in an armature coil (S_1 and F_1 , Fig. 1.43) which has its sides set, in a generator frame, the same distance apart as are a north and a south magnet that are forced to sweep continuously past the coil sides at a uniform speed. The distance between a north and a south pole is always called 180 electrical degrees. The distance between a north pole and the next north pole is called 360 electrical degrees. In any given generator, the circumferential distance is the same between any two adjacent north and south poles.

FIGURE 1.43 Elementary two-pole single-phase ac generator.

145. In actual ac single-phase generators there are a number of pairs of north and south poles arranged on a revolving-field structure. A corresponding number of coils, each having its sides set approximately 180 electrical degrees apart, is arranged around the

frame. Then the coils are connected in series so that their emf's will be additive. The combination of their emf's is the voltage which is impressed by the generator on the circuit. Some small revolving-armature ac generators have rotating armatures and stationary fields, but their principle is the same as that of the revolving-field machines.

146. For a single-phase circuit the relations between kilowatts and kilovolt-amperes are

$$\text{Kilovolt-amperes} = \frac{\text{volts} \times \text{amperes}}{1000} \quad \text{or} \quad \text{kVA} = \frac{E \times I}{1000} \quad (50)$$

$$\text{kW} = \text{kVA} \times \text{power factor} \quad \text{kVA} = \frac{\text{kW}}{\text{power factor}} \quad (51)$$

$$\text{Power factor} = \frac{\text{kW}}{\text{kVA}} \quad (52)$$

For an example see Fig. 1.42.

147. For a single-phase circuit, the following equations show the relations between power, current, voltage, and power factor:

$$I = \frac{W}{E \times \text{pf}} \quad E = \frac{W}{I \times \text{pf}} \quad W = E \times I \times \text{pf} \quad \text{pf} = \frac{W}{E \times I} \quad (53)$$

where I = current in amperes, W = power in watts, E = voltage between lines, and pf = power factor.

EXAMPLES Figures 1.43 and 1.44 show applications of the above equations. The product of volts and amperes (EI) is called voltamperes; see above paragraph.

FIGURE 1.44 A power-factor problem.

EXAMPLE In the circuit of Fig. 1.44, what is the actual load in watts? In kilowatts? Current = 40 A, voltage at load = 110, and power factor of load = 95 percent.

SOLUTION Substitute in the formula,

$$W = E \times I \times \text{pf} = 110 \times 40 \times 0.95 = 4180 \text{ W}$$

$$\text{kW} = \frac{W}{1000} = \frac{4180}{1000} = 4.18 \text{ kW}$$

FIGURE 1.45 Two-pole two-phase ac generator illustrating elementary principles.

148. A two-phase current consists of two currents that differ in phase by 90 degrees (see curves of Fig. 1.45). If two sets of coils are arranged on an armature (Fig. 1.45) so that their “starts” S_1 and S_2 are 90 electrical degrees apart, the emf in one set will attain its maximum value 90 degrees later than that in the other. The emf will force two-phase currents through an external circuit. Instead of being on the same armature, each of the sets of coils may be on different armatures which are so mechanically connected together as to preserve the 90-degree phase relation (see Div. 7, “Generators and Motors,” for information on practical machines).

149. Coil connections for two-phase windings. Figure 1.46 shows three methods of connecting two-phase generator coils.

FIGURE 1.46 Connections for two-phase-generator windings.

150. Relations of voltage, current, and power that apply to balanced two-phase circuits

$$I_p = \frac{W}{2E_p \times \text{pf}} \quad E = \frac{W}{2I_p \times \text{pf}} \quad W = 2E_p \times I_p \times \text{pf} \quad \text{pf} = \frac{W}{2E_p \times I_p} \quad (54)$$

$$\text{Kilovolt-amperes} = \frac{2E_p \times I_p}{1000} \quad \text{or} \quad \text{kVA} = \frac{\text{kW}}{\text{pf}} \quad (55)$$

$$kW = kVA \times pf \tag{56}$$

$$pf = \frac{kW}{kVA} \tag{57}$$

where I_p = phase current in amperes as designated in Fig. 1.46, E_p = phase voltage as designated in Fig. 1.46, W = power in watts, and pf = power factor.

151. Application of the two-phase system. Many years ago certain engineers advocated two-phase generators and distributing systems in preference to three-phase. They then believed that unbalanced load on the phases would have less adverse effect on the performance of the two-phase equipment. Experience has proved that the three-phase system is preferable to and more economical than the two-phase for both transmission and distribution. Two-phase equipment now is seldom purchased except for additions to existing two-phase installations. See Sec. 23 of Div. 3 for relative weights of copper for different systems.

152. A three-phase current consists of three alternating currents that differ in phase by 120 degrees, as indicated in Fig. 1.47. If three coils are arranged with their starts, S_1 , S_2 , and S_3 , 120 degrees apart on an armature (Fig. 1.47) and are connected each to an external circuit, a single-phase alternating emf will be impressed by each coil on its own external circuit when the field is rotated at uniform speed. The emf's will differ in phase by 120 degrees and therefore will constitute a three-phase system. The currents in the circuits will be 120 degrees out of phase with each other. Three single-phase generators, if mechanically coupled together so as to maintain a 120-degree phase relation, would produce a three-phase system.

Practical three-phase generators usually have more than two poles and consequently have more coils than are indicated in Fig. 1.47. Most ac generators have revolving fields and stationary armatures.

FIGURE 1.47 Two-pole three-phase alternator ensures 120° phase difference between emf's in line wires.

153. Phase connections. Figure 1.48 shows four methods of connecting the phases of a three-phase generator or other apparatus and the external circuits for each. Method I, although it would work, is seldom used for economic reasons given. It shows the elementary

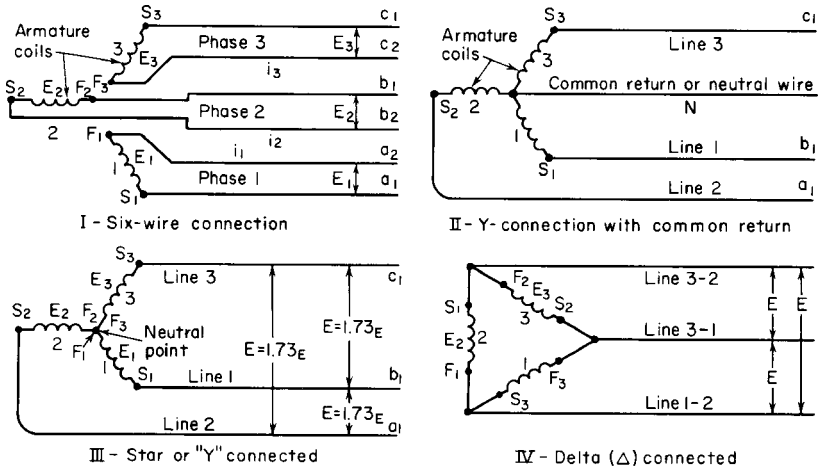

FIGURE 1.48 Connections for three-phase-generator windings.

three-phase circuit and illustrates the principle. Each of the three phases would carry a current differing in phase by 120 degrees from the currents in the other two. One common return, *N*, as shown at II, can be substituted for the three return wires of *I*. Now with a balanced load (one loading each of the phases equally) this return wire would carry no current; hence it may be omitted (star or Y connection of III). In IV is shown the delta connection.

154. The voltage and current relations in a star- or Y-connected three-phase circuit are indicated in Fig. 1.49. The armature coils of the generator shown in Fig. 1.49 are 120 electrical degrees apart (Fig. 1.47). These emf's will combine as shown in the phase diagram (Fig. 1.49) to produce the voltage *E* between line wires. The resultant voltage developed by any two of the coils is then equal to $\sqrt{3}$, or 1.73 times the voltage developed

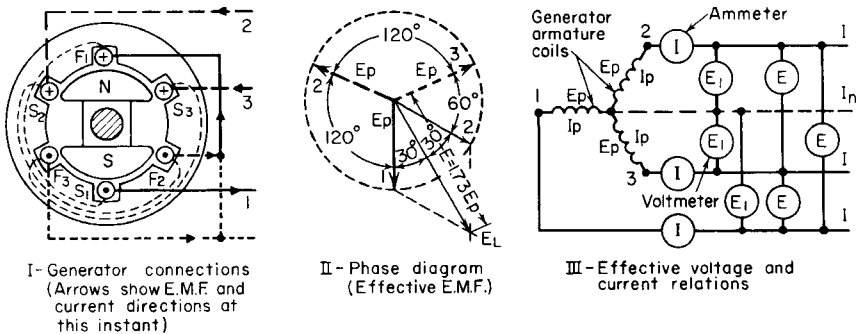

FIGURE 1.49 Star- or Y-connected three-phase generator and diagrams.

in one coil. The following formulas show the relation of voltage and current in the circuit. (All are effective values, and balance is assumed. See Fig. 1.49.)

$$I = I_p \tag{58}$$

$$E = E_p \times \sqrt{3} = E_p \times 1.73 \tag{59}$$

$$E_p = \frac{E}{\sqrt{3}} = \frac{E}{1.73} = E \times 0.577 \quad \text{or approximately } E_p = 0.58E \tag{60}$$

$$I_N = 0 = \sqrt{(I_p1)^2 + (I_p2)^2 + (I_p3)^2 - (I_p1 \cdot I_p2) - (I_p2 \cdot I_p3) - (I_p3 \cdot I_p1)} \tag{61}$$

where I = amperes per phase in the line, I_p = amperes per phase in each coil, E = volts between phase wires on the line, E_p = volts across each group of armature coils connected across each phase, and E_1 = volts between phase wires and neutral. The coils in Fig. 1.49, III, may represent the phase windings of a three-phase generator or transformer, or each coil may represent a transformer or other device, three of which are Y-connected.

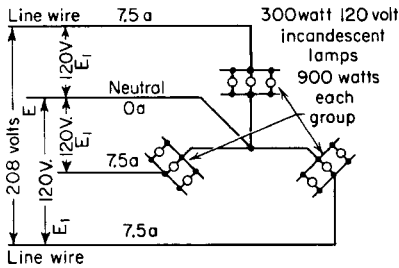

FIGURE 1.50 Incandescent-lamp groups connected in star or Y.

EXAMPLE What will be the voltage across line wires of the three-phase circuit for the 120-V Y-connected lamps in Fig. 1.50?

SOLUTION Substitute in the formula,

$$E = E_p \sqrt{3} = 120 \times 1.73 = 208 \text{ V}$$

155. Relations for a delta(Δ)-connected three-phase circuit

are shown in Fig. 1.51. When armature coils of a generator (see diagram I) are connected as indicated, the volt-

ages generated in them are 120 degrees apart. It would appear that the current might flow around through the coils and not into the external circuit, but it is evident from phase diagram II that the sum of the effective voltages 1 and 3 generated by two of the coils is equal and opposite to that of the third. Hence, instead of tending to force current around internally, the voltages tend to force current out into the line. The following formulas indicate

FIGURE 1.51 Delta(Δ)-connected three-phase generator and circuit.

the relations of the voltages and currents. (All are effective values, and circuit is assumed to be balanced. See Fig. 1.51.)

$$I_L = I_p \times \sqrt{3} = I_p \times 1.73 \tag{62}$$

$$I_p = \frac{I_L}{\sqrt{3}} = I_L \times 0.577 \quad \text{or approximately } I_p = I_L \times 0.58 \tag{63}$$

$$E = E_p \tag{64}$$

where the symbols have the same meanings as in Fig. 1.51, III.

NOTE: Each coil (Fig. 1.51) may represent the phase windings of a three-phase transformer or generator, or each coil may represent a transformer or other device, three of which are Δ -connected.

EXAMPLE If each of the coils of the generator in Fig. 1.51 can carry 100 A, what value of current may be drawn from the line wires leading from the machine?

SOLUTION Substitute in the formula,

$$I_L = I_p \times \sqrt{3} = 100 \times 1.73 = 173 \text{ A}$$

156. Relations of voltage, current, and power that apply to any balanced three-wire three-phase circuit either delta- or Y-connected. Refer to Fig. 1.52 for a key to the letters that appear in the following formulas. For a load with a power factor of 1,

$$I = \frac{W}{E \times \sqrt{3}} = \frac{0.577 \times W}{E} \quad \text{or approximately } = \frac{0.58 \times W}{E} \tag{65}$$

$$E = \frac{W}{I \times \sqrt{3}} = \frac{0.577 \times W}{I} \quad \text{or approximately } = \frac{0.58 \times W}{I} \tag{66}$$

$$W = E \times I \times \sqrt{3} = 1.73 \times E \times I \tag{67}$$

For any load

$$\text{pf} = \frac{W}{1.73 \times I \times E} = \frac{0.577 \times W}{I \times E} \quad \text{or approximately } = \frac{0.58 \times W}{I \times E} \tag{68}$$

$$E = \frac{W}{\text{pf} \times 1.73 \times I} = \frac{0.577 \times W}{\text{pf} \times I} \quad \text{or approximately } = \frac{0.58 \times W}{\text{pf} \times E} \tag{69}$$

$$I = \frac{W}{\text{pf} \times 1.73 \times E} = \frac{0.577 \times W}{\text{pf} \times E} \quad \text{or approximately } = \frac{0.58 \times W}{\text{pf} \times E} \tag{70}$$

$$W = 1.73 \times E \times I \times \text{pf} \tag{71}$$

$$\text{VA} = 1.73 \times E \times I \tag{72}$$

where I = line current, in each of the three wires, in amperes; W = the power transmitted by all three wires in watts; E = voltage across lines; and pf = the power factor of the circuit.

FIGURE 1.52 Relations for any Δ- or Y-connected three-phase circuit.

EXAMPLE What is the power factor in the 220-V circuit to the motor in Fig. 1.53? The three ammeters each indicate 90 A, and the three-phase wattmeter indicates 30 kW (30,000 W).

SOLUTION Substitute in the formula,

$$\begin{aligned}
 \text{pf} &= \frac{0.577 \times W}{I \times E} = 0.577 \times \frac{30,000}{90 \times 220} = \frac{17,310}{19,800} \\
 &= 0.88 = 88 \text{ percent power factor}
 \end{aligned}$$

FIGURE 1.53 Motor on a three-phase circuit.

EXAMPLE The power factor on the feeder of Fig. 1.54 is known to be 70 percent. The current in each line is 80 A, and the voltage across each phase is 220. What actual power is being delivered to the panel?

SOLUTION Substitute in the formula,

$$\begin{aligned}
 1.73 \times E \times I \times \text{pf} &= 1.73 \times 220 \times 80 \times 0.70 = 21,313.6 \text{ W} \\
 \text{kW} &= \frac{W}{1000} = \frac{21,313.6}{1000} = 21.3 \text{ kW}
 \end{aligned}$$

FIGURE 1.54 Load on a three-phase circuit.

EXAMPLES Figure 1.55 shows numerical examples of voltage and current relations in a three-phase circuit. Note that when a group of three devices or coils is connected in delta, as in the motor, each device or coil has line voltage impressed on it and must be designed for that voltage. The current in the line will be 1.73 times the current through the coil. When Y-connected, as on the low-voltage side of the transformers, each of the three coils need only be designed for 1/1.73, or 0.577 times the line voltage, and the line current will be the same as the current through each coil. Single-phase loads may be supplied either from line to neutral as with the 120-V lamps or from two lines as with the 208-V heater.

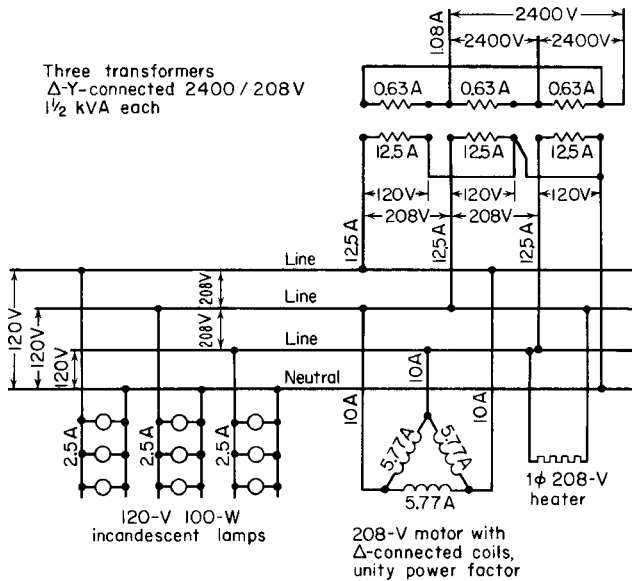

FIGURE 1.55 Examples of current and voltage relations in three-phase circuits.

157. The power loss in any circuit traversed by an alternating or a direct current is

$$W = I^2 \times R \quad \text{or} \quad I = \sqrt{\frac{W}{R}} \quad \text{or} \quad R = \frac{W}{I^2} \quad (73)$$

where W = the power lost in heat in the circuit in watts, I = effective current in amperes in the conductor, and R = resistance of the conductor in ohms. This rule is perfectly general and applies to all dc circuits and all ac circuits of ordinary voltages and frequencies. The watts power loss W reappears as heat power and heats the conductors. Watts loss is commonly called I^2R loss.

EXAMPLE What is the power loss in the incandescent lamp in Fig. 1.56?

SOLUTION Substitute in the formula,

$$W = I^2 \times R = (2.2 \times 2.2)98 = 4.84 \times 98 = 474 \text{ W}$$

FIGURE 1.56 Resistance in an ac circuit.

EXAMPLE What is the power loss in the inductive winding of Fig. 1.57 with an alternating current of 3 A?

SOLUTION Substitute in the formula,

$$W = I^2 \times R = (3 \times 3)7 = 9 \times 7 = 63 \text{ W}$$

FIGURE 1.57 Effective resistance in an inductive ac circuit.

NOTE: In the circuit of Fig. 1.57 the resistance of the coil to direct current is only 5 Ω. The increase in resistance to alternating current over its dc value is due to the power losses produced in the iron core (refer to Sec. 122).

158. Approximate Sparking Distances, in Air, for Various Mean Effective Voltages between Sharp Needle Points: Sine-Waveform Voltage

(Locke Insulators, Inc.)

Voltage	Distance		Voltage	Distance	
	In	Cm		In	Cm
1,000	0.06	0.152	20,000	1.00	2.54
2,000	0.13	0.33	25,000	1.30	3.3
3,000	0.16	0.41	30,000	1.63	4.1
4,000	0.22	0.56	35,000	2.00	5.1
5,000	0.23	0.57	40,000	2.45	6.2
10,000	0.47	1.19	50,000	3.55	9.0
15,000	0.73	1.84	100,000	9.60	24.4

NOTE: Above 100,000 V, the gap between needle points is approximately 1 in/10,000 V. Using infinitely sharp needle points up to at least 10,000 V, a graph of the voltage and the corresponding sparking distance would probably result in a straight line passing through the origin. (H. W. Fisher, *Trans. Int. Elect. Cong.*, vol. II, 1904, p. 294.)

159. Dielectric strength. When there is an emf between two conductors that are separated by an insulating material, electrical forces are exerted upon the electrons in the atoms of the insulating material. These forces are trying to pull the electrons out of the atoms. If they succeed in pulling the electrons out, the material ceases to be an insulator and becomes a conductor. When this occurs, it would be said that the insulation had broken down. When the voltage between the conductors is small, the forces exerted in the atoms are not great enough to pull the electrons out of the atoms. As the voltage between the conductors is increased, the forces on the electrons are increased. If the voltage continues to be increased, the forces will eventually become great enough to pull the electrons out of the atoms and the insulation will break down. The voltage at which the material ceases to be an insulator is called the *breakdown voltage*. Any insulating material can be broken down and cease to be an insulator if the voltage impressed across it is raised high enough. The breakdown voltage of any material depends upon the thickness, condition of the surface, and homogeneity of the material. The breakdown voltage does not increase directly with the thickness of the material; a piece of material 2 in thick will break down at a voltage less than twice the breakdown voltage of a piece 1 in thick. Any irregularities or sharp points on the surface will lower the breakdown voltage.

It is these considerations that govern the thickness of insulation required on conductors, the spacing of bare conductors, distance between live parts and ground, etc.

MEASURING, TESTING, AND INSTRUMENTS

160. The magneto test set is one of the most valuable testing instruments for practical people because of its simplicity and the fact that it is always ready for service. Figure 1.58 shows the circuit and Fig. 1.59 a perspective view of a testing magneto. The apparatus consists of a small hand-operated ac generator in series with a polarized electric bell. Alternating current will ring bells of this type. If the external circuit connected to the terminals of the magneto is closed and the crank of the generator is turned, current will flow and the bell will ring.

The resistance through which magnetos will ring is determined by their design. An ordinary magneto will ring through possibly 20,000 to 40,000 Ω . Electrostatic-capacity effects must be considered when testing with a magneto. When long circuits, such as telephone lines or circuits that are carried in cable for a considerable distance, are tested, the bell of the magneto may ring, owing to capacitance, apparently indicating a short circuit, whereas

FIGURE 1.58 Circuits of testing magneto.

FIGURE 1.59 Assembly of testing magneto.

FIGURE 1.60 Head-telephone and dry-battery testing set.

the circuit may be perfectly clear or open. Circuits associated with iron, such as field coils of generators, may have considerable inductance. With highly inductive circuits under test, the magneto may “ring open”; i.e., the bell may not ring at all even if the inductive circuit connected to it is actually closed. In ordinary interior-wiring work the effects of capacitance and inductance are usually negligible, and the true condition of the circuit will be indicated by the performance of the magneto bell.

161. A telephone receiver in combination with one or two dry cells constitutes excellent equipment for certain tests. A head-telephone receiver (Fig. 1.60) is usually preferable to a receiver of the watchcase type, because it is held on the head by a metal strap, allowing the unrestricted use of both hands. Metal testing clips are soldered to flexible testing cords. The telephone receiver is extremely sensitive and will give a weak click even when the current to it passes through an exceedingly high resistance. In use, one clip is gripped on one conductor of the circuit to be tested, and the other clip is tapped against the other conductor. Prolonged connection should be avoided because it will run down the battery. A vigorous click of the receiver indicates a closed circuit, while a weak click or none at all indicates an open circuit. After practice it is possible to determine approximately the resistance of the circuit under test by the intensity of the receiver click. When the battery and receiver test set are connected to a circuit having some electrostatic capacity, the receiver will give a vigorous click when the clips are first touched to the circuit terminals even if the circuit is open. With successive touchings the click will diminish in intensity if the circuit is open but will not diminish appreciably if the circuit is closed.

162. The advantages of the telephone receiver over the magneto for work of certain classes are: (1) The receiver-and-battery outfit costs little. (2) The outfit can be made so compact that it can be carried in a pocket. (3) In making insulation tests with a magneto the circuit may “ring clear”; i.e., the bell will not ring, apparently indicating high

insulation resistance, whereas the circuit may not be clear, but instead the magneto may be out of order or its local circuit may be open. The indication is negative. With the telephone receiver a slight click is produced even when testing through the highest resistances. The absence of a click usually signifies an open in the testing apparatus itself. Thus, the telephone-receiver indication is positive.

163. A telegraph sounder is sometimes used for testing. It is connected in the same way as the telephone receiver of Fig. 1.60 and is adaptable for rough work. When the circuit under test is closed and the flexible-cord clips are touched to the circuit conductors, the sounder clicks. When the circuit is open, there is no click. One feature of the sounder method is that the click is audible at a considerable distance from the instrument.

164. An electric-bell outfit for testing is shown in Fig. 1.61. When the free ends for testing are touched to a closed circuit of not too high resistance, the bell rings. If the circuit is open, the bell will not ring. Flexible cord can be used for the testing conductors of the outfit, and testing clips can be provided as in Fig. 1.60.

FIGURE 1.61 Electric-bell-testing outfit.

FIGURE 1.62 A practical test-lamp outfit.

165. A test lamp (Fig. 1.62), consisting merely of a weatherproof rubber-insulated socket into which is screwed an incandescent lamp of the highest voltage rating of the circuits involved, is very convenient for rough tests on interior-lighting and motor-wiring systems. Porcelain sockets are undesirable because they are so readily broken. Brass sockets should not be used because they may fall across conductors and thereby cause short circuits. Testing clips may be soldered to the ends of the leads which are molded in the socket. Some uses of the testing lamp are given below, and the lamp is very convenient in testing for defective fuses.

166. A very convenient and inexpensive test outfit consists of a pointer which moves along a scale inside an insulated case (Fig. 1.63). It indicates whether the circuit is alternating- or direct-current by vibrating on alternating current, the frequency of the vibrations showing whether the current is 25 or 60 Hz. It also indicates the range of voltage of

FIGURE 1.63 Voltage tester, 110 to 600 V. [Square D, Schneider Electric]

the circuit up to 550 ac or 600 dc. The sharp points on the ends of the lead wires can be used to pierce insulation for checking insulated leads without destroying the insulation.

FIGURE 1.64 Neon-glow lamp tester. [Littel-fuse, Inc.]

167. Neon-glow lamp testers provide a very convenient and compact device for determining if a circuit is live, for determining polarity of dc circuits, and for determining if a circuit is alternating- or direct-current. A neon tester for low-voltage work is illustrated in Fig. 1.64. It consists of a very small neon lamp in series with a 200,000- Ω protective resistance enclosed in a molded case. This tester is satisfactory for use on circuits of from 90 V dc or 60 V ac to 500 V ac or dc. With the test tips connected to a circuit, the presence of voltage within the above limits will be indicated by the glowing of the neon lamp. If both electrodes in the bulb glow, the voltage of the circuit is alternating. On direct current, only one electrode, the one connected to the negative side of the circuit, will glow. With experience the voltage of the line can be determined approximately by the intensity of the glow. In testing a circuit, it is best first to touch only one side of the line with one test tip, keeping the other test tip free. A glow with this connection will indicate the presence of high voltage. The tester shown is well constructed for safety. The molded case has a voltage breakdown value of 25,000 V and the leads are insulated for 5000 V and provided with insulated test prods. The testers are also available, as shown in Fig. 1.65, with the glow lamp in one of the tips, making it easier to see the voltage indication while looking at the tip placement. This arrangement also reduces the voltage reaching the leads. This tester is suitable for 80 to 600 V ac or dc.

168. A noncontact voltage tester is shown in Fig. 1.66. It provides both an audible and visual indication of voltage. Since it works by induction it is only rated for use on ac circuits, in this case from 40 to 600 V. It has the advantage that the insulation need not be disturbed or an exposed live part located in order for it to work; holding the tip on an energized conductor will make the tester respond.

FIGURE 1.65 Glow lamp tester in the probe tip. [Ideal Industries, Inc.]

FIGURE 1.66 Noncontact voltage tester. [Ideal Industries, Inc.]

169. Instruments for general-circuit and other industrial testing purposes are shown in Fig. 1.67. They are applicable for measurements on either dc or ac circuits. Only one instrument is required for measurements of voltage, current, and resistance.

FIGURE 1.67A Handheld digital multimeter. [Simpson Electric Co.]

FIGURE 1.67B Volt-ohm-milliammeter. [Simpson Electric Co.]

170. Rules for use of ammeter and voltmeter (William H. Timbie, *Elements of Electricity*). Place the ammeter in series, always using a short-circuiting switch, where possible, as shown in Fig. 1.68, to prevent injury to the instrument. Place the voltmeter in shunt (Fig. 1.68). Put the + side of the instrument on the + side of the line. Figure 1.68 shows the correct use of an ammeter and a voltmeter to measure the current and the voltage supplied to the motor. The short-circuiting switch S must be opened before the ammeter is read. All the current that enters the motor must then flow through the ammeter and be indicated. The ammeter is of very low resistance (about 0.001 or 0.002 Ω) and does not appreciably cut down the flow of current. The voltmeter is of very high resistance (about 15,000 Ω) and does not allow any appreciable current to flow through it. Yet enough goes through the voltmeter to cause it to indicate the voltage across the terminal AB of the motor. Let us suppose the voltage across the motor to be 110; what would happen if an ammeter of 0.002- Ω resistance were by mistake placed across AB ? (Remember that Ohm's law is always in operation.)

FIGURE 1.68 Ammeter and voltmeter connections.

171. All (except electrostatic) ammeters and voltmeters consume power when in use and introduce some error (William H. Timbie, *Elements of Electricity*). For minimum error (see Fig. 1.69, I) when measuring a low current and a high voltage, the voltmeter should be placed around both the ammeter and the apparatus under test.

When measuring the power consumed by a piece of apparatus through which a large current at low voltage is flowing, the voltmeter should be placed immediately across the piece of apparatus under test and should not include the ammeter (Fig. 1.69, II).

FIGURE 1.69 Correct methods of connecting instruments.

172. A method of measuring current with a voltmeter is shown in Fig. 1.70. If a resistor of known resistance is connected in series in a circuit and the voltage across the resistor is measured with a voltmeter, the current can be determined by Ohm's law.

FIGURE 1.70 Current measurement with voltmeter.

FIGURE 1.71 Millivoltmeters and shunts.

EXAMPLE (Fig. 1.70) If the drop around an $0.4\text{-}\Omega$ resistance in series in a circuit is 20 V , what is the current in the circuit?

SOLUTION Substitute in the Ohm's-law formula,

$$I = \frac{E}{R} = \frac{20}{0.4} = 50\text{ A}$$

173. A millivoltmeter is generally used for making measurements like that of Sec. 172. A millivoltmeter reads in thousandths of volts, so that a resistor of small resistance can be used. Ammeters, particularly those for large currents, are often millivoltmeters calibrated in amperes which are connected around a resistor, in series with the circuit (Fig. 1.71). The resistor sometimes is in the instrument case and sometimes is inserted in the busbars of a switchboard (see Fig. 1.71). Resistors of this type are called *shunts* and when furnished by instrument makers are carefully calibrated.

174. Split-jaw ammeters provide very useful and convenient test instruments. In many instances when it is desired to measure the current flowing in a cable or other conductor, it is inconvenient, even if it is permissible to break the circuit, to insert an ammeter. These instruments instantly measure alternating or direct current without opening or interrupting the circuit. Merely encircle the conductor with the jaws as illustrated in Fig. 1.72. As soon as the jaws close, a clear, accurate reading is instantly registered on the scale.

FIGURE 1.72 Application of a split-jaw ammeter. [Martindale Electric Co.]

For best results on circuits having harmonic content, as covered in Sec. 220, be sure to look for a meter advertising a "true RMS" capability. These meters compensate for harmonic waveforms and make certain that the instrument reports total amperage correctly.

When dc measurements are made, some meter instructions advise that the jaws should be opened and closed immediately before the reading is taken to reduce the error caused by hysteresis if the current is rising or falling. If the current is steady, the error can be minimized by reversing the tongs and taking the average of the two readings.

175. Resistances can be measured with a voltmeter as indicated in Fig. 1.73. This method is satisfactory for the measurement of resistances whose values range from a few to a few hundred ohms. A resistor of known resistance, a source of direct current, and one voltmeter are required. The same constant current flows through both the known and the unknown resistance. The voltmeter reading E is taken, and then the reading E_x . The voltage drops will be proportional to the resistances or

$$\frac{R}{E} = \frac{R_x}{E_x} \quad \text{or} \quad R_x = \frac{E_x \times R}{E} \quad (74)$$

EXAMPLE Substituting the values from Fig. 1.73 in the formula,

$$R_x = \frac{E_x \times R}{E} = \frac{42 \times 2}{30} = \frac{84}{30} = 2.8 \Omega$$

FIGURE 1.73 Resistance measurement.

FIGURE 1.74 Measurement of very low resistance.

176. Very small resistances can be measured, as indicated in Fig. 1.74, with an ammeter and a millivoltmeter. This method is generally satisfactory for resistances having a value of less than 1Ω and is convenient for measuring the resistance of busbars, joints between conductors, switch contacts, brush-contact resistance, and other low resistances. As large a current as is feasible should be used. This is another application of Ohm's law.

EXAMPLE What is the resistance of the portion of the busbar between A and B , Fig. 1.74?

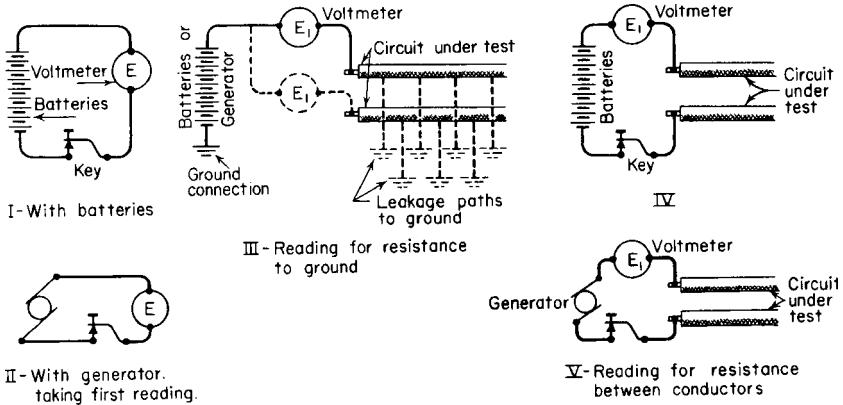

SOLUTION Substitute in Ohm's-law formula,

$$R = \frac{E}{I} = \frac{0.008}{50} = 0.00016 \Omega$$

In the application of Ohm's law as given here, the current through the voltmeter is neglected. Since the resistance of the voltmeter is generally large compared with the resistance to be measured, the error caused by neglecting the voltmeter current is generally negligible.

177. Insulation resistance is frequently measured as suggested in Fig. 1.75. A voltmeter of known resistance, preferably of high resistance, and a source of emf (batteries or a generator) are required. First the voltage of the emf source is taken as shown in diagram I or II. The apparatus is then arranged as shown in diagram III to measure the resistance from each side of the circuit to ground. In diagram IV or V are shown the connections for measuring the resistance between conductors. If E = voltage of source, E_1 = reading of the voltmeter when connected in series with insulation resistance to be measured, R_v = resistance in ohms of the voltmeter, and R_x = insulation resistance sought, the following formula is used (see Fig. 1.75):

$$R_x = R_v \left(\frac{E}{E_1} - 1 \right) \tag{75}$$

EXAMPLE In a certain test (Fig. 1.76) in which a 110-V generator was used as a source of emf and a voltmeter having a resistance of $15,000 \Omega$ was used to read voltages, the readings indicated in Fig. 1.76 were obtained. What was the insulation resistance to ground of each side of the circuit, and what was the insulation resistance between circuits?

SOLUTION For the resistance of conductor 1 (see Fig. 1.76) substitute in the formula,

$$\begin{aligned} R_x &= R_v \left(\frac{E}{E_1} - 1 \right) = 15,000 \left(\frac{100}{5} - 1 \right) = 15,000(22 - 1) = 15,000 \times 21 \\ &= 315,000 \Omega = \text{insulation resistance of counter 1 to ground} \end{aligned}$$

For the resistance of conductor 2 (see Fig. 1.76, III),

$$\begin{aligned} R_x &= R_v \left(\frac{E}{E_1} - 1 \right) = 15,000 \left(\frac{100}{4} - 1 \right) = 15,000(27.5 - 1) = 15,000 \times 26.5 \\ &= 397,500 \Omega = \text{insulation resistance of counter 2 to ground} \end{aligned}$$

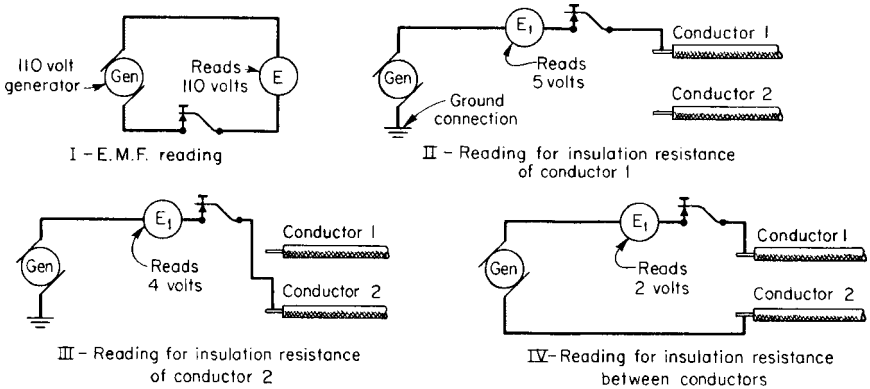

FIGURE 1.76 Example of insulation-resistance measurement.

For the insulation resistance between conductors,

$$R_x = R_v \left(\frac{E}{E_1} - 1 \right) = 15,000 \left(\frac{100}{2} - 1 \right) = 15,000(55 - 1) = 15,000 \times 54$$

$$= 810,000 \Omega = \text{insulation resistance between conductors 1 and 2}$$

FIGURE 1.77 Measuring insulation resistance of a generator.

178. The insulation resistance of a generator can be determined with a voltmeter of known resistance which is successively connected and read in positions I and II (Fig. 1.77). The formula of Sec. 177 is used. The external circuit connected to the generator should be cut off while the measurements are being taken so that its insulation resistance will not affect the readings.

179. The insulation resistance of motors, generators, electrical apparatus cables, and insulated conductors can be determined by the use of insulation testers utilizing microprocessor technology. See Fig. 1.78. These testers can be used in troubleshooting, preventative maintenance, and quality assurance programs. In preventive maintenance programs the apparatus or conductors are tested periodically and a written history is kept of the results. Trends showing lower resistance readings can detect failures, such as motor winding burnout, and reduction of downtime before failure or breakdown can be an economic bonus.

180. The ohmmeter is an instrument to measure resistance directly. The one illustrated in Fig. 1.79 has laboratory accuracy. It is especially advantageous for work in the field, since its small size allows the meter to be carried in the field. The meter is operated by rechargeable batteries with internal charger, which is mounted inside the meter case.

FIGURE 1.78 Megger microprocessor technology insulation tester. [Biddle Instruments, AVO International]

FIGURE 1.79 Digital low-resistance ohmmeter. [Biddle Instruments, AVO International]

181. A resistance tester (Fig. 1.80) is an instrument frequently used to measure high resistance. It consists of a magneto which is turned by a crank on the side of the case. The scale is calibrated directly in ohms. The resistance to be measured is connected across two terminals. The crank is turned at a moderate speed (about 120 rpm) until the pointer reaches a steady deflection.

FIGURE 1.80 Megger. [Biddle Instruments]

182. Power, in dc electric circuits or single-phase ac electric circuits with a power factor of 1, can be measured with a voltmeter and an ammeter. For two-wire circuits the power in watts, in accordance with Ohm's law, equals the product of volts times amperes; thus,

$$W = I \times E \tag{76}$$

where W = the power in watts, I = the current in amperes, and E = the emf in volts.

EXAMPLE See Sec. 111 for examples of power problems. Although no instruments are shown in these, the principles are the same as if instruments were used.

EXAMPLE In Fig. 1.81, I, the power taken by the motor is, substituting in the formula,

$$W = I \times E = 40 \times 220 = 8800 \text{ W}$$

or in kilowatts $= 8800/1000 = 8.8 \text{ kW}$.

FIGURE 1.81 Power measurements.

EXAMPLE In Fig. 1.81, II, the power taken by the lamps is

$$W = I \times E = 3 \times 100 = 330 \text{ W}$$

or in kilowatts $330/1000 = 0.33 \text{ kW}$.

183. Power in single-phase ac circuits must be measured with a wattmeter unless the power factor is 1. A wattmeter can also be employed for measuring the power of a dc circuit. A wattmeter has two internal coils, namely, a voltage coil and a current coil. The voltage coil is connected across the circuit in which the power is to be measured, and the current coil is connected in series with the circuit. The wattmeter gives a direct indication of the power of the circuit. Two methods of connecting a wattmeter for measuring the power of a dc circuit or of a single-phase ac circuit are shown in Figs. 1.41 and 1.42. In Fig. 1.41 the voltage coil is connected between the generator and the current coil of the wattmeter, while in Fig. 1.42 the voltage coil is connected between the load and the current coil of the wattmeter. The connection of Fig. 1.41 should be used for loads of small current and that of Fig. 1.42 for loads of large current.

184. Power in a two-phase system can be measured with two single-phase wattmeters connected as shown in Fig. 1.82. Each phase is treated as a separate circuit. One wattmeter reads the power of one phase and the other the power of the second phase. The total power is the arithmetical sum of the two wattmeter readings:

$$\text{Total power} = W_1 + W_2 \tag{77}$$

A polyphase wattmeter, connected as shown in Fig. 1.82, III, can be used for the measurement of the power of a two-phase system.

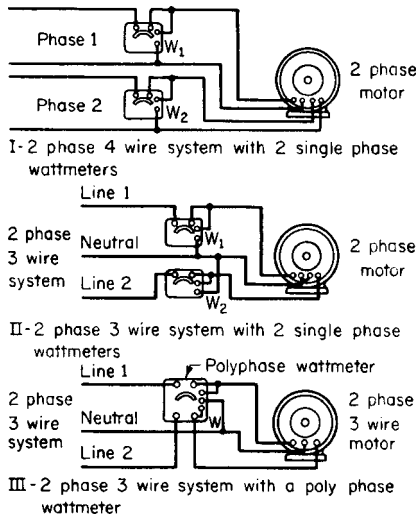

FIGURE 1.82 Measurement of power in two-phase systems.

185. Power in three-phase circuits can be measured with wattmeters by several different methods (see Fig. 1.83). In diagram I a polyphase wattmeter is shown. An instrument of this type automatically adds the portions of power consumed in each phase and indicates their sum. Instruments made by different manufacturers are arranged differently and must be connected accordingly. Directions accompany each instrument. Diagrams II and III show how the power can be measured, in a balanced circuit, with one

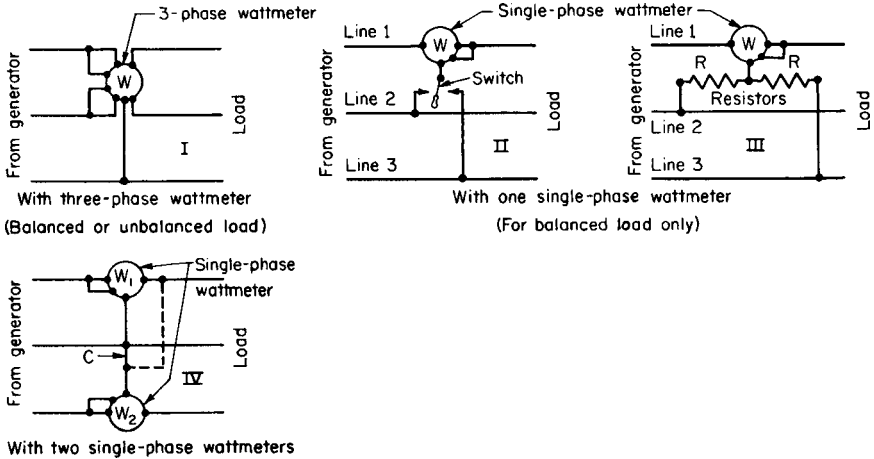

FIGURE 1.83 Three-phase power measurements with wattmeters.

wattmeter. One potential lead is connected to the line in which the wattmeter is inserted, and the other potential lead is connected successively to the other two lines. The total power in diagram II is equal to the sum or difference of the two readings. If resistors are used as indicated in diagram III, the power can be ascertained without shifting leads. The wattmeter reading of diagram III multiplied by 3 will be the true power in a balanced circuit. The resistance of each of the resistors R and R must equal the resistance of the potential or voltage coil of the wattmeter.

With two wattmeters (as in Fig. 1.83, IV) the total power is equal to the sum or difference of the two wattmeter readings. If the power factor is greater than 0.50, the total power is the arithmetical sum of the readings. If it is lower than 0.50, one of the readings is negative, and the power is the arithmetical difference of the two. To ascertain whether one of the wattmeters is reading negative, temporarily transfer the connection of one of the potential wires (for example, c in diagram IV, as shown by the dotted line) from the middle wire to the outside wire. If its wattmeter reverses, one of the instruments, that of the lesser indication, is reading negatively. The nature of the load usually enables one to judge roughly what the power factor is. With incandescent lamps and fully loaded motors the power factor will be high, but with underloaded and lightly loaded motors it is likely to be low. See Sec. 187 for the method of determining the power factor of three-phase circuits with wattmeters.

186. The power factor of a circuit can be determined from readings of volt-meters, ammeters, and wattmeters by use of the formulas of Secs. 146, 147, 150, and 156. The power factor of circuits can also be determined by instruments called *power-factor meters*, which when properly connected in a circuit read the power factor directly.

187. The method of determining three-phase power factor with wattmeters was well described by C. E. Howell in *Electrical World*. It is necessary to know the power factor to connect wattour meters correctly if the wiring is concealed. An abstract follows.

Case I: - Both readings positive. Divide smaller by larger reading. Find this ratio on right side of center line above. Follow up the ordinate at this point to its intersection with curve. Opposite this on center line find corresponding percent power factor (above 50 percent)

Case II: - One reading negative. Divide negative by positive reading. Find this ratio on left side of center line above. Follow up the ordinate at this point to its intersection with curve. Opposite this on center line find corresponding percent power factor (below 50 percent)

FIGURE 1.84 Power-factor curve.

Figure 1.84 shows the power-factor curve for two single-phase meters on a polyphase circuit. It also gives a diagram of connections and instructions on using the curve. The figure should be self-explanatory. Figure 1.85 gives, first, a method of checking results obtained by employing the curve in Fig. 1.84 and a diagram of the connections for obtaining data for the check. The second part of Fig. 1.85 gives a method of determining correct connections for two single-phase meters or one polyphase meter on a three-phase circuit. If this part of Fig. 1.85 is followed, errors in meter connections on three-phase circuits due to the power factor being near 50 percent should be minimal.

The above instructions may be illustrated as follows. A 100-hp three-phase 440-V induction motor was operating on 30 percent full load or 30 hp (29.8 kW) at 60 percent power factor (determined afterward) when an order came through to place a polyphase watt-hour meter on the installation. Immediately after the meter had been connected the following question was asked: "Should the light element add to or subtract from the heavy element; i.e., is the power factor above or below 50 percent?" As the meter leads were encased in pipe, they could not be traced; therefore the instructions in the second figure pertaining to this point were applied. The connected load of the motor having been thrown off, it was found that one element of the meter gave a negative reading. Sufficient load was then put on to bring the motor to about 80 percent of its full-load rating. Each element of the meter (taken separately) now read positively, but the element on which no load gave a negative reading, on 80 percent load read lower than the heavy element. The meter had been correctly connected when installed. Later both methods given above to determine the power factor of a three-phase circuit were applied, and both gave approximately 60 percent power factor (at 30 percent load).

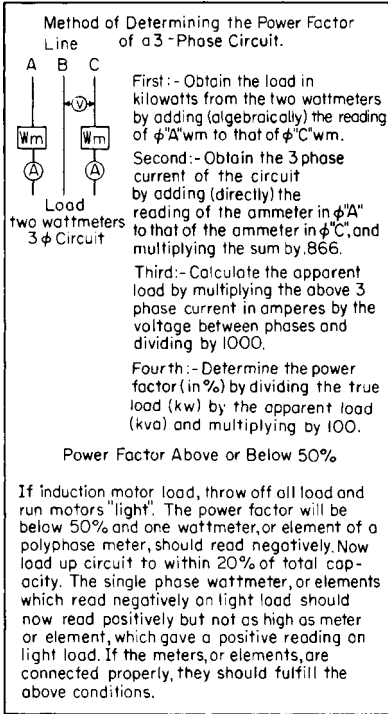

FIGURE 1.85 Chart of instructions for power-factor test.

188. To read correctly the consumption indicated on the dials of a recording wattour meter (sometimes, but erroneously, called a recording wattmeter), the directions given below should be followed (*Rules and Regulations* of the Commonwealth Edison Co., Chicago; see Fig. 1.86 for examples).

The pointer on the right-hand dial of a five-dial meter registers $\frac{1}{10}$ kWh or 100 Wh for each division of the dial. A complete revolution of the hand on this dial will move the hand of the second dial one division and register 1 kWh or 1000 Wh. A complete revolution of the hand of the second dial will move the third hand one division and register 10 kWh or 10,000 Wh, and so on.

Accordingly, read the hands from left to right and add two ciphers to the reading of the lowest dial to obtain the reading of the meter in watthours. If there are four dials on the meter, the pointer on the right-hand dial registers 1 kWh or 1000 Wh for each division of the dial, and it is necessary to add three ciphers to the reading on the lowest dial to obtain the reading in watthours, or the meter reads directly in kilowatthours.

Hands should always be read as indicating the figure which they have last passed, not the one to which they are nearest. Thus, if a hand

Reading 9499 kilowatt hours
Fort Wayne Type Watt Meter

Reading 1,188,900 watt hours
Thompson Recording Watt Meter

Reading 1965.9 kilowatt hour
Fort Wayne Type k Watt Meter

Reading 8889 kilowatt hours
Thompson Recording Watt Meter

FIGURE 1.86 Examples of wattour-meter readings.

is very close to a figure, whether it has passed this figure or not must be determined from the next lower dial. If the hand of the lower dial has just completed a revolution, the hand of the higher dial has passed the figure, but if the hand of the lower dial has not completed a revolution, the hand of the higher dial has not yet reached the figure even though it may appear to have done so.

When one pointer is on 9, special care must be taken that the pointer on the next higher dial is not read too high, as it will appear to have reached the next number but will not have done so until the hand at 9 has come to 0.

The hands on adjacent dials revolve in opposite directions. Therefore, a reading should always be checked after being written down, as it is easy to mistake the direction of the rotation. To determine the consumption for a given time, subtract the reading at the beginning of the period from the reading at the end. Always observe if a constant is marked at the bottom of the dial plate. If so, the difference of the readings must be multiplied by this constant to obtain the consumption.

189. The Wheatstone bridge is an instrument for measuring medium and high resistances. It is not suitable for measuring resistances of less than 1 Ω. An elementary diagram is shown in Fig. 1.87. R_1 , R_2 , and R are adjustable resistances, R_x is the unknown resistance, and G is a delicate galvanometer. A battery supplies emf. It can be shown that if, when both keys are pressed the galvanometer shows no deflection, then

FIGURE 1.87 Elementary diagram of the Wheatstone bridge.

$$\frac{R_1}{R} \quad \text{or} \quad R_x = \left(\frac{R_2}{R_1}\right)R \quad (78)$$

EXAMPLE If $R_2 = 100 \Omega$, $R_1 = 10 \Omega$, and $R = 672 \Omega$, what is the value of the unknown resistance?

SOLUTION Substitute in the formula,

$$R_x = \left(\frac{R_2}{R_1}\right)R = \left(\frac{100}{10}\right)672 = 10 \times 672 = 6720 \Omega$$

The unknown resistance is 6720 Ω.

In commercial bridges, the adjustable resistances R_2 and R_1 are usually so arranged that the ratio R_2/R_1 will be a fraction like $1/10$ or $1/100$ or a number like 10 or 100 so that R_x can be obtained readily by dividing or multiplying R by an easily handled number. R_1 and R_2 are sometimes called the *ratio arms*, and R is called the *rheostat arm*. For most accurate results the resistances R , R_1 , and R_2 should be as nearly as possible equal to R_x .

190. A diagram of a commercial bridge of the post-office pattern is shown in Fig. 1.88. Its principle is similar to that of Fig. 1.87. Brass plugs are used to vary the resistance in the arms R , R_1 , and R_2 . When a plug is inserted in the opening between two resistance

FIGURE 1.88 Post-office pattern of Wheatstone bridge.

coils, it shunts out the coil. When this bridge is used, the ratio R_2/R_1 is arranged by the operator, depending upon the relative value of R_x as compared with R . Then R is adjusted until a balance is obtained. When R_x is greater than R , the ratio must be 10, 100, or 1000, and when R_x is smaller than R , the ratio must be 0.1, 0.01, or 0.001. If $R_1 = R_2$, the value of R_x equals R .

191. Directions for using a Wheatstone bridge. (1) Insert the unknown resistance. (2) Make a mental estimation of the probable value of the unknown resistance. If it is not greater than the total resistance in the arm R or smaller than that of any one coil in R , then R_1 and R_2 can be made equal by taking plugs from the proper holes. (3) Take a plug from a coil in R of about the estimated resistance of R_x and press the keys. Note the deflection of the needle, whether it is to the right or to the left. Now unplug a coil in R of about twice the resistance of the first one unplugged. If the needle now deflects in the opposite direction, the value of R_x lies between these two values. If the deflection is in the same direction, the unplugged resistance in R is too great, and a value of about one-half of that originally selected should be tried. Systematically narrow the limits until the best possible balance is obtained. (4) Usually it is impossible to secure an exact balance. When this is the case, proceed as indicated in the following example. Assume that the coil of smallest resistance in the R arm is of 0.1Ω . With this added, the galvanometer deflects two divisions to the right. The deflection without is three divisions to the left. Therefore, a difference of 0.1Ω makes a difference of five scale divisions. The resistance that would give no deflection is $\frac{3}{5} \times 0.1 = 0.06 \Omega$. (5) Be careful not to allow the metal parts of the bridge plugs to become wet or greasy from the hands. (6) Use a twisting motion when inserting the plugs. Put them in firmly, but do not use enough force to twist off the insulating handles. (7) When closing the keys, close the battery first, and in opening the keys, open the galvanometer key first.

192. Locating faults in a cable (Standard Underground Cable Co.). Figure 1.89 shows a simple method, using a dynamo, a galvanometer, and 10 or 15 ft of bare wire. This method is applicable only when both conductors of the cable are of the same size. After making the connections shown, it is necessary only to move the stylus along the bare wire until the galvanometer is not deflected in either direction.

Let A = the length of the wire between the balance point B and the faulty conductor, C = the total length of the wire, and L = the total length of the cable circuit, or twice the length of the cable. Then the distance to the fault = $(A \times L)/C$.

FIGURE 1.89 Locating a fault in a cable.

FIGURE 1.90 Homemade wire bridge.

Figure 1.90 shows a simple form of wire bridge which can be used for tests of this kind. The length *A* can be read directly, and the value of *C* is 200. A telephone receiver can be used in place of the galvanometer.

193. Testing cable insulation with a telephone receiver and battery (Standard Underground Cable Co.).

An extremely simple way to determine whether the insulation resistance of a given wire is faulty is as follows. A telephone receiver and battery are connected as shown in Fig. 1.91. One side of the battery is attached to the lead sheath of the cable or to ground, and the other side to a telephone receiver. A rubber-insulated wire is attached to the other side of the telephone. To test, press the telephone receiver to the ear and touch the wire *L* to the conductor *E*; a click will always be heard the first time. After keeping both wires in contact for several seconds, break and make the connection once more; if no sound is heard at the instant of reconnection the wire is not faulty. With intervals of time between break and make of 1 s with a battery of 1 V, it can be assumed that no click indicates at least a resistance of 50 megohms. When more battery is used, this number is increased about in proportion to the number of cells. Care must be taken that sounds in the telephone due to induction are not misconstrued for those produced by leaks.

FIGURE 1.91 Test for insulation resistance.

194. Grounds on series lighting circuits frequently reveal their locations automatically.

If there are two good grounds on a circuit, the lamps connected in the line between the grounds will not burn because the grounds will shunt them out. For example, in Fig. 1.92 with a good ground at 1 and 11, lamps 2 to 10 would be shunted out.

FIGURE 1.92 Effect of two grounds on a series circuit.

Sometimes there may be two grounds on a circuit, but they may not be good enough to shunt out the lamps. (This paragraph and those that follow on testing series circuits are from *Electrical World*.)

The presence of only one ground on a circuit, irrespective of how good it is, will not reveal itself automatically, and the proper operation of the circuit will not be affected by one ground. However, if there is one ground, it constitutes a serious menace to the lives of the station operators and troubleshooters. Furthermore, at any time there may occur another ground that may cause the shunting out of lamps or possibly a fire or destruction of equipment. Hence, it is very desirable to maintain the circuits entirely clear of grounds. It is the practice in all well-maintained stations to test each series circuit for grounds every afternoon. If a ground is discovered, a troubleshooter is sent to locate and clear it before the circuit is thrown into service for the night.

195. The usual method of testing dead series circuits for grounds is to disconnect the circuit from all station apparatus and then to connect one terminal of a magneto test set to the circuit and the other to ground. If the bell rings vigorously when the crank is turned, the circuit is grounded. If it does not, the circuit is clear. If the circuit is very long or in cable for a considerable portion of its length, the bell may ring a little even if the circuit is clear of grounds.

196. The method of locating a ground on a dead series circuit is illustrated in Fig. 1.93. Disconnect all station apparatus and temporarily ground one side of the circuit as at *B* (Fig. 1.93). Proceed out along the line and connect some testing instrument (a magneto test set is most frequently used) in series with the circuit at some point. If when the crank is turned, the magneto bell rings, indicating a closed circuit, the tester is between the station ground and the ground on the circuit. If the magneto rings open, the tester is between the circuit ground and the ungrounded station end of the circuit. If in Fig. 1.93 the test is inserted at lamp 1, 2, or 3, the magneto should ring closed, while if it is inserted at any of the other lamps, it should ring open.

FIGURE 1.93 Locating a ground on a dead series circuit.

197. In locating either a ground or an open on a series circuit, unless the tester has an inkling of the location of the trouble, the tester should proceed first to the middle point of the circuit and there make the first test. This test will indicate on which side of the middle point the trouble is. The tester should then proceed to the middle point of the half of the circuit that shows trouble and there make another test. This will localize the trouble to one-fourth of the circuit. This halving of the sections of the circuit should be continued until the trouble has finally been found.

If there is more than one ground on a series circuit, the trouble is tedious to locate. If the tests made at different points on the circuit are confusing, indicating the existence of several

grounds, the best procedure is to open the circuit into several distinct sections and then test each one as a unit, following the methods described in preceding paragraphs.

198. A ground on a series circuit can sometimes be located with the current from the transformer by placing a temporary ground on the circuit at the station. For example, if in Fig. 1.93 a temporary ground is connected to terminal *B* and the device that supplies the operating current to the circuit is connected to terminals *C* and *D* and normal operating current is thrown out on the circuit, lamps 1, 2, and 3 will not burn, indicating that the ground is between lamps 3 and 4. This method is attended by some fire risk; hence, it should be used with caution.

199. A method of locating a ground on a series circuit with a lamp bank is suggested in Fig. 1.94. A bank of 110-V incandescent lamps, each of the same wattage, is connected in series as indicated, and one end of the bank is permanently grounded. There should be a sufficient number of lamps in the bank so that the sum of the voltages of all of the lamps is at least equal to the voltage impressed on the series circuit by the transformer. For instance, if the voltage impressed on the series circuit is 6600, there should be at least sixty 110-V incandescent lamps in the bank ($6600 \div 110 = 60$).

FIGURE 1.94 Locating a ground on a live series circuit with an incandescent-lamp bank.

In locating a ground, the flexible cord which is connected to the center point of the double-throw switch is placed successively on different points on the conductor that connects the incandescent lamps in series, the switch being thrown to one or the other of the circuit terminals *C* or *D*. Move the flexible cord along until the incandescent lamps in the bank, between the point of connection of the cord and the permanent ground, burn at about full brilliancy. When this condition obtains, the voltage impressed across the lamps that are burning fully brilliant is approximately equal to the voltage impressed on the portion of the circuit (to which the switch connects) between the station and the ground. The voltage required across each lamp of the outside circuit being known, the number of lamps between the station and the ground can be readily computed, and the ground is thereby located.

Great care must be exercised in using this method. Practically all series lighting circuits operate at very high voltage. Hence, when the flexible cord is being moved along the lamp bank, the transformer should be entirely disconnected. If it is not, voltage dangerous to life is present.

EXAMPLE Consider Fig. 1.94. There is a ground on the circuit. It is found that two of the incandescent lamps of the bank burn at full brilliancy between the flexible-cord connector and the lamp-bank ground. Since 110-V lamps are used in the bank, the voltage across these two is 220. This means that the voltage on the circuit between points *C* and *G* is about 220. Since the series lamps each require about 50 V, there must be $220 \div 50 = 4.4$, or in round

numbers, 4 series lamps between *C* and the ground *G*. After making a test with the switch point on *C*, it should be thrown over to *D*, and a check test made from the other end of the circuit. The method of figuring is the same in each case.

200. To locate an open on a series circuit, ground one end of the circuit at the station as in Fig. 1.93. Then make tests at different points out on the circuit with the magneto connected between line and ground. As long as the magneto bell indicates a closed circuit, the open is on the line side of the tester. When the magneto indicates an open circuit, the open is toward the station from the tester.

201. The testing out of a concealed wiring system for proper connections is illustrated in Fig. 1.95. It is assumed that the wires are installed and that the locations of their runs are concealed by the plastering. Only the ends of the conductors are visible at the outlets. It is necessary to identify the conductor ends at each outlet. These tests are usually made with an electric-bell outfit (Fig. 1.61) because the sound of the bell will indicate a closed circuit to the wire tester in a distant room. Hence, one person can test out such a system. In testing out, first skin the ends of all of the conductors and see that none is in contact with any other or with the outlet box. Next, select a pair of conductors (*A*, Fig. 1.95), preferably the pair that serves the group, and connect the bell outfit to the ends of the pair as shown. Then proceed to the outlet (*B*, Fig. 1.95) at which the pair of conductors should terminate and successively touch together the ends of all the wires that terminate in that box until a pair is discovered whose ends touched together ring the bell. This identifies one pair. Tag this pair so that it can be readily found again, and repeat the process on some other pair. Continue until all of the conductors have been identified. (These paragraphs on practical electrical tests are from *Electrical Engineering*.)

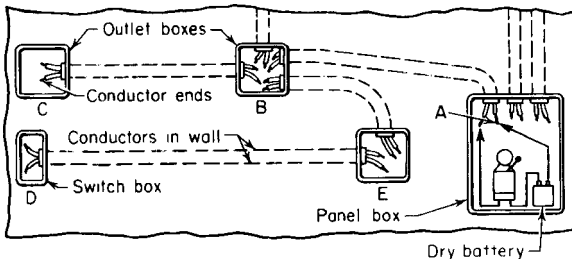

FIGURE 1.95 Testing out wiring for proper connections.

202. The method of testing out the connections for three-way switches is shown in Fig. 1.96. When finally connected, the circuits should be as shown in diagram I. It is assumed that the conductors are in place and concealed within walls or ceilings and that only the ends are visible at the outlets, as in Fig. 1.96, II. First, identify the feed conductors and bend back their ends at the outlet box as at A_3 . Next, twist together, temporarily, the bared ends of any two of the conductors at each of the switch outlets as at A_3 and C_3 . The conductors having their ends thus twisted together will be the switch conductors. Now, at the lamp outlet or outlets identify the short-circuited switch conductors as directed in a preceding paragraph, and connect these switch conductors together as at B_3 . Connect the remaining conductor ends at the lamp outlets to the lamps B_4 , connect one of the feed

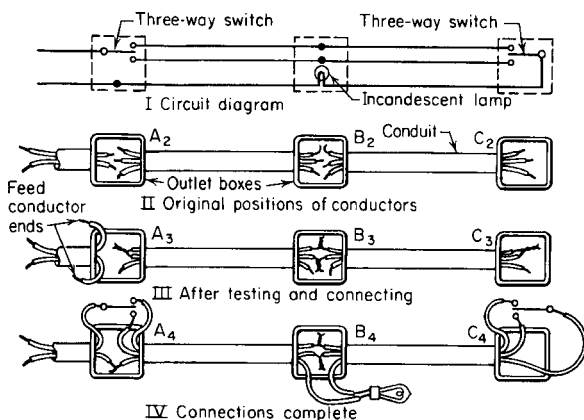

FIGURE 1.96 Testing out three-way-switch connections.

conductors to the center point of the three-way switch A_4 , and connect the other feed conductor to the lamp wire. The switch conductors are connected to the two points of the switch. At C_4 the same procedure is followed.

203. In testing out a new wiring installation for faults, each branch circuit, main, and feeder should be treated individually. It is usually impracticable to test an installation as a unit, as open switches and loose connections in cutouts may render such a test worthless. If a test is made from the cutout on the two conductors of each individual circuit, the above-mentioned possible elements of uncertainty are eliminated. Test each side of each circuit separately unless the lamps are in position.

204. Open circuits in multiple wiring installations are usually readily located. If the lamps are in position and lighting voltage is available, it can be impressed on the circuit. The lamps on the generator side of the open will then burn, while those on the far side will not, which localizes the open. If lighting voltage is not available, all the lamps can be taken out of the sockets, and each of the sides of the circuit can be grounded at the cutout. Then a telephone-and-battery, a bell-and-battery, or a magneto test set can be connected temporarily and successively between one line and ground and between the other line and ground at each outlet on the branch. When the test set indicates an open circuit, the open is between the tester and the ground made at the cutout.

205. The test for short circuits on a multiple system is made by temporarily connecting a test set across the terminals of each branch circuit at the cutout. If there is a short circuit on the lines under test, its presence will be immediately evident by the indication of a closed circuit.

206. The test for continuity of multiple wiring circuits is made by temporarily connecting a test set across the terminals of each branch cutout and successively short-circuiting, one at a time, the sockets of the branch with a screwdriver, a nail, or other metal object. The test

set will then indicate whether the wiring of the circuit is open or closed. If lighting voltage is available and plug cutouts are used, a lamp can be screwed into one socket of the cutout and a plug fuse into the other. Then the tester can proceed from socket to socket and short-circuit each. If the circuit to the socket is continuous, the lamp will light when the socket is short-circuited.

207. The test for grounds on a multiple wiring installation is made by temporarily connecting between line and ground a test set of one of the types previously described. If the test set indicates a closed circuit, the line being tested is grounded.

208. The testing of three-wire circuits to identify the neutral is effected as suggested in Fig. 1.97. If the neutral is grounded, a test lamp can be connected successively between each of the three conductors and ground (Fig. 1.97, I). When the ungrounded side of the lamp is touched to the neutral wire, it will not burn, but when touched to either of the outside wires, it will burn. A method that can be used with either a grounded or an ungrounded neutral is illustrated in Fig. 1.97, II. Connect the two test lamps in series successively between one of the line wires and the other two. When connected across the two outer wires, both lamps will burn at full voltage, but when connected between one of the outer wires and neutral, they will burn at only half voltage.

FIGURE 1.97 Locating neutral wire with a test lamp.

FIGURE 1.98 Determination of polarity with conductor ends in water.

209. To determine the polarity of dc circuits, hold the two conductors in a glass vessel of water as shown in Fig. 1.98. It may be necessary to pour a little common salt or acid into the water to render it conducting (pure water is a poor conductor). Bubbles will form only on the negative conductor, indicating the presence of current and the polarity of the circuit. Be careful not to touch the conductor ends together and cause a short circuit (see also Fig. 1.99 and Sec. 167 on neon testers).

210. The direction of current flow in a dc circuit can be determined with a compass as described in Sec. 89.

211. Ground detectors are desirable on ungrounded systems so that when an accidental ground occurs, it can be remedied before a second ground on another wire causes a short circuit. Control circuits especially should be suitably equipped with ground detectors, as a double ground may cause the closing or tripping of circuits carrying load, with serious consequences.

FIGURE 1.99 Blueprint paper used for testing polarity.

FIGURE 1.100 Two-lamp ground detector.

212. Ground detectors for two-wire dc circuits. Figure 1.100 shows a very good and simple detector for any two-wire low-voltage system. The lamps for the detector should each be of the same wattage and voltage, the voltage being about the same as that of the regular lamps in the plant, and two lamps which, when connected in series, burn with equal brilliancy should be selected. Although somewhat greater sensitiveness can be obtained with low-wattage lamps, such as 25-W lamps, for example, it is believed in general to be better to use lamps of the same wattage as those throughout the plant, because a burned-out or broken detector lamp can then be immediately replaced by a good lamp from the regular stock, thus avoiding the necessity of keeping on hand a few spare special lamps.

The detector lamps, being two in series across the proper voltage for one lamp, burn only dimly. If, however, a ground occurs on any circuit, as at *a*, the current from the positive busbar through lamp 1 divides on reaching *b* instead of all going through lamp 2, as it did when there was no ground. Part now goes down the ground wire and through the ground to *a*, as indicated by the broken line, and thence through the wires to the negative busbar. This reduces the resistance from *b* to the negative busbar, and therefore more current flows through lamp 1 than before, while less current flows through lamp 2. Lamp 1 consequently brightens, and lamp 2 dims. If the ground had occurred at *c* instead of *a*, lamp 2 would have brightened and lamp 1 would have dimmed.

Attention is called to the following points, which are frequently neglected in this form of detector:

1. The lamp receptacles should be keyless, and there should be no switches of any kind in any of the connecting wires, so that the detector will always be in operation. To be of greatest value, the detector must give indications instantly when a ground occurs. The observer should not have to wait until the engineer or electrician remembers to close a switch.
2. The wires should be protected by small fuses where they connect to the busbars. If these fuses are omitted, a short circuit across these wires would either burn up the wires or blow the main generator fuses.

3. The lamps should be placed very close together, within 1 or 2 in of each other if possible. The farther apart they are, the harder it is to detect any slight difference in brilliancy between them.
4. The ground wire should be carefully clamped to a pipe which is thoroughly connected to the ground, or some other equally good ground connection should be provided.

213. On dc control circuits, a telegraph type of relay, which will sound an alarm, is preferable to the lamps, since sufficient current can flow through the lamps as a result of double grounds to operate some relays and cause circuit breakers to operate.

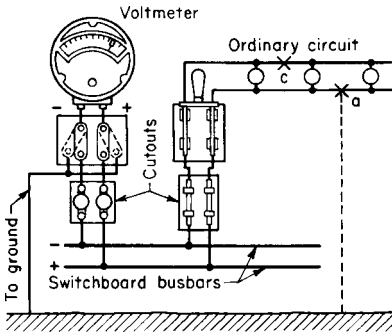

FIGURE 1.101 Voltmeter ground detector.

214. **An ordinary voltmeter can be used as an intermittent ground detector** on dc circuits of any voltage, as shown in Fig. 1.101. The voltmeter ordinarily used to indicate the voltage on the system can, of course, be used for this purpose, the voltmeter switch shown in the cut being arranged to give the different desired connections.

If, for example, the system shown in Fig. 1.101 were of about 100 V, the voltmeter would register 100 when the levers of the switch were on the inside contact points as shown. If, now, the right-hand lever were moved to the outside contact point as shown dotted and there were a ground on the system, as at *a*, current would pass from the positive busbar through the circuit to *a*, thence through the ground to the ground wire, and through the voltmeter to the negative busbar, causing the voltmeter to read something below 100 unless the ground at *a* were practically a perfect connection. In that case the voltmeter reading would be 100. If the positive side of the system were entirely free from grounds, the voltmeter reading would be 0.

Let us assume that under these conditions the voltmeter reads 50 and that the resistance of the voltmeter itself is 20,000 Ω. Since with no external resistance, when the voltmeter is connected directly to the busbars, it reads 100, while now it reads 50, the total resistance under the new conditions must be 40,000 Ω. The resistance of the ground at *a* is 40,000 – 20,000 = 20,000 Ω.

If the voltmeter had read only 20, the total resistance would have been $100/20 \times 20,000 = 100,000$, and the resistance of the ground 100,000 – 20,000 = 80,000 Ω.

FIGURE 1.102 Three-phase lamp detector.

215. Ground detectors for ordinary low-voltage three-phase ac circuits. A lamp detector connected as in Fig. 1.102 can be used. The indication is the same as that with the lamp detectors described above. Thus, when a ground comes on one wire, the lamp attached to that wire dims and the other two lamps brighten. The NEC® now requires ground detectors on ungrounded ac systems. To meet this market there are now listed, self-contained ground detectors available that are considerably more reliable than incandescent lamps. However, an understanding of how the lamp system works is important because there are untold thousands of such detection systems still in use.

For ordinary two-phase or quarter-phase systems, in which the phases are entirely insulated from each other, the two-lamp detector can be used, with one detector on each phase. There are, however, in this class of wiring several complicated systems, to all of which the lamp-detector principle is applicable, although the exact method of connections differs in each case, so that no general rule can be given.

216. Electrostatic ground detectors are used for high-voltage ungrounded ac systems. This instrument for use on three-phase circuits consists of a semispherical vane flexibly supported (Fig. 1.103). Around the circumference of the vane are three stationary curved plates, each being connected through a capacitor to one of the three phase lines. The operation is due to the electrostatic field created between the plates. The vane is grounded, and a ground on any line removes the charge between the plate connected to that line and the ground. This causes the vane to move toward the other two plates against the action of a spring. Thus, the vane being off center indicates a ground. The capacitors (Fig. 1.103) insulate the instrument from the high voltage of the line. A single-phase electrostatic ground detector is shown in Fig. 1.104.

FIGURE 1.103 Three-phase electrostatic ground detector. [Westinghouse Electric Corp.]

FIGURE 1.104 Single-phase electrostatic ground detector. [Westinghouse Electric Corp.]

217. A triplex voltmeter, which is an instrument containing three voltmeter movements with short scales (Fig. 1.105), can also be used on ac systems. Each voltmeter is connected between one line and ground. With no grounds all voltmeters should read zero, but a ground on one line will cause the other two meters to read. The magnitude of the reading will depend on the resistance of the meter and the resistance of the ground, a good ground being indicated by a full line-voltage reading.

218. Test to determine horsepower of an electric motor. By applying the principles outlined elsewhere in this division to a motor under test for output, the power delivered being measured with a Prony brake (Fig. 1.106) may be taken as an example.

FIGURE 1.105 Electrostatic ground detector (triplex voltmeter type). [General Electric Co.]

FIGURE 1.106 Horsepower determination with a Prony brake.

EXAMPLE The torque is 10 lb at 3-ft radius, or 30 lb · ft, or 30 lb at 1-ft radius. Since the motor pulley is turning at the rate of 1000 rpm, a point on its circumference travels $2\pi rR = 2 \times 3.14 \times 1 \times 1000 = 6280$ ft/min. At its circumference the pulley is overcoming a resistance of 30 lb. Therefore, it is doing work at the rate of $30 \times 6280 = 188,400$ ft · lb/min. Since, when work is done at the rate of 33,000 ft · lb/min, a horsepower is developed, the motor is delivering $188,400 \div 33,000 = 5.7$ hp. It should be noted that though the torque at the circumference of the motor pulley was considered in the example, it is not necessary to take the torque at that point. The torque may be taken at any point if the radius to that point is used instead of the radius of the pulley. The formula for determining the horsepower output of a motor under test with a Prony brake is

$$\text{hp} = 2 \times \pi TS \div 33,000$$

where $\pi = 3.1416$, $T =$ torque in pound-feet, and S is the speed of the motor in rpm. Substituting the values from the above example in this formula,

$$\text{hp} = 2 \times 3.14 \times 30 \times 1000 \div 33,000 = 5.7 \text{ hp}$$

This is the same result secured by the former and longer method. In metric units, work is expressed in kilogram-meters, so, conversely torque should be expressed in meter-kilograms or in kilograms at a given radius in meters.

219. The testing of motors and generators for faults is treated in Div. 7, "Generators and Motors."

HARMONICS

220. What are harmonics?* (Dave Dini-Underwriters Laboratories) The word *harmonics* was originally used to signify the appealing sounds obtained by touching various points along a vibrating string. When several of these musical vibrations are at frequencies that are integral multiples of a major frequency or tone, a musical chord is produced. Piano or guitar music is a good example of this. By definition, a harmonic is a sinusoidal component of a periodic wave which has a frequency that is an integral multiple of the fundamental frequency. To the electrical engineer, harmonics are voltages and currents which appear on the electrical system at frequencies that are integral multiples of the generated frequency (normally 60 Hz). Examples of 60-Hz harmonics would be 180 Hz (third), 300 Hz (fifth), 420 Hz (seventh), and so on.

When one or more harmonic components are added to the fundamental frequency, a distorted (nonsinusoidal) waveform is produced. Harmonic distortion is usually expressed as a percentage of the fundamental voltage or current, and the square root of the sum of the squares for all nonfundamental harmonics is commonly referred to as the total harmonic distortion (THD). Fig. 1.107 illustrates a nonsinusoidal waveform having 20 percent third harmonic and 15 percent fifth harmonic distortion (25 percent THD).

When analyzing a nonsinusoidal waveform, it is often important to know the magnitude and phase of the harmonic components present. To calculate this mathematically, the periodic waveform can be represented by a series of individual sinusoids added together. This

*This material is reproduced with the permission of Underwriters Laboratories, Inc., © 1995.

FIGURE 1.107 20 percent third harmonic and 15 percent fifth harmonic distortion (25 percent THD).

mathematical expression is known as a *Fourier series*, and is named after the famous French mathematician, Jean Babtiste Fourier (1768–1830), who first postulated this analytical technique in 1822.

The phase relationship between harmonic components is very important. Figures 1.108 and 1.109 illustrate a third harmonic component 20 percent of the fundamental added both in-phase and 60° out-of-phase with respect to the fundamental frequency. Addition of the in-phase fundamental reduces the peak value of the waveform while the out-of-phase fundamental increases it.

Symmetrical waveforms will contain only odd numbered harmonics (third, fifth, seventh, etc.), while nonsymmetrical waveforms can contain even and odd harmonics. Since most

FIGURE 1.108 20 percent third harmonic in-phase with respect to the fundamental frequency.

FIGURE 1.109 20 percent third harmonic 80° out-of-phase with respect to the fundamental frequency.

loads are essentially symmetrical, the odd number harmonics will be most noticeable in a waveform analysis. However, some loads, such as half-wave rectifiers, produce nonsymmetrical waveforms which contain both even- and odd-numbered harmonic components.

221. Why worry about harmonics? The problems associated with electric power system harmonics are nothing new. In fact, as early as the 1920s electric utility engineers recognized distorted waveforms on transmission lines. One of their major concerns was mutual inductive coupling between transmission lines and telephone circuits. Communication circuits are more sensitive to harmonic currents than they are to power frequency (60 Hz) signals since harmonic frequencies are closer to the audible frequencies that are most noticeable to the human ear. Today, with shielded cables and twisted pairs used more frequently in communication circuits, this problem with mutual coupling of circuits is less common [2]. With the substantial increase in nonlinear loads resulting from today's new technology electronic equipment, the problems with power system harmonics have returned, and a cure for the problem may not be as simple as twisting wires or shielding cables.

To the safety engineer, the problems associated with harmonics can generally be classified into two categories: (1) those which cause a nuisance or disruption to the normal operation of equipment, and (2) those which can increase the risk of fire or electric shock. Typical nuisance problems include audible noise, vibrations, decrease in motor torque, TV and radio interference, and errors in inductive watt-hour meter readings. Of much greater importance, however, is when harmonic voltages and currents lead to overheating of components and dielectric breakdown of insulation systems.

Harmonic current can cause overheating of conductors and insulating materials as a result of "skin effect." Skin effect describes the increase in ac resistance of a conductor as frequency increases. In a good conductor, the current density is greatest near the surface or skin of the conductor. The depth of current penetration, or "skin depth" as it is often called, is inversely proportional to the frequency of the current. Therefore, the higher the frequency, the less skin depth available in the conductor. Engineers do not worry about skin effect at 60 Hz, since it has been factored into most wire ampacity tables [3]. However, in many nonlinear electronic loads, over half of the rms current can be at a frequency greater than 60 Hz. Harmonic current can cause increased heating due to skin effect in wires,

cables, motors, and transformers. Harmonic current can also cause changes in the opening times for fuses and thermal-magnetic circuit breakers. Harmonic voltages can also have an undesirable effect on equipment. Since the reactance of a capacitor decreases with increasing frequency, line-to-ground and neutral-to-ground capacitors will “leak” more harmonic current to ground than they would at 60 Hz. Nonsinusoidal voltages can also have peak potentials greater than 1.4 times the rms voltage. These higher peak voltages can lead to increased dielectric breakdowns as most electric clearance and creepage distances are based on sinusoidal voltages.

Perhaps the greatest danger from harmonic distortion is with overheating of neutral conductors of 3-phase, 4-wire distribution systems. In a balanced 3-phase wye system with all sinusoidal currents (linear loads), the neutral current will be zero. Even with a maximum unbalance, the neutral current can be no greater than the maximum phase current. However, as will be shown later, certain harmonic currents that are odd multiples of the third harmonic (third, ninth, fifteenth, etc.) add rather than cancel in the neutral conductor. This could theoretically result in the neutral conductor carrying almost twice the rms current of a phase conductor, even in a balanced system.

222. Causes of harmonic distortion. For all practical purposes, it can be assumed that the main source of electric power, namely the utility system generator, is a good source of supply, and at the point of generation a pure sinusoidal waveform exists. Therefore, any distortion that occurs on the electric distribution system must be due to the load elements connected to the system. Of particular concern with harmonic distortion are nonlinear loads, those loads which have load current that is not proportionally related to the system voltage. In general, the major types of nonlinear loads can be divided into three categories: (1) ferromagnetic devices, (2) electronic switching power converters, and (3) arcing devices [2].

Motors and transformers comprise the largest amount of ferromagnetic loads connected to the distribution system. The load characteristics of motors tend to be more linear than transformers since motors have an air gap. Power transformers, on the other hand, typically are the first components to be seen on the distribution system, and can be an important factor when considering waveform distortion. Even partial saturation of the transformer iron core will cause harmonic magnetizing currents which differ significantly from a sinusoidal wave. Loads containing saturated iron cores, such as fluorescent lighting ballasts, will also draw distorted current, usually very high in third and fifth harmonics.

Traditional methods of power conversion are giving way to new technology electronic power converters. This class of equipment includes switch mode power supplies (SMPS), electronic motor speed controllers, uninterruptible power supplies (UPS), lighting dimmers, and electronic ballasts. The common element among these power converters is that they all use electronic switching to turn on and off current at specific phase angles. The effect of this nonlinear loading will draw currents with high harmonic content.

The third class of nonlinear loads is arcing devices which would include electric discharge lighting (i.e., fluorescent, sodium vapor, mercury vapor, etc.), and arc furnaces. Arc furnaces can induce harmonics onto the distribution system through a combination of arc ignition delays and the highly nonlinear arc current characteristics associated with the arc furnace electrodes [4]. Another type of arcing device, the electric discharge lamp, which is used extensively in commercial and industrial lighting, can produce high harmonic current draw, especially at 180 Hz (third harmonic).

Significant amounts of harmonic distortion on the distribution system may not only arise from large, high power nonlinear loads, but also from the compound effects of a large number of smaller loads. This is becoming more evident as the number of nonlinear loads on the distribution system increases. In the office environment, widespread use of SMPS can be

found in desktop computers, laser printers, monitors, copiers, and FAX machines. These high volume nonlinear loads, along with computer UPSs, fluorescent lighting, energy management light dimming, and ventilation system electronic fan speed controllers have all added to a sharp increase in the harmonic distortion of the office power distribution system.

In the factory environment, industrial automation equipment such as programmable controllers, electronic motor speed controllers, robotic controls, and automated machine work stations are becoming more common. These devices all produce an appreciable amount of harmonic current.

223. Effects of harmonic distortion. Harmonic distortion can affect the electrical distribution system and the loads connected to it in various ways. Of particular concern are (1) increased thermal stress due to skin effect heating, (2) increased insulation stress and dielectric breakdown due to voltage harmonics, and (3) nuisance or disruption of normal equipment operation due to nonsinusoidal voltages and currents [5]. Many of these influencing factors can result in increased safety risks from overheating equipment and conductors, line and ground faults, and failures of safety control systems to function properly. The following groups of products have been known to be sensitive to at least some of the effects of harmonic distortion.

Motors. Harmonic voltages and currents will increase the rotor winding and stator winding losses in motors. Since these losses are I^2R losses, increased heating due to skin effect would be expected at the higher harmonic frequencies.

Transformers. Waveform distortion will cause increased heating in all types of transformers. The increased heating is due to an increase in the frequency dependent eddy current and hysteresis core losses. Increased heating could also be expected from skin effect heating in the windings.

Capacitors. Since the impedance of a capacitor is frequency dependent (decreasing reactance with increasing frequency), capacitors are a load element which will be affected by harmonic distortion. The high frequency components found in distorted waveforms can cause additional leakage current in line-to-line and line-to-ground capacitors. Leakage current measurements in appliances operating from a pure 60-Hz voltage may be significantly less than the leakage current found in the same appliance supplied from a power source high in harmonics.

Air Gap Switches. Current interruption devices such as switches, relays, circuit breakers, etc., can be affected by current waveform distortion. The problem is most prevalent when the switch is made to interrupt nonsinusoidal current with a high di/dt value at current zero. This condition can make current interruptions more severe than interrupting sinusoidal current.

Thermal Overcurrent Protection. Thermal overcurrent protective devices, such as fuses and inverse-time circuit breakers, are affected by increased skin effect heating at the higher harmonic current levels. This excess heating can cause shifts in the time-versus-current characteristics of the protective device, usually resulting in nuisance tripping.

Induction Watthour Meters. Power system harmonics can cause errors in electric meter readings. Since induction discs in watthour meters are designed to monitor nondistorted fundamental current, harmonic current from nonlinear loads will cause measurement errors, usually, resulting in the consumer paying more for electricity than if the same rms current being drawn was sinusoidal.

Protective Relays. When protective relays are subjected to system harmonics, relay misoperation is possible, resulting in undesired pick-up values, changes in voltage and current operating characteristics, and false tripping.

Insulated Conductors. Both voltage and current harmonics can have undesirable effects on insulated conductors. Voltage harmonics can have rated peak voltage values greater than 1.4 times the rms voltage value. These higher than expected steady-state peak voltages can lead to insulation degradation and dielectric breakdown. In addition, the increased skin effect heating from current harmonics can also cause insulation degradation, and add to a decrease in cable life.

Neutral Currents. In a 3-phase, 4-wire wye distribution system (i.e., 120/208 V or 277/480 V), loads connected to the individual single phases (120 V or 277 V) will have load currents that return through the common neutral conductor. Since the phase voltages are 120° out of phase, the 60 Hz phase currents will cancel out when they return through the common neutral. If the system is balanced, and all three phase currents are equal, the 60 Hz neutral current will be zero. Figures 1.110, 1.111, and 1.112 illustrate this occurrence through the use of phasor diagrams.

FIGURE 1.110 60-Hz phase voltages.

FIGURE 1.111 60-Hz phase currents.

FIGURE 1.112 60-Hz neutral current.

FIGURE 1.113 Third harmonics.

A problem develops when the load current in the 3-phase wye system is nonsinusoidal, and some of the current being drawn by the load is at a frequency other than 60 Hz. For example, Figs. 1.113 and 1.114 show that the third harmonic currents (180 Hz) will be 360° ($120^\circ \times 3$) out of phase, and the fifth harmonic currents (300 Hz) will be 600° ($120^\circ \times 5$) out of phase. The phasor diagram for the fifth harmonic (Fig. 1.114) shows that the fifth harmonic currents will cancel just like the 60-Hz currents. In fact, using the same phasor technique it can be shown that all harmonics that are not multiples of the third harmonic will cancel in the neutral. All harmonics that are multiples of the third (third, sixth, ninth, etc.) will add rather than cancel in the neutral conductor (Fig. 1.113). These multiples of the third harmonic are often referred to as *triplen harmonics*, and they can have a very serious effect on overheating of the neutral conductor.

In a typical 3-phase, 4-wire distribution system, the neutral conductor has no overcurrent protection and is usually of a size not larger than the phase conductors. When all of the load currents are 60 Hz, this presents no problem since at maximum unbalance the neutral conductor will only carry a maximum of rated line current, and in most cases, due to phase balancing, the neutral current will be considerably less. When load currents are high in triplen harmonics, the situation in the neutral conductor is significantly different. Although theoretically the neutral current could approach three times the line current, this situation is rather improbable. However, in office areas with many computer products on the

FIGURE 1.114 Fifth harmonic currents.

120/208 V distribution system, or several electronic fluorescent lighting loads connected to the 277/480-V lighting system, neutral current in excess of the branch circuit protection rating is possible. Since there is no overcurrent protection in the neutral conductor, overheating of a nonoversized neutral conductor can occur.

224. Measurement of harmonics. The measurement of nonsinusoidal voltages and currents may require equipment different from the conventional meters used to measure sinusoidal waveforms. Many voltage and current meters respond only to the peak value of a waveform, and indicate a value that is equivalent to the rms value of a pure sine wave. For a sinusoidal waveform, the rms value will be 0.707 times the peak value. Meters of this type are known as *average responding meters* and will only give a true reading if the waveform being measured is sinusoidal. Both analog and digital meters may be average responding instruments. Voltages and currents which are nonsinusoidal, such as those with harmonic frequencies, cannot be accurately measured using an average responding meter. Only a meter that measures “true rms” can be used to correctly measure the rms value of a nonsinusoidal waveform.

When measuring a nonsinusoidal waveform, it is often desirable to also know the magnitude of each frequency present. To accomplish this, a *harmonic analyzer* is necessary. An analog harmonic analyzer is a voltage measurement instrument that uses selective filtering to tune out all frequencies except the one being analyzed (see Fig. 1.115).

With the widespread use of microprocessors, and recent advances in digital data acquisition, the analog analyzers have been superseded by analyzers capable of digital harmonic analysis. The most popular harmonic analyzers today use a Fast Fourier Transform (FFT) technique to breakdown a complex waveform into its individual frequency components.

FIGURE 1.115 An eight-channel analyzer for capturing transients, voltage sags, swells, harmonics, and other power disturbances. Used in conjunction with the PQ Task Card®, the Power Platform® can generate reports and do K-factor computations for transformer selection. [Dranetz Technologies, Inc.]

The FFT is a useful tool for quickly performing a Fourier analysis on a block of sampled data. Harmonic analyzers based on FFT also have the ability to display the phase as well as magnitude of each frequency present. Current transformers and clamp-on ammeters easily adapt to digital harmonic analyzers, making current as well as voltage harmonic measurements a simple procedure.

225. Eliminating harmonics. Eliminating harmonic voltages and currents from the electric distribution system is an important topic, not only from the standpoint of keeping nuisance problems to a minimum, but also in reducing the risk of a potential fire or electric shock. When the voltage on the electric distribution system becomes distorted, all loads become affected, as even a purely resistive load will provide distorted current if the voltage drop across it is distorted. Likewise, if a distorted current is injected across a resistance, the voltage drop across it will be distorted. Therefore, the first step in the management of harmonic distortion problems must be concerned with controlling the flow of harmonic currents, and preventing them from entering the distribution system where they can cause voltage distortion.

Eliminating harmonic distortion is much like eliminating electromagnetic interference (EMI). To control high-frequency interference, special EMI filters are often employed. Since a filter is designed to reduce the amplitude of one or more fixed frequency currents or voltages, a harmonic filter is one means of reducing waveform distortion. The difficulty with designing a harmonic filter versus an EMI filter are twofold. First, since the harmonic frequencies are very close to the power frequency (60 Hz), a very selective filter is required. Second, the power levels of the harmonic frequencies are much greater than the power of typical EMI frequencies.

Frequency selective harmonic filters can be used as either a series filter (Fig. 1.116) or a shunt filter (Fig. 1.117). A series filter uses a high impedance to block the flow of harmonic current from the nonlinear load back to the power source. A shunt filter provides a low impedance path to divert the harmonic current to ground. Although either method of filtering will reduce harmonics, the shunt filter is usually preferred since the series filter must be designed for full line current and insulated for line voltage, whereas the shunt filter does not [6].

FIGURE 1.116 Series filter.

FIGURE 1.117 Shunt filter.

Besides using passive filters for controlling harmonic distortion, a wide variety of active methods have been proposed for improving current waveform distortion. One promising application for active filtering is to incorporate this technology into the design of electronic switching power supplies, a product notorious for producing distorted current (typically greater than 100 percent THD). Although the circuitry to achieve active filtering is quite complex, all of the control functions associated with such a scheme have been incorporated into a single integrated circuit chip, thus making active filtering a practical choice for the electronic switching power supply manufacturer. Although this technology is relatively new and in many cases still being developed, some electronic power supply manufacturers have reported improvements in current distortion levels to as low as 3 percent THD [7]. When considering the vast numbers of desktop computer equipment being used in automated factories and office areas, any improvement in electrical power supply current distortion will have a significant impact on improving the overall quality of the electric distribution system.

Alternate methods of harmonic elimination involving cancellation of harmonic currents have also been proposed. These include magnetic flux compensation and current injection techniques. However, these methods usually have several disadvantages and are in need of much technical advancement before they can become practical.

PROPERTIES AND SPLICING OF CONDUCTORS

Electrical Conducting Wires and Cables	2.1
Cable Joints and Terminal Connections	2.61
Aluminum-Building-Wire Installation Practices	2.100
Termination and Splice Kits	2.144

ELECTRICAL CONDUCTING WIRES AND CABLES

1. Electrical conducting wires and cables are available in a great variety of types and forms of construction. To cover this one subject completely would require a large volume. The aim of the authors has been, therefore, to include in this division sufficient general information with respect to the materials employed, method of construction, and types available so that the reader can select intelligently the proper cable for a given application. At the end of the section, more detailed tabular information is included for the types of cables that the average worker will use most frequently.

2. Electric Wire and Cable Terminology

Wire. A slender rod or filament of drawn metal. (This definition restricts the term *wire* to what would ordinarily be understood by the term *solid wire*. In the definition the word *slender* is used in the sense that the length is great in comparison with the diameter. If a wire is covered with insulation, it is properly called an *insulated wire*, although the term *wire* refers primarily to the metal; nevertheless, when the context shows that the wire is insulated, the term *wire* will be understood to include the insulation.)

Conductor. A wire or combination of wires not insulated from one another, suitable for carrying a single electric current. (The term *conductor* does not include a combination of conductors insulated from one another, which would be suitable for carrying several different electric currents. Rolled conductors, such as busbars, are, of course, conductors but are not considered under the terminology given here.)

Stranded Conductor. A conductor composed of a group of wires or any combination of groups of wires. (The wires in a stranded conductor are usually twisted or braided together.)

Cable. (1) A stranded conductor (single-conductor cable) or (2) a combination of conductors insulated from one another (multiconductor cable).

The component conductors of the second kind of cable may be either solid or stranded, and this kind may or may not have a common insulating covering. The first kind of cable is a single conductor, while the second kind is a group of several conductors. The term

cable is applied by some manufacturers to a solid wire heavily insulated and lead-covered; this usage arises from the manner of the insulation, but such a conductor is not included under this definition of *cable*. The term *cable* is a general one, and in practice it is usually applied only to the larger sizes. A small cable is called a *stranded wire* or a *cord*, both of which are defined below. Cables may be bare or insulated, and insulated cables may be armored with lead or with steel wires or bands.

Strand. One of the wires or groups of wires of any stranded conductor.

Stranded Wire. A group of small wires used as a single wire. (A wire has been defined as a *slender rod* or filament of drawn metal. If such a filament is subdivided into several smaller filaments or strands and is used as a single wire, it is called *stranded wire*. There is no sharp dividing line of size between a stranded wire and a cable. If used as a wire, for example in winding inductance coils or magnets, it is called a stranded wire and not a cable. If it is substantially insulated, it is called a *cord*, defined below.)

Cord. A small cable, very flexible and substantially insulated to withstand wear. (There is no sharp dividing line in respect to size between a cord and a cable and likewise no sharp dividing line in respect to the character of insulation between a cord and a stranded wire.)

Concentric Strand. A strand composed of a central core surrounded by one or more layers of helically laid wires or groups of wires.

Concentric-Lay Conductor. A conductor composed of a central core surrounded by one or more layers of helically laid wires. (Ordinarily it is known as a concentric-strand conductor. In the most common type, all the wires are of the same size, and the central core is a single wire.)

Concentric-Lay Cable. A multiconductor cable composed of a central core surrounded by one or more layers of helically laid insulated conductors.

Rope-Lay Cable. A cable composed of a central core surrounded by one or more layers of helically laid groups of wires. (This cable differs from a concentric-lay conductor in that the main strands are themselves stranded and all wires are of the same size.)

Multiconductor Cable. A combination of two or more conductors insulated from one another. (Specific cables are called *3-conductor cable*, *19-conductor cable*, etc.)

Multiconductor Concentric Cable. A cable composed of an insulated central conductor with one or more tubular stranded conductors laid over it concentrically and insulated from one another. (This kind of cable usually has two or three conductors.)

***N*-Conductor Cable.** A combination of *N* conductors insulated from one another. (It is not intended that the name as given here be actually used. One would instead speak of a 3-conductor cable, a 12-conductor cable, etc. In referring to the general case, one may speak of a multiconductor cable, as in the definition for *cable* above.)

***N*-Conductor Concentric Cable.** A cable composed of an insulated central conducting core with tubular stranded conductors laid over it concentrically and separated by layers of insulation. (Usually it is only 2-conductor or 3-conductor. Such conductors are used in carrying alternating currents. The remarks on the expression “*N*-conductor” in the preceding definition apply here also.)

Duplex Cable. A cable composed of two insulated single-conductor cables twisted together with or without a common covering.

Twin Cable. A cable composed of two insulated conductors laid parallel and either attached to each other by insulation or bound together with a common covering.

Twin Wire. A cable composed of two small insulated conductors laid parallel and having a common covering.

Twisted Pair. A cable composed of two small insulated conductors twisted together without a common covering.

Triplex Cable. A cable composed of three insulated single-conductor cables twisted together.

Sector Cable. A multiconductor cable in which the cross section of each conductor is approximately the sector of a circle.

Shielded-Type Cable. A cable in which each insulated conductor is enclosed in a conducting envelope so constructed that substantially every point on the surface of the insulation is at ground potential or at some predetermined potential with respect to ground under normal operating conditions.

Shielded-Conductor Cable. A cable in which the insulated conductor or conductors are enclosed in a conducting envelope or envelopes, so constructed that substantially every point on the surface of the insulation is at ground potential or at some predetermined potential with respect to ground.

Composite Conductor. A conductor consisting of two or more strands of different metals, such as aluminum and steel or copper and steel, assembled and operated in parallel.

Round Conductor. Either a solid or a stranded conductor of which the cross section is substantially circular.

Cable Filler. Material used in multiconductor cables to occupy the spaces formed by the assembly of the insulated conductors, thus forming a core of the desired shape.

Cable Sheath. Protective covering applied to cable.

Insulation of a Cable. The part of a cable which is relied upon to insulate the conductor from other conductors or conducting parts or from ground.

Insulation Resistance of an Insulated Conductor. The resistance offered by a conductor's insulation to an impressed direct voltage, tending to produce a leakage of current through it.

Lead-Covered Cable (Lead-Sheathed Cable). A cable provided with a sheath of lead to exclude moisture and afford mechanical protection.

Serving of a Cable. A wrapping applied over the core of a cable before the cable is leaded or over the lead if the cable is armored. Materials commonly used for serving are jute, cotton, and duct tape.

Resistive Conductor. A conductor used primarily because it possesses high electric resistance.

3. Wire sizes. The size of wire is usually expressed according to a wire gage, and the different sizes are referred to by gage numbers. Unfortunately several systems of gages have been originated by different manufacturers for their products. However, it has become standard practice in the United States to employ the American wire gage (AWG), also known as the Brown and Sharpe (B&S), to designate copper and aluminum wire and cable used in the electrical industry. The names, abbreviations, and uses of the most important gages employed for the measurement of wires and sheet-metal plates are given in Table 4. A numerical comparison of these gages is given in Table 85. In most cases the larger the gage number, the smaller the size of the wire.

4. Names, Abbreviations, and Uses of the Principal Wire and Sheet-Metal Gages

Col. no. in Table 85	Names and abbreviations		Ordinarily used for measuring
	Usual	Others	
1	American wire gage (AWG)	Brown and Sharpe (B&S)	Copper, aluminum, copper-clad aluminum, and other nonferrous wires, rods, and plates. Wall thickness of tubes
2	Steel wire gage (SWG)	Roebing, American Steel and Wire, Washburn & Moen, National, G. W. Prentiss	Iron and steel wire. Wire nails. Brass and iron escutcheon pins
3	Birmingham wire gage (BWG)	Stubs iron wire gage, iron wire gage	Galvanized iron and steel wire. Iron and copper rivets. Thickness of wall of nonferrous seamless tubing
4	Stubs steel wire gage	Drill rod
5	British standard wire gage (SWG)	Imperial standard wire gage, standard wire gage, English legal standard	Legal standard wire gage for Canada and Great Britain; used sometimes by American telephone and telegraph companies for bare copper line wire
6	Steel music wire gage (MWG)	Hammacher, Schlemmer, Felten & Guilleaume	Steel music wire
7	U.S. Standard Gage (USG)	Stainless steel sheets
8	Manufacturers standard gage (MSG)	Legal standard for iron and steel plate. Monel metal. Galvanized sheets
9	American zinc	Sheet zinc
10	Birmingham gage (BG)	Legal standard for iron and steel sheets in Canada and Great Britain

5. How to remember the AWG or B&S wire-gage table (*Westinghouse Diary*).

A wire that is three sizes larger than another wire has half the resistance, twice the weight, and twice the area. A wire that is 10 sizes larger than another wire has one-tenth the resistance, 10 times the weight, and 10 times the area. Number 10 wire is 0.10 (more precisely 0.102) in (2.6 mm) in diameter; it has an area of 10,000 (more precisely 10,380) cmil (5.26 mm²); it has a resistance of 1 Ω/1000 ft (304.8 m) at 20°C (68°F); and it weighs 32 (more precisely 31.4) lb (14.24 kg)/1000 ft (304.8 m).

The weight of 1000 ft (304.8 m) of No. 5 wire is 100 lb (45.36 kg). The relative values of resistance (for decreasing sizes) and of weight and area (for increasing sizes) for consecutive sizes are 0.50, 0.63, 0.80, 1.00, 1.25, 1.60, 2.00. The relative values of the diameters of *alternate* sizes of wire are 0.50, 0.63, 0.80, 1.00, 1.25, 1.60, 2.00. To find resistance, drop one cipher from the number of circular mils; the result is the number of feet per ohm. To find weight, drop four ciphers from the number of circular mils and multiply by the weight of No. 10 wire.

6. Wire-measuring gages (Figs. 2.1 and 2.2) are made of steel plate. With the kind shown in Fig. 2.1, the wire being measured is inserted in the slots in the periphery until a slot is found in which the wire just fits. The wire's gage number is indicated opposite the slot. A measuring gage like that of Fig. 2.1 indicates the numbers of one gage or system only. A gage like that of Fig. 2.2 indicates the numbers of four gages but has the disadvantage that, to use it, the end of the wire must be available to be pushed through the slot. The wire is pushed as far toward the small end of the slot as it will go, and its gage number is then indicated opposite the point where the wire stops. The gage of Fig. 2.2 is arranged to indicate gage numbers for the American standard screw gage, English wire gage, and American wire gage, and one scale is divided into 30 seconds of an inch.

FIGURE 2.1 Standard wire gage (greatly reduced). **FIGURE 2.2** Angular wire gage (greatly reduced).

7. A micrometer is frequently used to determine the size of a given wire or cable. It provides an accurate means of measuring the diameter of the wire or cable to thousandths of an inch and of estimating to ten-thousandths.

After the diameter has been determined, the corresponding gage size may be ascertained by referring to a wire table. The wire to be measured is placed between the thumbscrew and the anvil (Fig. 2.3), and the screw is turned until the wire is lightly held between the screw and the anvil. The screw has 40 threads to the inch, so that one complete turn of the screw in left-hand direction will open the micrometer $\frac{1}{40}$ in. On the edge of the collar is a circular scale divided into 25 divisions; hence, when the screw is turned through one of these divisions, the micrometer will open $\frac{1}{25} \times \frac{1}{40}$ in = $\frac{1}{1000}$ in. The shaft on which the collar turns is marked into tenths of an inch, and each $\frac{1}{10}$ is subdivided into four parts. Each of these parts must be equal to $\frac{1}{10} \times \frac{1}{4}$ in =

FIGURE 2.3 A micrometer caliper.

$\frac{1}{40}$ in = 0.025 in. Therefore, a complete rotation of the collar or 25 of its divisions will equal one division of the shaft, or 0.025 in.

8. To read a micrometer (see Fig. 2.4 and the paragraph above), note the number on the circular scale nearest the index line. This indicates the number of thousandths. Note the number of small divisions uncovered on the shaft scale. Each one of these small divisions indicates 0.025 in ($\frac{25}{1000}$). Add together the number of thousandths indicated on the circular scale and 0.025 times the number of small divisions wholly uncovered on the shaft scale. The sum will be the distance that the jaws are apart. Examples are shown in Fig. 2.4.

FIGURE 2.4 A micrometer caliper.

9. Classification of wires or cables. Electrical conducting wires and cables may be classified in several different ways, depending upon the particular factor of consideration as follows:

1. According to degree of covering of wire or cable
2. According to material and makeup of electrical conductor
3. According to number of conductors in cable
4. If insulated, according to insulation employed
5. According to protective covering
6. According to service

10. Classification according to degree of covering. Probably the broadest classification of electrical wires and cables is according to the degree of covering employed, as follows:

1. Bare
2. Covered but not insulated
3. Insulated and covered

In many cases *bare* conductors without any covering over the metallic conductors are employed for electrical circuits. The conductors are supported on insulators so spaced, depending upon the voltage of the circuit, that the length of the air space between the conductors will provide sufficient insulation. Bare conductors are employed for most overhead transmission lines. They are also used for certain overhead telephone and telegraph circuits.

There is a definite distinction between the meanings of the words *bare*, *covered*, and *insulated* in electrical-cable terminology:

Bare. Designating a conductor having no covering or electrical insulation whatsoever.

Covered. Designating a conductor encased in material whose thickness or composition is not recognized by the National Electrical Code® (NEC) as electrical insulation.

Insulated. Designating a conductor encased in material whose thickness or composition is recognized by the Code as electrical insulation.

Insulated wires and cables consist of an electrical conductor covered with some form of electrical insulation with or without an outer protective covering. With covered wires the conductor is protected against mechanical injury by some form of covering applied directly over the conductor. This covering, however, does not provide insulation of the wet conductor to any great extent and often even becomes a fair conductor itself when moist. The covering therefore cannot be relied upon to afford consistently any insulation beyond that of the air spacing between the conductors.

Weatherproof wires may be divided into two general classes, those with fibrous coverings and those with homogeneous coverings (Sec. 12).

11. Weatherproof-covered wire with fibrous coverings is available in two types. Both are designated as URC and are manufactured according to specifications recommended by the Utilities Research Commission. The two types are distinguished by at least one manufacturer as O.K.-URC and Peerless URC. The O.K. is the more common type. The wire is covered with two or three weatherproof cotton braids, which are applied directly over the conductor. The braids are saturated with a black asphaltic compound. The outside surface of the outer braid is coated with mica flake to provide a smooth surface free of tackiness. The Peerless type, a better-grade covering, not only is longer-lived but provides some degree of overall electrical insulation to the conductor. The construction consists of a compacted pad of unspun cotton wrapped helically directly around the conductor and filled with asphalt. This pad provides a homogeneous wall of insulation without the usual braid interstices encountered in ordinary weatherproof-covered wire. The asphalt-impregnated pad is covered with a standard outer weatherproof braid. Peerless wire is made in two types, designated as double braid and triple braid. Actually there is only one braid in both types, but the combination of the cotton pad of different thicknesses and the braid gives a covering which is equivalent in thickness to the regular double- or triple-braid O.K. wires. Weatherproof-covered wire is available with the conductor material consisting of copper, solid copperweld, solid bronze, composite copper-copperweld, all aluminum, or steel-reinforced aluminum.

12. Weatherproof-covered wire with homogeneous covering is available in two types, neoprene and polyethylene.

The *neoprene type* has a homogeneous covering which consists of a tough and durable vulcanized neoprene compound. This type has the following advantageous characteristics:

1. Highly weather-resistant.
2. Not brittle under extremely low temperatures. It will not migrate under abnormally high temperatures.
3. Preventing normal moisture ingress to conductor, thus permitting maximum continuity of service under storm conditions.
4. Tough, with excellent resistance to mechanical abuse.
5. Light in weight and smooth-surfaced, with adhesion to the conductor. It can be handled and installed without special precautions.

The *polyethylene type* has a homogeneous, seamless thermoplastic covering which is applied by extrusion. Its more important characteristics may be summarized as follows:

1. Highly resistant to weathering, being both weather- and sun-resistant
2. Physically strong
3. Resistant to abrasion
4. Inherently tight on the conductor
5. Possessing a wide temperature range, -94°F (-70°C) to 176°F (80°C)
6. Light in weight

13. Material and makeup of electrical conductors. The conductor may consist of a single solid wire or a stranded cable made up of several individual bare wires twisted together. Stranded conductors are more flexible than a single solid wire. The flexibility of the cable increases with the number of strands and also depends upon the arrangement of the individual strands in the makeup of the conductor. Solid wires are used for conductors of the smaller sizes and stranded cables for the larger sizes. In the intermediate sizes both solid and stranded conductors are available.

Wires more finely stranded than class C require special provisions at terminations, as covered in Sec. 163. Although finely stranded conductors are readily available, they are commonly designated *welding cable*. Even if rated "600 V" the welding cable designation only means that these wires are listed for use in the secondary circuits of electric welders, as covered in Part IV of Article 630 in the NEC. Unless provided with additional or other markings, they are not listed for use in conventional building wiring. Building wire will have one of the designations in NEC Table 310.13(A) such as RHH or RHW or THW or XHHW, etc.

Electrical conducting cables are made of copper, copper-clad aluminum, aluminum, steel, bronze, or a combination of either copper or aluminum with steel. Because of its high conductivity, copper is the material most commonly employed. Practically all insulated wires and cables employ copper or aluminum conductors. Aluminum or steel wires and cables are frequently found to be more economical for certain classes of aerial construction. All-steel conductors are employed for telephone and telegraph work and certain rural distribution lines with light load densities. Steel-copper conductors are employed for long-span river crossings of power lines and for certain rural distribution lines.

A classification of electrical conductors with respect to standard materials and makeups available is as follows:

- A. Copper
 - 1. Solid
 - a. Round
 - b. Grooved
 - c. Figure eight
 - d. Figure nine
 - e. Square or rectangular
 - 2. Standard concentric stranded
 - a. Class AA
 - b. Class A
 - c. Class B
 - d. Class C
 - e. Class D
 - 3. Standard rope stranded
 - a. Class G
 - b. Class H
 - 4. Bunched stranded
 - 5. Bunched and rope stranded
 - a. Class J
 - b. Class K
 - c. Class L
 - d. Class M
 - e. Class O
 - f. Class P
 - g. Class Q
 - 6. Annular concentric stranded
 - 7. Special stranded
 - 8. Compact stranded
 - a. Round
 - b. Sector
 - c. Segmental
 - 9. Hollow-core stranded
 - 10. Tubular segmental (type HH)
- B. Iron or steel
 - 1. Solid
 - 2. Stranded
- C. Copper-steel
 - 1. Copperweld
 - a. Solid
 - b. Stranded
 - 2. Copperweld and copper
 - 3. Copper and steel stranded
- D. Aluminum
 - 1. Solid
 - 2. Stranded
 - 3. Compact stranded
- E. Copper-clad aluminum
 - 1. Solid
 - 2. Stranded
- F. Aluminum and steel (ACSR)
- G. Bronze

Refer to Table 86 for illustrations and applications of different makeups. Refer to Table 87 for a guide to applications of conductor materials.

14. Copper wire is made in three grades of hardness, known as hard-drawn, medium-hard-drawn, and soft or annealed. Hard-drawn wire has the greatest tensile strength and the least amount of elongation under stress and is the stiffest and hardest to bend and work. Soft-drawn or annealed wire has the lowest tensile strength and the greatest elongation under stress and is very pliable and easily bent. Medium-hard-drawn wire has characteristics intermediate between those of hard-drawn and soft-drawn wire. The conductivity of copper wires decreases slightly as hardness increases, but there is relatively little difference in the conductivity of the different grades.

Hard-drawn wire is used for long-span transmission lines, trolley contact wires, telephone wires, and other applications for which the highest possible tensile strength is desirable.

Medium-hard-drawn wire is employed for such applications as short-span distribution circuits and trolley feeders, for which slightly lower tensile strength is satisfactory and greater pliability is desired.

Soft-drawn or annealed copper is used for all covered or insulated copper conductors except weatherproof-covered cables. Wires with this covering are available in all the three grades of hardness. Bare or weatherproof-covered soft wire is used only for short spans.

Copper wire used for rubber-insulated cable must be *tinned* by coating with pure tin to protect the copper against chemical action caused by contact with the rubber.

15. Makeup of copper conductors. Copper conductors are manufactured in various forms of makeup as listed in Sec. 13, depending upon their size and application. An understanding of the construction of the different makeups and their applications can be gained from Table 86. The employment of solid or stranded conductors and the choice of the class of stranding depend upon the degree of flexibility desired. For very flexible cables for special applications, special strandings are employed. There is no fixed standard for these special strandings—practice varying with different manufacturers. Data for bare copper conductors of the different standard makeups are given in Tables 88 to 94.

16. Iron or steel electrical conductors. All-steel conductors for power circuits are made from special low-resistance, high-strength steel stock. They are available in both solid and three-strand construction. Each wire is protected by a heavy galvanized coating of zinc. Since all-steel conductors can be applied economically only for light electrical loads, these conductors are manufactured in only three standard sizes. Stranded conductors are used in preference to solid wires for longer-span construction because their inherent damping capacity reduces the amplitude of vibration in strong lateral winds.

Commercial galvanized-iron wire for telephone and telegraph circuits has been made for many years in three types designated as extra best best (EBB), best best (BB), and steel. These designations are somewhat misleading. Adopted many years ago, they refer to the electrical conductivity of the different grades. All three types are made from high-grade materials and meet the same standard of galvanizing.

Extra best best wire has the best conductivity but the lowest tensile strength. Its weight per mile-ohm is from 4700 to 5000 lb. This wire is uniform in quality, pure, tough, and pliable. It is used largely by commercial telegraph companies, in railway telegraph service, for tie wires, and for signal bonding.

Best best wire has a lower value of conductivity but greater tensile strength. Its weight per mile-ohm is from 5600 to 6000 lb. This grade is used very largely by telephone companies.

Steel is a stiff wire of high tensile strength and low conductivity. It is very difficult to work but is used on short lines which must be erected at low cost and for which conductivity is of little importance. Its weight per mile-ohm is 6500 to 7000 lb.

17. Copper-steel conductors. Electrical conductors consisting of a combination of copper and steel are frequently employed for certain types of circuits (see Sec. 13 and Table 87). Three general types of construction are listed in Sec. 13 and are illustrated in Table 86.

Copperweld wire is composed of a steel core with a copper covering thoroughly welded to it by a molten welding process. This process produces a permanent bond between the two metals which prevents any electrogalvanic action and which will withstand hot rolling, cold drawing, forging, bending, twisting, or sudden temperature changes. This wire is made in three grades: 30 percent conductivity, extra-high strength; 30 percent conductivity, high strength; and 40 percent conductivity, high strength. Solid conductors are made in sizes from 12 to 4/0 AWG. Concentric-stranded cables are available in sizes with outside diameters from 0.174 to 0.910 in (0.442 to 23.1 mm.). Weatherproof-covered copperweld solid wire is made in sizes from 12 to 2 AWG. Rubber-insulated twisted-pair cables in sizes 14 and 17 AWG are made for telephone, telegraph, and signal work. Single-conductor rubber-insulated wire may be obtained in any size. Rubber-insulated parallel drop wire is made in one size only, 17 AWG.

Composite cables (*copperweld and copper*) consisting of a combination of certain strands of copper wire with a number of strands of copperweld wire often are economical for aerial circuits requiring more than average tensile strength combined with liberal conductance.

Copper and steel cables consist of a combination of copper and steel wires stranded together. The strands of the different materials are not intended to serve in any dual capacity, and the conductivity of the cable is determined by the sectional area of the copper strands. The size of the cable is designated according to its total sectional area of copper, not according to the total sectional area of the whole cable. For instance, a cable designated as No. 4, consisting of two copper and one steel strands, has a total sectional area of 62,610 cmil (31.7 mm²) and a sectional area of copper of 41,740 cmil (21.1 mm²). The area of the copper, 41,740 cmil, corresponds to the area of a No. 4 wire. The cable is therefore designated as a No. 4 cable, although its total sectional area of copper and steel is between No. 3 and those of No. 2 wire.

These copper and steel cables are available in sizes from No. 2 to No. 12. All sizes except Nos. 10 and 12 consist of two plain hard-drawn copper wires and one extra-galvanized-steel wire. Wire cables of sizes 10 and 12 consist of one galvanized hard-drawn copper wire and two extra-galvanized-steel wires.

18. Copper-clad aluminum. Copper-clad aluminum is the newest conductor material on the market. A copper-clad aluminum conductor is drawn from copper-clad aluminum rod, the copper being bonded metallurgically to an aluminum core. The copper forms a minimum of 10 percent of the cross-sectional area of the solid conductor or of that of each strand of a stranded conductor.

Although copper-clad aluminum contains only 10 percent of copper by volume (26.8 percent by weight), its electrical performance is equivalent to that of pure copper. It is lighter and easier to handle, and the price advantage, which reflects the value of the copper content, can be as much as 25 percent when copper peaks to one of its periodic highs. Detailed studies by Battelle Laboratories have shown that copper-clad aluminum and copper have the same connection reliability.

Because the electrical industry consumes 60 percent of all copper used in the United States, it is critically affected by copper's fluctuating costs and uncertain supply. Until recently, however, aluminum was the only alternative to copper.

Aluminum, in the more than 70 years since its introduction as an electrical conductor, has significantly penetrated such areas as electric power transmission lines, transformer windings, and telephone communications cables. On the other hand, it has received relatively limited acceptance in nonmetallic-sheathed cable and other small-gage building wires. The reason has been a lack of acceptable means of connecting or terminating aluminum conductors of 6 AWG or smaller cross-sectional areas.

Connector manufacturers, the National Electrical Manufacturers Association (NEMA), Underwriters Laboratories (UL), and aluminum companies have devoted much attention to this connection problem. The most significant advance in aluminum termination has been the institution of UL's new requirements and testing procedures for wiring devices for use in branch-circuit-size aluminum conductors. Devices which meet the revised UL requirements are marked CO/ALR and carry that mark on the mounting strap. Only CO/ALR switches and receptacles should be used in aluminum 15- and 20-A branch-circuit wiring.

Copper-clad aluminum is now available to counter the disadvantages of high price and lack of availability of copper and the problems of connection reliability of aluminum. It is a product of a metallurgical material system, i.e., a system in which two or more metals are inseparably bonded in a design that utilizes the benefits of each component metal while minimizing their deficiencies. In copper-clad aluminum conductors, the electrical reliability of copper is combined with the abundant supply, stable price, and light weight of aluminum. Copper-clad aluminum is already being used for building wire, battery cable, magnet wire, and radio-frequency (rf) coaxial cable.

The ampacity (current-carrying capacity) of copper-clad aluminum conductors is the same as that of aluminum conductors. It is required that the wire connectors used with copper-clad aluminum conductors be recognized for use with copper and copper-clad aluminum conductors and be marked CC-CU or CU-AL, except that 12-10 AWG solid copper-clad aluminum conductors may be used with wire-binding screws and in pressure-plate connecting mechanisms that are recognized for use for copper conductors. Copper-clad aluminum conductors are suitable for intermixing with copper and aluminum conductors in terminals for splicing connections only when the wire connectors are specifically recognized for such use. Such intermixed connections are limited to dry locations.

19. Aluminum and aluminum steel-reinforced conductors often are economical for transmission and rural distribution circuits. Commercial hard-drawn aluminum wire has a conductivity at 20°C of 60.97 percent or a resistance of 17.010 $\Omega/\text{cmil} \cdot \text{ft}$. Its weight is 0.000000915 (91.5×10^{-8}) $\text{lb}/\text{cmil} \cdot \text{ft}$. An all-aluminum wire for equal conductivity must have a diameter 126 percent and an area 160 percent of that of a copper wire. All-aluminum conductors are available in bare, weatherproof-covered, rubber-insulated, and thermoplastic-insulated constructions. Aluminum steel-reinforced conductors, owing to their high tensile strength, are frequently used for long spans and for high-capacity lines requiring heavy conductors. They consist of a concentric-stranded aluminum cable with a reinforcing steel core. Except in the smaller sizes, the steel core is made up of several steel strands. Aluminum steel-reinforced conductors are available either bare or weatherproof-covered.

20. Number of conductors. Bare or covered (not insulated) cables must, of course, always be single-conductor. Insulated cables are manufactured with one, two, three, or even more conductors per cable. The choice between single- or multiconductor cable is affected by so many factors, which vary with the particular installation, that only general suggestions can be made here. The selection will be influenced by practical field conditions and facilities of installation, cost of cable and enclosure, physical dimensions of the cable and of the available enclosure, electrical load requirements, and voltage and type of power supply system. The use of multiconductor cables usually results in lower cable cost, smaller voltage drop, and more economical utilization of duct space. On the other hand, single-conductor cables are more flexible and are easier to splice and install. For underground transmission and primary distribution applications, single-conductor cable is generally used when the voltage exceeds 35 kV or when the load is 50,000 kVA or more. For all other underground transmission and primary distribution applications, both single-conductor and multiconductor cables are employed. In the past the use of multiconductor cable was most common, but the use of single-conductor cable in this field is rapidly growing. Single-conductor cable is generally preferred for secondary distribution because of the ease in making taps. For interior building wiring, single-conductor cable is most commonly employed in raceway systems.

21. Cable assembly. For the application of electrical conducting wires and cables, it is essential to have a general knowledge of the materials employed in their manufacture and also of the manner of assembling the component parts in the formation of the finished cable. For a bare wire the assembly is, of course, very simple, consisting only of the solid or stranded wire of the conductor. For insulated cables and especially for multiconductor cables, the use of many materials and different forms of assembly is involved. The component parts of the more common insulated cables, in the order in which the parts are employed in the manufacture of the cables, are as follows:

- A. Single-conductor cables
 - 1. Conductor
 - 2. Insulation
 - 3. Protective covering
- B. Multiconductor cables
 - 1. Without shielding or belting (no insulation around group of conductors)
 - a. Conductor
 - b. Conductor insulation
 - c. Conductor covering
 - d. Fillers
 - e. Protective covering
 - 2. Belted type (insulation around group of conductors)
 - a. Conductor
 - b. Conductor insulation
 - c. Conductor covering
 - d. Fillers
 - e. Belt insulation
 - f. Protective covering
 - 3. Shielded type
 - a. Conductor
 - b. Conductor insulation
 - c. Conductor shield
 - d. Fillers
 - e. Binder tape
 - f. Protective covering

22. Electrical shielding is often necessary on power cable to confine the dielectric field to the inside of the cable insulation so as to prevent damage from corona or ionization. The shield usually consists of a thin (3-mil, or 0.076-mm) conducting tape of copper or aluminum applied over the insulation of each conductor. The shielding tape sometimes is perforated to reduce power losses due to eddy currents set up in the shield. Sometimes semiconducting tapes consisting of specially treated fibrous tapes or braids are used. These semiconducting tapes are frequently employed for the shielding of aerial cable, since they adhere more closely to the insulation and thus tend to prevent corona.

23. Fillers are used in the manufacture of most multiconductor cables. Their purpose is to fill the spaces between the conductors to produce a solid round structure for the complete cable. The materials commonly employed for these fillers are saturated jute, asbestos-base caulk, rubber, and, in some cases, cotton.

24. Binder tapes are used in the construction of many multiconductor cables to bind conductors, shields, and fillers together in proper form during the addition of the protective covering. The more common types of binder tapes are rubber-filled cloth tape, combinations of cotton cloth and rubber compounds, steel, and bronze.

25. Insulation of electrical conductors. Except for aerial construction, interior exposed wiring on insulators, and special cases of interior-wiring feeder circuits, electrical conductors must be covered with some form of electrical insulation. An ideal insulating material for this purpose should have the following characteristics:

- 1. Long life
- 2. Long-time high dielectric strength
- 3. Resistance to corona and ionization
- 4. Resistance to high temperature
- 5. Mechanical flexibility

6. Resistance to moisture
7. Low dielectric loss

It is impossible to find any one material that is best when all these essential characteristics are considered. For instance, impregnated paper has the highest electrical breakdown strength coupled with the longest life of all the materials employed for the insulation of conductors. On the other hand, it is not moisture-resistant, is not so flexible as some other materials, and will not withstand such high temperatures as asbestos. Several different types of insulation are therefore employed. The insulation whose overall characteristics best meet the conditions of service for the particular application should be selected. Tables 76, 99, and 101 classify the different types of insulation with respect to temperature.

26. Rubber insulation. With respect to insulation, *rubber* is the word used to designate insulations consisting of compounds of natural rubber or synthetic rubber, or both, combined with such other ingredients as vulcanizing agents, antioxidants, fillers, softeners, and pigments. These natural-rubber and synthetic rubberlike compounds are used more than any other material for the insulation of electrical conductors. They have the desirable characteristics of moisture resistance, ease of handling and termination, and extreme flexibility. On the other hand, they will not withstand such high temperatures or voltage without deterioration as will some other types of insulation. The different ingredients of each compound are combined by the process of vulcanization into a single homogeneous material.

A large variety of rubber compounds are available, with different characteristics that depend upon the particular service conditions for which they have been developed. It is feasible to include here only those in most common use. For applications which require special characteristics, experts of the cable manufacturers should be consulted for advice on the best available compound.

In general, the physical and electrical properties of a compound increase with the rubber content. However, rubber alone would not provide suitable insulation. The proper choosing and proportioning of the other ingredients are important in obtaining the desired characteristics.

Heat-Resisting Rubber Compounds. These compounds, which will withstand considerably higher temperatures than the Code-grade rubber compound, have been developed. Such compounds meeting Underwriters Laboratories specifications are designated as *Type RHH insulation*.

Moisture-Resistant Rubber Compounds. These compounds are available for installations in which the wire will be subjected to wet conditions. They are called *moisture-resistant* and *submarine compounds*.

Moisture- and Heat-Resistant Compounds. These compounds combine the temperature- and moisture-resistance characteristics of Type RHH and Type RHW insulations. They are recognized by the Underwriters Laboratories designation of *Type RHW*, which is approved for use in wet or dry locations at a maximum conductor temperature of 75°C and RHW-2 for 90°C.

Type SA Wire. It is insulated with a silicone rubber compound. The outer covering of this type of wire must consist of heavy glass that is impregnated with a heat-, flame-, and moisture-resistant compound.

Many wire and cable manufacturers have a rubber compound for use on general power cables which is of a higher quality than required by the Underwriters Laboratories' specifications. These especially high-grade rubber compounds are designated by the individual manufacturer's trade name. Several other nonstandardized compounds, designated by the individual manufacturer's trade name, are available to meet special conditions of service, such as resistance to chemicals, ozone, and corona.

A low-voltage compound called *neoprene*, although not a rubber compound, is recognized by the Underwriters Laboratories as an approved insulation for Type RHW building wire without additional covering over the insulation. It is also widely used in many applications for which its superior mechanical properties are needed, such as self-supporting secondaries for services and service-drop cables, overhead line wires, and motor and appliance lead wires.

27. Thermoplastic insulation. Thermoplastic compounds have been developed for insulations of electrical wires. Those meeting the specifications of the Underwriters Laboratories are designated as *Type TW, THW, THWN, THHN, THHW, TBS, or MTW*. Type TW, THW, or THWN is moisture-resistant and can be used in wet locations. Type THW or THWN is both moisture- and heat-resistant and is approved for use in wet or dry locations at a maximum conductor temperature of 75°C. Type THHW is moisture- and heat-resistant and may be used in wet or dry locations at a maximum conductor temperature of 75°C in wet locations and 90°C in dry locations. Type TBS is thermoplastic insulation with a flame-retardant fibrous outer braid and is acceptable only for switchboard wiring. Type THWN is a moisture- and heat-resistant insulation that is approved for both wet and dry locations at a maximum conductor temperature of 75°C. It has an outer nylon jacket. Just as in the case of Type RHW, this insulation is also available in a form suitable for 90°C in wet locations, and it has the same "-2" suffix. Thus, Type THWN-2 can be used in wet locations and where exposed to high temperatures. Type THHN is similar to Type THWN, except that it is not moisture-resistant and may be used only in dry and damp locations at a maximum conductor temperature of 90°C. Type MTW is moisture-, heat-, and oil-resistant and is restricted to use in machine-tool wiring at a maximum conductor temperature of 60°C in wet locations and 90°C in dry locations.

28. Thermosetting insulation. Four high-quality wires are *Types XHH, XHHW, FEP, and FEPB*. Type XHHW is a moisture- and heat-resistant, cross-linked, thermosetting polyethylene with an insulating rating of 75°C in wet locations and 90°C in dry locations. Here also, Type XHHW-2 is available, which can be used for 90°C exposures in wet locations. Type XHH has a thermoset insulation that is rated at 90°C in dry or damp locations. Type FEP has a heat-resistant, fluorinated ethylene propylene insulation and is suitable for use in dry or damp locations at a maximum conductor temperature of 90°C, and Type FEPB is suitable for dry locations at 200°C for special applications.

29. Mineral insulation. The objective in developing mineral insulation was to provide a wiring material which would be as noncombustible as possible and thus eliminate the hazards of fire resulting from faults or overloads. This insulation consists of highly compressed magnesium oxide and is designated as *Type MI cable*. The outer metallic sheath is copper. A complete description of this cable is given in Sec. 54 of this division and in Div. 9.

30. Paper insulation. Impregnated-paper insulation provides the highest electrical breakdown strength, greatest reliability, and longest life of any of the materials employed for the electrical insulation of conductors. It will safely withstand higher operating temperatures than either rubber or varnished-cambric insulations. On the other hand, it is not moisture-resistant and must always have a covering which will protect the insulation from moisture, such as a lead sheath.

Paper-insulated cables are not so flexible and easy to handle as varnished-cambric or rubber-insulated cables and require greater care and time for the making of splices. They are available in the following types:

1. Solid-type insulation
2. Low-pressure gas-filled
3. Medium-pressure gas-filled
4. Low-pressure oil-filled
5. High-pressure oil-filled (pipe enclosed)
6. High-pressure gas-filled (pipe enclosed)
7. High-pressure gas-filled (self-contained)

The *solid-type insulation* is composed of layers of paper tapes applied helically over the conductor and impregnated with mineral oil (sometimes mixed with resin when so specified). A tightly fitting lead sheath is extruded over the assembled conductors and impregnated insulation. The oil must be heavy enough to prevent bleeding when the cable is cut for splicing and terminations but at the same time must remain semifluid at the lowest operating temperatures. For cables installed as vertical risers, on steep grades, or under high operating temperatures, a heavier oil, designated as a nonmigrating compound, is sometimes employed to prevent the migration of the oil from the high to the low points of the cable. The ordinary solid-type impregnated-paper insulation will give off flammable and explosive gases when exposed to extremely high temperatures. It is a common practice to clear cable failures on low-voltage network cables by leaving the power on and burning the fault clear. To reduce the possibility of damage to raceways and manhole structures from consequent explosions, special nonflammable, nonexplosive compounds are sometimes used to impregnate the paper insulation.

Low-pressure gas-filled cables, operating under nitrogen gas pressure of 10 to 15 lb/in² (68,947.6 to 103,421.4 Pa), are manufactured and impregnated in the same manner as solid-type cable, but prior to leading it is drained in a nitrogen atmosphere at a temperature somewhat above the maximum allowable operating temperature. To give the gas free access to the insulated conductors, longitudinal gas feed channels are placed in the filler interstices of the three-conductor construction and flutes or another type of channel under the sheath of the single-conductor construction. In the three-conductor construction, two of the three gas feed channels are obtained either by omission of filler material from the interstices or by use of an open helical coil made from steel strip. The third channel is a solid-wall metal tube filled with dry nitrogen gas and sealed off at each end before treatment of the cable length. The end of this solid-wall metal channel is opened at each joint location and ensures positive control of the pressure over the entire cable length by furnishing a bypass path for the gas at low points or dips in the cable run where "slugs" of surplus compound may gradually collect in service in the open-wall channels.

Cable operating records indicate that most service failures are attributable to damage to lead sheaths arising from a variety of causes or to leaks in joint wipes, terminals, or other accessories. An important advantage of low-pressure gas-filled cable, in common with low-pressure oil-filled cable, is that service failures from these causes are practically eliminated because a positive internal pressure is maintained continuously within the sheath, the

entrance of moisture is prevented, and operation can continue until it is convenient to make repairs.

Medium-pressure gas-filled cables operate under a nitrogen pressure of about 49 lb/in² (337,843 Pa). They are constructed in a manner similar to the low-pressure gas-filled cables, except that a reinforced lead sheath is employed to permit the use of the increased gas pressure.

In *low-pressure oil-filled cables*, the paper is impregnated with a relatively thin liquid oil which is fluid at all operating temperatures. The cable is so constructed that channels are provided for longitudinal flow of the oil, and oil reservoirs are furnished at suitable points in the cable installation. A positive pressure of moderate magnitude is thus maintained on the oil at all times, which prevents the formation of voids in the insulation due to changing temperature, stretching, or deformation of the lead sheath. When the cable is heated by load, the oil expands and flows lengthwise through the channels of the cable into the joints and out into the reservoirs. When the cable cools and the oil in the cable contracts, oil is forced back through the channels of the cable from the oil reservoirs. Any damage to the lead sheath will allow moisture to enter a solid-type insulated cable. With oil-filled cable, unless the damage is too severe, the positive internal oil pressure will prevent the entrance of moisture, so that although there will be some loss of oil, operation can continue until it is convenient to make repairs.

High-pressure oil-filled cables (pipe enclosed) are insulated and impregnated in the same manner as single-conductor solid-type cables. The necessary number of single-conductor cables are then pulled into a welded steel line pipe which is protected by a high-grade corrosion-protective covering. The enclosing pipe is then filled with oil, which is maintained under constant high pressure. An oil pressure of approximately 200 lb/in² (1,378,951 Pa) prevents the formation of voids in the insulation and is maintained by oil pumps at one or more points on the line.

To provide protection against moisture entrance during shipment, the cable may be shipped with a temporary lead sheath or on a special weathertight reel without a lead covering. In the former case a thin temporary lead sheath is extruded over the skid wires and is stripped from the cable during the pulling operation. When the cable is shipped without a temporary lead sheath, all seams of the weathertight reel are carefully welded. The outer layer of cable is covered by a "blanket" of material having a very low rate of moisture absorption and diffusion. The edges of the blanket are tightly sealed to the inside surface of the reel flange by a moisture-repellent plastic adhesive and sealing compound. Joints between external mechanical protection, such as lags, sheet-metal layers, etc., and the steel rim of the reel flange are sealed in a similar manner. Each reel is also equipped with a pocket containing a desiccant, and prior to shipment the reel interior is flushed carefully with dry nitrogen gas.

High-pressure gas-filled cable (pipe enclosed) is similar to the high-pressure oil-filled type in that the insulated conductors comprising the circuit are installed in a metal pipe but differs from it in that nitrogen gas at a pressure of approximately 200 lb/in² (1,378,951 Pa) is employed as a pressure medium in place of oil.

In the mass-impregnated type, the paper tape is applied to the conductor, and the cable is impregnated in the same manner as the solid type. Shipment is carried out in the same manner as that for high-pressure oil-filled cables, either with a temporary lead sheath or on a weathertight reel without a lead covering.

High-pressure gas-filled (self-contained) cables use a lead sheath reinforced with metallic tapes as the pressure-retaining member in place of the steel pipe. In these cables, the permanent lead sheath and the associated reinforcement and protective coverings are applied to the cable prior to shipment from the factory.

A special grade of untreated paper is sometimes employed for insulating magnet wires. It is applied to the conductor in ribbon form as a helix with approximately one-third to one-half

lap. This procedure provides a low-cost insulation of constant thickness and slightly higher dielectric strength than that provided by cotton yarn, but it is less sturdy.

31. Varnished-cambric insulation has characteristics which in almost every respect are midway between those of rubber and paper. It is more flexible than paper but not so flexible as rubber, except for large insulated cables. It is reasonably moisture-resisting, so that it need not always be covered with a lead sheath, but it cannot be operated without such protective covering if it is continuously immersed or is in continuously moist surroundings. With respect to dielectric strength, allowable temperature, and resistance to ionization and corona, it is better than rubber but not so good as impregnated paper. Varnished cambric is not affected by ordinary oils and greases and will withstand hard service.

The term *varnished cambric* is misleading, since the cotton-fabric base of the insulation is not cambric. The correct designation should be *varnished cloth*, but because of long-established custom the material is designated as varnished-cambric insulation. Varnished-cambric-insulated cable consists of conductors helically wrapped with cotton tape which has been previously filled and coated on both sides with insulating varnish. During the wrapping process, a heavy nonhardening mineral compound is applied between the tapings to act as a lubricant when the cable is bent and also to fill all spaces so as to prevent ionization and possible capillary absorption of moisture.

32. Silicone rubber provides a truly heat-resisting insulation suitable for use at temperatures beyond the limits allowable for other standard forms of cable insulation. However, it is satisfactory only for low-voltage installations (not more than 8000 V), since it cannot be applied to the conductors so as to give high dielectric strength to the cable insulation.

Type SA. Silicone rubber insulated with outer heavy glass.

33. Cotton yarn is often employed for the insulation of magnet wire. The wire is covered with one or more wraps of helically wrapped unbleached cotton yarn. When more than one wrap is employed, each wrap is applied in the reverse direction to that of the next inner wrap. The untreated cotton is neither heat-resisting nor impervious to moisture. It is not fully considered to be an insulation, and coils wound with it should be treated or impregnated with an insulating compound by an approved process. The cotton yarn acts as a mechanical separator, holding the conductors apart and providing a medium for the absorption and retention of the impregnating material. Cotton yarn is also used as a protective covering for enamel-insulated magnet wire.

34. Enamel is widely used as an insulation for magnet wire. It has excellent resistance to moisture, heat, and oil and possesses high dielectric strength. Enamel wire consists of a comparatively thin, even coating of high-grade organic insulating enamel applied directly to the bare wire. It is made in various types as given in Sec. 82.

35. Silk yarn is employed in the same manner as cotton yarn (Sec. 33) for the insulation of magnet wire. Silk coverings have better dielectric characteristics, give a neater appearance, and are mechanically stronger than cotton. Otherwise, all the statements in Sec. 33 respecting cotton-yarn insulations apply to silk.

Cellulose-acetate (artificial silk) tape or yarn is used in many applications for the insulation of magnet wire as a substitute for or in combination with natural silk. Artificial silk

has somewhat better electrical characteristics and gives a more uniform thickness of insulation. Its strength and abrasion resistance are not so good as those of natural silk.

36. Fibrous-glass yarn has been developed for the insulation of conductors. Up to the present time it has been employed only for the insulation of dynamo windings and magnet wire for classes of service requiring operation at high temperatures. The conductors are wound with one or more wraps of alkali-free fibrous-glass yarn.

37. Protective coverings. The insulation of most insulated conductors is protected from wear and deterioration due to surrounding conditions by a covering applied over the insulation. Protective coverings are also used on some noninsulated cables such as the weatherproof wire used for distribution purposes (see Secs. 10 and 11). The materials most commonly used for these protective coverings are listed in Sec. 38. No one covering will fulfill all the protective functions that are required for all classes of installations. Each has its particular advantages and limitations and consequently its proper field of application. In many cases a combination of two or more types of covering is required to provide the necessary protection to the conductor and its insulation.

38. Protective-covering materials and finishes

I. Nonmetallic

A. According to material of covering

1. Fibrous braids

a. Cotton

- (1) Light
- (2) Standard
- (3) Heavy
- (4) Glazed cotton

b. Seine twine or hawser cord

c. Hemp

d. Paper and cotton

e. Jute

f. Asbestos

g. Silk

h. Rayon

i. Fibrous glass

2. Tapes

a. Rubber-filled cloth tape

b. Combination of cotton cloth and rubber compounds

3. Woven covers (loom)

4. Unspun felted cotton

5. Rubber jackets

6. Synthetic jackets

7 Thermoplastic jackets

8. Jute and asphalt

B. According to saturant

1. Asphalt

2. Paint

3. Varnish

C. According to finish

1. Stearin pitch and mica flake

2. Paint

3. Wax

4. Lacquer

5. Varnish

II. Metallic

A. Pure lead sheath

B. Reinforced lead sheath

C. Alloy-lead sheath

D. Flat-band armor

E. Interlocked armor

F. Wire armor

G. Basket-weave armor

39. Fibrous braids are used extensively for protective coverings of cables. These braids are woven over the insulation so as to form a continuous covering without joints. The braid is generally saturated (Sec. 45) with some compound to impart resistance to some class of exposure such as moisture, flame, or acid. The outside braid is given one of the finishes described in Sec. 45 in accordance with the application of the cable.

The most common braid is one woven from *light, standard, or heavy cotton yarn*. Such coverings are designated, respectively, as ICEA Classes A, B, and C. (ICEA are the initials of the Insulated Cable Engineers Association.) The cotton can be furnished in a variety of colors for identification in accordance with an established color code in the industry.

Glazed-cotton braid is composed of light cotton yarn treated with a sizing material before fabrication.

Seine-twine or hawser-cord braid is composed of cable-laid, hard-twisted cotton yarn, braided to form a heavy, durable covering which will withstand more rough usage than a braid made from common cotton yarn.

Hemp braid is woven from strong, durable, long-fibered hemp yarn which will withstand even rougher usage than seine-twine braid.

Paper-and-cotton braid is composed of paper twine interwoven with cotton threads.

Jute braid is woven from yarn composed of twisted jute fibers.

Silk and rayon braids are manufactured in the same manner as glazed-cotton braid from real or artificial silk yarn.

Fibrous-glass braid is woven from fine, flexible glass threads and forms a covering resistant to flame, acids, alkalies, and oils.

40. Fibrous-tape coverings are frequently used as a part of the protective covering of cables. The material of tape coverings is fabricated into a tape before application to the cable, while the yarn in braid coverings is woven into a fabric during application to the cable. In applying tape coverings, the tape is wrapped helically around the cable, generally with a certain amount of overlapping of adjacent turns. The more common types of fibrous tapes employed in cable manufacturing are listed in Sec. 38. Except for duck tape, tape coverings are never used for the outer covering of a cable. They are employed for the covering directly over the insulation of individual conductors and for the inner covering over the assembled conductors of a multiconductor cable. Frequently they are used under the sheath of a lead-sheathed cable. Duck tape made of heavy canvas webbing presaturated with asphalt compound is frequently used over a lead-sheathed cable for protection against corrosion and mechanical injury.

41. Woven covers, commonly called *loom*, are used for applications requiring exceptional abrasion-resisting qualities. These covers are composed of thick, heavy, long-fibered cotton yarn woven on the cable in a circular loom like that used for fire hose. They are not braids. Although braid coverings also are woven, they are not designated as such.

42. Unspun felted cotton is manufactured into a solid felted covering for cables for some special classes of service.

43. Several types of rubber and synthetic jacket coverings are available for the protection of insulated cables. These types of coverings do not seem to be standardized. The different manufacturers have their own special compounds designated by individual trade names. These compounds differ from the rubber compounds used for the insulation of cable in that they have been perfected not for insulating qualities but for resistance to abrasion, moisture, oil, gasoline, acids, earth solutions, alkalies, etc. Of course, no one jacket compound will provide protection against all these exposures, as each has its particular qualifications and limitations.

A nonrubber compound with excellent characteristics for a jacket material is called *neoprene*.

Thermoplastic compounds are becoming more and more popular as jacket materials. Although no one material is perfect in all respects for jacket coverings, thermoplastic compounds possess many of the necessary characteristics for the coverings.

44. Jute and asphalt coverings are commonly used as a cushion between the cable insulation and a metallic armor. Frequently they are also employed as corrosion-resisting coverings over a lead sheath or metallic armor. They consist of asphalt-impregnated jute yarn served helically around the cable or of alternate layers of asphalt-impregnated jute yarn serving and asphalt-weatherproofing compound.

45. Saturants and finishes for fibrous coverings. Fibrous braids used for covering cables are thoroughly saturated, and the outer surface is finished to provide protection against moisture, flame, weathering, oil, etc. The common materials employed for saturating the braids are listed in Sec. 38*B*, and the common materials employed for finishing the outer surface in Sec. 38*C*.

46. A pure lead sheath of uniform thickness tightly applied over an insulated cable by the extrusion process at one time was practically a standard covering for use in underground raceways and other wet locations. If the cable will be exposed to special forms of corrosion, electrolytic action, or mechanical strain, one of the other coverings is used in combination with the lead sheath as a protective covering over the sheath.

47. A reinforced lead sheath is employed for mechanical strength when internal cable hydrostatic pressures exceed 15 lb/in² (103,421.4 Pa). This construction consists of a double lead sheath. Around the inner sheath is wrapped a thin tape of hard-drawn copper, bronze, or other elastic metal, preferably nonmagnetic in character. This tape imparts considerable additional strength and elasticity to the sheath. However, it must be protected against wear and corrosion. For this reason a second lead sheath is applied over the tape. Such a finish is recommended for internal pressures up to 30 lb/in² (206,842.7 Pa). It is commonly used on oil-filled cable near the bottom of severe grades or on solid cable at the base of vertical risers and at the bottom of extreme grades where pressure can accumulate.

48. An alloy-lead sheath is employed when additional mechanical strength and resistance to crystallization of the sheath are required. The most common alloy is one containing 2 percent tin. Sometimes an antimony-lead alloy is used. An alloy sheath is more resistant to gouging and abrasion during or after installation than a pure lead one.

49. Flat-band armor usually consists of two steel tapes applied on the outside of the cable so that the openings between successive turns of the inner tape are covered by the outer tape. Usually these tapes are applied over a jute bedding introduced between them and the lead sheath or cable insulation, and they are frequently finished with an overall layer of asphalted jute as a protection against corrosion. Ordinarily, plain steel tapes are

recommended. If corrosion conditions are apt to be severe, galvanized steel or nonferrous materials should be used.

50. Interlocked armor consists of a single strip of interlocking metal tape so applied over the insulation of the cable that the cable is always protected throughout its length. The interlocking construction prevents adjacent tapes from being squeezed together during installation or in service, with consequent damage to the edges of the tapes, which sometimes occurs with flat-band steel armor; in addition, it eliminates gaps or open spaces, as there is no break in the continuity of the interlocking strip. The armor is so shaped that its physical strength against mechanical injury to the cable is superior to that of flat-band armor. Its rounded surface tends to deflect blows from shovels or picks and also offers an additional buffer effect to blows that tend to pierce the armor, thereby minimizing damage to the lead sheath and insulation over which it is applied.

For rubber- or varnished-cambric-insulated cables used for interior work, the armor is generally applied over a jute bedding which is introduced between the armor and the cable insulation.

For underground installation a lead sheath under the jute bedding of armor is required for paper cables, varnished-cambric cables, or 20 or 25 percent Code-rubber cables.

An overall asphalt-jute finish is sometimes used as additional protection against corrosion, particularly if the cable is to be buried in the earth.

A thermoplastic jacket is often applied over the armor, particularly if corrosive conditions exist, as in chemical plants, paper and steel mills, and similar industrial establishments.

Galvanized steel is the standard material for armor employed in interior building wiring. For other power applications plain steel armor is standard and suitable for most installations, although galvanized armor will give a longer life. Nonmagnetic materials may be furnished for the larger single-conductor cables. Aluminum, copper, or bronze is frequently used when corrosion conditions are apt to be severe.

51. Wire armor consists of a layer of round metal wires wound helically and concentrically about the cable. The standard type employs galvanized-steel wires, but if desired, wire armor constructed of nonferrous materials can be obtained. Wire armor is recommended when extreme tensile strength and greatest mechanical protection are necessary. Galvanized-steel construction is stronger than nonferrous. Usually a layer of asphalt-treated jute is introduced between the armor and the sheath to prevent mechanical damage and to minimize electrolytic action. Galvanized armor can be used when corrosion would damage the iron, and further protection in the form of an overall asphalt-jute finish is not uncommon.

52. Basket-weave armor is used when light weight and compactness are important. It consists of a braid of metal wire woven directly over the cable as an outer covering. Galvanized-steel, bronze, copper, or aluminum wire is used for the braid, depending upon the service for which the cable is intended. This armor finish is used largely for shipboard wiring.

53. General-purpose power cables for underground raceways and interior wiring are available with rubber-, thermoplastic-, varnished-cambric-, paper-, or asbestos-insulated copper or aluminum conductors. The particular type of such an insulation may be any of the types previously listed, depending upon the requirements of the service.

Class B stranding is the adopted standard for copper conductors of these cables, but any of the more flexible standard concentric or rope strandings is available, and Class C stranding is becoming the predominant method of stranding due to greater ease of installation. In addition, varnished-cambric- and paper-insulated copper conductor cables may be obtained with the following construction:

<i>Construction</i>	<i>Available for</i>
Compact round	Single conductor from 1 AWG to 1,000,000 cmil Multiconductor from 1 AWG to 1,000,000 cmil Generally employed only for 1 AWG
Compact sector	Multiconductor 1/0 AWG and larger
Annular concentric	Single conductor, 750,000 to 5,000,000 cmil
Compact segmental	Single conductor, 1,000,000 to 4,000,000 cmil
Hollow-core stranded	Single conductor, oil-filled paper cables, 2/0 AWG to 2,000,000 cmil

General-purpose power cables are normally constructed in single- and three-conductor cables for all the types of insulations mentioned. Rubber-insulated wires are also regularly made in two-conductor construction. Four-conductor cables are not standard construction but can be obtained.

One common type of protective covering consists of a rubber-filled cloth tape and an outer cotton braid treated with moisture-resisting, flame-resistant, or moisture- and flame-resistant compounds. Another common protective covering is a neoprene jacket. If the cable will be subjected to rough usage, the outer braid should be made of seine twine, hawser cord, or hemp. If high flame resistance is required, since asbestos has been discontinued due to environmental concerns, one of the special insulations designed for such exposures must be used. For underground raceway installation and interior wiring in wet locations, suitable types should be used. If protection against corrosion, electrolysis, or damage due to accidental short-circuiting of open-circuited sheaths is required, the lead sheath is protected by an outer covering of duct tape, reinforced rubber, or jute and asphalt. For cable subjected to special exposures such as acids, alkalis, and gasolines, a suitable rubber or synthetic sheath should be employed (see Sec. 43). Thermoplastic- and latex-insulated wires do not require an outer protective covering. Interlocked metal armor is advantageous as the outer covering for many installations, both indoor and outdoor.

The covered (not insulated) wires described in Sec. 10 are included under the classification of general-purpose power cables.

General-purpose power cables with insulation and covering meeting the minimum requirements of the National Electrical Code are frequently called *building wires and cables*. The Code designation letters for these cables according to the type of insulation employed are given in Div. 9. In addition to these type letters, the Code uses the following suffix letters:

1. No suffix letter indicates a single insulated conductor.
2. Suffix letter *D* indicates two insulated conductors laid parallel within an outer non-metallic covering.
3. Suffix letter *M* indicates an assembly of two or more insulated conductors twisted spirally within an outer nonmetallic covering.

54. MI (mineral-insulated) cable was developed to meet the needs for a noncombustible, high-heat-resistant, and water-resistant cable. As described by the National

FIGURE 2.5 MI cable construction. [General Cable Co.]

Electrical Code, “MI cable (see Fig. 2.5) is a cable in which one or more electrical conductors are insulated with a highly compressed refractory mineral insulation and enclosed in a liquidtight and gastight metallic tube sheathing.” It is available in single-conductor construction in sizes from 16 AWG to 500 kcmil, in two-conductor construction in sizes from 16 to 1 AWG, in three-conductor construction in sizes from 16 AWG to 3 AWG, in four-conductor construction in sizes from 16 AWG

to 6 AWG, and in seven-conductor construction in sizes from 16 AWG to 8 AWG.

The cable is fabricated in the following manner. Magnesium oxide in powder form is molded under great pressure into cylinders approximately 2 in (50.8 mm) in diameter and length, with as many holes through the body of the cylinder as there are conductors in the cable. After molding, the magnesium oxide cylinders are completely dehydrated in electric furnaces. The cylinders are then placed inside a seamless uncoated copper tube whose inside diameter is slightly larger than the diameter of the molded cylinders. Solid uncoated high-conductivity copper rods are then inserted in the holes in the cylinders. After the ends of the filled copper tube have been sealed, the tube goes through a series of drawing and annealing operations. In the drawing process the compressive forces reduce the magnesium oxide cylinders to powder form and produce a dense homogeneous mass of magnesium oxide which transmits the compressive forces to the conductor rods. This drawing produces, in effect, the equivalent of a solid homogeneous rod with all members—copper tube, copper rods, and magnesium oxide—maintaining the same relative position to each other while being proportionately reduced in diameter and cross section and increased in length. (Each component maintains its original proportionate size and relative position throughout the remainder of the process until the desired finished sheath diameter is reached.) The assembly is annealed at intervals during the drawing process to eliminate the effect of work hardening on the metal, and the finished cable is supplied fully annealed.

A departure from the fabrication method just described has been adopted for some constructions. In this method the same starter tube stands vertically while the starter conductors are inserted and jugged into position. Then, dried magnesium oxide powder is introduced into the tube and tamped to the desired density. After completion of this vertical filling operation, a drawing and annealing sequence is employed as with the horizontal, plug-type filled-cable assembly.

55. Nonmetallic-sheathed building cable is employed for the economical wiring of residences, farm buildings, small stores, etc. It consists of two or more conductor, rubber- or thermoplastic-insulated cable. When desired, a bare or insulated copper ground wire is incorporated in the cable assembly. The ground wire is laid in the interstices between the circuit conductors under the outer braid. Non-metallic-sheathed cable is manufactured under several trade names. The overall dimensions will differ somewhat with different manufacturers. Type designations are NM, NMC, and NMS.

56. Armor-clad building cable consists of rubber- or thermoplastic-insulated copper wire protected by flexible galvanized-steel armor. Type AC cable is regularly available

in one-, two-, three-, and four-conductor assemblies in sizes from 14 AWG to 2 AWG and also in size 1 AWG for a single conductor only. Individual conductors are finished in different colors for identification of any conductor in installation. In installing these cables a short fiber bushing (see Div. 9) is inserted between the conductors and the steel armor wherever the cable is cut. They are also commonly called *BX cable*.

Armored ground wire consists of a bare copper conductor with a flexible steel armor covering applied directly over the wire.

57. Metal-clad cable. Type MC cable is a factory assembly of one or more conductors, each individually insulated with or without optical-fiber members and enclosed in a metallic sheath or interlocking tape or in a smooth or corrugated tube. This category includes wire protected by flexible galvanized-steel armor, aluminum sheathed in a liquidtight and gastight, close-fitting, and continuous aluminum sheath, or copper sheathed in a liquidtight and gastight, close-fitting, and continuous copper or bronze sheath. Type MC cable should not be used in or exposed to corrosive conditions or directly buried in earth or concrete unless it is provided with a metallic sheath which is suitable for the conditions and is protected by materials suitable for the conditions. Metal-clad cable shall be installed as required by Article 330 of the National Electrical Code.

58. Cablebus. This is an approved assembly of insulated conductors mounted in a spaced relationship in a ventilated metal-protective supporting structure, including fittings and conductor terminations. Usually assembled at the installation site from components furnished or specified by the manufacturer, cablebus may be used at any voltage or current for which the spaced conductors are rated. Components of this wiring system are described in Div. 9.

59. Class 2 and Class 3 remote-control, signaling, and power-limited circuits. These circuits are the portion of the wiring system between the load side of the overcurrent device or the power-limited supply and the connected equipment. For installation requirements, see Article 725 of the NEC.

60. Service cables. Special multiconductor cables have been developed to meet the requirements for connecting the pole line of the street distribution system with the service-entrance equipment on the consumer's premises. The following terminology derived from their application is used for service cables:

1. *Service-drop cables.* Overhead service conductors between pole and building.
2. *Service-entrance cables.* Service conductors which extend along the exterior and enter buildings to the meter, switch, or service equipment.
3. *Combination service-drop and service-entrance cables.* Service conductors continuing without a break from the pole to the meter, switch, or service equipment.
4. *Underground service-entrance cables.* Service conductors installed in conduit or directly in the earth and entering the building to the meter, switch, or service equipment.

Service cable is made in two different types designated by the Underwriters Laboratories. Service-entrance cable is available in sizes 12 AWG and larger for copper

and 10 AWG and larger for aluminum or copper-clad aluminum, with Types RHW, THWN, or XHHW conductors. The cables are classified as follows:

1. *Type SE.* Cable for aboveground installation.
2. *Type USE.* Cable for underground installation, including burial directly in the earth. Cable in sizes 4/0 AWG and smaller with all conductors insulated is suitable for all underground uses for which Type UF cable is permitted by the National Electrical Code. Type USE service-entrance cable is similar in general construction to general power cables for direct burial in the earth.

Service cables are either rubber- or thermoplastic-insulated. They are available in two-, three-, and four-conductor assemblies.

61. Aerial cables. Bare, weatherproof (weather-resisting) covered, and rubber-insulated tree wire are all used for overhead pole-line power circuits. Bare wire is used for most power transmission circuits. See Sec. 13 and Table 87 for conductor materials employed and their field of application. Weatherproof (heat-resisting) covered wire is the general standard for distribution and low-voltage transmission circuits. Tree wire is used in distribution circuits when heavy tree growth would make the use of weatherproof wire unsuitable. It consists of a rubber-insulated copper wire protected with an abrasion-resisting covering.

The application of multiconductor aerial power cables is continually increasing. For messenger-type construction, general-purpose power cable with an alloy-lead sheath is commonly employed. To minimize the weight of extremely large cables, it is generally advisable to eliminate the lead sheath. For such installations two types of cable construction have proved satisfactory. One type consists of either paper- or varnished-cambric-insulated cable supplied with a rubber hose jacket and an overall band or interlocked armor of either steel or bronze. The other type has utilized rubber- or varnished-cambric-insulated shielded cable and an overall seine twine or hawser braid saturated with a moisture-resisting compound. A layer of rubberized tape or presaturated duck tape is interposed between the overall shielding band and the outer braid. The rubber insulation should be a corona-resisting compound, except for the lower voltages.

Most of the new installations of multiconductor aerial power cables are of the pre-assembled self-supporting type. These cables consist of one or more (usually three) rubber-insulated conductors bound to a suitable messenger cable by a flat metallic strip applied with open-lay helical wrap. In some cables each insulated conductor is covered by a neoprene jacket. In others the insulation of each conductor is covered with a tough abrasion- and corrosion-resistant aluminum-bronze shielding tape. In a third type of construction each insulated conductor is shielded by means of a tinned-copper tape and then covered with a neoprene jacket.

62. Power cables for direct burial in the earth without raceways are available in both metallic and nonmetallic armored types. Cables of different manufacturers are fairly common in general construction but differ in details of assembly and manufacture.

The metallic types consist of a lead-sheathed general-purpose power cable protected with a jute and asphalt covering or a combination covering of a flat or interlocking tape armor together with jute and asphalt. Rubber is generally used for the insulation, but

paper or varnished cambric may be employed if desired. The cables are available in one-, two-, three-, and four-conductor assemblies. These metallic types are commonly called *parkway cables*.

The nonmetallic types consist of rubber-insulated conductors protected with some form of nonmetallic covering that will provide a moisture seal, resistance to corrosion, and sufficient mechanical strength. One type of armor assembly consists of a combination of layers of asbestos-base caulk coatings, asbestos braid filled with asbestos-base caulk, and treated fibrous tape, all enclosed in a presaturated heavy duck tape. The outer surface is finished with pitch and mica flake. A common armor assembly is the jute and asphalt covering described in Sec. 44. Rubber and synthetic jackets are also employed for the protective covering of nonmetallic cables for direct burial in the earth. The jackets are frequently enclosed in a saturated duck tape or sisal braid. All the nonmetallic types mentioned are available in one-, two-, and three-conductor assemblies. Some two-conductor cables are made with one central insulated conductor and one noninsulated conductor concentrically stranded over the insulation of the inner conductor.

Thermoplastic-insulated single-conductor and multiconductor Type UF cables are also available for use up to and including 600 V.

63. Network cables were developed primarily for underground raceway installation for low-voltage secondary network service. They are single-conductor nonmetallic-sheathed cables suitable for circuits operating at not more than 600 V. These cables are insulated with a special rubber compound covered with a neoprene jacket. Braid-covered or lead-sheathed network cables are also available.

64. Series street-lighting cables differ from other power cables in the thickness of the insulation employed on the wires. They are rubber-, varnished-cambric-, or thermoplastic-insulated single-conductor cables, available in shielded or unshielded types. Rubber-insulated cables can be obtained with an outer neoprene jacket or with a lead sheath. Lead-sheathed cables can be obtained with additional coverings of jute or jute and double flat steel-tape armor with jute overall for conditions requiring added protection. Varnished-cambric-insulated cables are always lead-sheathed and may be supplied with any of the additional coverings mentioned above for rubber-insulated leaded cable.

65. Ornamental-pole and bracket cable is a two-conductor, rubber-insulated cable specially designed for great flexibility and small overall diameter. It is used for the interior wiring of ornamental lighting poles fed by underground cable and for the exterior wiring of pole-type bracket or mast-arm street-lighting fixtures. For voltages not exceeding 4000, twin-type cable construction, consisting of two rubber-insulated, single-cotton-braid-covered conductors laid parallel and enclosed in overall tape and weatherproof braid, is employed. For voltages greater than 4000, belted construction is employed. This assembly consists of two rubber-insulated and single-cotton-braid-covered conductors laid parallel and enclosed in a close-fitting belt of insulating compound. The belt insulation is covered with a tape and weatherproof braid. Another assembly for belted cable consists of two thermoplastic-insulated conductors laid parallel and enclosed in a close-fitting belt of plastic which serves as both insulation and a jacket.

66. Borehole or mine-shaft cables are specially designed to withstand the mechanical strains to which long lengths of vertically suspended cable are subjected. Both rubber and varnished cambric are employed for insulation. The rubber-insulated cables are made both with and without a lead sheath, while the varnished-cambric cables are always lead-sheathed. The cable is protected with a steel-tape or steel-wire armor. Steel-tape armor should not be used unless supports can be provided at intervals not exceeding 50 ft (15.24 m). When the cable must be supported entirely from the top, wire armor must be used. The armor should be designed with sufficient strength to support the entire cable weight with a factor of safety of at least 5 and based on a tensile strength of 70,000 psi (482,632, to 482,990 Pa). The wire armor should be served with bands of steel wire to provide a suitable bond. Conductor-supported cables, instead of the above-described armor-supported ones, are sometimes used for this class of service. The rubber-insulated conductors are protected with a strong loom covering and installed in metallic borehole casings or conduit. Medium-hard-drawn copper is used for the conductors, which entirely support the cable through conductor clamps and strain insulators.

Cables similar to the steel-armor borehole cables are employed for the vertical risers of tall buildings. For nonleaded construction a factor of safety of at least 7 should be used in designing the wire armor, while for leaded construction the minimum factor of safety should be 4.

67. Submarine cables for installation under water in rivers, lakes, harbors, etc., are rubber-insulated power cables protected with a wire armor. The more common types of coverings employed are jute and wire armor; jute, wire armor, and jute; lead, jute, and wire armor; and lead, jute, wire armor, and jute. It is best to consider each submarine installation a separate engineering problem and obtain the recommendations of the cable experts of reliable cable manufacturers.

68. Control cables consist of an assembly of several small conductors for carrying the relatively small currents for remote control of motors, circuit breakers, or other power equipment; for relay and metering circuits; for traffic-light control systems; etc. Standard assemblies vary from 1 conductor per cable to 37 conductors per cable. The size of the conductors ranges from 14 AWG to 9 AWG. For most installations a 30 percent rubber compound is used for the insulation of the conductors, although varnished cambric and thermoplastic are also employed. For installations in which the temperature is higher than normal, either a heat-resisting rubber compound or felted asbestos should be employed, the choice depending upon the temperature of the surroundings. Each individual conductor is covered with a color-coded cotton braid for protection of the insulation and identification of circuits. The conductors are assembled with jute fillers and bound together with a rubber-faced or asbestos binder tape.

For rubber-insulated cables the outer covering may be a standard cotton weatherproof braid with a black weatherproof wax finish, a lead sheath, a neoprene jacket, metallic or nonmetallic armor for direct burial in the earth as described for power cable in Sec. 62, or a braid or jute bedding protected by interlocking steel-tape armor. With rubber-jacket construction, the binder tape is eliminated. For thermoplastic-insulated cables the outer covering is a thermoplastic jacket.

69. Traffic-control, fire-alarm, and signal cables are specially designed to meet the conditions encountered in these municipal signal systems. Both rubber-and

thermoplastic-insulated cables are used. For rubber-insulated cables various outer coverings are employed, depending upon the installation conditions. These coverings include heavy cotton braid, a plain lead sheath, a protected lead sheath, and a neoprene jacket. For thermoplastic-insulated cables the outer covering is a thermoplastic or similar jacket.

70. Special cables for electric transportation equipment are manufactured to meet the particular requirements of this class of service with respect to flexibility and resistance to vibration. The conductors are rubber-insulated. The cable covering usually consists of cotton braid or a rubber jacket.

71. Cables for gas-tube sign and oil-burner ignition systems should be of a type approved by the Underwriters Laboratories for this service.

The Underwriters kilovolt designations for cables for this service are GTO-5, GTO-10, and GTO-15. In each case the numeral indicates the cable rating in kilovolts. Approved cables made by different manufacturers differ in details of construction. At one time these cables were rubber-insulated. Today most of them are thermoplastic-insulated with an outer thermoplastic jacket.

72. X-ray cables are designed to meet the special conditions encountered in power supply circuits to high-voltage x-ray tubes and similar equipment. As produced by one manufacturer, they consist of a core made up of two rubber-insulated wires and two un-insulated wires. A semiconducting rubber compound is extruded over these conductors and covered with a layer of rubber insulation. Another semiconducting coating is applied over this insulation, and it, in turn, is covered with a close-covering annealed-copper shielding braid. The outer covering may be either cotton braid or a neoprene jacket.

73. Drive-in-theater cables are designed for direct installation in the earth under outdoor motion-picture-theater lots to serve sound-distribution networks from the projection booth to speaker posts installed adjacent to the designated automobile-parking stations. Two types of cable are available for this service: two-conductor rubber-insulated cable with an outer neoprene jacket and two-conductor cable with a uni-insulation and jacket of thermoplastic compound.

74. Portable power cables are designed for circuits supplying power to portable power equipment such as electric shovels, dredgers, air compressors, and welders. The individual conductors are generally insulated with a thermoset compound. Cables of this type for voltages not exceeding 600 V may be obtained with the following protective coverings: heavy cotton braid, seine-twine braid, loom sheath, thermoset jacket, or jute and wire armor. These coverings are listed in the order of increasing resistance to wear. Only rubber jackets, thermoset jackets, or jute-and-wire-armor coverings are employed for cables for voltages exceeding 600 V. These high-voltage cables may be obtained in the types shown in the accompanying table.

Type	Covering	Ground wires	Shielding	Max. voltage recommended
W	Thermoset jacket	Without	None	2500
G	Thermoset jacket	With	None	5000
SH-A	Rubber jacket	Without	On each conductor	
SH-B	Rubber jacket	Without	Over cabled conductor	
SH-C	Rubber jacket	With	Over cabled conductor	6000
SH-D	Rubber jacket or jute and wire armor	With	On each conductor	...*

*No standard above 6000 V; consult manufacturers.

The conductors of portable power cables are made especially flexible by the use of Class G or H stranding (see Table 93); for special applications requiring even greater flexibility, special stranding may be employed. Single-conductor cables are regularly available in sizes from 8 AWG to 500 kcmil. Two-, three-, four-, five-, and six-conductor cables are standard in sizes from 8 AWG to 4/0 AWG.

75. Fixture wire is used for the wiring of electrical fixtures. There are 31 approved types, which are listed and described in Table 76. Those wires with a single *F* in their designation may be either solid or 7-stranded. Those with *FF* must be made of wire with especially flexible stranding.

76. Fixture Wire*

(Table 402.3, 2008 National Electrical Code)

Trade name	Type letter	Insulation	Thickness of insulation		Outer covering	Maximum operating temperature	Application provisions	
			AWG	Mils				
				Thickness of asbestos (mils)				
				mm				
Heat-resistant rubber-covered fixture wire; flexible stranding	FFH-2	Heat-resistant rubber Cross-linked synthetic polymer	18–16	0.76	30	Nonmetallic	75°C (167°F)	Fixture wiring.
			18–16	0.76	30

^bInsulation and outer coverings that meet the requirements of flame-retardant, limited smoke, and are so listed shall be permitted to be marked limited smoke after the Code-type designation.

77. Flexible cord is the name applied to wires used to connect portable appliances, small tools, or machinery to the receptacles of the wiring installation or to wire the portable device itself. Flexible cords also are used to wire pendant fixtures from the outlet box to the fixture. NEC Table 400.4 lists the different types of approved flexible cords with their permitted uses.

78. Radio and TV wires. Special types of wires have been developed to meet the needs of the radio and TV industry. They include antenna, lead-in, coil-lead, hookup, and transmission-line wires and microphone cable.

79. Automotive and aircraft wires and cables are specially designed to meet the requirements of these two classes of service. They include high-tension ignition cables, primary wires for low-voltage service, and starter cables.

80. The telephone industry requires special types of wires and cables. The multi-conductor cables for main distribution circuits are dry-paper-insulated and lead-covered. A lead-antimony sheath is generally employed for aerial and underground installation in conduit or ducts. For direct burial in the earth and for some aerial work, the lead sheath is protected with jute and steel-tape armor. Specially designed steel-wire-armored cables are used for submarine installation. It is a common practice to terminate these paper-insulated cables by splicing to them a short length of textile-insulated lead-covered cable. A common type of this textile-insulated cable employs two layers of silk and one layer of cotton insulation on each conductor, the cable being protected with a pure lead sheath. Rubber-insulated two-conductor cables protected with a weatherproof braid are used for service drops from pole to house. Hard-drawn copper, bronze, and copperweld conductors are used for these cables.

For circuits exposed to severe moisture and requiring from 2 to 12 conductors, rubber-insulated lead-covered cables are frequently used.

For interior wiring of individual telephone circuits, twisted-pair rubber-insulated cotton-braid-covered cables are employed. There is a trend toward the use of thermoplastic-insulated conductors with thermoplastic or similar outer sheaths for interior work and direct burial in earth.

81. Cables for shipboard use should be designed for the special requirements and severe service encountered in installations on board ship. Such cables are generally made in accordance with Institute of Electrical and Electronic Engineers (IEEE) specifications, which are approved by the ICEA.

82. Magnet wire is the name applied to single-conductor insulated wires manufactured for the winding of coils for electrical circuits. Round magnet wire is made of soft annealed solid copper wire in sizes from 46 AWG to 4/0 AWG. Square- and rectangular-cross-section magnet wires are also available. Insulations used for magnet wire include baked films (enamel), cotton, silk, nylon yarn, paper, asbestos, fibrous glass, Dacron-glass, or combinations of these materials. The temperature rating of magnet wires depends upon the insulation employed and is based upon the temperature limits stated in Publication No. 1 of the IEEE (refer to Div. 7, Sec. 130). All magnet wire made by a reliable manufacturer

will meet certain specifications for physical and electrical characteristics that have been standardized by the National Electrical Manufacturers Association.

Enamel Coatings

Conventional Enamel (Generally Referred to Merely as Enamel). A baked-film insulation of an oleoresinous varnish having good moisture resistance and dielectric properties. Used widely in magnet wire coils of all types. 105°C Class A insulation.

Formvar Enamel. A baked-film insulation from a varnish based on vinyl acetal resin. Has excellent resistance to heat, abrasion, and solvents, combined with exceptional flexibility and adherence. 105°C Class A insulation.

Self-Bonding Formvar. A baked-film insulation consisting of Formvar over which is applied a thermoplastic overcoat. When formed into coils and baked or otherwise suitably heat-treated, the turns of wire, because of the thermoplastic overcoat, become bonded together, thus facilitating the fabrication of self-supporting coil assemblies. 105°C Class A insulation.

Nylon Enamel. A baked-film insulation from a varnish based on polyamide resin which solders readily (self-fluxing) unless it is overbaked. Excellent winding qualities. Not so good as Formvar in electrical properties and moisture resistance. 105°C Class A insulation.

Formvar and Nylon Enamel. A baked-film insulation consisting of Formvar over which is applied a coat of nylon enamel. Combines the advantages of good winding properties of the outer nylon enamel coating with the better electrical properties and moisture resistance of the underlying Formvar enamel coating. 105°C Class A insulation.

Enamel G. A baked-film insulation from a varnish based on polyurethane resin. Solders readily (self-fluxing). Good winding and moisture-resistance qualities. Good electrical properties even at high frequencies. Well suited for electronic and communication applications. 120°C, between Class A and Class B insulation.

Enamel Class B. A baked-film insulation from a varnish based on polyester resin such as Isonel or comparable materials. Handling properties comparable to Formvar, except for somewhat poorer heat shock test. Although stable up to 150°C, it is generally used as Class B (130°C) insulation.

Coverings

Cotton. Unbleached fine long-staple cotton yarn applied with proper techniques to provide a firm, even layer winding. Rated as 90°C Class O insulation when used alone. When impregnated or immersed in liquid dielectric, it is rated as 105°C Class A insulation.

Nylon Yarn. High-quality nylon tram supplied as an alternative to silk covering. When used alone, it is rated as 90°C Class O insulation.

Silk. The best grade of tram silk is particularly suitable for low-loss radio-frequency coils in which interturn and interlayer capacitances must be kept to a minimum. When used alone, it is rated as 80°C Class O insulation.

Paper. 100 percent manila-rope stock or equivalent grade in tape thicknesses of 0.85 to 3.0 mils (0.0216 to 0.0762 mm). When used alone, it is rated as 90°C Class O insulation. When impregnated or immersed in liquid dielectric, it is rated as 105°C Class A insulation.

Fibrous Glass. Pure, alkali-free, continuous-filament glass yarn is wrapped, saturated, and bonded to the conductor with high-grade insulating varnishes or compounds so applied as to yield a smooth, uniform, homogeneous insulating covering. When impregnated with conventional varnish, it is rated as 130°C Class B insulation. When treated with silicone varnish, it is rated as 180°C Class H insulation.

Dacron Glass. A combination insulation consisting of glass and Dacron fibers. Much better abrasion resistance, insulation adhesion, and flexibility than all-glass insulation. When impregnated with standard varnish, it is rated as 130°C Class B insulation. Rating when treated with silicone varnish is not yet established.

83. In the selection of the proper type of magnet wire for any application, the following factors should be considered:

- | | |
|---------------------------------|---------------------------|
| 1. Utilization of winding space | 4. Insulating qualities |
| 2. Resistance to abrasion | 5. Appearance |
| 3. Cost | 6. Operating temperatures |

84. Method of determining the approximate diameter of any cable. When the approximate overall diameter of a wire or cable not listed in conventional tables is desired, it may be determined by means of one of the following formulas. As a rule, results obtained from these formulas will give minimum outside diameters. To allow for manufacturing tolerances, add 50 mils (0.127 mm) to the outside diameters as obtained from the formulas to get approximate maximum diameters.

For single-conductor cables:

$$OD = d + 2T + 2t_c \tag{1}$$

For multiconductor nonshielded or belted cables:

$$OD = K(d + 2T + 2t_c) + 2t_o \tag{2}$$

For multiconductor belted cable:

$$OD = K(d + 2T) + 2t_B + 2t_o \tag{3}$$

For multiconductor shielded cable:

$$OD = K(d + 2T + 0.032) + 0.020 + 2t_o \tag{4}$$

where OD = outside diameter in inches, d = diameter of bare round conductor in inches, T = thickness of conductor insulation in inches, t_c = thickness of covering over insulation of individual conductors in inches, t_B = thickness of belt insulation in inches, t_o = thickness of overall protective covering in inches, and K = value from following table:

<i>Conductor</i>	<i>Value of K</i>
Two-conductor, round	2.00
Two-conductor, flat, maximum diameter	2.00
Two-conductor, flat, minimum diameter	1.00
Three-conductor, round	2.16
Three-conductor, ordinary sector	1.95
Three-conductor, compact sector	1.90
Four-conductor, round	2.41
Four-conductor, ordinary sector	2.20
Four-conductor, compact sector	2.15

For any conductor or cable with a known outside diameter, the outside cross-sectional area may be determined by

$$CSA \text{ (in}^2\text{)} = d^2 \times 0.7854 \tag{5}$$

where d = outside diameter in inches.

*The American wire gage sizes have been rounded off to about the usual limits of commercial accuracy.

86. Makeups of Electrical Conductors

Type	Illustration	Application
Copper		
Solid, round		Bare wire in sizes 4/0 to 45 AWG. Covered, noninsulated in sizes 4/0 to 14 AWG. Insulated in sizes 6 to 14 AWG for power work. Insulated in sizes 1/0 to 46 AWG for magnet wire
Solid, grooved		Trolley contact wire size 350,000 cmil to 1/0 AWG
Solid, figure eight		Trolley contact wire size 350,000 cmil to 1/0 AWG
Solid, figure nine		Trolley contact wire size 400,000 cmil
Solid, Square		Magnetic wire and windings for electrical equipment
Solid, rectangular		Magnet wire, windings for electrical equipment, busbars
Solid, channels		Busbars
Solid, angle		Busbars
Solid, tubes		Busbars
Standard, concentric-stranded		Bare, covered, and insulated in sizes 5 million cmil to 20 AWG

86. Makeups of Electrical Conductors (Continued)

Type	Illustration	Application
Copper		
Standard rope-stranded		Rubber-sheathed cords and cables in sizes 5 million cmil to 8 AWG
Bunched-stranded		Flexible cords and fixture wire in sizes 10 to 22 AWG
Annular concentric-stranded with rope core		Varnished-cambric-insulated and solid-type paper-insulated single-conductor cables in sizes 5 million to 750,000 cmil
Compact-stranded, round		Varnished-cambric-insulated and solid-type paper-insulated cables in sizes 1,000,000 cmil to 1 AWG single-conductor and size 1 AWG for multiconductor
Compact-stranded, sector		Multiconductor paper-insulated cables, both solid and oil-filled types, in sizes 1,000,000 cmil to 1/0 AWG
Compact-stranded, segmental		Varnished-cambric-insulated and solid-type paper-insulated single-conductor cables in sizes 4,000,000 to 1,000,000 cmil
Hollow-core, stranded		Oil-filled paper-insulated single-conductor cables in sizes 2,000,000 cmil to 2/0 AWG
Tubular-segment; Type HH		High-voltage long-distance transmission

86. Makeups of Electrical Conductors (Continued)

Type	Illustration	Application
Iron or steel		
Solid, round		Bare in sizes 4, 6, and 8 AWG for power work. Bare in sizes 4 to 14 AWG for telephone and telegraph work
Three-strand		Bare in sizes 4, 6, and 8 AWG
Copperweld		
Solid, round		Bare in sizes 4/0 to 12 AWG. Weatherproof covered in sizes 2 to 12 AWG. Rubber-insulated: single conductors in sizes 4/0 to 12 AWG and two conductors in sizes 14 and 17 AWG
Concentric-stranded		Bare or rubber-covered single-conductor in diameters from 0.0910 to 0.174 in
Copperweld and copper		
Stranded		Bare in various combinations of strands in cable sizes from 586,800 cmil to 8 AWG. Weatherproof covered in sizes 2 to 8 AWG
Copper and steel		
Three-strand		Bare in sizes 2 to 12 AWG
All-aluminum		
Solid, round		Bare wire in sizes 4/0 to 29 AWG. Covered, noninsulated in sizes 4/0 to 12 AWG. Insulated in sizes 6 to 12 AWG for power work. Insulated in sizes 4 to 26 AWG for magnet wire
Stranded		Bare or weatherproof covered in sizes 1,590,000 cmil to 6 AWG

86. Makeups of Electrical Conductors (Continued)

Type	Illustration	Application
Copper-clad aluminum		
Solid, round		Same as all-aluminum
Concentric-stranded		Same as all-aluminum
Aluminum and steel (ACSR)		
Annular aluminum, stranded with steel core		Bare in sizes 1,590,000 cmil to 4 AWG. Weatherproof, covered in sizes 4/0 to 8 AWG
Bronze		
Solid, round		Bare or weatherproof covered in sizes 4 to 14 AWG

*The breaking strengths are based on ASTM specification requirements, using minimum values for hard- and medium hard-drawn wire, and maximum values for soft wire.
†The resistance values in this table are trade maximums and are higher than the average values for commercial wire.

The following values for the conductivity of copper were used:

ASTM Requirements

	Conductivity, IACS % at 20°C	Resistivity, lb per mile-ohm at 20°C
Hard-drawn, 0.325 in and larger	97.16	900.77
Hard-drawn, 0.324 in and smaller	96.16	910.15
Medium hard-drawn, 0.325 in and larger	97.66	896.15
Medium hard-drawn, 0.324 in and smaller	96.66	905.44
Soft or annealed	98.16	891.58

89. Stranded Bare Copper Conductors

(Anaconda Wire and Cable Co.)

Size		Strand- ing, class*	Cable diam., in	Weight [†]		Hard- drawn, min breaking strength, lb [‡]	Medium hard- drawn, max breaking strength, lb [‡]	Soft- drawn, max breaking strength, lb [‡]

*Class of stranding in accordance with ASTM Specification B 8-35T.

†Weight increased 2 percent to allow for cabling, except as follows:

Cir mils	Percent
5,000,000 and 4,500,000	5
4,000,000 and 3,500,000	4
3,000,000 and 2,500,000	3

‡The breaking strengths are based on ASTM specification requirements, using minimum values for hard- and medium hard-drawn cable, and maximum values for soft cable.

§Optional construction, see Table 90.

AWG sizes for individual strands are permissible, provided their area is not more than 2 percent below required area. Sizes 2, 3/0, and 4/0 AWG can be supplied in alternate combinations as follows:

Wire size	2 AWG	3/0 AWG	4/0 AWG
Total number of strands	259	427	427
Diameter individual strands (mils)	16.0	19.8	22.3
Number of ropes	37	61	61
Number of strands each rope	7	7	7

Flexible stranded conductors Nos. 10 to 22 AWG are normally supplied in bunched-stranded form; refer to Table 93. Conforms to all requirements of ICEA Project 46.

The above data are approximate and subject to normal manufacturing tolerances.

95. Copper-Clad Aluminum Wire

Cladding calculations

A = Area or volume percentage of copper-clad aluminum wire.

W = Weight percentage of copper in copper-clad aluminum wire.

T = Radius thickness percentage of copper in copper-clad aluminum wire.

$$W = \frac{8.89A}{6.19A + 270} \times 100$$

$$T = \left(1 - \sqrt{1 - \frac{A}{100}} \right) \times 100$$

For 10% copper-clad aluminum wire $A = 10$.

$$\text{Then } W = \frac{88.9}{61.9 + 270} \times 100 = 26.785$$

$$\text{And } T = \left(1 - \sqrt{1 - \frac{1}{10}} \right) \times 100 = 5.13$$

*Higher ampacity applies if one conductor is used as a neutral.

100. Electrical resistance wire is wire that has high resistance to the flow of electric current. It is this higher-resistance characteristic which distinguishes resistance wire from conducting wire. The material used for conducting wires should have as low a resistance as possible. Electrical resistance wire is used for the wiring of rheostats, resistors, heaters, furnaces, electric ranges, etc. Metal alloys are used for the manufacture of resistance wires. The more common alloys employed are nickel-chromium, nickel-copper, nickel-chromium-iron, nickel-iron, and manganese-nickel.

CABLE JOINTS AND TERMINAL CONNECTIONS

101. Cable joints and connections are an essential part of any electric circuit. It is of utmost importance that they be properly made, since any system is only as strong as its weakest link. The basic requirements of any joint or connection are that it be both mechanically and electrically as strong as the cable with which it is used. High-quality workmanship and materials must be employed so that permanently good electrical contact and insulation (if required) will be ensured. The more common satisfactory methods of making joints and connections in electric cables are discussed in the following sections.

102. Joints and connections for insulated cables. There are two methods of making joints or connections for insulated cables: by means of soldered connections and by means of solderless connection devices (see Sec. 156). Soldered connections were formerly the accepted standard, but solderless splicing devices and connectors have gained wide favor for low-voltage work. The use of such devices materially reduces the time required for the making of splices and terminal lug connections. Moreover, if the device is of good design, in addition to the mechanical strength of the connection being fully as great as that of a good soldered connection, the solderless connection has the advantage that the electrical contact will not fail under short circuits or continuous overloads due to the melting of solder.

FIGURE 2.6 Split copper cable connecting sleeve.

Soldered joints may be made by means of soldered splices or by a copper sleeve (see Fig. 2.6 and Sec. 112) thoroughly sweated to the cable.

103. Insulation of joints. Every joint in insulated cable must be covered with insulation equivalent in insulating properties to that on the cable itself. Soldered joints in rubber-insulated cables are insulated with rubber tape. The rubber employed is a self-vulcanizing tape often referred to as *splicing gum*. Tapes made from different types of rubber compound are available. One type is made from normal-aging compound and may be used for cables insulated with NEC, intermediate, ASTM 30 percent Class AO, or performance-rubber compounds. A better grade of tape having better aging, heat-resisting, and moisture-resisting properties was developed for Performite-compound-insulated cables. It may be used for high-grade joints in any type of rubber-insulated cables. For insulating joints in cables insulated with an oil-base compound (corona- and ozone-resisting), a corona-resisting tape made from an oil-base compound should be used.

Soldered joints in thermoplastic-insulated wires and cables should be insulated with pressure-sensitive thermoplastic-adhesive tape.

Soldered joints in varnished-cambric- and paper-insulated cables are insulated with varnished-cambric tape.

Joints made with solderless connectors may be insulated as described above for soldered joints, or an insulating cover may be employed.

Refer to Secs. 114 and 115 for more detailed instructions for the application of insulating tapes.

104. Protection of joints. Some form of protection should be supplied over the insulating tape of a joint. For all types of braided cables the joint is protected by applying two layers of friction tape over the insulated joint. Friction tape is made of closely woven cotton fabric treated on both sides with a rubber compound of adhesive character.

Joints in thermoplastic-jacketed cable are protected with pressure-sensitive thermoplastic tape to the same thickness as the cable jacket. Joints in rubber-insulated neoprene-jacketed cable are protected with neoprene tape applied to the same thickness as the cable jacket. These joints are further protected by a covering of anhydrous tape painted with cable paint.

105. Completed joints. Cross-sectional views of typical completed joints are shown in Figs. 2.7, 2.8, 2.12 to 2.15, and 2.20 to 2.25.

FIGURE 2.7 Joint in rubber-insulated braided cable.

106. Removing protective covering. For braided cable, strip back the protective covering a sufficient distance from the ends of the cables to be jointed. Trim the edges with a sharp knife, taking great care not to cut the insulation or to leave loose ends to get under taping. For lead-sheathed cable proceed as follows (Rome Cable Corp.).

The length of lead sheath to be removed from single-conductor cables is determined by the creepage distance required for the operating voltage. For multiconductor cable the axial length required for offsetting the conductors is the determining factor. The length of sheath

FIGURE 2.8 Joint in varnished-cambric-insulated braided cable.

to be removed from each cable end is approximately $1\frac{1}{2}$ in (38.1 mm) less than one-half the total length of the lead sleeve indicated.

Cut halfway through the lead sheath all around at the location determined, and cut the sheath lengthwise to the end. Remove this section of sheath by grasping with pliers and tearing off. This will leave the remaining sheath ends slightly belled.

For belted cable, remove belt, insulation, and fillers to within 1 in (25.4 mm) of the end of the lead sheath.

For single-conductor shielded cable, remove shielding to within approximately $\frac{1}{4}$ in (6.35 mm) of the end of the lead sheath. For multiconductor cable, remove binder tape and fillers to the end of the lead sheath; remove the shielding tape as far as possible into the crotch.

If the cable is neoprene-jacketed, remove the jacket, underlying tapes, and shielding, if any. Use care not to damage the factory insulation on the cable.

107. Removing insulation from rubber- or thermoplastic-insulated cables.

Completely remove the insulation for a distance sufficient for making the joint. Cover the bared conductor with a few turns of friction tape so that the conductor will not be nicked. Pencil down the conductor insulation for a distance of $\frac{1}{2}$ in (12.7 mm; see Figs. 2.7 and 2.9). This penciling should be smooth and even and can be done best with a sharp knife, care being taken not to injure the conductor. All the exposed conductor insulation should then be made smooth with fine emery cloth to provide a good surface for the application of the splicing gum. Wrap the tapered ends of the insulation tightly with dry cotton tape, and tie the tape in place. The tape protects the insulation from scorching while the connector is being soldered to the conductors.

FIGURE 2.9 Methods of "skinning" wire.

108. Removing insulation from paper- or varnished-cambric-insulated cable (General Electric Co.).

The cable insulation should be removed in steps as indicated in Fig. 2.10. For paper-insulated cable, the steps should be made by tearing the paper tapes. A convenient method is to hold a loop of fine steel wire (about 0.015 in, or 0.381 mm, in diameter) in place around the insulation at each step in turn, beginning with the step farthest from the end of the cable, and tear the tapes at the wire. A weight of about $1\frac{1}{2}$ lb (0.68 kg) attached to each end of the wire will hold the loop in place while tearing the tape.

FIGURE 2.10 Method of stepping and binding insulation.

For varnished-cambric-insulated cable, the steps should be made by cutting the cloth tapes, exercising care to avoid cutting through tapes that will remain on the conductor.

It is recommended that in each case the first step adjacent to the conductor be about $\frac{1}{32}$ in (0.79 mm) in height by $\frac{1}{2}$ in (12.7 mm) in length and that the remaining steps be of equal height and spaced about $\frac{3}{4}$ in (19.1 mm) apart. The number of steps in any case will be the same as that shown in the illustration, but the height of the steps will vary with the thickness of the insulation on the conductor.

The number of tapes to be removed for any given step must be determined by counting the total number of tape layers and measuring the thickness of each. Total insulation usually comprises either paper tapes varying in thickness from 0.004 to 0.008 in (1 to 2 mm) or varnished-cambric tapes about 0.012 in (3 mm) in thickness.

Cotton yarn should be bound into the stepped corners of the insulation and into the corners between insulation and conductor parts (Fig. 2.10). The following procedure should be observed. Wash the exposed surfaces of stepped insulation and all metal conductor parts with high-quality Transil oil at a temperature of about 110°C to remove all impurities. Dip the roll of cotton yarn in clean Transil oil at a temperature of 110°C to remove possible moisture. Then wind the yarn in all the stepped corners of the insulation, the corners between the conductor and the insulation, and the corners between the conductor and the connector. In passing from one step of insulation to the next, bind the tape ends down with a turn of yarn. Excessive yarn should be avoided; that is, one turn in the lower steps and two in the higher steps should be sufficient.

109. Cleaning wire ends. Bare wire ends should be scraped bright with the back of a knife blade or rubbed clean with sandpaper or emery cloth to ensure that the solder will adhere readily.

110. Split Copper Sleeves for Standard Concentric Round Stranded Conductors. See Fig. 2.11.

111. A soldering flux removes or prevents the formation of an oxide during soldering so that the solder will flow readily and unite firmly the members to be joined. For copper wires the following solution of zinc chloride, which is recommended by Underwriters Laboratories, is good: saturated solution of zinc chloride, 5 parts; alcohol, 4 parts; glycerin, 1 part. Solutions made with acids should be avoided, as more or less corrosion usually occurs in joints made with them. Commercial soldering pastes and sticks give good satisfaction in cleaning joints to be soldered.

112. Insulation of joints in rubber-insulated cable. Remove the cotton tape that was wrapped around the tapered ends of the insulation. Clean the rubber insulation with a cloth dampened with high-test gasoline and allow it to dry. The surface over which the splicing tape is to be applied should then be covered with rubber cement, and the solvent allowed to evaporate until it is quite tacky. The rubber splicing tape should then be placed over the joint. Each layer should be applied smoothly and under tension so that there will be no air spaces between the layers. In putting on the first layer, start near the middle of the joint instead of at the end. The diameter of the completed insulated joint should be greater than the overall diameter of the original cable, including the insulation. When a standard split copper connector is used, the thickness of applied insulation over the maximum diameter of the connector should be at least 50 percent greater than the thickness of the insulation on the original cable as indicated in Fig. 2.7. Most splicing tapes are self-vulcanizing, and therefore it is not necessary to vulcanize the joint later.

113. Insulation of joints in varnished-cambric- or paper-insulated cables. Varnished-cambric tape of various widths is used for insulating these joints. A $\frac{1}{2}$ -in (12.7-mm) tape is used in the spaces between the cable insulation and the connector end; $\frac{3}{4}$ -in (19.1-mm) tape is used to continue the insulating to the original level of the cable insulation. A 1-in (25.4-mm) tape is used to complete the insulation of the joint or, in the case of joints for three-conductor belted-type cables, the overall of the crotch; 1-in tape is also used either for spacing reinforced conductors or for binding together reinforced conductors in the case of joints for 5-kV belted-type cables.

Before applying the tape, flush all exposed surfaces of the insulation and intervening conductor parts with high-quality Transil oil at 110°C to remove all impurities. Also, during the application of the tape, all surfaces on which the tape is applied and each layer of tape during wrapping should be flushed with a heavy oil compound applied at a temperature of about 20°C with a brush that has been cleaned in high-quality Transil oil at a temperature of approximately 110°C. Tape of $\frac{1}{2}$ - or $\frac{3}{4}$ -in (12.7- or 19.1-mm) width should be applied by drawing it tightly in half-lap wrappings; 1-in (25.4-mm) tape should be applied in butt wrappings.

The applied tape insulation should be built up until the thickness of insulation over the maximum diameter of the connector or splice is 50 percent greater than the thickness of the insulation on the original conductor (see Fig. 2.8).

114. Applying lead sleeve to lead-sheathed cable (Rome Cable Corp.). The lead sleeve is slid in place, and the ends are beaten down with a wood tool to fit snugly the lead sheath of the cable. Scrape the wiping surfaces clean and apply stearin flux. Apply paper pasters to limit the length of the wipes. Make the wiped joints by pouring molten solder on the joint. As the solder cools and becomes plastic, work the solder by wiping with a cloth.

Cut and raise V notches in the lead sleeve for filling and venting. Fill the lead sleeve with insulating compound, heated to the recommended temperature and poured into the sleeve through a funnel. The joint is completed by binding the V-notch flaps back in place and sealing them with 50-50 solder.

115. Cable joints. The following instructions in Secs. 118 to 121 for the splicing of cables are reproduced here through the courtesy of the Rome Cable Corp.

116. Straight splice for single-conductor unshielded cables (Fig. 2.12)

Conductor size AWG or kcmil	Length of L , in		
	600 V	3000 V	5000 V
8-4/0	6.5	7.5	8.5
250-500	7.5	8.5	9.5
600-1000	8.5	9.5	10.5

FIGURE 2.12 Straight splice for single-conductor shielded cable. [Rome Cable Corp.]

A. Rubber-Insulated Neoprene-Jacketed Cable

1. Form the two cables to be joined into their final position, allowing the ends to overlap. Mark the centerline of the joint on both cables, and cut off at this point so that the cables butt squarely together.
2. Strip the factory-applied jacket, insulation, and underlying tape, if any, from both cables for a distance equal to one-half the length of connector plus $\frac{1}{4}$ in (6.35 mm).
3. Apply compression or solder-type split tinned connector.
4. Pencil the jacketed insulation for a distance of 4 times the overall thickness of jacket and insulation. Apply special cement to the connector, exposed portions of the conductor, the pencils, and the adjacent jacket, allowing the cement to become tacky before proceeding with the joint.
5. Insulate with ozone-resistant rubber splicing tape applied one-half lap to a thickness over the connector of $1\frac{1}{2}$ times the factory-applied insulation and tapering off over the jacket to a point of $\frac{1}{2}L$ from the center.
6. Cover the hand-applied insulation and adjacent jacket for a distance of $1\frac{1}{2}$ in (38.1 mm) with special cement, allowing it to become tacky. Apply neoprene tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in beyond the end of the insulating tape.
7. Serve the entire joint with anhydrous tape, extending this serving $1\frac{1}{2}$ in beyond the end of the hand-applied jacket tape.
8. Paint the entire joint with cable paint.

B. Rubber-Insulated Thermoplastic-Jacketed Cable

Follow the procedure given in A, substituting the following for step 6:

6. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond the end of the insulating tape.

C. Thermoplastic-Insulated Thermoplastic-Jacketed Cable

- 1-2. Follow steps 1 and 2 as in A.

3. Clean the conductors, and apply a compression-type connector with hydraulic press and dies.
4. Pencil the jacketed insulation for a distance of 6 times the overall thickness of jacket and insulation.
5. Insulate with polyethylene-base splicing tape applied one-half lap to a thickness over the connector of 2 times the factory-applied insulation and tapering off over the jacket to a point $\frac{1}{2} L$ from the center.
6. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond the jacket end.
7. Complete as in steps 7 and 8 of A.

Conductor size AWG or kcmil	Length of L , in				
	5000 V		7500 V		15,000 V
	Grounded neutral or underground neutral	Grounded neutral	Underground neutral	Grounded neutral	Underground neutral
8-4/0	8.5	10.0	11.0	13.5	15.5
250-500	9.5	11.0	12.0	14.5	16.5
600-1000	10.5	12.0	13.0	15.5	17.5

FIGURE 2.13 Straight splice for single-conductor shielded cable. [Rome Cable Corp.]

117. Straight splice for single-conductor shielded cables (Fig. 2.13)

A. Rubber-Insulated Neoprene-Jacketed Cable

1. Form the two cables to be joined into their final position, allowing the ends to overlap. Mark the centerline of the joint on both cables, and cut off at this point so that the cables butt squarely together.
2. Remove the jacket and underlying tapes, if any, down to the factory-applied shielding from both cables for a distance equal to $\frac{1}{2} L$. Remove the factory-applied shielding and underlying tape, if any, to within $\frac{1}{4}$ in (6.35 mm) of the end of the jacket or for a distance of $\frac{1}{2} L$.
3. Strip the factory-applied insulation and underlying tape, if any, from both cables for a distance equal to one-half the length of connector plus $\frac{1}{4}$ in.
4. Apply compression or solder-type split tinned connector.
5. Pencil the factory-applied insulation for a distance equal to 4 times its thickness.

Apply special cement to the connector, exposed portions of conductor, the pencils, and the adjacent insulation, allowing the cement to become tacky before proceeding with the joint.

6. Insulate with ozone-resistant rubber splicing tape applied one-half lap to a thickness over the connector of $1\frac{1}{2}$ times the factory-applied insulation on the cable and tapering off over the cable insulation up to the end of the factory-applied shielding.
7. Cover the hand-applied insulating tape with $\frac{5}{8}$ -in ($15\frac{7}{8}$ -mm) tinned tinsel copper shielding braid, applied butt edge on the cylindrical portion and one-half lap on the tapered portions. Solder to the factory-applied shielding at both ends, and also apply a light line of solder along the tapered portions to prevent slippage. Use care to do this soldering quickly so as not to damage the shielding braid or insulation. Attach securely and solder the ground wires to the factory-applied shielding at each end of the joint.
8. Cover the shielding braid and the adjacent jacket for a distance of $1\frac{1}{2}$ in (38.1 mm) with special cement, allowing it to become tacky. Apply neoprene tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in beyond the jacket end.
9. Serve the entire joint with anhydrous tape, extending this serving $1\frac{1}{2}$ in beyond the end of the hand-applied jacket tape.
10. Paint the entire joint with cable paint.
11. Connect the cable shielding tape ground wires to ground.

B. Rubber-Insulated Thermoplastic-Jacketed Cable

Follow procedure given in A, substituting the following for step 8:

8. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond the jacket end.

C. Thermoplastic-Insulated Thermoplastic-Jacketed Cable

- 1–3. Follow steps 1, 2, and 3 as in A.
4. Clean the conductors and apply a compression-type connector with hydraulic press and dies.
5. Pencil the factory-applied insulation for a distance equal to 6 times its thickness.
6. Insulate with polyethylene-base splicing tape applied one-half lap to a thickness over the connector of 2 times the factory-applied insulation and tapering off over the cable insulation up to the end of the factory-applied shielding.
7. Cover the hand-applied insulating tape with $\frac{5}{8}$ -in ($15\frac{7}{8}$ -mm) tinned tinsel copper shielding braid applied as in step 7 of A.
8. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond the jacket end.
9. Complete as in steps 9, 10, and 11 of A.

118. Straight splice for three-conductor unshielded cable (Fig. 2.14)

A. Rubber-Insulated Neoprene-Jacketed Cable

1. Form the two cables to be joined into their final position, allowing the ends to overlap. Mark the centerline of the joint on both cables and cut off at this point so that the cables butt squarely together.
2. Remove the jacket and underlying tape, if any, from both cables for a distance equal to $\frac{1}{2}L$. Remove the fillers and cut at the ends of the jacket. Bind the conductors of each cable tightly together with a piece of dry cotton tape applied at the end of the

jacket. The tape prevents breaking the jacket when spreading the conductors. Spread the conductors radically, and form them into their final position, taking care not to spread them any more than is necessary for insulating. Strip the factory-applied insulation and underlying tape, if any, on each conductor for a distance equal to one-half the length of the connector plus $\frac{1}{4}$ in (6.35 mm).

3. Apply compression or solder-type split tinned connector.
4. Pencil the factory-applied insulation on each conductor for a distance equal to 4 times the thickness of the factory-applied insulation. Cover the connectors, the exposed portions of the conductors, the pencils, and the adjacent insulation with special cement, allowing it to become tacky before proceeding with the joint.
5. Insulate with ozone-resistant rubber splicing tape applied one-half lap to a thickness over the connector of $1\frac{1}{2}$ times the factory-applied insulation on each conductor, tapering off over the insulated conductor to a point *B* from the center.
6. Apply a one-half-lapped layer of friction tape over each insulated conductor, extending it as far as possible into the croches. Squeeze the conductors together by hand, and bind them in place with a serving of friction tape.
7. Cover the entire joint and adjacent jacket for a distance of $1\frac{1}{2}$ in (38.1 mm) with special cement, allowing it to become tacky. Apply neoprene tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in beyond the jacket end.
8. Serve the entire joint with anhydrous tape, extending this serving $1\frac{1}{2}$ in beyond the end of the hand-applied jacket tape.
9. Paint the entire joint with cable paint.

B. Rubber-Insulated Thermoplastic-Jacketed Cable

Follow the procedure given in A, substituting the following for step 7.

Conductor size AWG or kcmil	Length of <i>L</i> and <i>B</i> , in					
	600 V		3000 V		5000 V	
	L	B	L	B	L	B

1/0-4/0	9.5	3.75	10.5	4.00	11.5	4.50
250-500	12.0	4.75	13.0	5.00	14.0	5.50
600-1000	15.0	6.00	16.0	6.25	17.0	6.75

FIGURE 2.14 Straight splice for three-conductor unshielded cable. [Rome Cable Corp.]

7. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond the jacket end.

C. Thermoplastic-Insulated Thermoplastic-Jacketed Cable

- 1-2. Follow steps 1 and 2 as in A.
3. Clean the conductors, and apply a compression-type connector with hydraulic press and dies.
4. Pencil the factory-applied insulation on each conductor for a distance equal to 6 times its thickness.
5. Insulate with polyethylene-base splicing tape applied one-half lap to a thickness over the connector of 2 times the factory-applied insulation over each conductor, tapering off over the insulated conductor to a point *B* from the center.
6. Apply a one-half-lapped layer of friction tape over each insulated conductor, extending it as far as possible into the crotches. Squeeze the conductors together by hand, and bind them in place with a serving of friction tape.
7. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond its end.
8. Complete as in steps 8 and 9 of A.

119. Straight splice for three-conductor shielded cable (Fig. 2.15)

FIGURE 2.15 Straight splice for three-conductor shielded cable. [Rome Cable Corp.]

1. Form the two cables to be joined into their final position, allowing the ends to overlap. Mark the centerline on both cables, and cut off at this point so that the cables butt squarely together.
2. Remove the jacket and underlying tape, if any, from both cables for a distance equal to $\frac{1}{2} L$. Remove the fillers and cut at the ends of the jacket. Bind the conductors of each cable tightly together with a piece of dry cotton tape applied at the end of the jacket. This is to prevent breaking the jacket when spreading the conductors. Spread the conductors radially, and form them into their final position, taking care not to spread them any more than is necessary for insulating. Secure the shielding on each conductor at a point about $\frac{1}{4}$ in (6.35 mm) greater than B from the center of the joint, and strip the shielding and underlying tape, if any, from the point to the end. Strip the factory-applied insulation and underlying tape, if any, on each conductor for a distance equal to one-half the length of the connector plus $\frac{1}{4}$ in.
3. Apply compression or solder-type split tinned connector.
4. Pencil the factory-applied insulation on each conductor for a distance equal to 4 times the thickness of the factory-applied insulation. Cover the connectors, the exposed portion of the conductors, the pencils, and the adjacent insulation with special cement, allowing it to become tacky before proceeding with the joint.
5. Insulate with ozone-resistant rubber splicing tape applied one-half lap to a thickness over the connector of $1\frac{1}{2}$ times the factory-applied insulation on each conductor, tapering off over the insulated conductor to a point B from the center.
6. Cover the hand-applied insulating tape with $\frac{5}{8}$ -in ($15\frac{7}{8}$ -mm) tinned tinsel copper shielding braid, applied butt edge on the cylindrical portion and one-half lap on the tapered portions. Solder to the factory-applied shielding at both ends, and also apply a light line of solder along the tapered portions to prevent slippage. Use care to do this soldering quickly so as not to damage the shielding braid or insulation. Attach securely and solder ground wires to the factory-applied shielding on all three conductors at both ends of the joint. Squeeze the conductors together by hand, and bind them in place with a serving of friction tape.
7. Cover the entire joint and adjacent jacket for a distance of $1\frac{1}{2}$ in (38.1 mm) with special cement, allowing it to become tacky. Apply neoprene tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in beyond the jacket end.
8. Serve the entire joint with anhydrous tape, extending this serving $1\frac{1}{2}$ in beyond the end of the hand-applied jacket tape.
9. Paint the entire joint with cable paint.
10. Connect the cable shielding tape ground wire to ground.

B. Rubber-Insulated Thermoplastic-Jacketed Cable

Follow the procedure given in A above, substituting the following for step 7.

7. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond the jacket end.

C. Thermoplastic-Insulated Thermoplastic-Jacketed Cable

- 1–2. Follow steps 1 and 2 as in A.
3. Clean the conductors and apply a compression-type connector with hydraulic press and dies.
4. Pencil the factory-applied insulation on each conductor for a distance equal to 6 times its thickness.
5. Insulate with polyethylene-base splicing tape applied one-half lap to a thickness over the connector of 2 times the factory-applied insulation over each conductor, tapering off over the insulated conductor to a point B from the center.

6. Cover the hand-applied insulating tape with $5/8$ -in ($157/8$ -mm) tinned tinsel copper shielding braid applied as in step 6 of A.
7. Apply pressure-sensitive thermoplastic tape over the entire joint to the same thickness as the factory-applied jacket and extending $1\frac{1}{2}$ in (38.1 mm) beyond the jacket end.
8. Complete as in steps 8, 9, and 10 of A.

120. Terminating power cables. The following instructions in Secs. 122 to 130 for terminating power cables are reproduced here through the courtesy of the Rome Cable Corp.

General Instructions. This discussion covers outdoor and indoor terminations for single- and three-conductor unshielded and shielded, rubber- or thermoplastic-insulated cables with neoprene or thermoplastic jackets.

Although outdoor terminations are included for 7500 and 15,000 V, grounded and ungrounded neutral, porcelain potheads are recommended for permanent installations.

In general, cables fall into three classifications: unshielded, leaded, and shielded. Unshielded cables are terminated simply by applying the conductor terminal lug and forming a watertight seal, providing sufficient flashover distance to the nearest ground.

When a leaded or shielded cable is to be terminated, the grounded sheath or shielding must be removed from the cable end to provide sufficient flashover distance. Also, the electric field at the end of the grounded shield is concentrated owing to the divergence of the flux lines toward the thin edge of the shielding and must be relieved, since the high potential gradients may lead to eventual cable failure in this area.

This concentration of electrical stress is relieved by adding a *stress-relief cone* to the exposed insulation surface of the cable, which consists of a double cone of additional insulation with the metallic shielding extended to the middle of the double cone.

Stress-relief cones are recommended for all shielded cables and for 12-kV and higher single-conductor lead-covered cables. (Belling out the lead sheath is usually sufficient for lower-voltage lead-covered cables.)

On rubber-insulated cables, ozone-resistant rubber splicing tape is used as the cone insulation and tinned copper tinsel braid for the cone shielding. On thermoplastic-insulated cables, a polyethylene-base splicing tape is used.

In building the cone, start at the unshielded end and wrap the insulating tape down to the edge of the cable shielding. Continue wrapping back and forth to build up the double cone of proper dimensions. Starting at the middle of the cone, apply the copper tinsel braid to the lower half, making sure that the upper edge is smooth and even. The braid is then tucked under and soldered to the lead sheath or wrapped over and soldered to the cable shielding.

121. Outdoor termination for single-conductor unshielded cable (Fig. 2.16)

Rubber- or Thermoplastic-Insulated Neoprene- or Thermoplastic-Jacketed Cable

1. Remove the jacket, factory-applied insulation, and underlying tape, if any, for a distance from the end of the cable equal to the depth of the hole in the lug plus $1/2$ in (12.7 mm) for cable sizes up to 4/0 AWG and 1 in (25.4 mm) for larger cables.
2. Apply a shoulder of friction tape to support the rubber rain shield, when required. This support should be so located that when the rain shield is seated on the support, the bottom will be about 3 in (76.2 mm) from any grounded surface and the distance *A* as given in the tables. Put the rain shield in place, and apply ozone-resistant rubber splicing tape to form a watertight seal.

A - Minimum length to grounded surface
 1 - Jacket
 3 - Insulating tape
 4 - Anhydrous tape - cable paint
 5 - Friction tape
 10 - Rain shield

Conductor size, AWG or kcmil	Length of A, in		
	600 V	3000 V	5000 V
8-1000	5	7	10

FIGURE 2.16 Outdoor termination for single-conductor unshielded cable. [Rome Cable Corp.]

3. Apply a compression or solder-type lug on the conductor. A compression-type lug must be used on thermoplastic-insulated cables. Pencil the factory-applied insulation and jacket for a distance equal to 4 times the overall thickness of insulation and jacket. Apply ozone-resistant rubber splicing tape to form a watertight seal.
4. Apply two one-half-lapped layers of anhydrous tape over the tape seals at the lug and upper end of the rain shield. Paint the anhydrous tape with cable paint.

122. Indoor termination for single-conductor unshielded cable. Follow the procedure given in Sec. 123, eliminating the rain shield and using the accompanying table for dimension A, which would be the minimum length to grounded surface.

Conductor size, AWG or kcmil	Length of A, in		
	600 V	3000 V	5000 V
8-1000	3	5	8

123. Outdoor termination for single-conductor shielded cable (Fig. 2.17)

A. Rubber-Insulated Neoprene- or Thermoplastic-Jacketed Cable

1. Remove the jacket, factory-applied shielding, insulation, and underlying tapes, if any, for a distance from the end of the cable equal to the depth of the hole in the lug plus 1/2 in (12.7 mm) for cable sizes up to 4/0 AWG and 1 in (25.4 mm) for larger cables.

- | | |
|-----------------------------------|---|
| A - Minimum length | 6 - Tinsel shielding braid |
| B - Stress cone length | 7 - Binding wire |
| 1 - Jacket | 8 - Ground wire |
| 2 - Cable shielding | 9 - Stress cone - thickness, same as cable insulation |
| 3 - Insulating tape | 10 - Rain shield |
| 4 - Anhydrous tape - cable point. | |
| 5 - Friction tape | |

Conductor size, AWG or kcmil	Length of A, and B, in					
	5000 V		7500 V		15,000 V	
	A	B	A	B	A	B
8-1000	14	2	17	2.5	24	3.5

FIGURE 2.17 Outdoor termination for single-conductor shielded cable. [Rome Cable Corp.]

2. Remove all outer coverings down to the factory-applied shielding for a distance *A* from the end of the factory-applied insulation. Remove the factory-applied shielding and underlying tape to within $\frac{1}{4}$ in (6.35 mm) of the jacket.
3. The factory-applied shielding must be terminated in a stress cone. Form a stress cone of the proper dimensions, using ozone-resistant rubber splicing tape. Shield the stress cone with $\frac{5}{8}$ -in (15 $\frac{7}{8}$ -mm) tinned tinsel copper shielding braid, terminating the shielding at the point of maximum diameter with a binder of fine copper wire. Solder the braid to the end of the factory-applied shielding and attach the ground wire. Complete the stress cone with a serving of two one-half-lapped layers of anhydrous tape extending up over the end of the jacket.
4. Seal the rain shield and complete the termination as in steps 2, 3, and 4 of Sec. 123.

B. Thermoplastic-Insulated Thermoplastic-Jacketed Cable

Handle in the same way as A except to apply a compression-type lug with hydraulic press and dies. If unpigmented polyethylene-insulated cable is being terminated, it should be covered with two layers of black pressure-sensitive thermoplastic tape applied one-half lap for the distance *A* prior to application of stress cone and rain shield after removal of shielding tapes.

124. Indoor termination for single-conductor shielded cable. Follow the procedure given in Sec. 125, eliminating the rain shield and using the accompanying table for dimensions *A* and *B*.

Conductor size, AWG or kcmil	Length of <i>A</i> and <i>B</i> , in					
	5000 V		7500 V		15,000 V	
	<i>A</i>	<i>B</i>	<i>A</i>	<i>B</i>	<i>A</i>	<i>B</i>
8–1000	10	2	13	2.5	20	3.5

125. Outdoor termination for three-conductor unshielded cable (Fig. 2.18)

A. Rubber-Insulated Neoprene- or Thermoplastic-Jacketed Cable

1. Remove the jacket and underlying tape, if any, for the distance *A* as measured from the center conductor of the termination. (NOTE: Allowance must be made for forming the outer conductors into position.) Remove the fillers and cut at the end of the jacket. Bind the conductors tightly together with a piece of dry cotton tape applied at the end of the jacket before the conductors are spread apart. Spread the conductors radially, and form them into their final position, taking care not to spread them any more than is necessary to permit applying the rain shields and allowing sufficient clearance (1 in, or 25.4 mm/kV) between lugs. Bare the end of each conductor for a length equal to the depth of the hole in the lug plus $\frac{1}{2}$ in (12.7 mm) for cable sizes up to 4/0 AWG and 1 in for larger cables.
2. Terminate each conductor as described in steps 2, 3, and 4 of Sec. 123.
3. Form a watertight seal with ozone-resistant rubber splicing tape at the end of the jacket. Apply two one-half-lapped layers of anhydrous tape over the tape seal, and paint with cable paint.

Conductor size, AWG or kcmil	Length of A, in		
	600 V	3000 V	5000 V
8-1000	8	10	13

FIGURE 2.18 Outdoor termination for three-conductor unshielded cable. [Rome Cable Corp.]

B. Thermoplastic-Insulated Thermoplastic-Jacketed Cable

Handle in the same way as A except to apply a compression-type lug with hydraulic press and dies. If unpigmented polyethylene-insulated cable is being terminated, it should be covered with two layers of black pressure-sensitive thermoplastic tape applied one-half lap for the distance A prior to application of stress cone and rain shield.

126. Indoor termination for three-conductor unshielded cable. Follow the procedure given in Sec. 127, eliminating the rain shield and using the accompanying table for dimension A.

Conductor size, AWG or kcmil	Length of A, in		
	600 V	3000 V	5000 V
8-1000	8	10	12

127. Outdoor termination for three-conductor shielded cable (Fig. 2.19)

A. Rubber-Insulated Neoprene- or Thermoplastic-Jacketed Cable

1. Remove the jacket and underlying tape, if any, for the distance *A* as measured for the center conductor of the termination. (NOTE: Allowance must be made for forming the outer conductors into position.) Remove the fillers and cut at the end of the jacket. Bind the conductors tightly together with a piece of dry cotton tape applied at the end of the jacket before the conductors are spread apart. Spread the conductors radially, and form them into their final position, taking care not to spread them any more than is necessary to permit applying the rain shields and allowing sufficient clearance (1 in, or 25.4 mm/kV) between lugs. Bare the end of each conductor for a length equal to the depth of the hole in the lug plus 1/2 in (12.7 mm) for cable sizes up to 4/0 AWG and 1 in for larger cables.
2. Terminate each conductor as described in steps 2, 3, and 4 of Sec. 125. (NOTE: Remove shielding and underlying tapes to within 6 in, or 152.4 mm, of the jacket.)

Conductor size, AWG or kcmil	Length of <i>A</i> and <i>B</i> , in			
	5000 V		7500 V	
	<i>A</i>	<i>B</i>	<i>A</i>	<i>B</i>
8-1000	20	2	22	2.5

FIGURE 2.19 Outdoor termination for three-conductor shielded cable. [Rome Cable Corp.]

3. Form a watertight seal with ozone-resistant rubber splicing tape at the end of the jacket. Apply two one-half-lapped layers of anhydrous tape over the tape seal and paint with cable paint.

B. Thermoplastic-Insulated Thermoplastic-Jacketed Cable

Handle in the same way as A except to apply a compression-type lug with hydraulic press and dies. If unpigmented polyethylene-insulated cable is being terminated, it should be covered with two layers of black pressure-sensitive thermoplastic tape applied one-half lap for the distance A prior to application of stress cone and rain shield.

128. Indoor termination for three-conductor shielded cable. Follow the procedure given in Sec. 129, eliminating the rain shield and using the accompanying table for dimensions A and B.

Conductor size, AWG or kcmil	Length of A and B, in			
	5000 V		7500 V	
	A	B	A	B
8-1000	16	2	19	2.5

129. Arc proofing. For increased reliability, it may be required or desired to arc proof underground systems if primary cables or a combination of primary and secondary cables are contained in a manhole. If a primary cable fails even though fast cutoff devices are used, fire protection will prevent damage to the adjacent cables. Former procedures that relied on thick layers of asbestos materials are no longer used. Newer techniques use thinner wraps that produce a thermally-insulating char when exposed to flame, thereby safely preventing a nearby arc from damaging the protected conductors underneath. Generally, any cable within 18 in is considered capable of compromising another cable during a high-energy arcing failure, although this is only a rule of thumb. The process works well as long as the response time of the circuit protective devices has been coordinated with the degree of protection provided by the arc proofing.

For small cables (up to about 1 1/2 in or 38 mm) in diameter use 1 1/2-in arc proofing tape; for larger cables use 3-in (76 mm) tape. The tape will not self-adhere but when pulled tight it will conform to the shape it is covering without wrinkles. To start the wrap make a complete turn or two and secure it with at least two complete turns, one directly on top of the other, of an adhesive glass cloth tape. Then wrap helically, overlapping each turn with a half-wrap on the next turn. As rolls of tape run out, secure the ends with glass tape as at the beginning, and start the next roll so the end of the previous roll is overlapped by at least 6 in (152 mm). For best results, start at one end of the manhole and go to the other. Typical test results indicate that a half-wrap covering will resist the effects of a nearby sustained arc for about 75 cycles; if that is not enough a second layer can be applied with about double the withstand time.

130. Portable-cable joints. The following instructions in Secs. 133 to 145 for making joints in all-rubber portable cables have been reproduced here through the courtesy of the General Electric Co.

131. A typical single-conductor portable-cable joint is shown in Fig. 2.20. The following directions for making this kind of joint refer to that figure.

1. Bring the cables in position for splicing, with their ends overlapping a little, and cut the cable ends off squarely.
2. Remove $3\frac{3}{8}$ in (85.725 mm) of rubber sheathing from the end of each cable. Remove the reinforcing braid for a distance of $2\frac{3}{8}$ in (60.325 mm), and remove the conductor insulation for a distance of $\frac{7}{8}$ in (22.225 mm).

(a) - Rubber sheathing, reinforcing braid, and conductor insulation removed, and conductor insulation penciled

(b) - Copper connector assembled and rubber sheathing penciled

(c) - Splice completed with splicing gum, friction tape, and rubber tape applied. The joint should now be vulcanized

Conductor size, AWG	Thickness of insulation, T , in	Overall diam of cable, D , in	Conductor size AWG	Thickness of insulation, T , in	Overall diam of cable, D , in
8	$\frac{3}{64}$	0.44	3	$\frac{4}{64}$	0.64
6	$\frac{4}{64}$	0.50	2	$\frac{4}{64}$	0.67
5	$\frac{4}{64}$	0.53	1	$\frac{5}{64}$	0.73
4	$\frac{4}{64}$	0.58	0	$\frac{5}{64}$	0.82

FIGURE 2.20 Single-conductor soldered joint in an all-rubber portable cable. [General Cable Co.]

3. Pencil down the conductor insulation for a distance of $\frac{1}{2}$ in (12.7 mm). This penciling should be smooth and even and can be done best with a sharp knife, taking care not to injure the conductor. All the exposed conductor insulation should then be made smooth with fine emery cloth to provide a good surface for the later application of the splicing gum.
4. Wrap the tapered ends of the insulation tightly with dry cotton tape and tie the tape in place. The tape protects the insulation from scorching while the connector is being soldered to the conductors.
5. Assemble the connector in place over the conductor joint. The connector should be made of soft-drawn copper strap, $\frac{3}{4}$ in (19.05 mm) wide and $\frac{1}{32}$ in (0.79 mm) thick and long enough to wrap around the conductor without overlapping. Apply a coating of nonacid soldering flux over the surface of the conductor and then slide the connector over the conductor; let the connector slot come at the top, and place it so that the two conductors butt at the center of the connector. Pinch the connector with pliers so that it closes into maximum contact with the conductor. Solder the conductor fast to the connector by pouring hot solder over the joint until it is thoroughly heated and the solder runs freely through the slot and into the strands of the cable. Solder that collects on the bottom of the connector should be brought to the top to fill the slot. Before the solder sets, wipe the connector smooth and clean with a piece of cloth. After cooling, any sharp projections should be smoothed off with a file and fine emery cloth.
6. Remove the cotton tape that was wrapped around the tapered ends of the insulation. Clean the rubber insulation with a cloth dampened with high-test gasoline, and allow it to dry. Then apply a coating of rubber cement over the entire surface on which the splicing gum is to be applied, and allow the solvent to evaporate before applying any tape.
7. Apply the splicing gum and build it up over the rubber insulation to a diameter of about $\frac{1}{16}$ in (1.58 mm) larger than the rubber insulation on the cable, as shown in Fig. 2.20.
8. Apply one layer of friction tape half-lapped over the splicing gum and over the ends of the reinforcing braid, as shown in Fig. 2.20.
9. Pencil the rubber sheathing as shown, and clean the tapered surface and the outside surface of the cable for a distance of at least $\frac{3}{4}$ in (19.05 mm) at each end with fine emery cloth and high-test gasoline; allow to dry.
10. Cover the entire surface of the joint with a coating of rubber cement. Be sure to cover all the surface over which the final wrapping is to be applied.
11. After the solvent has evaporated, apply the rubber tape in half-lapping; build it up to a diameter of about $\frac{1}{16}$ in (1.58 mm) greater than the diameter of the cable, and let it extend over the surface of the rubber sheathing as indicated in Fig. 2.20, so that the overall length of the joint will be 9 in (228.6 mm).
12. The joint should now be vulcanized in a suitable mold. The inside diameter of the mold should be about the same as the diameter of the cable. If a steam vulcanizer is used, a steam pressure of about 30 lb (206,843 Pa) should be applied for 15 to 30 min, depending on the size of the mold and the joint that is being vulcanized.
13. To complete the process, cover the joint with black wax and wipe it smooth.

132. Typical examples of multiconductor portable-cable joints are shown in Figs. 2.21 and 2.22. In each case, sufficient rubber sheathing and fillers are removed from

FIGURE 2.21 Joint for multiconductor Type W and Type G portable cable and two-conductor flat cable. [General Electric Co.]

FIGURE 2.22 Joint for Type SH, Class A portable cable. [General Electric Co.]

the cable ends to permit staggering the individual splices as shown in Fig. 2.23 in order to obtain a flexible joint of approximately the same outside diameter as the cable. The individual conductors are spliced in the same way as described for single-conductor cable. The individual joints and the ends of the rubber-filled tape, if present, are bound with one layer of friction tape, half-lapped, as shown in the illustrations.

To maintain the overall length of the joint within a given dimension it is necessary that the first splice be at a minimum distance from the end of the rubber sheathing. This dimension

FIGURE 2.23 Joint for 600-volt three-conductor portable Type W cable, showing the staggering of individual splices. [General Electric Co.]

is given in the data accompanying the illustrations. The distance between the individual splices is approximately 3 in (76.2 mm).

In splicing Type G cable, exercise care to avoid damaging the ground wires. These wires should be bent out of the way until the individual conductors have been insulated.

In splicing Type SH, Class A cable, each of the single conductors must be completely shielded; i.e., the copper-mesh shielding must be carried across the joint and soldered, as shown in Fig. 2.22. The cable-shielding braid is removed $\frac{1}{2}$ in (12.7 mm) farther than the rubber-filled tape on each end of each conductor. The remaining braid is then opened and turned back $\frac{1}{2}$ in, care being taken not to loosen the braid farther than this point; such loosening is prevented by applying and soldering at this point three or four turns of tightly drawn 0.0126-in (0.32-mm) tinned-copper wire. The $\frac{3}{4}$ by 0.015-in (19.05 by 0.381-mm) flat copper braid is then applied half-lapped over the unshielded portion of the insulation. The $\frac{1}{2}$ in of cable-shielding braid, which was just turned back, is drawn over the $\frac{3}{4}$ -in-wide shielding braid, and the two shields are bound together by continuing the tightly drawn butt wraps of 0.0126-in tinned-copper wire for a total distance of $\frac{7}{8}$ in (22.225 mm). The wire should then be soldered to the braid, using a nonacid soldering flux; this is necessary because there must be a positive electric contact across the joint. In applying the shield, be sure that no gaps or openings are left, since an opening in the shielding of one conductor might lead to corona.

Bring the single conductors together with approximately the same twist as the rest of the cable.

In the case of Type G cable, the ground wires should now be cut to their proper length. They should be connected in the same manner as the cable conductors, and all sharp projections removed. The bare wire must be wrapped with friction tape, half-lapped. The ground wire should then be placed in the interstices.

In joining the shields of Type SH, Classes C and D cable, follow in general the same instructions as given for Type SH, Class A, and in joining the ground wires follow the instructions for Type G cable.

Returning to the instructions for all types, fill the interstices and make the cable its proper shape by means of a suitable filler. The type of filler used depends on the makeup of the cable being spliced. If rubber filler is used in the cable, rubber filler should be used in the joint. If jute fillers are used in the cable, jute fillers should be used in the joint.

Rubber filler is applied by placing a coating of rubber cement over the entire surface of the individual conductors and filler space and, when the solvent has evaporated, by laying strips of splicing tape longitudinally in the interstices until these are filled completely.

When jute fillers are used, the individual conductors, the jute fillers, and the ground wires, if any, should be covered completely with one layer of half-lapped friction tape. The surface of the friction tape should then be wrapped with reinforcing cord. Apply the cord in tightly drawn wraps spaced $\frac{1}{2}$ in (12.7 mm) apart, having a pitch of approximately 2 in (50.8 mm). The joint should be wrapped first with the pitch in one direction and then with the pitch in the opposite direction, thereby obtaining the equivalent of a reinforcing braid. Tie the cord firmly at both ends.

The rubber sheathing should then be tapered and cleaned as described for single-conductor cable. All the surface that is to be covered with splicing gum should first be covered with a coating of rubber cement. When the solvent has evaporated, wrap the surface with splicing tape to the diameter shown in the illustrations.

The joint is now ready to be vulcanized. The same vulcanizing process is used for both shielded and nonshielded cables. Preheat the vulcanizer before inserting the joint, and vulcanize according to instructions furnished with the particular vulcanizing equipment. If a steam vulcanizer is used, a steam pressure of about 30 lb (206,843 Pa) should be applied for 30 to 60 min, depending on the size of the mold and the joint that is being vulcanized. It is sometimes necessary to apply a dressing of thin paper to the mold to prevent sticking of the rubber. After vulcanizing, the joint should be covered with black wax and wiped smooth (see the instructions for vulcanizing).

If the voltage is 2500 or above, a feeder cable that contains provision for a ground connection should be used. The power-line end must be grounded to a suitable permanent ground, and the end at the apparatus must be grounded securely through a bolted connection to the apparatus frame.

Included in this instruction is one method for making the conductor splice. Other methods can be used successfully. Most operating companies have their own ideas as to how these joints should be made. One suggestion is added: the copper splice should be made as smooth as possible and as close to the original diameter as practical.

133. Nonsoldered joints (for types of cable used in mines). These instructions apply to types of all-rubber portable cable which are widely used in coal and other mines on such equipment as gathering-reel locomotives, cutters, loaders, and drills. The types covered are single-conductor, two-conductor flat (with the conductors side by side), and two-conductor concentric (with an inner and outer conductor).

This method of jointing eliminates solder, and although it is thus particularly applicable to work in a mine where the explosive hazard is high, it can, of course, be used for any job (600 V and below) for which the omission of solder seems to be justified or desirable. This type of connector is useful for emergency repairs because it is simply and easily installed.

134. Nonsoldered joint for single-conductor portable cable (refer to Fig. 2.24)

1. Remove the outer jacket and insulation for a distance of approximately 5 in (127 mm) from each cable end.
2. Overlap the two conductor ends, as shown in the drawing, and install two Newberry clamps at the ends of the conductors.
3. Taper the insulation on each side of the joint, leaving $\frac{1}{2}$ in (12.7 mm) of bare conductor between the end of the taper and the edge of the connector.
4. Remove the outer jacket and reinforcing braid to the final dimensions.
5. Thoroughly clean the surface to which splicing gum is to be applied and cover with a coating of rubber cement. Allow the solvent to evaporate.
6. Apply splicing gum to the dimensions as shown in Fig. 2.24.
7. Cover the splicing gum with one layer of friction tape, half-lapped and finally wrapped with reinforcing cord.
8. Taper the ends of the outer rubber jacket and clean the entire surface of the joint.
9. Apply a coating of rubber cement over the entire joint. When the solvent has evaporated, apply the outer jacket with wrappings of splicing gum.
10. Vulcanize the joint.

FIGURE 2.24 Nonsoldered single-conductor cable joint. [General Electric Co.]

135. Nonsoldered joint for two-conductor (flat) portable cable (refer to Fig. 2.25)

1. Remove the outer jacket to the dimensions shown in the drawing, making an allowance for an approximately 5-in (127-mm) overlap of the conductors.
2. When the cable is supplied with jute fillers, the fillers should be laid back over the cable and reassembled later.
3. Remove sufficient insulation from each of the four cable ends to allow installation of the connectors.
4. The conductors are then connected by overlapping the two ends as shown in the drawing, and a Newberry clamp is installed at each of the conductor ends. This clamp has been used very successfully around mines for a number of years.
5. Remove the outer tape or braid to the dimensions shown.
6. Taper the conductor insulation on each side of the connectors as shown in the drawings.
7. Thoroughly clean the surface over which splicing gum is applied, and apply a coating of rubber cement. After the solvent has evaporated, wrap splicing gum to a diameter slightly greater than that on the original cable.
8. Cover each insulated conductor with a layer of friction tape half-lapped.
9. If the original cable is supplied with jute or rope fillers, they should be replaced in the interstices of the joint. If rubber fillers were used in the original cable, they should be replaced by rubber fillers (see standard instructions for splicing portable cables in Sec. 134).
10. After the fillers have been applied, cover the insulated conductors and fillers with a layer of friction tape half-lapped and wrap with reinforcing cord (see the instructions for the splicing of standard portable cables).
11. Taper the ends of the overall jacket, thoroughly clean the entire surface which is to be covered by rubber tape, and apply a coat of rubber cement.
12. After the solvent has evaporated, apply the outer jacket with wrappings of rubber tape to the dimensions that are shown on the drawing.
13. Vulcanize the joint.

FIGURE 2.25 Nonsoldered two-conductor (flat) cable joint. [General Electric Co.]

136. Vulcanizers are easy to operate and can be used very successfully by people with little experience. These instructions should enable anyone to operate the average steam vulcanizer without trouble. Steam vulcanizers are generally shipped without water in the jacket. The user should make sure that the water is placed in the unit to the proper level before the vulcanizer is employed.

Most units are equipped with a relief or safety valve. This valve is set to “pop” at a given pressure. It can be adjusted by removing the top and tightening the screw to increase pressure or loosening the screw to lower the pressure. The pressure control can be set to open at from 30 to 65 lb (206,843 to 448,159 Pa) pressure and to close at from 25 to 60 lb (172,369 to 413,685 Pa). This control can generally be adjusted by tightening or loosening the control-spring tension in the same way as the relief valve is adjusted.

The heaters should always be covered with water to prevent their burning out. If no steam is escaping anywhere, a filling of water should last a considerable time even when used daily. The water should normally be checked about once a week. The vulcanizer should be placed in a practically level position while the current is connected; otherwise the water may drain away from the immersion heaters.

Most steam vulcanizers are operated with electric-heating units, but any form of heat can be used, provided it can be carefully controlled so that a constant heat is applied to the joint to be vulcanized. Gas furnaces and blowtorches have been successfully used.

137. General instructions for operation of vulcanizers. Three factors are essential for the successful vulcanizing of rubber-jacketed cables: time, temperature, and cleanliness.

138. The time required to vulcanize rubber is approximately 20 min; however, not every vulcanizing job can be done in this time. First, the mass of rubber, cable, and copper conductors must be brought up to temperature before the cure begins.

The outer rubber that comes in direct contact with the mold begins to cure before the inner mass, but the work must be left in the vulcanizer long enough to cure all the rubber. Therefore, the time will vary considerably, depending on the volume to be heated and the temperature of the work before it is put into the vulcanizer. For instance, in winter a cable brought into a shop or repaired outdoors will require more time than if vulcanized in the hot summer. Also, a large cable will require more time than a small one. With these factors in mind, it is readily seen that a definite time schedule cannot be set forth.

In most cases the time will be between 30 and 45 min, although there are conditions that require 1 h or even more and others that require only 20 min.

The exact length of time for curing is not known. In the first place, there is no positive schedule to follow. After a few jobs have been done, the time can be estimated. It is best to leave the first few jobs in slightly longer than might seem necessary to be sure of a full cure. Then reduce the time as you gain experience. An approximate schedule for a novice is as follows:

<i>Cable Size, In</i>	<i>Time, Min</i>
$\frac{3}{4}$ and smaller	20
$\frac{3}{4}$ – $1\frac{1}{4}$	25
$1\frac{1}{4}$ – $1\frac{3}{4}$	30
$1\frac{3}{4}$ – $2\frac{1}{4}$	35
$2\frac{1}{4}$ –3	40
3– $3\frac{1}{2}$	50

This schedule is an estimate for complete splices. When only small patches are made, the time will be somewhat less, as the small volume of new rubber and the adjacent old rubber are quickly brought up to temperature and may be cured before the mass of cable has been fully heated.

Care must be taken not to undercure a joint because undercured rubber deforms easily and therefore makes a poor joint from the standpoint of abrasion. A simple method of determining an undercure is to cut in two a piece of the surplus fin; if the fin will stick together where it was cut, the joint was undercured. Because the fin is thin, it will always cure first. Therefore, the fin might be overcured, but the joint itself might still be undercured. This does not necessarily mean an unsatisfactory job but is mentioned simply as an aid to the operator.

139. Temperature for vulcanizing. The controls on vulcanizers are set to open at from 30 to 65 lb (206,843 to 448,159 Pa) steam pressure and close at from 25 to 60 lb (172,769 to 413,685 Pa). This range under ordinary conditions provides a sufficiently accurate temperature for curing the rubber.

About the only condition that might require any change would be subzero weather during which the vulcanizer itself is exposed. In such cases the radiation is so severe that it may be necessary to increase the pressure by adjusting the control. Since cables are usually repaired indoors, however, extremely cold weather is seldom a factor.

140. Cleanliness in vulcanizing. The important reason for vulcanizing electric-cable splices is to make them watertight and give them added strength. Obviously, it is necessary for the applied rubber to mold into a solid mass and to stick to the old cable jacket.

One of the chief aids in obtaining these results is keeping the work clean. Oil or grease is known to be detrimental to rubber, and dust or dirt on the surface of the rubber being applied is likely to prevent its molding together. When new rubber is applied to the old cable jacket, it must be absolutely clean to obtain adhesion.

141. How to patch a jacket. The amount of work to be done depends on the extent of the injury. For instance, in many cases a small cut can be patched simply, whereas a severe injury may require the removal of the portion of jacket that is injured and replacing this portion with new rubber. In any case, thoroughly inspect the conductor insulation at the injury to be sure it is not also injured. If it is, the jacket should be removed for a sufficient length to repair the conductor insulation properly. It may be necessary to make a complete splice.

To vulcanize new rubber to old rubber, it is necessary to roughen the old rubber and scrape or grind off any old scale or coating at the place where the new rubber is expected to stick. The old rubber should also be prepared for 1 in (25.4 mm) around the injured spot.

When the jacket must be removed, it will be found easier to clean and roughen the cable for about 2 in (50.8 mm) each way beyond the portion to be removed before cutting it out.

Two kinds of rubber are used in the repair of electric cables: jacket rubber and insulating rubber. Insulating rubber is used only for conductor insulation. Jacket rubber is used for all outside work.

When new rubber is applied to the old, proceed as follows:

1. Clean and roughen old rubber as described previously.
2. With naphtha or benzol, thoroughly clean the areas where the rubber is to be applied and allow them to dry.

3. Brush rubber cement over the surfaces to which the new rubber is expected to stick, as well as an inch or so beyond. Allow the solvent to evaporate.
4. Apply new rubber, which is supplied in tape form. If the rubber is wrapped tightly and evenly, all air is excluded, and the new rubber need not be built up much larger than the mold. Only a little experience is necessary to demonstrate how much rubber to apply.
5. The repair is now ready to vulcanize. Naturally a suitable mold must be on hand. Molds are made in several types and sizes to fit the particular joint in question.

The proper mold should be hot when ready to use. Swab or brush sparingly an application of mold dressing in the mold before putting in the job.

Shut the mold to within $\frac{1}{6}$ in (4.23 mm) of being closed, depending on the size of the cable, and allow to set for about 5 min to permit the rubber to soften; then close the mold. When this procedure is followed, there is a better chance of filling out low places due to unevenness in wrapping. Furthermore, when a complete splice is made, there may be a distortion of core assembly if full pressure is applied before the rubber is allowed to soften.

6. After curing, remove from the mold, cut off surplus fins, apply wax, and the job is finished. The joint should be allowed to cool somewhat before it is removed from the mold.

142. Temporary vulcanizing equipment. Frequently it is necessary to vulcanize a cable joint in the field, and no equipment is available. To cope with this condition, temporary vulcanizing equipment can be constructed.

An open-top vat of suitable size should be obtained. This vat should be large enough to allow the entire joint to be submerged in heated liquid in the vat when the spliced cable is placed directly over the vat, allowing the cable joint to dip into the vat.

Paraffin is generally used in the vat for the vulcanizing medium, but any wax with a high enough boiling point could be used. In no case should oil be used.

After the joint has been constructed in the usual manner, it should be placed in a suitable mold. There are a number of different molds that can be easily constructed.

1. Split a piece of pipe which has approximately the same inside diameter as the completed splice. The two pieces of pipe should be held tightly on the joint by wrappings of wire or metal tape or by standard U clamps.
2. In a metal block, drill a hole of approximately the same diameter as the splice. Split the block in half, and place it over the joint. The two halves of the block should be held tightly together by bolts or acceptable clamps.

If possible, the molds should be heated up to about 275°F (135°C) before they are placed over the joint. The inside of the molds should be coated with an approved mold dressing to obtain the best and most workmanlike finished splice.

143. The procedure to follow in vulcanizing a joint with the equipment of Sec. 142 is as follows:

1. Make up the joint in the usual manner.
2. Preheat the molds if possible up to 275°F (135°C), coat them with a mold dressing, and clamp them over the joint.
3. In the meantime, the paraffin in the vat should be heated and held to from 275 to 300°F (149°C) by satisfactory heating equipment. Blowtorches or gas furnaces can be used for

this purpose, as can any available heating equipment which will hold these temperatures satisfactorily.

4. Place the joint in the heated paraffin, bearing in mind that the entire joint and mold are submerged in the liquid.
5. Hold the joint in this medium for a period of time depending on the size of joint involved and the thickness of rubber to be vulcanized, keeping the temperature of the paraffin as nearly constant as possible. The approximate time required to vulcanize the joint is listed in the steam-vulcanizer instructions. The exact time for curing a splice can best be obtained by experience with the particular equipment used.
6. When the splice has been cured, it should be removed from the vat and allowed to cool for some time before removing the mold.

It is natural that perfect results cannot be obtained with this temporary equipment, but a number of splices have been vulcanized by this method, and all have operated satisfactorily when properly made.

The mold dressing generally used is a saturated solution of soap chips.

144. Terminal connections of conductors should be made by means of solder lugs or solderless connectors, except that 10 AWG or smaller conductors may be connected to binding posts by clamps or screws, provided the terminal plates of the binding parts have upturned lugs. The upturned plates are necessary so that the wires will not be forced out of place as the screw or nut is tightened.

145. The correct method of "making up" a lead wire around a binding post is shown in Fig. 2.26. First, an eye, of such internal diameter that it will slip over the post, is bent with pliers in the bared-and-cleaned end of the lead wire, as illustrated at I. Then the eye is dropped down over the post (III) in such a position that rotation of the bolt or nut in tightening will tend to wrap the eye and around the post rather than to unwrap it. That is, the eye should wrap around the post in a right-handed direction, in the same direction as that in which the nut rotates while being turned on. If the eye is laid on left-handed as at II, it will unwrap and open while the nut is being turned tightly down on it.

FIGURE 2.26 How a wire should be "made up" on a binding post.

146. Soldering wires in terminal lugs. If many lugs are to be soldered, a convenient and timesaving method of making the connections is to melt a pot of solder over a plumber's furnace, heat the lug in the solder, pour the solder in the hole in the

lug, and then plunge the bared end of the conductor into it, as shown in Fig. 2.27. The insides of the holes of many commercial lugs are “tinned” so that the solder adheres to them readily. The bared end of the conductor should also first be tinned. This may be done as follows. The end of the wire is carefully scraped with a knife or with a piece of fine sandpaper (sandpaper is best because it cannot nick the wire) and then smeared with soldering flux and thrust into the solder pot. If a soldering stick is used, the wire must be heated in the solder before the stick compound will melt and adhere. It requires only a short time to tin the wire end in the pot.

NOTE: Immediately after the tinned end is pushed into the hold in the lug, the lug should be soused with a piece of wet waste to cool it rapidly. Scrape or file off any shreds or globules of solder that adhere to the exposed surfaces of the lug and brighten it with fine sandpaper if necessary.

FIGURE 2.27 Soldering wire to lug.

147. In skinning a wire end which is to be soldered into a lug, the insulation

should be cut back just far enough so that it will abut against the shoulder of the lug, as suggested in Fig. 2.28, I. The appearance is very unsightly and indicates careless work if there is a gap between the shoulder and the insulation, as at II. If because of some mishap a connection has the appearance of II, a partial correction can be made by filling the gap with servings of tape, as shown at III. Tape of standard $\frac{3}{4}$ -in (19.1-mm) width should be torn into strips about $\frac{1}{4}$ in (6.35 mm) wide before applying.

FIGURE 2.28 Finished connections.

148. Only enough molten solder should be poured into the hole in the lug to fill it almost to the brim when the conductor is in position. If too much is poured in, it will be squeezed out by the wire and will flow over the lug. It must then be removed at a sacrifice of time.

149. To ensure proper adhesion between wire, solder, and lug, the temperature of all three must be above the melting point of solder when they are brought together in soldering. If this condition is not fulfilled, only a good friction fit of all three parts will result. Such a friction fit does not afford a good electrical connection. To secure maximum mechanical strength and electrical conductivity, it is essential that the solder be maintained at the melting point until it has thoroughly permeated the interstices of the conductor.

150. The wire terminal and lug should be held in the molten solder until they acquire the temperature of the solder. To prevent adhesion of solder to the outside of the lug, a light oil or possibly soft soap should be applied to its outer surfaces.

Be careful to see that no oil is permitted to reach the inside of the lug. When holding the bared ends of heavy conductors in the solder pot, it is advisable to wrap the insulation with a rag previously wrung out in cold water to prevent, insofar as possible, the melting of the insulating compound and the consequent smearing of the terminal. Such smearing will not impair the effectiveness of a properly made joint, though it will detract from the appearance of the finished job.

151. Another method of soldering wires in lugs is to heat the lug with a blowtorch flame. When the lug is sufficiently hot, wire solder is fed into the hole. The solder melts and the bared conductor end is then thrust into it, as described above. However, the use of a blowtorch in this way should be avoided if possible, as it blackens the exposed surfaces of the lug. Cleaning with fine sandpaper is then necessary, and it requires considerable time.

152. Some suggestions for handling liquid-fueled blowtorches. Only the very best grade of gasoline should be used, and it must be clean and be kept in a clean can; otherwise the burner will become clogged. Never try to fill a torch from a big can. A pint or quart receptacle should be used for this purpose. If this is done, the torch can be held in one hand and filled with the other without danger of overfilling or spilling. The torch should be a little more than two-thirds full, so that there will be room for sufficient air to prevent the necessity of frequent repumping to maintain the pressure. See that the filler plug is closed tight to prevent the escape of air from tank. The fiber washer under the plug must be replaced when worn out. Common washing soap rubbed into thread and joints will stop leaks. The pump should be in good working order; a few drops of lubricating oil well rubbed in will soften the pump washer. Do not turn the needle valve too tight, as there is danger of enlarging the orifice of the burner. See that the burner is sufficiently heated when starting. One filling of the drip cup is generally sufficient if the flame is shielded from draft while heating the burner; if it is not, fill the cup again and light the gasoline as before. A long or yellow flame or raw gasoline shooting from the burner shows that the burner is not hot enough to properly generate gas. When a gasoline torch is used, as much as 90 percent of its heat may be dissipated without doing any work whatever. In performing most blowtorch operations, a great part of this heat may be readily saved by making a shield of sheet iron or asbestos to direct the heat to the object to be heated.

153. Wire connectors. The selection of proper wire connectors for various sizes, combinations, and types of conductors is an extremely important factor in a sound electrical installation.

Wire connectors are generally classified as either thermal or pressure types. Thermal connectors include those in which heat is applied to form soldered, brazed, or welded joints and terminals. Soldered joints and lugs for copper conductors have been used for many years and, except for service-wire and ground connections, are still permitted. However, soldering is rarely used in modern installations because of the greater dependability and installation ease of present-day solderless pressure connectors. And although it is possible to solder aluminum conductors, this is not recommended unless the installer is fully familiar with the special techniques involved. On the other hand, welded aluminum connections in circular-mil sizes are very satisfactory and provide the best possible joint for aluminum conductors. At the same time, this process is generally restricted to the types of installations in which the cost of the necessary equipment and skilled labor can be justified.

There is wide use of grounding grids or busing on large construction jobs, and grounding connections must be permanent in the interests of safety. For joining bare copper conductors together or to reinforcing rods, ground rods, or steel surfaces, a mold-type welding process is highly recommended (exothermic welding). This process makes use of a mold and starting and mixing powder. After conductors, sleeves, and/or lugs have been placed in the mold, a flint gun is used to ignite the starting powder. This forms a liquid copper, which fuses conductors into a solid mass and welds a permanent electrical connection. Offered by several manufacturers, the mold-type welding process can be performed easily without special training.

154. Solderless connectors. A solderless pressure connector is a device which establishes the connection between two or more conductors or between one or more conductors and a terminal by means of mechanical pressure and without the use of solder. This broad definition covers most solderless connectors and terminal lugs.

155. Twist-on pigtail connectors. The common twist-on pigtail connector (see Fig. 2.29) consists of an insulated cap made of plastic, Bakelite, porcelain, or nylon and an internal threaded core with or without a metallic coil spring. Such connectors require no hand tools and are simply twisted onto appropriate combinations of bared conductors. Connector types consisting of metallic spring coils (copper-coated or steel) are listed by Underwriters Laboratories as pressure cable connectors, which means that they can be used for connecting branch-circuit conductors 14 AWG and larger according to listed sizes and combinations. Sometimes these connectors can also be used as fixture-splicing connectors, in which case they will be dual-listed by Underwriters Laboratories.

Connectors without metallic coil springs are regarded as fixture-type splicing connectors for joining fixture wires or branch-circuit wires to fixture wires in a combination of sizes from 18 AWG to 10 AWG within the listed capacities of the connector. They are not acceptable for general use in branch-circuit wiring.

Most twist-on connectors are designed for copper-to-copper wire connections. UL has recently listed a twist-on connector suitable for aluminum to copper marked AL/CU that is very useful for retrofit applications. The connector (illustrated in Fig. 2.57) is filled with a special aluminum oxide cutting compound to prevent corrosion. The crimp-type connector (Copalum by AMP) is another UL-listed connector for splicing small copper-to-aluminum conductors, but it must be applied using special tooling provided by its manufacturer.

With twist-on-type connectors, solid conductors are inserted parallel into the connector. Then the connector is twisted to form a locking action on the conductors and provide a dependable connection. Stranded wires in smaller sizes are twisted together before the

FIGURE 2.29 Typical solderless pigtail connectors. [Electrical Construction and Maintenance]

connector is installed. And in all cases, proper-size connectors should be selected to accommodate the size and combination of conductors involved in each splice.

Maximum voltage ratings for twist-on connectors are 600 V (1000 V inside a fixture or sign), although some types cannot be used on circuits of more than 300 V. Also, temperature ratings will vary according to the type of insulating cap. Data for voltage and temperature ratings of the various connectors can be obtained from individual manufacturers' catalogs.

156. Bolted-type pressure connectors include those for making pigtail, straight, T, or terminal connections. Such connectors depend on the applied force of bolts or screws to produce the clamping and contact pressures between conductors and the connector. Figure 2.30 shows typical examples.

FIGURE 2.30 Typical coupling-type solderless pressure connectors. [*Electrical Construction and Maintenance*]

For making pigtail connections in wire combinations up to 10 AWG, setscrew connectors with separate insulated caps, which thread onto the connectors after securing the wires, are readily available. These connectors are used in branch-circuit wiring, fixture hanging, and equipment hookups. The only tool required is a screwdriver, and the connectors can be reused. As such, they are especially recommended in installations where wiring connections will be changed frequently. They are also useful for applications that may require circuit testing while energized, since by removing the insulating cap the connection will be completely accessible while remaining intact. Various setscrew connectors with thread-on insulated caps are suitable as pressure wire connectors or fixture-splicing connectors according to individual manufacturers' listings (see Fig. 2.29).

Other types of bolted connectors are available for practically any desired wire combinations, sizes, or arrangements. Such connectors are constructed of copper, bronze, or alloys of similar metals for use with copper conductors. Connectors for joining aluminum wires together are constructed of aluminum, tin-plated silicon bronze, or tin-plated copper-alloy materials.

If copper or copper-clad aluminum conductors will be connected to aluminum conductors, select connectors which are designed for this purpose and which provide bimetal or tinned spacers in other than dry locations. Bimetal or tinned spacers permit separation of aluminum and copper conductors, thus preventing the possibility of galvanic corrosion. Careful compliance with manufacturers' recommendations as to cleaning aluminum conductors, applying connector aids, and properly positioning the aluminum and copper conductors will provide a satisfactory joint.

157. Run and tap connectors. Many forms of bolted connectors, such as those shown in Fig. 2.31, are designed for making branch connections from main conductors. In such instances, minimum and maximum wire sizes are listed for both main and branch (tap)

FIGURE 2.31 Typical run and tap solderless pressure connectors.
[*Electrical Construction and Maintenance*]

ranges. Such ranges in wire sizes are listed for each connector and for satisfactory connections should be carefully observed. Split-bolt, clamp-type, gutter-tap, and parallel cable-tap connectors are a few of the common types used for splicing branch conductors to main conductors. Except for the parallel cable-tap type, these connectors must be taped after the wires have been connected. Some parallel cable-tap connectors feature a two-piece molded-plastic cover that fits over the connector and covers uninsulated parts. This eliminates the time required for taping, and makes it possible to remove the connector quickly if this ability is a factor to be considered.

158. Bolted-type lugs. Wires are fastened to bolted-type lugs by one or more bolts, depending on design and ampere ratings. Two- to four-barrel lugs are used to terminate multiple conductors.

159. Terminal and power distribution blocks. If numerous connections are necessary, as in complex control circuitry, consideration should be given to the use of terminal blocks and terminal-block kits made available by a number of manufacturers. Such assemblies contain bolted-type terminal blocks. The terminal blocks can be obtained in fully assembled or individual blocks, and the terminals are available for a wide range of wire sizes. With these units connections can be made quickly, and all terminals can be readily identified, thus simplifying troubleshooting or later changes in circuitry.

Larger terminal blocks, called *power distribution blocks* in the NEC, are often positioned in wireways and similar enclosures to provide for feeder taps to equipment fed from those enclosures. The enclosure must be large enough so that the block and the terminating conductors, at any cross section, do not exceed more than 75 percent of the cross-sectional area of the enclosure. In addition, the distribution block must be so positioned that when the cables are terminated, the minimum bending space as required in NEC 312.6(B) is provided. Finally, the distribution block must be equipped with a cover so that uninsulated live parts are not exposed within the wireway, whether or not the wireway cover is in place.

160. Compression-type connectors and lugs include those in which hand, pneumatic, or hydraulic tools indent or crimp tubelike sleeves which hold one or more conductors. The crimping action changes the size and shape of the connector; and a properly crimped joint deforms the conductor strands enough to provide good electrical conductivity and mechanical strength. With the smaller sizes of solid wires, some indenter splice caps require that the wires be twisted together before being placed in the cap and crimped, whereas others are intended to be inserted parallel. The distinction will vary with the type of indentations, and the manufacturer's recommendations on the correct method of making the splice should be followed. See Figs. 2.29 and 2.34.

FIGURE 2.32 Solderless connectors of the pressure-washer type.
[Electrical Division of H. K. Porter Company, Inc.]

FIGURE 2.33 Solderless lugs of pressure-washer type.

One of the disadvantages of indenter or crimp connectors is that special tools are required to make the joint. However, their use can be justified by the assurance of a dependable joint and low cost of connectors.

161. Connector designations and markings. Connectors are designed for copper, copper-clad aluminum, or aluminum conductors, or for all of them. Connectors with no markings are generally suitable for copper conductors only. If a connector bears the marking AL, it is designed solely for the connection of aluminum conductors. Connectors marked AL-CU or CU-AL are for use with either copper, copper-clad aluminum, or aluminum conductors; however, a copper wire and an aluminum wire must never be in direct physical contact unless the connector has additional markings. Connectors rated for copper and aluminum wires in direct contact will say “(intermixed–dry locations)” and are limited to dry locations.

Straight coupling connectors marked AL-CU are ideal if aluminum conductors are run to equipment with terminals designed for copper conductors. In such cases, a short piece of copper wire extends from the equipment terminals to one side of the straight coupling connector, and the aluminum conductor is connected to the opposite side. On the other hand, terminals in many new meter sockets, switches, and panelboards are designed for connection to either copper, copper-clad aluminum, or aluminum wires. If this is the case, a statement to that effect will appear on the inside of the enclosure, and no markings will be found on the terminals.

Wire connectors as shown in Figs. 2.30 through 2.33 have limitations with respect to their application on stranded wire. Unless provided with specific markings (such as “SOL” or “STR”), wire connectors for 30 through 10 AWG sizes can be used for both stranded and solid conductors, and wire connectors rated for 8 AWG and larger wires are for stranded conductors only. Connectors used for aluminum stranded conductors can be used for Class B

FIGURE 2.34 Typical compression connectors, crimp or indenter types. [*Electrical Construction and Maintenance*]

concentric, compressed, and unidirectional lay compact stranding. Connectors used for stranded copper terminations are suitable for Class B concentric and compressed conductors, and also Class C concentric conductors. Connectors used for compact-stranded copper are marked for that purpose either on the connector or on the smallest unit carton in which the connectors are sold.

Connectors suitable for more finely stranded conductors, such as Class H or Class M stranding, are marked with the additional stranding class designation and also the number of strands. Most listed connectors for fine-stranded conductors are in the form of crimp-on lugs, as in Fig. 2.34, that force the strand ends together into a homogeneous mass of metal.

162. Splice kits for circuits over 600 V. For electrical connections in circuits rated above 600 V, proper insulation is as important as providing the actual continuity of the current path. Splices and terminals must be made carefully in full conformity with instructions of connector manufacturers.

Several manufacturers feature splicing kits for making high-voltage splices. These kits vary according to the circuit voltage and type of cable (interlocked armor, neoprene-jacketed with or without shielding, or lead-covered) for the particular conductor insulations.

A common high-voltage connecting device is the pothead, which is used to connect cables to equipment or to other circuits. A pothead is a sealed terminal which provides connection to the conductor in the cable, furnishes moisture proofing for the conductor's insulation, and seals in cable-impregnating oil. Stress cones are also available in kit forms.

163. Splices in covered aerial conductors are made in the same manner as splices in bare aerial conductors of the same material. The splice may be covered simply with friction tape as shown in Fig. 2.35, but it is preferable to apply rubber tape covered with two layers of friction tape as shown in Fig. 2.36.

FIGURE 2.35 Western Union splice insulated with tape.

FIGURE 2.36 Splice in covered conductor.

164. Splices in steel or copper-and-steel stranded cables are generally made with seamless solderless splicing sleeves. Steel sleeves are used for all-steel wires, and either copper or steel sleeves for the combination cables.

165. Splices in copperweld or copperweld-and-copper cables are made with seamless solderless splicing sleeves. Two sleeves should be used for making each splice in extra-high-strength cable.

166. Splices in all-aluminum cable or in aluminum cable, steel-reinforced, are made by means of twisted solderless oval sleeves or solderless compression sleeves. The former joints are made with oval single-tube sleeves of seamless aluminum. For all-aluminum cables, one sleeve is sufficient for each joint. For aluminum cable, steel-reinforced, two sleeves should be used for each joint, except for Nos. 8 and 7 cables, for which one sleeve is sufficient. Two twisting wrenches (Fig. 2.37) are employed for twisting the sleeve and cable into the finished joint. The wrenches should be rotated in a clockwise direction when facing the mouth of the sleeve. Before making the joint, be sure that the inside of the sleeves and the ends of the cable are perfectly clean and free from dirt and grease. The following methods of making the joints are recommended by the Aluminum Co. of America.

FIGURE 2.37 Twisting wrench for applying aluminum twisting sleeves. [Aluminum Co. of America]

1. For aluminum cable, steel-reinforced (ACSR), sizes 4/0 to 1/0, give each sleeve 4 1/2 complete twists distributed as shown in Fig. 2.38. This requires setting one wrench at the inner end of each sleeve and setting the other wrench 3 times progressing toward the outer end of each sleeve. Make these in the order shown in the illustration. At the ends

FIGURE 2.38 Joint for ACSR cable sizes 4/0 to 1/0. [Aluminum Co. of America]

of the joint the wrench should not be less than $\frac{1}{4}$ in (6.35 mm) from the end of the sleeve.

- For aluminum cable, steel-reinforced (ACSR), sizes 1 to 6, give each sleeve four complete uniform twists, as shown in Fig. 2.39. This requires one setting of the twisting wrenches at the ends of each sleeve. The wrenches should not be less than $\frac{1}{4}$ in (6.35 mm) from the end of the sleeve.
- For twisting joints, consisting of a single sleeve, as used on all-aluminum cables and sizes 7 and 8 ACSR, give the middle third as many complete twists as it will stand (from 2 to $3\frac{1}{2}$, depending upon the size of cable and length of sleeve). Then give each end third length one complete twist.

FIGURE 2.39 Joint for ACSR cable sizes 1 to 6. [Aluminum Co. of America]

167. Compression joints on all-aluminum cable are made by compressing a seamless aluminum sleeve (Fig. 2.40) over the butted ends of the two cable lengths. A portable hydraulic compressor and dies are required for making these joints. The following method of making a joint is recommended by the Aluminum Co. of America.

- Impregnate the cable ends thoroughly with red-lead paint (red lead and linseed oil) by dipping them in a bucket of paint a little deeper than one-half the length of the joint.
- Slip the cable ends into the joint, taking care that they meet exactly at the middle.
- Compress the joint, starting at the center and working toward the ends, allowing dies always to overlap the previous position.

For old or blackened cable, each strand should be scraped or sandpapered clean. The bore of the joint is large enough to insert the end of the cable easily after the strands have been opened up, cleaned, and rearranged.

In making a repair joint between a piece of new cable and a piece of old cable, the most convenient method is first to run the end of the old cable clear through the joint, then to open up and clean the end of each strand for a distance equal to one-half the length of the joint. Replace the strands, impregnate with red-lead paint, and pull the cable back until the end is exactly in the middle of the joint. Then insert the new cable at the outer end of the joint after first removing grease from the strands and impregnating with red-lead paint.

FIGURE 2.40 Seamless aluminum sleeve for compression joint in all-aluminum cables. [Aluminum Co. of America]

168. Compression joints for most aluminum cable, steel-reinforced, consist, as illustrated in Fig. 2.41, of a steel compression sleeve (item 1) on the steel core and an aluminum compression sleeve (item 2) on the complete cable. The overall compression sleeve is fitted with two holes through which a heavy red-lead filler is injected. The holes are sealed with aluminum plugs (item 3). The following method of making a joint is recommended by the Aluminum Co. of America.

FIGURE 2.41 Compression joint for ACSR cable. [Aluminum Co. of America]

1. Before applying the joint, see that its bore and the ends of cable to be jointed are free from grease and dirt, i.e., thoroughly clean.
2. Slip the aluminum compression joint over one cable end and back out of the way along the cable.
3. Using a hacksaw, cut off the aluminum strands, exposing the steel core for a distance of a little more than half the length of the steel compression joint. Use care not to nick the steel core with the saw. Before doing this, serve the cable with wire just back of the cut.
4. Insert the steel core into the steel compression joint, bringing the ends exactly to the center.
5. Compress the steel compression joint, beginning at the center and working out toward the ends, allowing dies always to overlap the previous position.
6. Remove serving from the cable and slip the aluminum compression joint up over the steel compression joint. Center the aluminum joint by sighting the ends of the steel joint through the filler holes in the aluminum joint.
7. Using a caulking gun ($1/4$ -in. or 6.35-mm, round nozzle, maximum), inject heavy red lead (approximately 93 percent red lead, 7 percent linseed oil by weight) through both holes provided in the aluminum joint until the space between the aluminum joint and the steel joint is completely filled. This can be observed through the filling holes.
8. Insert the aluminum plugs in the filler holes and hammer them firmly in place. They will be completely locked during compression.
9. Compress the aluminum compression joint, starting at the center and working toward the ends, allowing dies always to overlap the previous position.

Some types of aluminum cable, steel-reinforced, have such a large percentage of steel that the steel compression sleeve of the above joint has a larger diameter than the complete cable. This necessitates the use of the joint shown in Fig. 2.42. One end of the overall aluminum sleeve is counterbored so that it can be slipped over the steel sleeve. The space between the counterbore and the cable is filled with a third aluminum sleeve (item 4). The procedure in making such a joint is in general the same as previously described. It is self-evident, however, that the aluminum joint (item 2) must be slipped over the cable with that end which has the smaller bore first and also that the sleeve (item 3) must be slipped on the other end of the cable—both before the steel joint (item 1) is applied. After the steel joint is applied and before the aluminum joint is slipped into place, the sleeve is slipped along until it is flush with the ends of the aluminum strands. Otherwise the procedure is the same as previously described for making compression joints in aluminum cable, steel-reinforced.

FIGURE 2.42 Compression joint for ACSR cable with large steel core. [Aluminum Co. of America]

ALUMINUM-BUILDING-WIRE INSTALLATION PRACTICES

169. Aluminum building wire (The Aluminum Association, Inc.)

A. Basic Installation Techniques

1. *Stripping insulation.* Never ring a conductor when stripping insulation. One way to avoid ringing is to pencil or whittle the insulation (Fig. 2.43). Another method is to skin the insulation back from the cut end of the conductor and then cut outward (Fig. 2.44). For the smaller sizes of wire the insulation may be removed quickly and easily by means of a wire stripper (Fig. 2.45). Be sure to match the size of notch on the stripper to the size of the wire.
2. *Splicing.* To splice two lengths of aluminum conductor use an aluminum compression-type splicing connector (Fig. 2.46). Manufacturers supply connectors filled with joint compound to seal the splice against moisture and other contaminants.

FIGURE 2.43 Never ring a cable: ringing may lead to a break. Remove insulation as you would sharpen a pencil.

FIGURE 2.44 Another safe method of removing insulation from conductors is to peel the insulation back and then cut outward.

FIGURE 2.45 Use a wire stripper for removing insulation from smaller wire sizes. Match stripper notch to the wire size.

FIGURE 2.46 Splice aluminum wires with a plated aluminum compression-type splicing connector. The compound in the connector seals the joint against moisture.

First, strip the insulation from the end of each conductor by one of the methods described. Strip back far enough so that the conductor will go fully into the connector, but also make sure that the insulation fits closely to the connector.

Next, insert the stripped end of the conductor into the connection as far as it will go. Then apply the crimping tool designed for the type of connector you are using and crimp fully in accordance with the manufacturer's instructions (Fig. 2.47). Be sure to select the correct crimping tool die for the size of conductor being spliced.

Finally, wipe off any excess joint compound and apply insulating tape according to the usual procedure (Fig. 2.48 and accompanying tables).

3. *Pulling conductors in conduit or electrical metallic tubing.* The following procedures are applicable to conduit of all types including aluminum. (a) Run a "fish" line through the conduit, either by attaching the line to a piston-type device propelled through the conduit by compressed air or by pushing a round flexible speedometer-type steel wire through the conduit. Polyethylene fish tapes may be used for shorter runs of up to about 100 ft (30.5 m). (b) Attach a

FIGURE 2.47 The crimping tool and its die must be correct for the conductor size being terminated to make a satisfactory joint. Apply enough pressure to distort all strands fully and make required number of crimps.

CROSS-LINKED POLYETHYLENE CABLES

Insulation thickness, in	A, in	Minimum no. of tape (half-lapped layers)
.055	2 1/2	2
.065	2 3/4	2
.075	2 3/4	3
.085	3	3
.095	3	4

4/64	.030	3 1/4	4
5/64	.045	3 3/4	5
4/64	.065	4	5

FIGURE 2.48 Apply insulating tape according to the usual procedure, making sure to protect the joint from physical damage.

FIGURE 2.49 Use an insulated basket grip to attach a pull line to the conductors. A bare steel grip should not be used because it will score the inside of the conduit.

FIGURE 2.50 When a rope pull must be used, skin the cable ends and stagger them after locking with tape. This procedure will hold the tie to a minimum cross section.

cleanout brush to the fish line, and behind it attach the pull line; then pull both through the conduit by means of the fish line. (c) Attach the pull line to the conductor or conductors. A basket grip over the insulation may be used provided it is of a type that will not score the conduit during the pull (Fig. 2.49). A bare steel basket grip should not be used. (d) If conductors are pulled with a rope, stagger the conductor ends and anchor in position with tape to provide maximum flexibility around bends (Fig. 2.50).

FIGURE 2.51 Plan pulls so that the cable moves downward. This will speed the work and reduce the strain on the cables and pull line.

(e) Try to feed conductors into the conduit end closest to the first bend to reduce pulling tension. (f) Use pulling equipment with adequate power available to make a steady pull on the cables without jerking. (g) Use a pulling compound compatible with the conductor insulation as the conductors are fed into the conduit to reduce the coefficient of friction and the required pulling tension. (h) For single conductors on reels, stagger reels one behind another while feeding in conduit in order to maintain equal pulling tensions and prevent conductors from crossing over and jamming in the conduit. (i) Whenever possible, pull conductors downward to allow gravity to assist in pulling with reduced tension (Fig. 2.51). (j) Arrange pulls for large conductors so that maximum pulling tension

on conductors does not exceed $0.006 \times N \times \text{cmil}$, where N = the number of conductors pulled and cmil = the circular-mil area for each conductor. (k) When conductor ends are prepared for pulling, be sure not to nick the stranded aluminum conductor during insulation removal. Damaged strands can reduce the pulling tension capabilities of the conductor. To avoid this, pencil the insulation for removal, as described above; do not ring-cut the insulation. (l) Adhere to all NEC requirements.

4. *Pulling conductors in trays.* If aluminum cable is to be pulled in trays or cable racks, take the following precautions, plus those applicable to conduit. (a) If pulling attachments are used on the conductors, cover them with rubberlike or plastic tapes to prevent scoring of the trays and installation sheaves during a conductor pull (Fig. 2.52). (b) Use lightweight (aluminum) large-radius sheaves around bends and smaller sheaves on the straight sections of cable-support trays to facilitate cable installations and to reduce required pulling tensions. (c) Maintain minimum bending radii on all cable turns, bends, and drops (see Table 171F). (d) If cables are anchored on trays, be sure that straps or other cable-anchoring devices do not cut into the insulation. (e) Conductors in the same circuit should be grouped together, but whenever possible maintain spacing between conductors in different circuits to obtain optimum current-carrying capacity and prevent hot spots. (f) Be sure that tray supports are capable of handling the maximum weight of conductors and planned conductor additions.

FIGURE 2.52 When bare steel basket grips and similar pull-line-to-cable devices must be used, cover them with plastic tape or rubberlike shields.

FIGURE 2.53 Use proper connectors and sufficient insulation, and leave enough slack for possible wiring changes and cable movement. The connector allows a tap without cutting the feeder (A).

If permanent bends are made at terminations in aluminum building wires, the following are the minimum recommended bending radii (see Table 171F) based on the overall diameter (OD) of insulated conductor (inches):

1.000 and less	4 × OD
1.001 to 2.000	5 × OD
2.001 and over	6 × OD

It is recommended that such bends be made before the terminal is applied to minimize electrical-contact distortion.

5. Junction boxes. Junction boxes are used when abrupt changes in direction of conduit runs are made, to provide for expansion and contraction of the conductors upon heating and cooling, and when tap connections are to be made (Fig. 2.53). Tap connectors are described in Subsec. B.

6. Joint compound. Connections in larger-size aluminum conductors are made with the aid of joint compound, as indicated above under splicing instructions. The compound is applied to the bare conductor after it has been wire-brushed. A coating of joint compound remains on the surface of the conductor, preventing the oxide from re-forming when it is broken in the installation operation. Manufacturers usually supply compression connectors already filled with joint compound to seal the connection from moisture and other contaminants. The compound must be added to connections made with mechanical connectors.

If current density is not high, successful long-lived connections may be made in aluminum conductors in sizes used in branch circuits and in residential wiring without joint compound, although it is a preferred practice to use the compound on all connections.

The user is cautioned that two classes of joint compounds are available and that each has its own applications. The type used with connections contains small metallic particles that help penetrate the aluminum oxide. The second type of compound does not contain these particles and should be used only for flat-surface, lug-to-lug, and lug-to-bus connections.

B. Connectors. Only all-aluminum pressure-type connectors marked AL-CU to indicate that they have been tested and are listed by Underwriters Laboratories for aluminum copper, or aluminum-to-copper connections interchangeably should be used. The connectors are usually plated to avoid the formation of oxide and to resist corrosion. Copper-clad aluminum conductors in feeder sizes also require the use of UL-listed AL-CU or CC-CU connectors.

FIGURE 2.54 Connectors have been designed and manufactured for every conceivable contingency. Make sure the connector is Underwriters Laboratories-listed for aluminum.

Pressure connectors are of two basic types, a mechanical screw type and a compression type applied with a tool and die. Both are designed to apply sufficient pressure to shatter the brittle aluminum oxide from the strand surfaces and provide low-resistance metal-to-metal contact. Both basic types work reliably with aluminum, although many contractors prefer compression connectors because they are less susceptible to installation error.

Connectors for every conceivable need are available. Some typical connectors are shown in Fig. 2.54. Whichever type you use, follow the manufacturer's instructions carefully.

There are available copper-bodied connectors that carry the AL-CU designation and are tin-plated and resemble aluminum. They should not be used with aluminum conductors larger than 6 AWG. If in doubt, file the edge of the connector to see if copper shows through.

In making connections, first strip the insulation as instructed in Subsec. A1. Then apply joint compound if it is not already contained in the connector. If the connector is a mechanical screw type, apply the manufacturer's recommended torque (Fig. 2.55). If it is a compression type, crimp it as recommended by the manufacturer (Fig. 2.56). Be sure to select the correct size of die and close the tool completely for full compression. Wipe off any excess compound. Then tape the joint as instructed in Subsec. A2, or apply the insulating enclosure that comes with some types of connectors. There is now a twist-on aluminum to copper wire connector listed by UL as conforming to UL 486C that is suitable for retrofit installations. A specially formulated compound inside the connector cuts aluminum oxide and prevents corrosion. See Fig. 2.57.

Connections in branch circuits may be made with approved pigtail connectors of the crimp-on type (Fig. 2.70). No joint compound is required on such connections if load

FIGURE 2.55 Proper torque is important: overtightening may sever the wires or break the fitting; undertightening will lead to overheating and failure.

Mechanical Terminals

FIGURE 2.56 The crimping tool must be fully closed. Failure to close the tool will lead to an unsatisfactory and weak joint.

FIGURE 2.57 On the left a twist-on wire connector suitable for underground on direct burial. On the right is a UL-listed-twist-on connector suitable for aluminum to copper retrofit applications. [Ideal Industries Inc.]

currents are low because of a limitation to small wire size (10 AWG maximum), although its use is preferred because it generally improves performance.

C. Terminations. Plated aluminum-bodied terminal lugs are used to connect aluminum conductors to transformers, switches, busbars, motors, and other equipment. Like connectors, they are of two basic types, a mechanical screw type and a compression type applied with tool and die. Some typical terminal lugs are shown in Fig. 2.58. They are applied to the conductor in the same manner as described above under “Connectors.”

Insist that all equipment be furnished with all-aluminum terminals that carry the UL AL-CU label. Terminals that are copper-bodied and tin-plated should not be used with aluminum conductors larger than 6 AWG.

Compression Terminal Lugs

FIGURE 2.58 Typical plated aluminum terminal lugs come in a variety of styles and are applied in the same manner as standard connectors.

When all components (bus, studs, lugs) are aluminum, only aluminum bolts should be used to make the connections. The following procedures should be used. (a) Aluminum bolts should be anodized-alloy 2024-T4 and conform to ANSI B18.2.1 specifications and ASTM B211 or B221 chemical and mechanical property limits. (b) Nuts should be aluminum-alloy 6061-T6 or 6262-T9 and conform to ANSI B18.2.2. (c) Washers should be flat aluminum-alloy aluminum-clad 2024-T4, Type A plain, standard wide series, conforming to ANSI B27.2. SAE or narrow-series washers should not be used. (d) Hardware should be assembled as shown in Fig. 2.59. (e) All hardware should be lubricated with a suitable joint compound before tightening. (f) Bolts should be tightened to the manufacturer’s recommended torque. In the absence of such recommendations, torque values listed in NEMA CC-1 should be used. See Table C-1.

FIGURE 2.59 When all components are aluminum, aluminum hardware should be used and installed as shown.

TABLE C-1

Diameter of bolt, in	Nominal torque	
	ft/lb	in/lb
3/8 (L)	19	228
1/2 (L)	40	480
5/8 (L)	55	660

NOTE L = lubricated.

TABLE C-2

Belleville			
Bolt size, in	Diameter, in	Thickness, in	Nominal load, lb, to flatten
1/4	11/16	0.050	800
5/16	13/16	0.060	1000
3/8	15/16	0.070	1400
5/8	1 3/16	0.085	2700
1/2	1 1/2	0.100	4000

NOTE Material is hardened steel; finish, cadmium plate.

If you are adding to an existing installation containing copper bus or studs or if it is impossible to obtain the required equipment with aluminum terminations, use a steel bolt with a Belleville spring washer to allow for the differing rates of thermal expansion of the materials. The following procedures should be used. (a) The steel bolt should be plated or galvanized, medium-carbon-steel-heat-treated, quenched, and tempered equal to ASTM A325 or SAE Grade 5. (b) Nuts should be heavy semifinished hexagon, conforming to ANSI B18.2.2, the thread to be unified coarse series (UNC), Class 2B. (c) Flat washers should be steel, Type A plain standard wide series, conforming to ANSI B27.2. SAE or narrow-series washers should not be used. (d) Belleville conical spring washers come in sizes for use with bolts ranging in sizes indicated in Table C-2. (e) Hardware should be assembled as shown in Fig. 2.60. (f) All hardware should be lubricated with a suitable joint compound before tightening. (g) Bolts should be tightened sufficiently to flatten the spring washer and be left in that position.

With equipment having terminals that will accommodate only copper conductors, a “gutter” splice may be used to connect the aluminum conductor. The aluminum conductor is spliced to a short length of copper conductor, and the copper-conductor stub is then connected to the equipment terminal (Fig. 2.61). An AL-CU compression-type connector is used to make the splice.

FIGURE 2.60 A Belleville spring washer is used to make an aluminum-to-copper or steel joint. Note that the crown of the washer should be under the nut.

FIGURE 2.61 A gutter splice is used when the terminal lugs are not removable and are approved for copper-cable connection only.

Wiring devices on branch circuits having ratings not exceeding 35 A usually are furnished with binding-screw terminals.

The installation of aluminum nonmetallic sheathed cable (Type NM) for branch circuits in buildings is the same as for residential wiring, which is covered in Subsec. 171E.

Figures 2.62 to 2.68 show typical connections of aluminum conductors to equipment terminals.

D. Service Entrances

1. Industrial. With the aluminum service-drop cable in general use today, the connection of the service cable to aluminum service-entrance conductors requires only simple splices made as described in Subsec. A2, "Splicing." Connection of aluminum service-entrance conductors is made in the same manner when copper service-drop cable is still in use. In that case be sure to use compatible aluminum-bodied connectors.

FIGURE 2.62 Method of connecting large aluminum conductors to equipment studs or terminal pads made of copper. If the bolts are made of aluminum, it is not necessary to provide the Belleville-spring washer.

TABLE C-3 Bolt Loading

Bolt size, in	Current capacity, A
3/8	225
1/2	300
5/8	375
3/4	450

Two-hole lugs should be used for size 4/0 and larger conductors, and each bolt connecting a lug to a terminal or bus should not carry current exceeding the value in Table C-3.

In connecting large aluminum conductors (500,000 cmil, or 253.35 mm², and up) to heavy equipment having copper terminal studs or pads, or both, large compression-type lugs, preferably with two holes, should be used (Fig. 2.62).

With other than aluminum bolts, Belleville spring washers and heavy flat washers in consecutive arrangement as shown in Fig. 2.62 must be used. If aluminum bolts and nuts are used, only the heavy washer bearing on the aluminum lug is necessary.

FIGURE 2.63 Where possible, current transformer terminals should be replaced with a compression type (B). If they cannot be removed, a section of copper cable should be spliced to aluminum (A).

FIGURE 2.64 Copper power transformer terminals require a short copper stub spliced to aluminum cable.

FIGURE 2.65 When connecting aluminum conductors to a unit substation with copper bus, use compression-type aluminum lugs attached with a Belleville washer (A). Copper primary leads on the transformer are connected to aluminum feeders in aluminum connectors and bolted back to back with Belleville washers (B).

FIGURE 2.66 Copper lug connections on switchgear are replaced with equivalent aluminum connectors by using double-barrel lugs. A Belleville washer is used with copper or steel studs.

FIGURE 2.67 Copper terminations on switch connections may be replaced with aluminum by using smaller multiple aluminum conductors to reduce the voltage drop and increase the current-carrying capacity.

FIGURE 2.68 Three methods of making motor connections are shown in (A). All terminals are preferably aluminum. If the bolt is steel or copper, a Belleville washer is necessary (B).

Underground service cable also is largely aluminum today. This is true of both small- and medium-size services at secondary voltages as well as of large installations with transformers or unit substations supplied at primary voltages. A typical medium-size service entrance is shown in Fig. 2.69.

2. Residential. The connection to service-drop cable in residential services is made in the same manner as in small industrial or commercial service entrances. Type SE aluminum cable is used for this purpose and is connected to the utility service drop with splicing connectors, as described in Subsec. A2.

The size of service-entrance cable to be used depends on the load to be served. The 2008 NEC requires at least 100-A service for all single-family residences, which requires as a minimum 2 AWG aluminum SE cable. The NEC requires that service-entrance cable be not smaller than 6 AWG, except in certain light-load installations. In any event, the size of service-entrance cable should be chosen in accordance with NEC requirements and the installation made in the manner required by local codes. In most areas local code bodies have adopted the NEC for electrical installations.

Meter boxes and service panels are generally available with aluminum ALCU terminals, and aluminum service-entrance cable may be connected directly to these.

With equipment having terminals suitable only for copper cable, a gutter splice may be used to connect the aluminum cable, as described in Subsec. 171C, "Terminations."

E. Circuit-Size Wiring. Because of reports of field failures originating at receptacle outlets wired with aluminum and a subsequent investigation indicating the apparent cause of many to be insufficient tightening of binding screws at the time of installation, UL revised

the requirements for solid aluminum conductors in November 1971. UL also instituted new requirements and new testing procedures for wiring devices for use with circuit-size aluminum conductors.

One of the basic requirements for both wire and devices is a critical heating test of 500 four-h cycles with high overload currents. The new tests were designed to simulate field conditions with marginal workmanship. A 20-A device is tested on cyclic loads of 53 A, with binding screws tightened to a low torque of only 6 lb · in. Solid aluminum 12 AWG conductors are tested at 40 A (267 percent of rated load), with binding screws tightened to 6 lb · in.

Solid aluminum-alloy conductors must meet these requirements before receiving UL listing as "insulated aluminum wire." Devices which pass the revised UL requirements are rated CO/ALR and carry that marking on the mounting strap. Field reports confirm the reliability of the new, more flexible alloy wire and the CO/ALR switches and receptacles. Only these products should be used in aluminum 15- and 20-A branch-circuit wiring.

FIGURE 2.69 Most service-drop cables are now aluminum; they may be quickly field-spliced to aluminum service-entrance cable with a variety of compression connectors. A drip loop should be provided. If either the service-drop cable or the service-entrance cable is copper, the aluminum should always be higher than the copper.

Pigtailing Method. Pigtailing, either field- or factory-wires, as illustrated in Fig. 2.70, is recognized by the NEC.

Note: Detailed installation instructions provided with pressure wire connectors must be followed.

FIGURE 2.70 Pigtailing copper-to-aluminum conductors.

Step A: Strip and wrap wire

Step B: Tighten screw to full contact

Step C: Complete connection

FIGURE 2.71 Correct method of terminating aluminum wire at wire-binding screw terminals of receptacles and snap switches. [Underwriters Laboratories Inc.]

The correct method of terminating aluminum wire at a binding screw (Fig. 2.71) is as follows. (a) Wrap the freshly stripped end of the wire two-thirds to three-fourths of the distance around the wire-binding screw post as shown in Fig. 2.71A. The loop is made so that the rotation of the screw in tightening will tend to wrap the wire around the post rather than to unwrap it. (b) Tighten the screw until the wire is snugly in contact with the underside of the screw head and with the contact plate on the wiring device as shown in Fig. 2.71B. (c) Tighten the screw an additional half turn, thereby providing a firm connection. If a torque screwdriver is used, tighten to 12 lb · in (see Fig. 2.71C). (d) Position the wires behind the wiring device so as to decrease the likelihood of the terminal screws' loosening when the device is positioned into the outlet box.

Figure 2.72 illustrates incorrect methods for connection that should not be used. In the following types of devices the terminals should not be connected directly to aluminum conductors but may be used with UL-labeled copper or copper-clad conductors: receptacles and snap switches marked "AL-CU"; receptacles and snap switches having no conductor marking; receptacles and snap switches having back-wired terminals or screwless terminals of the push-in type.

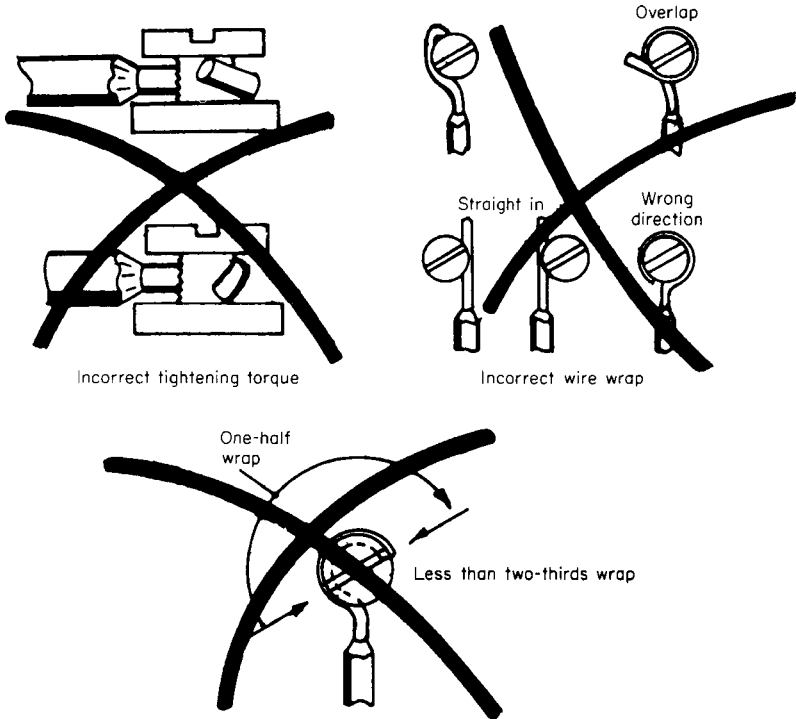

FIGURE 2.72 Incorrect methods of terminating aluminum wire at wire-binding screw terminals of receptacles and snap switches. [Underwriters Laboratories Inc.]

The new CO/ALR marking applies only to 15- and 20-A wiring devices such as receptacles and switches. All other devices such as circuit breakers, fusible protection, and oven or dryer receptacles continue to be marked AL-CU when approved for use with aluminum.

You may be called upon to inspect homes wired with aluminum between 1965 and 1972 to determine whether or not the installation is functioning satisfactorily. If examination discloses overheating or loose connections, it is advisable to replace the older receptacles with new devices carrying the CO/ALR marking. The UL-listed crimp-on compression tool (Copalum by AMP) may be used. See Fig. 2.70.

169F. Bending Radii for Cable Not in Conduit or on Sheaves or While under Tension

Power cables without metallic shielding or armor

The minimum recommended bending radii as multiples of the overall cable diameter given in the following tabulation are for both single and multiconductor cable with or without lead sheath and without metallic shielding or armor.

Thickness of conductor insulation, 64ths in	Minimum bending radius as multiple of cable diameter; overall diameter of cable, in		
	1.00 and less	1.01 to 2.00	2.00 and over
10 and less	4	5	6
11 to 20	5	6	7
21 and over		7	8

Power cables with metallic shielding or armor

- a. *Interlocked armored cables.* The minimum recommended bending radius for all interlocked armored cables is in accordance with table but not less than 7 times the overall diameter of the cable, except as noted in (c) for shielded cable.
- b. *Flat-tape- and wire-armored cables.* The minimum recommended bending radius for all flat-tape-armored and all wire-armored cables is 12 times the overall diameter of the cable.
- c. *Shielded cables.* For all cables having metallic shielding tapes the minimum recommended bending radius is 12 times the overall diameter of the completed cable.
- d. *Wire-shielded cables.* Wire-shielded cables should have the same bending radius as power cables without metallic shielding tape.

NOTE Reprinted in whole or in part from ICEA S-66-524, NEMA WC-7.

TERMINATION AND SPLICE KITS

170. All-tape and tape-cast termination and splices (3M Company). The 3M system for splicing and terminating consists in part of a series of engineered drawings for splicing and terminating power cables. These data sheets contain data for splicing and terminating solid dielectric shielded power cable, as shown in Fig. 2.73. The designs include all-tape and tape-cast (tape-resin) in-line and T splices for 5- to 25-kV cable, all-resin in-line and T splices for 5- to 8-kV cable, and all-tape terminations for 5- to 25-kV cable, copper or aluminum conductors from 8 AWG to 2500 kcmil. Each engineered drawing includes comprehensive, step-by-step installation instructions and complete bills of materials and dimensions.

The application of these data sheets is for splicing and terminating 5- to 25-kV (up to 8-kV for all-resin splices) metallic and wire shielded-type power cables from 8 AWG to 2500 kcmil copper or aluminum conductors on the following solid cables: polyethylene (high- and low-density), cross-linked polyethylene (XLP), ethylene propylene rubber (EPR), and butyl rubber.

Splices and terminations for shielded cable operating from 5000 to 25,000 V (to 8000 V for all-resin splices) shall be made by using tape and/or materials in accordance with drawings engineered by the manufacturer of the splice material. The terminations, as constructed according to these designs, shall meet all the design dielectric requirements of the IEEE 48-1990 standard for potheads. The splices, as constructed according

FIGURE 2.73 Shielded cable. [3M Co.]

to these designs, shall meet the requirements of the IEEE standard for power-cable joints. All splices and terminations constructed according to these designs must be able to be hipotted (submitted to a high-voltage test) according to ICEA standards S-66-524 and S-19-81.

Splices and terminations for metallic shielded-type cables, operating from 5000 to 25,000 V (to 8000 V for all-resin splices), shall be made by using materials in accordance with drawings engineered by the manufacturer of the splice material, such as the 2047 splice and termination drawing series available from the 3M Company. In-line splices shall be made according to engineering drawing 2047-A-1, 2047-K-4, or 2047-X-1; T splices shall be made according to engineering drawing 2047-C-2, 2047-M-2, or 2047-Y-1; and standard terminations shall be made according to engineering drawing 2047-B-2. In areas where space is limited, terminations shall be made according to engineering drawing 2047-B-16.

The tape and tape-cast 3M systems for splicing and terminating designs can be used on cables with a rated operating temperature of 90°C and an emergency overload rating of 130°C.

All termination designs meet the design dielectric requirements of the IEEE 48-1990 standard for potheads. All splice designs meet the requirements of the IEEE standard for power-cable joints. All splices and termination made according to these designs may be dc-hipotted according to ICEA standards S-66-524 and S-19-81.

171. In-line splicing kits for 15-kV and 25-kV URD cable (3M Company: see Fig. 2.74). These are specifically engineered for direct-burial URD applications. Quick-Splice accommodates a wide variety of cable types, both 15-kV and 25-kV, for use with nominal 175- to 280-mil (4.45- to 7.11-mm) polyethylene and cross-linked polyethylene (XLP) or ethylene propylene rubber (EPR), insulated concentric neutral (URD) cable, aluminum or copper, stranded or solid conductor. Its application range is as follows: 15 kV, from 2 AWG to 750 kcmil; 25 kV, from 2 AWG to 500 kcmil.

FIGURE 2.74 3M “Quick-Splice” in-line URD splice kit. [3M Co.]

Installation

1. Prepare cables as you would any splice. Apply one half-lapped layer of vinyl tape over the semiconductive jacket of the cables.
2. Apply silicone grease over cable insulation and vinyl tape. Then slide splice end caps onto each cable until they are butted against the concentric neutral wires. Slide the splice body onto the cable.
3. Crimp the connector over the conductors. Use conventional crimping tools; no special tools or techniques are required.
4. Slide the splice body into its final position over the connector. Leave a small area of insulation exposed at both ends of the splice body. Remove the applied vinyl tape.
5. Slide end caps onto the splice body. Return concentric neutral wires to the edge of the splice body and connect to the ground eyes.

172. Resin splicing kits (3M Company). A full line of splicing kits utilizing a resin sealing compound in a voltage range of 600, 1000, and 5 kV is available.

- A. **Multimold Splicing Kit** (see Fig. 2.75) Odd-size and odd-shaped splices can be difficult to insulate, especially when they must be moistureproof for underground applications. Versatile multimold splicing kits are designed to handle almost any type of splice configuration up to 1000 V either aboveground or buried. Each kit contains a wraparound mold body of porous webbing on a thin, tough polyester film to ensure the proper thickness of resin around the connection, sealing putty strips on the mold body to form a resin-tight envelope for the resin, and Scotchcast brand electrical insulating resin

FIGURE 2.75 Multimold splice kit. [3M Co.]

4 AWG, packed in a Unipak brand container to ensure convenience and proper mixing ratios.

Use multimold splicing kits for any odd-shaped and odd-size splices, as in secondary distribution, plant grounds, parking-lot and airport-runway lighting, electrical sprinkling systems, sheath repair, remodeling wiring, sealing anodes, leads, and cathodic protection. The kits are for use on cables operating at 1000 V and under.

B. Y and In-Line Splicing Kit (see Fig. 2.76) Each kit is packaged to simplify the job and contains all the materials necessary to make a splice. The contents include two-piece snap-together mold bodies, tape for sealing ends, two funnels, and insulating and sealing compound Scotchcast brand 4 AWG resin in a Unipak container. These field-splicing kits conform in strength and electrical properties to the cable. To use them, snap the transparent mold bodies over the prepared cable, mix the resin in the Unipak container, and pour. When the resin cures, in about 30 min, a moisture-tight seal and a perfect electrically insulated splice are complete. Scotchcast splicing kits can be used for overhead, underground, or direct-burial applications.

FIGURE 2.76 Y and in-line splice kit. [3M Co.]

173. Porcelain termination kits (3M Company; see Fig. 2.77). It is possible to make a custom pothead in the field with a Scotchcast porcelain termination kit. Such a kit will terminate 2 AWG to 750 kcmil shielded or concentric neutral cable from 5 to 25 kV (see Fig. 2.77 and accompanying tables).

High-quality wet-process porcelain insulators assure maximum reliability for a non-tracking surface. They are sky-blue to blend against the horizon.

3M has designed a sealed metal topcap which not only assures a permanent seal but also eliminates the necessity for special internal or external connectors on copper conductors. A pressure contact is made on the conductor by a pad which is driven against the conductor by a setscrew. Load-cycling tests prove that this pressure contact will prevent overheating of the pothead. The entire contact is sealed when the poured elastomeric compound has hardened and the metal sealing plug is installed. The aerial wire connection is made in the same manner and has a quick disconnect feature. Special termination lugs are necessary for aluminum conductors.

To accommodate a wide range of cable sizes and handle shielded and concentric neutral cables, an elastomeric insulation is molded around the cable on the job. The elastomeric compound cures to a solid void-free elastomer in minutes; no outside heat is required.

For use on concentric neutral (URN) and synthetic insulated shielded cable. The terminations meet the design dielectric requirements of the IEEE No. 48 standard for potheads.

*Basic impulse insulation level.

FIGURE 2.77 Porcelain termination kit. [3M Co.]

The termination kits are provided with a single-tongue mounting which is made of a conductive chromate-coated casting and is an integral part of the termination. The ring can be attached to a standard crossarm bracket.

Special termination lugs which adapt the kits for use on cables with aluminum conductors have been designed. Conventional crimping tools are used.

174. Molded-rubber termination kits for 2 AWG to 500 kcmil (3M Company). Each 3M Quick-Term MT-series kit will handle a wide range of cable and conductor sizes. The kits are lightweight and are available in skirted or tubular silicone rubber insulators. They permit free-hanging applications or standard mounting with optional cable support.

The skirted insulators are designed to protect termination on 15-kV concentric neutral cable in contaminated environments (see Fig. 2.78, I). The tubular insulators are for indoor use, pad mounts, switchgear, or mildly contaminated environments (see Fig. 2.78, II).

3M stress cones are designed to slide easily over cable insulation. A fold-back base permits visual alignment and sealing. Skirted and tubular insulators come prestretched over a collapsible core. They position quickly, then shrink tightly in place when the core is unwound.

Installation

1. Lubricate the prepared cable and the bore of the stress cone with the silicone grease provided. The specially formulated rubbers slide easily over the cable insulation, and live action ensures a tight interface fit during load cycling.

FIGURE 2.78 Molded-rubber termination kits. [3M Co.]

FIGURE 2.79 Stress cone for rubber termination kit.
[3M Co.]

2. The base of the stress cone comes rolled back to help assure proper alignment with cable-shield cutoffs, thus providing a close, void-free fit between the cable shield and the base of the stress cone even if the cable jacket is not cut off squarely. See Fig. 2.79.
3. The base of the stress cone unrolls down over the cable shield to form a tight-fitting, weatherproof seal-and-jacket continuity even if the cable is in a bent position. The ground wire is fastened as the last step in the installation of the stress cone.

DIVISION 3

CIRCUITS AND CIRCUIT CALCULATIONS

Types of Circuits	3.1
Electrical Systems	3.8
Circuit Calculations	3.20
NEC Ampacity Rules for Conductors	3.64

TYPES OF CIRCUITS

1. A series circuit is one in which all components are connected in tandem as in Figs. 3.1 and 3.2. The current at every point of a series circuit is the same. Series circuits find their most important commercial application in some airport runway lighting and in series street lighting, although this is falling out of favor. They are seldom if ever used in the United States for the transmission of power.

2. Multiple, parallel, or shunt circuits are those in which the components are so arranged that the current divides between them (Figs. 3.3 and 3.4). Commercially, the distinction between multiple and series circuits is that in series lighting circuits the current is maintained constant and the generated emf varies with the load, whereas in multiple circuits the current through the generator varies with the load and the generator emf is maintained practically constant.

3. Adding receivers in parallel on multiple circuits is really equivalent to increasing the cross section of the imaginary conductor formed by all the receivers in parallel between the + and the - sides of the circuit.

4. The distribution of current in a multiple circuit is shown in Fig. 3.5. Motors, heating devices, or other equipment requiring electricity for their operation could be substituted for the incandescent lamps if the proper current values were substituted for those shown. Note that the current in the main conductors decreases toward the end of the run and that the current supplied by the source, the generator, is equal to the sum of the currents required by all the components. The voltage at the end of the run is less than that at the generator.

FIGURE 3.1 Series electric-bell circuit.

FIGURE 3.2 Series street-lighting circuit.

FIGURE 3.3 Electric bells in parallel.

FIGURE 3.4 A multiple circuit for light and power.

FIGURE 3.5 Multiple-circuit currents.

5. A multiple-series or parallel-series circuit consists of a number of minor circuits in series with each other and with several of these series circuits then connected in parallel, as shown in Figs. 3.6 and 3.7. Incandescent lamps and motors used in railway work are sometimes arranged in this way. For example, on a railway car operating from a 600-V

FIGURE 3.6 Multiple-series circuit supplying lamps on railway cars.

FIGURE 3.7 Multiple-series circuit supplying motors on railway cars.

third rail, the 120-V lamps are connected five in series (see Fig. 3.6). The motors on railway cars which operate from a 3000-V dc overhead trolley wire are usually connected two in series so that the voltage per motor will be only 1500 V (see Fig. 3.7).

6. A series-multiple or series-parallel circuit is one in which first a number of minor circuits are connected in parallel and then several of the parallel-connected minor circuits are connected in series across a source of emf as in Fig. 3.8. This method of connection is seldom used. (There appears to be a difference of opinion as to what constitutes a series-multiple and what a multiple-series circuit. The definitions of Secs. 5 and 6 are in accordance with the practice of the General Electric and Westinghouse Electric companies.)

FIGURE 3.8 A series-parallel or series-multiple circuit.

FIGURE 3.9 A divided circuit.

7. A divided circuit (Fig. 3.9) is really one form of multiple or parallel circuit. The distinction between the two sorts appears to be that, as ordinarily used, the term *divided* refers to an isolated group of a few conductors in parallel rather than to a group of a large number of conductors in parallel.

8. The joint resistance of a number of conductors in parallel can be computed with the following formula. There should be as many terms in the denominator of the formula as there are conductors in parallel.

$$R = \frac{1}{\frac{1}{r_1} + \frac{1}{r_2} + \frac{1}{r_3} + \frac{1}{r_4}, \text{ etc.}}$$

EXAMPLE What is the joint resistance of the conductors in the divided circuit shown in Fig. 3.9? In other words, what is the resistance from A to B?

SOLUTION Substitute in the formula

$$\begin{aligned} R &= \frac{1}{\frac{1}{r_1} + \frac{1}{r_2} + \frac{1}{r_3}} = \frac{1}{\frac{1}{5} + \frac{1}{10} + \frac{1}{15}} = \frac{1}{\frac{6}{30} + \frac{3}{30} + \frac{2}{30}} \\ &= \frac{1}{\frac{11}{30}} = 1 \times \frac{30}{11} = 2.73 \Omega \end{aligned}$$

9. Multiple circuits are employed for the distribution of electrical energy for all lighting and power work with the exception of street lighting, for which series circuits are still used in some locations.

10. The complete electric system from the generating plant to the particular piece of equipment utilizing the electrical energy for heating, lighting, power, etc., may be divided into three main parts. These are the transmission system, the distribution system, and the interior wiring in the building where the energy is utilized. Two simple complete electric systems illustrating the component parts are shown in Figs. 3.10 and 3.11. All wires of a circuit are represented for simplicity by a single line. Voltages commonly used for the different parts of the system are indicated in the figures. In the system shown in Fig. 3.10 the electricity is generated as alternating current at 2300 V. At the generating station it is stepped up to 44,000 V and transmitted at this voltage over the transmission system to the substation. In the substation the energy is converted by means of a rotary converter to direct current. From the substation the energy is distributed over two distribution systems to the different buildings. One of these distribution systems is two-wire 230-V direct current for the motor load, and the other is three-wire 115- to 230-V direct current supplying the energy for lighting. As noted in Sec. 24, this system is almost unheard of today. In the system of Fig. 3.11 the energy is generated, transmitted, and distributed as alternating current throughout. This system is far more common.

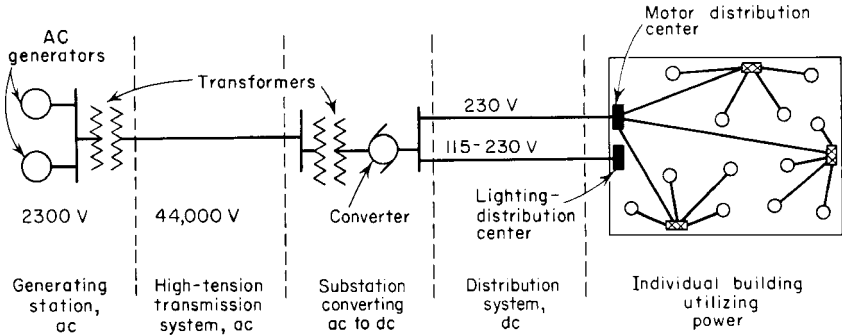

FIGURE 3.10 Simple complete electric system, generating and transmitting alternating current, distributing direct current.

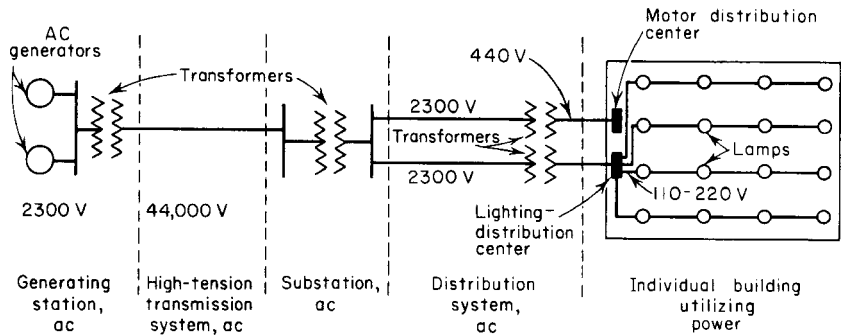

FIGURE 3.11 Simple complete electric system, generating, transmitting, and distributing alternating current.

11. A feeder or feeder circuit (Figs. 3.12 and 3.13) is a set of conductors in a distributing system extending from the original source of energy in the installation to a distributing center and having no other circuits connected to it between the source and the center. The source may be a generating station or a substation or, in the case of building or house wiring, a connection to the service conductors from the street (see Figs. 3.12 and 3.13).

12. A subfeeder is an extension, fed through a cutout, of a feeder or of another subfeeder from one distributing center to another and having no other circuit connected to it between the two distributing centers. Although commonly used as trade slang by electricians, note that the NEC has dropped all use of the word because all subfeeders also meet the NEC definition of feeders.

13. A main (Figs. 3.12 and 3.13) is any supply circuit to which other energy-consuming circuits (submains, branches, or services) are connected through automatic

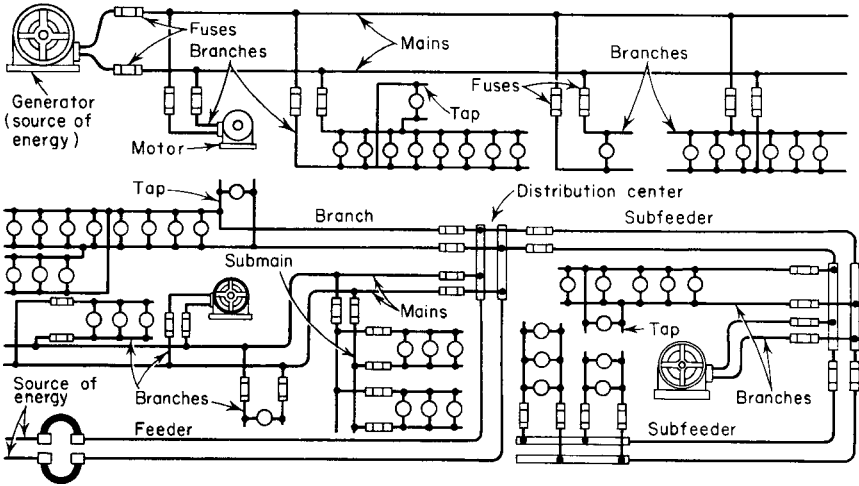

FIGURE 3.12 Diagram illustrating circuit nomenclature.

cutouts (fuses or circuit breakers) at different points along its length, which is of the same size of wire for its entire length, and which has no cutouts in series with it for its entire length. If a main is supplied by a feeder, the main is frequently of smaller wire than the feeder which serves it. An energy-utilizing device is never connected directly to a main, a cutout always being interposed between the device and the main.

If one building or structure is fed from another, as in campus-style distributions at factory or institutional facilities (or even a detached garage at a residence) that remote building or structure will usually have a local disconnecting means on site. In general the NEC intends that such buildings be capable of disconnection in an emergency without needing to enter a different building. These main disconnects are usually referred to as "building disconnects." They are never "service disconnects" unless they actually qualify as service equipment as covered in Sec. 18.

FIGURE 3.13 Examples of feeders, mains, and branches.

14. A submain (Fig. 3.12) is a subsidiary main, fed through a cutout from a main or from another submain, to which branch circuits or services are connected through cutouts. A submain is usually of smaller wire than the main or other submain which serves it. Here again, like subfeeders, all submains are mains under current NEC usage.

15. A branch or branch circuit (Fig. 3.12) is a set of conductors feeding, through an overcurrent device (from a distribution center, main, or submain) to which one or more energy-consuming devices are connected directly, i.e., without the interposition of additional overcurrent devices. The only overcurrent device associated with a branch is the one through which the branch is fed at the main, submain, or distribution center.

16. A tap or tap circuit (Fig. 3.12) is a circuit which serves a single energy-utilizing device and is connected directly to a branch without the interposition of a cutout.

17. A distributing or distribution center in an electrical-energy distribution system is the location at which a feeder, subfeeder, or main connects to a number of subordinate circuits which it serves. The switches and automatic overcurrent devices for the control and protection of the subcircuits are usually grouped at the distributing center. In interior-wiring parlance, a distributing center is often an arrangement or group of fittings by which two or more minor circuits are connected at a common location to another larger circuit. A panelboard with circuit breakers or a group of fuses is a distribution center (see Fig. 3.12).

18. A service is the conductors and equipment for delivering energy from the serving utility to the wiring system of the premises served. Only a utility supply creates a service; if the local supply system is from some on-site power production facility, then the NEC defines the supply as a “separately derived system.” Just as in the case of one building fed from another, the local distribution will originate at a “building disconnect” and not at service equipment.

A *service cable* is the service conductors made up in the form of cable.

Service conductors are the conductors from the service point or other source of power to the service disconnecting means.

A *service drop* is the overhead service conductors from the last pole or other aerial support to and including the splices, if any, connecting to the service-entrance conductors at the building or other structure.

A *service lateral* is that portion of underground service conductors between the street main, including any risers at a pole or other structure or from transformers, and the first point of connection to the service-entrance conductors in a terminal box meter or other enclosure with adequate space, inside or outside the building wall. Where there is no terminal box or meter or other enclosure, the point of connection shall be considered to be the point of entrance of the service conductors into the building.

Service-entrance conductors (overhead system) are the service conductors between the terminals of the service equipment and a point usually outside the building, clear of building walls, where joined by a tap or splice to the service drop.

Service-entrance conductors (underground system) are the service conductors between the terminals of the service equipment and the point of connection to the service lateral.

Where service equipment is located outside the building walls, there may be no service-entrance conductors or they may be entirely outside the building.

Service equipment is the necessary equipment, usually consisting of a circuit breaker or switch and fuses and their accessories, connectors to the load end of service conductors to a building or other structure or an otherwise-defined area that is intended to constitute the main control and means of cutoff of the supply.

ELECTRICAL SYSTEMS

19. Electrical systems. Several systems can be used for distributing electrical energy over the various arrangements of circuits previously described. They are as follows:

1. Direct-current two-wire (Fig. 3.14)
2. Direct-current three-wire (Fig. 3.15 or 3.16)
3. Single-phase two-wire (Fig. 3.14)
4. Single-phase three-wire (Fig. 3.15)
5. Two-phase four-wire (Fig. 3.17)
6. Two-phase three-wire (Fig. 3.18)
7. Two-phase five-wire (Fig. 3.19)
8. Three-phase three-wire (delta connection) (Fig. 3.20)
9. Three-phase four-wire (wye connection) (Fig. 3.21)
10. Three-phase four-wire (from a delta connection) (Fig. 3.26)

It is generally not good practice to supply lamps and motors from the same circuit (unless the motors are of small, fractional-horsepower size) for the following reasons.

1. When the motors are started, the large starting current causes a voltage drop on the feeder, which will make the lights grow dim or blink.
2. Overloads and short circuits are more common on motor circuits and should not be the cause of putting the lights out.
3. Lamps for satisfactory service must operate within closer voltage limits than motors, and therefore the circuits must be designed for less voltage drop than is allowable on motor circuits.
4. Frequently it is more economical to operate motors on a higher voltage than that of the lighting circuit.

In installations in which busway wiring is employed, it is often very satisfactory to have a common motor and lighting bus for the feeders and mains. If these systems are properly planned with generous allowance in the size of the buses, they will overcome the above criticisms of the common system and provide a very economical installation.

In the illustrations of the various systems, motors and lamps are shown connected to the same circuits simply to indicate the manner in which the different loads would be connected to that type of circuit. The reader is cautioned against forming the impression that they should

FIGURE 3.14 Two-wire system (direct-current or single-phase).

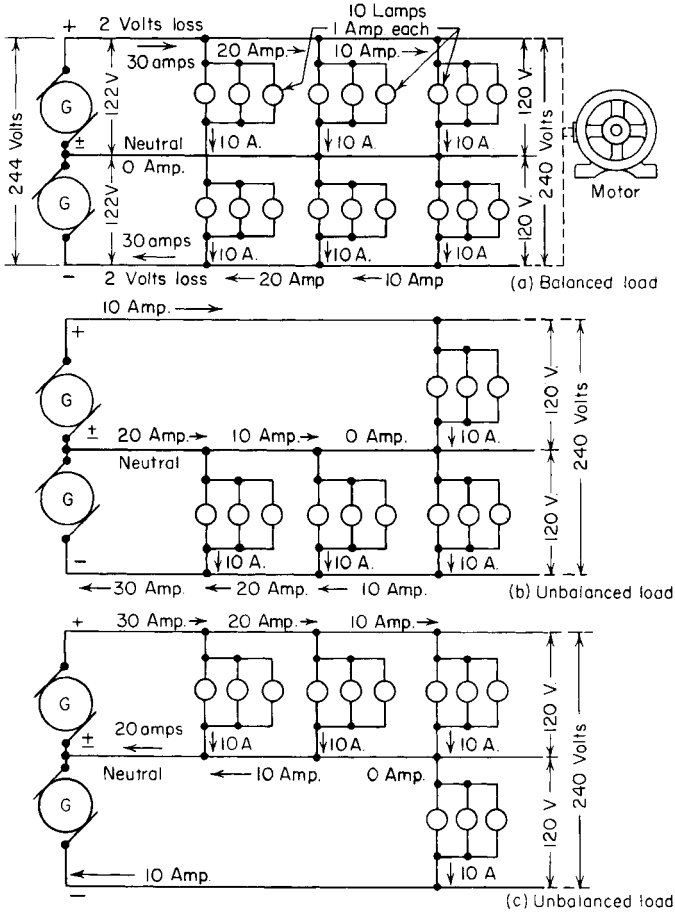

FIGURE 3.15 Three-wire system (direct-current or single-phase).

FIGURE 3.16 Three-wire convertible system (direct-current or single-phase): (a) connections when operating three-wire; (b) connections when operating two-wire. In the case of arc lamps and Cooper-Hewitt lamps, it is important that they all be connected on the side of the circuit which does not reverse polarity when operating two-wire.

FIGURE 3.17 Two-phase four-wire system.

FIGURE 3.18 Two-phase three-wire system.

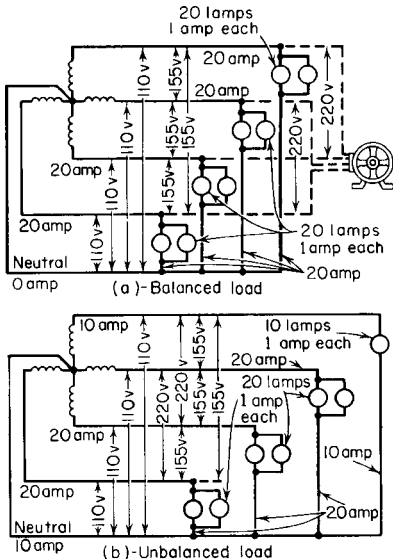

FIGURE 3.19 Two-phase five-wire system.

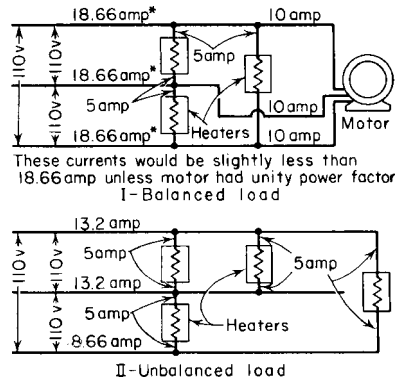

FIGURE 3.20 Three-phase three-wire system.

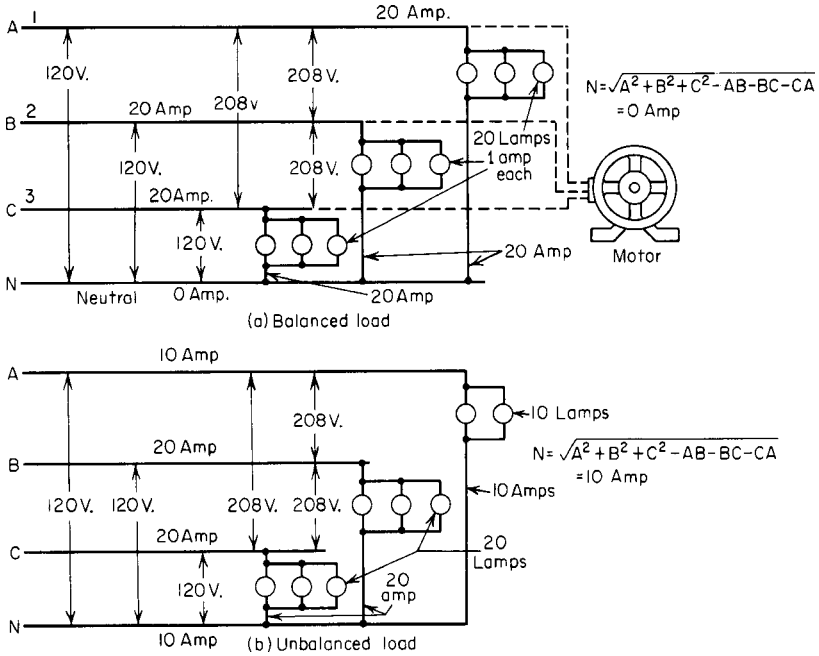

FIGURE 3.21 Three-phase four-wire wye system.

be connected to the same circuit except in special cases. In considering any one of the illustrations, if one were dealing with a motor circuit, the lamps should be eliminated from the figure, or if one were dealing with a lighting circuit, the motors should be eliminated.

20. The three-wire dc or single-phase ac system is used because it saves copper (see Figs. 3.15 and 3.22). Incandescent lamps for 110 to 120 V are more economical

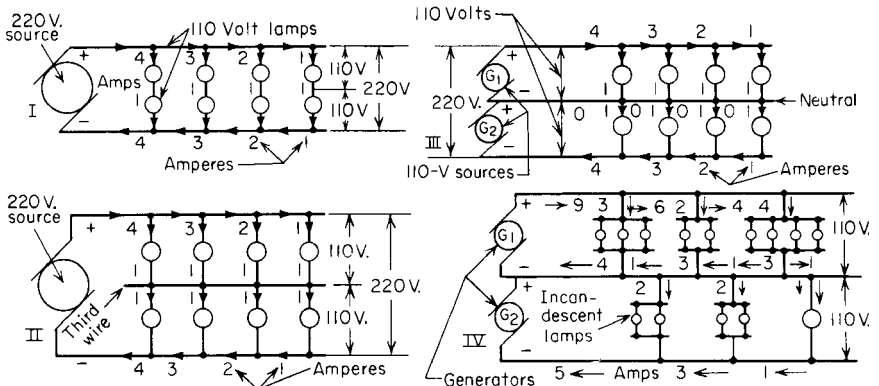

FIGURE 3.22 Elements of the three-wire system.

than those for higher or lower voltages. A system of any consequence operating at 110 V would require very large conductors to maintain the line drop within reasonable limits. With the three-wire system, a low voltage, say 110, is impressed on the receivers while one twice as great, say 220, is used for distribution. Since the weight of conductors for a given power loss varies inversely as the square of the voltage, it is evident that a considerable saving is possible with the three-wire system. In the United States the three-wire system is of most importance as applied to 110/220-V lighting systems.

21. The principle of the three-wire dc or single-phase ac system is illustrated in Fig. 3.22. Incandescent lamps for 110 V could be connected two in series across 220 V as shown at I, and although each lamp would operate at 110 V, the energy to the group would be transmitted at 220 V and the outside conductor could, with equal loss, be one-fourth the size that would be necessary if the energy were transmitted at 110 V. This arrangement (Fig. 3.22, I), although it would operate, is not commercially feasible because each lamp of each pair of lamps in series must be of the same size, and if one lamp goes out, its partner is also extinguished. These disadvantages might be partially corrected by running a third wire, as at Fig. 3.22, II. Then one lamp might be turned off and the others would burn, and a single lamp might be added to either side of the system between the third wire and either of the outside wires. But unless the total resistance of all the lamps connected to one side was practically equal to that of all the lamps connected to the other side, the voltage across one side would be higher than that across the other. On the high side the lamps would burn bright and on the low side dim. Obviously, it is not feasible in practice to arrange or balance the sides so that they will have the same resistance. Hence practicable three-wire systems must use some other method whereby the electricity will be transmitted at, say, 220 V and the pressure across the lamps will be, say, 110 V.

22. Commercial three-wire dc or single-phase ac systems (Fig. 3.22, III and IV) consist of two outer conductors, having (for lighting installations) a pressure of 220 V impressed across them and a neutral wire so connected to sources of voltage that the pressure between it and either of the outside wires is 110 V. In Fig. 3.22, III, generators are the sources of voltage. The neutral wire joins at the point where the generators are connected together. When the system is perfectly balanced, the neutral wire carries no current and the system is in effect a 220-V system. Perfect balance seldom obtains in practice. When the balance is not perfect, the neutral wire conveys a current equal to the difference between the current taken by one side and that taken by the other side. Note from Fig. 3.22, IV, that the current in different parts of the neutral wire may be different and that it is not necessarily in the same direction in all parts of the neutral wire. Each incandescent lamp in Fig. 3.22, IV, is assumed to take 1 A, and the small figures indicate the currents in different parts of the circuit.

23. Comparisons of systems. The relative weights of copper required for the different systems are given in Fig. 3.23. The weight of the copper required for the conductors of a two-wire dc circuit is assumed for convenience to be 100 percent. The values given in the column headed "Relative weights of copper in percentage based on voltage drop" are true for direct current, if we assume for all systems equal voltages on the lamps or other receivers, equal amounts of power transmitted, equal voltage drops, and balanced loads. For ac circuits the values are true for circuits in which the effect of inductance is negligible. For ac circuits in which the effect of inductance is not negligible, the amount

System	Connections	Voltage relations	Relative weights of copper in percentage based on voltage drop	Relative weights of copper in percentage based on carrying capacity

FIGURE 3.23 Copper economics of different electric systems.

of copper to produce the same voltage drop would be somewhat larger than the values shown in the table. The values given in the last column are based on the assumption that the carrying capacity of a wire is directly proportional to its cross-sectional area. Since the larger the wire, the smaller the allowable carrying capacity per unit of cross-sectional area, the percentages for systems of more than two wires would be somewhat less than shown. The actual saving in dollars gained by one of the systems that employs more than two wires will not be so great as that indicated in the table, owing to the fact that the total cost for a single large wire is less than for two small wires containing the same total amount of copper.

24. Application of alternating current and of direct current. AC systems have become almost universally standard in the United States for the transmission, distribution, and utilization of electrical energy. This is true because of the flexibility of ac systems in economically stepping up or down the voltage without the use of rotating equipment. Some vestiges of old Edison dc systems still exist both for city distribution and in old office buildings served by isolated plants.

When special characteristics of the load, such as electroplating or adjustable-speed motors, make the utilization of direct current either necessary or advisable, the alternating current can be converted to direct current by means of motor-generator sets, rectifiers, or, in special cases, converters.

25. Standard DC Voltages and Their Applications

Voltages		Application
Generators and energy-delivering apparatus	Motors and energy-utilization apparatus	
125 ^a	115	Used for multiple-circuit lighting. Usually obtained from a 115/230-V three-wire system
125 ^a -250 ^a 575-600 ^a	$\left\{ \begin{array}{l} 100^a-220 \\ 115^a-230^a \\ 550^a \end{array} \right\}$	Direct-current motors
600 ^a	Urban and interurban electric railways
1,200 1,500 } }	Interurban railways
3,000	Trunk-line railways

26. Standard AC Voltages and Their Applications

Voltage		Application
Generators and energy-delivering apparatus	Motors and energy-utilization apparatus	
120/208	110 110 single-phase motors 110–120 lamps and appliances	Single-phase, used for small motors, lighting, and appliances, usually obtained from a 120/240 V, three-wire, single-phase system or a three-phase, four-wire system
240 480 600	220 440 550	Usually three-phase three-wire, used for distribution for power for polyphase motors up to possibly 50 to 60 hp sizes. 220 V used occasionally for lamps and heaters. 265/460 V, four-wire, three-phase system is often used (265 V for fluorescent lamps and 460 V for supplying motors)
2,400	2,200	Single-phase for primary distribution in residential districts; three-phase, three-wire for polyphase motors greater than about 60 or 100 hp, feeders for large industrial plants
2,400/4,160	2,300/4,000	For three-phase four-wire distribution in moderately heavily loaded districts
6,900 11,500 13,800 18,000	6,600 11,000 13,200	Highest voltages for which generators or motors can, ordinarily, be effectively designed. Distribution systems for large cities; for power transmission over distances of a few miles. For high-voltage distribution feeders in industrial plants and large office buildings
23,000 34,500 46,000 69,000 115,000 138,000 230,000	The voltages higher than 13,200 are used for transmission only and not for generation or utilization.	For power transmission overhead and underground, for distances up to about 125 miles, selection being roughly on the basis of 1,000 V per mile of transmission distance
154,000 220,000 275,000	345,000 500,000 765,000	For long-distance power transmission over aerial lines

NOTE These voltages have been standardized by various standards making bodies, including the American National Standards Institute, the National Electrical Manufacturers Association, and the Institute of Electrical and Electronic Engineers.

27. Selection of a frequency. Two frequencies now are standard in the United States: 25 and 60 Hz. A frequency of 50 Hz has been used considerably in Europe and in some installations in the United States. All other things being equal, 25 Hz would seem at first sight preferable because there is less inductive effect with it than with a higher frequency. It therefore follows that the inherent voltage regulation of a 25-Hz system is better than that of a 60-Hz system and also that the 25-Hz system is a trifle more efficient. For transmission distances of less than a few miles neither of these factors is of much consequence one way or the other. Alternating current at 25 Hz is not particularly well adapted for electric lighting because a flickering due to the filament cooling down every half cycle while the current is at a low value is very noticeable and causes eyestrain. At 60 Hz the time of low current values is so short that no flickering is noticeable.

Many years ago 25 Hz was considered necessary for the satisfactory operation of rotary converters, so most dc electric traction systems have used a 25-Hz transmission system. All dc railroad electrifications have also used 25 Hz because of the higher power factor and better commutation of the 25-Hz series motors. Again, it is not economically feasible to build large slow-speed motors for main drives in steel mills and cement plants at 60 Hz, so these types of plants have often adopted 25 Hz. Transformers and most other apparatus, except the motors indicated, are cheaper for 60 Hz, and delivery time is shorter.

Since 60 Hz is best for most installations, it has become practically the standard frequency in the United States, and probably more than 95 percent of the equipment sold is for 60 Hz. Most of the 50-Hz installations have been or are being changed over to 60 Hz.

Higher frequencies than the standard 60-Hz distribution frequency are sometimes used for special applications, such as the operation of high-speed motors and fluorescent lamps (refer to Divs. 7 and 10). These higher application frequencies are obtained from the 60-Hz supply by means of conversion equipment.

28. Effect of increased voltage and decreased voltage on generators, lines, transformers, meters, lamps, and motors. Sometimes it is necessary or desirable to adopt, for some existing installation, a voltage either higher or lower than that which has been in use. The table below indicates the general effects of such a change. The voltage impressed on incandescent lamps should be between 110 and 120. In new installations it is well to adopt a high lamp voltage, say, about 120. The operating voltage of an old installation may be gradually increased sometimes as much as 10 V without adverse results (*Electrical World*).

Effect of Increased Voltage on Generators	Effect of Decreased Voltage on Generators
Increase in excitation. Will the exciter voltage be sufficient to produce the required excitation at full load or at partial load of low power factor?	Decrease in excitation. Is the resistance of the field rheostat sufficient to maintain the lower voltage at no load?
Will the fields overheat at the increased excitation required?	Decrease in core loss.
Increase in core loss. Will the iron overheat?	Increase in armature copper loss for the same kilovolt-ampere output.
Decrease in armature copper loss for same kilovolt-ampere output. Will this offset the additional field and core loss?	Will this be offset by the reduction in field and core losses?

Lines	Lines
Increase in transmission radius for the same kVA output.	Decrease in transmission radius for the same kVA output.
Transformers For the same kVA output, increase in core losses, decrease in copper losses, somewhat lower all-day efficiency.	Transformers For the same kVA output, decrease in core losses, increase in copper losses, somewhat higher all-day efficiency.
Meters Effect negligible.	Meters Effect negligible.
Lamps No effect after the new voltage lamps are installed.	Lamps No effect after the new voltage lamps are installed.
Motors Reduced slip. Increased torque. Increased efficiency. Decreased power factor of induction motors.	Motors Increased slip. Decreased torque. Decreased efficiency. Increased power factor of induction motors.

29. Common distribution systems (electrical systems design). Basically distribution systems are classified according to the voltage level used to carry the power either directly to the branch circuits or to load-center transformers or substations at which feeders to branch circuits originate. The following are the most common types of distribution systems based on voltage.

1. 120/240-V three-wire single-phase combination light and power distribution to lighting and appliance branch-circuit panelboards and to power panels (Fig. 3.24). This type of system is restricted to applications in which the total load is small and is primarily lighting. Stores, small schools, and other small commercial occupancies use this system. In most cases of small commercial buildings, the use of 208Y/120-V three-phase distribution offers greater economy because of the higher operating efficiency of three-phase circuits. In cases in which 120/240-V distribution is used as the basic distribution, the service to the premises is made at that voltage. Of course, 120/240-V distribution is frequently an effective and economical system for lighting-subfeeder distribution in electrical systems which use a higher-voltage basic distribution system with load-center step-down to utilization voltages for local and incidental lighting and receptacle circuits.

FIGURE 3.24 Single-phase three-wire distribution system.

2. 208Y/120-V three-phase four-wire distribution (Fig. 3.25a) is the most common type of system used in commercial buildings, in some institutional occupancies, and in some industrial shops with limited electrical loads. This system offers substantial economy over the 120/240-V system in the amount of copper conductor required to carry a given amount of power to a load. It is a combination light- and power-distribution system, providing 120 V phase-to-neutral for lighting and single-phase loads and 208 V phase-to-phase for single- or three-phase motor or other power loads. This distribution system is used as the basic distribution in occupancies in which the service to the building is

For three-phase power circuits and single-phase light and power branch circuit

(a) - Three-phase, 4 wire wye (or star) with grounded neutral rated 120/208 volts

For three-phase power circuits and lighting circuits using 227 volts ballasts.

120 volt lighting and receptacle loads are fed from this system through single-phase transformers rated 480/120-240volts or three phase transformers rated 480/120-208 volts

(b) - Three phase, 4-wire wye (or star) with grounded neutral rated 480Y/277 or 460Y/265, depending upon voltage spread under local conditions

For three-phase power circuits and single-phase light and power branch circuits

FIGURE 3.26 Three-phase delta distribution system.

FIGURE 3.25 Three-phase Y distribution systems.

of the same voltage. It is also the most common subdistribution system for lighting and receptacle circuits in occupancies using higher-voltage distribution to load centers.

3. 240-V three-phase three-wire distribution (Fig. 3.26 without the neutral connection) is a common system for power loads in commercial and industrial buildings. In such cases, service to the premises is made at 240 V, three-phase. Feeders carry the power to panelboards or wireways supplying branch circuits for motor loads. Lighting loads are usually handled by a separate single-phase service to the building. This system offers economic application when the power load is large compared with the lighting load. In some 240-V three-phase three-wire systems (Fig. 3.26 as drawn), a grounded center tap on one of the phases is used as a neutral to provide 120 V for lighting and receptacle circuits. Note that the voltage between the neutral and point "A" in the drawing is not 120 V as it is between the neutral and points "B" and "C". It is 208 V and 120 V loads must never be connected to the "A" phase. The NEC requires that the "A" phase conductor in this case (known in the trade as the high or stinger leg) be distinctively marked with orange color. Any switchboard or panelboard that contains this system must also be marked with the voltage to ground that applies to this phase leg.
4. 480-V three-phase three-wire distribution is commonly used in commercial and industrial buildings with substantial motor loads. Service to the building can be made at this

voltage, and the 480-V feeders carried to motor loads and to step down transformers for lighting and receptacle circuits. In many cases, 480-V feeders will be derived from load-center substations within the building and carried to motor loads or power panels. Although less common, 600-V three-phase three-wire distributions are still in common use in industrial occupancies for similar purposes.

5. 480Y/277-V three-phase four-wire distribution (Fig. 3.25*b*) has become an important system for use in commercial buildings and industrial buildings. In office and other commercial buildings, the 480-V three-phase four-wire feeders are carried to each floor, where 480 V, three-phase, is tapped to a power panel or to motors; general area fluorescent lighting using 277-V ballasts is connected between each phase leg and the neutral; and 208Y/120-V three-phase four-wire circuits are derived from step-down transformers for local lighting, appliance, and receptacle circuits. Application of this system offers an economic advantage over a 208Y/120-V system when less than about half of the load devices require 120- or 208-V power. When the 480Y system can be used, it will cost less than the 208Y/120-V system owing to copper savings through the use of smaller sizes of conductors and the lower cost of system elements because of lower current capacities. If the required amount of 120- or 280-V power is more than half of the total load in a building, the cost of the step-down transformers to supply these circuits will offset the savings in the 480-V circuiting. The 480Y system is more advantageous in high-rise or other large-area buildings than in small buildings.
6. 2400-V three-phase distribution is an industrial-type system used to feed heavy motor loads directly and motor and lighting loads through load-center substations and lighting transformers.
7. 4160/2400-V three-phase four-wire distribution with a grounded neutral is a more common industrial system than the above 2400-V, delta-connected system. This system is widely used to supply load-center substations in which the voltage is stepped down to 480 to feed motors and lighting transformers for 120/240- and/or 208Y/120-V circuits. It can also be used in distribution to substations stepping down the voltage directly to 208Y/120.
8. 4800-V three-phase distribution is a delta-connected industrial system for feeding 480-V substations supplying motors and lighting transformers.
9. 7200-V three-phase distribution is another industrial system used with substations for stepping down voltage to lower levels for power and lighting.
10. 13.2Y/7.2-kV (or 13.8-kV) three-phase four-wire distribution is a modern, widely used distribution system for large industrial plants. Power at this voltage is delivered to substations which step down the voltage to 480 for motor loads and which supply 480/120/240- or 480/208Y/120-V transformers for lighting. Or 480Y/277-V substations can be used to supply motor loads and 277-V fluorescent or mercury-vapor lighting for office and industrial areas. Lighting transformers are then used to supply 120-V circuits for lighting and convenience receptacles.

The voltage values given for these distribution systems are, of course, subject to the usual variation or spreads due to distance of transmission and distribution, local conditions of utility supply, and settings of transformer taps. In addition to the distribution voltages given, other systems may operate at 6.6, 8.3, 11, and 12 kV. Of the high-voltage (over 600 V) distribution systems, 4160 and 13,200 V are the most common and represent good design selection and economy of application for most cases. In many areas, delta-connected supplies have been changed to four-wire Y systems with consequent increase in power-handling capacity as a result of increased phase-to-phase voltage. The trend today is toward the use of the 13-kV systems instead of other high-voltage distribution systems for large

industrial plants. To a limited extent, high-voltage distribution finds application in large commercial buildings. The most recent trend in distribution in office and other multifloor commercial buildings is toward distribution at 480Y/277 V, three-phase four-wire, with grounded neutral.

CIRCUIT CALCULATIONS

30. Five factors should be considered in determining the size of wire for the distribution of electricity. A wire should be of such size that (a) the current will not heat it to a temperature that would ruin the insulation or cause a fire, (b) it will have sufficient mechanical strength so that it will not be broken under the ordinary strains to which it is reasonable to assume that it will be subjected, (c) it will not be so large as to exceed the limitations required for its economical installation, (d) it will carry the electricity to the point at which it will be used without an excessive drop or loss of voltage, (e) the cost of energy lost—the I^2R loss—due to the voltage overcoming the resistance will not be excessive (refer to Sec. 82). A conductor may satisfy any one of the five conditions and not satisfy the four others.

31. Safe current-carrying capacity should always be considered in designing circuits. When current passes through a conductor, some of the electrical energy is converted into heat energy, the amount of energy thus converted being equal to I^2R (see Div. 1). This heat energy raises the temperature of the conductor and its insulation and covering above that of the surrounding medium and is dissipated into the atmosphere through thermal conduction of the metal of the conductor, conductor insulation and covering, and surrounding materials (such as conduit, ducts, earth, etc.) and through convection of the surrounding air over these materials. It is not good practice to operate bare conductors at a temperature in excess of from 70 to 80°C, since trouble is apt to occur at joints and connections when they are operated at higher temperatures. A curve for determining current capacities of bare copper conductors is given in Sec. 15 of Div. 12. For covered and insulated cables the maximum allowable temperature of the conductor is limited by the maximum temperature that will not be harmful to the insulating and covering materials (refer to Div. 2 for maximum safe temperatures for different types of insulation). The allowable safe current-carrying capacity of an insulated conductor will therefore depend upon the type of conductor insulation and covering, the conditions of installation (whether in conduit, exposed to air, or buried in earth, and the number of conductors grouped in close proximity to each other), and the temperature of the surrounding atmosphere or earth (ambient temperature). A curve for determining the carrying capacity of weatherproof copper conductors when installed outside buildings is given in Sec. 16 of Div. 12. Curves for aluminum cable, steel-reinforced, are given in Sec. 26 of Div. 12, and a table for parkway cables buried directly in the ground is given in Sec. 27 of Div. 12. It would require more space than is available in this book to include the necessary tables for allowable carrying capacities of cables installed in underground raceway systems. Complete tables can be obtained from the various cable manufacturers or from the Insulated Cable Engineers Association (ICEA).

The maximum allowable safe current-carrying capacities of wires for interior wiring are specified by the National Electrical Code (see Tables 17 to 23 of Div. 12). The maximum current that a wire will have to carry should never exceed the allowable safe carrying capacity for the size of wire, type of insulation employed on the wire, and method of installation as given in these tables except in the case of motor circuits. Motors draw a current at the

instant of starting that is much greater than the normal full-load running current. Owing to the fact that this large starting current lasts for only a short time, the Code does not require that the carrying capacity of the wires for motor circuits be as great as the starting current. For branch circuits supplying continuous-duty motors the size of the wire must be sufficient to carry at least 125 percent of the full-load rated current of the motor. The wires of branch circuits supplying motors in classes of service having short-time, periodic or varying duty must have carrying capacities as large as the average load currents required by the motors. In the majority of cases, the average load currents required by motors of this class will not exceed the percentages of the full-load rated currents given in Table 12 of Div. 12. The wires between the slip rings of wound-rotor induction motors and the secondary controller must have a carrying capacity of at least 125 percent of the full-load secondary current of the motor. The wires between the secondary controller and the resistors must have a carrying capacity that is not less than the percentages of the full-load secondary currents given in Table 13 of Div. 12. The size of wire for motor feeders or mains must be sufficient to carry at least the maximum-demand running current of the motors supplied by the circuit. The method of computing the maximum-demand running current is given in Sec. 54.

The ampacities which are listed in Tables 18 to 23 of Div. 12 are based upon ambient air temperatures of 30°C except the high-temperature conductors in Tables 21 and 22 of Div. 12 are based on 40°C ambient air temperature. If the ambient air will have a temperature greater than this, the ampacities listed in the table should be multiplied by the proper correction factor as given in Tables 18, 19, 21, and 22 of Div. 12.

32. Mechanical strength of wires. Wires should be of sufficient size so that their mechanical strength will be great enough to withstand the strains of installation and of the service to which they will be subjected. For general overhead distribution mains, no wire of soft-drawn copper smaller than 6 AWG should be used. If medium- or hard-drawn copper is used, no wire smaller than 8 AWG should be employed. For overhead outside wiring on private premises, no wire smaller than 10 AWG should be used for spans up to 50 ft and no wire smaller than 8 AWG for longer spans. Service drops from an overhead distribution main to the service-entrance conductors must not be smaller than 10 AWG if of soft-drawn copper or smaller than 12 AWG if of medium- or hard-drawn copper. The service-entrance conductors to a building shall generally not be smaller than 8 AWG copper or 6 AWG aluminum or copper-clad aluminum:

1. For installations to supply only limited loads of a single branch circuit, such as small polyphase power, controlled water heaters, and the like, they shall not be smaller than the conductors of the branch circuit. The disconnecting means must be rated not less than 15 amperes.
2. For installations consisting of not more than two two-wire branch circuits, the service disconnecting means shall have a rating of not less than 30 amperes.
3. One-family residences must have not less than a 3-wire 100-ampere service.
4. For other installations the service disconnect must be no smaller than 60 amperes.

In the interior wiring of buildings no wire smaller than 14 AWG can be used except for the following special cases:

1. For fixture wiring, 16 AWG up to 100 ft and 18 AWG up to 50 ft for fixture wire can be used.
2. Flexible cord as small as 18 AWG can be used where supplied as part of a specific listed appliance or luminaire. In addition, flexible cord as small as 16 AWG can be used for extension cords, or as small as 18 AWG if listed for this purpose. These cords (18 AWG)

usually have fuses incorporated into their plugs. Also, tinsel cords or cords having equivalent characteristics of smaller size may be approved for use with specific appliances.

3. Smaller wire (down to 18 AWG) can be used for stationary motors, rated 1 hp or less, for the conductors between a motor and a separate terminal enclosure. The wire must meet the minimum ampacity requirements for motor circuit generally and the separate terminal enclosure must meet the requirements in NEC 430.245(B).
4. For elevator, dumbwaiter, and escalator wiring, except for conductors which form an integral part of control equipment, the minimum allowable size of conductors is as follows:
 - a. *Traveling cables.*
 - (1) For lighting circuits, 14 AWG copper, except that 20 AWG copper or larger conductors may be used in parallel provided the carrying capacity is equivalent to at least that of 14 AWG copper
 - (2) For other circuits, 20 AWG copper
 - b. *Other wiring.* 24 AWG copper. Smaller size listed conductors are permitted.
4. For industrial machinery wiring governed by NFPA 79, *Electrical Standard for Industrial Machinery*, the following exceptions are allowed:
 - a. Conductors to moving parts: copper conductors for control purposes to continuously moving parts may be 16 AWG if all such conductors are insulated for the maximum voltage of any conductor in the cable or tubing.
 - b. Conductors to electronic programmable control I/O; and static control: copper conductors to electronic and precision devices may be 22 AWG, except that if pulled into raceways they shall not be smaller than 24 AWG, except 30 AWG may be used in jacketed multiconductor cables.
5. For remote-control limited-power and signaling circuits, 18 and 16 AWG conductors may be used provided they are installed in a raceway or a listed and cable approved enclosure or in listed flexible cords (Class 1 circuits). The National Electrical Code gives detailed rules for these cases.

33. There are certain limitations in the size of wires that it is feasible to employ to satisfy construction and installation requirements. For convenience in installation, it is seldom advisable to use larger than trade size 3 (metric designator 78) conduit. When all the wires of a circuit are run in the same conduit, this limits the size of the conductors to 500,000 cmil (336 mm²), although a larger fill is possible for certain combinations of conductor insulation and raceway materials. It is seldom wise or convenient to install conductors of larger size than 1,000,000 cmil (673 mm²). A trade size 2½ (metric designator 63) conduit is about as large as can usually be installed between floors and ceilings. In such cases, therefore, the size of wire is limited to 300,000 cmil (201 mm²) if four wires are placed in the same conduit. For open wiring, wires larger than 1,000,000 cmil are cumbersome to handle.

34. Percentage line drop, or voltage loss, can be figured as either a percentage of the voltage required at the receiver or as a percentage of the voltage impressed by the generator or other energy source on the line. For instance, in Fig. 3.27, the voltage impressed on the receivers (lamps and motor) is 220. The line loss is 11 V; hence the pressure impressed on the line is 220 + 11 = 231 V. The voltage loss as a percentage of the voltage at the receiver is $11/220 = 0.05 = 5$ percent. The voltage loss as a percentage of the voltage impressed on the line is $11/231 = 0.048 = 4.8$ percent. In practical work the percentage loss or drop is usually taken as a percentage of the voltage required at the receivers, because this is the most convenient and direct method. In this book the term *percentage drop* refers to a percentage of the voltage required at the receivers unless otherwise noted.

FIGURE 3.27 Percentage line drop.

35. Allowable voltage drops. The conductors of an interior-wiring system should be of sufficient size so that the voltage drop from the point of service entrance to the equipment utilizing the energy, such as lamps or motors, is not excessive. If the voltage drop is too great, the operating conditions will not be satisfactory, owing to one or more of the following causes:

1. Shortened life of lamps caused by overvoltage under light-load conditions
2. Unsatisfactory illumination under maximum-load conditions
3. Unsatisfactory motor speed, torque, or temperature

No definite standards have been adopted for the maximum allowable voltage drop in most instances. There is a good reason for this. In most cases voltage drop is an inefficiency or inconvenience, but it does not rise to the level of a safety hazard. For example, a motor run at 10% voltage drop, but with appropriate running overload protection, will have a greatly reduced life span, but not create a shock, fire, or electrocution hazard. The National Electrical Code does note however, in a nonmandatory explanatory note, that if the voltage drop from the point of service entrance to the final outlet does not exceed 5%, there will be "reasonable efficiency of operation." The note also explains that not more than 3% voltage drop should occur in the feeder system ahead of the branch-circuit supply points, which leaves the other 2% for the branch circuit.

There are some instances, however, where voltage drop does directly bear on safety and the NEC contains rules accordingly. For example, if the conductors to a fire pump are not sized to prevent the voltage drop while starting (that is, while under locked-rotor conditions) from exceeding 15%, measured at the controller terminals, the control contactor for the motor may chatter and not reliably hold in, resulting in a failure to start with disastrous consequences.

Values of voltage drop that will be in accordance with good practice for different systems are given in Table 48 of Div. 12.

36. Allowance for growth in planning circuits. In installing the wiring for electric power and lighting installations, the demands that may be placed upon the system in the future should be carefully considered. It requires a relatively small additional expense, when installing a system, to put in wires somewhat larger than are required by the present lighting equipment. On the other hand, if the wires installed are of just sufficient size to accommodate the present load and it is necessary to increase the load at some future date, the cost of removing the old installation and installing a new one is considerable.

Standards of illumination have been continually increasing, and it is reasonable to assume from the trend of practice that the general level of illuminating intensities employed will be still further increased. Both employees and employers are appreciating more and more the benefits to be gained from high intensities of illumination. On the other hand, steady advances have been and continue to be made in the area of energy efficiency, driven by energy costs and recent environmental concerns. To a large degree these efforts have blunted the former steady increases in demand for electricity. Former editions of this book have run demand calculations on these pages based on the current code minimum requirements, along with a second set of calculations described as “future load” based on the maximum load that could be connected under conditions of continuous loading. In order to maintain continuity with prior editions, this edition will make the same calculations, but describe the results as “maximum allowable loads” instead.

It would certainly be good practice to limit the initial loading of branch lighting circuits to 50 percent of their maximum allowable load, but that much reserve capacity may be impossible to sell in today’s economic environment. In the end, it is the owner’s decision, because the NEC does not mandate design flexibility. Over 70 years ago the NEC stated in its opening section, and continues to say today, that “This Code contains provisions that are considered necessary for safety. Compliance therewith and proper maintenance results in an installation that is essentially free from hazard but not necessarily efficient, convenient, or adequate for good service or future expansion of electrical use.” Just as with voltage drop, the designer and owner have to make the difficult decisions around how much additional capacity beyond code minimums to incorporate into their facilities.

The layout and equipment in industrial and commercial buildings are continually being changed. These changes frequently involve increased load requirements. Therefore, no definite rules can be laid down for the proper allowance that should be made for growth, since conditions vary so widely for different installations. Each installation requires careful study with respect to probable future load requirements. The actual connected loads on the circuit should be increased by a sufficient amount so that the size of circuit will be ample to accommodate whatever loads it is estimated may be connected to the circuit in the future. For good general practice, here again it is recommended that the allowance for growth be at least 50 percent of the initial load, and here again the owner may well be unable to afford what that would entail.

37. Calculation of load in amperes on two-wire branch lighting and appliance circuits. The actual load in amperes on a two-wire branch lighting circuit is equal to the sum of the watt ratings of the individual loads connected to the circuit divided by the voltage of the circuit. Each heavy-duty lampholder outlet for lighting other than general illumination should be figured at 600 VA. Each plug receptacle outlet connected to the circuit should be figured at at least 180 VA per outlet. If the load to be connected to a plug outlet is known to be more than 180 VA, its load should be considered as the actual known wattage that it will supply.

For show-window lighting a load of not less than 200 VA for each linear foot of show window, measured horizontally along its base, may be allowed in lieu of the 180 VA per outlet. If fixed multioutlet assemblies are supplied by the circuit, each 5 ft (1.52 m) or fraction thereof of each separate and continuous length of the assembly should be considered as a load of 180 VA, except in locations in which a number of appliances are likely to be used simultaneously. In that case each 1 ft (305 mm) or fraction thereof should be considered as a load of 180 VA. In computing the load of lighting units that employ ballasts, transformers, or autotransformers, such as fluorescent-lighting units, the load must be based on the volt-ampere load or current of the complete unit and not simply the wattage of the lamp. For incandescent-lighting units the volt-ampere loads will be the same as the rated watts of the lamps. For branch lighting circuits it is sufficiently accurate to assume that the total

volt-ampere load is equal to the direct numerical summation of the individual volt-ampere loads. This is also true for the summation of lighting loads in terms of amperes.

The future load on branch lighting and appliance circuits in commercial and industrial installations is taken as 80 percent of the rating of the branch circuit because the lighting loads in these occupancies almost always operate for continuous periods (defined in the NEC as 3 hours or more. As covered in this division beginning with Sec. 89, most electrical devices cannot be safely operated above 80% of their ratings for continuous periods.

The standard sizes of lamps are given in Table 1 of Div. 12 and more complete data in Div. 10.

EXAMPLE A two-wire, 120-V, 20-A branch lighting circuit supplies five 200-W incandescent lamps. Determine the actual connected and probable future load.

SOLUTION Present connected load = $\frac{5 \times 200}{120} = 8.3 \text{ A}$

Maximum allowable load = $0.80 \times 20 = 16 \text{ A}$

EXAMPLE A two-wire, 120-V, 20-A branch lighting circuit supplies four 150-W and three 200-W incandescent lamps. Determine the actual connected and probable future load.

SOLUTION Present connected load = $\frac{(4 \times 150) + (3 \times 200)}{120} = 10 \text{ A}$

Maximum allowable load = $0.80 \times 20 = 16 \text{ A}$

38. Calculation of load in amperes on three-wire branch lighting and appliance circuits. The actual and future loads in amperes on either side of a three-wire branch lighting circuit can be computed in the same manner as for two-wire circuits in Sec. 37, the voltage between the neutral and either outside wire and the loads connected between the neutral and the one outside wire under consideration being used.

EXAMPLE A three-wire, 120/240-V, 15-A branch lighting circuit supplies the loads in the following diagram. Determine the actual connected and probable future loads.

SOLUTION Present connected load 1 to $N = \frac{4 \times 200}{120} = 6.7 \text{ A}$

Present connected load 2 to $N = \frac{5 \times 150}{120} = 6.3 \text{ A}$

Maximum allowable load 1 to $N = 0.80 \times 15 = 12 \text{ A}$

Maximum allowable load 2 to $N = 0.80 \times 15 = 12 \text{ A}$

39. Calculation of load in amperes on branch electric-range circuits. For electric ranges and other cooking appliances of $1\frac{3}{4}$ -kW rating or less, the load on the branch circuit is equal to the ratings of the appliances. For ranges or cooking appliances of

ratings greater than $1\frac{3}{4}$ kW the watt load on the branch can be computed in accordance with Table 2 of Div. 12.

For two-wire branches, the load in amperes is equal to the watt load, as determined above, divided by the voltage of the circuit. For three-wire branches, the load in amperes on each outside wire of the circuit is equal to the watt load, as determined above, divided by the voltage between outside wires. The load in amperes on the neutral wire can be taken as 70 percent of the load on an outside wire.

40. Calculation of lighting and appliance load on two-wire dc or single-phase distribution panels. The actual connected load is equal to the sum of the actual connected loads of all the branch circuits fed from the panel. Each appliance circuit in the panel should be figured at at least 10 A for a circuit rated 15 A and at least 15 A for a circuit rated 20 A. The future load on the panel is figured in the same manner as the actual load, the future loads of the branch circuits being used instead of the actual loads and each appliance or spare circuit being figured at at least 15 A. If an appliance circuit is of a type allowing more than 15 A, the circuit should be figured at its maximum allowable amperage as given in Div. 9.

EXAMPLE Determine the actual connected and maximum allowable future loads on a two-wire 120-V lighting panel supplying the following circuits:

Circuit number and rating	Present load, amp	Maximum allowable load, amp
1–15 amp lighting	10	12
2–15 amp lighting	7	12
3–20 amp lighting	9	16
4–15 amp appliance	10	15
5–15 amp lighting	8	12
6–20 amp appliance	15	20
7–15 amp spare		15
8–15 amp spare		15
	59	117

Present connected load on panel = 59 A

SOLUTION Maximum allowable load = 117 A

41. Calculation of lighting and appliance load on three-wire dc or single-phase distribution panels. The actual connected load on each side of the panel is computed in the same manner as for two-wire panels in Sec. 40, using the voltage between the neutral and one outside wire and making separate calculations for each line wire. If the circuits have been well laid out, there should not be much difference between the loads on the two sides of the panel.

EXAMPLE A three-wire 120/240-V lighting panel supplies the following circuits. All branch circuits are two-wire, 120 V. Determine the actual connected and the probable future loads. All circuits are rated 15 A.

Branch circuits between wire 1 and neutral			Branch circuits between wire 2 and neutral		
Circuit	Present load, amp	Maximum allowable load, amp	Circuit	Present load, amp	Maximum allowable load, amp
1	7	12	1	8	12
2	8	12	2	7	12
3	8	12	3	8	12
4	7	12	4 (receptacle)	10	15
5 (plug)	10	15	5 (spare)		15
6 (spare)		15	6 (spare)		15
	40	78		33	81

SOLUTION The present connected load would be taken as 40 A. The maximum allowable load would be taken as 81 A.

42. Calculation of lighting and appliance load on two-phase three-wire distribution panels. The loads for the two-line wires are computed as in Sec. 41. The actual and future loads on the common wire of the panel are taken as equal to 1.41 times the actual and future loads, respectively, of the more heavily loaded side of the panel.

EXAMPLE A three-wire two-phase 120-V lighting panel supplies the same circuits on the two sides of the panel as given in the example under the three-wire single-phase panel. Determine the actual connected and probable future loads.

SOLUTION The actual connected load on each outside wire of the panel would be taken as 40 A.

The maximum allowable load on each outside wire of the panel would be taken as 81 A.

The actual connected load on the neutral would be $1.41 \times 40 = 56.4$ A.

The future load on the neutral would be $1.41 \times 81 = 114.2$ A.

43. Calculation of lighting and appliance load on four-wire three-phase distribution panels. The actual connected load on any one bus except the neutral bus is computed as in Sec. 41. The load on each of the four buses usually is taken as being equal to that of the most heavily loaded outside bus. Note that this is only true for the neutral bus in the unusual case (true in this example) where the entire load is connected from one of the lines to the neutral. Line-to-line load, such as 240 V electric heating appliances, does not impact the loading on the neutral bus.

44. Fundamentals of load calculations on mains and feeders. In some cases the carrying capacity of feeders or mains need not be so great as the total ampere load of all the equipment supplied by the circuit. This is due to the fact that all the apparatus may not be operating at the same time or, if operating, may not all be taking full-load current from the line at the same time. A demand factor is employed to determine the maximum current that it is estimated the circuit will ever be required to carry. A demand factor is the ratio between the maximum current that the circuit will ever have to carry and the total load connected to the

circuit. The maximum-demand current of a circuit, therefore, is equal to the total connected load times the proper demand factor (see Table 4, Div. 12, for lighting demand factors; Table 6, Div. 12, for maximum-demand factors for motor circuits; Table 2, Div. 12, for demand factors for household electric ranges, wall-mounted ovens, counter-mounted cooking units, and other household cooking appliances; and Table 3, Div. 12, for demand factors for household electric clothes dryers). If four or more fastened in place appliances, other than electric ranges, clothes dryers, air-conditioning equipment, or space-heating equipment, are connected to the same feeder or main in a one-family, two-family, or multifamily dwelling, a demand factor of 75 percent may be applied to the nameplate-rating load. The computed load of a feeder supplying fixed electrical space-heating equipment shall be the total connected load on all branch circuits, except that if reduced loading of the conductors results from units operating on duty cycle, intermittently, or from all units not operating at one time, the authority enforcing the Code may grant permission for feeder conductors to be of a capacity less than 100 percent, provided the conductors are of sufficient capacity for this load.

45. Calculation of load on two-wire dc or single-phase ac lighting and appliance feeders or mains. The ampere or watt load is equal to the sum of the maximum-demand lighting and portable-appliance load, the maximum-demand fixed-appliance load, and the maximum-demand electric range load. The present or future maximum-demand lighting and portable-appliance load is equal to the sum of the actual or future lighting and portable-appliance loads fed from the circuit times the proper demand factor as determined from Table 4, Div. 12. The maximum-demand fixed-appliance load is figured in accordance with Sec. 44. The maximum-demand electric-range load is figured in accordance with Table 2, Div. 12.

In one-family dwellings, in individual apartments of multifamily dwellings having provisions for cooking by tenants, and in each hotel suite having cooking facilities or a serving pantry, a feeder load of not less than 1500 VA for each two-wire 20-A branch circuit (and there must be at least two such circuits) shall be included for small appliances (portable appliances supplied from receptacles of 15- to 20-A rating) in pantry and breakfast room, dining room, kitchen, and laundry. This is a National Electrical Code requirement.

EXAMPLE An apartment in a multifamily dwelling has a total floor area of 700 ft². It is not equipped with an electric range. Determine the maximum-demand present load for a two-wire 120-V feeder supplying the apartment.

SOLUTION

$$\text{General lighting load from Table 4, Div. 12} = 700 \times 3 = 2100 \text{ VA}$$

$$\text{Small-appliance load, two circuits, each at 1500 W} = 3000 \text{ VA}$$

$$\text{Total computed load} = 5100 \text{ VA}$$

Application of demand factor:

$$3000 \text{ VA at } 100\% = 3000 \text{ VA}$$

$$2100 \text{ VA at } 35\% = \frac{735 \text{ VA}}{\quad}$$

$$\text{Maximum-demand load} = 3735 \text{ VA}$$

$$\text{Maximum-demand current} = \frac{3735}{120} = 31.1 \text{ A}$$

46. Calculation of load on three-wire dc or single-phase ac lighting and appliance feeders or mains. The load on either outside wire is equal to the sum of the maximum-demand lighting and portable-appliance load, the maximum-demand fixed-appliance load, the maximum-demand electric-range load, and the maximum-demand household electric-clothes-dryer load fed from that wire. The present or future maximum-demand lighting and portable-appliance load is equal to the sum of the actual or future lighting and portable-appliance loads of all the panels fed from that wire times the proper demand factor as determined from Table 4, Div. 12. The maximum-demand fixed-appliance load is equal to the sum of all the fixed-appliance load fed from that wire times the proper demand factor as given in Sec. 44. The maximum-demand current for the electric-range load is equal to the maximum-demand watt range load as determined in accordance with Table 2, Div. 12, divided by the voltage between outside wires of the circuit. Refer to Sec. 45 for required allowance for small appliances in dwelling occupancies. The maximum-demand current for the household electric-clothes-dryer load is equal to the maximum-demand watt clothes-dryer load as determined in accordance with Table 3, Div. 12, divided by the voltage between outside wires of the circuit. In adding branch-circuit loads for space heating and air cooling in dwelling occupancies, the smaller of the two loads may be omitted from the total if it is unlikely that both of the loads will be served simultaneously. The air-cooling (air-conditioning) load is a motor load. Therefore for the calculation of load on circuits of this character refer to Secs. 53, 54, and 55.

The load on the neutral wire is the maximum unbalance of the load on the two sides of the system. The maximum unbalanced load is the sum of the maximum-demand lighting and portable-appliance load, the maximum-demand fixed-appliance load, and the maximum-demand electric-range load for the more heavily loaded side of the circuit. The maximum-demand household electric-range load is considered as 70 percent of the electric-range load on the outside conductors as determined from Table 2 of Div. 12. The same percentage allowance applies to clothes dryers. If the maximum unbalanced load for the neutral as determined from the above procedure is more than 200 A, then a further demand factor of 70 percent can be applied to that portion of the unbalanced load in excess of 200 A. There shall be no reduction of the neutral capacity for that portion of the load which consists of electric discharge lighting or other nonlinear loads (refer to Div. 1, Sec. 222, etc.).

The National Electrical Code allows the following optional method of calculation of load for a one-family residence or apartment unit. For each dwelling unit served by a 120/240-V or 208Y/120-V, three-wire, 100-A or larger service when the total load is supplied by one feeder or one set of service-entrance conductors, the following percentages may be used in lieu of the method of determining feeder (and service) loads detailed previously in this section.

Optional Calculation for Dwelling-Unit Load in Kilovolt-Amperes (220.82, NEC). Add the result in "A" to the result in "B" below:

- A.** 100 Percent of the first 10 kVA of all other load and 40 percent of the remainder of all other load described in this part:
1. 3 VA per ft² for general lighting and general purpose receptacles.
 2. 1500 VA for each two-wire 20-A small-appliance branch circuit and each laundry circuit.
 3. The nameplate ratings of all appliances fastened in place, permanently connected, or located to be on a specific circuit; plus the ratings of all ranges, wall-mounted ovens, and counter-mounted cooking units; plus the ratings of any clothes dryers not connected to a laundry circuit covered in (1); plus the nameplate ratings of any water heaters.

B. Largest of the following six selections:

1. 100 percent of the nameplate rating(s) of the air conditioning and cooling.
2. 100 percent of the nameplate rating(s) of the heat pump when the heat pump is used without any supplemental electric heating.
3. 100 percent of the nameplate rating(s) of the heat pump compressor and 65 percent of the supplemental electric heating for central electric space-heating systems. If the heat pump compressor is prevented from operating at the same time as the supplemental heat, it does not need to be added to the supplementary heat for the total central space load.
4. 65 percent of the nameplate rating(s) of electric space heating if less than four separately controlled units.
5. 40 percent of the nameplate rating(s) of electric space heating of four or more separately controlled units.
6. 100 percent of the nameplate rating(s) of electric thermal storage and other heating systems where the usual load is expected to be continuous at the full nameplate value. Systems qualifying under this selection shall not be figured under any other selection in this group.

The following example is given in the National Electrical Code for explanation of the optional method of load calculation for a one-family dwelling.

EXAMPLE The dwelling has a floor area of 1500 ft² exclusive of unfinished cellar not adaptable for future use, unfinished attic, and open porches. It has a 12-kW range, a 2.5-kW water heater, a 1.2-kW dishwasher, 9 kW of separately controlled electric space heating installed in five rooms, a 5-kW clothes dryer, and a 6-A, 230-V room air-conditioning unit.

SOLUTION The air conditioner is $6 \times 230 \div 1.38$ kVA. This is less than the connected load of 9 kVA of space heating; therefore the air-conditioner load need not be included in the service calculation.

1500 ft ² at 3 VA	4.5 kVA
Two 20-A appliance outlet circuits at 1500 VA each	3.0 kVA
Laundry circuit	1.5 kVA
Range (at nameplate rating)	12.0 kVA
Water heater	2.5 kVA
Dishwasher	1.2 kVA
Clothes dryer	5.0 kVA
	29.7 kVA

$$\text{First 10 kVA at 100\%} = 10.00 \text{ kVA}$$

$$\text{Remainder at 40\% (19.7 kVA} \times 0.4) = 7.88 \text{ kVA}$$

$$\text{Total general load under part "A" above} = 17,880 \text{ VA}$$

$$9 \text{ kVA of heat at 40\% (9000 VA} \times 0.4) = 3,600 \text{ VA (Part "B")}$$

$$\text{Calculated load for service size} = 21,480 \text{ VA (Parts A+B)}$$

$$21,480 \text{ VA} \div 240 \text{ V} = 89.5 \text{ A}$$

Therefore this dwelling may be served by a 100-A service.

The neutral load is calculated under the general rules instead of this optional procedure. This load is based on the line-to-neutral loading represented in the load profile, as follows:

1500 ft ² at 3 VA	4.5 kVA
Two 20-A appliance outlet circuits at 1500 VA each	3.0 kVA
Laundry circuit	1.5 kVA
Subtotal	9.0 kVA
3 kVA at 100% (Table 5, Div. 12)	3.0 kVA
9 kVA – 3 kVA = 6 kVA at 35% (Table 5, Div. 12)	2.1 kVA
Subtotal	5.1 kVA
Range (8 kVA from Table 2, Div. 12 at 70% per Sec. 46)	5.6 kVA
Clothes dryer (5 kVA at 70% per Sec. 46)	3.5 kVA
Dishwasher	1.2 kVA
	5.0 kVA
Total	15.4 kVA

The minimum size for the neutral of this service is $15,400 \text{ VA} \div 240 \text{ V} = 64.2 \text{ A}$

47. Calculation of load on four-wire two-phase lighting and appliance feeders or mains. The ampere loads on either phase can be computed as in Sec. 45, each phase being considered a separate single-phase circuit.

48. Calculation of load on three-wire two-phase lighting and appliance feeders or mains. For the two-line wires proceed as in Sec. 46.

The load on the neutral wire will be 1.41 times the load for the neutral as determined in accordance with the procedure of Sec. 46. If the load on the neutral as determined in this manner is more than 200 A, no further demand factor can be applied to that portion of the load for this type of system.

EXAMPLE Determine the present and future loads for a three-wire two-phase feeder in an industrial building of 9000 ft² supplying the following loads:

Panels connected between wire 1 and common wire			Panels connected between wire 2 and common wire		
Panel	Present load, amp	Max. allowable	Panel	Present load, amp	Max. allowable
A	50.8	65.2	A	47.8	61.3
B	43.7	55.6	B	52.7	67.9
C	41.4	54.7	C	36.8	45.9
	135.9	175.5		137.3	175.1

SOLUTION From Table 4, Div. 12, the demand factor is 1.0.

Present load on wire 1 = $135.9 \times 1.0 = 135.9 \text{ A}$.

Maximum allowable load on wire 1 = $175.5 \times 1.0 = 175.5 \text{ A}$.

Present load on wire 2 = $137.3 \times 1.0 = 137.3 \text{ A}$.

Maximum allowable load on wire 2 = $175.1 \times 1.0 = 175.1 \text{ A}$.

Present load on common wire = $137.3 \times 1.41 = 193.6 \text{ A}$.

Maximum allowable load on common wire $175.5 \times 1.41 = 248 \text{ A}$.

49. Calculation of load on five-wire two-phase lighting and appliance feeders or mains. For the four line wires proceed as for the line wires in Sec. 46.

The following example shows how to compute the maximum demand for the four-line conductors and the common neutral of a typical five-wire two-phase system:

EXAMPLE The actual connected loads on the four outside wires of a five-wire two-phase lighting feeder are 100.5, 97.8, 95.4, and 100.0 A. The feeder is supplying the load in a factory building. Determine the present load for the neutral wire.

SOLUTION From Table 4, Div. 12, the demand factor is 1.0. The load on the neutral = $(100.5 \times 1.0)1.41 = 142$ A.

50. Calculation of load on four-wire three-phase lighting and appliance feeders or mains. The ampere load on any outside wire is computed as in Sec. 46, except for the calculation of the maximum-demand current for the electric-range load. The maximum-demand current for the range load should be determined from the following formula:

$$\text{Maximum-demand range current} = \frac{\begin{array}{l} \text{watt load as determined from Table 2,} \\ \text{Div. 12, for twice the number of range} \\ \text{connected between any two outside wires} \end{array}}{2 \times \text{voltage between an outside wire and neutral}} \quad (1)$$

For the ampere load of the neutral wire, proceed as for the neutral in Sec. 46.

EXAMPLE Thirty ranges rated at 12 kW each are supplied by a three-phase four-wire 120/208-V feeder, 10 ranges on each phase. Determine the maximum-demand current for each outside wire.

SOLUTION As there are 20 ranges connected to each ungrounded conductor, the load should be calculated on the basis of 20 ranges (or in case of unbalance, twice the maximum number between any two-phase wires), since diversity applies only to the number of ranges connected to adjacent phases and not to the total.

The current in any one conductor will reflect the contribution of load from each of the adjacent phase connections. Since the 20 connected ranges have a table demand of 35 kVA, each adjacent phase is contributing 17.5 kVA of load to the conductor. When adjacent phases contribute load, the combination is never the sum of each, because the phase connections reach their load maximums at different points in time. Instead, for equal loading, it is the load from one-phase connection (in this case 17.5 kVA) multiplied by $\sqrt{3}$. To determine current, divide VA by line-to-line voltage. In the case of three-phase four-wire wye-connected systems, the line-to-line voltage is the line-to-neutral voltage multiplied by $\sqrt{3}$. Therefore, the line current is simply one-half the total watt load of two adjacent phases divided by the line-to-neutral voltage, because the $\sqrt{3}$ terms in both numerator and denominator cancel. Therefore, the current in the feeder conductor would be

$$17,500 \div 120 = 146 \text{ A}$$

51. Determining size of distribution panel buses. The required ampere capacity of the buses in distribution panels can be calculated in the same manner as given in the preceding sections for the calculation of the ampere loads on feeders and mains.

52. Minimum allowable load to use for any lighting feeder or main. The National Electrical Code specifies definite rules for computing the minimum loads for a given area. Feeders or mains must be of sufficient size to carry safely at least the amperes required by these rules regardless of the actual connected load. The areas employed in applying the rules should be gross floor areas as determined from the outside dimensions of the building and the number of floors. Floor areas of open porches, garages in connection with dwelling occupancies, and unfinished and unused spaces in dwellings, unless adaptable for future use, need not be included.

The minimum allowable watt load for the feeder or main supplying power to any area for lighting and appliances must be equal to the sum of the minimum allowable general-lighting load, the portable-appliance load, the fixed-appliance load (other than ranges), fixed electrical space-heating equipment load, and the electric-range load. The minimum allowable general-lighting load is equal to the area times the minimum allowable watts per square foot for that type of area times the proper demand factor. The minimum allowable watts per square foot and the allowable demand factors for different types of areas are given in Table 5 of Div. 12. The portable-appliance load requirements are given in Sec. 5 of Div. 12. If in normal operation the load on the installation will continue for 3 hours or more, as in store lighting, the minimum allowable load, as determined above, must be increased by 25 percent. The fixed-appliance load is equal to the summation of the watt rating of the actual fixed appliances installed in the area if the number of such appliances is four or less. For electric ranges, and other cooking appliances of 1³/₄-kW rating or less, a load equal to the summation of the watt ratings of the ranges or appliances installed must be included. For electric ranges and other cooking appliances rated more than 1³/₄ kW, the minimum allowable load can be computed for Table 2 of Div. 12. If a number of ranges are supplied by a three-phase four-wire feeder, the minimum allowable watt load should be computed from the following formula:

Note that but for two differences this result is the same as in Sec. 50. First, there has been no division at the end by voltage because we are still determining the load (volt-amperes) and not line current. Assuming three equally-loaded phases, the Sec. 50 result is also, as shown above, multiplied by 3 in order to carry the total system load and not the current on any one of the three-phase conductors.

$$\text{Minimum allowable range watt load} = 3 \times \frac{\text{watt load as determined from Table 2, of Div. 12, for twice the number of ranges connected between any two outside wires}}{2} \quad (2)$$

The minimum allowable load for motor circuits is identical with the values obtained from the instructions of Secs. 53 and 54.

The minimum allowable load for circuits supplying both motors and other loads is equal to the motor load plus the minimum allowable load of other types. After the minimum allowable voltampere load has been determined, the corresponding ampere load can be determined from the following formulas and instructions, depending upon the type of electric system employed:

$$I = \frac{\text{minimum allowable voltamperes}}{KE} \quad (3)$$

where $K = 1$ for two-wire dc or two-wire single-phase ac
 $= 1.73$ for three-wire three-phase ac
 $= 2$ for three-wire dc, three-wire single-phase ac, three-wire two-phase ac, or four-wire two-phase ac

- = 3 for four-wire three-phase wye-connected ac
- = 4 for five-wire two-phase ac
- E = voltage between outside wire and neutral if the system has a neutral; otherwise the voltage between any two line wires
- I = current in any line wire except the neutral

For neutral for three-wire dc, three-wire single-phase ac, or four-wire three-phase, follow instructions given in Sec. 46.

For neutral for three-wire or five-wire two-phase, follow instructions given in Secs. 48 and 49.

EXAMPLE Determine the minimum allowable loading of a feeder supplying a multifamily dwelling having an area of 30,800 ft² with 44 apartments. There is no electric-range load and laundry facilities are owner provided.

SOLUTION From Sec. 5, Div. 12, 3.0 VA must be allowed for each square foot plus 3000 VA for appliances for each apartment. The demand factor from Table 5A of Div. 12 is 1.0 for the first 3000 VA, 0.35 for the next 117,000 VA, and 0.25 for all load in excess of 120,000 VA.

$$\text{Lighting load} = 3 \times 30,800 = 92,400$$

$$\text{Appliance load} = 44 \times 3000 = 132,000$$

$$\text{Total load based on area} = 224,400 \text{ VA}$$

Minimum allowable voltampere load

$$\begin{aligned} &= 3000 + (117,000 \times 0.35) + (224,400 - 120,000)0.25 \\ &= 70,050 \text{ VA} \end{aligned}$$

For a two-wire 120-V single-phase or dc system:

$$I = \frac{70,050}{120} = 584 \text{ A}$$

For a three-wire 120/240-V single-phase or dc system:

$$I(\text{outside wires}) = \frac{70,050}{2 \times 120} = 292 \text{ A}$$

$$I(\text{neutral}) = 200 + (92 \times 0.70) = 264.4 \text{ A}$$

For a four-wire 115-V two-phase system:

$$I = \frac{70,050}{2 \times 115} = 304.6 \text{ A}$$

For a three-wire 115-V two-phase system:

$$I(\text{outside wires}) = \frac{70,050}{2 \times 115} = 304.6 \text{ A}$$

$$1.41 \times 304.6 = 429.5 \text{ A}$$

$$(\text{common wire}) = 429.5 \text{ A}$$

For a five-wire 115/230-V two-phase system:

$$I(\text{outside wire}) = \frac{70,050}{4 \times 115} = 152.3 \text{ A}$$

$$I(\text{neutral}) = 1.41 \times 152.3 = 214.7 \text{ A}$$

For a four-wire 208Y/120-V three-phase system:

$$I(\text{outside wires}) = \frac{70,050}{3 \times 120} = 194.6 \text{ A}$$

$$I(\text{neutral}) = I(\text{outside wire}) = 121 \text{ A}$$

EXAMPLE Determine the minimum allowable loading for a three-wire 120/240-V feeder supplying an apartment house having a total floor area of 32,000 ft² with 40 apartments. One-half of the apartments are equipped with electric ranges of 10 kW each and laundry facilities are owner provided.

SOLUTION From Sec. 5, Div. 12, 3 VA must be allowed for each square foot plus 3000 VA for appliances for each apartment. The demand factor for the lighting and appliance load from Table 5A of Div. 12 is 1.0 for the first 3000 VA, 0.35 for the next 117,000 VA, and 0.25 for all load in excess of 120,000 VA. From Table 2 of Div. 12, the maximum demand for the range load is 35 kW.

Lighting load = $3 \times 32,000$	= 96,000
Appliance load = 40×3000	= 120,000
Total lighting and appliance load	= <u>216,000 VA</u>
Minimum allowable lighting and appliance load 3000	
+ $(117,000 \times 0.35) + (216,000 - 120,000)0.25$	= 67,950 VA
Range load	= <u>35,000 VA</u>
Total minimum allowable voltampere load	= 102,950 VA

$$I(\text{outside wires}) = \frac{102,950}{2 \times 120} = 429 \text{ A}$$

Neutral feeder:

Lighting and small-appliance load = 67,950 VA
Range load, 35,000 W at 70% = <u>24,500 VA</u>
Computed load (neutral) = 92,450 VA
$92,450 \div 240 = 385 \text{ A}$

Further demand factor:

200 A at 100% = 200 A
185 A at 70% = <u>130 A</u>
Maximum-demand neutral wire = 330 A

EXAMPLE Determine the minimum allowable general-lighting load for a feeder supplying an office building having an area of 100,000 ft².

SOLUTION From Table 4, Div. 12, $3\frac{1}{2}$ VA plus 1 VA for receptacle loads must be allowed per square foot. From Table 5A, Div. 12, the demand factor is 1.0.

Voltampere load based on area = $100,000 \times 4.5 = 450,000$ VA
 For a four-wire 120/208-V three-phase system:

$$I(\text{outside wires}) = \frac{450,000}{3 \times 120} = 1250 \text{ A}$$

$$I = 200 + (1250 - 200)0.70 \\ = 935 \text{ A}$$

53. Calculation of load on motor branch circuits. For continuous-duty motors the load on the branch circuit feeding a single motor is taken as 125 percent of the full-load rated current of the motor. The load on a branch circuit supplying a motor in a class of service having short-time duty depends upon the character of the loading. In the majority of cases the load need not be greater than the percentages of the full-load rated currents given in Table 12 of Div. 12. The average full-load rated currents of the different types and sizes of motors are given in Tables 7 to 10 of Div. 12.

The load on conductors connecting the secondary of a wound-rotor, polyphase induction motor to its controller is taken as 125 percent of the full-load secondary current of the motor for continuous-duty motors and not less than the percentages given in Table 12 of Div. 12 of the full-load secondary current for short-time-duty motors. The loads on the conductors connecting the controller with the secondary resistors must be taken at not less than the proper percentage, as given in Table 13 of Div. 12, of the full-load secondary current. The value of the full-load secondary current, if not marked on the nameplate of the motor, should be obtained from the manufacturer of the motor, since its value will depend upon the design of the motor. For preliminary studies the secondary current may be taken to be equal to the motor full-load line current for values of full-load current up to about 20 A. For larger motors the secondary current is usually less than the full-load line current. For a motor with a full-load line current of about 50 to 70 A, the secondary current is about two-thirds of that value; for a full-load line current of about 80 to 120 A, the secondary current is about one-half of that value; for a full-load line current of about 150 to 250 A, the secondary current is about one-third the full-load line value.

It is important to recognize that most motor circuits divide the responsibility for protecting motor-circuit conductors against failure. If the motor is overloaded for a sustained period, protective devices must take the motor off the line before the conductors, the motor windings, or both fail to the point of creating a fire hazard. To this end, the NEC requires running overload protection, either built into the drive mechanism, or in thermal protective devices within the motor, or in separate overload relays. Running overload protection is usually set at 125 percent of the rated motor full-load current. Conductors and motor windings can carry overloads for some time before failing in this way, and for this reason properly arranged running overload protection does not open the circuit unless the overload is sustained for a period running from tens of seconds to many minutes, depending on the degree of overload. In fact motors under some duty cycles, such as elevator motors (intermittent duty) that could only operate continuously in a building of infinite height, do not even require running overload protection. Because overload protection will operate correctly at any point in the motor circuit, it need not be installed at the point where the circuit originates.

On the other hand, a short circuit or a ground fault in a motor circuit must be cleared as close to instantaneously as possible, certainly within a few cycles and preferably within a

fraction of a cycle. Most overload protective devices will not respond in this way. Further, since such a failure could occur at any point on a motor circuit, the protective device must normally be installed where the circuit originates, although there are some limited allowances for taps. Motor circuits use fuses or circuit breakers, or other devices based on similar principles of operation, to achieve this protection, but they are not sized to the conductor in the same way as on other circuits. For all these reasons the NEC very carefully avoids describing these protective devices as “overcurrent protection.” Overcurrent protection is protection against all forms of conductor and component overheating, whether by sustained overload or by short circuits and ground faults, and these devices are not that. They are, by NEC description and point of fact, “short-circuit and ground-fault protective devices.”

54. Calculation of load on motor feeders and mains. Two values of load should be computed for motor feeders or mains: one the maximum-demand starting current and the other the maximum-demand running current. The maximum-demand running current can be used in determining the size of wire required to carry the current safely. Although this meets the requirements of the NEC, many authorities consider it better practice to use the maximum-demand starting current in determining the size of wire according to carrying capacity. This builds in some leeway to accommodate sustained overloads on several motors simultaneously. The maximum-demand running current is used for computing the voltage drop of the circuit. The maximum-demand starting current is effectively employed in determining the proper size of short-circuit and ground-fault protective devices for the circuit, because the short-circuit and ground-fault protective device must be able to hold in when the largest motor is trying to start, which is a locked-rotor condition until rotation begins. Values of the average starting currents of motors are given in Tables 42 and 43 of Div. 12.

The National Electrical Manufacturers Association (NEMA) adopted in 1940 a standard of identifying code letters that must be marked by manufacturers on motor nameplates to indicate the motor kilovolt-ampere input with locked rotor. These code letters with their classification are given in Table 42 of Div. 12. In determining the starting current to employ for circuit calculations, use values from Table 43 of Div. 12.

In many installations in which the number of motors exceeds five, all the motors will not be running at full load at the same time. It is general practice, therefore, on such feeders or mains to use a maximum-demand factor so that the estimated maximum-demand current is less than the sum of the full-load rated currents of all the motors fed from the circuit. Values of maximum-demand factors that have been found satisfactory for ordinary installation are given in Table 6 of Div. 12. It should be remembered, in applying these demand factors, that they are average values satisfactory for ordinary installations. Before they are used, a careful study of the operating conditions of the plant should be made to determine whether the conditions of instantaneous loading of the motors will come within the average conditions or whether there are special requirements that will submit the feeders to a greater loading than will be taken care of by these factors.

The NEC provision that allows the application of demand factors operates by “special permission,” which is the written permission from the authority enforcing the code. Some authorities recommend that no demand factor be used in determining the size of circuit to install so that the additional current capacity, thus allowed in the circuit, will give some spare capacity for growth. On the other hand, one of the major and repeated areas of discussion by the code making panel responsible for load calculations involves the repeated and well documented oversizing of industrial feeders in this area. Electric utilities know how much power they provide to their customers, and it too often does not compare well with load calculations run without appropriate demand factors. The express allowance for the judicious use of demand factors in the NEC for these loads is something that well

deserves careful consideration. The factors given in Table 6 of Div. 12 are an excellent place to start. Refer to Sec. 36 for further discussion on allowance for growth.

The following formulas give the methods of computing the maximum-demand starting and running currents for motor feeders and mains:

$$\left(\begin{array}{c} \text{Starting} \\ \text{current} \end{array} \right) = \left(\begin{array}{c} \text{starting current} \\ \text{of largest motor} \end{array} \right) + \left(\begin{array}{c} \text{demand} \\ \text{factor} \end{array} \right) \left(\begin{array}{c} \text{sum of full-load rated currents} \\ \text{of all the motors except largest} \end{array} \right) \quad (4)$$

$$\left(\begin{array}{c} \text{Running} \\ \text{current} \end{array} \right) = \left(\begin{array}{c} 1.25 \times \text{full-load current} \\ \text{of largest motor} \end{array} \right) + \left(\begin{array}{c} \text{demand} \\ \text{factor} \end{array} \right) \left(\begin{array}{c} \text{sum of full-load rated currents} \\ \text{of all the motors except largest} \end{array} \right) \quad (5)$$

If a number of motors of equal horsepower rating are the largest in the group supplied by the circuit, one of these motors should be taken as the largest motor for the calculation of the load on the circuit.

If two or more motors must be started at the same time, it will generally be necessary to increase the load on the circuit above the values obtained from Eqs. (4) and (5).

EXAMPLE Determine the load on a 230-V feeder supplying two 10-hp and two 15-hp motors. All the motors are the three-phase, squirrel-cage induction, normal-starting-current type started at reduced voltage.

SOLUTION From Table 10 of Div. 12, the full-load current of a 10-hp 230-V squirrel-cage induction three-phase motor is 28 A and the full-load current of a 15-hp motor is 42 A. The starting current of a 15-hp squirrel-cage induction motor started at reduced voltage from Table 43 of Div. 12 is 250 percent of the full-load current with an inverse time branch circuit breaker. There has been no credit given for reduced-voltage starting effective with the 1996 NEC.

$$\begin{aligned} \text{Maximum-demand starting current} &= (2.50 \times 42) + 42 + (2 \times 28) \\ &= 84 + 42 + 56 \\ &= 203 \text{ A} \end{aligned}$$

$$\begin{aligned} \text{Maximum-demand running current} &= (1.25 \times 42) + 42 + (2 \times 28) \\ &= 150.5 \text{ A} \end{aligned}$$

EXAMPLE Determine the load on a 480-V feeder supplying three 5-hp motors, two 10-hp motors, and three 15-hp motors. All the motors are of the squirrel-cage type, three-phase.

SOLUTION From Table 10 of Div. 12 the full-load current of a 5-hp three-phase squirrel-cage motor is 7.6 A; of a 10-hp motor, 14 A; and of a 15-hp motor, 21 A. From Table 6 of Div. 12 the maximum-demand factor is 0.75. Permission has been obtained for the use of this factor.

$$\begin{aligned} \text{Maximum-demand starting current} &= (2.5 \times 21) + 0.75[(3 \times 7.6) + (2 \times 14) + (2 \times 21)] \\ &= 52.5 + 0.75(22.8 + 28 + 42) \\ &= 122 \text{ A} \end{aligned}$$

$$\begin{aligned} \text{Maximum-demand running current} &= (1.25 \times 21) + 0.75[(3 \times 7.6) + (2 \times 14) + (2 + 21)] \\ &= 26.25 + 0.75(22.8 + 28 + 42) \\ &= 96 \text{ A} \end{aligned}$$

EXAMPLE Determine the load on a 240-V dc feeder supplying three 3-hp motors, five 5-hp motors, and one 20-hp motor.

SOLUTION From Table 7 of Div. 12 the full-load current of a 3-hp 240-V dc motor is 12.2 A; of a 5-hp motor, 20 A; of a 20-hp motor, 72 A. The starting current of a dc motor from Table 43 of Div. 12 is 150 percent of its full-load current. From Table 6 of Div. 12 the maximum demand factor for nine motors is 0.75. Permission has been obtained for the use of this factor.

$$\begin{aligned} \text{Maximum-demand starting current} &= (1.50 \times 72) + 0.75[(3 \times 12.2) + (5 \times 20)] \\ &= 108 + 0.75(36.4 + 100) \\ &= 108 + 102 = 210 \text{ A} \end{aligned}$$

$$\begin{aligned} \text{Maximum-demand running current} &= (1.25 \times 72) + 0.75[(3 \times 12.2) + (5 \times 20)] \\ &= 90 + 0.75(36.4 + 100) \\ &= 90 + (0.75 \times 136.4) \\ &= 90 + 102 = 192 \text{ A} \end{aligned}$$

55. Load on combined motor and lighting circuits. If both motors and lamps are fed from the same circuit, proceed as follows in determining the total load of the circuit:

1. Determine the lighting and appliance load.
2. Determine the motor load.
3. Total load is equal to the sum of the lighting and motor loads.

56. General considerations in computing voltage drop. As covered in Sec. 35, voltage drop in a circuit is usually a design issue and not a matter of code enforcement. The calculations that follow are conservative, and biased toward aggressive designs that will minimize voltage drop. The reader is cautioned to consider the design objectives of the owner, which may not be as aggressive, and modify the parameters in these calculations accordingly. For example use of the maximum allowable load for lighting circuits is probably excessive in many instances. When calculations are made for the voltage drop in a circuit, the analysis that follows uses the maximum allowable current (Sec. 36) for lighting and appliance circuits, the maximum running current with allowance for growth (Secs. 36 and 54) for motor feeders or mains, and the full-load current for motor branch circuits.

The resistance employed in the calculations should be the value corresponding to the operating temperature of the conductors. The following rules with respect to the values of

operating temperature to employ in voltage-drop calculations represent good practice for wires that are loaded between 50 and 100 percent of their allowable carrying capacity. Note that the values in NEC Tables 8 and 9 now use 75°C as the starting point for dc resistance tabulations to account for conductor operating temperatures

1. Use 50 to 60°C for wires insulated with Code or moisture-resistant rubber compounds, synthetic rubberlike compounds, or thermoplastic compounds: Type TW wire.
2. Use 70°C for wires insulated with heat-resistant rubber compounds, varnished cambric, paper, thermoplastic, slow-burning compounds, or weatherproof compounds: Types RHW, THW, THWN, and MI.
3. Use 90°C for all wires not included in Pars. 1 and 2. For wires loaded less than 50 percent of their allowable carrying capacity the temperature should be reduced from 15 to 20°C below the above values. The resistance of copper wire varies somewhat with the method of drawing the wire. As a general rule the voltage drop of a circuit will depend upon several variables, the value of which cannot possibly be determined accurately. It is not practical, therefore, to spend too much time in accurately determining the value of the resistance of the wires. An average value of 98 percent conductivity for copper wires is generally satisfactory. Copper of 98 percent conductivity has a resistivity of approximately 10.6 Ω/cmil · ft at 20°C, 11.2 Ω at 30°C, 11.6 at 40°C, 11.8 at 50°C, 12.3 at 60°C, and 12.7 at 70°C. Tables of resistance of wires are given in Div. 12.

The length of the circuit should be taken as the distance along the circuit from the supply end to the load center. If a load is distributed along the circuit, the total current does not flow the complete length of the circuit. Therefore, if the actual length of the circuit were used in computing the voltage drop, the drop determined would be greater than the drop that would actually occur. The load center of a circuit is that point in the circuit where, if the load were concentrated at that point, the drop would be the same as the voltage drop to the farthest load in the actual circuit.

57. The load center of a circuit can be determined in the following manner. Multiply each load by its distance from the supply end of the circuit. Add these products for all the loads fed from the circuit and divide this sum by the sum of the individual loads. The result thus obtained is the distance from the supply end of the circuit to the load center. It is this length that should be employed in computing the voltage drop of the circuit (see solution of example in Fig. 3.28).

The load center of a group of receivers symmetrically arranged (Fig. 3.29) and all of the same output will be in the middle of the group. Always take the distance along the circuit as L , Fig. 3.29.

58. Calculation of voltage drop in dc two-wire circuits by means of formula.

The voltage drop can be calculated by means of either Eq. (6) or Eq. (7), and the size of wire to produce a given voltage drop can be calculated by Eq. (8).

$$VD = 2R \times L \times I \quad (6)$$

where VD = drop in volts in the circuit, R = resistance of wire in ohms per foot (values of resistance for copper or aluminum conductors can be obtained from Table 57 of Div. 12), I = current in amperes, and L = length one way of circuit in feet, or

$$VD = \frac{2K \times L \times I}{\text{cmil}} \quad (7)$$

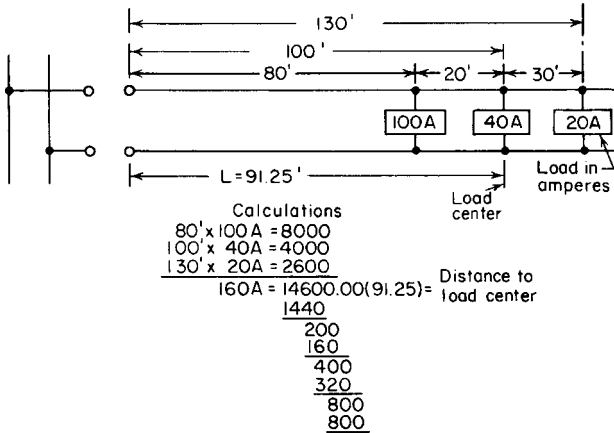

FIGURE 3.28 Method of computing location of load center.

FIGURE 3.29 Location of load center.

where VD = drop in volts in the circuit; K = resistivity of material of conductor in ohms per circular mil-foot (values of K for copper conductors can be obtained from Sec. 56; sufficient accuracy will be obtained for most cases by using the following more approximate values: 12 for circuits loaded between 50 and 100 percent of their allowable carrying capacity and 11 for circuits loaded at less than 50 percent of their allowable carrying capacity); I = current in amperes; L = length one way of circuit in feet; and cmil = area of conductor in circular mils. $K = 18$ for aluminum conductors.

$$\text{cmil} = \frac{2K \times I \times L}{VD} \tag{8}$$

59. Determination of voltage drop in dc two-wire circuits by means of chart.

A graph for computing the voltage drop in circuits (Sec. 49 of Div. 12) was originally proposed by R. W. Stovel and N. A. Carle in *The Electric Journal* for June 1908. It is based on a resistivity of $10.7 \Omega/\text{cmil} \cdot \text{ft}$ of copper wire. The chart will therefore give satisfactory results for circuits loaded at less than 50 percent of their allowable carrying capacity. For most circuits which are loaded to between 50 and 100 percent of their allowable carrying

capacity, the voltage drop obtained from the chart should be increased by 10 percent. The length of the circuit that should be employed in using the chart is the distance from the supply end to the load center. The voltage drop as read from the chart is the total drop in both wires. To determine the voltage drop of a circuit from the chart, proceed as follows:

1. Start on the lower left-hand scale with the current for the circuit.
2. Follow this point vertically upward to the diagonal line for the size of wire of the circuit.
3. From this intersection proceed horizontally to the right to the diagonal line representing the length of the circuit one way.
4. At this intersection drop vertically to the voltage-drop scale.
5. The reading on the voltage-drop scale will be the drops in both wires of the circuit for lightly loaded circuits as discussed above.
6. For normally loaded circuits the voltage drop will be equal to 1.1 times the value read from the chart.

EXAMPLE What will be the voltage drop of the motor feeder for the last problem of Sec. 54 if the length of circuit is 150 ft and a 4/0 AWG Type RH wire is employed?

SOLUTION The maximum-demand running current of 195 A should be used in determining voltage drop. From Table 57 of Div. 12 a 4/0 AWG wire has 211,600 cmil and from Table 18 of Div. 12 has a carrying capacity of 230 A.

Using the formula,

$$VD \times \frac{24 \times I \times L}{\text{cmil}} = \frac{24 \times 195 \times 150}{211,600} = 3.32 \text{ V drop}$$

Using the chart, start at the bottom of the chart on the left-hand side at 195 A and follow this point vertically upward until it intersects the diagonal line marked No. 0000. From this intersection proceed horizontally to the right until the diagonal line marked 150 is reached. At this intersection drop vertically downward to the voltage-drop scale, and read 3.0 V. Since the wire is loaded to more than 50 percent of its capacity, the voltage drop equals $3.0 \times 1.1 = 3.3$ V.

60. Determination of voltage drop in dc three-wire circuits. Either the formulas of Sec. 58 or the chart of Sec. 49, Div. 12, can be used for determining the voltage drop of dc three-wire circuits. In either case the current used should be that of the more heavily loaded outside wire and the size of conductor that of the outside conductors. The drop thus obtained from either the formula or the chart will be the drop between the outside wires. What is desired is the drop across each receiver or the drop between an outside wire and the neutral wire. The approximate voltage drop to each receiver will be one-half of the value determined from either the formula or the chart. This value will be correct for a balanced load. When the load is unbalanced, the current in the neutral wire will cause an additional voltage drop which will not have the same effect on the two sides of the circuit. Since in a well-laid-out system the load will be nearly balanced, the method given is satisfactory for most cases.

EXAMPLE Determine the voltage drop on a three-wire lighting feeder 100 ft long. The actual load on one side is 147 A, and on the other side 158 A. The future load on one side is 170 A, and on the other side 175 A. A 4/0 AWG Type TW wire is used for the outside copper conductors.

SOLUTION The future load on the more heavily loaded side should be used in determining voltage drop. A 4/0 AWG Type TW wire from Table 57, Div. 12, has 211,600 cmil, and from Table 18, Div. 12, a carrying capacity of 195 A.

Using the formula,

$$VD \times \frac{24 \times I \times L}{\text{cmil}} = \frac{24 \times 175 \times 100}{211,600} = 1.98 \text{ V}$$

Using the chart, start at the bottom of the chart on the left-hand side at 175 A and follow this point vertically upward until it intersects the diagonal line marked No. 0000. From this intersection follow horizontally to the right until the diagonal line marked 100 is reached. At this intersection drop vertically downward to the voltage-drop scale, and read 1.8 V drop. The voltage drop will be equal to $1.8 \times 1.1 = 1.98$.

The drop across each receiver is one-half of the drop determined by the formula or chart. The drop across each receiver is, therefore, 0.99 V determined from either formula or chart.

61. The voltage drop in ac circuits is affected by several factors that have no effect in dc circuits. These factors are (1) power factor of the load, (2) inductance of the circuit, (3) capacity of the circuit, and (4) increased resistance of the circuit to alternating current.

As discussed in Div. 1, when alternating current flows in a circuit, the resistance is increased owing to skin effect. This increase in resistance for most circuits is so small that it need not be considered. Unless the size of the conductor is greater than 750,000 cmil (380 mm^2) for 25-Hz circuits or 300,000 cmil (152 mm^2) for 60-Hz circuits, skin effect can be neglected and the resistance of the wire taken in the same way as for direct current.

As discussed in Div. 1, the phenomenon of inductance causes a voltage which opposes the flow of current in the circuit to be induced in an ac circuit. Inductance therefore offers opposition to the flow of alternating current in a circuit. This opposition is called the inductive reactance of the circuit and is represented by the symbol X_L . The value of the inductive reactance of a circuit depends upon the size of the wire, the distance between the wires of the circuit, the frequency of the current flowing in the circuit, the material of the conductor, and the presence of any magnetic material in proximity to the circuit. The voltage drop due to inductance produced in a circuit is equal to the current times the inductive reactance. For small-size conductors the effect of inductance is so small that it can be neglected (see Table 50 of Div. 12).

The two conductors of any circuit with the insulation between them produce a capacitor. They therefore introduce capacitance into the circuit. The effect of capacitance in an ac circuit is to offer opposition to the flow of current. This opposition is called capacitive reactance and is denoted by the symbol X_c . The voltage drop in a circuit due to capacitance is equal to the current times the capacitive reactance. The effect of capacitance upon the voltage drop of the circuit is so small except for high-voltage long-distance transmission lines that it is neglected.

The total voltage drop in an ac circuit due to the resistance and reactance is affected by the power factor of the load connected to the circuit.

62. Summary of factors that must be considered in calculating drop for ac circuits. Skin effect can usually be neglected unless the size of wires is greater than 300,000 cmil (152 mm^2) for 60-Hz circuits or 750,000 cmil (380 mm^2) for 25-Hz circuits.

The effect of capacitance can be neglected except for long-distance transmission lines.

The effect of inductance can be neglected unless the size of wire exceeds the values given in Table 50 of Div. 12.

63. Line or circuit reactance can be reduced in three ways. One way is to diminish the distance between wires. The extent to which this can be carried is limited, in the case of a pole line, to the least distance at which the wires are safe from swinging together in the middle of a span. In inside wiring (knob or tube work), it is limited by the spacings required by the National Electrical Code. In conduit work, nothing can be done about reducing the distance between wires. Another way of reducing the reactance is to increase the size of the conductors, but it is not possible to secure much reduction by this method unless the size is increased by an excessive amount. The third way of reducing reactance is to divide the load into a greater number of circuits. Voltage drop in lines due to inductive reactance is best diminished (Mershon) by subdividing the copper or by bringing the conductors closer together. It is little affected by changing the size of the conductors.

64. Determining power factors of feeders or mains. Although the values of power factors obtained by the following method are approximate, they are accurate enough for most circuit calculations. To determine the power factor of a circuit supplying several motors proceed as follows:

1. Multiply the horsepower of each motor by its power factor at 75 percent of rated load.
2. Add these products for all the motors fed from the line.
3. The approximate power factor of the circuit will equal the sum obtained in Par. 2 divided by the total horsepower connected to the circuit.

Approximate power factors of different types of loads are given in Table 52 of Div. 12.

EXAMPLE Determine the power factor for a feeder supplying two 5-hp motors, five 10-hp motors, and one 50-hp motor.

SOLUTION

Hp of motor × power factor = product of hp and pf (From Table 52, Div. 12)				
5	×	0.83	=	4.15
5	×	0.83	=	4.15
10	×	0.86	=	8.6
10	×	0.86	=	8.6
10	×	0.86	=	8.6
10	×	0.86	=	8.6
10	×	0.86	=	8.6
50	×	0.89	=	44.5
110 total connected hp				95.8

$$\text{Approximate power factor of circuit} = \frac{\text{sum of products of hp and pf}}{\text{total connected hp}}$$

$$= \frac{95.8}{110} = 87.1$$

65. Calculation of voltage drop in two-wire single-phase circuits when effect of inductance can be neglected. These circuits can be calculated in the same way as dc circuits, by means of either the formulas of Sec. 59 or the chart of Sec. 49 of Div. 12.

66. Calculation of voltage drop in three-wire single-phase circuits when effect of inductance can be neglected. Circuits of this type can be calculated in exactly the same manner as three-wire dc circuits (see Sec. 60).

67. Calculation of voltage drop in four-wire two-phase circuits when effect of inductance can be neglected. A four-wire two-phase circuit can be considered as two separate single-phase circuits, and the voltage drop computed in the same manner as given for two-wire dc circuits in either Sec. 58 or Sec. 59.

68. Calculation of voltage drop in three-wire two-phase circuits when effect of inductance can be neglected. The voltage drop in the common wire of three-wire two-phase systems somewhat unbalances the voltages of the two phases, and therefore the voltage drop of the two phases is not the same. An exact method of the calculation of the voltage drop of these circuits is too complicated for the scope of this book. The following method will give the approximate voltage drop on the phase having the greater voltage drop. It is accurate enough for most interior-wiring calculations. Proceed as follows:

1. Determine the voltage drop in one outside wire. It will be equal to one-half of the voltage drop determined by means of either the formulas of Sec. 58 or the chart of Sec. 49 in Div. 12.
2. Determine the voltage drop in the common wire. It will be equal to one-half of the voltage drop determined by means of either the formulas of Sec. 58 or the chart of Sec. 49 in Div. 12, the size of wire and current for the common wire being used.
3. The total voltage drop is taken as equal to the drop in one outside wire plus 0.8 times the voltage drop in the common wire.

EXAMPLE Determine the voltage drop of a three-wire two-phase 60-Hz lighting feeder which is 200 ft long and installed in conduit. The current in each outside wire is 130 A. A 2/0 AWG wire is used for the outside wires, and a 4/0 AWG for the common wire. All wires are Type TW.

SOLUTION Since the largest wire used is 4/0 AWG from Table 50 of Div. 12, the effect of inductance can be neglected. From Table 57 of Div. 12 a 2/0 AWG wire has 133,100 cmil, and a 4/0 AWG wire 211,600 cmil. From Table 18 of Div. 12 all wires are loaded to more than 50 percent of their carrying capacity.

$$\text{Drop in two outside wires} = \frac{24 \times I \times L}{\text{cmil}} = \frac{24 \times 130 \times 200}{133,100} = 4.7 \text{ V}$$

$$\text{Drop in one outside wire} = \frac{4.7}{2} = 2.35 \text{ V}$$

$$\text{Current in common wire} = 1.41 \times 130 = 183.5 \text{ A}$$

$$\text{Drop in common wire} = \frac{24 \times I \times L}{2 \times \text{cmil}} = \frac{24 \times 183.5 \times 200}{2 \times 211,600} = 2.08 \text{ V}$$

$$\begin{aligned} \text{Total voltage drop} &= 2.35 + (0.8 \times 2.08) = 2.35 + 1.66 \\ &= 4.01 \text{ V drop} \end{aligned}$$

69. Calculation of voltage drop in five-wire two-phase circuits when effect of inductance can be neglected. In a well-laid-out system the load will be very nearly balanced under normal load conditions. Therefore, there will be practically no current in the neutral wire. For lighting loads supplied by this system the lamps are connected between the neutral wire and the respective outside wires. The drop to any lamp, therefore, is equal to the drop in one outside wire. The drop in one outside wire will be equal to one-half of the drop determined by either the formulas of Sec. 58 or the chart of Sec. 49 of Div. 12. The drop to motors fed by this system will be equal to the drop in two outside wires and, therefore, to the drop determined by either the formulas or the chart.

70. Calculation of voltage drop in three-wire three-phase circuits when effect of inductance can be neglected. The voltage drop in these circuits will be equal to 0.866 times the voltage drop of a two-wire dc circuit carrying the same current as the three-phase circuit. This drop may be determined from either the formulas of Sec. 58 or the chart of Sec. 49 of Div. 12.

EXAMPLE Determine the voltage drop of a three-wire three-phase 60-Hz motor feeder which is 150 ft long. Three 2 AWG Type TW wires are installed in conduit. The current is 85 A.

SOLUTION Since the size of wire is 2 AWG from Table 50 of Div. 12, the effect of inductance can be neglected. From Table 57 of Div. 12 a 2 AWG wire has 66,360 cmil, and from Table 18 of Div. 12 a carrying capacity of 95 A.

$$\begin{aligned} \text{Drop in a two dc circuit carrying 85 A over a 2 AWG wire} &= \frac{24 \times I \times L}{\text{cmil}} \\ &= \frac{24 \times 85 \times 150}{66,360} \\ &= 4.61 \text{ V} \end{aligned}$$

$$\begin{aligned} \text{Therefore} \quad \text{Drop of the three-phase system} &= 0.866 \times 4.61 \\ &= 4.0 \text{ V} \end{aligned}$$

71. Calculation of voltage drop in four-wire three-phase circuits when effect of inductance can be neglected. In a well-laid-out system the load will be very nearly balanced under normal load conditions. Therefore, there will be practically no current in the neutral wire. For lighting loads supplied by this system the lamps are connected between the neutral wire and the respective outside wires. The drop to any lamp, therefore,

is equal to the drop in one outside wire. The drop in one outside wire will be equal to one-half of the drop determined by either the formulas of Sec. 58 or the chart of Sec. 49 of Div. 12. The drop to motors fed by this system is the drop between any two outside wires. This drop is equal to 0.866 times the voltage drop of a two-wire dc system carrying the same current as the three-phase system. (Use either the formulas of Sec. 58 or the chart of Sec. 49 of Div. 12 for determining the dc drop.)

72. Calculation of circuits when effect of inductance cannot be neglected.

Two methods are given in the following paragraphs for calculating the voltage drop of circuits when the effect of inductance is so great that it cannot be neglected (see Table 50 of Div. 12 for rules indicating when inductance must be considered). In one of these methods the voltage drop in the actual ac circuit is calculated by multiplying the drop of a dc circuit by a factor called the drop factor. This drop factor is the ratio between the actual drop and the drop that would occur if there were no inductance. The drop factor is affected by the size of wire, spacing of the wires of the circuit, the frequency of the current, and the power factor of the load. Values of drop factors for various conditions in which concentric stranded copper conductors are used are given in Table 55 of Div. 12.

The other method given for computing the voltage drop of circuits when the effect of inductance cannot be neglected makes use of a diagram called the Mershon diagram (Fig. 3.30).

Under ordinary conditions of use both of these methods will give results of about the same degree of accuracy. If the Mershon diagram is used carefully, it will give the more accurate results of the two. But since in the calculation of most circuits several factors are based on assumption, the greater accuracy of the Mershon diagram is of questionable value. The drop-factor method is certainly accurate enough for the calculation of all interior-wiring circuits, and the authors believe that it is the more easily applied method of the two. For circuits employing

FIGURE 3.30 Illustrating the application of the Mershon diagram for computing a single-phase circuit. The side of each small square equals 1 percent; percentage resistance is measured horizontally and percentage reactance vertically.

some type of conductor material or construction other than standard copper, the Mershon diagram must be used, since no data are given for drop factors for conductors of other types.

73. Drop-factor method of calculating voltage drop when effect of inductance cannot be neglected. Proceed as follows:

1. Determine from either Sec. 58 or Sec. 59 the voltage drop of a two-wire dc system carrying the same current and using the same size of wire.
2. Determine the ratio of reactance to resistance for the size of wire, spacing of wires, and frequency of the circuit considered (see Table 53 or 54 of Div. 12).
3. Determine the power factor of the circuit (see Sec. 64 and Table 52 of Div. 12).
4. Determine the drop factor for the circuit corresponding to the determined ratio of reactance to resistance and the power factor of the circuit from Table 55 of Div. 12.
5. The voltage drop of the circuit then is determined as follows, depending upon the electric system:

For two-wire single-phase systems:

$$\text{Voltage drop} = \text{drop factor} \times \text{dc voltage drop} \quad (9)$$

For three-wire single-phase systems:

$$\text{Voltage drop between outside wires} = \text{drop factor} \times \text{dc voltage drop} \quad (10)$$

$$\text{Voltage drop between outside wire and neutral (lamps)} = 1/2 (\text{drop factor} \times \text{dc voltage drop}) \quad (11)$$

For four-wire two-phase systems, each phase is considered as a separate two-wire single-phase system:

$$\text{Voltage drop} = \text{drop factor} \times \text{dc voltage drop} \quad (12)$$

For three-wire system tapped from four-wire three-phase system:

$$\text{Voltage drop} = 0.75 (\text{drop factor} \times \text{dc voltage drop}) \quad (13)$$

For three-wire two-phase systems, two dc drops must first be determined: one for a two-wire dc circuit carrying the same current and with the same size of wire as the outside conductors of the two-phase system, and the other for a two-wire dc circuit carrying the same current and with the same size of wire as the common wire of the two-phase system. Then

$$\begin{aligned} \text{Voltage drop of two-phase three-wire system} = & \frac{\text{drop factor} \times \text{dc voltage drop for current and size of outside wire}}{2} \\ & + \left(0.8 \times \frac{\text{drop factor} \times \text{dc voltage drop for current and size of outside wire}}{2} \right) \quad (14) \end{aligned}$$

For five-wire two-phase systems:

$$\text{Voltage drop for lamps} = \frac{\text{drop factor} \times \text{dc voltage drop}}{2} \quad (15)$$

$$\text{Voltage drop for motors} = \text{drop factor} \times \text{dc voltage drop} \quad (16)$$

For three-wire three-phase systems:

$$\text{Voltage drop} = 0.866 \times \text{drop factor} \times \text{dc voltage drop} \quad (17)$$

For four-wire three-phase systems:

$$\text{Voltage drop for lamps} = \frac{\text{drop factor} \times \text{dc voltage drop}}{2} \quad (18)$$

$$\text{Voltage drop for motors} = 0.866 \times \text{drop factor} \times \text{dc voltage drop} \quad (19)$$

EXAMPLE Determine the voltage drop of a two-wire single-phase 60-Hz motor circuit carrying a current of 250 A for a distance of 150 ft. A 300,000-cmil Type RH wire is used, installed in conduit. The power factor of the circuit is 80 percent.

SOLUTION From Table 50 of Div. 12, since the size of wire is 300,000 cmil, the effect of inductance cannot be neglected. The carrying capacity from Table 18 of Div. 12 is 285 A.

The drop of a two-wire dc circuit carrying 250 A over a 300,000-cmil wire for 150 ft is

$$\frac{24 \times I \times L}{\text{cmil}} = \frac{24 \times 250 \times 150}{300,000} = 3.0 \text{ V}$$

From Table 53 of Div. 12 the ratio of reactance to resistance for a 300,000-cmil wire installed in conduit on a 60-Hz system is 1.01.

From Table 55 of Div. 12 the drop factor for a ratio of reactance to resistance of 1.01 and a power factor of 80 percent is 1.40.

Voltage drop of the actual circuit = drop factor \times dc drop = $1.40 \times 3.0 = 4.2 \text{ V}$.

EXAMPLE Determine the voltage drop of the above circuit if it were a three-wire single-phase one.

SOLUTION The voltage drop between outside wires would be equal to the drop factor times the drop of a two-wire dc system carrying the same current = $1.40 \times 3.0 = 4.2 \text{ V}$.

Voltage drop across lamps if connected to the circuit would be the drop between an outside wire and the neutral = $\frac{1.40 \times 3.0}{2} = 2.1 \text{ V}$.

EXAMPLE Determine the voltage drop of the above circuit if it were three-wire tapped from a four-wire three-phase system.

SOLUTION Voltage drop across lamps = $0.75 \times 1.4 \times 3.0 = 3.15 \text{ V}$.

EXAMPLE Determine the voltage drop of the preceding circuit if it were a four-wire two-phase system.

SOLUTION Voltage drop = drop factor \times dc drop
 $= 1.40 \times 3.0 = 4.2 \text{ V}$

EXAMPLE Determine the voltage drop of the preceding circuit if it were a three-wire two-phase one. The 250 A is the current in the outside wires.

SOLUTION The current in the common wire = $1.41 \times 250 = 352 \text{ A}$. Use a 500,000-cmil wire for the common.

The voltage drop for a two-wire dc system carrying 250 A over a 300,000-cmil wire for

$$150 \text{ ft} = \frac{24 \times I \times L}{300,000} = \frac{24 \times 250 \times 150}{300,000} = 3.0 \text{ V}$$

The voltage drop for a two-wire dc circuit carrying 352 A for 150 ft over a

$$500,000\text{-cmil wire} = \frac{24 \times I \times L}{500,000} = \frac{24 \times 352 \times 150}{500,000} = 2.54 \text{ V}$$

From preceding problems the drop factor for the outside conductors is 1.40.

From Table 53 of Div. 12 the ratio of reactance to resistance for a 500,000-cmil wire installed in conduit on a 60-Hz system is 1.75.

From Table 55 of Div. 12 the drop factor for a ratio of reactance to resistance of 1.75 and a power factor of 80 percent is 1.88.

$$\begin{aligned} \text{Voltage drop of actual circuit} &= \frac{\text{drop factor} \times \text{dc voltage drop for current and size of wire of outside wires}}{2} + 0.8 \times \frac{\text{drop factor} \times \text{dc voltage drop for current and size of wire of common wire}}{2} \\ &= \frac{1.40 \times 3.0}{2} + \frac{0.8 \times 1.88 \times 2.54}{2} = 2.1 + 1.91 \\ &= 4.01 \text{ V} \end{aligned}$$

EXAMPLE Determine the voltage drop of the preceding circuit if it were a five-wire two-phase system.

SOLUTION Voltage drop for motors = drop factor \times dc voltage drop
 $= 1.40 \times 3.0 = 4.2 \text{ V}$

If any lamps were connected to the circuit, the voltage drop across each lamp

$$\begin{aligned} &= \frac{\text{drop factor} \times \text{dc voltage drop}}{2} \\ &= \frac{1.40 \times 3.0}{2} = 2.1 \text{ V} \end{aligned}$$

EXAMPLE Determine the voltage drop of the preceding circuit if it were a three-wire three-phase system.

SOLUTION

$$\begin{aligned}\text{Voltage drop} &= 0.866 \times \text{drop factor} \times \text{dc voltage drop} \\ &= 0.866 \times 1.40 \times 3.0 = 3.64 \text{ V}\end{aligned}$$

EXAMPLE Determine the voltage drop of the preceding circuit if it were a four-wire three-phase system.

SOLUTION

$$\begin{aligned}\text{Voltage drop for motors} &= 0.866 \times \text{drop factor} \times \text{dc voltage drop} \\ &= 0.866 \times 1.40 \times 3.0 = 3.64 \text{ V}\end{aligned}$$

If any lamps were connected to the circuit, the voltage drop across each lamp

$$\begin{aligned}&= \frac{\text{drop factor} \times \text{dc voltage drop}}{2} \\ &= \frac{1.40 \times 3.0}{2} = 2.1 \text{ V}\end{aligned}$$

74. Calculation of voltage drop of two-wire single-phase circuits by Mershon diagram when effect of inductance cannot be neglected. Proceed as follows:

1. Determine the ac resistance of the total length of wire. This will be equal to the resistance per foot of wire of the size and material employed multiplied by 2 times the length of circuit one way in feet. Care should be exercised in taking values of resistance from the tables to observe in what units the resistance is given. Some values are given in $\Omega/1000$ ft, and others in Ω/mi . For copper conductors use Table 57 of Div. 12. The ac resistance will be equal to the dc resistance at the working temperature of the wire times the skin-effect correction factor.
2. Determine the resistance volts drop. This drop will be equal to the resistance of the total length of wire as has been determined in step 1 and multiplied by the current.
3. Determine the inductive reactance of the total length of wire. This will be equal to the reactance per foot of wire for the size, material, and spacing of wires multiplied by 2 times the length of circuit one way in feet. Care should be exercised in taking values of reactance from the tables to observe in what units the reactance is given. Some values are given in $\Omega/1000$ ft, and others in Ω/mi .
4. Determine the reactance volts drop. This drop will be equal to the reactance of the total length of wire as has been determined in step 3 and multiplied by the current.
5. Find what percentage the resistance volts drop is of the voltage delivered at the end of the line.
6. Find what percentage the reactance volts drop is of the voltage delivered at the end of the line.

7. Determine the power factor of the circuit (see Sec. 64 of this division and Table 52 of Div. 12).
8. On the Mershon diagram (Fig. 3.30) start at the point where the vertical line corresponding to the power factor of the circuit intersects the smallest circle.
9. From this point lay off horizontally to the right the percentage of resistance volts drop. From the point thus obtained lay off vertically upward the percentage of reactance volts drop.
10. The circle upon which the last point obtained falls will give the voltage drop in percentage of the voltage at the end of the line.

75. Calculations of voltage drop by Mershon diagram for any circuit when effect of inductance cannot be neglected. First determine, as outlined in Sec. 74, the voltage drop for a two-wire single-phase circuit of the same size of wire carrying the same current as the actual circuit. Then proceed as follows for the particular system involved.

Three-wire single-phase:

$$\text{Voltage drop between outside wires} = \text{drop as read from diagram} \quad (20)$$

$$\text{Voltage drop between outside wire and neutral (lamps)} = \frac{\text{drop as read from diagram}}{2} \quad (21)$$

Three-wire tapped from three-phase four-wire:

$$\begin{aligned} \text{Voltage drop between outside wire and neutral (lamps)} \\ = 0.75(\text{drop as read from diagram}) \quad (22) \end{aligned}$$

Four-wire two-phase systems: Each phase is considered as a separate two-wire single-phase system.

Three-wire two-phase systems: Determine two drops from the diagram, one for a circuit with the size of wire and current of outside wires of a two-phase system, and the other for a circuit with size of wire and current of common wire.

Then

$$\text{Voltage drop} = \frac{\text{drop for circuit with size of wire and current of outside wires}}{2} + 0.08 \times \frac{\text{drop for circuit with size of wire and current of common wire}}{2} \quad (23)$$

Five-wire two-phase systems:

$$\text{Voltage drop for lamps} = \frac{\text{drop from diagram}}{2} \quad (24)$$

$$\text{Voltage drop for motors} = \text{drop as read from diagram} \quad (25)$$

Three-wire three-phase systems:

$$\text{Voltage drop} = 0.866 \times \text{drop as read from diagram} \quad (26)$$

Four-wire three-phase systems:

$$\text{Voltage drop for lamps} = \frac{\text{drop from diagram}}{2} \quad (27)$$

$$\text{Voltage drop for motor} = 0.866 \times \text{drop as read from diagram} \quad (28)$$

EXAMPLE Determine the voltage drop for the circuit of the example in Sec. 74 for the different systems.

SOLUTION By referring to the problem in Sec. 74, the voltage drop of the circuit for a two-wire single-phase system is 8.25 V.

For a three-wire single-phase system:

$$\begin{aligned} \text{Voltage drop for motors} &= \text{drop as read from diagram} \\ &= 8.25 \text{ V} \\ \text{Voltage drop for lamps} &= \frac{\text{drop as read from diagram}}{2} = \frac{8.25}{2} = 4.13 \end{aligned}$$

For a four-wire two-phase system:

$$\text{Voltage drop} = \text{drop as read from diagram} = 8.25 \text{ V}$$

For a three-wire two-phase system:

Use must be made of the Mershon diagram to determine another voltage drop. The drop obtained in Sec. 74 is for a two-wire single-phase circuit carrying the same current as the outside wires of the three-wire two-phase circuit and with the same size of wire as the outside wires. Another voltage drop for a two-wire single-phase circuit carrying the same current as the common wire of the three-wire two-phase circuit and with the size of wire of the common must be determined.

$$\text{Current in common wire} = 1.41 \times 200 = 282 \text{ A}$$

Assume that a 400,000-cmil wire is used for common wire (as large a size would not be required by carrying capacity).

If the Mershon diagram is applied, a two-wire single-phase circuit of 85 percent pf carrying 282 A over 400,000-cmil wires spaced 6 in apart will give a 7.3 percent volts

$$\text{drop, or } \frac{7.3 \times 110}{100} = 8.03 \text{ V.}$$

$$\begin{aligned} \text{Voltage drop for three-wire two-phase circuit} &= \frac{8.25}{2} + \left(0.8 \times \frac{8.03}{2} \right) \\ &= 4.13 + 3.21 \\ &= 7.34 \end{aligned}$$

For a five-wire two-phase system:

$$\text{Voltage drop for lamps} = \frac{\text{drop from diagram}}{2} = \frac{8.25}{2} = 4.13$$

$$\begin{aligned} \text{Voltage drop for motors} &= \text{drop as read from diagram} \\ &= 8.25 \text{ V} \end{aligned}$$

For a three-wire three-phase system:

$$\begin{aligned} \text{Voltage drop} &= 0.866 \times \text{drop as read from diagram} \\ &= 0.866 \times 8.25 = 7.15 \text{ V} \end{aligned}$$

For a four-wire three-phase system:

$$\begin{aligned} \text{Voltage drop for lamps} &= \frac{\text{drop from diagram}}{2} = \frac{8.25}{2} \\ &= 4.13 \text{ V} \end{aligned}$$

$$\begin{aligned} \text{Voltage drop for motors} &= 0.866 \times \text{drop as read from diagram} \\ &= 0.866 \times 8.25 = 7.15 \text{ V} \end{aligned}$$

76. How to proceed in determining the proper size of wire for a circuit

1. Determine the ampere load on the circuit.

For branch lighting and appliance circuits refer to Secs. 36 to 38. For two-wire dc or single-phase ac lighting and appliance mains or feeders refer to Secs. 40, 44, and 45.

For three-wire dc or single-phase ac lighting and appliance mains or feeders refer to Secs. 41, 44, and 46.

For four-wire two-phase lighting and appliance mains or feeders refer to Secs. 44 and 47.

For three-wire two-phase lighting and appliance mains or feeders refer to Secs. 42, 44, and 48.

For five-wire two-phase lighting and appliance mains or feeders refer to Secs. 44 and 49.

For four-wire three-phase lighting and appliance mains or feeders refer to Secs. 43, 44, and 50.

For circuits supplying electric ranges refer to Secs. 39 and 45.

For branch motor circuits refer to Sec. 53.

For motor feeders or mains refer to Sec. 54.

2. For branch lighting or appliance circuits refer to Div. 9 and determine if outlets and equipment supplied by circuits meet the National Electrical Code requirements.
3. For lighting feeders or mains determine the minimum allowable load (refer to Sec. 52).
4. Select from Secs. 17 to 23 of Div. 12 the size of wire that will carry safely the current with the type of insulation employed on the wires (see also Secs. 30 and 31).

For 15-A branch lighting circuits, although 14 AWG wire will safely carry the current, it is best not to use smaller than 12 AWG wire. If the length of the branch lighting circuit to the load center is over 75 ft, wire at least as large as 10 AWG should be used.

A branch circuit supplying an electric range with a rating of $8\frac{3}{4}$ kW or more must not be smaller than 8 AWG except for the neutral conductor, which must not be smaller than 10 AWG.

For lighting feeders or mains use the estimated maximum allowable load current unless for some reason it is less than the minimum allowable load, in which case the minimum allowable load must be used.

For continuous-duty branch motor circuits use 125 percent of the full-load rated current of the motor.

For branch motor circuits supplying short-time-duty motors, use the proper percentage of the rated current as given in Table 12 of Div. 12.

For motor feeders or mains use the maximum-demand running current with allowance for growth.

For the determination of the required carrying capacity of the neutral wire refer as follows:

For three-wire dc or single-phase systems refer to Sec. 46.

For three-wire two-phase systems refer to Sec. 48.

For five-wire two-phase systems refer to Sec. 49.

For four-wire three-phase systems refer to Sec. 46.

The neutral conductor of a three-wire circuit supplying a household electric range, a wall-mounted oven, or a counter-mounted cooking unit with a maximum demand of $8\frac{3}{4}$ kW or more is allowed to have a carrying capacity of only 70 percent of the outside wires provided that the neutral is not smaller than 10 AWG.

5. Determine whether the size of wire required according to carrying capacity is sufficient for mechanical strength (refer to Sec. 32).

Be sure that the size of wire required according to carrying capacity is not too large for satisfactory installation (refer to Sec. 33).

6. Find the distance to the load center of the circuit (refer to Sec. 57).

7. Decide what voltage drop is allowable in the circuit (refer to Sec. 35, and Table 48 of Div. 12).

8. Determine what the voltage drop in the circuit will be in using the size of wire required according to carrying capacity.

If the circuit is an ac one, before calculating the voltage drop, determine from Sec. 62 and Table 50 of Div. 12 whether or not the effects of inductance and skin effect can be neglected.

For branch lighting circuits use the maximum allowable load current unless the maximum allowable load for the type of branch circuit as given in Div. 9 is less than this value. In that case, use the maximum allowable load.

For lighting feeders or mains use the maximum allowable load current unless it is smaller than the minimum allowable load, in which case the minimum allowable load must be used.

For branch motor circuits use the full-load current of the motor. For motor feeders or mains use the maximum-demand running current with proper allowance for growth.

For the length of the circuit use the distance from the source of supply to the load center, measured along the circuit.

For methods of calculating voltage drop refer to the following sections:

Direct-current two-wire Sec. 58 or 59

Direct-current three-wire Sec. 60

Alternating-current when inductance can be neglected:

Single-phase two-wire	Sec. 65
Single-phase three-wire	Sec. 66
Two-phase four-wire	Sec. 67
Two-phase three-wire	Sec. 68
Two-phase five-wire	Sec. 69
Three-phase three-wire	Sec. 70
Three-phase four-wire	Sec. 71
Alternating-current when the effect of inductance cannot be neglected	Sec. 73
	Or
	Secs. 74 and 75

9. If the voltage drop determined in step 8 is greater than the allowable amount, take the next larger conductor and determine the voltage drop it will give. Proceed in this way until the conductors are large enough to keep the voltage drop within the required amount. For ac circuits, this would sometimes require too great an increase in the size of the conductors. In such cases it is best to replan the system so as to divide the load among a greater number of circuits. For systems employing a common or neutral wire, when the size of wire must be increased to keep the voltage drop within the allowable amount, it is best to increase the size of the neutral in the same proportion as the outside wires are increased.

EXAMPLE Determine the proper size of wire to use for a two-wire single-phase 15-A 60-Hz 115-V branch lighting circuit supplying six 150-W lamps. The length of the circuit to the load center is 50 ft. The wires are to be installed in conduit and have rubber insulation.

SOLUTION

$$\text{Actual connected load} = \frac{6 \times 150}{115} = 7.8 \text{ A}$$

$$\text{Maximum allowable load (sec. 37)} = 0.80 \times 15 = 12 \text{ A}$$

The maximum allowable load of 12 A will be used in selecting the size of wire according to both carrying capacity and voltage drop.

From item 4 of this section at least a 14 AWG wire is required by the Code, but it is best to use not smaller than 12 AWG wire.

From Table 48 of Div. 12 a voltage drop of 2.3 V would be allowable.

Determine the voltage drop (Sec. 58 or 59) for a 12 AWG wire carrying 12 A 50 ft.

$$\text{Voltage drop with 12 AWG wire} = \frac{24 \times 12 \times 50}{6530} = 2.21 \text{ V}$$

Since this drop is less than the allowable amount, two 12 AWG wires should be used.

EXAMPLE A two-wire 15-A single-phase 60-Hz 115-V branch lighting circuit supplies seven 150-W lamps. The length of the circuit to the load center is 100 ft. The wires are to be installed in conduit and to be rubber-insulated. Determine the proper size of wire to use.

SOLUTION

$$\text{Actual connected load} = \frac{7 \times 150}{115} = 9.13 \text{ A}$$

$$\text{Maximum allowable load} = 0.80 \times 15 = 12 \text{ A}$$

The maximum allowable load of 12 A will be used in selecting the size of wire according to both carrying capacity and voltage drop.

From item 4 of this section at least a 14 AWG wire is required, but it will be best to use not smaller than 10 AWG wire when the circuit is over 100 ft long.

From Table 48 of Div. 12 a voltage drop of 2.3 V would be allowable.

From Table 50 of Div. 12 the effect of inductance can be neglected for a lighting circuit using 10 AWG wire on a 60-Hz system.

$$\text{Voltage drop with 10 AWG wire} = \frac{24 \times 12 \times 100}{10,380} = 2.77 \text{ V}$$

Since this voltage drop is greater than the allowable amount, take the next larger size of wire, 8 AWG, and check for voltage drop.

$$\text{Voltage drop with 8 AWG wire} = \frac{24 \times 12 \times 100}{16,510} = 1.74 \text{ V}$$

Since this voltage drop is less than the allowable amount, two 8 AWG wires should be used. As noted in Sec. 3 to 56, use of the maximum allowable load current to begin this calculation may not be acceptable to the owner. Should that be so, use of the actual connected load gives a different result that is within the recommended allowances:

$$\text{Voltage drop with 10 AWG wire} = \frac{24 \times 9.13 \times 100}{10,380} = 2.11 \text{ V}$$

EXAMPLE Determine the proper size of service lateral for the three-wire 115/230-V ac main of the example under Sec. 46. The length of the circuit is 125 ft. The wires are to be thermoplastic-covered, Type TW, and installed in conduit. The installation has only a main and branch circuits, no feeder.

SOLUTION From Sec. 46, the current in the outside main wires is 89.5 A and the current in the neutral is 64.2 A. From Table 48 of Div. 12 a voltage drop of 2.3 V is allowable on the feeder conductors that supply the lighting load. The smallest conductors allowable for this service using TW wire, per Table 18 of Div. 12, is 2 AWG for the outside wires and 4 AWG for the neutral. The calculations must be done separately, using the loads developed in Sec. 46.

$$\text{Voltage drop one way on an outside wire} = \frac{12 \times 89.5 \times 125}{66,360} = 2.0 \text{ V}$$

$$\text{Voltage drop one way on the neutral wire} = \frac{12 \times 64.2 \times 125}{41,740} = 1.9 \text{ V}$$

The total voltage drop of almost 4 V exceeds the recommended 2.3 V

$$\text{Voltage drop, outside wire raised to 1/0 AWG} = \frac{12 \times 89.5 \times 125}{105,600} = 1.3 \text{ V}$$

$$\text{Voltage drop, neutral wire raised to 1/0 AWG} = \frac{12 \times 64.2 \times 125}{105,600} = 0.9 \text{ V}$$

Now the total voltage drop of 2.2 V is within the recommended 2.3 V

EXAMPLE Determine the proper size of wire to use for a branch motor circuit supplying a 10-hp 460-V three-phase squirrel-cage induction motor on continuous duty. The motor is of the normal-starting-current, normal-torque type started with reduced voltage. It is a 60-Hz system. The length of the circuit is 50 ft. The wires are to be thermoplastic-covered. Type TW, installed in conduit.

SOLUTION From Table 10 of Div. 12 the full-load current = 14 A.

$$125 \text{ percent of the full-load current} = 14 \times 1.25 = 17.5 \text{ A}$$

From Table 18 of Div. 12 a 12 AWG wire is required to carry $= 14 \times 1.25 = 17.5 \text{ A}$.

From Table 48 of Div. 12, 4.4 V drop is allowable.

From Table 50 of Div. 12 the effect of inductance can be neglected for a 60-Hz motor circuit using 12 AWG wire.

The voltage drop on a two-wire dc circuit carrying 14 A (full-load current) over a 12 AWG

$$\text{wire for 50 ft} = \frac{24 \times 14 \times 50}{6,530} = 2.58 \text{ V.}$$

$$\text{Voltage drop of actual circuit} = 0.866 \times 2.58 = 2.24 \text{ V}$$

Since this drop is less than the allowable amount, three 12 AWG wires should be used.

EXAMPLE Determine the proper size of wire to use for a branch motor circuit supplying a series-wound dc motor on a 30-min rating varying duty. The motor is a 15-hp 230-V machine. The length of the circuit is 100 ft. The wires are Type RHW and installed in conduit.

SOLUTION From Table 7 of Div. 12 the full-load current is 55 A.

Since this is a short-time-duty service, by referring to Table 12 of Div. 12, use 150 percent of the full-load current in determining size of wire according to carrying capacity.

From Table 18 of Div. 12 a 4 AWG wire is required to carry $(1.50 \times 55) = 83 \text{ A}$ when Type RHW wire is used.

From Table 48 of Div. 12, 4.4 V drop is allowable.

In determining voltage drop, use full-load current.

$$\text{Voltage drop} = \frac{24 \times 55 \times 100}{41,740} = 3.16$$

Since this drop is less than the allowable amount, two 4 AWG wires would be used.

EXAMPLE Determine the proper size of wire to use for a three-wire, three-phase 460-V, 60-Hz feeder supplying five 10-hp motors, six 15-hp motors, and two 50-hp motors. All the motors are of the normal-torque, normal-starting-current, squirrel-cage type, started with reduced voltage. It is a 60-Hz circuit, 200 ft long. The wires are installed open with a regular flat spacing of 6 in. Type RHH insulation is employed on the wires. Permission to use a demand factor of 0.6 has been obtained from the officials enforcing the Code.

SOLUTION From Table 10 of Div. 12 the full-load current of a 10-hp motor of this type is 14 A; of a 15-hp motor, 21 A; and of a 50-hp motor, 65 A.

By using the formula of Sec. 54,

$$\text{Starting current of 50-hp motor (Sec.43 of Div. 12)} = 2.0 \times 65 = 130 \text{ A}$$

$$\begin{aligned} \text{Maximum-demand starting current of feeder} \\ &= [(5 \times 14) + (6 \times 21) + (1 \times 65)] \times 0.6 + 130 \\ &= (261 \times 0.6) + 130 = 286 \text{ A} \end{aligned}$$

$$\begin{aligned} \text{Maximum-demand running current of feeder} \\ &= [(5 \times 14) + (6 \times 21) + (1 \times 65)]0.6 + (65 \times 1.25) \\ &= (261 \times 0.6) + 81 = 238 \text{ A} \end{aligned}$$

From Table 19 of Div. 12 a 1/0 AWG wire is required to carry 238 A (maximum-demand running current) if Type RHH (90°C) insulation is employed.

From Sec. 48 of Div. 12, 17.6 V drop is allowable.

$$\text{Effective spacing of wires (Sec. 51, Div. 12)} = 1.26 \times 6 = 7.56$$

From Sec. 50 of Div. 12 the effect of inductance cannot be neglected.

Determine the voltage drop according to the method given in Sec. 73, using the maximum-demand running current.

$$\text{Voltage drop of a two-wire dc circuit carrying 238 A 200 ft over 1/0 AWG wire} = (24 \times 238 \times 200)/105,560 = 10.8 \text{ V.}$$

Ratio of reactance to resistance for 1/0 AWG wires spaced 8 in apart on a 60-Hz circuit (Table 53 of Div. 12) = 0.9.

Power factor of circuit (Sec. 64 and Table 52, Div. 12):

$$\begin{aligned} 5 \times 10 \times 0.86 &= 43.0 \\ 6 \times 15 \times 0.86 &= 77.4 \\ 2 \times 50 \times 0.89 &= 89.0 \\ &\hline &209.4 \end{aligned}$$

$$\text{pf} = \frac{209.4}{240} = 87.5$$

Drop factor of circuit from Table 55 of Div. 12 for a ratio of reactance to resistance of 0.9 and a power factor of 0.875 = 1.34.

$$\text{Voltage drop of circuit} = 0.866 \times 1.34 \times 10.8 = 12.3 \text{ V.}$$

Since this drop is less than the allowable amount, use three 1/0 AWG wires.

77. In determining circuit lengths from drawings or blueprints a long piece of tough paper divided into the same measure as the drawing (see Fig. 3.31) can be effectively

FIGURE 3.31 Paper scale for measuring circuit lengths.

FIGURE 3.32 A rotometer.

used in scaling distances. Always allow for rises or drops for wall outlets. The rotometer (Fig. 3.32) is a convenient tool for scaling distances. The little wheel is run over the course of the circuit. The pointer indicates feet directly for drawings of certain scales. For other scales the dial reading must be multiplied by a constant to obtain actual lengths.

78. Indicating loads on diagrams. In computing the ampere loads on circuits, if drawings are available, it is good practice to note the amperes of the loads on the drawings alongside the circuits. It is good practice to indicate both the present and the estimated future loads, one colored pencil being used for the present load and another colored pencil for the future loads.

79. Use of tables in circuit calculations. If tables that will give the values of loads, voltage drops, etc., are laid out when circuit calculations are made, much time

can be saved in checking the size of circuits or in making changes in the system. A typical table is given in Sec. 80.

80. Branch Lighting Circuits

Panel	Branch circuit	Present load, amp	Max. allowable load, amp	Size wire according to carrying capacity	Length, ft	Volts drop	Size wire to use	Remarks
A	1	10.0	12	14 AWG	50	3.50	10 AWG	No. 10 used to keep drop to 1.39 To keep voltage drop down
.....	2	7.8	12	14 AWG	25	1.75	14 AWG	
.....	3	9.1	12	14 AWG	30	2.10	12 AWG	
.....	4	8.0	12	14 AWG	20	1.40	14 AWG	
B	etc.		48					

81. The question of energy loss in a circuit should not be slighted in circuit calculations. It is well known that in overcoming resistance electrical energy is wasted, and as it costs money to develop or buy electrical energy, it is evident that in any commercial system such waste must be kept to a minimum. This can be done by decreasing the resistance of the conductors or, what amounts to the same thing, by increasing the size of the conductors. In as much as this is also an expensive matter, care must be exercised

that the additional sum added to the expenditure in copper (and conduit if used) is not so excessive as to more than counterbalance the cost of the energy continually saved.

82. Conductor economy in interior-wiring installations should always be considered a matter subordinate to the National Electrical Code and recommended voltage-drop requirements. Obviously, any conductor selected for a specific installation must fulfill the requirements of mechanical strength, ample carrying capacity, and recommended voltage drop. Frequently one of these three considerations will definitely determine the size of the conductor; however, a calculation may show that the resistance or I^2R (power) loss is excessive. Then it may be desirable to use a larger size of conductor than would otherwise be necessary.

83. Annual charges may be considered, in connection with the economical selection of a conductor size, as being made up of two items, *resistance-loss charges* and *investment charges*. Resistance-loss charges depend upon the resistance, the current, and the unit cost of energy and can be decreased by an increase of conductor size. This, however, calls for a greater investment with corresponding larger investment charges. A conductor should, for maximum economy, be selected of such a size that the total annual charge will be a minimum. In Fig. 3.33 the effect of a variation of conductor size on resistance-loss charge, investment charge, and total annual charge is shown graphically for wires not installed in race-ways. The interest charges on the conductor increase directly with its cross-sectional area (curve A, Fig. 3.33). If the wires were installed in conduit, the cost of the conduit and fittings should be added to the conductor cost. The resistance-loss charges decrease inversely as the cross-sectional area of the conductor (curve B, Fig. 3.33). The total annual charge (curve C, Fig. 3.33), the sum of curves A and B, is at its minimum value directly over the point where curves A and B intersect. That is, the conductor size which will have the least total annual cost is the one for which the annual interest charge equals the annual resistance-loss charge. This proposition was demonstrated by Lord Kelvin.

FIGURE 3.33 Graph illustrating Kelvin's law.

84. Kelvin's law was deduced in 1881 by Sir William Thomson (Lord Kelvin). The original law was modified into the following more exact form by Gisbert Kapp: "The most economical area of conductor is that for which the annual cost of energy wasted is equal to the interest on that portion of the capital outlay which can be considered proportional to the weight of copper used." On the basis of the above law it can be shown that

$$\text{cmil} = 55,867 \times I \times \sqrt{\frac{C_e}{C_c \times A}} \tag{29}$$

where cmil = area, in circular mils, of the most economical conductor; I = the mean annual current; C_e = cost of energy per kilowatt-hour, in dollars; C_c = cost of copper, in dollars, per pound installed; and A = annual charge, in percentage, of the cost of the conductor. This can ordinarily be assumed to be about 10 percent.

¹For derivation see *The Electrical Engineer's Pocketbook* (International Textbook Company). See also A. V. Abbot, *Transmission of Electrical Energy*; Louis Bell, *Electric Power Transmission*; Alfred E. Still, *Overhead Electric Power Transmission*.

Note that the length of the circuit is not a factor in the equation. The above equation is best adapted to the solution of cases in which the conductors are not insulated. The method of the following paragraph should always be used to check it.

85. Method of determining economical conductor size. This method involves the preparation of a table, as shown below, showing energy cost and interest cost of an arbitrarily chosen length of conductor for a number of sizes of conductor. The cost per unit length of conductors (preferably 1000 ft, or 305 m) can be obtained from the manufacturers' wire lists. For conduit installations the corresponding cost of conduit and fittings should be added to the cost of conductors. The cost of energy lost can be computed from the equations of Sec. 86 or from Sec. 87. By use of a comparative table, as given below, costs are effectively shown and a decision can be speedily reached. This method can be used as a check upon the Kelvin's-law equation. In the table the least total annual cost is \$15.69. Hence a 4/0 conductor is, for this case, the one of maximum economy.

Size of rubber-covered conductor	3/0 AWG wire	4/0 AWG wire	250,000-cir-mil wire	300,000-cir-mil
Cost of 400 ft of conductor	\$100.00	\$120.00	\$160.00	\$200.00
Annual charges on above cost at 10 percent	\$ 10.00	\$ 12.00	\$ 16.00	\$ 20.00
Cost of energy lost in conductor at 2 cts per kwh	\$ 5.94	\$ 3.69	\$ 2.64	\$ 2.27
Total annual cost of conductor	\$ 15.94	\$ 15.69	\$ 18.64	\$ 22.27

86. Cost of energy lost. If we take 12Ω as the resistance of a circular mil-foot of commercial copper wire at 50°C , the power loss in any conductor can be found thus:

$$P = \frac{12 \times I^2 \times L}{\text{cmil}} \quad (30)$$

where p = power lost in the conductor in watts, I = the mean annual current in amperes in the conductor, L = length of the conductor in feet, and cmil = area of the conductor in circular mils.

The cost of energy lost can be computed from the following formula:

$$\text{Cost of energy per year in dollars} = \frac{N \times P \times 8760 \times R}{1000 \times 100} \quad (31)$$

where N = number of conductors; P = power loss in one conductor; and R = cost of electric energy in cents per kilowatthour. In the formula, the 8760 is the number of hours in a year, the 1000 is the factor to change watts to kilowatts, and the 100 changes cents to dollars.

87. Cost of Energy Lost for 500 H of Operation with Cost of Electrical Energy at 2 Cents per Kilowatthour

Wire size, AWG	Length of run, ft	Load, amp													
		6	10	15	20	25	30	35	40	50	60	70	80	90	100

$$\text{Cost of energy lost per year in dollars} = \frac{H \times R \times K}{500 \times 2} \tag{32}$$

where H = hours of operation of circuit per year; R = cost of electrical energy in cents per kilowatthour; K = dollars as obtained from table for size of wire, current, and length of run.

The table and formula can be used for dc or single-phase ac circuits. If the load on a three-wire dc or single-phase ac circuit is nearly balanced, the formula will give satisfactory results if the current is taken as the current in the more heavily loaded wire.

88. Factors for determining the mean annual current. To ascertain the mean annual current for substitution in the Kelvin's-law equation (29) or in Eq. (30) of Sec. 86 multiply the maximum current by the ratio applying to the conditions under consideration, which is given in the column headed "Factor" in the following table. The table is calculated on the basis $24 \text{ h} \times 365 \text{ days} = 8670 \text{ h}$ per year.

EXAMPLE If a maximum current of 1000 A (I) flows three-fourths of the time, or 6570 h per year, and a current of 750 A ($3/4I$) flows one-fourth of the time, or 2190 h per year, the factor 0.944 would be used. That is, $0.944 \times 1000 \text{ A} = 944 \text{ A} =$ mean annual current for substitution in Kelvin's-law equation.

	Proportion of maximum current I carried				Factor
	$1/4I$	$1/2I$	$3/4I$	I	
Proportion of time current is carried	0	0	0	1	1.000
	0	0	$1/4$	$3/4$	0.944
	0	$1/4$	0	$3/4$	0.901
	0	0	$1/2$	$1/2$	0.844
	0	0	0	$3/4$	0.866
	$1/4$	0	0	$3/4$	0.875
	0	$1/4$	$1/4$	$1/2$	0.838
	0	0	$3/4$	$1/4$	0.820
	$1/4$	0	$1/4$	$1/2$	0.810
	0	$1/2$	0	$1/2$	0.790
	0	$1/4$	$1/2$	$1/4$	0.771

NEC AMPACITY RULES FOR CONDUCTORS

89. NEC rules for the ends of a wire differ from those for the middle. (Adapted from *Practical Electrical Wiring*, 20th edition, © Park Publishing, 2008, all rights reserved). The key to applying these rules, and the new NEC Example D3(a) in Annex D on this topic is to remember that the end of a wire is different from its middle. Special rules apply to calculating wire sizes based on how the terminations are expected to function. Entirely different rules aim at assuring that wires, over their length, don't overheat under prevailing loading and conditions of use. These two sets of rules have nothing to do with each other—they are based on entirely different thermodynamic considerations. Some of the calculations use, purely by coincidence, identical multiplying factors. Sometimes it is the termination requirements that produce the largest wire, and sometimes it is the requirements to prevent conductor overheating. You can't tell until you complete all the calculations and then make a comparison. Until you are accustomed to doing these calculations, do them on separate pieces of paper.

90. Current is always related to heat. Every conductor has some resistance and as you increase the current, you increase the amount of heat, all other things being equal. In fact, as is covered in Sec. 110 of Div. 1 and elsewhere, you increase the heat by the square of the current. The ampacity tables in the NEC reflect heating in another way. As the reproduction of NEC Table 310.16 (see Table 18 in Div. 12) shows, the tables tell you how much current you can safely (meaning without overheating the insulation) *and continuously* draw through a conductor under the prevailing conditions—which is essentially the definition of ampacity in NEC Article 100: *The current in amperes that a conductor can carry continuously under the conditions of use without exceeding its temperature rating.*

91. Ampacity tables show how conductors respond to heat. The ampacity tables (such as Table 18 in Div. 1) do much more than what is described in the previous paragraph. *They show, by implication, a current value below which a wire will run at or below a certain temperature limit.* Remember, conductor heating comes from current flowing through metal arranged in a specified geometry (generally, a long flexible cylinder of specified diameter and metallic content). In other words, for the purposes of thinking about how hot a wire is going to be running, you can ignore the different insulation styles. As a learning tool, let's make this into a "rule" and then see how the NEC makes use of it:

A conductor, regardless of its insulation type, runs at or below the temperature limit indicated in an ampacity column when, after adjustment for the conditions of use, it is carrying equal or less current than the ampacity limit in that column.

For example, a 90°C THHN 10 AWG conductor has an ampacity of 40 amps. Our "rule" tells us that when 10 AWG copper conductors carry 40 amps under normal-use conditions, they will reach a worst-case, steady-state temperature of 90°C just below the insulation. Meanwhile, the ampacity definition tells us that no matter how long this temperature continues, it won't damage the wire. That's not true of the device, however. If a wire on a wiring device gets too hot for too long, it could lead to loss of temper of the metal parts inside, cause instability of nonmetallic parts, and result in unreliable performance of over-current devices due to calibration shift.

92. Termination rules protect devices. Because of the risk to devices from overheating, manufacturers set temperature limits for the conductors you put on their terminals. Consider that a metal-to-metal connection that is sound in the electrical sense probably conducts heat as efficiently as it conducts current. If you terminate a 90°C conductor on a circuit breaker, and the conductor reaches 90°C (almost the boiling point of water), the inside of the breaker won't be much below that temperature. Expecting that breaker to perform reliably with even a 75°C heat source bolted to it is expecting a lot.

Testing laboratories take into account the vulnerability of devices to overheating, and there have been listing restrictions for many, many years to prevent use of wires that would cause device overheating. These restrictions now appear in the NEC. Smaller devices (generally 100 amp and lower, or with termination provisions for 1 AWG or smaller wire) historically weren't assumed to operate with wires rated over 60°C such as TW. Higher-rated equipment assumed 75°C conductors but generally no higher for 600-volt equipment and below. This is still true today for the larger equipment. (Note that medium-voltage equipment, over 600 volts, has larger internal spacings and the usual allowance is for 90°C, but that equipment will not be further considered at this point.) Today, smaller equipment increasingly has a "60/75°C" rating, which means it will function properly even where the conductors are sized based on the 75°C column of Table 18, Div. 1.

Figure 3.34 shows a "60/75°C" marking on a 20-amp circuit breaker, which means it can be used with 75°C conductors, or with 90°C conductors used under the 75°C ampacity

FIGURE 3.34 A 20-A circuit breaker marked as acceptable for 75°C terminations.

column. Both the panelboard and the device at the other end of the wire must make the same allowance for a 75°C temperature assumption to be acceptable. Otherwise the 60°C column applies.

In the case of a circuit breaker, using the allowance for 75°C terminations requires that both the CB as well as its enclosing panelboard carry this designation. Always remember, though, that wires have two ends. Successfully using the smaller (higher ampacity) wires requires equivalent markings on both the circuit breaker and panelboard (or fused switch) and the device at the other end. Refer to Fig. 3.35 for an example of this principle at work.

FIGURE 3.35 Always consider both ends of a wire when making termination temperature evaluations.

93. Splices are terminations. Not all terminations occur on electrical devices or utilization equipment. Some terminations occur in the middle of a run where one conductor is joined to another. The same issue arises when we make a field connection to a busbar that runs between equipment. Busbars, usually rectangular in cross section, are often used to substitute for conventional wire in applications involving very heavy current demands. When

you make a connection to one of these busbars (as distinct from a busbar within a panel), or from one wire to another, you only have to be concerned about the temperature rating of the compression connectors or other splicing means involved. Watch for a mark such as “AL9CU” on the lug. This one means you can use it on either aluminum or copper conductors, at up to 90°C, but only where the lug is “separately installed” (NEC text).

Lug temperature markings usually mean less than they appear to mean. Many contactors, panelboards, etc., have termination lugs marked to indicate a 90°C acceptance. Ignore those markings because the lugs aren’t “separately installed.” Apply the normal termination rules for this kind of equipment. What’s happening here is that the equipment manufacturer is buying lugs from another manufacturer who doesn’t want to run two production lines for the same product. The lug you field install on a busbar, and use safely at 90°C, also works when furnished by your contactor’s OEM. But on a contactor you don’t want the lug running that hot. The lug won’t be damaged at 90°C, but the equipment it is bolted to won’t work properly.

94. Protecting devices under continuous loads. The NEC defines a continuous load as one that continues for 3 hours or longer. Most residential loads aren’t continuous, but many commercial and industrial loads are. Consider, for example, the banks of fluorescent lighting in a store. Not many stores always stay open less than 3 hours at a time. Although continuous loading doesn’t affect the ampacity of a wire (defined, as we’ve seen, as a continuous current-carrying capacity), it has a major impact on electrical devices. Just as a device will be affected mechanically by a heat source bolted to it, it also is affected mechanically when current near its load rating passes through it continuously. To prevent unremitting thermal stress on a device from affecting its operating characteristics, the NEC restricts the connected load to not more than 80% of the circuit rating. The reciprocal of 80% is 125%, and you’ll see the restriction stated both ways. Restricting the continuous portion of a load to 80% of the device rating means the same thing as saying the device has to be rated 125% of the continuous portion of the load. If you have both continuous and noncontinuous load on the same circuit, take the continuous portion at 125%, and then add the noncontinuous portion. The result must not exceed the circuit rating.

EXAMPLE Suppose, for example, a load consists of 51 amps of noncontinuous load and 68 amps of continuous load (119 amps total). Calculate the minimum capacity we need to allow for our connected equipment as follows:

$$\text{Step 1: } 51 \text{ A} \times 1.00 = 51 \text{ A}$$

$$\text{Step 2: } 68 \text{ A} \times 1.25 = 85 \text{ A}$$

$$\text{Step 3: Minimum} = 136 \text{ A}$$

Note that this is also the profile used in Example D3(a) of Annex D of the NEC. This discussion has been arranged to track this NEC coverage.

A device such as a circuit breaker that will carry this load profile must be rated no less than 136 amps, even though only 119 amps actually passes through the device. In the case of overcurrent protective devices, the next higher standard size would be 150 amps. In general, for overcurrent protective devices not over 800 amps, the NEC allows you to round upward to the next higher standard overcurrent device size. In this case, suppose a standard wire size had an ampacity of 140 amps (there doesn’t happen to be one, but this is only for discussion). The NEC normally allows a 150-amp fuse or circuit breaker to protect such a conductor.

Having gone this far, it’s easy to make two mistakes at this point. First, although you can round up in terms of the overcurrent device rating, you can’t round up in terms of

conductor loading, not even 1 ampere. Number 1 AWG conductors in the 75°C column can carry 130 amps. If your actual load runs at 131 amps, you have to use a larger wire. Second, when continuous loads are a factor, you have to build in additional headroom on the conductor sizes to ensure that the connected devices perform properly. This last point continually results in confusion because it may seem to contradict what was said about conductor ampacity tending to be the factor that determines minimum wire size.

In our work we handle conductors, and we worry about conductors getting overheated. Device manufacturers don't worry about conductors in this sense; they worry about their devices getting overheated and not performing properly. Continuous loads pose real challenges in terms of heat dissipation from the inside of mechanical equipment. Remember that when you bolt a conductor to a device, the two become one in the mechanical as well as the electrical sense. Device manufacturers rely on those conductors as a heat sink, particularly under continuous loading. The NEC allows for this by requiring conductors carrying continuous loads to be oversized according to the same formula that applies to the device, namely, an additional 25% of the continuous portion of the load.

EXAMPLE Our 10 AWG THHN conductor, for example, will carry 40 amps for a month at a time without damage to itself. But under those conditions the conductor would represent a continuous 90°C heat source. Now watch what happens when we (1) size the conductor *for termination purposes* at 125% of the continuous portion of the load, and (2) use the 75°C column for the analysis. This calculation assumes the termination is rated for 75°C instead of the default value of 60°C:

Step 1: $1.25 \times 40 \text{ A} = 50 \text{ A}$

Step 2: Table 310.16 at 75°C = 8 AWG

We go from a 10 AWG conductor to an 8 AWG conductor (6 AWG if the equipment doesn't have the allowance for 75°C terminations). Now that is just one customary wire size, but look at it from the device manufacturer's perspective. Number 10 AWG carrying 40 amps continuously is a continuous 90°C heating load. What about the 8 AWG? Use the ampacity table in reverse, according to our "rule." Forty amps happens to be the ampacity of an 8 AWG, 60°C conductor. Therefore, any 8 AWG wire (THHN or otherwise) won't exceed 60°C when its load doesn't exceed 40 amps. By going up just one wire size, the termination temperature dropped from 90°C to 60°C. The NEC allows manufacturers to count on this headroom.

To recap, if you have a 40-amp continuous load, the circuit breaker must be sized at least at 125% of this value, or 50 amps. In addition, the conductor must be sized to carry this same value of current *based on the 75°C ampacity column (or 60°C if not evaluated for 75°C)*. The manufacturer and testing laboratory count on a relatively cool conductor to function as a heat sink for heat generated within the device under these continuous operating conditions.

In the feeder example, including the 125% on the continuous portion of the load brings us to a 136-amp conductor, and the next larger one in the 75°C column is a 1/0. Remember to use the 75°C column here because the 150-amp device exceeds the 100-amp threshold (below which the rating is assumed to be 60°C). Remember, only 119 amps (68 amps + 51 amps) of current actually flows through these devices. The extra 17 amps (the difference between 119 amps and 136 amps) is phantom load. You include it only so your final conductor selection is certain to run cool enough to allow it to operate in accordance with the assumptions made in the various device product standards.

There are devices manufactured and listed to carry 100% of their rating continuously, and the NEC recognizes their use in exceptions. Typically these applications involve very large

circuit breaker frame sizes in the 600-amp range (although the trip units can be smaller). Additional restrictions accompany these products, such as on the number that can be used in a single enclosure and on the minimum temperature rating requirements for conductors connected to them. Learn how to install conventional devices first, and then apply these 100%-rated devices if you run across them, making sure to apply all installation restrictions covered in the directions that come with this equipment. The warning about wires having two ends applies here with special urgency; be aware that one of these devices at one end of a circuit doesn't imply anything about the suitability of equipment at the other end.

95. Grounded conductors have a special allowance. The 2008 NEC includes exceptions for both feeder and branch-circuit grounded conductors that allow them to be excluded from the upsizing requirement for continuously loaded wiring, provided they do not terminate on an overcurrent device. This is appropriate for feeder conductors that run from busbar to busbar and have no relevance as a heat sink for a connected device. This is more questionable for a branch circuit where a grounded conductor originating on a busbar arrives at a receptacle or other comparable device. The device manufacturer may not have assumed that the grounded conductor could be smaller than the ungrounded conductors, particularly in two-wire or three-phase corner-grounded applications where it will carry identical current as the ungrounded conductors and terminate in the same manner. Although the branch-circuit exception is in print [at 210.19(A)(1) Exception No. 2] the safest course for now is to ignore this exception on branch circuits and only apply it to feeder conductors [see 215.2(A)(1) Exception No. 2] that run between busbars.

96. The middle of a wire—preventing conductors from overheating. None of the preceding discussion has anything to do with preventing a conductor from overheating. That's right. All we've done is to be sure the device works as the manufacturer and the test lab anticipate in terms of the terminations. Now we have to be sure the conductor doesn't overheat. Again, ampacity is by definition a continuous capability. *The heating characteristics of a device at the end of the run don't have any bearing on what happens in the bowels of a raceway or cable assembly.*

To reiterate, you have to compartmentalize your thinking at this point. We just covered the end of the wire; now we'll get to the middle of the wire. Remember being asked to do these on separate pieces of paper? Lock the first one up, and forget everything you just calculated. It has absolutely no bearing on what comes next. Only after you've made the next series of calculations should you retrieve the first sheet of paper. And only then should you go back and see which result represents the worst case and therefore governs your conductor choice.

If you have trouble making this distinction, and many do, apply an imaginary pull box at each end of the run (Fig. 3-36). Actually, with the cost of copper near historic highs, the imaginary pull boxes are becoming real. One large contractor, faced with installing a 300 ft triple run of Type MC cable for a 1200-A feeder, installed three sets of 500 kcmil cable made up with 90°C THHN (ampacity = 1290 A) between pull boxes at each end. From each pull box he extended 600 kcmil conductors into the device terminations (75°C ampacity = 1260 A). The savings in copper more than paid for the labor and materials expense of providing the pull boxes.

To begin this part of the analysis, review the ampacity definition. Conductor ampacity is its current-carrying capacity *under the conditions of use*. For NEC purposes, two field conditions affect ampacity, and they are mutual heating and ambient temperature. Either or both may apply to any electrical installation. Both of these factors reduce ampacities from the table numbers.

FIGURE 3.36 These imaginary pull boxes at each end of the run illustrate how to separate raceway/cable heating calculations from termination calculations.

97. Mutual conductor heating. A conductor under load dissipates its heat through its surface into the surrounding air; if something slows or prevents the rate of heat dissipation, the temperature of the wire increases, possibly to the point of damage. The more current-carrying conductors there are in the same raceway or cable assembly, the lower the efficiency with which they can dissipate their heat. To cover this mutual heating effect, the NEC imposes derating penalties on table ampacity values. Penalties increase with the number of current-carrying conductors in a raceway or cable assembly. NEC Table 310.15(B)(2)(a) (reproduced in Sec. 17 of Div. 12) limits the permissible load by giving derating factors that apply to table ampacities. For example, if the number of wires exceeds three but is fewer than seven, the ampacity is only 80% of the table value; if the number exceeds six but is fewer than 11, 70%; more than ten but fewer than 21, 50%, and so on. However, if the raceway is not over 24 in. long (classified as a nipple), the NEC assumes heat will escape from the ends of the raceway and the enclosed conductors need not have their ampacity derated.

Count only current-carrying conductors for derating calculations. Grounding conductors as covered in Sec. 340 of Div. 9 are never counted. A neutral wire that carries only the unbalanced current of a circuit (such as the neutral wire of a three-wire single-phase circuit, or of a four-wire three-phase circuit) is not counted for derating purposes in some cases. But remember: Grounded wires are not always neutrals. (Grounded wires are covered in Sec. 345 of Div. 9 and elsewhere; suffice it to say for now that in most modern systems one conductor is deliberately connected to ground, and neutrals are almost always grounded.) The grounded (“white”) wire of a three-wire corner-grounded delta power circuit is a phase conductor carrying the same current as the two ungrounded phase conductors and is *not* a neutral. It must be counted for derating purposes.

98. How (and when) to count neutrals. Although neutral conductors are counted for derating purposes only if they are actually current carrying, it is increasingly common

in commercial distribution systems derived from three-phase, four-wire, wye-connected transformers to find very heavily loaded neutrals. If the circuit supplies mostly electric-discharge lighting (fluorescent, mercury, and similar types discussed in Div. 10), you must always count the neutral. In such circuits, the neutral carries a “third harmonic” or 180-Hz current produced by such luminaires. The explanation of why such luminaires produce such a 180-Hz current is beyond the scope of this book, although it is partially covered at the end of Div. 1. But be aware that the neutrals of such circuits or feeders must be counted because those harmonic currents add together in the neutral instead of canceling out, and therefore require derating.

In addition, harmonic currents from other nonlinear loads often add instead of canceling in three-phase, four-wire, wye-connected neutrals as well. In fact, there are conditions where such loads cause the neutral to carry *more load* than the ungrounded conductors. There are now Type MC cable assemblies manufactured with oversized neutral conductors to address this problem. Finally, any time you run just two of the three-phase conductors of a three-phase, four-wire system together with the system neutral, that neutral always carries approximately the same load as the ungrounded conductors and must always be counted. This arrangement is very common on large apartment buildings where the feeder to each apartment consists of two-phase wires along with a neutral, but the overall service is three-phase, four-wire.

99. How (and when) to count control wires. Many types of control wires, such as motor control wires and similar wires that carry only intermittent or insignificant amounts of current need not be counted, provided the continuous control current does not exceed 10% of the conductor ampacity. For example, a motor starter with a 120-volt coil might require 100 VA to operate, or less than 1 amp. Since that is an intermittent load, and in any event it is less than 10% of the ampacity of 14 AWG, you could use 14 AWG wires for this control circuit and run them in the same raceway as the power wires without counting them for derating purposes. Since derating applies to every current-carrying wire in the conduit, for a typical three-wire control circuit this special allowance has a major impact on the ampacity of those power wires. For a normal three-phase motor circuit running in the same conduit, it allows the power wires to be counted at 100% of their table value instead of 80%.

100. Conductor ampacity derating. Now that you know how to count the number of current-carrying wires in a conduit, it's time to learn how to apply NEC rules to the result. Using the NEC directly means going from the ampacity table to the derating factor (by which you multiply), and comparing the result to the load. That's great for the inspector who checks your work, but it doesn't help you pick the right conductor in the first place. You want to go the other way: Knowing the load, you want to select the proper conductor. Consider the first example in Sec. 94, using a feeder with 51 amps of noncontinuous load and 68 amps of continuous load.

Suppose you have two of those feeders supplying identical load profiles and run in the same conduit. That would be (as previously noted we are counting the neutrals) eight current-carrying conductors in the raceway. *For this part of the analysis, ignore continuous loading and termination problems.* Remember, you should be using a fresh sheet of paper for this calculation.

Start with 119 amps of actual load (51 amps + 68 amps), and *divide* (you're going the other direction, so you use the opposite of multiplication) by 0.7 [the factor in NEC Table 310.15(B)(2)(a) and Sec. 17 of Div. 12], to get 170 amps in this case. In other words, any conductor with a table ampacity that equals or exceeds 170 amps will mathematically be

guaranteed to carry the 119-amp load safely. A 1/0 AWG THHN conductor, with an ampacity of 170 amps, will carry this load safely under the conditions of use, and it might appear to work. Whether it represents your final choice depends on the outcome of the analysis explained in the later topic on choosing a conductor.

101. Ambient temperature problems. High ambient temperatures hinder the dissipation of conductor heat just as in the case of mutual heating. To prevent overheating, the NEC provides ambient temperature derating factors at the bottom of the ampacity tables. Suppose, for example, circuit conductors go through a 35°C ambient. Their ampacity goes down (for 90°C conductors) to 96% of the base number in the ampacity table. Here again, start with 119 amps, and *divide* by the 0.96 to get 124 amps. Any 90°C conductor with an ampacity equal to or higher than 124 amps would carry this load safely. What happens if you have *both* a high ambient temperature *and* mutual heating? Divide twice, once by each factor. In this case:

$$119 \div 0.7 \div 0.96 = 177 \text{ A}$$

A 2/0 AWG THHN conductor (ampacity = 195 amps) would carry this load without damaging itself. Again, this would be true whether or not the load was continuous, and whether or not the devices were allowed for use with 90°C terminations. Don't cheat; the termination calculations are still supposed to be locked up in another drawer.

102. When diminished ampacity applies to only a small part of the run. You will run into installations where most of a circuit conforms to NEC Table 310.16 but a small portion requires very significant derating. For example as illustrated in Fig. 3.37, your circuit may be 207 ft long, with 200 ft in normal environments and 7 ft of it passing through a corner of a boiler room with a very high ambient temperature. The NEC generally observes the weak-link-in-the-chain principle and requires the lowest ampacity anywhere over a run to be the allowed ampacity. However, for very short runs where the remainder of the circuit can function as a heat sink, the NEC allows the higher ampacity to be used.

Specifically, any time ampacity changes over a run, determine all points of transition. On one side of each point the ampacity will be higher than on the other side. Now measure

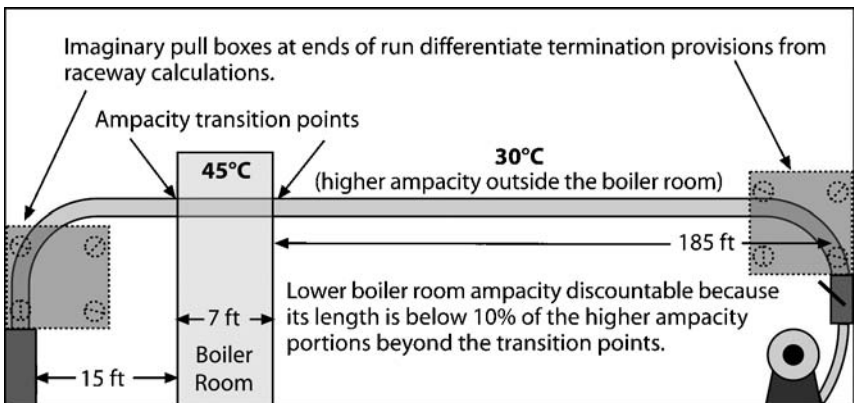

FIGURE 3.37 There is a limited exception to the weak link in the chain principle.

the length of the wire having the higher ampacity (in this example, the portions *not in* the boiler room) and the length having the lower ampacity (in this example, *in* the boiler room). Compare the two lengths. NEC 310.15(A)(2) Exception allows you to use the higher ampacity value beyond the transition point for a length equal to 10 ft or 10% of the circuit length having the higher ampacity, whichever is less.

In this case of the 200-ft run beyond the 7 ft in the boiler room, 10% of the circuit length having the higher ampacity would be 20 ft, but you can't apply the rule to anything over 10 ft. Since 7 ft is less than or equal to 10 ft (and less than the 10% limit of 20 ft), the exception applies and you can ignore the ambient temperature in the boiler room in determining the allowable ampacity of the wires passing through it. In the words of the exception, the "higher ampacity" (which applies to the run outside the boiler room) can be used beyond the transition point (the boiler room wall) for "a distance equal to 10 ft or 10% of the length figured at the higher ampacity, whichever is less."

103. Choosing a conductor. Now you can unlock the drawer and pull out the termination calculations. Put both sheets of paper in front of you, and design for the worst case by installing the largest conductor that results from those two independent calculations. The termination calculation (Sec. 94) came out needing conductors sized, under the 75°C column, no less than 136 amps even though the actual load was only 119 amps. You could use 1/0, either THHN or THW.

Suppose you put two feeders (eight conductors) in a conduit, as in Sec. 100. The termination calculation comes out 1/0, and as we've seen, the raceway derating calculation also comes out 1/0 AWG THHN. Here, the termination rules happen to agree with the raceway analysis. If the same raceway also goes through the area with high ambient temperature, however, you will need 2/0 THHN. Now the raceway conditions are limiting and you size accordingly. Section 100 shows the calculations under both conditions. Finally, suppose for a moment that the neutrals do not carry heavy harmonic loading and therefore need not be counted, and suppose the ambient temperature does not exceed 30°C. With only six current-carrying conductors, the derating factor drops to 0.8, so the required ampacity becomes $119\text{A}/0.8 = 149\text{ A}$, seemingly allowing 1 AWG THHN (90°C) conductors. Now the termination rules (mandating a 75°C temperature evaluation) would be the worst case and would govern the conductor selection process.

Remember, the terminations and the conductor ampacity are two entirely separate issues. Just because you need to use the 75°C column for the terminations doesn't mean you start in that column to determine the overall conductor ampacity. Go ahead and make full use of the 90°C temperature limits on THHN, and its resulting ampacity, to solve derating problems.

Don't get confused by the fact that the derating factor for continuous loads (0.8) is the same as the one for four to six conductors in a raceway (0.8). This is only a coincidence. One applies to devices and terminal heating at the end of a conductor, and the other applies over the interior of the raceway. They never apply at the same point in a circuit because the technical basis for each is entirely different. The middle is never the end, so never apply the rules for one to the other. The calculations in this discussion illustrate this through different instances of similar connected loading. In one case the termination requirements force an increase in conductor size. In another case the termination requirements agree with the results of the ampacity calculations; and in yet another case the ampacity calculation forces you to use a larger conductor than what the termination rules would predict.

104. The conductor must always be protected. Don't lose sight of the fact that the overcurrent device must always protect the conductor. For 800-amp and smaller circuits, NEC 240.4(B) allows the next higher standard size overcurrent device to protect conductors.

Above that point, NEC 240.4(C) requires the conductor ampacity to be no less than the rating of the overcurrent device. As a final check, be sure the size of the overcurrent device selected to accommodate continuous loads protects the conductors in accordance with these rules; if it doesn't you will need to increase the conductor size accordingly. Refer to the discussion of noncontinuous loads, in Sec. 106 for an example of where, even after doing both the termination and the ampacity calculations, this consideration forces you to change the result.

105. Small conductors. Small conductors (14, 12, and 10 AWG) present an additional wrinkle. The NEC imposes special limitations on overcurrent protection beyond the values in the ampacity tables for these small wires. Generally, the overcurrent protective device for 14 AWG wire can't exceed 15 amps; for 12 AWG wire, 20 amps; for 10 AWG wire, 30 amps. The higher ampacities of these conductors remain what the table says they are, however, and there are cases, notably including motor circuits, where this restriction doesn't apply. In general, perform all ampacity calculations as described previously, based on the ampacity table limits. But at the very end, make sure your overcurrent device doesn't exceed these specific ampere limits unless you fall into one of the exceptions specifically tabulated in NEC 240.4(G).

106. Noncontinuous loads. Suppose none of the load is continuous on our 150-amp feeder in Sec. 94, and suppose the character of the load on the neutrals does not require them to be classified as current-carrying conductors. Looking at the two feeders in Sec. 100, suppose the ambient temperature doesn't exceed 30°C. The termination need not include any phantom load allowance, but it still needs to assume 75°C termination restrictions. A 1 AWG conductor will carry the actual 119-amp load without exceeding 75°C, and therefore would seem to be usable until you consider the mutual effects of multiple conductors in the common raceway. Suppose you went to a 1 AWG THHN conductor, ampacity 150. Will it carry the 119-amp load safely? Yes, because $150 \text{ A} \times 0.8$ (the derating factor for six conductors) = 120 A. Will it overheat the breaker terminations? No, because 1 AWG copper is 1 AWG copper no matter what insulation style it has around it, and it won't rise to 75°C until it carries 130 amps. But its final derated ampacity within the conduit is 120 amps. The next higher standard-sized overcurrent device is 125 amps. The 150-amp breaker does not protect this wire under these conditions of use, and has to be reduced to 125 amps, or else you need to increase the wire size to 1/0 AWG.

107. Neutral sizing. As noted previously this example provided the basis for what is now Example D3(a) in NEC Annex D. The NEC example also calculates neutral sizing, based on a worst-case-scenario continuous neutral load of 42A. The D3(a) example notes that this wire runs busbar to busbar and does not require upsizing by 25% (see "Grounded conductors have a special allowance" in Sec. 95), leading to a preliminary size of 8 AWG under the 75°C column. However, this size would be inadequate to clear a line-to-neutral short circuit because 8 AWG is smaller than the minimum equipment grounding conductor that could be installed on a 150-A feeder as covered in NEC 250.122 and in Table 339 in Div. 9. Therefore, the minimum size becomes 6 AWG, as required in NEC 215.2(A)(1) (second paragraph).

There is another issue to be addressed at this point, and it will require interpretation on the part of the authority having jurisdiction until the NEC is clarified. NEC 250.122(B) requires that if ungrounded conductors are increased in size, a proportional increase must

be made in the size of the equipment grounding conductor. The size of the ungrounded conductors determined in this part of Div. 3 (in some cases as large as 2/0 AWG copper) are the smallest size allowed by the NEC under the specified conditions. No increase for voltage drop or other design consideration has been made. On the other hand, such sizes are larger than the sizes specified in NEC Table 310.16 and Table 18 in Div. 12. The historical context for the rule addressed instances where increases to lower voltage drop implied a similar benefit for a long equipment grounding conductor. The substantiation for the change pointed to instances where designers would ignore the rule by simply stating that the increase was for design reasons unrelated to voltage drop. None of this has anything to do with an increase to meet minimum NEC requirements, even on a feeder that is only 10 ft long. NEC Example D3(a) does not make this increase, but the issue is likely to be reviewed in a forthcoming edition of the NEC.

In the event that the rule is applied literally and to any increases beyond NEC Table 310.16 for whatever reason, then perform the following calculation, where “CSA” means “cross-sectional area” and “EGC” means “equipment grounding conductor”:

$$\begin{aligned} \text{New EGC CSA} &= \frac{\text{ungrounded conductor CSA} \times \text{base EGC CSA}}{\text{CSA of base ungrounded conductors from table}} & (33) \\ \text{New EGC CSA} &= \frac{(2/0 \text{ AWG} = 133,100 \text{ cmil}) \times (6 \text{ AWG} = 26,240 \text{ cmil})}{(1 \text{ AWG} = 83,690 \text{ cmil})} \\ &= (41,740 \text{ cmil} = 4 \text{ AWG}) \end{aligned}$$

The conductor cross-sectional areas are from Chapter 9, Table 8 of the NEC, which is included in Div. 12 as Table 57. The minimum equipment grounding conductor under this interpretation, and therefore the minimum neutral conductor per NEC 215.2(A)(1) second paragraph, would be 4 AWG.

108. Wires in parallel. Instead of using a very large wire, NEC 310.4 permits two or more smaller wires to be connected in parallel for use as a single wire. There are seven conditions, all of which must be met. All the wires that are to be paralleled to form the equivalent of one larger wire must (1) be 1/0 AWG or larger; (2) be of the same material (all copper, all aluminum, all copper-clad aluminum, etc.); (3) have precisely the same length; (4) have the same cross-sectional area in circular mils; (5) have the same type of insulation; (6) be terminated in the same manner (same type of lug or terminal on all); and (7) be arranged so the same number of conductors run in each paralleled raceway or cable, each of which must have the same electrical characteristics.

109. Keep the wires to be paralleled as equal as possible. The seven conditions noted in the previous paragraph must be met as exactly as possible. A very slight difference in length, for example, produces a slight difference in resistance and therefore impedance. Even slight differences in impedance can cause very significant inequalities in the way current divides between the conductors in the parallel circuit. Any inequality in current division is a potential hazard because paralleled runs don't, by definition, have individual overcurrent protection on each conductor. Consider a 500-amp parallel make-up with two legs sized for 250 amps each. If one of the legs carries 300 amps and the other 200 amps, the overloaded leg will burn up without any immediate response from the overcurrent device.

It is a wise practice to cut all paralleled conductors of any given phase at the same time, prior to installation, when they can be laid out and cut to exactly the same length. (Note that

Phase A wires can be longer than Phase B, etc., as long as all wires comprising any given phase have the same characteristics.) Consider leaving them long enough to loop at terminations if the enclosure is large enough. Then, after pulling them into the conduits, each loop can be adjusted in size easily to take up any additional length resulting from the geometry of the paralleled run and the position of the terminals relative to the conduit entry point. If you must cut a conductor, measure the amount that you cut and then trim the others to the same length.

As an example of a practical application of paralleled circuiting, consider a task of providing a three-wire circuit carrying 490 amps. According to NEC Table 310.16 (75°C column), you will need 800-kcmil wire. In place of each 800-kcmil wire, you can use two smaller wires each having half the required ampacity, or 245 amps. According to NEC Table 310.16, two 250-kcmil wires each with an ampacity of 255 would appear to be suitable.

But if you plan to run all six wires through one conduit, 250-kcmil wire is not suitable because you will have six wires in one conduit, and therefore must derate the wire's normal ampacity of 255 to 80%. The ampacity of the 250-kcmil wire then becomes 80% of 255, or 204. Use 350-kcmil wire with an ampacity of 80% of 310, or 248.

110. Use parallel raceways as well as wires. Instead of running all wires through one conduit as described in the previous paragraph, use two separate conduits with three wires in each (or instead of two conduits you may use three or even more conduits provided all the requirements outlined are met); then derating is not required and 250-kcmil wire is suitable. But note that the conduits or other raceways through which the wires run must have the same physical characteristics; all might be steel rigid conduit, or all might be EMT. It would not be permissible to use one steel and one aluminum conduit.

When running paralleled wires through a raceway, special care must be used to meet the requirements of NEC 300.20. One wire of each phase must be run through each conduit. See Fig. 3.38 which shows six wires in two conduits. Wires *A* and *a* are paralleled with each other, but they must not run together in the same conduit. Likewise wires *B* and *b* are paralleled, and again must not run in the same conduit. The same applies to *C* and *c*. If you ran, for example, *a*, *b*, and *B* in one conduit, and *c*, *A*, and *C* in the other, each conduit would contain wires of only two of the three phases. In that case considerable induced and eddy currents would be set up in the conduits themselves, resulting in excessive heating and power losses.

FIGURE 3.38 Where paralleled wires are run through conduit, each conduit must contain one wire from each phase. The installation shown does not include a neutral.

There is one common exception to the rule about running one of each of the phase conductors in each raceway. These are referred to as “isolated phase installations” in NEC 300.5(I) Exception 2. If you’re using nonmetallic raceways in an underground application, you can run all the *A* phase conductors in one conduit, all the *B* phase conductors in another, and so on. You have to be sure that when you enter the switchboard or other enclosure that you meet NEC 300.20, such as by providing a nonmetallic window through which all the conduits enter, preventing inductive reactance. Often these large installations enter a pit in

a concrete floor below the switchboard, for example, and having all of one phase together simplifies landing the conductors on their terminations. It also facilitates making all the conductors the same length.

The neutral wire of a feeder or circuit might often be smaller than the hot wires. If that is the case in your installation, the neutral also must be paralleled even if its ampacity is less than that of the hot wires, just so that their combined ampacity is equal to that which would be required if the neutral were not paralleled. But the 1/0 threshold still applies, and the paralleled neutrals cannot be reduced below that size. This is shown in Fig. 3.39 except that the neutral has been added, labeled *N* and *n*. If the wires are installed in a nonmetallic raceway, the raceway cannot serve as the equipment grounding conductor, and in that case an equipment grounding conductor must usually be installed in each raceway.

FIGURE 3.39 Same as Fig. 3.38 except a neutral has been added.

Conductors in parallel are quite common where using one wire would require a very large wire. The smaller wires have much higher ampacity per thousand circular mils than the larger one. Thus much less copper by weight is used when two smaller wires are paralleled to replace one larger one. The total installation cost is reduced. However, when you use two smaller wires in place of one larger wire, the combined circular-mil area of the two smaller wires will be less than that of one larger wire. That will result in a somewhat greater voltage drop than you would have using one wire of the larger size. If the circuit is long, you might have to increase the size of the paralleled wires to offset the difference in voltage drop.

111. Special rules for sizing grounding conductors in parallel make-ups. If you use separate grounding conductors for any reason, as in the case of rigid nonmetallic conduit, refer to the size of the overcurrent protective device and choose an equipment grounding conductor no smaller than required by NEC Table 250.122. Run this full-size grounding wire in each conduit. The NEC imposes this requirement because there are cases when a single such equipment grounding conductor will be called upon to return fault current contributed by all of the paralleled conductors of the faulted phase due to backfeed into a fault through the downstream connections. Note, however, that the 1/0 AWG threshold that normally applies to paralleled conductors does not apply to equipment grounding conductors. For example, if you run two nonmetallic conduits with 3/0 AWG THWN (200 amp) conductors in each for a 400-amp feeder, the equipment grounding conductor in each run must be at least 3 AWG (NEC Table 250.122). This is larger than the 6 AWG required for 200-amp circuits, but smaller than the 1/0 AWG minimum that applies to other paralleled wiring.

This rule also applies to cabled wiring methods run in parallel. Type MC cable is very commonly used in large feeders. Suppose you need to run a 600-amp feeder, and you decide to run two parallel 350-kcmil cables (75°C ampacity = 310 A each). Be sure you inspect the grounding conductor in the cable. The manufacturer probably assumed that his

350-kcmil cable would be used on a 300-amp circuit, and NEC Table 250.122 lists a 4 AWG equipment ground as adequate in such cases. Number 4 AWG is far below the 1 AWG required for 600-amp circuits. Each 350-kcmil cable run must include the 1 AWG grounding conductor. The proper cable is available, but usually only on special order.

112. Ampacities for large numbers of conductors in a common raceway.

[Adapted with permission from the *Engineers's Edition, Illustrated Changes in the 1999 National Electrical Code*, © 1998, Penton Business Media. All rights reserved.] The current edition of the NEC generally makes it prohibitive to install more than nine conductors in a raceway due to the prohibitive derating factors for mutual conductor heating (See Sec. 97) that take effect at that point. For example, just ten current-carrying conductors invoke a 50% derating factor, and the derating penalties get worse from there. However, there is an alternative, namely, Annex B, Sec. B.310.11. Access to Annex B is through engineering supervision, but if that is achievable, the old ampacity derating factors are revivable.

This table is almost the same table as the one the industry used under the old Note 8 for about 30 years, from the late 1950s to the late 1980s. Originally, this table was based on an assumption that when ten or more conductors were in a raceway, half of them were control circuits energized in the 1 to 2 A range. If all the conductors were, however, energized and supplying power loads, then the allowable currents had to be further decreased. To that effect, the 1987 NEC added a cautionary asterisk note stating that table factors were based on 50% diversity. Eventually the table was exiled to Annex B where it resides today, and Table 310.15(B)(2)(a) (in the main body of the Code) reflects the worst possible case of zero diversity on any of the wires. As a practical matter, that is not a realistic assumption.

The table differs from the one in Article 310 in its three break points over the nine-conductor fill level. Specifically, the next cut point is 10 to 24 conductors and the derating factor is 70%, followed by 25 to 42 conductors taken at 60%, and 43 to 85 conductors taken at 50%. These three levels are qualified by a note that indicates that they assume a "load diversity" of 50%. The purpose of this analysis is to make that statement usable so the table itself can be used easily.

113. Verification of table validity. The table comes with a fine print note that includes a formula that underlies the table and that can be used to deal with more complicated "real-world" diversity questions, such as all the conductors being energized, but carrying varying loads.

$$A_2 = \sqrt{\frac{0.5N}{E}} \times (A_1) \text{ or } A_1, \text{ or } A_1, \text{ whichever is less} \quad (34)$$

where

A_1 = ampacity from Table 310.16, etc., multiplied by the appropriate factor from Table B.310.11

N = total number of conductors used to obtain the multiplying factor from Table B. 310.11

E = desired number of conductors in the raceway or cable

A_2 = ampacity limit for the current-carrying conductors in the raceway or cable

For example, if twenty 12 AWG THHN conductors are involved having an ampacity (from Table 310-16) of 30 A, a diversity of 50% could mean only 10 are carrying current

at a particular time. From Table B.310.11, the derating factor (under engineering supervision) to be applied is 70%.

$$\text{Allowable ampacity} = 30 \text{ A times } 0.70 = 21 \text{ A}$$

Figuring the heating effect of the 10 conductors fully loaded to 21 A produces the following:

$I^2R = 10 \text{ times } 21^2 \text{ times } R = 4410 \text{ R}$ (R being the resistance per unit length of 12 AWG copper, which will be taken as a constant for these calculations).

Expressed in English, the formula says that the desired ampacity (A_2) is the square root of one half the ratio of the total number of current carrying conductors (N) to the number of energized conductors (E), all times the “old-fashioned” ampacity as calculated from Appendix B.310.11 (A_1).

Therefore, working from this formula, first calculate the “old-fashioned” ampacity (Table 310.16 ampacity times B.310.11 factor). In this case, that would be 30 A times 0.7 = 21 A. This is the number that goes into the formula as “ A_1 ”.

Then, the final ampacity is:

$$A_2 = \sqrt{[0.5N \div E]} \text{ times } A_1$$

$$A_2 = \sqrt{[0.5 \text{ times } (20 \div 20)]} \text{ times } 21 \text{ A}$$

$$= 0.71 \text{ times } 21 \text{ A} \approx 15 \text{ A}$$

The ratio between the developed ampacity here (15 A) and the Table 310.16 ampacity (30 A) is 50%; which is identical to that shown in Table 310.15(b)(2)(a) for a similar conductor fill, and the heating effect is:

$$I^2R = 20 \times 15^2 \times R = 4500 \text{ R}$$

The close agreement between the two results (4410 R vs. 4500 R) validates this approach and holds on other numbers of conductors in a raceway. This is no accident, since both Sec. 310.15(b)(2)(a) and the formula are based on the same laws of physics. The principle can be broadened to allow a qualified engineer to develop corrected ampacities under many other load conditions and numbers of conductors in a raceway or cable, as covered in the next section.

114. Applying the formula to general cases. The table footnote actually refers to a “load diversity” of 50%. This is not a defined term in the Code, and can refer to other circuit configurations than half fully on/half off. The overall approach is to first figure the limiting amount of heat $W = N(I^2R)$ that the conductors in the raceway to be evaluated will generate assuming a 50% diversity and using the adjustment factor in Table B.310.11. This sets the limit on the amount of heat that is allowable. If there are different size conductors involved, then begin with the 50% that will give the largest I^2R heating when loaded as allowed in the table.

The next step is to work backward and calculate the ampacity of the conductors under the actual conditions. If all the conductors are the same size, plug the amount of heat just calculated (“W”) into the rearranged formula $I = \sqrt{W \div NR}$; this gives the equivalent allowable heating with “N” conductors equally loaded. Calculations involving combinations of conductor sizes are more complicated but the principle is the same. Remember to factor in the resistances as ratios (based on Chapter 9 Table 8, or from Table 57 in Div. 12) to the conductor resistance used in the initial determination of allowable heating. This way the resistance per unit length (“R”) is a constant and need not be actually calculated. Figure 3.40

FIGURE 3.40 Examples of multiple-conductor heating. The bottom example (below the line) shows mixed size conductors in a common raceway.

shows a worked-out example of 12 and 14 AWG conductors mixed in the same raceway, along with other loading vs. heating examples of interest.

As shown in Fig. 3.40, many different combinations of numbers of conductors energized versus reduced loads can amount to “a load diversity of 50%.” As currents fall away from their theoretical maximums, the heating falls by the square of those decreases. This is the reason that under actual loading conditions there was very little documentation of any problems with the traditional approach. The example also shows how a possible design load at zero diversity (all 24 wires carrying 16 A each) could overheat the conductors. This is why Table 310.15(b)(2)(a) was changed a few cycles back.

INTRODUCTION

1. Introduction. In this division the miscellaneous equipment, materials, and devices which are employed for electrical installations are discussed. Certain items which are used for specific types of installations have not been included in this division; an explanation of these devices or materials will be found in Div. 8, "Outside Distribution," or in Div. 9, "Interior Wiring." Since there is so much material to cover for generators, motors, and transformers, a separate division (Div. 7) has been devoted to generators and motors and another (Div. 5) to transformers.

The aim in the preparation of Div. 4 has been to present the different types of equipment, materials, and devices which are available, with sufficient explanation of their characteristics, installation, and maintenance so that proper equipment can be intelligently selected, installed, and maintained in good condition for satisfactory service. Much useful information that is not ordinarily readily available at short notice has been included.

SWITCHES

2. A switch is a device for making, breaking, or changing connections in an electric circuit under the conditions of load for which it is rated. It is not designed for interruption of a circuit under short-circuit conditions. Refer to Sec. 59 for a discussion of the difference between circuit breakers and switches.

3. Switches may be classified in several different ways:

- I.** According to number of poles
 - A.** Single-pole
 - B.** Two- or double-pole
 - C.** Three- or triple-pole
 - 1.** Standard
 - 2.** Solid-neutral
 - D.** Four-pole: standard
 - E.** Four-pole: solid-neutral
 - F.** Five-pole: standard
 - G.** Five-pole: solid-neutral
- II.** According to number of closed positions
 - A.** Single-throw
 - B.** Double-throw
- III.** According to type of contact
 - A.** Knife-blade
 - B.** Butt-contact
 - 1.** Single-line
 - 2.** Multiple-line
 - 3.** Surface
 - C.** Mercury
- IV.** According to number of breaks
 - A.** Single-break
 - B.** Double-break
- V.** According to method of insulation
 - A.** Air-break
 - B.** Oil-immersed
- VI.** According to method of operation
 - A.** Operating force
 - 1.** Manual
 - 2.** Magnetic
 - 3.** Motor or solenoid
 - B.** Mechanism
 - 1.** Lever
 - 2.** Dial
 - 3.** Drum
 - 4.** Snap
 - a.** Tumbler
 - b.** Rotary
 - c.** Pushbutton
- VII.** According to speed of operation
 - A.** Quick-break
 - B.** Quick-make
 - C.** Slow-break
- VIII.** According to enclosure
 - A.** Open
 - B.** Enclosed
 - 1.** General-purpose
 - 2.** Driptight
 - 3.** Weather-resisting
 - 4.** Watertight
 - 5.** Dusttight
 - 6.** Submersible
 - 7.** Hazardous locations
 - 8.** Bureau of Mines
- IX.** According to protection provided to circuits or apparatus
- X.** According to type of service
 - A.** Power switches
 - 1.** General-purpose
 - a.** Open
 - b.** Safety
 - 2.** Disconnecting
 - 3.** Motor-circuit
 - 4.** Motor-starting
 - 5.** Field switches
 - 6.** Service-entrance
 - 7.** Bolted-pressure contact
 - B.** Wiring switches
 - 1.** According to method of installation
 - a.** Flush-mounting
 - (1)** Standard
 - (2)** Interchangeable
 - (3)** Combination
 - b.** Surface
 - c.** Pendant
 - d.** Through-cord
 - e.** Door
 - f.** Canopy
 - g.** Appliance
 - h.** Special exposures
 - 2.** According to function
 - a.** General-purpose
 - (1)** Single-pole
 - (2)** Double-pole
 - b.** Three-way
 - c.** Four-way
 - d.** Three- or four-pole
 - e.** Multiple-circuit or electrolier
 - f.** Momentary-contact
 - g.** Heater
 - h.** Dimmer
 - C.** Control switches
 - D.** Instrument switches
 - E.** Miscellaneous types

4. A pole of a switch is that part of a switch which is used to make or break a connection and which is electrically insulated from other contact-making or -breaking parts. A single-pole switch will make or break connections in only one conductor or leg of a circuit; a two-pole switch, in two legs, etc. Schematic diagrams illustrating the meaning of the number of poles are shown in Fig. 4.1.

FIGURE 4.1 Meaning of poles.

For some installations in systems having a grounded neutral wire, it is always desirable to break the neutral connection as the circuit passes through a switch. In these cases, a regular switch with a number of poles one less than the number of conductors of the circuit can be used. The neutral conductor is then carried directly to a neutral bar in the switch. Another installation can be made by the use of a *solid-neutral switch* (Fig. 4.2). The number of switch blades or contacts for a solid-neutral switch is one less than the number of conductors of

I Schematic diagram of three-pole solid-neutral switch

II Three pole, unfused switch

FIGURE 4.2 Solid-neutral switch and connections.

the circuit, but a neutral strap is located between two of the switch blades or contacts to carry the neutral leg solidly through the switch without breaking the circuit of the neutral conductor. A switch designated as a three-pole solid-neutral switch will accommodate a three-conductor circuit and provides two switched poles and one solid-neutral strap. A solid-neutral switch is shown in Fig. 4.2, II. Figure 4.15 shows a three-pole switching-neutral fused switch which satisfies National Electrical Code requirements.

FIGURE 4.3 Single- and double-throw switches.

5. A single-throw switch (Fig. 4.3, I) will make a closed circuit only when the switch is thrown in one position. A *double-throw switch* (Fig. 4.3, II) will make a closed circuit when thrown in either of two positions. Special *multiple-throw switches* can be made to meet the requirements of conditions which require that a switch make a closed circuit when thrown in more than two positions. Examples of multiple-throw switches are the dial and drum switches employed for control and instrument work.

6. Switch contacts. In the construction of switches, different methods are employed for making contact between the movable and stationary parts of the poles. *Knife-blade switches* consist of some form of movable copper blade which makes contact by being forced between forked contact jaws, as illustrated in Fig. 4.4.

FIGURE 4.4 Knife-blade switch parts.

The construction of the contact members of *butt-contact switches* varies widely with different manufacturers. In all cases, however, the contact is formed by pressing the movable member against the stationary contact. (The two contacts are butted together when closed.) The two members are so constructed that there will be a stiff spring action between them to ensure a good contact when in the closed position. The contact formed between the two members may be of the *single-line*, *multiple-line*, or *surface* type. Single-line contact is obtained by making the surface of the contacting members curved so that, when closed, the members are in contact only along a single line instead of over the entire surface. With multiple-line contacts the two members are not in contact over their entire surfaces, contact being made along several lines. The multiple lines of contact are obtained by making the movable member of laminated (brush) or cylindrical construction. In butt-contact switches of the surface type, the contact members, when in the closed position, are butted together so that they are in contact over as much of the surface

as possible. The disadvantage of the surface type of contact is that it is very difficult to obtain a good contact over the entire surface. Typical butt-contact constructions are illustrated in Fig. 4.5.

One of the essential functions of any switch is to maintain a good low-resistance contact in the closed position. If the contact is poor, there will be considerable resistance at this point. The high contact resistance will result in overheating of the switch and possible

FIGURE 4.5 Butt-contact constructions.

opening of the circuit due to the functioning of circuit-overload protective devices. Switches are generally constructed so that the contacts will be closed under pressure with a sliding or rolling action to maintain clean, low-resistance contacts. The contact surfaces are frequently silver-plated to prevent oxidation and reduce contact resistance.

7. Mercury contact switches are sometimes used for low-capacity circuits in control wiring. They consist of a glass tube containing mercury and two stationary contact members located in opposite ends of the tube. The tube is mounted in a supporting case so that the position of its axis can be changed by an operating handle. When the handle is in the off position, the axis of the tube is tilted so that the mercury is at one end of the tube and makes contact with only one of the stationary contacts. When the handle is thrown to the closed position, it rotates the tube, causing the mercury to move in the tube in a manner that closes the circuit from the stationary contact at one end of the tube through the mercury to the stationary contact at the other end of the tube. Amid current environmental concerns concerning the long-term effects of mercury being released in landfills at the end of the useful lives of this equipment, the use of mercury has become largely obsolete. For example, vials of mercury were standard in thermostats for generations, and they have been almost entirely superseded by electronic types that do not rely on this metal.

8. Both knife-blade and butt-contact switches are made in single- and double-break types. A single-break switch, in opening, breaks each pole of the circuit at only one point. A double-break switch, in opening, breaks each pole of the circuit at two points. Breaking the circuit in two places doubles the quenching effect of the switch in suppressing the arc. This reduction in the arcing at the contacts prolongs the life of the contacts by reducing the formation of destructive beads and pitted areas.

9. Insulation of switches. The great majority of switches are designed to interrupt the circuit in the surrounding air. The live parts must be spaced far enough apart so that the air space between them will have sufficient insulating ability for the voltage which exists between the adjacent parts. Oil switches (Fig. 4.6) have their contact parts immersed in oil so that the circuit is interrupted under oil.

10. Switches can be operated by hand (Fig. 4.7), by electromagnets (Fig. 4.8), by motors (Fig. 4.8), or by means of solenoids (Fig. 4.8). Most power switches are operated by means of simple lever action (Fig. 4.4) or by means of a lever attached to the switch through a toggle mechanism. Dial switches consist of a movable contact mounted on a rotatable arm and of several fixed contacts arranged in circular form. As the arm is rotated, the movable contact makes connection with the successive fixed contacts, one at a time. This type of switch is used for instrument, control, storage-battery end-cell, and transformer tap-changing switches. Drum switches consist of a set of contact segments mounted on a central movable drum and a set of stationary contact fingers (Fig. 4.9). Drum switches are employed for motor-starting, control, and instrument switches.

Magnetic switches consist of switch contacts operated by means of an electromagnet. They are used extensively as the switching element for motor controllers. They also find application in general wiring work when it is desired to control a circuit at some point remote from the switch. See Secs. 36 and 37.

III. High-voltage industrial type. [General Electric Co.]

FIGURE 4.6 Oil switches.

Snap switches are small-capacity switches in which the circuit is made or broken with a quick motion independent of the speed of operation of the switch by the operator. Figures 4.10 and 4.11 show some antique versions of these devices. The tumbler or toggle switch (Fig. 4.12) typically relies on the action of the operator to make the contact through actuation of the toggle with the spring retaining the contacts in the closed position. When the operator moves the toggle to the open position the spring-and-cam mechanism moves the contact arm to the open position. Some toggle switches employ the opposite sequence.

II. Lever and toggle mechanism. [Westinghouse Electric Corp.]

III. Double throw safety switch. [Square D, Schneider Electric]

FIGURE 4.7 Operating mechanisms for manual switches.

11. Speed of operation of switches. With an ordinary manual switch the speed of closing or opening a switch depends upon the operator. If current conditions are such that an arc may be drawn, attachments which make it impossible to open the switch slowly and thus draw a dangerous arc should be provided. Many switches are provided with quick-make as well as quick-break features. A quick-break attachment for an open knife switch is shown in Fig. 4.13. When the switch is opened, the auxiliary blade is held in the switch jaws by friction until the main blade has been withdrawn. Withdrawal of the main blade increases the spring tension so that it suddenly jerks the auxiliary blade out of the jaws and quickly breaks the circuit. In switches of the enclosed safety type, the operating handle is frequently connected through linkages and a spring so that after the handle has been moved a certain distance, the spring quickly completes the closing or opening action, giving the switch quick-break or -make features.

FIGURE 4.13 A quick-break switch.

12. Enclosure of switches. Switches may be classified as open or enclosed, depending upon whether their current-carrying parts are exposed or enclosed in a protecting box or casing. All switches should be of the enclosed type (externally operated) unless they are mounted on switchboards or panelboards. Even in these cases it is generally better practice to use switchboards and panelboards of the dead-front-construction type. In no case should open switches be employed where they may be operated by unqualified persons.

Switches can be obtained with enclosures to meet the requirements of different classes of exposures. The standard (National Electrical Manufacturers Association) types of non-ventilated switch enclosures are as follows:

Type 1. Type 1 enclosures are intended for indoor use primarily to provide a degree of protection against limited amounts of falling dirt, in locations where unusual service conditions do not exist. Type 1 enclosures may be of the nonventilated or the ventilated type.

Type 3R. Type 3R enclosures are intended for outdoor use primarily to provide a degree of protection against rain, sleet, and damage from external ice formation. They are not intended to provide protection against conditions such as internal condensation, or internal icing. Type 3R enclosures may be of the nonventilated or the ventilated type.

Type 4. Type 4 enclosures are intended for indoor or outdoor use primarily to provide a degree of protection against windblown dust and rain, splashing water, and hose directed water; and to be undamaged by the formation of ice on the enclosure. They are not intended to provide protection against conditions such as internal condensation or internal icing.

Type 7. Type 7 enclosures are intended for use indoors in locations classified as Class I, Group A, B, C, or D, as defined in the National Electrical Code. The letters A, B, C, and D indicate the gas or vapor atmospheres in the hazardous location. The enclosures are marked with the appropriate class and group(s) for which they have been qualified. These enclosures are capable of withstanding the pressures resulting from an internal explosion of the specified gases and containing such an explosion sufficiently that an explosive gas-air mixture existing in the atmosphere surrounding the enclosure will not be ignited. Enclosed heat-generating devices do not cause external surfaces to reach temperatures capable of igniting explosive gas-air mixtures in the surrounding atmosphere.

Type 9. Type 9 enclosures are intended for indoor use in locations classified as Class II, Groups E, F, or G, as defined in the National Electrical Code. The letters E, F, and G indicate the dust atmospheres in the hazardous location. The enclosures are marked with the appropriate class and group(s) for which they have been qualified. These enclosures are capable of preventing the entrance of dust. Enclosed heat-generating devices do not cause external surfaces to reach temperatures capable of igniting or discoloring dusts on the enclosure or igniting dust-air mixtures in the surrounding atmosphere.

For complete listings of NEMA enclosures, see Secs. 7-253 and 7-253A.

13. Overcurrent protection for circuits or apparatus is frequently incorporated with a switch. For the protection of circuits the protective device incorporated with the switch consists of fuses. For the protection of equipment the protective device may be any one of the types listed in Sec. 46 (I, II, IV, and V). Standard fused switches are equipped with fuse clips for accommodating Class H cartridge fuses or, in some cases, Type S screw-base plug fuses if the switch rating is 30 A.

Fused switches used on systems with a grounded neutral may have one less pole than the number of conductors of the circuit, or a solid-neutral or switching-neutral switch may be employed. In the first case, the neutral leg is not carried through the switch, but the neutral conductor is simply carried through the switch box in the space around the switch. A solid-neutral switch (Fig. 4.14) has one less blade or contact than the number of conductors of the circuit, with a neutral strap located in the space between two of the switch blades or contacts to carry the neutral leg solidly through the switch without breaking the circuit of the neutral conductor. No fuse is located in the neutral leg. A switching-neutral switch (Fig. 4.15) has a blade or contact for each conductor of the circuit. The blade or contact for the neutral conductor is connected by a copper strap to its terminal without any fuse clips. Such a switch opens the neutral conductor leg and all other circuit conductors when the switch is opened and satisfies NEC rules.

FIGURE 4.14 Three-pole solid-neutral fused switch.

FIGURE 4.15 Three-pole switching-neutral fused switch.

14. General-purpose or general-use power switches are intended for use in general-distribution and branch circuits. They are rated in amperes and are capable of interrupting their rated current at their rated voltage. These switches may be of the open or enclosed externally operated type. The enclosed switches are generally referred to as safety switches.

General-purpose or general-use switches are NEMA-designated as Type HD, ND, or LD switches, depending upon the severity of service for which they are designed. *Type HD* (heavy-duty) switches, the most ruggedly constructed of the three types, are designed for the heaviest-duty service with respect to both frequency of operation and current capacity for handling heavy overloads. *Type ND* (normal-duty) switches are of lighter construction than Type HD and are designed for service conditions in which frequent operation is not required and overload conditions are not severe. *Type LD* (light-duty) switches are of light construction and are designed primarily for entrance service and general-purpose use when the load is light and operation very infrequent.

15. Open switches are constructed with their current-carrying parts exposed. Most open switches are of the plain lever knife-blade type. Knife-blade switches in very heavy current-carrying capacities are hard to operate owing to the large rubbing-contact surfaces required. For this reason open switches of very large capacity are usually of the brush-but-contact type (Fig. 4.5, IV).

Most open lever-type knife-blade switches are of the single-break type; they are made in a variety of forms. They can be obtained in single-, double-, triple-, and four-pole types, for either front or rear connection (see Figs. 4.16 and 4.17). They may be of the fused or unfused type and either single- or double-throw.

Open switches are used principally for mounting on live-front switchboards.

FIGURE 4.16 Front-connected knife-blade switches. [*Electric System Handbook*]

FIGURE 4.17 Rear-connected knife-blade switches. [*Electric System Handbook*]

16. The names of knife-switch parts are given in Fig. 4.4. The contact between the break jaws and the blade should be carefully inspected, as it is at this point that knife switches are most apt to give trouble by overheating. The contact between the hinge jaws and the blade seldom limits the capacity of a switch, because it is under pressure from the hinge bolt and the spring washers. The capacity of a switch is determined by its temperature rise.

About 1000 A/in^2 (645 mm^2) of copper section and 50 to 75 A/in^2 of sliding-contact surface are usually allowed in designing switches.

A switch that will carry, possibly, 1000 A with a 20°C temperature rise will carry possibly 2000 A with about a 60°C rise. The radiation of heat from the switch increases more rapidly than does the rise in temperature, and as the heat generated varies as the square of the current, it is evident that the temperature rise will be somewhat less than proportional to the square of the current.

With a given current, a switch will break about double the voltage with alternating current that it will with direct current. This is due to the fact that an alternating current decreases to a zero value during each cycle. Never assume that the ac voltage rating of a switch (or a circuit breaker or any other device called upon to open a circuit under load) is the same as its dc voltage rating; in fact, many ac-rated switches have no dc ratings and therefore cannot be installed on dc systems.

The voltage drop from contact block to hinge block of a good switch should not exceed about 12 mV with full-load current.

17. Safety switches consist of a switch mounted inside a sheet-metal or cast-iron box and operated from outside the box by a handle connected to the switch mechanism. Various types are available with contacts of either the single- or the double-break type employing either knife-blade or butt-contact construction. The operating handle may be located on the side of the switch box, in the center of the front cover, or in the front side of the box (see Fig. 4.18).

Certain safety switches are so arranged that their doors cannot be opened when the switch is closed. Others possess this feature and the additional one that absolutely no live metal parts are exposed when the switch and door are open.

Safety switches are made in two-, three-, four-, and five-pole assemblies either fused or unfused and in single- or double-throw types. The three-, four-, and five-pole switches may be of the standard, solid-neutral, or switching-neutral type. Safety switches are made in HD, ND, and LD types of construction. They can be obtained with or without a quick-break

Cutler-Hammer Products]

FIGURE 4.18 Safety switches showing different types of operating-handle arrangement.

mechanism. Many switches are constructed to give quick-make action in closing the switch as well as quick-break action in opening. Typical constructions for Class HD knife-blade safety switches are shown in Figs. 4.19 and 4.20. Butt-contact design (Fig. 4.21) generally results in a more compact construction with smaller overall dimensions. A very compact type of rotary knife-blade switch (Fig. 4.22) is made, however, in 30- to 100-A sizes.

18. To make a contact between switch blade and jaws, considerable skill is required. After a switch has been assembled, the jaws are first bent into correct position either by hand or by driving a block of wood against the distorted portion with a hammer. Then they are ground in with Vaseline and fine (FF) pumice. Often the fit of a switch is reasonably good at the start, and merely working the blade in and out of the jaws by hand will grind them in. Before the grinding process is started, the portion of the blade that wipes the jaws should be daubed with the Vaseline-and-pumice compound. The abrasive not only grinds in the fit but wears off the lacquer, which if it remained, might cause a bad contact. The surplus compound should be removed with a rag.

FIGURE 4.21 Side-operated heavy-duty rain-tight safety switch. [Crouse-Hinds Co.]

FIGURE 4.22 600-V visible-blade safety switch. [Square D, Schneider Electric]

19. A test for good blade contact can be made by trying to insert a “feeler,” a leaf of very thin steel, mica, or paper, between the jaws and the blade at the corners and sides. About 0.001 to 0.004 in (0.0254 to 0.1016 mm) is about the right thickness for a feeler. An excellent feeler can be made by hammering down to a knife edge the edges of a strip of very thin metal possibly 4 in (101.6 mm) long and $\frac{3}{4}$ in (19.05 mm) wide. If the feeler slips in at any point, it is evident that the fit is poor at that point and the contact bad. Proper forming of the jaw will correct the difficulty. In some cases switches have been made to carry, without excessive temperature rise, currents 50 percent greater than their normal ratings merely by carefully fitting their jaws to their blades.

20. The standard sizes of general-purpose power switches are listed in NEMA Standards.

21. High-capacity switches. There are three basic types of fused high-capacity, load-break switches in ratings from 800 to 6000 A (ac). These switches are shown in Fig. 4.23.

1. Bolted-pressure-contact switches contain a pressure mechanism which firmly bolts the blades to the contacts when the switch handle is moved to the closed position. Auxiliary springs maintain an initial pressure during opening and closing of the blades to prevent arcing and pitting of the main contacts. Class L fuses are bolted to fuse terminals.
2. Circuit-breaker-type switches are actually circuit breakers with the overload trips removed, and bolt-on Class L current-limiting fuses are used as the overcurrent protection.
3. Fused circuit breakers include all the mechanical features of conventional large-capacity circuit breakers and, in addition, have replaceable Class L fuses which function to increase the fault-current-interrupting ability. They are intended to be used in the same manner as other circuit breakers and are mounted in enclosures with hinged doors or covers over the accessible fuses. They are rated at 600 V or less.

Fused circuit breakers are classified in two categories, Classes 1 and 2.

- a. Class 1 fused circuit breakers meet all the performance requirements of large branch-circuit and service circuit breakers. The Class L fuses function only to extend the fault-current-interrupting rating beyond the short-circuit test requirement applicable.
- b. Class 2 fused circuit breakers use fuses so coordinately that they function at currents below those specified in short-circuit test requirements. Except for this feature of short-circuit operation, Class 2 fused circuit breakers meet all requirements applicable to large branch-circuit and service circuit breakers and, in addition, are required to clear circuits up to and including 25 times their ampere rating, and circuits of 1000 A or less regardless of ampere rating, without causing the operation of any fuses which are part of the device. Class 2 devices are limited to constructions which are designed to accommodate and coordinate with Class L fuses.

All the high-capacity switches described in Sec. 21 use Class L current-limiting fuses with interrupting-current (IC) ratings of 100,000 or 200,000 A rms, and they are designed for ac circuits. Typical switch ratings are 240, 480, 500, and 600 V. Since the NEC prohibits the use of fuses in parallel (unless factory-assembled and approved for the purpose), one of

FIGURE 4.23 High-capacity switches (800 to 6000 A).

these switch types will be required if fuse ratings larger than 600 A are needed for a given service or circuit.

All these high-capacity switches incorporate a manual means of disconnection. In addition, shunt-trip coils can be provided to permit electrical operation of switches. With an electrically operated switch ground-fault interrupters can be added to open the main circuit in the event of line-to-ground faults. Such devices are described in Sec. 7.3 and shown in Fig. 4.101.

22. Isolating switches are intended simply to isolate circuits from their source of power. They are not intended to be used to interrupt the current of the circuit and are to be operated only when the circuit has been opened by some other means. The principal application of these switches is to isolate equipment or parts of an electric circuit for inspection or repair. They are commonly used on circuits rated at more than 600 V. The switches are made in a great variety of open knife-blade types to meet different requirements of both indoor and outdoor service. Since they are generally located out of arm's reach, they are provided with an eye on the free end of the blade for operation with a hook rod. Typical switches of this type are shown in Fig. 4.24. Enclosed safety industrial disconnecting switches are shown in Figs. 4.25 and 4.26.

I. Fused type.

FIGURE 4.24 Open-type knife-blade disconnecting switches.

FIGURE 4.25 Safety enclosed fusible disconnecting switch. [General Electric Co.]

FIGURE 4.26 Manual-magnetic safety disconnecting switch with motor-circuit switch and control transformer. [Eaton Corp., Cutler-Hammer Products]

23. Motor-circuit switches are used to interrupt current in motor circuits. They are rated in horsepower and must be capable of interrupting at their rated voltage the maximum operating overload current of a motor of the same horsepower as the switch rating. The maximum operating overload current is taken as 6 times the rated full-load motor current for ac motors and 4 times the rated full-load motor current for dc motors. Motor-circuit switches are of the same construction as the general-purpose safety switches discussed in Sec. 17. See Table 46, Div. 12, for horsepower ratings of fused switches. The switches are rated in amperes for general use and are given a horsepower rating for motor-circuit application.

FIGURE 4.27 Multiple-contact open knife-blade switch for motor starting. [Electric System Handbook]

24. Motor-starting switches are employed to start motors which may be started directly across the line. Standard motor-circuit switches may be used for this purpose, but it is generally better practice to employ a switch designed specifically for starting duty. These switches are made in manual and magnetic types. They generally are provided with some form of motor-overload protective device. For a discussion of motor-starting switches, refer to across-the-line starting equipment in Div. 7. When the control of a dc motor is mounted on a switchboard, a multiple-contact open knife switch (Fig. 4.27) is frequently employed to cut out the starting resistance. These switches may be provided with a ratchet device on the hand lever so that they cannot be moved too rapidly from step to step.

25. Field switches are used to interrupt the field current of generators and synchronous motors. These switches (Fig. 4.28) are provided with an auxiliary contact, an extra blade attached to one of the main blades, and auxiliary quick-break blades attached to each main blade. In operating the switch to disconnect the field from its source, the auxiliary quick-break blades do not break contact with their jaws until after the short auxiliary blade has made contact with the extra jaws. Thus the field circuit is shorted through the discharge resistance before the circuit is disconnected from its source. Since the field circuit is highly inductive, if the circuit were suddenly broken, a high induced voltage which might puncture the insulation of the field coils would be produced. The field switch of Fig. 4.28 is for mounting on the front of the switchboard or panel. A preferable arrangement is to employ a switch mounted on the rear of the board, as shown in Fig. 4.29. There are electrically operated field switches which allow the field switch to be mounted near its machine while its operation is controlled from the switchboard.

26. Service or entrance switches. The service equipment of a building consists of the necessary circuit breaker or switch and fuses and their accessories, which are located near the point of entrance of the supply conductors. It constitutes the main control and means of cutoff for the supply to that building from the facilities of the serving utility. In large industrial plants comprising several buildings, the service equipment for each building will generally consist simply of a fused safety switch or an industrial circuit breaker. It is important to remember that by NEC definition, only a utility interface is controlled by service equipment. For campus-style distribution in industrial and institutional settings, this

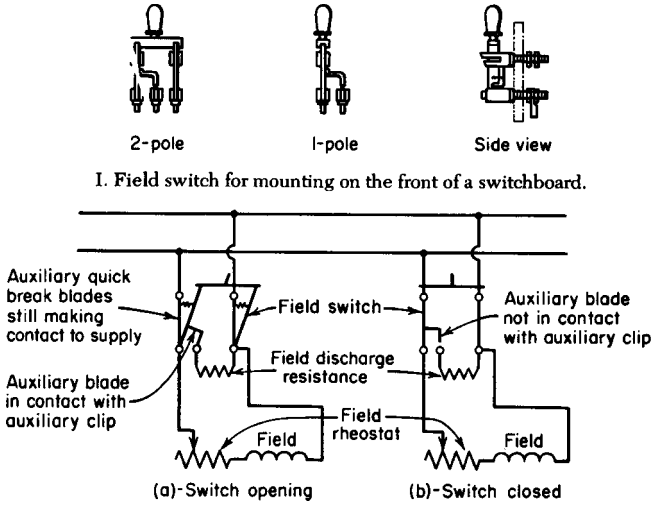

FIGURE 4.28 Field switch.

FIGURE 4.29 Field switch for mounting on the rear of a switchboard with front-operating handle.

frequently means a single service point, often at an elevated voltage, with each building equipped with its own building disconnect. Such disconnects must not be labeled as service disconnects. For single buildings supplied directly from a utility company's lines, the service equipment must include a switch, fuses, and a meter or a circuit breaker and a meter. The meter is furnished by the utility, but the rest of the equipment must generally be supplied by the consumer. Service or entrance switches are specifically designed to meet these entrance conditions so that the meter and fused switch can be mounted in a convenient, neat, and compact manner. One end of many switch boxes is provided with knockouts or hubs for conduit connection (Fig. 4.32). This allows the box to be connected by conduit to a separate meter trough either for a single meter or for several meters, as shown in Fig. 4.30. Combination units consisting of the switching member and a meter socket (Fig. 4.33) are available in different types of design.

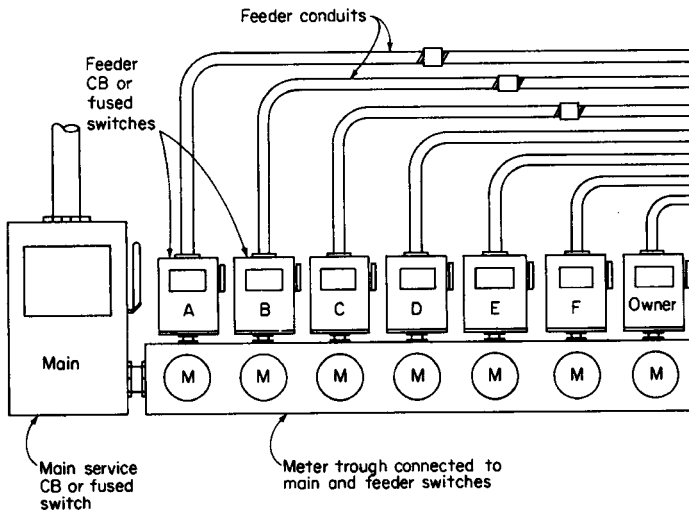

FIGURE 4.30 Installation of service switches connected with conduit to a separate meter trough.

27. Service or entrance switches are made in a great variety of types to meet the desired sequence between meter, switch, and fuses (refer to Div. 9) and the other requirements of individual utility companies. It has been impossible to introduce any standardization into the types of service switch owing to the divergence of opinion among utility representatives. Some of these switches simply include the entrance switching device (Figs. 4.30, 4.31, and 4.32) and overload protection for the service. Others have in addition a switching device and overload protection for an electric-range circuit. Still others, which combine the service-entrance equipment with overload protection for branch circuits, frequently are called load and service centers (Figs. 4.34 and 4.35). There are available types which include test links mounted on the main switch base so that the utility company can test the meters without disconnecting the load and interrupting the customer's service. In some types the main fuses are accessible to the customer, while in others they may be sealed by the utility company so that they are not accessible to the customer.

Today many meter enclosures frequently include a bypass mechanism so the meter can be removed without a service interruption. It is very important to recognize that such bypass switches must never be used to either make or break a load, but only to maintain

FIGURE 4.31 Fuse-puller type of service switch. [Crouse-Hinds Co.]

FIGURE 4.32 Circuit-breaker type of service switch. [Crouse-Hinds Co.]

continuity. Set the bypass, remove the meter, replace the meter, and open the bypass in that order. In addition, many utilities are requiring meter disconnect switches ahead of their meters so their personnel can safely remove voltage from the metering enclosure. Although load-break rated, these switches differ from service disconnects because they are not intended as the normal means of disconnecting power. They are only intended for use by utility personnel.

Service switches may be divided broadly into three types, depending upon the type of main switching device: fuse-puller switches (Fig. 4.31), circuit breakers (Figs. 4.32, 4.33, 4.34, and 4.35), and the standard type of safety switch (Fig. 4.30). When the main switching device is a circuit breaker, the equipment generally is of the load-center type, each branch being provided with a circuit breaker. This type has the advantage that it

FIGURE 4.33 Raintight combination meter socket circuit-breaker type of service switch. [Crouse-Hinds Co.]

FIGURE 4.34 Homeline load center. [Square D, Schneider Electric]

FIGURE 4.35 Combination circuit-breaker-type service switch and load center with a split neutral bus. [Crouse-Hinds Co.]

FIGURE 4.36 Raintight socket meter trough for a single meter. [Square D, Schneider Electric]

furnishes a means of switching as well as overload protection for each branch. The other types of load center provide only overload protection for the branches with no means of switching.

FIGURE 4.37 Multiple meter-socket meter stack. [Square D, Schneider Electric]

28. Service-entrance equipment utilizes the detachable socket type of meter. The meter is provided with prongs that fit into clips or jaws provided in a meter-mounting trough. Some of these troughs are wired on the job, and others are factory-wired by the manufacturer. They are made in indoor and outdoor weatherproof types. Examples of troughs and installations of this type are shown in Figs. 4.33, 4.36, and 4.37.

29. Service switches are available in raintight enclosures so that the service-entrance equipment can be located on the outside of the building. Typical equipment is shown in Fig. 4.33.

30. Wiring switches, as designated in this book, include all the relatively small switches that are employed in interior-wiring installations for the control of branch circuits and individual lamps or appliances. Except for mercury switches, the switching mechanism consists of a snap action operated by one of the methods given in Sec. 10. Wiring switches are made in many types to meet the requirements for different conditions of mounting.

The *ac* snap switches are the type of switches installed in virtually all of today's new construction and renovations. These switches are quiet in operation and have a long life because of their silver-alloy butt contacts. Unlike ac, dc switches, the ac snap switch can be used up to its full ampere rating for incandescent-lamp and fluorescent-lamp loads and any

other resistive or inductive loads except motors. Motor loads are limited to 80 percent of the ac switch rating.

Although the ac snap switch is limited to ac circuits, it is obvious that such switches can be used on most installations because ac supplies represent more than 98 percent of the systems in the United States. Ratings of ac snap switches are 15, 20, or 30 A at 120 or 120/277 V. These switches are widely used for local control of 277-V fluorescent luminaires, which are supplied by 480Y/277-V branch circuits. A version of these switches with a unique mounting hole dimension of 3.475 in. is rated for 600 Y/347-V branch circuits. The yoke mounting dimensions ensure that they will not be used on conventional plaster rings or in conventional boxes because the spacings would be inappropriate for the elevated voltage.

Ac snap switches are available in a wide variety of shapes and styles to blend with modern decor. The switches are available in single-pole, double-pole, three-way, four-way, and momentary-contact types. In addition, lighted (to indicate an off position) or pilot-light (to indicate an on position) operating handles are available in these switches. Terminals are either screw-type or pressure-locking push-in types. Only the screw terminals are suitable for the connection of aluminum conductors. See Sec. 3 of Div. 9 for definitions of various types of snap switches.

The *flush* ac, dc switch (Figs. 4.38 and 4.39) consists of a switch mechanism mounted in a composition molded case, the complete unit being designed to be mounted inside a switch box, outlet box, or conduit fitting so that the operating handle or button is the only portion of the switch which extends beyond the cover of the box or conduit fitting. The contacts may be of the knife-blade or the mercury type (Sec. 7). Those with knife blades are available with toggle (tumbler), pushbutton, or locking types of operating mechanisms. Mercury switches are almost completely silent in operation, making practically no noise on the make or break. They are used in installations where the click of a switch might prove disturbing, as in hospitals and nurseries, and they are rated as ac snap switches as well as ac, dc types. As previously noted, however, these switches are seldom available due to environmental concerns. Locking switches do not have a protruding operating handle but are operated by a key inserted in a slot in the face of the switch mounting.

Flush-mounted switches may be classified into subtypes depending upon the physical size and mounting of the switch. The *standard line* of switches (Figs. 4.38 and 4.39) is made with more generous proportions and is the more rugged of the two types. It should be used for heavy-duty installations and in locations where frequent operating is required. The overall dimensions range from 1 to 2 in (25.4 to 50.8 mm) in depth, $1\frac{7}{16}$ to 2 in (36.5 to 50.8 mm) in width, and $2\frac{7}{8}$ to $3\frac{3}{16}$ in (60.3 to 80.9 mm) in length. Most of these switches are supplied with two sets of supporting screw holes, spaced from center to center $3\frac{3}{32}$ and $2\frac{3}{8}$ in (83.3 and 60.3 mm), respectively. They are made in sizes up to 30 A capacity.

FIGURE 4.38 Standard line of flush snap switches. [Pass & Seymour, Inc.]

FIGURE 4.39 Locking type ac switch. [Pass & Seymour, Inc.]

FIGURE 4.40 Method of assembling units and strap.

Switches of standard-line dimensions are made in regular tumbler, pushbutton, locking, and mercury types.

The modern *dimmer snap switch* is an electronic device which provides full-range dimming of incandescent lamps from off to full brightness. These devices are rated from 600 to 1000 W and are wired in the same manner as the standard single-pole switches. Similar devices are available for use with special rapid-start ballasts for the dimming of fluorescent lamps.

The *interchangeable line* of switches (Figs. 4.40 and 4.41) is constructed in a much more compact manner with less generous proportions. As many as three of these switches can be installed in the space required for a single standard-line switch. The largest size of switch made in this line is 20 A. Three switches or a combination of three units of switches, receptacles, and pilot lights can be assembled on a single supporting strap yoke and mounted in a single-gang outlet box or switch box (see Figs. 4.40 and 4.41).

Surface switches (Figs. 4.42 and 4.43) are designed for mounting on the surface of a wall, ceiling, or box so that all or practically all of the switch body extends beyond the surface upon which it is mounted. The contacts are of the knife-blade type operated by tumbler or rotary action. A line of outlet fittings for surface mounting is available for use with exposed nonmetallic-sheathed-cable wiring (refer to Sec. 203, Div. 9).

FIGURE 4.41 Typical assemblies of interchangeable wiring devices.

FIGURE 4.42 Surface-wiring switches.

FIGURE 4.43 Ceiling types of pull rotary switches.

Pendant switches (Fig. 4.44) are used for the control of lamps or other devices which are mounted overhead out of reach from persons standing on the floor. These switches are supported at the end of a pendant two-conductor cord.

Through-cord switches (Fig. 4.45) are designed to be inserted in a portable cord for control of the cord circuit.

FIGURE 4.44 Pendant switches.

FIGURE 4.45 Through-cord switch. [Pass & Seymour, Inc.]

Door switches (Fig. 4.46) are designed to control circuits through the opening and closing of doors. They are mounted in boxes located in the doorjamb. Two types are available, one constructed so that the switch is closed when the door is open and the other so that the switch is closed when the door is closed.

Canopy switches (Fig. 4.47) are small, compact switches for mounting in the canopies of lighting fixtures for the control of the lamps directly at the fixture. They can be obtained in pull-chain or toggle-switch types.

Appliance switches are made in a variety of types for mounting in the appliance enclosure.

FIGURE 4.46 Door switch. [Pass & Seymour, Inc.]

FIGURE 4.47 Types of canopy switches.

FIGURE 4.48 Connections and functions of single- and double-pole switches.

Rotary surface switches mounted in special enclosures to meet the conditions of special exposures, such as weather, water, or explosive atmospheres, can be obtained.

31. Wiring switches are available in different types to perform different functions in the wiring system. The regular switches designated simply as *single-pole* or *double-pole* are for the general-purpose use of opening and closing circuits for the control of lamps or other devices from a single point. The single-pole switches (Fig. 4.48, I and II) break the circuit of only one side of the line, while the double-pole switch (Fig. 4.48, III) breaks the circuit of both sides.

Three-way switches are used if it is desired to control lights from two different points, such as a hall light to be controlled from the lower hall and the upper hall. The lights can be turned on or off from either position. Three-way switches when properly connected (see Sec. 32) break the circuit of only one side of the line; they do not isolate the circuit from the supply. The method of controlling a lamp from two positions with two three-way switches is shown in Fig. 4.49.

Four-way switches in conjunction with two three-way switches are used if it is desired to control lights from three or more different points. Two three-way switches are required with as many four-way switches connected between them as there are points of control in excess of two. Thus to control lights from four different points requires two three-way switches with two four-way switches connected between them. The method of control from

FIGURE 4.49 Connections and functions of three-way switches.

FIGURE 4.50 Connections and functions of three-way and four-way switches.

three different locations is shown in Fig. 4.50. Four-way switches when properly connected break the circuit of only one side of the line.

Momentary-contact switches are used if it is desired to close or open a circuit for only a short length of time. The switch is provided with a spring so that it will return to its original position as soon as the handle or button is released. These switches are available in standard-line tumbler and pushbutton types of flush switches and in pushbutton surface types.

Pilot handle switches are often used instead of providing a separate pilot light; the lit handle serving as the pilot light without the bother of mounting an additional piece of equipment. These switches have an additional terminal to make a connection to the grounded circuit conductor. *Lighted handle* switches have a handle that is lit when the switch is off, so the switch can be found in the dark.

32. Caution should be exercised in connecting three-way and four-way switches, since it is possible to connect these switches with both sides of the circuit connected to each switch. This is an improper connection which should never be used. The switch is not designed for this purpose and in case of failure of the switch mechanism a short circuit may result. The acceptable methods of connection are shown in Fig. 4.57. Refer to Sec. 40 for additional information on connection of these switches.

33. The rating of snap switches for general wiring installation must be in accordance with the requirements of the National Electrical Code. For this purpose the Code classifies loads into three types: (1) noninductive loads other than tungsten-filament lamps, (2) tungsten-filament lamps, and (3) inductive loads.

Snap switches shall be used within their ratings. AC general-use snap switches are suitable only for use on alternating-current circuits to control resistive and inductive loads, including electric discharge lamps, not exceeding the ampere rating of the switch at the voltage involved; tungsten-filament lamp loads not exceeding the ampere rating of the switch at 120 V; and motor loads not exceeding 80 percent of the ampere rating of the switch at its rated voltage.

AC-DC general-use snap switches are suitable for use on either ac or dc circuits to control resistive loads not exceeding the ampere rating of the switch at the voltage applied and inductive loads not exceeding 50 percent of the ampere rating of the switch at the applied voltage. Switches rated in horsepower are suitable to control motor loads within their rating at the voltage applied.

The common types of inductive loads encountered in general wiring installations are fluorescent lamps and mercury-vapor or other HID lamps. Switches used on signs and outline lighting must conform to the Code requirements given in Article 600 of the Code.

FIGURE 4.51 Rotary type of control switch. [Westinghouse Electric Corp.]

FIGURE 4.52 Bypass contact control switch. [Westinghouse Electric Corp.]

One plug is used for each set of common receptacles so that it is impossible to make cross connections. Examples of plug-and-receptacle equipment are shown in Figs. 4.54 and 4.55.

34. Control switches are used for controlling from a switchboard the operation of electrically operated equipment such as switches, circuit breakers, rheostats, and prime-mover governors. They are generally of the drum or rotary type. Two representative control switches are shown in Figs. 4.51 and 4.52. Pilot lamps are generally used in connection with control switches to indicate to the operator the position of the controlled equipment.

35. Instrument switches are employed to change the connections of meters from one circuit to another. The most common type is of rotary construction, as shown in Fig. 4.53. The plug-and-receptacle type of switch is also employed to connect a common voltmeter, ammeter, or synchroscope to various circuits.

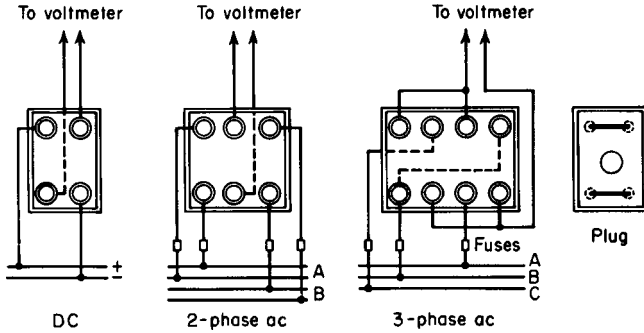

FIGURE 4.54 Voltmeter receptacles and plug. [*Electric System Handbook*]

FIGURE 4.55 Synchronizing plugs and receptacles. [*Electric System Handbook*]

36. Low-voltage relay control systems are widely used in installations which require multiple-switch control of outlets. To a large degree such systems replace conventional three-way and four-way switch control, particularly when a large number of multiple-switch locations are required in a given installation. Figure 4.56 shows three basic types of low-voltage relay switching systems. The system shown in Figure 4.56, 1, operates on a 24-V system, and the switching relay, located at the controlled outlet, contains an on-off latching-type double coil wired to one or more single-pole, double-throw, momentary-contact switches. Pressing to the on position of any switch operates the on coil and closes the single-pole contact which completes the circuit to the connected load. After the on button is released, the current does not flow through the coil, but the single-pole line contacts remain in the closed position because they are mechanically latched. Pressing to the off position of any of the paralleled switches energizes the off coil in the relay, and the single-pole line contacts are opened, disconnecting the load; the contacts remain mechanically latched in the open position until the on switch position is operated again.

In Fig. 4.56, 2, a two-wire latching relay is operated at 12 or 24 V by one or more single-pole, single-throw, momentary-contact switches (placed in parallel). Thus, every time that a momentary-contact switch is actuated, the relay either closes or opens the circuit and latches in either position like a pull-chain type of fixture.

The system shown in Fig. 4.56, 3, uses a compact transformer relay in a single unit and is located at each controlled outlet. This unit operates on a thermal principle and trips the

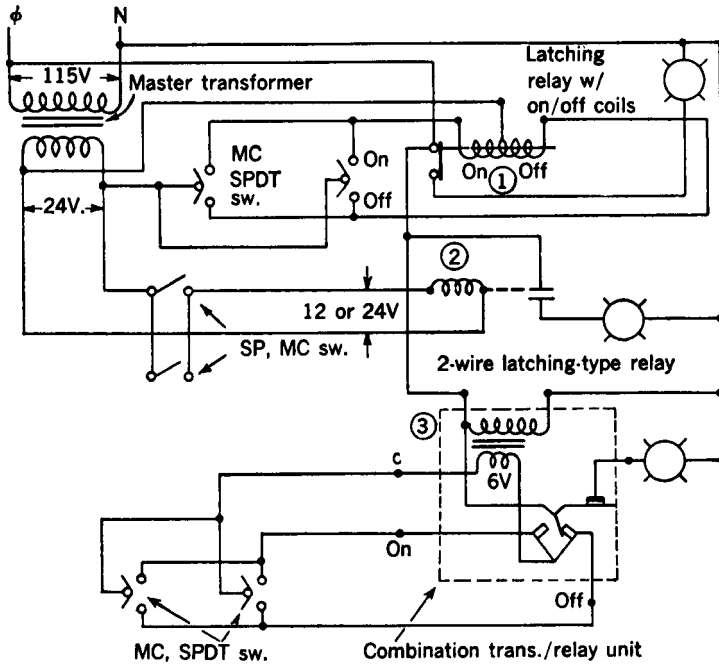

FIGURE 4.56 Three types of low-voltage relay switching systems.

single-pole 115-V contacts into the on or off position according to the operation of the single-pole, double-throw, momentary-contact switches. Although this transformer-relay system is no longer manufactured, it is described so that the reader will understand the principle of operation because numerous systems of this type are still in existence.

The system in Fig. 4.56, 1, is the most popular low-voltage relay system and is available from several manufacturers. This system lends itself to a *master* and *submaster* control so that many circuits can be operated at once through a motorized master unit. Special relays and switches are available to provide pilot-light indication at switches to show when the controlled load is in the on position. In most cases the relay is located at the outlet to which the controlled load is connected.

The system in Fig. 4.56, 2, is available from only one manufacturer. Generally, the relays are in a large, centrally located junction box or panel, and the 115-V circuits extend from this central point to each controlled outlet. This system can also be converted to a master system, and pilot-light indicators are available.

Full details, diagrams, and suggested layouts are available from manufacturers of these systems in the form of wiring handbooks. Switch ratings are 10 to 15 A at 120 or 277 V.

37. Magnetic switches in ratings up to several hundred amperes are available in either magnetically held or mechanically held types. Voltage ratings are 600 V or less.

A magnetically operated switch is an on-off switch in which the opening and closing operations are effected by energizing an electromagnetic mechanism. Such switches or contactors are used to provide automatic and/or remote switching of feeders, branch circuits, and individual loads.

The basic switch is operated by energizing its coil to close the contacts, and it is held in the closed position by maintaining current through the coil.

A variation of the magnetically held contactor is the mechanically held contactor, in which the operating coil is momentarily energized to close the contacts and momentarily energized to open the contacts. Because of the definite switch action with mechanically maintained open and closed positions, such as magnetic contactor is commonly distinguished from the magnetically held type by calling it a *remote switch*, a mechanical switch which can be operated by means of a control circuit to a remote switch.

A remote switch permits the operation of the contact assembly from one or more distant control stations. In such applications the switch is placed in the circuit which it is to control. This may be in the middle of a split-bus panelboard, where the switch controls one section of bus. It may be adjacent to a panel, where the switch controls a branch circuit or feeder from the panel. Or it may be placed on a column, where it switches lighting circuits for a given area. Then, in each case, control conductors are run in cable or conduit from the switch enclosure to one or more control points at which pilot devices provide for operation of the remote switch.

The pilot devices may be pushbuttons, toggle switches, or an automatic device, such as a time switch.

A basic contactor application for a full panel control might involve locating the contactor at widely spaced lighting panelboards supplying outdoor lighting, with all the control circuits being brought to pilot switches at a common point of control. For the control of individual circuits supplying lighting loads, contactors may be located near the panelboard or near the load.

38. Miscellaneous types of switches are available for special applications. Knife-blade switches of reduced dimensions are available for low-voltage circuits such as telephoning, signaling, and battery circuits.

INSTALLATION OF SWITCHES

39. A switch or a circuit breaker must not be installed so that it will disconnect a grounded conductor of a circuit unless the switching mechanism simultaneously disconnects all wires of the circuit, or is so arranged that the grounded conductor cannot be disconnected until the ungrounded conductor or conductors have first been disconnected.

40. Three-way and four-way switches are in reality single-pole switches and therefore must be installed so that all switching is done only in the ungrounded conductor. When the wiring for these switches is enclosed in a metal enclosure, the wiring must be so installed that at every point the same enclosure includes wires of both polarities. Standard and special methods of wiring such switches are illustrated in Figs. 4.57 and 4.58. Refer to Secs. 31 and 32 for additional information on three- and four-way switches.

41. Position of mounting. Single-throw knife switches shall be mounted so that gravity will tend to open and not to close them, or when approved for the use in the inverted position, they shall be provided with a locking device that will ensure that the blades remain

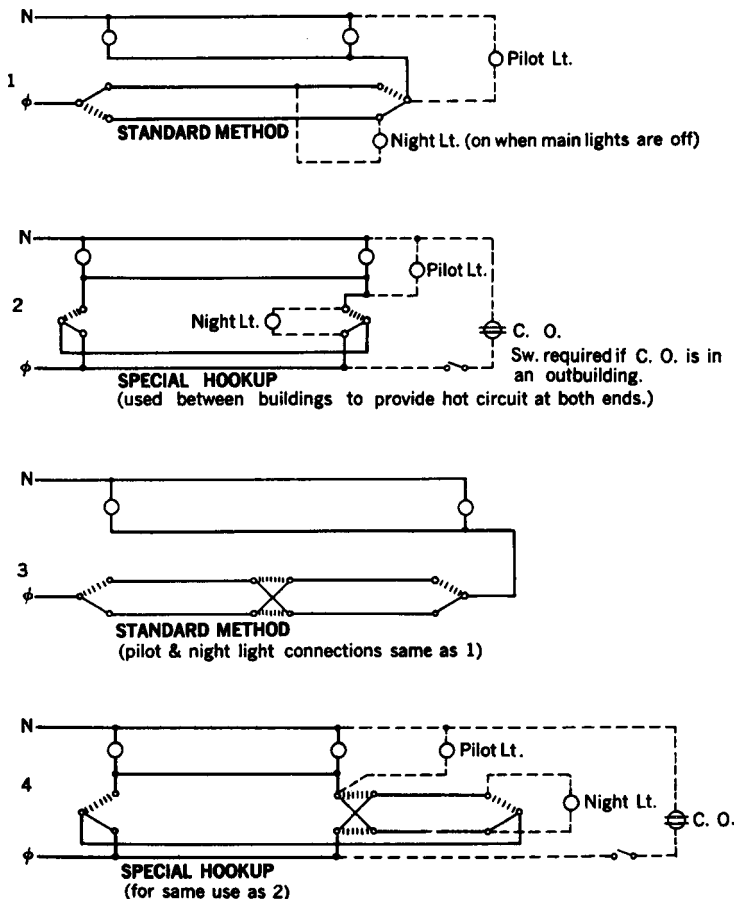

FIGURE 4.57 Standard and special hookups with three- and four-way switches and connections of night (neon) lights and pilot lights.

FIGURE 4.58 How wires of opposite polarity must be enclosed in the same conduit in the wiring of three-way switches.

in the open position when so set (Figs. 4.59 and 4.60). Double-throw switches can be mounted so that the throw is either vertical or horizontal. If mounted with the throw vertical, a switch must be provided with a locking device which will hold the blades in the open position when so set.

42. In connecting knife switches in a circuit, the switch should be wired so that the blades will be dead when the switch is open (Figs. 4.61 and 4.62).

A fused switch should always be wired so that the fuses will be dead when the switch is open.

PROTECTIVE DEVICES

43. Various forms of protective devices are employed to protect electrical circuits and equipment from injury under abnormal conditions. These devices may be classified as follows according to the type of protection which they provide:

1. Overload protection
2. Underload protection
3. Undervoltage protection
4. Overvoltage protection
5. Reverse-current or power protection
6. Reverse phase rotation
7. Lightning and surge protection
8. Ground-fault protection

44. Relays and releases. Protection for the various types of abnormal conditions is in many cases provided by relays or release devices which actuate the opening of circuit breakers or switches. If protection is afforded by a simple release device, the abnormal condition causes the functioning of the release device, which acts directly upon a holding catch of the switch or breaker mechanism. With relay protection the abnormal condition causes the functioning of the relay, which opens or closes an auxiliary electric circuit, which in turn trips the switch or breaker mechanism.

Release devices may be of thermal or magnetic types. Thermal releases can be employed only for overload protection. Their operation depends upon the deflection of a bimetallic element as it is heated by the current of the circuit. Magnetic releases consist of a solenoid acting upon an iron plunger or armature. For current protection the coil of the solenoid is connected in series with the circuit, while for voltage protection the coil is connected across the circuit which is to be protected.

Relays may be of thermal, magnetic, or induction types. The principles of operation of the thermal and magnetic types are the same as those for releases of the same type. Induction relays operate upon the same general principle as induction motors and therefore are applicable only to ac systems.

45. Time characteristics. Relays and release devices may be classified according to the time that will elapse between the occurrence of the abnormal condition and the opening of the circuit. There are three general types: the instantaneous or high-speed, the definite-time, and the inverse-time. In the instantaneous type, time delay is purposely omitted from its action so that the circuit is opened almost instantaneously upon the occurrence of the abnormal condition for which the release or relay is set. A definite-time relay or release is purposely so designed that there is a definite-time delay in its action. The abnormal condition must exist for a definite time before the device will function to open the circuit. The length of time of the disturbance required to cause the device to function is independent of the magnitude of the disturbance. An inverse-time relay or release is purposely so designed that there is a time delay in its action. The length of time of the disturbance required to cause the device to function is dependent upon the magnitude of the disturbance. The greater the magnitude of the disturbance, the quicker will the device function to open the circuit. All thermal relays and releases, owing to the principle of their construction, provide inverse-time protection.

46. Overcurrent protective devices are used to protect wires, wire fittings and devices, and apparatus against excessive currents. The several types of overcurrent protective devices may be divided into the following groups:

<i>Means of Protection</i>	<i>For Protection of</i>
I. Fuses	
A. Low-voltage fuses	
1. Ordinary Edison-base plug fuses	Replacement in existing installations in which there is no evidence of tampering or overfusing for branch incandescent-lighting and heating-appliance circuits
2. Dual-element plug fuses	Any type of branch circuit and small motors; standard screw-base (Edison) fuses have same limitations as above.
a. Standard screw-base type	
b. Type S	

3. Ordinary one-time cartridge fuses	Mains or feeders in which faults occur very infrequently
4. Renewable cartridge fuses, time-delay or standard	Mains or feeders in which faults occur frequently; limited to existing installations in which there is no evidence of tampering or overfusing.
5. Dual-element cartridge fuses	Most mains or feeders, motor or appliance branch circuits, and overload on motors
6. Silver-sand fuses	
<i>a.</i> High-interrupting type	Mains and feeders in which high interrupting capacity is necessary
<i>b.</i> Current-limiting type	Mains and feeders in which magnitude of fault current must be limited
<i>B.</i> High-voltage fuses	Motors
II. Thermal cutouts	
III. Circuit breakers actuated by	
<i>A.</i> Thermal overcurrent release device	Circuits
<i>B.</i> Thermal relay	Circuits
<i>C.</i> Magnetic release device	Circuits and apparatus
<i>D.</i> Magnetic relay	Circuits and apparatus
<i>E.</i> Combined thermal and magnetic release	Circuits and apparatus
<i>F.</i> Induction relays	Circuits and apparatus
IV. Manual switches actuated by thermal releases	Motors
V. Magnetic switches actuated by	
<i>A.</i> Thermal relays	Motors
<i>B.</i> Magnetic relays	Motors
VI. Ground-fault interrupters	
<i>A.</i> Ground-fault circuit interrupters (GFCI)	Persons
<i>B.</i> Ground-fault protection of equipment (GFPE)	Circuits and apparatus
VII. Arc-fault protection (AFCI)	Circuits and apparatus

With fuses and thermal cutouts, in case of overcurrent the circuit is opened inside the device itself. These two overcurrent protective devices must be capable, therefore, of interrupting the line current and of extinguishing the arc thus formed. Relays or overload release devices themselves do not interrupt the line current of the circuit which they are protecting. An overload release device, when operated by a current greater than that for which it is set, trips the holding catch of the switch mechanism and thus allows the switch mechanism to open. The current is interrupted by the switch mechanism and not by the overload release device. An overload relay, instead of acting directly upon the holding catch of the switch mechanism, opens an auxiliary circuit. This auxiliary circuit may be the operating coil of a magnetic switch or the shunt-trip coil of a circuit breaker. As with the overload release devices, the relay does not interrupt the main-line current itself. The main circuit is opened by the contacts of the switch mechanism.

47. Fuses and circuit breakers are used for the overcurrent protection of both circuits and apparatus. Thermal cutouts, thermal overload release devices, and thermal relays

are used for the protection of motors against overloads. They should not be used for the protection of circuits unless they are specifically designed and approved for that purpose. Thermal overload protective devices have admirable characteristics for the protection of motors against overloads, but they should not be relied upon for protection against short circuits unless they are specifically designed and approved for that purpose. Unless they are so designed, in the case of a short circuit there is danger of the excessive current destroying the thermal element before it has actuated the switch mechanism, with the consequent failure of opening the circuit. Circuit breakers actuated by thermal overload release devices and designs for protection against short circuits have been developed and are widely used for the protection of circuits of small and medium current-carrying capacity. When thermal overload protective devices are employed to protect motors, fuses of the proper rating or circuit breakers with the proper setting should always be located at some point back in the line ahead of the thermal protective device.

48. Short-circuit calculations. When considering the use of circuit breakers and fuses, the amount of short-circuit current available at the *line terminals* of such devices must be known so that an overcurrent device with the proper interrupting-capacity (IC) rating can be selected.

Ordinary plug fuses and Class H cartridge fuses, in general, are tested for short circuits not exceeding 10,000 A. Most common-type small-frame-size molded-case circuit breakers have IC ratings of 5000 A, although the present trend is toward ratings of 10,000 A. Larger breakers have IC ratings of 10,000, 15,000, 25,000 and up to 200,000 A, according to types and voltage ratings. The IC ratings for high-interrupting-capacity and/or current-limiting fuses are shown in Fig. 4.65.

Under normal conditions a circuit draws current according to the load impedance and the applied voltage. When a solid short circuit occurs, there will be an abnormally high flow of fault current until the overcurrent device opens. If the short-circuit current is higher than the interrupting rating of the affected overcurrent device, the device may be completely destroyed. In addition, its destruction may cause considerable damage to other equipment.

There is no easy method of calculating available short circuits at various points of a given installation because numerous factors and terms must be clearly understood before such calculations can be made accurately. To explain these factors would require a complete book.

A conservative rule-of-thumb formula which can be used to determine the short-circuit current at the load terminals of a supply transformer would be $I_{sc} = 100\% / \%Z_t \times I_s$, where I_{sc} = maximum secondary short-circuit current based on transformer impedance and assuming a primary source of *infinite capacity*, $\%Z_t$ = transformer impedance, and I_s = full-load secondary current.

EXAMPLE Assume a 75-kVA transformer with a 5 percent impedance and a 120/240-V secondary. The full-load secondary current $I_s = 75,000/240 = 312$ A; then $I_{sc} = 100\% / 5\% \times 312 = 6240$ A. Thus, the maximum short-circuit current is 20 times the full-load secondary current for this transformer. If the transformer impedance were 2½ percent, the short-circuit would be 40 times the full-load secondary current, or 12,480 A. Thus, the transformer impedance is a major factor in determining the maximum secondary short-circuit current. Equally important is the available primary current, which is almost always less than what would be considered an “infinite” capacity. For a given transformer, the lower the available primary current, the lower the secondary short-circuit current, which identifies the previously described formula as quite conservative.

Another major point is that the maximum secondary short-circuit current determined by the previous formula is applicable directly at the secondary terminals of the transformer.

The short-circuit current will be reduced at all downstream points according to the line impedance of the secondary supply conductors. As a result, a fairly long run of conductors from a pole transformer to the service switch would appreciably reduce the maximum short-circuit current available at this point from that shown in the previous example.

It should also be emphasized that certain equipment, such as motors or capacitors, in operation at the time a fault occurs will *add* current to the fault and *increase* the short-circuit current.

49. Low-voltage enclosed fuses (600-V or less) may be classified as follows:

- A. Type of enclosure and contact construction
 1. Plug
 2. Cartridge
 - a. Ferrule contact: Class CC, G, H, J, K, R, or T (60 A or less)
 - b. Knife-blade: Class H, J, K, L, R, or T (601 to 6000 A)
- B. Renewability
 1. One-time
 2. Renewable
- C. Time overload present for fuse to blow
 1. General purpose type; very little time delay
 2. Time delay

The basic features of the different types of enclosures and contact construction are shown in Figs. 4.63 and 4.64. Plug fuses are made in sizes up to and including 30 A. Class CC, G, H, J, K, and R cartridge fuses with ferrule contacts are made in sizes up to and including 60 A. Class H, J, K, R, and T cartridge fuses with knife-blade contacts are made in sizes from 70 up to and including 600 A. Above 600 A, Class L current-limiting fuses are available in ratings up to 6000 A.

One-time fuses cannot be reused after they have operated from the occurrence of a fault. Renewable fuses are designed so that the fusible element can be replaced, after it has operated, by a new element. Thus the fuse cases can be used over and over, and the fuse expense is thereby reduced in service in which the operation of fuses is frequent and short-circuit currents are less than 10,000 A. However, these fuses are now limited by the NEC to existing installations where there is no evidence of misuse through tampering or overfusing.

There is a certain lapse of time for all fuses between the occurrence of an overload and the opening of the circuit by melting of the fusible element. For the ordinary type (the original one-time fuse) this time lapse is very short. The ordinary plug fuse, for example, opens the circuit in approximately 3 s at 200 percent load. The time lapse required for a fuse to open can be controlled through proper design. According to the standards of National Electrical Manufacturers Association (NEMA) and Underwriters Laboratories, certain fuses with an opening time greater than 12 s at 200 percent load are characterized as a time-delay (time-lag) fuse. Such fuses are marked with the letter D, time-delay or dual-element. Other classes require 8 to 10 s at 500 percent.

FIGURE 4.63 Class H and K standard fuses and holders.

FIGURE 4.64 Ampere classifications of Class CC, G, H, K, J, L, and T high-interrupting-capacity or current-limiting cartridge fuses.

Low-voltage fuses rated 600 A or less are of standard ratings and dimensions as established by the National Electrical Code, NEMA and the Underwriters Laboratories. The standard dimensions for Class H cartridge fuses are given in Sec. 50. The dimensions for fuses rated above 600 A are covered by UL 248-10, high-interrupting-capacity fuses, current-limiting type (Type L), and UL 248-15, Class T fuses.

Fuses are made in several types as listed previously. Certain types are definitely limited in their application, some can be used for nearly any application, and others are designed for special applications for which their characteristics are required so that proper protection may be realized and system coordination maintained.

50. Underwriters Laboratories standards on fuses require that all fuses meet the following requirements:

1. The standard on fuses requires that the fuses be of certain dimensions within specified tolerances and meet the following tests:
2. They must withstand heavy short circuits. Failure to do this would result in a very great fire hazard, as such failure would mean that the fuse would explode or belch fire.
3. They must operate at a reasonably low temperature. Failure to do this would make a hazard of the fuse.
4. They must carry rated current. Failure to do this would result in premature burnout, causing unnecessary expense and annoyance. All fuses are required to carry a 100 percent indefinitely when tested in the open. When fuses are installed in enclosures, as is usually the case, they carry less current. Hence the 100 percent requirement makes sure that they carry rated current in actual practice.
5. They must operate promptly at an overload. Failure to do this would result in repair bills amounting to many times the cost of the fuse. The requirements are that fuses operate at a 35 percent overload when tested in the open so that they will blow at a 25 percent overload when installed in an enclosure, as they usually are. The interruption time permitted on 0- to 60-A fuses is 1 h and on larger fuses 2 h.

Voltage	Rated capacity, A	A	B	C	D	E	G

51. Cartridge-fuse types. Cartridge fuses come in a wide range of types, sizes, and ratings. Various classes are designated by NEMA standards and Underwriters Laboratories (UL) standards. In broad terms, these fuses are classified as one-time, renewable, dual-element, current-limiting, or high-interrupting-capacity.

Present NEMA and UL standards indicate that standard (so-called National Electrical Code type) cartridge fuses of one-time or renewable types are designated as Class H. Such fuses are generally classified at an interrupting-capacity rating of 10,000 A. Refer to Sec. 50 for dimensions of 250- or 600-V fuseholders.

1. Interrupting rating 200,000 A rms symmetrical.
2. 250 or 600 V ac.
3. Current-limiting.
4. Dimensions are the same as standard Class H fuses.
5. Fuseholders with a Class R rejection feature will not accept Class H fuses.

Class T fuses: ferrule type

1. Interrupting rating 200,000 A rms symmetrical.
2. 300 or 600 V ac.
3. Current-limiting.
4. Class T fuseholders will not receive fuses of any other type.
5. For 300 V use fuse clip or bolted-in mounting for knife-blade type, and bolted-in mounting for 600 V knife-blade type.
6. 300-V fuses may be used on 277/480-V systems where the voltage of the supply does not exceed 300. The same is true for Class G (300-V) fuses.

FIGURE 4.65 Class R and T current-limiting fuses.

Cartridge-fuse classifications, based on existing UL requirements at IC ratings above 10,000 rms symmetrical amperes, are Class J, L, R, T, G, CC, or K. These fuses are high-interrupting-capacity and current-limiting types. They are shown in Figs. 4.64 and 4.65. The term *high-interrupting-capacity fuse* indicates a fuse interrupting rating at some value above 10,000 to 300,000 rms symmetrical amperes, depending upon the particular fuse. A *current-limiting fuse* is a fuse which safely interrupts all available currents within its interrupting rating and limits the peak let-through current I_p and the total amperes squared-seconds I^2t to a specified degree. UL states that *current-limiting* indicates that a fuse, when tested on a circuit capable of delivering a specific short-circuit current (rms symmetrical amperes) at rated voltage, will start to melt within 90 electrical degrees and will clear the circuit within 180 electrical degrees ($1/2$ cycle). Current-limiting fuses are available with even faster clearing times.

1. Class J and L Fuses. Both the Class J and the Class L fuses are current-limiting, high-interrupting-capacity types. The interrupting rating is 200,000 rms symmetrical amperes, or even 300,000 rms amperes for some models, and it is marked on the label of each Class J or L fuse.

Class J fuse dimensions are different from those for standard Class H cartridge fuses of the same voltage rating and ampere classification. As such, they require special fuseholders

that will not accept non-current-limiting fuses. This arrangement complies with the last sentence of Sec. 240.60(B) of the National Electrical Code, which reads: "Fuseholders for current-limiting fuses shall not permit insertion of fuses which are not current limiting."

Class J fuses of 60 A or less are ferrule type, and from 61 to 600 A they have slots in the fuse blades to permit bolted or knife-blade connections to fuseholders.

Class L fuses are divided into several different amperage classifications; and fuse-blade mounting holes, the number of which varies according to fuse sizes, permit bolted connection to fuseholders.

UL standards list specific dimensions for Class J fuses and recommend specific dimensions for Class L fuses. Both Class J and Class L fuses, covered in these UL rules, closely parallel the existing NEMA standard (FU-1), "Low-Voltage Cartridge Fuses," which includes construction and test recommendations for Class J and Class L fuses.

2. Class G Fuses. Any 480-V cartridge fuse intended to be used on circuits exceeding 10,000 rms symmetrical amperes has been given a designation by UL as Class G. These 480-V or 600-V cartridge fuses successfully passed UL-supervised tests at 100,000 rms symmetrical amperes. Figure 4.64 shows the dimension of these fuses.

3. Class K Fuses. These fuses have interrupting ratings from 50,000 to 200,000 rms symmetrical amperes at various peak let-through currents I_p and maximum let-through energy conditions I^2t . Initially these fuses were divided into three groups, K1, K5, and K9. These groups indicate the degree of I^2t and I_p values. Class K1 fuses provide more current limitation than do K5 or K9 fuses. UL can verify proposed available current ratings of switches or motor starters, based on the use of a specific K-type fuse (K1, K5, etc.). K9 fuses have virtually disappeared from the marketplace.

4. Class R Fuses. These fuses are cartridge-type with a high interrupting capacity and are current-limiting with a built-in rejection feature that prohibits the installations of standard Class H fuses in Class R fuseholders. Class R fuses may be inserted in fuseholders of the standard Class H design. The fuses have passed the UL tests at 200,000 rms symmetrical amperes and have a current-limiting range for the individual case sizes. Class R fuses are divided into two subclasses according to the peak let-through current and total amperes-squared-seconds characteristics. These subclasses are identified by the designations RK1 and RK5 and are physically interchangeable. Figure 4.65 shows these fuses.

5. Class T Fuses. These fuses are cartridge-type with a high interrupting capacity and are current-limiting. The fuses are intended for use with fuseholders which will properly receive Class T fuses but will not receive fuses of any other type. The fuses have passed UL tests of 200,000 rms symmetrical amperes with peak let-through currents and total amperes-squared-seconds characteristics specified for the individual case sizes. Fig. 4.65 shows these fuses. There are two voltage classes, 300 and 600.

All presently UL-listed Class K fuses have the same dimensions as conventional Class H 250-V or 600-V, 0- to 600-A fuses (Fig. 4.63). Because of this interchangeable feature, Class K fuses are not labeled "current-limiting" even though the I_p and I^2t values of K1 fuses compare closely with those for Class J fuses.

52. The ordinary one-time cartridge fuse

(Fig. 4.66) is the oldest type of cartridge fuse in common use today. It consists of a tube of vulcanized fiber, paper, or some similar material within which the fuse element is mounted.

FIGURE 4.66 Ordinary one-time fuse. [Cooper Bussman, Inc.]

The fuse terminals are connected to contact pieces at the ends of the tube. An insulating porous powder resembling chalk surrounds the fuse and fills or nearly fills the tube. When the fuse operates, the powdered material quenches the arc. The ordinary type of cartridge fuse is available in ratings from 1 up to and including 600 A and for use on circuits with maximum voltages of 250 or 600 V, respectively. These fuses have very little time delay, and their use therefore is limited to short-circuit protection on circuits in which faults occur infrequently. They are known as Class H fuses and have an interrupting-capacity rating of 10,000 A in UL listings.

FIGURE 4.67 Ferrule-contact time-lag renewable cartridge fuse. [Cooper Bussman, Inc.]

used on circuits that could subject the fuse to more than 10,000 amperes of available fault current. They are available in ratings from 2 up to and including 600 A and for use on circuits with maximum voltages of 250 or 600 V, respectively. Most renewable cartridge fuses are of the time-delay type. The time delay is accomplished through special link construction that combines parts with a heavy cross-sectional area with parts having a very reduced cross-sectional area. As an example, consider the superlag fuse shown in Fig. 4.69. In this fuse, heavy lag plates are attached to the center of the link. The principal blowing parts of the fuse are near the terminals. The heavy lag plates keep the center of the link relatively cool. An extra reduced section is provided in the center of these plates so that they do not increase the current-carrying capacity of the link too much. As a result, the lag plates serve only to help the terminals conduct away and temporarily store some of the heat generated in the weak spots so that it takes a longer time to get the weak spots heated sufficiently to blow. Thus a time lag far in excess of that of other types of fuses is obtained.

FIGURE 4.68 Knife-blade-contact time-delay renewable cartridge fuse. [Reliance Fuse Division of Reliance Electric Corp.]

FIGURE 4.69 Cutaway view of time-lag fuse of the renewable type. [Superlag fuse of the Cooper Bussman, Inc.]

On light overloads the center weak spot of the superlag link will sometimes burn out. This happens because the rise in temperature of the entire strip is so gradual that the heavy metal terminals of the fuse can conduct the heat away from the end weak spots fast enough to keep them relatively cool. Whether the two end weak spots or the center weak spot of the bus superlag fuse blows first, the superior time lag obtained through the use of the lag plates is not affected.

When a short circuit occurs, the two end weak spots melt instantaneously, and because of the well-known fact that two arcs in series cannot maintain themselves as long as a single arc on the same voltage, much less metal is vaporized.

The thick lag plates also serve to reduce the amount of metal vaporized. First, their cooling effect at ordinary overloads makes it possible to reduce the amount of metal in the weak spots. Second, the thick lag plates in the center of the link serve to keep cooler the entire

53. Renewable cartridge fuses

(Figs. 4.67 to 4.69) are designed so that the fusible element can be readily replaced when blown by a new element. These fuses are now limited by the NEC to existing installations where there is no evidence of misuse through tampering or overfusing. They must never be

mass of metal in the center, and therefore the arc that follows the short circuit cannot so readily melt this center section. As a consequence, less metal is vaporized on short-circuits than with any other type of fuse.

The time-delay renewable fuse is used to take advantage of lower replacement costs for the protection of mains and feeders in which faults occur frequently.

54. Dual-element Class R cartridge fuses combine a thermal element for protection against overloads up to approximately 800 percent of their rating and a fuse link element for protection against heavier overloads and short circuits. They are available in ratings of 1/10 up to and including 600 A and for use on circuits with maximum voltages of 250 or 600 V, respectively.

A typical dual-element fuse is shown in Fig. 4.70. It consists of two copper links *A* and *C* located in the two end sections of the container and a heavy copper center strap *B*. The center strap *B* is held in position by a soldered connection to a spring. The soldered connection acts as the thermal element, while the copper links in the end sections provide the short-circuit element.

Moderate overloads will not melt the short-circuit element but will open the circuit through the action of the thermal element. The center strap *B* is heated by the light overloads. When *B* is heated up to the melting point of the solder, the spring is released and the thermal-cutout portion opens. The heat coil and center strap are quite heavy, so that it takes considerable time to raise the temperature of the strap sufficiently to melt the solder. This feature together with the time required to melt the solder gives the fuse its time-lag characteristics. On heavy overloads the fuse operates immediately, before the thermal-cutout portion has time to function.

Dual-element fuses provide highly desirable protection for most circuits, including mains, feeders, and lighting and appliance branch circuits, as well as motor branch circuits and the overload protection of the motor itself. Their long time lag prevents useless shut-downs caused by ordinary fuses or breakers opening on motor-starting currents or other harmless overloads. They will hold even if all motors on a circuit start at one time; yet they protect against short circuits with all the speed of an ordinary fuse.

Dual-element fuses have a lower resistance than any ordinary fuses. Hence switches and panelboards will operate at a much cooler temperature with dual-element fuses than with ordinary fuses. This prevents damage and the needless operation of fuses so often caused by excessive heating.

Dual-element fuses also give a new kind of protection to switches and panelboards: thermal protection. The thermal cutout in a dual-element fuse will open whenever its temperature reaches approximately 280° (138°C). Thus if poor contact heat develops from any cause, the dual-element fuse cuts off the current before damaging temperatures can be reached.

On motor installations dual-element fuses are particularly advantageous. On normal installations, because of their long time lag, a fuse of a size of about 110 to 125 percent of ampere rating can be installed in a disconnect switch or branch-circuit panel. When so used, dual-element fuses give motor-running protection as safe and dependable as that furnished by the most expensive devices made.

Double protection can be given to motors already protected by other devices simply by replacing the fuses used for short-circuit protection with dual-element fuses of motor-running-protection size. Then if such other devices fail for any reason, the dual-element fuses will open to protect the motor against any dangerous overload or single-phasing condition.

FIGURE 4.70 Nonrenewable dual-element cartridge fuse. [Fusetron of the Cooper Bussman, Inc.]

On new installations, dual-element fuses permit use of proper-size switches and panels instead of oversize ones. With ordinary fuses, switches and panels must be oversized because fuses much larger than the operating load must be used to hold the starting current. But dual-element fuses hold starting currents; therefore proper-size switches and panels to fit the load can be installed. Their use often solves the problem of finding space for the switch or panel and generally saves money as well.

On present installations, by replacing oversize fuses with dual-element fuses switches or panels can be loaded near their capacity. A larger motor or additional motors can often be installed without the trouble of changing the switch or panel.

Refer to Table 46, Div. 12, for increased horsepower ratings of fused switches when time-delay fuses are used as the branch-circuit protection for motors.

55. Small-dimension fuses are available for the protection of instruments and other special apparatus. Fuses for instrument protection generally are enclosed in clear glass containing tubes.

56. Fuse accessories which are advantageous in the use of fuses for special applications are available.

Clip-clamps (Fig. 4.71) which will ensure good contact between the fuse terminals of cartridge fuses and the fuse clips are available.

Fuse reducers (Fig. 4.72) make it possible to use cartridge fuses of a smaller size than that for which the fuse clips are intended. They are available for the following reductions:

For 250-volt Fuses, Amp	For 600-volt Fuses, Amp
60-30	60-30
100-30	100-30
100-60	100-60
200-60	200-60
200-100	200-100
400-200	400-200
600-400	600-400

FIGURE 4.71 Clip-clamps for cartridge fuses. [Cooper Bussman, Inc.]

FIGURE 4.72 Fuse reducers. [Cooper Bussman, Inc.]

FIGURE 4.73 Types of plug fuses. [Cooper Bussman, Inc.]

57. Plug fuses are available in three types (refer to Fig. 4.73): (a) the general purpose type, (b) the time-delay type with standard Edison screw base, and (c) the Type S (tamper-resisting) type. All plug fuses are of the one-time type. The standard sizes are 15, 20, 25, and 30 A. Sizes of 1, 2, 3, 5, 6, 8, and 10 A are also regularly available. Fuses of 15-A capacity or less are provided with a hexagonal window, and those of greater capacity with a round window. Plug fuses should be used only in circuits not exceeding 125 V or in circuits of a system having a grounded neutral and no conductor at more than 150 V to ground. Plug fuses installed in residences should be of the time-delay type on circuits of 20 A or less.

The general purpose *plug fuse* (Fig. 4.74) consists of a wire or strip of fusible alloy mounted in a porcelain, glass or thermoplastic container. The container is fitted with a screw base corresponding to the standard medium lamp-base dimensions and threads. The top of the container is transparent to make the fuse link visible. Since the ordinary plug fuse has very little time delay (it opens in approximately 3 s at 200 percent load), it is subject to opening on harmless transient overloads. This practically limits the satisfactory use of the ordinary plug fuse to incandescent-lighting or heating-appliance circuits.

FIGURE 4.74 Edison-base type of plug fuse.

Plug fuses of the time-delay type are available in both the Edison-base type (Fig. 4.75) and the Type S (tamper-resisting type; Fig. 4.76). Edison-base plug fuses are approved only as a replacement item in existing installations in which there has been no evidence of over-fusing or tampering.

FIGURE 4.75 Time-lag fuse with Edison screw base. [Buss Fusetron of the Cooper Bussman, Inc.]

FIGURE 4.77 Construction of a time-lag fuse of the screw-base type. [Cooper Bussman, Inc.]

FIGURE 4.78 Time-lag fuse for protection of small motors. [Cooper Bussman, Inc.]

A *dual-element, time-delay type* of standard screw-base plug fuse is shown in Figs. 4.77 and 4.78. This fuse consists of a fuse link to which a thermal cutout is added. The internal construction of the screw-base type is shown in Fig. 4.77. An overload causes the thermal cutout to heat up, and if the overload is continued long enough, the solder in the thermal cutout softens to permit the spring to pull out the end of the fuse link, thus opening the circuit. Because it takes some time to melt solder even with a high overload current, the thermal cutout does open quickly, and the fuse link is heavy enough so that it will not open quickly on motor-starting currents.

Hence the time-lag fuse will not open on motor-starting currents that last only a short while. When a short circuit or an overload of approximately 800 percent occurs, the fuse link opens in exactly the same manner as an ordinary fuse.

A time-lag fuse designed especially for the protection of small motors is shown in Fig. 4.78. It is intended to be mounted directly on the motor. When the receptacle is properly installed, the heat from the motor windings is conducted to the thermal cutout in the time-lag fuse at point 1. Should the windings reach a prohibitive temperature with just a normal amount of current flowing, the time-lag fuse will open at point 1, and the motor will be shut down. The opening of the time-lag fuse under these conditions is primarily due to the heat of the motor windings rather than to the current flowing through the fuse. Thus the motor is automatically protected against an excessive rise of the ambient temperature or failure of air circulation or any other condition causing excessive heating of the motor without a corresponding rise in the flow of current. If, on the other hand, the flow of current is so high that the insulation in the motor will be injured or destroyed before the mass of the motor is heated sufficiently to operate the time-lag fuse, as mentioned above, the thermal cutout is heated by the excessive flow of current through the heat coil and opens at point 2. The flow of current is stopped no matter how cold the exterior of the motor may be. If the motor does not properly come up to speed owing to low voltage, a tight belt, dry bearings, or any other cause, the time-lag fuse will open at point 1 or 2. If the motor should be stalled, the excessive flow of current would cause the time-lag fuse to open at point 2. If a short or ground should occur, the excessive current would cause the fuse to open in the fuse link, point 3. However, this method generally has been replaced with thermal devices similar to those described in Sec. 67.

The *tamper-resisting type of plug fuse* (Fig. 4.76) is known as the Type S fuse. It is identical with the standard screw-base type of time-delay plug fuse except for the construction of the base. The Type S fuse has a different-size base which is screwed into an adapter. The

complete assembly is then screwed into a regular Edison-base fuseholder. Adapters are made in sizes from 1 to 30 A. The 15-A adapter will take fuses of any size from 7 to 15 A. The 20-A adapter will take only a 20-A fuse, and the 30-A adapter will accommodate a 20-, 25-, or 30-A fuse. Type S fuses make safe protection remain safe, since (1) once the correct adapter has been installed, an oversize fuse cannot be inserted, and (2) bridging and tampering are practically impossible. They give the best fuse protection for ordinary lighting, appliance, and small motor branch circuits, and they are required when plug fuses are to be used as overcurrent protection in new installation.

58. High-voltage fuses. Fuses for circuits having a voltage greater than 600 are specially constructed so that they will be safe for the interruption of current under such voltages. Two types for protection of power circuits are shown in Figs. 4.79 and 4.80. The fuse of Fig. 4.79 is of the oil-fuse-cutout type. The fuse link shown at II has a section of fusible alloy at the bottom. The entire link except the top laminated-metal terminals is enclosed in flat tubing of insulating material. The link is mounted in a casing and immersed in oil. The fuse of Fig. 4.80 consists of a tube lined with boric acid, which provides a source of deionization for extinguishing the arc. A high-voltage fuse for protecting a potential transformer is shown in Fig. 4.81.

FIGURE 4.79 D&W oil fuse cutout. [General Electric Co.]

59. Circuit breakers are of the two basic types, air circuit breakers (frequently called switchgear) and molded- (insulated-) case breakers. They are switching devices designed to open a circuit automatically at a predetermined overcurrent without damage to themselves when applied within their ratings. Circuit breakers can be closed and opened manually or electrically. Additionally, they have inherent short-circuit ratings to distinguish them from switches, which have limited current-interruption ability.

A circuit-breaker assembly essentially includes (1) an operating mechanism, (2) a contact-and-arc extinguisher system, and (3) an intelligence or current-detection scheme.

A. Overload Response. Early switchgear circuit breakers utilized air dashpots, but modern designs use solid-state circuitry and current transformers. To provide a trip response for overload current, molded-case circuit breakers employ (1) bimetals, (2) hydraulic dashpots, or (3) electronic circuits. State-of-the-art circuit breakers use current transformers and

FIGURE 4.81 High-voltage fuse mounted on potential transformer. [Westinghouse Electric Corp.]

solid-state circuitry to provide inverse-time delay to overloads. Conventional molded-case breakers use bimetals or a cylindrical dashpot having a dynamic core which moves within a fluid.

1. Bimetal designs include two bonded metallic strips having dissimilar thermal-expansion rates. Heat generated by the current causes the bimetal to bend against a trip bar, which unlatches the spring mechanism and opens the contacts as shown in Fig. 4.82. The time-current curve (or inverse-time delay) of a typical 100-A molded-case breaker is also shown in Fig. 4.82; it illustrates the rapid decrease of trip time with increasing overload.
2. Dashpots provide inverse delay to overloads by means of a movable slug inside a hermetically sealed tube (Fig. 4.83). A bias spring positions the slug (core) away from the pole face until an overload through the coil attracts the core upward, which enhances the magnetic field, pulling the armature down to unlatch the breaker. The core does not

Bimetal heats and bends to open contacts on overload

FIGURE 4.82 Principle of thermal trip action. [Westinghouse Electric Corp.]

FIGURE 4.83 Principle of magnetic breaker.

move until minor overloads overcome the bias-spring force. The speed of the core motion varies with increasing current, but tripping due to short-circuit current occurs instantaneously owing solely to the magnetomotive force of the coil.

B. Magnetic (Instantaneous) Trip Action. Electromagnets in series with the load current effect tripping without delay, typically within 1 cycle for molded-case breakers (Fig. 4.84, I). Fault current passing through the breaker causes the electromagnet to effect unlatching and open the contacts. The breaker trips at a predetermined pickup point A in Fig. 4.84, III.

C. Thermal-magnetic Breakers. Combine the thermal and instantaneous features described above and employ both bimetals and electromagnets to provide a trip curve (Fig. 4.84, III). Conventional 150-A and smaller frames have fixed instantaneous trip levels (Fig. 4.84, I), but larger frames have adjustable trip levels to suit user requirements. Figure 4.84, III depicts this adjustment feature, which is usually from 3 to 10 times the nominal trip unit rating.

The National Electrical Code (NEC) defines thermal-magnetic designs as inverse-time, and they satisfy the large majority of circuit-breaker applications. They are sensitive to temperature changes to protect cable and equipment, allow longer overloads under low-temperature conditions, and trip instantly during short circuits.

FIGURE 4.84 Magnetic and thermal-magnetic breakers. I. Magnetic (instantaneous) trip action. II. Thermal-magnetic action. III. Typical time-current curve for a 100-A thermal-magnetic breaker. [Westinghouse Electric Corp.]

D. Temperature Consideration (Ambient Compensation). The thermal elements of molded-case breakers can be modified to compensate for ambient-temperature variations and minimize the need to uprate them in lower temperatures and derate them for high ambients. An additional bimetal is used in the thermal element to coordinate with the primary bimetal and counteract the effects of varying ambient temperature (Fig. 4.85). This provides a more constant current rating and reduces nuisance tripping for installations having a circuit breaker at a location and ambient temperature different from those of the circuit conductor.

FIGURE 4.85 Ambient-compensating breaker. [Westinghouse Electric Corp.]

60. Current-limiting fused circuit breakers. There are available both switch-gear and molded-case circuit breakers which combine special current-limiting fuses to provide compact devices having high fault interruption, typically 200 kA at 600 V ac. Their prime advantage lies in avoiding useless melting of fuses due to over-loads and moderate short circuits by utilizing the breakers for opening and having the fuses operate only during major faults. Additionally, these designs have inter-locks to prevent single-phase operation. Refer to Fig. 4.86, I and II, for a typical molded-case design and a schematic of the trip action.

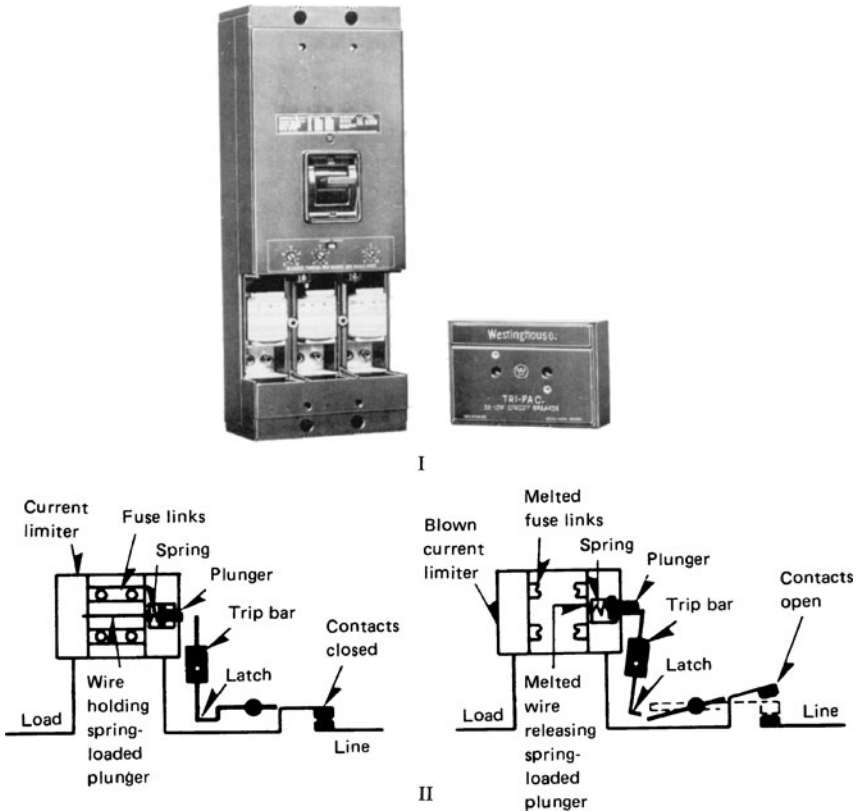

FIGURE 4.86 High-interrupting-capacity breakers. I. High-interrupting-capacity breaker by use of current-limiting devices. II. Current-limiter action. [Westinghouse Electric Corp.]

FIGURE 4.87 Contact action during fault interruption. I. Contact closed: on position. II. Contacts open: position during high-level fault interruption. [Westinghouse Electric Corp.]

61. Current-limiting circuit breakers. Molded-case circuit breakers are also available with special contact designs to provide current limiting without fuses. They are listed by Underwriters Laboratories and represent state-of-the-art construction. They effect rapid arc extinction, minimize potential circuit problems, and protect conventional downstream devices. Figure 4.87 illustrates one pole of a typical design.

62. Class CTL devices. Certain types of plug-in molded-case breakers are designed to satisfy Sec. 408.54 of the National Electrical Code, which requires that the number of circuit devices (fuses or breakers) not exceed the number of circuits for which a panelboard is designed. Consequently, the circuit breakers have unique dimensions and mounting configurations to comply with the maximum number of poles for which the panelboard is designed.

The circuit limiting (Class CTL) requirement first entered the NEC in its 1965 edition. In order to provide replacements for breakers already in use in panels that were installed

previous to this time, UL continues to list the old designs, but they must be prominently marked to indicate that they are not CTL rated and are for replacement purposes only in non-CTL assemblies. Figure 4.88 shows two tandem breakers designed to fit in one normal circuit position) from the same manufacturer. One is CTL-rated for current panels, and has a rejection feature that only allows its use where the manufacturer intends it to be applied. The other has no rejection feature, being thereby capable of occupying any position or any number of positions within a panel, easily defeating the intent of the limitation. They should never be used except on very old panels and only to the extent absolutely necessary.

FIGURE 4.88 A 20-amp Class CTL tandem (left) and a non Class CTL tandem (right) circuit breaker shown for comparison. The CTL breaker set has a restricted-height bus connection slot (compare the dimension markings) that will only mount where a bus stab has been slotted by the panelboard manufacturer.

63. Electronic circuit breakers. State-of-the-art designs of both molded-case and switchgear types of circuit breakers have replaced conventional thermal-magnetic and dashpot trips with current transformers, flux-transfer shunt trips, and solid-state circuitry which are an integral part of the breaker construction (Fig. 4.89). The result is increased accuracy, reliability, and repeatability that were never available with previous breakers. Typically, electronic-circuit-breaker designs have the same physical dimensions and nominal ratings as the conventional breakers they supersede (Fig. 4.90).

The electronic-type units use current transformers to reduce the current to the correct ratio for input to the printed-circuit board (Fig. 4.91). Dual transformation provides an efficient intelligence circuit with low power requirements. Under prolonged overloads or short-circuit conditions, the circuit board generates an output to a low-power flux-transfer device which trips the circuit breaker.

Solid-state circuitry allows users to fashion the trip curve to their exact needs, in that *both* current magnitude *and* time are adjustable with the turn of a dial. Furthermore, latest designs have inherent equipment ground-fault protection, enabling users to dial both pickup and trip time on overloads, short circuits, and ground-fault currents.

FIGURE 4.89 Solid-state circuit breaker. [Westinghouse Electric Corp.]

64. Manual or magnetic switches provided with thermal or magnetic overload relays are commonly used for the overload protection of motors. These switches are discussed in Div. 7.

65. Motor burnouts usually are caused by currents which exceed the motor current rating. In the thermal overload relay, excessive current is translated into a temperature increase. The elevated temperature actuates the relay to trip the motor from the line.

A heater element in the relay is connected in series with the motor. Tripping is usually accomplished by the relay opening the motor-control circuit. The trip point (expressed in amperes) is determined by the heater rating.

Heaters of various current ratings are interchangeable within the specific product lines of any given manufacturer. All heaters, also called current elements, perform the same function; they interpret an increase in motor current as a temperature increase in the overload relay.

66. Types of thermal overload relays. The two main types of thermal overload relays in use today are the bimetallic and the eutectic-alloy types. Bimetallic types (see Fig. 4.92) operate much in the manner of a common bimetallic-element thermostat. Current passing through the heater heats the bimetallic strip, causing it to deflect. In deflecting, the

FIGURE 4.90 Solid-state Sentron Series Sensitrip[®] circuit breaker. [Siemens Energy & Automation, Inc.]

LC

FIGURE 4.91 Printed circuit board used in Seltronic. [Westing-house Electric Corp.]

FIGURE 4.92 Bimetallic overload relay. [Westinghouse Electric Corp.]

strip opens a normally closed contact which is wired into the motor's control circuit. Operation of a bimetallic-type overload relay is illustrated in Fig. 4.93.

Eutectic-alloy relays are commonly called solder-pot overload relays. Operation of a solder-pot relay is illustrated in Fig. 4.94. In such a relay, the contacts are kept closed by a spring-loaded pawl engaging a ratchet. When the motor current is below the value of the heater rating, the ratchet shaft is secured by a pool of hardened solder (eutectic-alloy). As the current rises to a value determined by the heater rating, the solder melts, permitting the ratchet to slip and disengage the pawl.

Both types of thermal overload relays have specific advantages. The bimetallic type is considered more versatile than the solder-pot variety. For applications requiring automatic reset, ambient compensation, and adjustment between incremental heater ratings, the bimetallic type must be used. On the other hand, the solder-pot type performs better

FIGURE 4.93 Operation of bimetallic overload relay. [Westinghouse Electric Corp.]

FIGURE 4.94 Operation of a eutectic alloy (solder pot) overload relay.

when abnormal physical shock and vibration are encountered and when higher control-circuit ratings are required. Both are available in single-pole and three-pole configurations (Fig. 4.95).

In most applications, however, the critical factor is not the choice of solder-pot versus bimetallic overload relay. The essential consideration is proper selection of the heater element. Base the selection on the full-load current of the specific motor being protected, as marked on its nameplate. The relay will be designed to take into account the difference between that number and the point where the NEC requires a sustained overload to be stopped (typically 125% of rated full-load current). Never make this calculation first and then specify the heater element. Doing so will oversize the relay (typically resulting in a 125% of 125% or 156% result) and effectively void the intended protection.

All thermal overload relays have a class designation that specifies the maximum number of seconds in which an overload relay will trip when carrying a current equal to 600 percent of the heater-element rating. Present industry standards recognize Class 10, 20, and 30 overload relays. They require that Class 10 and 30 relays be marked with their class designation. Class 20 overload relays need not be marked.

FIGURE 4.95 Thermal overload relays. [Westinghouse Electric Corp.]

Class 10 overload relays should be used for hermetic refrigerant motor-compressors, submersible pumps, and similar applications in which the motor can only tolerate stalled (locked) rotor conditions for less than 10 s. Class 30 overload relays may be required for motors driving high-inertia loads, such as ball mills, reciprocating pumps, loaded conveyors, etc. Most motors will be properly protected by a Class 20 overload relay selected in accordance with the control manufacturer's instructions.

67. A thermal protector is another form of heat-sensitive element that is authorized for running overcurrent protection. One or more thermal protectors are included in the motor windings at the time that the motor is manufactured. They respond to the temperature at their location by opening a circuit. Thermal protectors may open the power circuit within the motor itself or may open a control circuit which deenergizes a motor controller, thus removing power from the motor. Thermal protectors are rated in motor horsepower and operate in response to currents that are high multiples of a nominal motor full-load current (140 to 170 percent).

FIGURE 4.96 Magnetic inverse-time overload relay. [Square D, Schneider Electric]

68. Magnetic relays and magnetic overload release devices consist of a solenoid acting upon an iron plunger or armature (Fig. 4.96). The coil of the solenoid is connected in series with the circuit to be protected or frequently in ac circuits to the secondary of a current transformer which has its primary connected in series with the main circuit. The current at which the relay will function can be regulated by adjusting the height of the plunger or the position of the movable armature. Instantaneous-type relays and overload release devices function instantaneously upon the occurrence of an overload of any value of current above that for which the device is set.

By the attachment of an air bellows or an oil dash-pot to the plunger the device can be given inverse- or definite-time characteristics. With the inverse-time type, the time that an overload must exist before the device functions is inversely proportional to the severity of the overload. A slight overload must continue for a considerable time before the device will function, while a heavy overload will cause the device to function almost instantaneously. With the definite-time type, the device does not function until the overload has persisted for a certain definite length of time, depending upon the setting of the device. The elapsed time between the occurrence of the overload and the functioning of the device does not depend upon the severity of the overload. The essential difference between a magnetic relay and a magnetic overload release device is the same as for thermal relays and thermal overload release devices. The overload release device acts directly upon the catch of the switch mechanism, while a relay acts upon an auxiliary circuit, which in turn trips the switch mechanism.

Magnetic relays are used in conjunction with circuit breakers and magnetic switches for overload protection. Magnetic overload release devices are employed in conjunction with circuit breakers only.

An inverse-time magnetic overload relay, which is used with magnetic contactors in motor controllers, is shown in Fig. 4.96.

1. Moldarta case.
2. Handle indication. Operational positions of the handle are clearly marked "on" and "off." After a fault clearance, service is restarted by turning handle back to on position.
3. Trip-free toggle mechanism.
4. Free bearing surfaces. These are of dissimilar metals to prevent sticking and bearing wear.
5. Corrosion resistance. All nonhardened ferrous parts are cadmium-plated with a chromate dip which provides maximum resistance to corrosion.
6. Self-cleaning contact. Moving on a sliding pivot point, the contact arm causes a wiping motion of the contacts whenever they are opened or closed. This action assures low contact resistance and long contact life.
7. High-speed arc blowout. When the circuit is broken, a coil-formed stationary contact creates a magnetic field, forcing the arc into the arcing chamber. Arcing takes place on special surfaces, not on contact surfaces used for normal contact.
8. Accurate protection.
9. Hydraulic-magnetic trip unit.
10. Auxiliary switch. A single-pole double-throw auxiliary switch is available as an optional feature when required. Contacts are mechanically actuated by a toggle mechanism but are electrically isolated from the breaker circuit. Auxiliary switches are rated 5 A, 125 V; 1 A, 50 V dc, noninductive.
11. Rear-connected terminals.
12. Threaded inserts. To ensure simplicity of mounting threaded brass inserts are provided to prevent stripping during installation.

FIGURE 4.97 Hydraulic-magnetic circuit breaker. [Westinghouse Electric Corp.]

A modified type of magnetic overload release, called a hydraulic-magnetic release, is used on some circuit breakers. A breaker equipped with this type of release is shown in Fig. 4.97. The hydraulic-magnetic tripping element of this circuit breaker is simply a soleinoid coil wound around a hermetically sealed nonmagnetic cylinder containing a spring-loaded movable iron core and a silicone fluid. When a current up to and including the rated current is passing through the coil, the iron core stays at the end of the cylinder opposite the tripping armature, as shown in Fig. 4.98, I.

When the iron core reaches the opposite end of the cylinder, the magnetic field has increased in intensity to a point to attract the armature. In turn, the armature releases the tripping mechanism, and the circuit breaker opens the circuit (see Fig. 4.98, III). On short circuits, the magnetic flux produced in the coil alone is strong enough to attract the armature regardless of core position, and the circuit interruption is instantaneous.

FIGURE 4.98 Hydraulic-magnetic overload release. [Westinghouse Electric Corp.]

FIGURE 4.99 Combined thermal and magnetic-trip molded-case circuit breaker rated 100 A, 480 V ac, 250 V dc. [Square D, Schneider Electric]

69. A combined thermal and magnetic overload release is used on some circuit breakers. A breaker with this combined release is shown in Fig. 4.99. The inverse-time element of the thermal release provides overload protection for overloads of ordinary magnitude without causing circuit interruption on harmless overloads. The magnetic instantaneous trip provides for split-second tripping on short circuit.

70. Induction-type overload relays are seldom used for ordinary interior-wiring work. They are widely used by central-station companies for the protection of circuits and apparatus. A detailed discussion of these relays is outside the scope of this book. Induction relays operate upon the general principle of induction motors and therefore are applicable only to ac systems. They can be obtained with instantaneous-, inverse-, or definite-time characteristics.

71. Comparison of the time characteristics of overcurrent protective devices. Typical time-current characteristics of the different overcurrent protective devices are illustrated in Fig. 4.100. The curve shown for thermal and magnetic devices is typical. All such devices will have a characteristic of the form shown, although different devices, depending upon design, will vary from that shown in the time of opening the circuit for the various overloads. Time-lag fuses have characteristics similar to those shown for the thermal and magnetic devices. The curve labeled “fuse” is for the ordinary type of fuse, not for time-lag ones. It will be noticed that fuses of the regular type have a considerable time-delay characteristic. They will not blow immediately on an overcurrent unless the overcurrent is approximately 200 percent or greater than the rating of the fuse. Fuses will carry indefinitely a current of 80 percent of their rating. The inverse-time overload protective devices of the thermal, magnetic, and time-lag fuse type have a greater time-delay

characteristic than regular fuses and will therefore allow much greater overloads for a short period without interrupting the circuit. These inverse-time characteristics make these overload protective devices ideal for the overload protection of motors. They will allow the heavy starting current to pass but will protect the motor against sustained overloads that would be harmful to it. They will also permit the motor to operate with intermittent peak overloads of short duration. If ordinary fuses are used for the overload protection of induction motors, the fuses must be shorted during the starting period, for a fuse of proper rating to protect the motor would not allow the starting current to pass. Although ordinary fuses will permit a motor to operate with moderate intermittent peak overloads, they are not nearly so flexible in this respect as the thermal and magnetic protective devices. Devices with inverse-time characteristics are also advantageous for protection of circuits, since they will prevent interruption of the circuit due to short overloads, which, although of high magnitude, would be harmless to the circuit.

FIGURE 4.100 Time-current characteristics of overcurrent protective devices.

72. Protection other than overload protection can be provided by means of release devices or relays employed in connection with circuit breakers or magnetic switches.

Undervoltage protection may be provided by relays or releases actuating hand-operated circuit breakers or by magnetic switches. With magnetic switches, under-voltage protection is generally provided through the operating coil of the switch. When the voltage drops below a certain value, the current of the operating coil is so reduced that it will no longer hold the switch in the closed position.

Underload, overvoltage, or reverse-current, power, or phase-rotation protection can be provided by means of relays employed in connection with circuit breakers or magnetic switches.

73. Ground-fault interrupters. There are two basic types of ground-fault interrupters. They are intended for two very different types of protection. The first, termed a ground-fault circuit interrupter (GFCI) is designed for personnel protection. These devices detect a very low level (milliampere range) line-to-ground fault. Upon detecting these low level ground-faults, the GFCI opens the circuit before a person can suffer serious and possibly fatal effects of the electric shock. The second type of device is called ground-fault protection for equipment (GFPE). Other types of overcurrent protection do not provide reliable protection from line-to-ground faults because of widely varying ground-path impedances, including the arc itself in arcing ground faults. As a result, conventional overcurrent devices may see the arcing ground fault only as a load current. And the continuation of the arcing ground fault will eventually cause a fire or damage equipment. The GFPE device detects these types of arcing ground faults and clears the circuit before damage to the equipment or building.

The basic principle of a ground-fault interrupter is to sense current leakage to ground and then cause an interrupting device to trip open the faulted circuit. Ground-fault circuit-interrupters (GFCIs) are described in (Fig. 4.101.1). The GFCI is designed for life protection, which means that it must cause the circuit to open at very low magnitudes of current

Interrupter senses unbalance in circuit when hot wire becomes grounded. Then a semiconductor differential CB causes circuit to open. Unit opens in less than 25/1000 s when a leakage of 5 mA or more occurs.

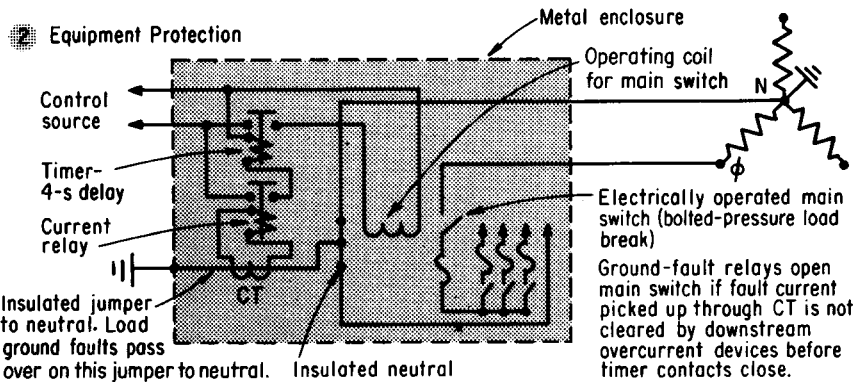

FIGURE 4.101 Two classifications of ground-fault circuit interrupters.

(4 to 6 mA). The heart of such an interrupter is a toroidal coil through which all circuit conductors pass. The interrupter senses any unbalance in the circuit, notably including leakage to ground on one of the circuit conductors as occurs when a person becomes a line-to-ground conductor. The resulting current returning over an equipment grounding conductor is routed so as to not pass through the sensor. Thus, if someone is getting a 5 mA shock from an appliance drawing 10 A, the toroid will see 10 A in one line, 9.995 A in the second line, with the other 0.005 A bypassing the toroid. After this unbalance is detected, a differential transformer and solid-state circuitry supply a current to the coil operating the interrupting mechanism and the circuit is opened within milliseconds (as fast as 25/1000 s) after the ground-fault occurs.

The tripping speed is based on an inverse time principle, and must not be more than $(20/I)^{1.43}$ seconds where I is the current in milliamperes. This is an exponential function, but for a simple point of reference consider a 20 mA ground fault. Since I raised to any power is 1, a 20 mA ground fault must trip the device in not more than one second. Note that the typical self-testing circuit injects about 7 milliamps of unbalanced current through the toroid, and most GFCI devices still trip much faster than one second when tested. This type of ground-fault interrupter is widely used in 120- and 240-V electrical circuits supplying swimming-pool equipment and receptacles in kitchens, bathrooms, basements, in crawl spaces, outdoors,

and on construction sites and in any other applications for which protection from line-to-ground shock hazards are deemed necessary. GFCI protection is available in 50 and 60A for the protection of spas, hot tubs or other larger loads requiring GFCI (people) protection.

GFCIs are available in the form of receptacles, circuit breakers, or as plug-in devices as shown in Fig. 4.102. Note that cord-and-plug type GFCIs (Photo II) also incorporate open neutral protection. If the grounded conductor is open for any reason, the device will not pass current. This prevents the device from failing closed. If the frame of an appliance were hot, and the grounded conductor open due to a field failure, the appliance would otherwise stay energized because the GFCI would not have the 120 V it needs to function.

GFCIs do not require an equipment grounding conductor to function properly; if someone is receiving a shock there will be an unbalanced current through the device that will be detected. However, GFCI testers rely on equipment grounding return path to simulate a current imbalance. Therefore if a GFCI protected outlet on a branch circuit with no equipment grounding conductor is checked with a tester, it will erroneously indicate that the GFCI is nonfunctional. The only way to test a GFCI protected circuit with no equipment grounding conductor is by using the test button on the GFCI device. Note that under the most recent revisions to the GFCI product standard, a GFCI device that fails to operate properly when its test button is pushed immediately trips open and cannot be returned to service.

FIGURE 4.102 I. 15A GFCI receptacle. [Pass & Seymour]

FIGURE 4.102 II. In-line GFCI. [Pass & Seymour]

The second type of ground-fault interrupter is designed for *equipment protection*. Figure 4.101, 2, shows the basic function of this system. With this type of interrupter an electrically operated main or feeder switch or circuit breaker is operated through current and time-delay relays, which are energized when a current transformer detects a ground fault flowing through a main (at the service location) or a system (at a separately derived system source location) bonding jumper. These conductors run from the metal enclosure to the insulated circuit neutral conductor, and constitute the bonding mechanism between the equipment grounding conductors of the system and the grounded circuit conductors of the system. These current relays are adjustable so that the value of ground-fault current

flowing in the circuit can be selected for a given installation before the switch or circuit breaker will trip open. Usually such interrupter devices are set at specific current ratings to allow downstream overcurrent devices to open when grounds occur on the load side of them. Thus, the main switch or circuit breaker opens only when downstream overcurrent devices fail to open under ground-fault conditions.

A zero-sequence ground-fault protection system consists is the other method of providing GFPE, and typically consists of five basic units: (A) ground relay, (B) power unit, (C) zero-sequence-coupling transformer, and (D) a main circuit breaker or bolted-pressure contact switch with a 120-V shunt-trip device mounted in the same enclosure. It functions as follows.

All incoming (three-phase and neutral) conductors pass through the window of the zero-sequence-coupling transformer. The secondary of this transformer is connected to the ground relay. The power unit provides dc control voltage to the sensing element of the relay and the main breaker shunt trip for tripping from a 120-V ac source.

Under normal conditions, the load current flowing in the cables creates a magnetic flux in the zero-sequence-coupling transformer that characteristically balances exactly, thereby canceling the flux. No signal is produced. When insulation fails or leakage current reaches a predetermined level anywhere on the downstream side of the zero-sequence-coupling transformer, a signal is produced to the trigger element. This, in effect, closes the circuit to the shunt trip instantly, thereby tripping the main circuit breaker and isolating the fault. Although these systems operate in the range of hundreds or even thousands of amperes, they differ only in scale and not kind from the toroid in a GFCI that will trip at 0.005 amperes.

The generic term for a sensing device that operates in this way is a *residual current device*. A third style in this category is used for equipment protection on some branch circuits. For example, most electric heat tracing on pipelines and vessels, including frost protection on water lines, requires GFPE because the long, resistive heating components of these systems often fail with low-level arcing to grounded surfaces. If not properly protected, such arcing faults can continue for long periods and start fires because the total current is often well below the tripping point of a conventional overcurrent device. Accordingly the NEC requires GFPE on these circuits. GFPE circuit breakers have been developed for this purpose. They look like GFCI circuit breakers, but they trip at about 30 mA and do not provide shock protection, only equipment protection.

Section 230.95 of the 2008 NEC requires ground-fault protection on services, and Sec. 215.10 requires similar protection for feeders. It should be evident that in large installations in which the incoming service is high-voltage, for example, 13,800 V, and the distribution system consists of several step-down transformers to perhaps 480 V or less, the need for ground-fault protection on all these individual main 480-V feeder circuits is just as important as if the main service to the facility were 480 V. Ground-fault protection must be applied as follows:

1. On grounded Y circuits
2. 150 V to ground or higher
3. Up to 600 V phase to phase
4. Maximum setting, 1200 A or lower
5. Services or feeders rated 1000 A or higher

For feeders, GFPE can be omitted if there is upstream GFPE that is not on the other side of a transformer. For both services and feeders, GFPE can be omitted in the context of continuous industrial process work where a nonorderly shutdown would create a greater hazard. Explanatory notes in Sec. 230.95 advise that to obtain coordination for faults on feeders and branches it is usually desirable and sometimes necessary that ground-fault protection be included on the feeders as well as on the main service. With multiple levels of

protection an outage is limited to a protected feeder instead of the entire building. For health care facilities, NEC Sec. 517.17 requires multiple levels of protection due to the catastrophic consequences of a GFPE trip taking out an entire hospital.

Though not stated in Sec. 230.95, ground-fault protection is very useful on circuits of 240/120 V and 208 Y/120 V and all grounded delta circuits. Uncleared ground faults can be equally damaging on these applications, which are not covered at present in the NEC. It is true, however, that the lower instantaneous maximum voltage to ground (170 V) on these systems poses less of a restrike hazard than on a 480 Y/277 V system. These systems have a much higher instantaneous maximum voltage to ground of 392 V ($277 \text{ V} \times \sqrt{2}$). At this voltage, arcing faults tend to constantly restrike after each current zero, resulting in far greater damage. That is why the NEC mandates the protection at the higher voltages.

Ground-Fault System. Modern ground-fault-protection (GFP) systems operate on the principle of *zero-sequence detection* or *core balance*, as it is more commonly known. This basic approach has been made practical by the advent of solid-state relays, with their inherent low burden characteristics. A GFP system consists of a special-design CT, or ground sensor, and a solid-state relay. The Y-connected 3- to 4-W transformer source is solidly grounded, and three single-phase loads are connected to it. The ground sensors are available with small or large window configurations, designed to enclose all phase and neutral bus or cable conductors but not the ground conductor (see Fig. 4.103 III).

FIGURE 4.103 Family of ground fault sensors and relays. [Square D, Schneider Electric]

The sensors will respond only to ground-fault currents. Balanced or unbalanced load currents and two-phase or three-phase short circuits not involving a ground return will have no effect on the sensor.

Application of a ground-fault system is simple and direct. One sensor and one relay are used with any type of circuit. The sensor is selected by physical size; the relay, by sensitivity range and speed of operation. A minimum pickup setting on the relay offers maximum system protection but at a possible sacrifice in selectivity, depending on the downstream-equipment characteristics. The application does not require a special insulated enclosure or similar complexities. It should be noted that the system neutral must never be grounded on the load side of the ground sensor, that is, at downstream panelboards. Doing so violates numerous NEC rules and provides a parallel return path for fault current over the supply neutral. When the returning fault current over this path reaches the GFPE sensor window, it is detected as normal neutral current, effectively desensitizing the GFPE protection.

Operational Tests. Section 230.95(C) of the NEC requires a performance test when a ground-fault protection system is first installed. It is not necessary to schedule periodic maintenance and testing of the system. However, if tests are desired to confirm the proper functioning of the system, one of the following procedures can be used. With draw-out relays, tests can be accomplished by a simple push-to-test-button operation (see Fig. 4.104).

FIGURE 4.104 Push-to-test ground-fault relay. [Square D, Schneider Electric]

1. Mounted in switchgear.
 - a. After deenergizing the main, set the ground-fault relay to minimum amperes.
 - b. Loop a test coil of approximately No. 14 wire through the sensor window. Special multiturn test cables are available (see Fig. 4.105).
 - c. Apply enough test amperes so that the ampere turns exceed the relay ampere setting. The relay will trip the breaker. Immediately return the test current to zero.
2. Bench tests (without circuit breaker).
 - a. Set the ground-fault relay to minimum amperes.
 - b. Connect the relay and sensor as shown in Fig. 4.106 (typical).
 - c. Apply enough test amperes so that the ampere turns exceed the relay ampere setting. The auxiliary relay will pick up when ground-fault relay operates. Immediately return the test current to zero.

FIGURE 4.105 Special multiturn cable.

FIGURE 4.106 Bench test.

Precaution. The relay output circuit will be damaged unless a normally open auxiliary switch opens the trip circuit after the trip operation.

74. Lightning protection. High voltages may be electrostatically induced in outdoor electric lines during lightning storms. These voltages produce traveling surges of high voltage which travel along the lines and into electrical equipment, whether it is located outdoors or inside buildings. The high induced voltages would puncture the insulation of equipment and be dangerous to life. Lightning arresters are used to limit these voltages to a safe value and provide a path to ground for the dissipation of the energy of the surge. To provide this protection satisfactorily, lightning arresters must fulfill the following functions:

1. They must not allow the passage of current to ground as long as the voltage is normal.
2. When the voltage rises to a definite amount above normal, they must provide a path to ground for dissipation of the surge energy without further rise in voltage of the circuit.
3. As soon as the voltage has been reduced below the setting of the arrester, the arrester must stop the flow of current to ground and reseal itself so as to insulate the conductor from ground.
4. Arresters must not be injured by the discharge and must be capable of automatically repeating their action as frequently as is required.

Lightning arresters should be provided on all overhead systems. For the small consumer who purchases power from a public utility, this protection may be supplied by the utility on its distribution circuits. For a large consumer it may be advantageous to install lightning arresters between the public-utility lines and the consumer's substation. All communication circuits entering a building must be provided with a protector which will give protection against abnormal voltage to ground caused not only by lightning but by accidental contact between communication circuits and power circuits. This protection is usually provided by the communication company which is supplying the service. All signal circuits which are run outdoors for any part of their length or which are installed so that there is any possibility of accidental contact between the signal circuit and power conductors must be provided with a protector.

The National Electrical Code requires radio equipment to be protected against lightning as follows. In receiving stations, each conductor of a lead-in from an outdoor antenna shall be provided with a listed antenna discharge unit, except that where the lead-in conductors are enclosed in a continuous metallic shield, the lightning arrester may be installed to protect the shield or may be omitted if the shield is permanently and effectively grounded. Lightning (surge) arresters shall be located outside the building or inside the building between the point of entrance of the lead-in and the radio set or transformers and as near as practicable to the entrance of the conductors into the building. Antenna discharge units shall not be located near combustible material or in a hazardous location.

Grounding conductors shall be not smaller than No. 10 copper or No. 8 aluminum or No. 17 copper-clad steel or bronze.

75. Surge (lightning) arresters are made in many different forms. A discussion of the construction, application, and installation of the various types is outside the scope of this book. Typical types for power work are illustrated in Fig. 4.107, and types for signal and communication work in Fig. 4.108. Effective with the 2008 NEC, the term "surge

I-Crystal valve
(Elec. Service Supply Co.)

II-Pellet type
(Gen. Elec. Co.)

III Autovalve type
(Westinghouse Elec. & Mfg. Co.)

FIGURE 4.107 Surge arresters of the power type.

II. Arrester for signal circuits.
[General Electric Co.]

FIGURE 4.108 Surge arresters of the low-voltage type.

arrester” only applies to equipment installed on wiring systems running over 1000 V. Surge protection for 600 V and lower systems is to be provided by “surge protective devices”, covered in Sec. 76.

Surge arresters can be installed indoors or outdoors. They must not be accessible to unqualified persons unless listed for accessible areas.

An arrester must not be located in a hazardous location (see Div. 9). When surge arresters are used, an arrester should be installed for each ungrounded circuit wire. The National Electrical Code requires that the connections between an arrester and a line wire or bus, and between the arrester and ground shall be of copper wire or cable or the equivalent. Except for secondary services these connections shall not be smaller than No. 6. The connections shall be made as short and as straight as practicable, avoiding as far as possible all bends and runs, especially sharp bends.

Proper grounding of lightning arresters is of utmost importance. Refer to Div. 9 for discussion of grounding rules and practice.

76. Surge protective equipment at utilization voltages (600 V and below) is provided by surge protective devices [formerly known as transient voltage surge suppressors (TVSS)], is used in connection with lightning (surge) arresters and in large power systems to limit the value of short-circuit current. These devices are also installed to protect sensitive equipment from voltage surges that originate on site or that get past the incoming service line protection. Surge protective devices can be built in the form of branch circuit breakers by the use of metal oxide varistors (Fig. 4.109).

The NEC recognizes three types of surge protective devices. Type 1 devices correspond to surge arresters and are suitable for installation on the line side of the service equipment. Type 2 devices can be installed at any point on the load side of a service disconnect. They are also permitted on the load side of the first overcurrent device in a building or other structure supplied by a feeder. When special arrangements are made for overcurrent protection, these devices can also go on the line side of the service. Type 3 devices, the least robust, are permitted only on the load side of branch circuit protective devices and with the further restriction that they are at least 30 ft, measured along the conductors, from the service or local feeder disconnect for the building.

Some surge-protective equipment consists of coils of wire connected in series with the circuit for the purpose of introducing inductance. Coils used with surge arresters are called choke coils. The inductance of the coils tends to shunt the high-frequency lightning surge away from the apparatus and through the arrester to ground. Those used for limiting short-circuit currents are called reactors and are usually wound on an iron core to increase reactance.

FIGURE 4.109 15 or 20 A circuit breaker with built-in surge protection. [Siemens Energy & Automation, Inc.]

77. Arc-fault circuit interrupters (AFCIs) are the newest type of circuit protection. AFCIs are intended to mitigate the effects of arcing faults that pose a risk of fire ignition when the arcing persists. Arcing is defined as a luminous discharge of electricity across an insulating medium. Arcing can occur between line and neutral or line and ground in which case it is a parallel arc. Arcing can also occur when a single line conductor is severed with a load still connected, which is called a series arc. Arcing at current levels below the instantaneous trip level of conventional over-current devices is frequently sufficient to ignite nearby combustible material, and some decomposition products of electrical insulation are also combustible. Arc-fault circuit interrupters incorporate residual current protective functions (See Sec. 73) along with additional electronics that assess the duration and energy release rates of likely arcing events.

Arc fault circuit interrupters are now required (2008 NEC) to protect all circuits that supply outlets (receptacle and lighting) in dwelling unit family rooms, dining rooms, living rooms, parlors, libraries, dens, bedrooms, sunrooms, recreation rooms, closets, hallways, or similar rooms or areas. Most receptacle outlets in bathrooms, basements, kitchens, garages, and outdoors require GFCI protection. The result is that virtually every outlet in a dwelling unit must now have some form of residual current detection, and in most areas a failure in the branch-circuit wiring itself will also be detected and opened. Although it would be theoretically possible to omit protection of a lighting circuit that only served a kitchen or bathroom or both, as a practical matter essentially all general-purpose lighting and receptacle outlets throughout the entire dwelling must be protected on installations governed by the 2008 NEC and thereafter.

What devices are available?

There are two broad classifications of arcing failures that can be addressed by AFCI technology, namely, a line-to-line or line-to-ground failure that can occur in parallel with a connected load or even with no energized load in operation, or a failure between two severed ends of the same conductor, or at a poor connection point for such a conductor, either one in series with a connected load. The first AFCI devices in wide usage, configured as an additional tripping provision in certain circuit breakers (and designated as “Branch/Feeder AFCIs” by UL), addressed the more common parallel events only, and the NEC permitted the use of this more limited protection until January 1, 2008. Meanwhile, the only design that addressed the series failure was configured as part of a duplex receptacle akin to a GFCI receptacle. These are designated by UL as an “Outlet/Branch Circuit AFCI”, and if located as the first outlet on a branch circuit, provide series protection for the entire branch circuit and parallel protection for all downstream portions of the circuit.

The “outlet/branch-circuit” devices have not, as of this writing been commercially manufactured although prototypes exist and at least one manufacturer has a listing. The reason for this is the restrictive nature of the NEC conditions for which such a device is permitted to qualify as the required AFCI protection for a branch circuit. Under the 2005 NEC the device had to be located not over 6 ft from the point of branch circuit origination with the distance to be measured along the conductors, and metallic wiring methods employed between the two locations. Under the 2008 NEC, the distance can be any length, but the wiring methods must be steel, either as a cable assembly (e.g. steel Type AC, but not the usual Type MC with aluminum armoring) or as one of three specified steel tubular raceways (IMC, RMC, or EMT) but not, technically, wireways or other wiring methods even if made of steel. It remains to be seen whether this will be a sufficient concession to bring these devices to market.

Effective January 1, 2008 under the 2005 NEC, and also as incorporated into the 2008 NEC, AFCI protective devices must combine the best protective features of both parallel and series protective devices. These devices are what the NEC refers to as “combination-type”;

they are marked accordingly and Fig. 4.110 shows an example. *This designation has nothing to do with a device that provides both AFCI and GFCI protection*, although the technology is mutually compatible and devices that provide both shock protection and arc-fault mitigation are available from some manufacturers.

Not all manufacturers are currently making two-pole AFCI circuit breakers, although that will probably change with time. This is important because, just as in the case of GFCI protection, a two-pole device is required to be used with a multiwire branch circuit. Some, but not all manufacturers make AFCIs in bolt-on configurations for commercial and multifamily residential applications. Of course, the bolt-on configuration can be used anywhere but it is more prevalent in the larger quasi-commercial applications. Until the supply chain becomes completely up to speed on current applications, this will be an issue, particularly on retrofits. Note that at least one manufacturer of two-pole AFCIs also makes classified AFCI circuit breakers that are rated for a number of competitors' panels, so that could be another way out for now. Note that such classification ratings are limited to some extent, particularly for applications involving available fault currents over 10 kA

What arcing failures need to be addressed?

On ac circuits electrical arcs tend to self extinguish on the first current zero, and on 120 V circuits the peak voltage of 170 V ($120\text{ V} \times \sqrt{2} = 170\text{ V}$) normally will not restrike an arc. However, there are exceptions that make sustained arcing on 120 V circuits possible, and the results, if uncleared, can easily result in fire. One method of arc restrike involves the breakdown of insulation surrounding a damaged copper wire. As the metal separates (or short-circuits from a conductive penetration) while energized, the initial arc will go out quickly, like a snap switch opening. However, the heat from that initial arc will decompose some of the surrounding insulation, and can cause the separating metal surfaces to become contaminated with carbon and other decomposition compounds capable of thermionic emission, similar to the electrodes in a fluorescent lamp. If the wire is flexed so the contact is renewed and re-broken, the juncture between the cut or broken conductor ends may eventually accumulate enough contaminants so the arc can restrike at voltages below 170 V, particularly given the very short distances separating the conductor ends. If this occurs from line-to-line, or line-to-ground, the normal power available in a circuit can easily produce a release of energy that will cause a fire.

Another related problem involves the deposition of enough carbon in char, together with certain decomposition products of typical insulation, to produce a small, semi-conductive path that produces tracking that will pass enough current at the prevailing voltage to result in red hot conditions at the point of damage. Loose connections at terminals can overheat due to intermittent contact as well (the “glowing contact” phenomenon). These types of series failure will not trip a parallel-responding AFCI device unless the damage happens to progress to the point of line-to-line or line-to-ground failures. In addition, some decomposition products of insulation are combustible and capable of ignition and if this happens the energy released can easily ignite adjacent combustible materials.

How are AFCI devices tested?

Arc fault protective devices that meet the current provisions of the NEC, i.e. combination-type AFCIs, are engineered to address all of these conditions. They do not

FIGURE 4.110 Arcing-fault circuit interrupter. [Square D, Schneider Electric].

guarantee perfect protection, but they are far better than providing no such protection, as will be seen from the tests they must pass under UL 1699. High-current testing (relatively speaking, and resulting from likely parallel events) begins with a “*point contact arc test*” where a knife edge makes solid contact with one conductor and just touches another, arranged with enough impedance so the resulting short circuit is below the instantaneous pick-up point for a conventional circuit breaker, and the resulting intermittent arcs may not actuate the long-time pick-up either. The initial fault current is 75 A, because even in the worst-case residential application, there will be at least that much fault current available in a cord. Additional tests are run at higher fault currents. The device must open anytime there are more than 8 half-cycles of arcing in a half-second (60 half-cycle) period, and a surgical cotton fire indicator at the fault location must not ignite.

To address the problem of line-to-line arc restrike due to the effects of degraded insulation, the device must pass a “*carbonized path arc interruption test*.” A test specimen is cut all the way through to the metal, wrapped with tape, and then conditioned line-to-line with a high-voltage low-current transformer until there is enough carbon to make the juncture capable of striking and restriking an arc at 120 V nominal. The sample is then tested with 75 A and 100A of available fault current and the device must also clear if there are more than 8 half-cycles of arcing in a half-second interval.

The next test is the “*carbonized path arc ignition test*.” This is a series test. The ungrounded conductor only in Type NM-B cable is severed with the other conductors left in place without damage. The cut is wrapped in tape and then surgical cotton, and conditioned with a similar transformer to make the juncture semi-conductive. The device must open the circuit without causing ignition at representative test currents of 5 A, 10 A, rated branch-circuit current, and 150% of rated current. Note that outlet/branch circuit GFCIs must also pass this test for series arcing even when it occurs on the line side of the device; this is possible because of the series connection involved.

The next test is also a series test. The “*carbonized path arc clearing time test*” uses the same test currents, but parallel cord (SPT-2) with no equipment grounding conductor. The cord is cut across with a knife to expose the conductors, but not sever any strands, and then conditioned by exposure to sufficient high voltage and current to thermally degrade the insulation and carbonize the path between conductors. Specifically, in this test the conductivity across the carbonized path must be such that a series-connected 100W lamp will start to glow, or draw 0.3 A. After wrapping the damaged cable in a double layer of electrical tape and a double layer of fiberglass tape, as in the other cases, a current-limiting variable resistor is put in series so the low-current arcing will continue, and the device must open according to published criteria. For example, a 20 A AFCI circuit breaker must trip on a 5 A fault within 1 sec (120 arcing half-cycles) and on a fault of 150% of the breaker rating (30 A in this case) within 0.11 sec (13 arcing half-cycles).

What about nuisance tripping?

This part of the testing is to be as certain as possible that AFCI devices do not trip on harmless arcing that occurs routinely in electrical systems. For example, series motors such as those in vacuum cleaners produce constant arcing at the brush contacts on the rotating armature. Under the “*unwanted tripping tests*” AFCI devices must not trip on loads in this category, whether high or low current in nature. AFCIs must also not trip under the influence of environmental electronic noise, and must demonstrate immunity to electrostatic discharge, radiated electromagnetic fields, electrical transients, voltage surges and dips, and induced disturbances from RF (radio frequency) fields conducted to the devices. This list can be updated as the state of the art progresses. For example, effective February 10, 2008, UL 1699 requires that AFCIs must not nuisance trip on paddle fans and their associated controls, or on air purifiers with UV lighting.

The opposite of a nuisance trip, and more dangerous, is a trip that didn't happen because its effects were masked by a load on the circuit. To this end, UL performs "*operation inhibition tests*" that run the low-current AFCI tests described previously with a series motor operating as part of the load circuit. This gives the current signature a strong inductive component that is significantly different from the basic test and the AFCI must still perform as intended.

What about GFPE?

All circuit-breaker configured AFCI protective devices now on the market use low-level GFPE to comply with the carbonized path arc ignition test. As the arc progresses it very quickly generates leakage current to the equipment grounding conductor. Just as in the case of GFCI protection, low-level GFPE devices use a toroid to detect line-to-line current imbalances, but in these cases the trip is typically set for about 30 mA. Experience and testing history has shown that even the lowest-level arc fault evaluated as part of the test will produce leakages of that amount of current in applications where an equipment grounding conductor is present and the result is a trip before the designated cotton sample can be ignited. Although the scope of the UL 1699 AFCI standard pointedly declares that "these devices are not intended to detect glowing connections" there is a fair amount of experience to the effect that a glowing connection (usually from arcing under a binding screw due to a loose connection) will also generate enough leakage current to trip an AFCI before a fire starts. However, keep in mind that it is possible to meet the testing criteria by developing some other approach because the standard does not mandate this method of compliance. The GFPE approach has an additional advantage in that the technology has been around for a very long time, and nuisance trips on these devices are exceedingly rare. For example, it is almost impossible to confuse the imbalance sensed by a toroid with distorted current waveforms produced by switch-mode power supplies in computers or electronic fluorescent lamp ballasts.

SWITCHBOARDS AND SWITCHGEAR

78. A switchboard is defined in the National Electrical Code as a large single panel, frame, or assembly of panels on which are mounted, on the face or back or both switches, overcurrent and other protective devices, buses, and, usually, instruments. Switchboards are generally accessible from the rear as well as from the front and are not intended to be installed in cabinets.

79. The types of switchboards, classified by basic features of construction, are as follows:

1. Live-front vertical panels
2. Dead-front boards
3. Safety enclosed boards (metal-clad)

Live-front switchboards (Fig. 4.111) have the current-carrying parts of switching equipment mounted on the exposed face or front of the panels. They are not as a rule employed in new boards when the voltage exceeds 600 V.

FIGURE 4.111 Live-front switchboard panel.

FIGURE 4.112 Dead-front switchboard panel.

Large-capacity equipment with resultant increases in weight makes enclosed metal-clad switchboards more desirable from a structural and safety point of view. If high short-circuit currents are available, it is much safer to confine short circuits to metal-clad equipment for the protection of personnel and buildings.

On existing live-front switchboards, obsolete equipment and panels can be replaced with more modern components. In drilling new holes in slate or marble a standard steel twist drill may be used if the heel of the drill is ground off, thus providing the drill with a sharper angle. Slate panels are drilled dry, whereas marble panels must be drilled with the use of water. It is best, however, to use modern masonry drills when drilling such panels.

Avoid excessive pressure when drilling through panels. Abandoned holes can be filled with cement or plaster.

Dead-front switchboards (Fig. 4.112) are the more modern type and are employed for systems of all voltages. With this type no live parts are mounted on the front of the board.

Safety enclosed boards are used for most new installations. Common terms used to designate equipment of this type are *metal-enclosed switchgear* and *metal-clad switchgear*. Most safety enclosed boards are of the unit or sectional type. They consist of a combination of the desired number and type of standardized unit sections. Each section is a standard factory-assembled combination of a formed steel panel and apparatus mounted on a steel framework.

Safety enclosed switchgear of the truck or draw-out type (Figs. 4.113 and 4.114) consists of a steel enclosure mounted on an angle-iron framework. All apparatus which requires attention or inspection is mounted on a truck or draw-out structure. The equipment for each circuit is mounted on either a separate truck, which can easily be rolled out from the rest of the structure, or a metal structure supported on guides so that it can easily be slid in and out from the enclosure (Fig. 4.114).

FIGURE 4.113 Draw-out type of safety enclosed vacuum circuit-breaker switchgear assembly. [Siemens Energy & Automation, Inc.]

FIGURE 4.114 Draw-out type of vacuum circuit-breaker. [Siemens Energy & Automation, Inc.]

80. Safety enclosed switchgear may be classified with respect to purpose of application as follows:

1. General medium- or high-voltage switchgear
2. Primary unit substations
3. Rectifier unit substations
4. Secondary unit substations or power centers
5. General low-voltage switchgear
6. Low-voltage distribution switchboards
7. Motor-control-center switchboards

Medium-voltage switchgear (Fig. 4.115) provides for the required control and metering equipment for generators, transformer supply circuits, feeders, large motors, etc., for systems with voltage up to 15,000 V. A large variety of standardized units is available.

FIGURE 4.115 Medium-voltage metal-enclosed switchgear. [Westinghouse Electric Corp.]

Primary unit substations of the metal-clad type (Figs. 4.116 and 4.117) consist of one or more transformers mechanically and electrically connected to and coordinated with one or more feeder or motor-control sections. A variety of combinations is available in both outdoor and indoor construction.

Rectifier unit substations provide the transforming, rectifying, switching, metering, and control equipment necessary for the conversion of three-phase ac power at any of the conventional voltages to direct current.

FIGURE 4.116 Installed power-distributing center for a brewery in the northeastern United States.

FIGURE 4.117 Outdoor metal-enclosed switchgear. [Westinghouse Electric Corp.]

Secondary unit substations (Fig. 4.118) permit the distribution of power in industrial plants or other large buildings at the higher, more economical voltages and the transformation of the power to the desired utilization voltage at points near the load. They usually consist of three basic types of components: high-voltage (incoming) section, transformer section, and low-voltage (outgoing) sections.

General low-voltage switchgear (Figs. 4.119 and 4.120) provides for the required control and metering equipment for generators, incoming circuits from transformers, feeders, large motors, etc., for systems with voltage not greater than 600 V. A large variety of standardized units is available.

FIGURE 4.118 Secondary unit power center. [Westinghouse Electric Corp.]

FIGURE 4.119 General-purpose low-voltage switchgear assembly. [Westinghouse Electric Corp.]

Low-voltage distribution switchboards may be of the so-called building type or of the multipurpose type. The building type is specifically designed for the control of low-voltage distribution circuits (600 V and below) in offices, hospitals, and commercial types of buildings. A circuit-breaker type is shown in Fig. 4.121 and a fusible-switch type in Fig. 4.122. Multipurpose distribution switchboards are for general use in commercial or industrial

FIGURE 4.120 Typical low-voltage distribution switchgear assembly. [Siemens Energy & Automation, Inc.]

FIGURE 4.121 Power-style distribution switchboard. [Square D, Schneider Electric]

FIGURE 4.122 Power-control-center switchboard. [General Electric Co.]

applications. Typical assemblies are shown in Fig. 4.123, which also indicates the major features of a well-designed modern switchboard.

In general, low-voltage distribution switchboards fall into three distinct NEMA classifications encompassing specific structural features, equipment arrangement, and electrical characteristics, which are noted as follows. Common to all classes are total metal enclosure (except bottom), top or bottom gutter, and vertical sections electrically connected.

Class I. Maximum current limited to 2000 A; group-mounted branches; wall-supported; front accessibility only for line and load connections; flush back.

Class II. No maximum current requirement; group-mounted branches; branches front-accessible only; main bus rear-accessible; self-supported.

Class III. No maximum current requirement; individually mounted branches; branches and mains rear-accessible; self-supported.

Motor-control centers (Fig. 4.124) provide a compact centralized location for full-voltage motor-control equipment. Each compartment contains a magnetic starter with a circuit breaker or a fused switch.

81. Materials employed for the panels of switchboards are slate, marble, ebony-asbestos, and steel. At one time slate was the material principally used for switchboard panels, but it has been almost entirely replaced by ebony-asbestos for live-front boards and by steel for dead-front and safety enclosed ones. Marble is used on live-front

FIGURE 4.123 A modern switchboard with a main disconnect switch and feeder circuit breakers. [Square D, Schneider Electric]

FIGURE 4.124 Motor starter panelboard. [Square D, Schneider Electric]

boards sometimes for its higher insulation qualities over slate but more often for its better appearance.

The supporting frame for panels may be of angle iron or pipe.

82. Location of switchboards. Switchboards of the safety enclosed type may be placed in any nonhazardous location without restriction. Switchboards with exposed live parts must be located in permanently dry locations and only where they will be under competent supervision and accessible only to qualified persons. The rear of a switchboard may be made accessible only to qualified persons by a metal grillwork enclosure, entrance to which is by means of a locked door. Switchboards should be located so as to reduce to a minimum the probability of communicating fire to adjacent easily ignitable material. A clearance of at least 900 mm (3 ft) must be left between the top of a board and a nonfire-proof ceiling unless an adequate fireproof shield is provided between the board and the ceiling or the switchboard is totally enclosed. Refer to Sec. 110.26 of the National Electrical Code for required clearances around switchboards and control centers operating at 600 V and below, and 110.32 to 110.34 for medium voltages.

83. Spacings required by the National Electrical Code. Except at switches and circuit breakers, at least the distance between bare metal parts, busbars, etc., shown in the accompanying table shall be maintained. It should be noted that these distances are the minimum allowable, and it is recommended that greater distances be adopted wherever conditions permit.

	Opposite polarity when mounted on the same surface,		Opposite polarity when held free in air,		Live parts to ground,	
	mm	(in.)	mm	(in.)	mm	(in.) ^a
Not over 125 V	19.1	$\frac{3}{4}$	12.7	$\frac{1}{2}$	12.7	$\frac{1}{2}$
Not over 250 V	31.8	$1\frac{1}{4}$	19.1	$\frac{3}{4}$	12.7	$\frac{1}{2}$
Not over 600 V	50.8	2	25.4	1	25.4	1

^a For spacing between live parts and doors of cabinets, see Sec. 312.11(A) of the NEC.

At switches, enclosed fuses, etc., parts of the same polarity may be placed as close together as convenience in handling will allow unless close proximity causes excessive heating.

84. Busbar Spacings, Minimum Distance between Parts of Opposite Polarity and Minimum Distance between Live Parts and Ground for Different Voltages

(Electrical Engineer's Equipment Co.)

Voltage	Distance between centers of buses, in		Minimum distance between opposite live parts, in		Minimum distance between live parts and ground, in	
	A	B	A	B	A	B
250	$1\frac{1}{2}$	$2\frac{1}{2}$	1	2	$\frac{3}{4}$	$1\frac{1}{2}$
600	2	3	$1\frac{1}{2}$	$2\frac{1}{2}$	1	2
1,100	4	5	$2\frac{1}{2}$	$3\frac{1}{2}$	$1\frac{1}{2}$	$2\frac{1}{2}$
2,300	5	$6\frac{1}{2}$	$2\frac{3}{4}$	4	2	$2\frac{3}{4}$
4,000	6	$7\frac{1}{2}$	3	$4\frac{1}{2}$	$2\frac{1}{4}$	3
6,600	7	8	$3\frac{1}{2}$	$4\frac{1}{2}$	$2\frac{1}{2}$	3
7,500	8	9	4	$4\frac{1}{2}$	$2\frac{3}{4}$	$3\frac{1}{4}$
9,000	9	10	$4\frac{1}{4}$	$4\frac{1}{2}$	3	$3\frac{1}{2}$
11,000	9	11	$4\frac{1}{2}$	$4\frac{3}{4}$	$3\frac{1}{4}$	$3\frac{3}{4}$
13,200	9	12	$4\frac{3}{4}$	5	$3\frac{1}{2}$	$4\frac{1}{4}$
15,000	9	14	5	$5\frac{1}{2}$	$3\frac{3}{4}$	$4\frac{1}{2}$
16,500	10	14	$5\frac{1}{2}$	6	$4\frac{1}{2}$	5
18,000	11	14	6	7	5	6
22,000	12	15	$7\frac{1}{2}$	9	6	7
26,000	14	16	10	12	8	9
35,000	18	22	12	15	10	12
45,000	22	27	16	18	$13\frac{1}{2}$	15
56,000	28	31	$17\frac{1}{2}$	19	16	$17\frac{1}{2}$
66,000	34	38	22	24	$18\frac{1}{2}$	23
75,000	36	42	26	30	25	$27\frac{1}{2}$
90,000	46	54	32	35	27	29
104,000	54	60	$34\frac{1}{2}$	39	$28\frac{1}{2}$	32
110,000	60	72	38	41	33	36
122,000	66	78	42	47	$35\frac{1}{2}$	39
134,000	74	84	$48\frac{1}{2}$	56	39	41
148,000	82	96	59	67	45	50
160,000	88	104	70	84	53	62

NOTE: The distances given in the A columns are based on a safety factor of 3.5 between live parts of opposite polarity and safety factor of 3 between live parts and ground. B column shows good practice for the larger plants. Tubular buses should be used on all buses above 22,000 V. Bus support porcelains should have a wet test of 2 times the voltage used.

PANELBOARDS

85. A panelboard as defined by the National Electrical Code is a single panel or a group of panel units designed for assembly in the form of a single panel; including buses, automatic overcurrent devices, and equipped with or without switches for the control of light, heat, or power circuits, designed to be placed in a cabinet or cutout box placed in or against a wall or partition and accessible only from the front. Panelboards provide a compact and convenient method of grouping circuit switching and protective devices at some common point.

Panelboards may be of either the flush or the surface type (Fig. 4.125). The flush type is used with concealed-wiring installations and has the advantage of not taking up space in the room by extending beyond the surface of the wall. Surface-type boxes are used for installations employing exposed wiring. The boxes are generally constructed of sheet steel, which must be not less than 0.053 in. (1.35 mm) in thickness. The steel must be galvanized or be covered with some other protective coating to prevent corrosion.

Gutters are provided around the panelboards in cabinets to allow sufficient space for wiring (Figs. 4.125 and 4.126). The Code requires that all cabinets which contain connections to more than eight conductors be provided with back or side wiring spaces. These wiring spaces must be defined within the panelboard or other devices in the cabinet by partitions or posts or other permanent methods so that, in combination with the back, sides, and front cover they will be separate closed compartments, unless all wires are led from the cabinet at points directly opposite their terminal connections to the panelboard. The minimum width of gutters required if conductors are deflected upon entering or leaving cabinets is given in Div. 12, Table 33. If the wires enter or leave the enclosure through the wall opposite the terminal, then the increased spacings in Div. 12, Table 34 apply. See Div. 9, Sec. 350 for additional rules and potential exceptions to the increased spacings frequently required in these cases.

A panelboard consists of a set of copper or plated-aluminum busbars, called mains, from which provision is made for tapping off several circuits through overcurrent protective devices and/or switching mechanisms. The provisions for taps generally are built up from unit sections assembled to form the complete board. This plan allows the manufacturers to build a few standard types of unit sections which can be assembled in a great variety of combinations to meet the varying requirements of different installations. This results in economy of manufacture and in the greatest flexibility of possible combinations to meet all requirements. Old-fashioned fusible panelboard construction is illustrated in Fig. 4.126, although the same principles apply to more modern work, and many of the older units are still in use. This figure shows several types of unit sections in the same panelboard to illustrate the flexibility of assembly. Similar panelboards are designed for plug-in or bolt-on circuit breakers or fuse assemblies.

All panelboards have ampere ratings, and such ratings are shown on the name-plate of each panelboard along with the voltage rating. The panelboard ampere rating is the ampacity of the busbars to which the branch overcurrent units are connected.

Main circuit breakers, fused pullouts, or fused switches can be provided in a panelboard. A panelboard without integral main overcurrent protection is called *mains only*,

FIGURE 4.125 Panel boxes.

1. Galvanized sheet-steel box
2. Panel adjusting screws
3. Galvanized channel irons
4. Removable frame barrier separating wiring gutter from panelboard, simplifying panel adjustments
5. Molded Bakelite end section covering main lugs or neutral bar
6. "Plug fuse only" unit section
7. Branch-circuit terminal screws
8. Single-fusing snap-switch, plug-fuse type of unit section
9. Molded Bakelite section plates
10. Double-fusing, two-pole snap-switch, plug-fuse type of unit section
11. Index numbers for identification of circuits
12. Single-fusing snap-switch, cartridge-fuse type of unit section
13. Wiring gutter
14. Double-fusing, two-pole snap-switch, cartridge-fuse type of unit section
15. Snap switches *entirely* removable from front, each enclosed with an individual Bakelite cover
16. Standard knockout arrangement, usually satisfactory for most installations

II. Panelboard assembly, illustrating flexibility of construction.

FIGURE 4.126 Typical panelboard construction. [General Electric Co.]

which means that the panel has only main lugs. Such panelboards are shown in Figs. 4.127 and 4.128.

If a panelboard supplies wiring installed by nonmetallic methods or any other system which will include equipment grounding conductors in a raceway or cable, a grounding terminal bar must be installed to terminate all such grounding wires. The grounding terminal bar must be bonded to the cabinet. It can be bonded to the *neutral* bar of a panelboard only if the panel is used as service equipment.

To provide a high degree of selectivity and flexibility most panelboards today are designed for insert-type fusible or circuit-breaker assemblies. These assemblies are plugged into or bolted onto "receiver" panel interior busbars. With such an arrangement the installer or designer can select the proper size of overcurrent devices for circuits or feeders. Overcurrent-device assemblies are available in single-, two-, and three-pole units.

In selecting a panelboard for any installation it is good design to provide enough space so that additional overcurrent devices may be inserted at a later date.

It is also wise to use surface-mounted panelboards in areas where surface-type wiring is acceptable. This will enable new raceways or cables to be added with less difficulty.

FIGURE 4.127 Circuit-breaker type of lighting panelboard without main breaker. [Square D, Schneider Electric]

FIGURE 4.128 A 480Y/277-V circuit-breaker lighting panelboard without an integral main breaker. [Square D, Schneider Electric]

If installations require concealed wiring, spare conduits should be stubbed to accessible areas, such as above the lift-out ceiling-panel construction in common use today. In such areas the NEC includes an allowance for running multiple nonmetallic cable assemblies through a vertical riser. This facilitates the use of Type NM cables for light commercial construction; a surface panel can go on the wall at a convenient point with a single large riser conduit stub poked through the suspended ceiling to receive the cables. There are numerous limitations to be observed, but the result may make this approach worthwhile. Specifically, the installation must meet the following conditions:

- a. The cables must have entirely nonmetallic sheaths.
- b. The raceway must enter the top of the cabinet.
- c. The raceway must be nonflexible, such as EMT.
- d. The raceway must be no shorter than 18 in., nor longer than 10 ft.
- e. Every cable entering the raceway end must be secured not over 12 in. from the entry point to the raceway.
- f. The raceway must extend directly above the cabinet.
- g. The raceway must not penetrate a structural ceiling.
- h. The raceway must be equipped with fittings on both ends to protect the cables from abrasion.
- i. The outer raceway end must be sealed or plugged by an approved means to prevent debris from falling into the cabinet. Duct seal is often used for this purpose.
- j. The cables that run to the enclosure must have their sheaths intact through the entire raceway section.
- k. The raceway must be supported in accordance with the rules that apply to the wiring method employed.

- l. The cable-fill limitations must be observed. This means the cables cannot occupy more than 40% of the raceway internal cross-section, and for elliptical cables, the cable cross-section is taken as the area of a circle whose diameter equals the major axis of the ellipse.
- m. The mutual conductor heating rules, as covered in Div. 3 Sec. 97, must be applied. This is perhaps the most problematic constraint, however, if the raceway riser does not exceed 24 in. in length, those rules can be ignored because the raceway now qualifies as a nipple.

Every panelboard should include a circuit legend with a neatly typed and accurate description of the circuits supplied by each overcurrent device. Circuit identification is a National Electrical Code requirement and is extremely useful when troubleshooting, repairs, or additional wiring is required. The 2008 NEC includes very specific rules on this point. The prevalence of modern word processing software (and even circuit directory software) makes compliance with these rules far simpler than previously. All circuit directories must meet the following requirements:

- a. Every circuit must have a directory entry, which must be legible.
- b. Every directory entry must describe a “clear, evident, specific purpose or use.”
- c. Every directory entry must include a sufficient degree of detail to distinguish it from all others. This could include outlet faceplate markings correlated with unique directory entries, such as “receptacle outlets in Room A identified as “Ckt ###”, etc.
- d. No directory entry can use a description that depends on transient conditions of occupancy. For example, terminology such as “Ed’s bedroom” or “Annie’s Hair Salon” must be rejected in favor of handing (left or right), or points of the compass, or the use of a map with room numbers, specific receptacle locations, etc.
- e. Spare overcurrent devices must be identified as such on the circuit directory.
- f. Circuit directories must be posted on the face or inside of the panel door (panelboards) and at each switch on a switchboard.

Many panelboards and attached overcurrent devices contain terminals which are suitable for both copper and aluminum wire terminations. In such cases an AL-CU marking will appear in the panelboard and/or on the overcurrent assemblies. If there is no marking as to what type of conductor material may be attached to terminals, it can be assumed that only copper conductors are suitable. In such cases aluminum wire can still be used by splicing a short length of copper wire to the aluminum connector with a suitable connector, especially in the case of branch-circuit connections.

86. Individual protection for panelboards. For some seventy years, the NEC maintained special rules for a classification of panelboards described as *lighting and appliance branch-circuit panelboards*, however, effective with the 2008 NEC, this classification has been abolished. For example, these panelboards required individual protection in accordance with their busbar ratings, whereas power panels did not require individual protection; now all panelboards require individual protection, but the former NEC limit on the numbers of circuit positions (42) has been deleted. The distinctions were a response to a fire in a New York hotel in the 1930s involving large numbers of rubber-insulated wires in a panel, and no longer had technical validity with today’s wire insulation and panel construction methods. Take care, however, to continue to observe any restrictions the manufacturer places on the intended number of circuit connections, as covered in Sec. 62. These limits continue to be enforceable.

There are exceptions to the individual protection rule, as follows:

1. An existing panelboard with up to six circuit breakers may continue to be used without individual protection provided it is used as service equipment for an individual dwelling unit. Figure 4.131 is an example of one of these old “split-bus” panels.
2. A panelboard with up to six circuit breakers may be installed without individual protection provided it is used as service equipment. In this case, with more than two main breakers installed in a new panelboard, the use of a second bus structure within the panelboard as shown in Fig. 4.131 is now expressly prohibited. In other words, for a new installation the top half of Fig. 4.131 would be permitted, but the second, lower bus structure would be located remotely in a separate main-lug panelboard. This type of arrangement is common in many parts of the country, with an outdoor service panel breaking out major loads and an indoor subpanel supplying the various lighting, small appliance, and receptacle circuits. A panelboard with two main breakers is covered in the next topic.
3. A panelboard with two main breakers, as shown in Fig. 4.129, is still permitted provided it qualifies under the old 42-circuit limitation on numbers of circuits for lighting and appliance branch-circuit panelboards. The combined main breaker ratings must not exceed the panel rating.

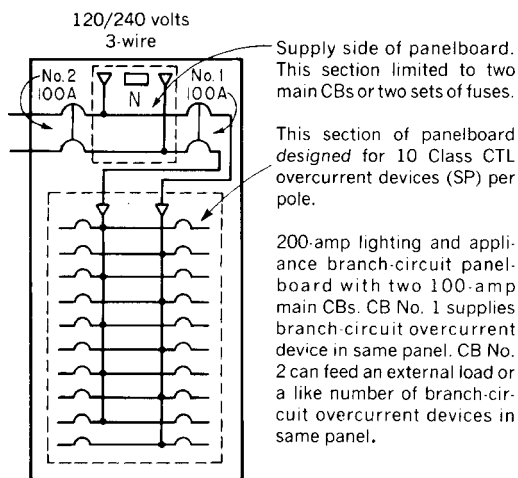

FIGURE 4.129 Typical arrangements of a split-bus lighting panelboard which has two main circuit breakers and Class CTL branch breakers.

Other National Electrical Code provisions which apply to *all* types of panelboards are:

1. Panelboards equipped with snap switches rated 30 A or less, as shown in Fig. 4.126, shall have overcurrent protection not in excess of 200 A. Circuit breakers are not considered snap switches.
2. Panelboards having switches on the load side of any type of fuse shall not be installed except for use as service equipment. In Fig. 4.126 the snap switch is on the line side of the plug fuses and satisfies this Code rule.
3. The individual protection required for panelboards must be located on the load side of any transformer unless the transformer is either a simple two-winding type or a delta-delta

type. For example, a 120/240 V three-wire secondary with a neutral connection, or a 208 Y/120 V four-wire secondary with a neutral connection would not qualify under the exception, and a panelboard connected to the secondary of such a transformer must have its protective device on the secondary side of the transformers. On the other hand, the primary side protection would be acceptable on two-winding or delta-delta connections if it protected the panelboard after considering the transformer winding ratio.

4. Back-fed-type circuit breakers used to supply a panelboard, such as when a main breaker is field added to a main-lug only panelboard to establish individual protection for that panel, must be bolted in place or secured with an additional fastener such that a mere pull

will not release the device from its connection to the busbars. These are available as panelboard accessories from all manufacturers.

FIGURE 4.130 A 54-circuit panelboard with a main breaker used as a service disconnect. Effective with the 2008 NEC, the former 42-circuit limitation has been discontinued. Panelboards of this size have been available for many years in foreign jurisdictions.

5. Three-phase four-wire delta distributions, as shown in Fig. 4.135, should be separated as shown in that drawing. “Delta breakers” in a single-phase panel are not allowed. At one time, “delta breakers” were used to combine both the three-phase and the single-phase loads from a delta distribution into a single-phase panel with only two phase buses for the line-to-neutral loads. The delta breaker took three circuit positions, but only two of those connections contacted the panel busbars. The third pole position consisted of two terminals, one for the third supply phase and one for the load connection to that phase. These breakers were likely to backfeed voltage from their load connections into the panelboard buswork even when the panel main was off, because the main did not interrupt the third phase.

87. Service-equipment panelboards. Panelboards with a single main overcurrent device used as the service disconnect are extremely common (as in Fig. 4.130 but usually with fewer breaker positions). Panelboards with up to six breakers used as service equipment are covered in the preceding topic, particularly under the second topic covering exceptions to the individual protection rule. Since almost all service equipment installations and modifications are subject to inspection, it is not as necessary to provide individual protection for these panelboards. Downstream panels, however, are very likely to be added to without careful loading calculations and the individual protection requirement applies in these cases.

88. Feeder distribution panels generally contain circuit overcurrent devices rated at more than 30 A to protect *subfeeders* that extend to smaller branch-circuit panelboards. This nomenclature is not recognized in the NEC.

89. Power-distribution panels are similar to the feeder-distribution type. This nomenclature has been discontinued by the NEC effective with the 2008 edition; refer to Sec. 86 for an analysis of panelboard requirements that now apply to all panelboards alike.

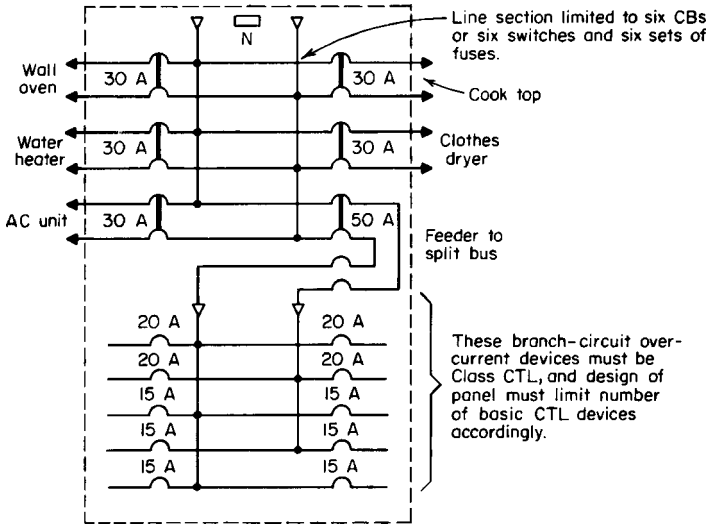

FIGURE 4.131 Suitable arrangement for an existing 200-A lighting panelboard used as service equipment for an individual residential occupancy.

Panelboards formerly described in this way typically have busbars rated up to 1200 A at 600 V or less and contain control and overcurrent devices sized to match connected motor or other power circuit loads. Generally, the devices are three-phase (see Figs. 4.132, 4.133, and 4.134). The discussion in this part of the book now applies to all panelboards.

Figure 4.133 shows a fusible panelboard. It is equipped with Class R (rejection) fuse clips that reject the use of noncurrent-limiting fuses, accepting only those such as illustrated in Fig. 4.70.

FIGURE 4.132 Circuit-breaker type of power-distribution panelboard. [Square D, Schneider Electric]

FIGURE 4.133 Power panelboard with fused-switch units. [Square D, Schneider Electric]

FIGURE 4.134 Converti-fuse power panelboard; fuse-puller switching units.

Special panelboards containing relays and contactors can be obtained and installed when remote control of specific equipment is specified. A thorough knowledge of all available types of panelboards facilitates selection and installation of the proper unit.

90. Location and installation. All panelboards should be located as near as possible to the loads that they supply and control. Mounting heights should be such that the distance from the floor or working level to the center of the grip of the operating handle of the uppermost overcurrent device is not more than 2.0 m (6 ft 7 in.).

Panels to be installed in wet or damp locations, in dust-laden areas, outdoors, or in any hazardous area must be of the type approved for use in such locations.

If qualified persons only are to have access to panelboards, install panel trims with locking-type catches on the doors.

There are several precautions that can simplify panelboard installation, improve workmanship, and produce a neater job. Among them are:

1. Coordinate panelboard cabinet installation with the raceway system, and maintain proper alignment.
2. Align floor-slab conduit stub-ups with openings in the bottom of the cabinets. Maintain alignment during a concrete pour by using interlocking conduit spacer caps or a wood or metal template. This is exceptionally important when the cabinet is to be surface-mounted.
3. Cabinet knockouts should be properly sized and spaced to match feeder and branch-circuit raceway layouts. Most often the standard prestamped single and/or multiple-concentric cabinet knockouts are used. On some installations, however, it is best to order blank enclosures and cut the required knockouts at the jobsite.
4. If cabinets are to be installed flush in a wall, provide temporary anchoring facilities to position the cabinet securely until the wall is constructed. Enclosures supported only by conduit attachments often are knocked out of alignment.
5. Surface-mounted panelboard enclosures should be securely fastened to the wall or other structural surface. In the case of large, heavy panelboards, the addition of supplementary pedestals or "legs" (structural-steel or pipe sections with floor flanges) will increase rigidity and help distribute the weight.

FIGURE 4.135 An effective way of separating single- and three-phase loads of four-wire delta supplies.

6. If a number of panelboard enclosures are to be mounted side by side, the addition of a suitably sized auxiliary gutter, wiring trough, or pull box in between, above, or below the grouped cabinets will facilitate cable pulling and circuit installation. A typical installation is shown in Fig. 4.135. In many cases, it will eliminate the need for oversize cabinets to accommodate the required conductors. Section 312.8 of the National Electrical Code definitely prohibits the use of enclosures for switches and overcurrent devices (and this includes panelboard cabinets) as a feedthrough or splicing gutter for conductors unless the enclosure has been designed to provide adequate space for this.

GENERAL WIRING MATERIALS AND DEVICES

91. Insulators of various types are employed for interior-wiring work when the conductors are not installed in raceways. The more common types may be classified as knobs, cleats, tubes, crane insulators, and rack insulators. The accompanying sections and illustrations give data on many standard types. Insulators for outdoor and underground installations are discussed in Div. 8.

Split knobs are shown in Figs. 4.136 and 4.137. Those of Fig. 4.136 are factory-assembled with a supporting nail or screw. Various standard types of solid-knob insulators are shown in Fig. 4.138. Standard types of rack

FIGURE 4.142 Crane insulators.

93. Use of screws or nails with split knobs. Nails hold better than screws in certain woods. The breaking of knobs at the time of putting them up with screws is not the only source of trouble, for the binding tension applied often acts to crack the knob a considerable time after it has been put in place. It is an objectionable practice of many wire installers in putting up knobs with screws to drive the screws in nearly all the way with a hammer, giving them only a couple of turns with a screwdriver to tighten them. The principal argument in favor of the use of nails is the resulting great saving of the installers' time as compared with the time required for putting in screws. The insulating value of the two constructions is practically the same.

FIGURE 4.143 Insulated cable rack. [Westinghouse Electric Corp.]

three, and four cables and can be supplied with insulator openings of inside diameters ranging from $\frac{3}{16}$ to 3 in (4.8 to 76.2 mm). The diameters vary by $\frac{1}{16}$ in (1.6 mm) from $\frac{3}{16}$ - to $\frac{5}{8}$ -in (4.8- to 15.9-mm) sizes and by $\frac{1}{8}$ in (3.2 mm) from $\frac{5}{8}$ - to 3-in (3.2- to 76.2-mm) sizes.

96. Porcelain tubes are made in three types: standard solid tube, split tube, and floor tube. The standard lengths, as indicated by the L dimension in Fig. 4.145, are $\frac{1}{2}$, 1, 1 $\frac{1}{2}$, 2, 2 $\frac{1}{2}$, 3, 4, 5, 6, 8, 10, 12, 14, 16, 18, 20, 22, and 24 in (12.7, 25.4, 38.1, 50.8, 63.5, 76.2, 101.6, 127.0, 152.4, 203.2, 254.0, 304.8, 355.6, 406.4, 457.2, 508.0, 558.8, and 609.6 mm). The diameters are given in Sec. 97.

II- Standard tube

III- Split tube

FIGURE 4.145 Porcelain insulating tubes.

94. Insulated racks are often convenient for supporting cables in open-wiring installations. They consist (Fig. 4.143) of porcelain insulators mounted in an iron base and clamped together with an iron top for dc work and a brass top for ac work.

They are made in assemblies for one, two,

98. Receptacles and caps or plugs are wiring devices for the purpose of providing a convenient means of attaching cord-and-plug-connected appliances or equipment. See Figs. 4.146 and 4.147. Such devices are available in a wide variety of voltage (600 V or less) and ampere ratings (10 to 400 A). The two broad classifications are grounding and non-grounded types.

The National Electrical Code requires all 15- and 20-A receptacles to be grounding types, and nongrounding-type receptacles can be used only for replacement purposes. Because millions of nongrounding-type receptacles were installed before the Code rule which required grounding types, it was obvious that nongrounding types would have to continue to be manufactured for replacement purposes. Also, because many existing receptacle outlets are not grounded, the Code states that grounding-type receptacles shall not replace nongrounding-type receptacles unless the receptacle outlets are properly grounded. The reason for this rule is to prevent a false sense of security that would exist if a grounding-type receptacle were attached to an existing outlet with no ground connection

I. Double (duplex) grounding-type receptacle.

to the grounding terminal of the receptacle. Ground-fault circuit-interrupter (GFCI) receptacles may be used to replace nongrounding receptacles without the necessity of providing grounding conductors and these receptacles shall be marked “No Equipment Ground.” Existing nongrounding-type receptacles shall be permitted to be replaced with grounding-type receptacles where supplied through a GFCI receptacle, and the receptacles shall be marked “GFCI Protected” and “No Equipment Ground.”

Another significant development concerning receptacles is a National Electrical Code rule which states: “*Grounding-type* receptacles shall be installed only on circuits of *voltage class and current* for which they are rated.” Figures 4.148 and 4.149 list the various receptacles and caps for general-purpose nonlocking and locking types.

The nonlocking-type plug-and-receptacle configurations shown in Fig. 4.148 include both grounding and nongrounding types. Current ratings are 15 to 60 A, and voltage ratings range from 125 to 600 V and two-pole, two-wire to four-pole, five-wire.

FIGURE 4.149 National Electrical Manufacturers Association configurations for locking-type plugs and receptacles. [This figure is reproduced by permission from NEMA WD 6-1988, "Specific-Purpose Wiring Devices."]

Figure 4.149 shows the receptacle-and-plug configurations for locking types, in ratings of 15, 20, and 30 A at 125 to 600 V, two-pole, two-wire to four-pole, five-wire.

Figures 4.148 and 4.149 are the configurations adopted by ANSI and NEMA; these configurations satisfy the National Electrical Code rule which calls for specific voltage and current ratings for all grounding-type receptacles. Also, these configurations are designed so that lower-voltage-rated receptacle caps cannot be inserted into receptacles supplied at higher voltages. This plan also achieves a high degree of standardization so that manufacturers of cord-and-plug-equipped apparatus can provide standard plug caps for such equipment and be reasonably assured that installers will provide a matching receptacle for a given current and voltage class.

Another significant advantage of the NEMA configurations is the wide selection of receptacles to allow different configurations on the same installation if several different voltages, classes of current (ac or dc), or different frequencies are used. In such cases, maintenance personnel usually install plug caps to match specific receptacle configurations.

99. Construction features of receptacles. In many smaller ratings, such as 15 A, 125 V, receptacles are available with single-wipe or double-wipe contacts to receive plug caps. The single-wipe contact is in contact on only one side of the blade of an inserted plug cap. The other side of the plug-cap blade is wedged against a non-current-carrying part of the receptacle. With double-wipe contacts *both sides* of a plug-cap blade are in contact with the receiving part of the receptacle when inserted, and this ensures better contact. Better-grade receptacles have double-wipe contacts, and they should be used whenever possible to avoid early failures or loose connections when plug caps are inserted frequently.

In general, smaller receptacles (15 or 20 A) use binding screws, recessed pressure-locking terminals, or a combination of both as a means of connecting supply wires. With binding screws, supply wires are skinned and wrapped around the screw in a *clockwise* direction. Since the screw is tightened in a clockwise position, this ensures a secure connection. Never fasten a wire around a binding screw in a counterclockwise direction because a poor connection will result when the binding screw is tightened.

The pressure-locking terminals are recessed inside the receptacles. The supply wires are simply skinned about $\frac{1}{2}$ in. (12.7 mm) and are then pushed through a hole (usually in the rear of the receptacle) into the pressure-locking contact. As the wire is inserted, the spring-held contact separates, and when the wire is pushed all the way in, it is firmly gripped. These devices are now limited to 14 AWG conductors; 12 AWG wiring, such as for kitchen receptacles, must be backwired on binding screws.

Some receptacles contain binding screws and pressure-locking terminals so that an installer can select either method of connection. It should be noted that the only type of terminal suitable for the termination of aluminum wire at a receptacle (15- or 20-A) is the binding-screw type marked CO/ALR. The highest quality receptacles have rear connections, but instead of a push-in connection, the receptacles have an internal binding clamp that compresses the inserted conductor as the side binding screw is tightened. These connections are particularly helpful and reliable when the branch-circuit wiring consists of stranded wire, particularly the Class C concentric stranding (19-strand as covered in Div. 2, Sec. 91) that is very common today. The clamp arrangement makes it almost impossible for a strand to escape the terminal and create a short circuit or ground fault at some future time.

Receptacles 30 A or larger generally have *setscrew* terminals, and in such cases the terminals will be marked. AL-CU if suitable for the connection of aluminum conductors. If there is no such marking, it can be assumed that only copper wire connections are permitted.

A class of receptacles has been developed for hospital use. These devices are subjected to more severe damage tests than conventional receptacles. They are identified by the

marking “hospital grade” and by a green dot on the face of the receptacle. These receptacles are for use in nonhazardous locations in health care facilities. The see-through construction of the plugs permits visual inspection of the connections. A special form of hospital grade receptacle is the *tamper-resistant* type, which has been mandatory in pediatric wards of hospitals since the 1981 NEC. These receptacles incorporate an internal shutter mechanism that prevents access to the energized receptacle contacts unless both straight-blade slots are engaged simultaneously.

These *tamper-resistant* receptacles are now (effective with the 2008 NEC) mandatory for new construction for all dwelling unit receptacles installed to comply with the receptacle placement requirements for dwelling units generally. This is virtually every 15- and 20-A 125-V receptacle installed at a dwelling. To meet this greatly broadened requirement, receptacle manufacturers now have residential-grade product lines available.

Receptacles installed in damp or wet locations may deteriorate both due to moisture and the resulting corrosion, and also due to ultraviolet light exposure to the receptacle face if the exposure is outdoors. *Weather-resistant* receptacles are designed to meet this problem, and they are now mandatory for all 15- and 20-A, 125- and 250-V configurations installed in either damp or wet locations. For a dwelling unit, an outdoor receptacle would therefore need to be rated both *weather resistant* (usually marked “WR”) and *tamper resistant*.

Figure 4.150 depicts a method of isolating the equipment-grounding conductor from the yoke of the receptacle. Electronic equipment frequently picks up radio-frequency interference and transient signals through the conventionally grounded system. The complicated circuitry of medical and communication systems is particularly susceptible to transient signals of a very low magnitude. The NEC permits the grounding terminals of receptacles to be isolated from the yoke so that a conductor may be run directly to the grounding-electrode connection in the service equipment. Receptacles with an isolated ground shall be appropriately

FIGURE 4.150 A standard receptacle and an isolating receptacle with the grounding conductor isolated from the yoke of the receptacle. [Pass & Seymour, Inc.]

identified using an orange triangle on the face. Although such receptacles most commonly have an entirely orange face, the only requirement is the triangle, and these receptacles are available with the orange triangle applied to a variety of receptacle colors.

A GFCI switch to feed receptacles and other loads is shown in Fig. 4.151. This device is very useful when GFCI protection must be arranged at a location where a receptacle outlet is not permitted or desired. Ground-fault circuit interrupters for receptacles are required on construction sites; in bathrooms, grade level portions of unfinished accessory buildings used for storage or work areas and garages, crawl spaces, unfinished basements, and outdoor receptacles of dwellings; and within 6 ft of wet bar sinks and receptacles to serve kitchen countertop surfaces. GFCI protection for 125-V, single-phase, 15- and 20-receptacles are required for bathrooms and rooftops of buildings other than dwelling units. Trip units are set at 5 mA and will clear as fast as 25/1000 s. These GFCI receptacles are equipped with a reset button if the unit should trip and a test button that should be used monthly to ensure proper operation of the GFCI. The receptacles may be obtained with a feed-through feature to protect other downstream receptacles. Should a leakage current of 5 mA occur from either phase conductor to ground, the shunt trip will energize and disconnect the receptacle from the circuit. However, line-to-line leakage will not affect the GFCI receptacle trip unit.

FIGURE 4.151 Class A ground-fault circuit interrupter to feed receptacles or a swimming pool. [Pass & Seymour, Inc.]

100. Split-bus receptacles. In the 125-V, 15- or 20-A sizes, parallel-blade-type duplex receptacles are available with break-off jumpers or links so that one or both sides of the receptacles can be separated to avoid feed-through connections. With such receptacles it is common practice to break the connection on only one side of the receptacle that contains the screw connections for the ungrounded circuit conductors. With this connection separated, each half of the duplex receptacle can be connected to a different circuit or switch, or one-half of the receptacle can be controlled by a switch while the other half remains energized at 120 V continuously.

The break-off link on the other side is broken only when two separate circuits are required, particularly when these circuits are *not* three-wire, 120/240 V. Some receptacles with pressure-locking terminals have break-off features also. Be aware, however, that the NEC now requires that a means to simultaneously disconnect all ungrounded conductors arriving at a common yoke must be provided at the panelboard. This could be a multipole circuit breaker or a multipole switch installed adjacent to a fusible panelboard. This common disconnect rule applies to any combination of devices on a single yoke, including a snap switch on the same yoke as a receptacle, and other combinations including field-arranged interchangeable devices covered below.

101. Interchangeable line. Receptacles for use in the interchangeable line are available in 15- and 20-A two-pole, two-wire and two-pole, three-wire. One such type rated at 15-A 125-V two-pole, two-wire is shown in Fig. 4.41, along with other interchangeable devices. For new installations such a receptacle would have to be a two-pole, three-wire, grounding type.

102. Special four-pole, five-wire receptacles. Harvey Hubbell, Inc., has developed a line of five-wire receptacles and caps, rated at 30 A, 250 V ac, dc, or 600 V ac, which retain the advantages of locking-type receptacles. These receptacles are available in eight noninterchangeable center-pin and slot configurations as illustrated in Fig. 4.152. This permits a user to designate one configuration for one voltage, amperage, and/or frequency; a different configuration for a different voltage, amperage, and/or frequency; and so on. Such a system prevents the connection of equipment into the wrong source of power.

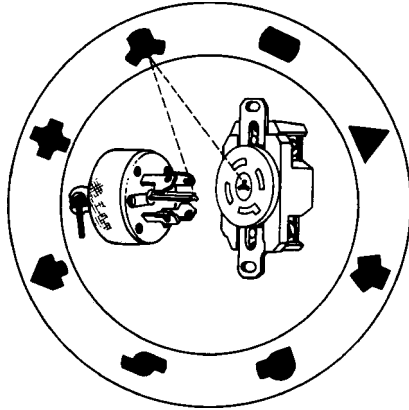

FIGURE 4.152 Noninterchangeable center-pin and slot configurations permit the use of eight differently rated circuits. [Harvey Hubbell, Inc.]

103. Heavy-duty industrial receptacles. Figure 4.153 shows a typical heavy-duty industrial receptacle and a corresponding plug which are available in “pin and sleeve” configurations in ratings up to 400 A at 600 V ac. The devices shown in Fig. 4.153 are five-pole, four-wire and are rated at 60 A, 250 V dc, 600 V ac. The receptacle contains a spring door which closes the plug opening when the plug is removed. Such covers are recommended in many industrial applications to prevent the entry of water, dirt, or dust.

FIGURE 4.153 Heavy-duty industrial receptacle and mating plug. [Crouse Hinds Co.]

104. Range and clothes-dryer receptacles. Figure 4.154 shows three-pole four-wire flush- and surface-mounted range receptacles rated at 250 V ac, 50 A. The three-wire receptacles are only permitted for existing branch-circuit installations. All new installations require a four-wire configuration so that an equipment grounding conductor will be used to ground the frames of ranges and dryers. This crowfoot configuration was commonly used for connecting cord-and-plug-equipped 115/230-V household electric ranges in which the neutral conductor is used to ground the frame of the range. A similar receptacle, rated 30 A, is used for the connection of cord-and-plug-equipped electric clothes dryers of 5.5 kW or less at 115/230 or 120/208 V. The major difference is that the neutral pole is an L shape.

FIGURE 4.154 50-A range outlets. [Pass & Seymour, Inc.]

105. Special receptacle housings are available for receptacles installed outdoors, in hazardous locations, or for other applications in which receptacles must be protected from weather elements, contaminants, or hazardous concentrations of flammable gases, liquids, or dust.

106. A box must be installed at each outlet, switch, or junction point for all wiring installations except for exposed wiring on insulators or cable. An outlet is any point in a wiring system where current is taken for supplying fixtures, lamps, heaters, or any other current-consuming equipment. The boxes must be constructed of metal except for open wiring on insulators, concealed knob-and-tube work, or other nonmetallic wiring methods. In these installations boxes made of insulating material can be used (see Div. 9). Boxes used in interior-wiring work may be classified as outlet, utility, sectional switch, and floor boxes. Utility boxes are designed principally for exposed wiring. Conduit fittings (see Div. 9) are used at the outlets for many exposed-conduit wiring installations. Sectionalized device boxes are used in concealed wiring if they are not embedded in masonry structure. Floor boxes are used for making outlets in floors from conduit wiring systems. Boxes are made of No. 10 to No. 14 gage sheet steel. The surfaces are galvanized. Galvanized boxes will resist corrosion and preserve the electrical conductivity of the raceway system. The different types of boxes are illustrated in Sec. 113 with the dimensions in which they are most commonly available.

107. Box accessories consist of support brackets or ears, studs, cable clamps, and covers. Many boxes are equipped with some form of mounting bracket or with mounting ears. Some of the available types of supporting brackets are shown in Table 111. Standard

mounting ears for the support of device boxes are shown in Table 117 along with other methods of supporting sectional device boxes. Many boxes are provided with fixture studs for the support of a fixture which receives its electrical supply through the outlet box. Boxes are often equipped with clamps for attaching armored cable or nonmetallic-sheathed cable to the box. Different types of clamps are shown in Table 112.

108. Covers for outlet boxes are made in a variety of types. Some of the types available are shown in Table 114.

109. Outlet boxes are made in round, square, octagonal, and oblong shapes. Round boxes should never be used when a conduit must enter the box through the side, as it is difficult to make a good connection with a locknut or bushing on a rounded surface.

The *round* and *octagonal* boxes are used for ceiling outlets in all types of concealed wiring installed in buildings of all types of construction. The octagonal boxes are also used for wall-bracket lighting outlets. Both round and octagonal boxes are made with various combinations of knockouts in sides and bottom and with built-up clamps for armored cable or nonmetallic-sheathed cable. They can be obtained with built-in $\frac{3}{8}$ - or $\frac{1}{2}$ -in fixture studs or with holes for mounting a separate fixture stud. Various types of covers are available for these boxes as shown in Sec. 114. Some are of the flat type, while others have the central portion of the cover raised so that additional interior space is made available in the box. Octagonal boxes constructed especially for concrete work have the bottom or back plate, as it is called, detachable from the sides. The back plate and sides are provided with conduit knockouts. The back plate may be provided with $\frac{3}{8}$ - or $\frac{1}{2}$ -in built-in fixture studs or with holes for mounting a separate fixture stud.

Square and *oblong* boxes are used principally for sidewall outlets in conduit wiring when these are embedded in masonry or installed in brick or tile walls. Sometimes they also are used with conduit wiring in other types of building construction. The square boxes are used sometimes for ceiling outlets. The oblong boxes, which frequently are called gang boxes, are used if more internal space is required than is provided by the square boxes. The term *gang* refers to the number of standard-line wiring devices which the box will accommodate. A three-gang box will accommodate three standard wiring devices mounted side by side. They are made with various combinations of knockouts in sides and bottom. The square boxes may be provided with $\frac{3}{8}$ - or $\frac{1}{2}$ -in built-in fixture studs or with holes for mounting separate fixture studs. Various types of covers are available for the square boxes shown in Sec. 114. Covers are available with openings and supporting lugs for the accommodation of flush wiring devices. The opening is then covered with a standard flush plate. The portion of the box cover around the central opening is raised so that the box is set back a slight amount in the wall and the cover brings the surface of the wiring device flush with the wall surface. The box and the box cover are plastered over a sufficient amount so that the remaining openings will be completely covered with the flush plate. Covers are available with the central portion raised by different amounts to accommodate different thicknesses of plaster. The covers for the oblong boxes are always of the type just described. When the square boxes are used in exposed wiring, a flush plate would not give a neat appearance, and an outlet-box cover which covers the entire opening of the box therefore is used. Openings in the cover accommodate switch handles or receptacles.

110. Utility boxes are designed for use in exposed-conduit wiring installations to produce a neat-appearing job. They are provided with knockouts in bottom and sides. Data on covers are given in Sec. 114.

110A. Sectional device boxes are employed in concealed-wiring installations which are not embedded in masonry. They are constructed with removable sides so that any number of boxes can be ganged side by side to provide compactly for several wiring devices at one location. No covers are required, since the boxes are designed to accommodate the standard flush wiring devices with standard flush plates. They are made in types with conduit knockouts and with clamps for armored cable, nonmetallic-sheathed cable, and loom. Most boxes are 3-in long and 2-in wide.

110B. Extension rings (Fig. 4.155) are available for octagonal and square boxes to increase the depth of the boxes. The standard depths in which they are available for the different boxes are given in Sec. 113.

I - For square box

II - For octagonal box

FIGURE 4.155 Outlet-box extension rings.

111. Bracket Identification^a

Bracket designation		Description and application
B		For mounting on the face of stud. Can be offset from studding to clear door frame or snugged up against studding as desired
F		A sturdy, simple flat bracket for easy side mounting. Exceptionally rigid and easy to install. Hugs close to studding
A		Angle bracket snugs against both face and side of studding. When nails are driven both ways, it becomes the strongest mounting available. Stands up under the strain of marking box openings in dry wall
O		Side-mount bracket mounts on face and side of studding. Locating lugs engage face of studding for normal plaster thickness. Lugs are easily removed so box can be mounted on side of studding in various positions to accommodate all wall thicknesses
D		The D bracket is an integral part of the box, affording great strength and rigidity. These boxes are extremely versatile—easily adapted for 3/8, 1/2 and 5/8-in. wall thickness. Wall thickness is marked on box
E		Face-mounting bracket on end of device box for horizontal mounting of switches or receptacles
T		Exceptionally strong twin mounting bracket for oversize 4- by 2-in. device boxes. Can be nailed from front or side or both. Box stands out from stud for door frame clearance

112. Clamp Identification^a

Clamp designation		For use with	Description and application
C		BX armored cable	For outlet and bar hanger boxes. Two-way entrance design permits cable to enter through side or back of box. Well suited for ceiling work
K		Nonmetallic and BX armored cable	For outlet boxes and device boxes. Provides visual inspection of antishort bushings. Holds bushings tightly against armor stop
D		Nonmetallic cable	For outlet boxes and device boxes. Two-way entrance design permits cable to enter through side or back of box. Compresses when tightened; grips cables firmly
L		Nonmetallic cable	For outlet boxes and device boxes. Compresses when tightened; grips cable firmly. Particularly adaptable for side-entry installations
No. 9		Nonmetallic cable or loom	For ceiling pan installations
No. 10		Nonmetallic cable	For ceiling pan installations. Tapped for outside clamp screw. Compresses when tightened; grips cable firmly
No. 12		BX armored cable	For shallow pans. Tapped hole for outside clamp screw
BD		Nonmetallic cable	For beveled-corner device boxes. Holds cable with even pressure

	Raised 1 in. for one-gang plate		For single push-button switch
	Raised 1 1/4 in. for one-gang plate		For standard duplex receptacle
	Raised 3/4 in. for two-gang plate		For standard square-handle toggle switch
For Oblong Gang Boxes for Accommodating Flush Wiring Devices and Flush Plate Covers			For single T-slot and Edison-base receptacle
	Available for two-, three-, four-, five-, six-, seven-, eight-, and nine-gang flush plates		Cover with knockouts for interchangeable devices

115. Nonmetallic boxes. The material used in the construction of nonmetallic boxes is porcelain, polyvinyl chloride (PVC), fiberglass, or Bakelite. Except for surface-type wiring with nonmetallic-sheathed cable, porcelain boxes are not used because they are easily broken.

Polyvinyl chloride boxes are widely used with rigid nonmetallic conduits, and the boxes are shaped similarly to the more common metal types. Refer to Div. 9 for uses of these boxes with nonmetallic conduits.

Some of the boxes shown in Fig. 4.156 have no cable clamps. When so configured one more wire is permitted in the box in determining the maximum number according to Sec. 314.16(A) of the National Electrical Code. Without cable clamps nonmetallic-sheathed cables must be supported within 8 in. of nonmetallic boxes, and this allowance only applies to single-gang boxes; for all others the cable must be secured to the box. Another important advantage is that no grounding connection is required to the box as with metallic boxes. When nonmetallic cables, which contain grounding wires, enter nonmetallic boxes, they are spliced together with an approved solderless pigtail connector. If a grounding-type

FIGURE 4.156 Plastic boxes for use with nonmetallic-sheathed cable.

receptacle is attached to a non-metallic box, the pigtail connection should include a short lead for connection to the grounding terminal on the receptacle.

If a metallic switch plate is to be attached to a flush switch, switches are available with a grounding terminal. Then the grounding conductor of the supply cable is connected to this terminal, and the metal frame of the switch is grounded. This, in turn, will ground the attached metal switch plate.

116. Flush plates are covers which are used with flush wiring devices in concealed-wiring installations to produce a neat covering of the outlet. They are supported by screws turning into tapped holes in mounting ears or straps on sectional boxes or on covers for square or oblong boxes as described in Sec. 114. Holes in the plates accommodate the handles of flush switches or plugs for flush receptacles. The plates are made in single-, two-, and three-gang sizes with various types and combinations of openings to meet almost any combination of flush wiring devices. Flush plates made of Bakelite, brass, enameled metal, or stainless steel can be obtained. The standard finish for brass plates is brush brass. Plates can be obtained with almost any special finish to meet the requirements of any interior. Some of these special finishes are listed below:

FLUSH PLATE FINISHES

Aluminum (spray)	Bronze, polished	Gilt, rich
Black lacquer	Statuary (light)	Gunmetal
Bower-Barff lacquer	Brown lacquer (imitation Bakelite)	Ivory enamel Nickel, dull
Brass, sand blast, antique	Cadmium, brushed	Polished
Sand blast, brush	Polished	Silver, butler's (brushed)
Flemish	Chromium, dull	Oxidized
Lemon	Polished	Polished
Oxidized	Copper, antique	Satin
Polished	Brush	Verd-antique lacquer
Bronze, antique	Mottled	White enamel
Brush	Oxidized	Various colors
Japanese (dark)	Polished	Wood grain

Flush plates are made for the standard and interchangeable lines of wiring devices. Typical plates are shown in Figs. 4.157 and 4.158. Some manufacturers offer engraved plates to identify standard or special equipment. Some manufacturers maintain standard ordering procedures that allow them to routinely punch any combination of device configurations as required in metal faceplates to meet special installation circumstances. This option is not available, however, with nonmetallic faceplates because special molds have to be constructed for each configuration.

FIGURE 4.157 Flush plates for standard-line wiring devices.

FIGURE 4.158 Flush plates for interchangeable-line wiring devices.

117. Types of Mounting Features for Sectional Boxes

Name	Illustration	Description
Standard mounting ears		<p>Box equipped with two ears, one secured to each end of box with two 8-32 large fillister-head screws. Ears adjustable and reversible. Set of extra holes (not tapped) in each side for changing position of ears to sides if desired (8-32 tap required)</p>
Rectangular mounting bracket without lath support		<p>For plaster or wallboard jobs, with holes for gripping plaster and with aligning-cleat prongs and four nail holes. Bracket is perfectly flat so it does not interfere with wallboard. Bracket is welded to box</p>
Extended mounting ears	 <p>Ears on ends for vertical mounting in plaster with lath support.</p>	<p>For mounting in plaster or baseboard. Each ear fastened to box with two 8-32 fillister-head screws. Can be located on sides or ends. Tapped mounting holes supplied regularly only on ends. Aligning cleat prongs and adequate nail holes for rigid fastening</p>
Box supports and lath holders		<p>For mounting in plaster walls. Supports available in lengths of 16¹/₂, 18¹/₂, 20¹/₂, 22¹/₂, 24¹/₂, and 26¹/₂ in.</p>
Rectangular mounting bracket with lath support		<p>Same as item 2 with lath supports welded to box for wood-lath or wall-board jobs. Back lip of support projects beyond front lip providing adequate support behind wall board and still retaining channel for supporting end of wood lath front and back</p>
Extended mounting ears	 <p>Ears on sides for horizontal mounting in baseboards.</p> <p>Ears on sides for horizontal mounting in plaster.</p> <p>Ears on ends for vertical mounting in plaster without lath support.</p>	<p>For mounting in plaster or baseboard. Each ear fastened to box with two 8-32 fillister-head screws. Can be located on sides or ends. Tapped mounting holes supplied regularly only on ends. Aligning cleat prongs and adequate nail holes for rigid fastening</p>

118. Depth of outlet boxes. The National Electrical Code specifies that outlet boxes intended to enclose flush devices must have an internal depth of at least $1\frac{5}{16}$ in (23.8 mm). No box may have a depth of less than $\frac{1}{2}$ -in (12.7 mm). Boxes enclosing large equipment must be capable of accommodating the rearward projection of any such equipment. Outlet boxes with conduits entering the side should be $2\frac{1}{8}$ in (54 mm) deep for installation in lath and plaster. Boxes $1\frac{1}{2}$ in (38.1 mm) deep will generally be satisfactory for brickwork. Shallow boxes of $\frac{1}{2}$ - or $\frac{3}{4}$ -in (12.7- or 19.1-mm) depth are sometimes used on terracotta ceilings with the box set on the surface of the tile and embedded in the plaster. The conduits are brought into the back of the box.

119. Metal straps for supporting outlet boxes can be obtained in various types with or without attached fixture studs. Several representative types are described below.

For shallow boxes in new work or for holding boxes to concrete forms. With boxes of a depth of $\frac{1}{2}$ in (12.7 mm), in which the bar is nailed to joists or studding, the edge of the box will be flush with ordinary plaster. It will fit any box having a $\frac{1}{2}$ -in knockout. It is made in 18- and 24-in (457- and 609-mm) lengths.

For boxes $1\frac{1}{2}$ in (38.1 mm) deep without switch covers or plaster rings; offset brings the box edge flush with the plaster. It will fit any box having a $\frac{1}{2}$ -in (12.7-mm) knockout. The length of the bar is $19\frac{1}{2}$ in (749 mm). Offset is $1\frac{1}{16}$ in (27 mm) deep.

For boxes $1\frac{1}{2}$ in (38.1 mm) deep with switch covers or plaster rings; offset brings covers $\frac{5}{8}$ in (15.9 mm) high, flush with plaster. It will fit any box having a $\frac{1}{2}$ -in (12.7-mm) knockout. The length of the bar is $19\frac{1}{2}$ in (749 mm). Offset is $1\frac{11}{16}$ in (43 mm) deep.

For mounting shallow boxes or plates in buildings already plastered. Make a small hole about $1\frac{1}{2}$ in (38.1 mm) in diameter; push bar all the way into the hole, long end first as shown in cut; hold stud in one hand and pull wire with the other until the bar is centered across the hole. It will fit any box having a $\frac{1}{2}$ -in (12.7-mm) knockout. The length of the bar is 12 in (305 mm).

For boxes $1\frac{1}{2}$ in (38.1 mm) deep with covers and integral studs or without studs. Offset has slots for stove bolts to hold the box and is the right depth to bring $\frac{5}{8}$ -in (15.9-mm) covers flush with the plaster. The length of the bar is 21 in (533 mm). Offset is $1\frac{11}{16}$ in (43 mm) deep.

120. Wallboard hanger (General Electric Co.). Instructions for supporting a switch box with a special wallboard hanger are given below and illustrated in Fig. 4.159.

For installing switch boxes in old work where plaster, wallboard, plasterboard, or similar construction is present:

1. Cut hole the exact size of the switch box.
2. Assemble the switch box and hanger. Only partially tighten the bolt.
3. Push assembly into the wall hole until the sides of the hanger spring free on the inside wall.
4. Tighten by screwing the bolt on the inside of the box.

Inside and outside pressure against the wall give the box a rigid installation.

121. Floor boxes (Fig. 4.160) are made in adjustable and nonadjustable types to provide outlets from concealed conduits embedded in floors. The adjustable ones allow the top to be adjusted in height and angle to suit the floor conditions. They may be obtained in single- and multiple-outlet units.

FIGURE 4.159 Wallboard switch hanger. [General Electric Co.]

FIGURE 4.160 Adjustable floor box with flush grounding-type receptacle. [Steel City Division of Midland-Ross Corp.]

122. Door boxes (Fig. 4.161) are for the installation of door switches in the jamb of the door. They are made in different types to accommodate the different types of door switches.

FIGURE 4.161 Type of door box.

123. Pull boxes are described in Div. 9.

124. Lampholders consist of an assembly for supporting lamps, comprising the lamp socket, protective and insulating covering, and means for attachment to some form of support. The term *socket* is sometimes incorrectly used in place of lampholder. Each lampholder must have a lamp socket, but the socket is only the part of the lampholder which engages with the base or terminal of the lamp. Lampholders are made in a great variety of types to fulfill the requirements of all classes of installations and types of lamp bases.

125. Brass-shell-type interchangeable lampholders are the old standard type for incandescent lamps. They consist of two fundamental parts, a body (Fig. 4.162, III) and a cap (Fig. 4.162, I) or base (Fig. 4.162, II). The two parts are held together by means of a fluted catch which allows them to be easily separated or assembled. Any cap or base can be used with any body. The body consists of a socket mounted on a porcelain or composition support and encased in an outside brass shell.

FIGURE 4.162 Fluted-catch interchangeable lampholders. [General Electric Co.]

The socket is insulated from the shell by means of a fiber casing. When the porcelain or composition portion of the body simply forms a support and assembly for the socket and electric-circuit connecting screws, it is known as a keyless body. If the body contains a small switch for turning the lamp on or off, it may be of the key, pull-chain, or push type (Fig. 4.163). Caps are made with standard inside pipe thread for connection to $1/8$ -, $1/4$ -, $3/8$ -, or $1/2$ -in pipe or with $3/8$ -in male thread. Caps are also constructed with porcelain- or composition-bushed holes or with cord-lamp grip for pendant support on a drop cord. The cord holes are 0.406 in (10.31 mm) in diameter, and the cord grips will accommodate cords from 0.375 to 0.5000 in (from 9.525 to 12.7 mm) in diameter. Bases are available for mounting directly on outlet boxes and for exposed wiring of either the cleat-mounting or the concealed-base type.

FIGURE 4.163 Fluted-catch lampholder bodies.

126. Threaded-catch interchangeable lampholders for incandescent lamps (Fig. 4.164) are a new development. They consist of a body fastened by means of a threaded ring to a cap or base. The bodies, caps, and bases may have outer brass shells or may be made of composition. The same types of bodies, caps, and bases are made as for the fluted-catch ones of Sec. 125. The line is interchangeable in that any cap or base will fit any body.

FIGURE 4.164 Threaded-catch interchangeable lampholders. The threaded metal ring (I), knurled to provide a grip, holds the cap and shell together. The cap (II) cannot pull loose from the shell, and no amount of vibration will loosen the threaded ring when it is properly assembled. A lug in the cap fits in the shell slot, preventing rotation between cap and shell. After the cap has been fitted to the shell, the flange on the threaded ring fits over the flange on the cap, and the ring is securely threaded to the shell.

FIGURE 4.165 Porcelain snap-catch interchangeable lampholders.

127. The porcelain snap-catch interchangeable line of lampholders for incandescent lamps (Fig. 4.165) is used in installations subjected to moisture, acid fumes, or other corroding influences. The bodies are fitted with two bayonet hooks, which engage two flexible phosphor-bronze contacts in the cap or base. The two parts are thus securely locked together when assembled but permit easy disassembly without affecting the wiring. The bayonet hooks and bronze contact catches provide the electrical connection between cap and

body as well as supplying the means of mechanically supporting the body from the cap. The same general types of caps, bases, and bodies are included in this line as for the

fluted-catch line. A porcelain line for the same type of applications is made with the cap and body fastened together by means of two screws.

128. Noninterchangeable lampholders are made in a great variety of types to meet the requirements for lampholders for show-window, showcase, cove, trough, or reflector lighting; candelabra or intermediate-base lamps; Lumiline or fluorescent lamps; mounting on outlet boxes; mounting in fixture canopies; lamp outlets in exposed wiring on insulators; and sign lighting, etc. Most of these holders are made of porcelain, but plastic materials are used to a limited extent. A few of the more common types are shown in Fig. 4.166.

I A plastic body lampholder for outlet box mounting. Porcelain holders of same type more commonly used.

II Screw ring porcelain lampholder for mounting in fixture canopies

III Porcelain lampholder for surface mounting

IV Porcelain lampholder for surface mounting in cleat wiring installation

FIGURE 4.166 Types of interchangeable lampholders.

129. Holders are available for surface mounting for use primarily in installations wired with nonmetallic-sheathed cable (Figs. 4.167 and 4.168). For dry locations these holders have cases of all-plastic construction. Holders for excessively moist or dusty locations have porcelain bases and plastic tops. Both types are made in keyless and pull-chain constructions.

FIGURE 4.167 All-plastic lampholders for use with nonmetallic-sheathed cable.

FIGURE 4.168 Porcelain-base lampholders for use with nonmetallic-sheathed cable.

130. Weatherproof lampholders (Fig. 4.169) with one-piece porcelain, composition, or rubber cases are made with sealed-in leads for wet locations.

I-Bakelite type

II Porcelain type

III-Rubber type

131. Shade holders. Many lampholders have the body supplied with threads or grooves for engaging shade holders. Shade holders are made with openings of 2 1/4, 3 1/4, and 4 in

FIGURE 4.169 Weatherproof lampholders. [General Electric Co.]

FIGURE 4.170 Shade holders.

(57.15, 82.55, and 101.6 mm) diameter for accommodating shades. Shades may be held to the shade holder with a wire spring or by means of screws (Fig. 4.170).

132. Insulating socket bushings must be used where a cord enters a socket to protect it against abrasion and grounding against the shell. The most popular bushings are of hard rubber or of a compound resembling it. Patented bushings which automatically grip the cord by a wedging action can be purchased.

Most lampholders of the pendant type are fitted with an approved bushing constructed as an integral part of the lampholder cap.

133. Rosettes are devices for supporting and connecting to the circuit the cord and sockets of flexible drop cords. They are made in different types for open wiring and for attaching to outlet boxes or moldings. Rosettes similar to the one shown in Fig. 4.171 are used for open-wiring work, and ones similar to that of Fig. 4.172 for attachment to outlet boxes. The drop cord passes through the hole in the center and is attached to connections inside the body of the rosette. The connections should be relieved of any strain by making a knot in the wires just inside the rosette body. Fused rosettes were at one time employed, but they are no longer allowed by the National Electrical Code rules.

An all-plastic rosette for use with nonmetallic-sheathed cable is shown in Fig. 4.173.

FIGURE 4.171 Cleat-base rosette for open wiring.

FIGURE 4.172 Rosette for attachment to outlet box.

134. Lampholders for fluorescent lamps are available in various types to meet all the usual conditions of installation. Combination lampholders and starter sockets also are available. Typical constructions are shown in Fig. 4.174.

FIGURE 4.173 All-plastic rosette for use with nonmetallic-sheathed cable.

POWER CAPACITORS

135. Power capacitors are capacitors with relatively large values of capacitance which are used on power-distribution systems or in industrial plants for improving the power factor. Since many power companies include low-power-factor penalties, kilovolt-ampere demand rates, or power-factor bonuses in their rate schedules, it is often economical for industrial consumers to install capacitors for power-factor improvement. These capacitors are connected across the line and neutralize the effect of lagging power-factor loads, thus reducing the current for a given kilowatt load. The amount of reactive kilovolt-amperes of capacitors required to raise the power factor to any given value can easily be determined from the chart of Fig. 4.175.

The best point to connect capacitors to the circuit depends upon cost considerations. Relatively small capacitor units, *A* in Fig. 4.176, can be connected at the individual loads, or the total capacitor kilovolt-amperes can be grouped at one point and connected to the main bus. Both of these methods are shown schematically in Fig. 4.176. Greater power-factor corrective effect for a given total capacitor kilovolt-amperes will result with the capacitors located directly at each individual load, since the current is thereby reduced all the way from the load to the source. The first cost of an installation of individual capacitors will be greater, however, than that for one unit of the same total kilovolt-amperes located at a central point. The greater saving in operating expense due to individual capacitors must be weighed against their increased first cost.

136. A complete capacitor bank is made up of the necessary standard units to give the desired kilovolt-amperes, connected in parallel with each other. Each unit consists of one or more cells enclosed in a hermetically sealed steel box (Fig. 4.177). The cells are aluminum-foil, paper- or film-insulated capacitors impregnated with insulating fluid. Standard units can be obtained with the cells internally connected for single-, two-, or three-phase operation. The units may be of enclosed- or rack-type construction. The enclosed construction is made primarily for individual motor applications (Fig. 4.181). It consists of a dusttight steel conduit box (Fig. 4.178) mounted on top of the hermetically sealed

© 1921. Westinghouse Electric & Mfg. Co.

FIGURE 4.175 Chart for use in determining the percentage of reactive kilovolt-amperes required to raise the power factor to a desired value.

capacitor. The conduit box contains the terminals, discharge resistor, and fuses if desired (see Fig. 4.182). Rack-type banks consist of the required number of hermetically sealed capacitors with exposed terminals, supported on a steel rack. The complete structure may be provided with enclosing screens, dusttight steel enclosing cases, or a steel enclosing cabinet for outdoor installation. Each capacitor unit of the bank is individually fused, and the entire bank is provided with discharge resistors or coils inside the enclosure (see Fig. 4.183). Typical assemblies for wall, ceiling, and floor mounting are shown in Figs. 4.179 and 4.180.

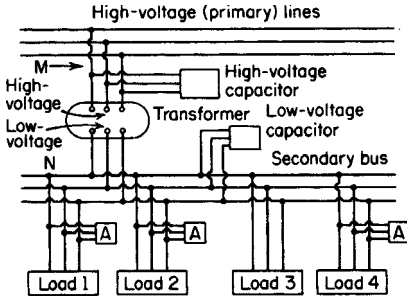

FIGURE 4.176 Location of capacitors in electric system. [General Electric Co.]

FIGURE 4.177 Three-phase capacitor unit enclosed in a hermetically sealed steel box. [Westinghouse Electric Corp.]

FIGURE 4.178 Enclosed capacitor unit.

137. Drainage of stored charge. When capacitors are disconnected from the supply, they are generally in a charged state. Considerable energy is stored in a capacitor under this condition, and there is a voltage present between its terminals. If the capacitor were left in this charged state, a person servicing the equipment might receive a dangerous shock or the equipment might be damaged by an accidental short circuit. Therefore, all capacitors

FIGURE 4.179 Low voltage fixed capacitors shown on the left and automatic capacitor bank shown on the right. [Square D, Schneider Electric.]

FIGURE 4.180 Typical small rack capacitor bank for wall or ceiling mounting. [Western Electric Corp.]

must be provided with a means of draining the stored charge (see Figs. 4.182 and 4.183). The National Electrical Code requires that the drainage equipment shall be so designed that it will discharge the capacitor to 50 V or less within 1 min after the capacitor has been disconnected from the source of supply in capacitors rated 600 V or less and in 5 min in capacitors rated more than 600 V. The discharge equipment may consist of resistors or inductive coils which are permanently connected to the terminals of the capacitor bank. If the discharge circuit is not permanently connected to the terminals of the capacitor bank, automatic means must be provided for connecting the capacitor to the discharge circuit on the removal of the supply voltage. When the capacitors are connected directly to other equipment

FIGURE 4.181 Schematic diagram of connections when an enclosed capacitor is installed at motor terminals. [General Electric Co.]

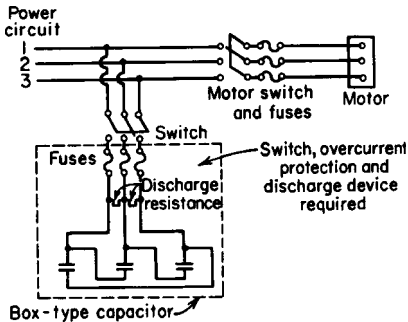

FIGURE 4.182 Connection diagram of enclosed capacitor unit, with fuses, installed on the line side of a motor switch.

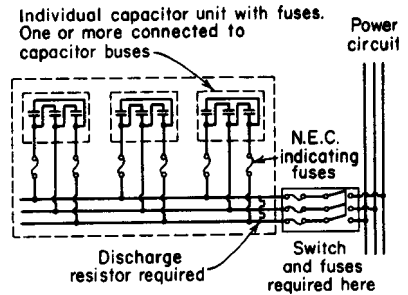

FIGURE 4.183 Connection diagram of rack-type three-phase 230-, 460-, or 575-V capacitor installed on power circuit.

without a switch or overcurrent device being interposed, a means shall be provided to reduce residual voltage to 50 V or less within 5 min of disconnection (Fig. 4.181).

138. The National Electrical Code rules for size of conductors, overcurrent protection, and disconnecting means are given below:

1. **CAPACITOR RATING** The maximum capacitor ratings that are permitted for use with NEMA-type three-phase 60-Hz Classification B motors are presented in Table 11 of Div. 12.
2. **CAPACITOR CIRCUITS** Capacitor circuits shall conform to the following:

a. Conductor ratings. The current-carrying capacity of capacitor circuit conductors shall be not less than 135 percent of the rated current of the capacitor. The current-carrying capacity of conductors which connect a capacitor to the terminals of a motor or to motor-circuit conductors shall be not less than one-third of the carrying capacity of the motor-circuit conductors but not less than 135 percent of the rated current of the capacitor.

b. Overcurrent protection

(1) An overcurrent device shall be provided in each ungrounded conductor for each capacitor bank.

Exception: A separate overcurrent device is not required on the load side of a motor overload protective device.

(2) The rating or setting of the overcurrent device shall be as low as practicable.

c. Disconnecting means

(1) A disconnecting means shall be provided in each ungrounded conductor for each capacitor bank.

Exception: A separate disconnecting means is not required for a capacitor connected on the load side of a motor controller.

(2) The disconnecting device shall open all ungrounded conductors simultaneously.

(3) The disconnecting device may be used for disconnecting the capacitor from the line as a regular operating procedure.

(4) The rating of the disconnecting device shall be not less than 135 percent of the rated current of the capacitor.

3. RATING OR SETTING OF THE MOTOR OVERCURRENT DEVICE If a motor installation includes a capacitor connected on the load side of the motor-overload device, the rating or setting of the motor-overload device shall be based on the improved power factor of the motor circuit. The effect of the capacitor shall be disregarded in determining the motor circuit conductor rating.

4. GROUNDING Capacitor cases shall be connected to an equipment grounding conductor.

5. ENCLOSING AND GUARDING Capacitors containing more than 11 L (3 gal) of flammable liquid shall be enclosed in vaults or outdoor fenced enclosures. Capacitors shall be enclosed, located, or guarded so that persons cannot come into accidental contact or bring conducting materials into accidental contact with exposed energized parts, terminals, or buses associated with them except that no additional guarding is required for enclosures accessible only to authorized and qualified persons. For isolation by elevation, see Sec. 37 of Div. 12.

6. IDENTIFICATION Each capacitor shall be provided with a nameplate giving the maker's name, rated voltage, frequency, kilovar or amperes, number of phases, and, if filled with a flammable liquid, the volume of liquid in gallons.

139. Capacitors which are constructed with a liquid which will not burn can be placed at any convenient location provided that they are not exposed to mechanical injury. If exposed to combustible dust or flyings or if located in the vicinity of easily ignitable material, they must be enclosed in dusttight metal enclosures. Capacitors constructed with a flammable liquid must be installed in vaults unless each container does not contain more than 11 L (3 gal) of liquid. Vaults, when required, should be constructed to meet the same requirements as for transformers (see Div. 5).

BATTERIES: GENERAL

140. An electric battery is a device for producing an emf by chemical means. When such a source of emf is connected to a closed electric circuit, chemical energy is transformed into electrical energy. An emf will be produced by chemical means whenever two dissimilar solid conductors are immersed in a conducting liquid. The solid conductors are called electrodes, and the conducting liquid is called the electrolyte. Such a combination of chemical resulting in the production of an emf is called a voltaic cell. A battery may consist of a single cell or a combination of cells. The voltage of a cell depends upon the material of the electrodes and the electrolyte and is independent of the dimensions of the cell. The current and power capacity of a cell are, however, directly dependent upon the dimensions of the cell and the weight of active material in the electrodes. Although there are an infinite number of different combinations of electrodes and electrolytes which will produce a voltaic cell, there are only a limited number of combinations which are practicable.

141. Classifications of batteries. For practical purposes, batteries may be classified as primary and secondary. A *primary battery* is used only for discharge (conversion of chemical energy into electrical energy). As such a battery is discharged, the material of one of the electrodes goes into solution in the electrolyte. The electrode is thus consumed, and the character of the electrolyte is altered so that with primary batteries it is necessary to renew from time to time both the electrode which goes into solution and the electrolyte. A *secondary battery* is alternately discharged and charged. As a battery discharges, the electrodes and electrolyte undergo chemical changes. After a secondary battery has been discharged, the electrodes and electrolyte can be restored to their original charged condition by passing a current through the battery in the reverse direction from that of discharge. In charging a battery, electrical energy is transformed into chemical energy. *Secondary batteries* are generally called *storage batteries*.

142. The internal resistance of batteries is the resistance offered to the flow of current inside the battery due to its electrodes and electrolyte. Owing to this internal resistance, the voltage at the terminals of a battery is less when it is discharging than when it is on open circuit. The internal resistance of a battery will change with the condition of discharge. As the battery discharges, the internal resistance increases, so that the terminal voltage decreases as the battery discharges. The terminal voltage of a battery is thus dependent upon the rate of discharge and the length of discharge. The voltage of a battery will decrease rather slowly as the battery discharges until nearly all the active material of the electrode has gone into solution. The battery is then discharged, and the voltage will drop rapidly to a very low value with any further attempt to discharge.

PRIMARY BATTERIES

143. The standard Daniell cell is a primary cell that has an emf which is practically 1 V when delivering a constant current. There are many forms of Daniell cell, each of which is particularly adapted to certain services, but all have very nearly the same emf ($1.07 + V$). The emf is not changed appreciably by the degree of concentration of the solutions, by the temperature, by the resistance, or by the purity of the zinc or copper, etc. In short, it makes a very good rough-and-ready standard.

A very good model is that used by the British Post Office. The jar is made with two compartments, one containing a porous cup immersed in water, in which are placed a copper plate and crystals of copper sulfate, the other containing a zinc plate and a 50 percent saturated solution of zinc sulfate. The zinc plate is fastened so as to be just clear of the solution, and a pencil of zinc is placed in the bottom. When in use, the porous cup is placed in the second compartment, thus raising the level of the zinc solution so as to immerse the zinc. Under working conditions the emf is about 1.07 V; when new, it is about 1.079 V.

144. The gravity-type primary cell, which is used in telegraph work, is suitable for closed-circuit work but should not be used for applications in which it is apt to stand for a long time on open circuit.

145. In setting up the gravity cell, place the copper electrode (–) in the bottom of the jar and pour in about 3 lb (1.36 kg) of copper sulfate crystals. Next place the zinc electrode (+) and fill with water to cover the zinc; to the water add a tablespoonful of sulfuric acid. Cover the electrolyte with a layer of pure mineral oil, which should be free from naphtha or acid and have a flash point about 400°F (204°C). If the oil is not used, the creeping can be stopped by dipping the edge of the jar in hot paraffin. When the cell is thus set up, it should be short-circuited for a day or two to form zinc sulfate which will protect the zinc electrode; this preliminary run also reduces the internal resistance. The temperature of the cells should be kept above 70°F (21°C), since the resistance increases rapidly with a decrease in temperature.

The internal resistance of the gravity cell is ordinarily from 2 to 3 Ω . A blue color in the bottom of the cell denotes a good condition, but a brown color shows that the zinc is deteriorating. When renewing the copper sulfate, it is best to empty the cell and set it up with a completely new electrolyte. The blue line, which marks the boundary between the copper sulfate and the zinc sulfate, should stand about halfway between the electrodes. If it comes too close to the zinc, some of the copper sulfate can be siphoned out, or the cell can be short-circuited so as to produce more zinc sulfate. If the blue line goes too low, some water and crystals of copper sulfate should be added.

146. The Fuller cell is well adapted to telephone work or any intermittent work. It can stand on open circuit for several months at a time without any appreciable deterioration.

147. The Fuller cell is set up as follows: Mix the electrolyte by adding 6 oz (0.17 kg) of potassium bichromate and 17 oz (0.48 kg) of sulfuric acid to 56 oz (1.59 kg) of soft water; pour this mixture into a suitable glass jar. Into a suitable porous cup put 1 teaspoonful of mercury and two teaspoonfuls of salt; place the cup and a zinc electrode in the glass jar, and fill to within 2 in (50.8 mm) of the top with soft water. Put on the cover, insert a carbon electrode, and the cell is ready for use.

The color of the solution is orange when in working order. The resistance varies from 0.5 to 4 Ω , depending upon the condition and dimensions of the porous cup and upon the concentration of the solution.

148. The Lalande cell, frequently called the caustic soda cell, is suitable for either open- or closed-circuit work. The mechanical construction of this cell is especially good.

The positive pole is a plate of compressed oxide of copper, the surfaces of which are reduced to metallic copper to improve the conductivity. This form of plate also acts as a depolarizer. The negative pole is of pure zinc amalgamated throughout by adding mercury when the casting is made. The electrolyte is a solution of caustic soda. The top of the solution is covered with a heavy mineral oil to prevent the solution from evaporating.

The emf of all types and sizes of caustic soda cells initially is approximately 0.90 V per cell. The voltage on closed circuit will depend upon the rate of discharge and the size of cell. The larger sizes, having lower internal resistance, will, of course, have a higher voltage for a given rate of discharge than the smaller cells under similar conditions. For ordinary purposes, however, it is safe to figure a mean effective voltage of approximately 0.67 V per cell at normal temperature.

149. Primary batteries are manufactured by the Primary Battery Division of Thomas A. Edison Industries in three types: the renewable carbon type, the nonrenewable Carbonaire battery, and the renewable copper oxide type.

These batteries are an ideal power supply for many low-voltage dc services for which the utmost freedom from power interruptions is extremely important. Their inherent operating advantages make them particularly desirable for the following applications in which batteries are used for direct operation or as an emergency standby power supply:

1. Navigation aids (river, channel, pier, and obstruction lights)
2. Alarm systems (municipal, police, and fire-alarm installations; fire and burglar alarms in factories, schools, office buildings, banks, public institutions, and private properties)
3. Annunciator systems
4. Electric fences
5. Elevator signals
6. Farm radios
7. Laboratory services and apparatus (industrial, school, and scientific)
8. Mine signal and communication systems
9. Railway signal and communication service
10. Telegraph service (local sounder and main-line circuits)
11. Telephone service (operation of transmitters on magneto switchboards, intercommunicating systems, interrupters or pole changers)
12. Time-clock systems (program, self-winding, etc., in schools, factories, and public buildings)

These primary batteries offer the following advantages:

1. Unlike storage cells, they provide a self-contained power supply requiring no charging. They can be applied anywhere, whether or not commercial power is accessible, and are therefore ideal for operating isolated installations.
2. They consistently deliver rated ampere-hour capacity at satisfactory operating voltage in continuous or intermittent service.
3. They require little attention or maintenance other than occasional inspection from the time they are placed in service until they are exhausted.

4. They eliminate the cost of providing and maintaining battery-charging facilities.
5. They are easy to install without experienced help. Transporting batteries to and from a charging station is unnecessary.
6. In the renewable-type cells, there are accurate visual indicator panels which warn of approaching and complete exhaustion of rated capacity. This feature makes it possible to see and make sure that ample battery capacity is always available—a decided advantage in preventing service failures due to exhausted batteries.

150. The Edison Carbonaire battery is a nonrenewable primary battery of the air-depolarized, add-water type, sealed in a single molded hard-rubber case. The battery is shipped dry and is made ready for use merely by adding a small quantity of water.

The add-water construction has a distinct advantage in that the battery is kept inert and free from internal deterioration during storage.

During its service life, the Carbonaire requires no maintenance other than infrequent inspections of the solution height and the addition of a small amount of water if the solution has fallen below the recommended operating level.

There are no visual indications of exhaustion in the Carbonaire, and its service life must be calculated on the basis of the known current consumption of the connected apparatus.

Carbonaire batteries (Fig. 4.184A) are manufactured in four types: the 2-S-J-1, the 3-S-J-1, the Crystallaire, Type F, and the Type Y. The Carbonaire batteries shown in Fig. 4.184B have largely replaced the hard-rubber-case types shown in Fig. 4.184A.

The technical details and nominal service ratings for the Carbonaire batteries in Fig. 4.184A are given in the accompanying table. They may be applied to many services for which a large ampere-hour reserve of dependable low-voltage current is needed and for which their simplicity of handling, setting up, and maintenance may be used to good advantage.

Characteristics	2-S-J-1	2-M-J-1	3-S-J-1	Y
Over-all dimensions, in.				
Length	85/16	85/16	12	8 ¹ / ₄
Width	7 ³ / ₈	7 ³ / ₈	7 ³ / ₈	8 ¹ / ₄
Height	9 ¹ / ₂	9 ¹ / ₂	9 ¹ / ₂	13 ¹ / ₂
Shipping weight, lb	24	24	35	33 ¹ / ₂
Service weight, lb	29 ¹ / ₄	29 ¹ / ₄	45	40 ¹ / ₂
Nominal capacity, amp-hrs	1000	2000	1000	2500
Nominal voltage	2.4–2.5	1.2–1.25	3.6–3.75	1.2–1.25
Nominal current, amp	0.25	0.50	0.25	1.00

When the battery is filled, it will get warm and then cool off, which causes the solution to rise a little and then to recede. This is normal, and no more water need be added on this account.

I. Type 2-S-J-1 Carbonaire battery.

II. Type 3-S-J-1 Carbonaire battery.

III. Type Y.

FIGURE 4.184A Edison Carbonaire batteries. [McGraw-Edison Co., Power Systems Division]

FIGURE 4.184B Edison Types ST-22 and ST-33 renewable Carbonaire primary batteries. [McGraw-Edison Co., Power Systems Division]

There is no advantage in maintaining the solution level at any exact point during the battery life except that if it falls below 2 in (50.8 mm) from the top of the filler, the level should be brought up to 1½ in (38.1 mm) by adding water. The top of the battery, especially the central carbons, should be kept clean and dry.

If the battery is used outdoors, it should be protected in a well-ventilated housing. Where temperatures are extreme, the housing should be partially sunk in the ground but constructed of material not permeable to dampness. Ventilation provides air for the battery to breathe and dissipates dampness.

Under adverse climatic conditions, there may be a minor wetness, or salt formation, around the battery top. This may be wiped off.

In connection with battery housings, it should be noted that since the Carbonaire requires oxygen for its operation, it should never be installed in completely airtight or watertight housings.

The batteries may be stored for any reasonable length of time, and they will remain inert and free from internal deterioration. This is due to the fact that they are shipped dry with the openings sealed at the factory.

STORAGE BATTERIES: GENERAL

151. A storage battery is a device which can be used repeatedly for storing energy at one time in the form of chemical energy for use at another time in the form of electrical energy. It consists of two kinds of plates bearing the necessary electrochemically active materials immersed in a proper solution. The solution is called the electrolyte. Charging a battery consists of connecting the two terminals to a dc supply of proper polarity for a sufficient length of time. Electrical energy is delivered by the dc supply to the battery, in which it produces certain chemical reactions so that the energy is converted into chemical energy. If a charged battery has its two terminals connected through a closed external electric circuit, the active materials of the plate will react chemically with the electrolyte, producing a flow of current in the circuit. This conversion of chemical energy into electrical energy is called discharging the battery. Charging is the process of putting energy into the battery (delivering energy to the battery), while discharging is the process of taking energy from the battery (battery delivering energy to external electric circuit).

152. Storage cell is the name given to the fundamental unit of any storage battery. It consists of one positive plate or a group of positive plates electrically connected together, one negative plate or a group of negative plates electrically connected together, separators, electrolyte, and a suitable container. A storage battery may consist of a single cell or a group of cells electrically interconnected.

153. Types of storage batteries. Storage batteries may be classified in two ways as follows:

1. According to fundamental type of service for which they are suitable
 - a. Stationary
 - b. Portable
2. According to fundamental materials of construction
 - a. Lead-acid
 - b. Nickel-iron-alkaline
 - c. Nickel-cadmium

Stationary batteries are those designed for service in a permanent location.

Portable batteries are those designed for service requiring the transportation of the batteries during service.

154. Storage-battery terminology. Most of the following definitions of terms are taken from the standards of the Institute of Electrical and Electronic Engineers.

Active materials. Materials of plates reacting chemically to produce electrical energy during the discharge. The active materials of storage cells are restored to their original composition, in the charged condition, by oxidation or reduction processes produced by the charging current.

Grid. A metallic framework for conducting the electric current and supporting the active material.¹

Positive plate. The grid and active material from which the current flows to the external circuit when the battery is discharging.

Negative plate. The grid and active material to which the current flows from the external circuit when the battery is discharging.

Electrolyte. An aqueous solution of sulfuric acid used in lead cells and of certain hydroxides used in nickel-iron-alkaline cells.

Separator. A device for preventing metallic contact between the plates of opposite polarity within the cell.

Group. Assembly of a set of plates of the same polarity for one cell.

Element. The positive and negative groups with separators assembled for a cell.

Couple. The element of a cell containing two plates, one positive and one negative. This term is also applied to a positive and negative plate connected together as one unit for installation in adjacent cells.

Jar. The container for the element and electrolyte of a cell. Specifically, a jar for lead-acid cells is usually of hard-rubber composition or glass, but for nickel-iron-alkaline cells it is a nickel-plated-steel container frequently referred to as a can.

Tank. A lead container, supported by wood, for the element and electrolyte of a cell. This is restricted to some relatively large types of cells.

Case. A container for several cells. Specifically, wood cases are containers for cells in individual jars; rubber or composition cases are provided with compartments for the cells.

Tray. A support or container for one or more cells.

Terminal posts. The points of the cell or battery to which the external circuit is connected.

End cells. The cells of a battery which may be cut in or out of the circuit for the purpose of adjusting the battery voltage.

Pilot cell. A selected cell whose temperature, voltage, and specific gravity of electrolyte are assumed to indicate the condition of the entire battery.

Ampere-hour capacity. The number of ampere-hours which can be delivered by a cell or battery under specified conditions as to temperature, rate of discharge, and final voltage.

¹ In certain types of batteries the active material is enclosed in containers which are held in place by the grid.

Energy density. The watthours per pound (Wh/lb) of battery weight.

Power density. The watts per pound (W/lb) of battery weight.

Watt-hour capacity. The number of watthours which can be delivered by a cell or battery under specified conditions as to the temperature, the rate of discharge, and the final voltage.

Time rate. The rate in amperes at which a battery will be fully discharged in a specified time, under specified conditions of temperature and final voltage, as, for example, the 8-h rate or the 20-min rate.

Open-circuit voltage. The voltage of a cell or battery at its terminals when no current is flowing. For the purpose of measurement, the small current required for the operation of a voltmeter is usually negligible.

Closed-circuit voltage. The voltage at the terminals of a cell or battery when current is flowing.

Average voltage. The average value of the voltage during the period of charge or discharge. It is conveniently obtained from the time integral of the voltage curve.

Initial voltage. The voltage of a cell or battery at the beginning of a charge or discharge. It is usually taken after the current has been flowing for a sufficient period of time for the rate of change of voltage to become practically constant.

Final voltage. The prescribed voltage upon reaching which the discharge is considered complete. The final voltage is usually chosen so that the useful capacity of the cell is realized. Final voltages vary with the type of battery, the rate of the discharge, temperature, and the service in which the battery is used.

Polarity. An electrical condition determining the direction in which current tends to flow. By common usage the discharge current is said to flow from the positive or peroxide plate through the external circuit. In a nickel-iron-alkaline battery the positive plate is that containing nickel peroxide.

Charge. The conversion of electrical energy into chemical energy within the cell or battery. This consists of the restoration of the active materials by passing a unidirectional current through the cell or battery in the opposite direction to that of the discharge. A cell or battery which is said to be charged is understood to be fully charged.

Charging rate. The current expressed in amperes at which a battery is charged.

Constant-current charge. A charge in which the current is maintained at constant value. For some types of lead batteries this may involve two rates called the starting and the finishing rates.

Constant-voltage charge. A charge in which the voltage at the terminals of the battery is held at a constant value. A modified constant-voltage system is usually one in which the voltage of the charging circuit is held substantially constant but in which a fixed resistance is inserted in the battery circuit, producing a rising-voltage characteristic at the battery terminals as the charge progresses. This term is also applied to other methods for producing automatically a similar characteristic.

Boost charge. A partial charge, usually at a high rate for a short period.

Equalizing charge. An extended charge given to a battery to ensure the complete restoration of the active materials in all the plates of all the cells.

Trickle charge. A continuous charge at low rate approximately equal to the internal losses and suitable to maintain the battery in a fully charged condition. This term is also applied to very low rates of charge suitable not only for compensating for internal losses but for restoring intermittent discharges of small amounts delivered from time to time to the load circuit.

Finishing rate. The rate of charge expressed in amperes to which the charging current for some types of lead batteries is reduced near the end of charge to prevent excessive gassing and temperature rise.

Discharge. The conversion of the chemical energy of the battery into electrical energy.

Reversal. Change in normal polarity of a storage cell.

Local action or self-discharge. The internal loss of charge which goes on continuously within a cell regardless of connections to an external circuit.

Floating. A method of operation in which a constant voltage is applied to the battery terminals sufficient to maintain an approximately constant state of charge.

Specific gravity of electrolyte. The electrolyte of lead-acid batteries increases in concentration to a fixed maximum value during charge and decreases during discharge. The concentration is usually expressed as the specific gravity of the solution. This variation of the specific gravity of the solution affords an approximate indication of the state of charge of the battery.

The specific gravity of the electrolyte in nickel-iron-alkaline batteries does not change appreciably during charge or discharge and therefore does not indicate the state of charge. The specific gravities, however, are an indication of the electrochemical usefulness of the electrolyte.

Gassing. The evolution of oxygen or hydrogen or both.

Efficiency. The ratio of the output of a cell or battery to the input required to restore the initial state of charge under specified conditions of temperature, current rate, and final voltage.

Ampere-hour efficiency (electrochemical efficiency). The ratio of the ampere-hours output to the ampere-hours of the recharge.

Volt efficiency. The ratio of the average voltage during the discharge to the average voltage during the recharge.

Watt-hour efficiency (energy efficiency). The ratio of the watt-hours output to the watt-hours of the recharge.

General data. Batteries are usually rated in terms of the number of ampere-hours which they are capable of delivering when fully charged and under specified conditions as to

temperature, rate of discharge, and final voltage. For different classes of service, different time rates (see definition of *time rate*) are frequently used. For comparing the capacities of batteries of different size but of the same general design, it is customary to use the same time rate, and a comparison based on the different lengths of time they will discharge at the same rate is not recommended, as it is misleading.

Misrating. A battery which fails to deliver its rated capacity on the third successive measured cycle of charge and discharge under specified current rates, temperature of electrolyte, specific gravity, and final voltage shall be considered to be improperly rated.

LEAD-ACID STORAGE BATTERIES

155. Lead-acid batteries.¹ In the charged condition the active materials consist of lead peroxide on the positive plate and sponge lead on the negative plate. The electrolyte is a mixture of sulfuric acid and water. The strength of the electrolyte is measured in terms of specific gravity, which is the ratio of the weight of a given volume of electrolyte to an equal volume of water. Concentrated sulfuric acid has a specific gravity of about 1.830; water has a specific gravity of 1.000. The acid and water are mixed in a proportion to give the specific gravity desired. For example, an acid manufacturer to supply electrolyte of 1.210 gravity will mix roughly about 1 part of concentrated acid to 4 parts of water.

In a fully charged battery all the active material of the positive plates is lead peroxide, and that of the negative plates is pure sponge lead. In a fully charged battery all the acid is in the electrolyte, and the specific gravity is at its maximum value. The active material of both the positive and the negative plates is porous, so that it has absorption qualities similar to those of a sponge, and the pores are therefore filled with some of the battery solution. As the battery discharges, the acid, which is in the pores of the plates, separates from the electrolyte, forming a chemical combination with the active material, changing it to lead sulfate. As the discharge continues, additional acid is drawn or diffused from the electrolyte into the pores of the plates and further sulfate is formed. It can be readily understood that as this process continues, the specific gravity of the electrolyte will gradually decrease, because the proportion of acid is decreasing. On charge the reverse action takes place: the acid in the sulfated active material is driven out and back into the electrolyte. This return of the acid to the electrolyte increases the specific gravity, so that it will continue to rise until all the acid is driven out of the plates and back into the electrolyte. After all the acid has been driven back into the electrolyte, further charging will not raise the specific gravity any higher, as all the acid in the cells is in the electrolyte, and the battery is said to be fully charged. The material of the positives is again lead peroxide, and that of the negatives is spongy lead; the specific gravity is maximum.

Practically speaking, on discharge the plates absorb acid, and the specific gravity of the electrolyte decreases. On the charge the plates return the absorbed acid to the electrolyte, and the specific gravity increases. Figure 4.185, showing a cell charged, discharging, discharged, and charging, illustrates clearly the chemical action which takes place on charge and discharge.

When a cell is fully charged [Fig. 4.185(1) of the diagram], the negative plate is lead sponge, Pb; the positive plate is PbO₂; and the specific gravity of the electrolyte (sulfuric acid, H₂SO₄, and water, H₂O) is at its maximum. Chemical energy is stored in the cell in this condition.

¹ A large portion of the following information in this section on lead-acid batteries has been taken from the literature of the Electric Storage Battery Co.

FIGURE 4.185 Chemical action in a cell on cycle of discharge and charge.

When a cell is put on discharge [Fig. 4.185(2)], the H_2SO_4 of the acid is divided into H_2 and SO_4 . The H_2 passes in the direction of the current to the positive plate and combines with some of the oxygen of the lead peroxide and forms H_2O ; the SO_4 combines with the liberated Pb of the positive plate to form lead sulfate. The SO_4 also forms lead sulfate at the negative or lead sponge (Pb) plate. As the discharge progresses, both plates finally contain considerable lead sulfate, $PbSO_4$ [see Fig. 4.185(3)]. The water formed has diluted the acid, lowering the specific gravity of the electrolyte. When the plates are entirely sulfated, current will cease, since the plates are then identical, and any active electric cell requires two dissimilar plates in electrolyte. In common practice, however, the discharge is always stopped before the plates have become entirely reduced to lead sulfate.

During charge [Fig. 4.185(4)], the lead sulfate, $PbSO_4$, on the positive plate is converted into lead peroxide, PbO_2 , while the lead sulfate on the negative plate is converted into sponge lead Pb , and the electrolyte gradually becomes stronger as the SO_4 from the plates combines with hydrogen from the water to form acid, H_2SO_4 , until no more sulfate remains and all the acid has been returned to the electrolyte. It will then be of the same strength as before the discharge, and the same acid will be ready to be used over again during the next discharge.

156. Change in electrolyte during charge and discharge. During discharge, as stated in Sec. 155, some of the acid leaves the electrolyte and combines with the plates. During charge, the acid which has been absorbed by the plates is driven back into the electrolyte. When all the acid has been driven back into the electrolyte, the battery is fully charged.

When all the acid has been driven into the electrolyte, the electrolyte is stronger than when some of the acid is in the plates. This strength is measured in terms of specific gravity. The specific gravity of the electrolyte, therefore, changes as the battery charges or discharges. It falls on discharge and rises on charge. It is, then, an excellent indication of the state of charge of a battery, being greatest when the cell is fully charged and least when discharged.

The difference between the full-charge and discharge values of the gravity depends upon the type of cell under consideration. For example, for the type of cell in use in starting work in automobiles, the full-charge gravity in temperate climates is 1.280; discharged, 1.150.

FIGURE 4.186 Use of hydrometer in determining specific gravity of electrolyte.

The specific gravity of the electrolyte is readily determined by means of a float called a hydrometer. With a high specific gravity, the hydrometer, or float, does not sink so far in the electrolyte as it does when the specific gravity is low (see Fig. 4.186).

157. Voltage characteristics. The voltage of each cell is approximately 2 V on an open circuit but is higher than this when the battery is being charged and lower when being discharged. The nominal voltage of a battery is, therefore, the number of cells multiplied by 2.

The voltage at any time on discharge or charge depends upon several factors, such as the current rate, the state of charge or discharge, and the temperature. No general averages to cover all conditions can therefore be given. In usual 6- to 8-h discharge service, the average cell voltage (Sec. 154) during discharge is roughly 1.95 V with a final voltage of about 1.75 V. As soon as the cell is put on charge, its voltage rises to about 2.15 V and then increases during charge until at the end it is between 2.4 and 2.7, depending upon local conditions. The average voltage during the entire charge is usually considered to be 2.33 V.

Typical voltage-discharge characteristics are given in Figs. 4.187 and 4.188. The effect of the discharge rate upon the voltage characteristics is shown in Fig. 4.189.

FIGURE 4.187 Type MVM Exide-Ironclad discharge characteristics at the 6-h rate. [Electric Storage Battery Co.]

FIGURE 4.188 Type MVM Exide-Ironclad discharge characteristics at the 8-h rate. [Electric Storage Battery Co.]

FIGURE 4.189 Type MVM Exide-Ironclad initial, average, and final volts at various discharge rates. [Electric Storage Battery Co.]

158. High discharge rates (amperes) are often confused with overdischarge (too many ampere hours taken out). A lead-acid battery of the type sold under the trade names Exide, Chloride, and Ironclad can be discharged, without injury to the plates, at any rate of current that it will deliver. The maximum permissible rate of discharge is limited only by the current-carrying ability of the wiring, motor, or other apparatus to which the battery is connected or by the current-carrying ability of the cell terminals and connectors and not by the plates themselves.

159. Rating of lead-acid batteries. All batteries are given a normal (ampere-hour) capacity rating based on a certain time rate of discharge under specified conditions of temperatures and final voltage. For example, a certain battery may have an 8-h rating of 100 Ah discharging to 1.75 V per cell at a temperature of 77°F (24°C).

The ampere-hour capacity of a battery depends upon the amount of available active material in the plates that can be reached by the electrolyte, the amount of sulfuric acid in the electrolyte, the rate of discharge, and the allowable safe limit of discharge. To produce an ampere-hour of electricity on discharge requires the combination of a certain amount of sponge lead (negative active material) and a certain amount of peroxide of lead (positive active material) with a certain amount of sulfuric acid from the electrolyte. The allowable rating therefore depends upon the construction of the plates and the number of plates that are constructed in parallel on each side of the battery.

160. Effect of discharge rates on discharge capacity of lead-acid batteries.

The useful ampere-hour capacity of a storage battery depends on the rate of discharge and is greater for a long low rate or an intermittent rate than for a short high rate. Any particular battery is given a so-called normal rate. This so-called normal rate is not the capacity obtainable under all conditions. Each different rate of discharge governs the available capacity that can be obtained from the battery.

When a battery is discharged continuously at a constant rate, its available ampere-hour capacity is a function of the rate of discharge, the available capacity being lower at the higher rates, as is shown in Fig. 4.190. The reduction in available capacity of high-rate continuous discharge is due to depletion of the acid in the pores of the plates. The depletion is due to the fact that at high rates of discharge the acid in the pores of the plates combines with the active material and is withdrawn from the solution more rapidly than it can be replenished by diffusion from the free electrolyte in the cell. It is this limitation of available acid in the pores of the plates that limits the capacity at high continuous rates of discharge, rather than any limitation due to the plates themselves. This explains the fact that after a battery has been exhausted at a high discharge rate, the balance of its normal capacity can be obtained by continuing the discharge at lower rates or by allowing the battery to recuperate while standing on open circuit for a time and

FIGURE 4.190 Curve illustrating effect of discharge rate upon available ampere-hour capacity of lead-acid storage batteries. [Electric Storage Battery Co.]

then continuing the high-rate discharge. For this reason also, as stated in Sec. 158, it is impossible to damage the plates by overdischarge at high rates, as the voltage of the battery will drop below a usable value before the active material in the plates has been discharged to the danger point.

Figure 4.190 shows the available capacity per positive plate of an Exide-Ironclad battery when discharged continuously, in varying lengths of time.

If a battery is discharged intermittently, it is evident that during periods of rest between discharges diffusion will continue, thus renewing the strength of acid in the pores of plates and increasing the available capacity corresponding to the discharge rate. The rate of diffusion depends on the difference in strength of the acid in the pores and that outside the plates, and if this difference is great, the diffusion is rapid at first but decreases as the two strengths become more nearly equal. It follows from this reasoning that the reduction in available capacity due to high rates of discharge largely disappears when the discharge is intermittent.

If the total elapsed time during which discharges are made is greater than 6 h, and if the discharges are distributed throughout that time so that there is time for this diffusion to take place, the full 6-h capacity of the battery will be available regardless of the rates at which the discharges are taken.

An illustration of the effect of acid diffusion is given in Fig. 4.191, which shows a test made on a cell of the type used in submarine boats by the United States government.

This cell has a rated capacity of 3000 A for 1 h. The curve shows it to have been discharged at that rate for 58 min, at which time it was practically exhausted at that rate, and if the discharge had been continued at that rate, the voltage would have fallen rapidly. The rate of discharge was, however, reduced to 1350 A and continued for 45 min, then to 910 A for 30 min, then to 525 A for 1 h and 20 min, and finally to 300 A for 3 h and 15 min. At each reduction in the rate of discharge the rate of acid absorption by the plates was reduced, thus allowing diffusion to strengthen the acid in the pores of the plate and so permitting the discharge to be continued. In each case the voltage at the lower discharge rate was higher than the voltage at the preceding higher rate. During the 300-A discharge it will be noted

FIGURE 4.191 Curves showing effect of acid diffusion in lead-acid storage batteries on intermittent discharge. [Electric Storage Battery Co.]

that the voltage continued to rise for over an hour after the start at that rate, showing that the acid from the free electrolyte was entering the pores of the plates faster than it was being absorbed.

The curve showing ampere-hour output shows that 6000 Ah was delivered by the cell and that after the battery had been exhausted at the high rate of discharge, as much more energy was still available at lower rates.

161. Discharge limits of lead-acid batteries. In an emergency, little if any permanent harm will result if the battery is discharged to the full amount that it will give, provided that it is promptly recharged.

It has already been pointed out that the drop in specific gravity of electrolyte should not exceed a certain definite value, which varies according to the type of cell and will be furnished on application to the manufacturer.

The danger of harm from overdischarge may be illustrated by a comparison between the active material of the plates and the action which goes on when some of the electrolyte is allowed to act on copper wiring terminals of a battery. It is noticeable that a comparatively large amount of copper sulfate is formed when only a small quantity of the metal is eaten away by the acid. In the same manner, when the acid combines with the lead in the active material, the resulting lead sulfate occupies more space than the active material from which it is formed. The active material of all battery plates is porous, and this expansion of the sulfated material is accommodated by reduction in the size of pores in the active material. All battery plates are designed to accommodate a certain amount of this expansion of the active material during sulfation, and in batteries of the type under consideration this is limited to the amount represented by a certain specific-gravity reading.

Further discharge, even if it can be obtained at a satisfactory voltage, results in an excessive expansion, which so closes the pores in the active material that it becomes increasingly difficult to recharge the battery properly after an excessive discharge, and unless a proper recharge is given, the battery is likely to deteriorate.

162. Charging and charging rates for lead-acid batteries. A battery must, of course, be charged with direct current, and the current must be connected to the battery so that it will go through it in the proper direction. The positive pole of the charging source must be connected to the positive terminal of the battery, and the negative of the charging source to the negative of the battery.

While a battery is being charged, the amount of sulfate in the plates decreases, and the ability of the plate to give up the acid becomes reduced; in other words, during the early part of a charge the plates can give up the acid at a rapid rate, as there is a large amount of sulfate available. Therefore a battery that is considerably discharged can be charged at a high rate, but as the charge approaches completion, currents at a high rate cannot be utilized, and if high rates are maintained, only a portion of the current is used to withdraw acid from the plates, and the balance of the current acts to decompose the water in the electrolyte into oxygen and hydrogen, which are given off in the form of gas. Gassing of the battery, therefore, at any time shows whether or not the charging rate is too high. Consequently, when the cells are gassing on charge the rate of charge should be reduced so as not to waste the current. Furthermore, the action of the bubbles of gas in escaping from the pores of the plates and in "boiling" to the top of the electrolyte has a tendency to wash and wear the active material away from the plates, particularly the positive.

It is a well-known fact that batteries wear out. This wear shows itself to the eye principally in the positive plate, the active material of which softens with use, and were it not for this unavoidable fact, the life of batteries would be very much longer than at present. As

the active material of the plate softens with use, there is a tendency for the softened material on the surface of the plate to fall to the bottom of the jar in the form of sediment. The action of the gas in escaping from the pores of the plates and the little whirlpools created in the electrolyte when the bubbles of gas boil to the surface hasten this shedding of material and shorten the life of the battery.

Excessive gassing, therefore, should be avoided if the best life of the battery is to be obtained. A small amount of gassing at low rates and for a short time, at the completion of a charge, is not objectionable, but violent gassing having the appearance of boiling should be avoided.

163. Charging methods for lead-acid batteries. In practice, charging methods vary with the type of service. For example, in propelling electric vehicles, the battery is discharged over a period of time and then recharged. The rate in amperes to use for recharge depends upon the time available and the type of cell. The lower the rate of charge the longer will be the time required. The shorter the time available, the higher the rate must be to recharge, provided the rate is not higher than recommended for the type of cell. In any event, the rate must always be low at the end of charge when gassing begins. This is known as the finish charge rate.

Batteries charged by this cycle method of discharge and charge can have their charging equipment arranged and designed to provide a taper charge rate automatically and inherently, i.e., high at the start of charge, when a high rate can be utilized, and low at the end of charge, when gassing begins. In addition, the equipment can be arranged to stop the charge at the proper time, and all without any manual attention whatever.

Batteries, used in starting, lighting, and ignition work on automobiles equipped with a generator for charging are charged whenever the engine is running at ordinary speeds. At very low speeds or when the engine is not running, the battery supplies current for lights, ignition, and cranking. In automobile service, the rate must be sufficient to keep the battery charged and yet not overcharge it.

Batteries used for reserve emergency, standby, or voltage regulation are kept fully charged by a trickle current or floating charge. A constant voltage of appropriate value impressed across the battery terminals is sufficient for proper charging.

Regardless of the charging method, the rate in amperes must not cause excessive gassing; neither should the cell temperature rise above 110°F (43°C).

164. Equalizing charge for lead-acid batteries. Wherever practicable, batteries are given an equalizing charge at regular intervals, for example, weekly for batteries used in propelling vehicles and other services in which the battery is discharged considerably and then recharged, monthly in floating service.

In cycle service an equalizing charge is a continuation of the regular charge at a low rate. In floating service the equalizing charge is obtained by raising the voltage across the battery to increase the current into the battery. The equalizing charge continues until all cells gas freely and until it is certain by taking voltage and gravity readings that *all* cells are fully charged.

As has already been pointed out, the object of charging is to withdraw all acid from the plates. In practice, the regular charges in cycle service are not always given long enough to withdraw all the acid completely from the plates. In fact, this is not necessary, provided the acid is completely withdrawn regularly by giving an equalizing charge. If this is not done and some sulfate is allowed to remain in the plates for a considerable time, it will gradually increase, the pores of the plate will become clogged, and the battery will lose capacity and deteriorate in such a way that it becomes increasingly difficult to restore it to its normal condition. To carry frequent (such as daily) regular charges to the full extent would involve an unnecessary amount of charging and gassing, which is not desirable.

A battery is not fully charged until all the acid has been driven out of the plates by charging. To charge a battery fully, do not try to charge to a fixed or definite gravity, but charge until the specific gravity or voltage stops rising.

165. Effect of temperatures upon lead-acid batteries. The cell temperature should not exceed 110°F (43°C). The effect of high temperature is primarily to shorten the life of the wood separators which are installed between the positive and negative plates of some types of cells.

There is always a tendency for wood in contact with sulfuric acid to become carbonized. This tendency is greatly increased at temperatures above 110°F. If a battery is operated regularly under such conditions, it will probably be necessary to renew the wood separators before the battery itself is worn out.

In the materials used in any commercial storage battery, there are also present some impurities which cause very slight action in the cell even when it is not in active operation. At high temperatures, these internal losses are increased, as is evidenced by the fact that a battery placed in storage will not lose its charge seriously over a period of, say, 6 months if kept in a cool place. If kept in a temperature around 100°F (38°C), it will lose much more of its charge in, say, 3 months.

Low temperature temporarily decreases both the discharge voltage and the ampere-hour capacity which can be taken out of the battery. The battery acts as if it were numbed by the cold and unable to make the same effort as at normal temperature. The effect of cold is only temporary, the battery returning to its normal state upon its return to normal temperature even without charge. There is no danger of the electrolyte freezing in a fully charged cell, but this is likely to occur in an overdischarged battery or in one that has had water added without subsequent charging.

166. Types of lead-acid storage batteries. Lead-acid storage batteries may be roughly divided into three groups, depending upon the class of service for which they are intended. Those for automobile starting, lighting, and ignition work consist of cells assembled in a single hard-rubber container (Fig. 4.192). Those for electric-vehicle applications consist of ironclad-type cells assembled in a suitable container (Fig. 4.193). Those for stationary service consist of cells enclosed in glass jars (Fig. 4.194).

FIGURE 4.192 Automobile type of lead-acid storage battery. [Electric Storage Battery Co.]

FIGURE 4.193 Ironclad type of lead-acid storage battery. [Electric Storage Battery Co.]

FIGURE 4.194 Lead-acid storage battery in enclosing glass jar. [Electric Storage Battery Co.]

167. Lead-acid batteries are easily kept in good condition for a long time of trouble-free service if the following maintenance instructions are observed:

1. Keep battery clean outside (Sec. 166).
2. Add water at regular intervals (Secs. 169 and 170).
3. Maintain battery in a healthy state of charge (Secs. 172 and 173).
4. Keep written records (Sec. 174).

168. Cleanliness

1. Keep the battery, its connections, and surrounding parts clean and dry by wiping with a dry rag, but do not remove the grease from the seal nuts. Keep the vent plugs in place and tight, and make sure their gas-escape holes are open. If electrolyte is spilled or if any parts are damp with acid, apply a solution of ammonia or of baking soda in the proportions of 1 lb (0.45 kg) of soda to 1 gal (3.8 L) of water, then rinse with water and dry; do not allow solution to get into cells. If this treatment is given two or three times a year and the battery kept clean between times by regular washings with water or blowing off with an air jet, the life and service of the battery in general and trays or supports in particular will be increased considerably. Before hosing a battery without removing it from the compartment, consult equipment manufacturer for permission. When washing high-voltage batteries, open the connections at several places to avoid possible shocks.
2. If the terminals or connections show any tendency to corrode, scrape the corroded surface clean, wash it with soda solution or with ammonia solution, rinse with water, and coat it thinly with Vaseline or No-Ox-Id grease. No corrosion will occur unless electrolyte is spilled and allowed to remain.
3. Soda solution or ammonia will neutralize the effect of acid on clothing, cement, etc.

169. Adding water

1. During operation, water must be regularly added to each cell. Do not allow the surface of the electrolyte to get below the level specified by the manufacturer. Keep it above this point by removing the vent plugs regularly from all the cells and adding sufficient approved water to each cell as often as necessary. Do not fill so high that electrolyte will be lost through the vent plugs, eventually resulting in ruined cells. Less harm will result in allowing the level to get a little low than in adding water too high. After filling, be sure to replace and securely tighten the plugs. The intervals at which water must be added depend largely on the operating schedule, but it should not be necessary to add water more often than once a week; otherwise the battery is being given too great a charge.
2. In cold weather the time to add water is just before a charge, so that gassing (bubbling of the electrolyte resulting from charging) will ensure thorough mixing and any danger of the water freezing will be avoided.
3. Electrolyte loses some of its water by the charging of the battery and some by evaporation, but its acid is never lost in this manner; therefore, it will not be necessary to add new electrolyte unless some should get outside the cell through carelessness or by adding too much water so that the container is too full.

4. Nothing but water is required to be added to storage batteries. Never add any special powders, solutions, or jellies. A great many special powder solutions or jellies are injurious, having a corrosive or rotting action on the battery plates, reducing the voltage and capacity of the cells.
5. All the cells in the battery should take the same amount of water. If one cell takes more than the others, examine it for leakage.
6. Keep a written record of the amount of water that is being added from time to time.

170. Kind of water

1. The quality of water to add is distilled (not merely boiled) or other approved water. By approved water is meant that of which the battery manufacturers have analyzed a sample and found safe for their batteries. The local source of water is usually suitable, but before using it the battery manufacturers should be consulted. Most companies will do this without charge for users of their batteries. Transportation charges should be pre-paid, and the sample marked for identification.
2. If water is drawn from a tap or spigot, it should be allowed to run a few moments before it is used, to remove pipe accumulations. Water should not be transported or stored in a vessel of any metal except lead. Glass, earthenware, rubber, plastic, or wooden receptacles that have been used for any other purpose are satisfactory.

171. Discharge limits

1. In an emergency, little if any permanent harm will result if the battery is discharged to the full amount that it will give, provided that it is promptly and fully recharged.
2. If an ampere-hour meter is in use, the discharge should be stopped and the battery promptly recharged before or upon reaching its capacity limit in ampere-hours, as given by the manufacturers. The ampere-hour meter will run slow if the discharge is at high rates or if the meter is not calibrated at proper intervals and will then show less discharge than the battery actually gives. This fact should not be overlooked.
3. The specific gravity of the electrolyte falls on discharge and is therefore an indication of the amount of discharge. The difference between the full-charge and discharge values of the gravity depends on the type of cell. The manufacturer of the battery should be consulted for the proper values for any particular cell.

172. Hydrometer readings: specific gravity

1. If the specific-gravity or hydrometer reading is known, one can tell that the battery is fully charged or the amount by which it is discharged. With all cells connected in series, the gravity reading of one cell, known as a pilot cell, will indicate the state of discharge or charge of the whole battery.
2. The specific gravity is easily determined by allowing a hydrometer to float in the electrolyte. When the specific gravity is high, the hydrometer will not sink so far into the electrolyte as when the specific gravity is low (see Fig. 4.186).
3. To take a reading, insert the nozzle of the hydrometer syringe (Fig. 4.195) into the cell, squeeze the bulb, and then slowly release it, drawing up just enough electrolyte from the cell to float the hydrometer freely. With the syringe held vertically, the reading on the stem of the hydrometer at the surface of the liquid is the gravity reading of the electrolyte. After the testing is completed, always return the electrolyte to the cell from which it was taken.

FIGURE 4.195 Hydrometer syringe.
[Electric Storage Battery Co.]

FIGURE 4.196 Vent-plug hydrometer syringe.
[Electric Storage Battery Co.]

4. Both temperature and level of electrolyte affect the specific-gravity reading somewhat, and it is therefore desirable to record the temperature and level of the electrolyte at the same time its gravity reading is taken. A gravity reading should not be taken immediately after adding water, as the reading will give a false indication of the specific gravity. Allow a day or so for the water to mix with the electrolyte by gassing (bubbling) of the electrolyte resulting from charging or floating the battery.
5. After every 50-odd gravity readings of a pilot cell, a different cell should be used as a pilot to avoid lowering of its gravity due to possible loss of a small amount of electrolyte each time the gravity is read.
6. Hydrometer syringes are available for mounting through the vent plug of a pilot cell (Fig. 4.196). Since they are continuously in place, no dripping is experienced and the pilot cell need not be changed after every 50-odd readings.

173. Full-charge specific gravity

1. The proper specific gravity of the electrolyte with the cells fully charged and with the electrolyte at the proper level, as specified by the maker, will vary somewhat with different types of batteries. The manufacturer should be consulted for the proper value.
2. The specific gravity of a new battery is adjusted at the factory and will not require adjusting during the life of the battery unless electrolyte is actually lost out of the battery. If, however, electrolyte is lost, it should be replaced with electrolyte of about the same specific gravity as in the surrounding cells.

3. The full-charge specific gravity will decrease in value as the battery ages. No definite value can be given, but this decrease is very small: not over a few points per year at the most. This change is mentioned so that it will be understood.
4. Before adjusting low gravity, first make sure charging will not raise gravity. To do this, continue an equalizing charge until the specific gravity shows no rise and then for 3 h more. Never make a gravity adjustment on a cell which does not gas when it is being charged.
5. To adjust low gravity, first have ready sulfuric acid of specific gravity between 1.265 and 1.300, sufficiently pure for storage-battery use. Add this instead of water when restoring level until the gravity at the end of an equalizing charge is normal. Then stop adding acid and return to the use of water. A quicker method, but one requiring more work and acid, is to withdraw some of the low-gravity electrolyte from the cell and at once replace it with this new electrolyte. Do not allow a cell to stand partly empty. The amount to withdraw will have to be determined by trial, as it depends upon the gravities of both the old and the new electrolyte. Charge until all cells have been gassing for 1 h. Then, if the gravity is not normal, repeat adjustment until it is.
6. To adjust high gravity, remove some of the electrolyte and replace with water until the gravity at the end of an equalizing charge is normal.

174. Readings: written records

1. To facilitate following the operation of the battery, it is advisable to record the specific gravity and voltage of each cell at intervals. The relative state of charge should be the same each time readings for record are taken: for instance, on a manually cycled battery, at the end of a charge; on a floated battery, 10 to 15 min after starting the monthly equalizing charge.
2. Cell voltage readings should be taken while the charging current is being maintained and not after it has been reduced or interrupted. During these readings the battery voltage or the charging current into the battery should be kept constant. Cell gravities should be taken 10 or 15 min after charge has been completed and not while cells are gassing heavily.
3. The individual cell voltages, read to the hundredth of a volt, should be recorded once a month, in which case three or four times a year will be sufficient for recording the cell gravities. Otherwise cell gravities should be recorded monthly.
4. Review the monthly cell readings and compare with those for the previous month promptly. Plotting the readings saves time in reviewing and comparing. Prompt action upon indication of trouble may save time and expense later (see Sec. 175).

175. Trouble

1. The chief indications of trouble in a cell are falling off in gravity or voltage relative to the rest of the cells and lack of gassing on equalizing charge.
2. If a battery seems to be in trouble, the first thing to do is to give it an equalizing charge (Sec. 164). Then take a gravity reading of each cell. If all the cells gas evenly on the equalizing charge and the gravity of them all goes above a certain value as specified by the manufacturer, then all the battery needed was the charge. Before making an adjustment, determine whether the jar is cracked by adding water to the proper height and allowing the cell or jar to stand several hours, noting whether level falls. If a jar is cracked, change it. Never make a gravity adjustment on a cell which does not gas. If a

cell will not gas on the equalizing charging, investigate for impurities or inspect it for short circuits. For the latter, remove the elements from the jar and examine the separators carefully to make sure that none is broken or damaged, thus causing a short circuit. Also examine plates to see that they are in good condition, and note the height of sediment in the bottom of the jar. Remove any collection of "moss" on the top or edges of the plates. Handle elements very carefully so that plates will not be broken from the straps. Replace damaged separators.

176. Impurities. Impurities in the electrolyte will cause a cell to work irregularly. If it is known that any impurity has got into a cell, it should be removed at once. In case removal is delayed and any considerable amount of foreign matter becomes dissolved in the electrolyte, this solution should be replaced with new solution immediately, thoroughly flushing the cell with water before putting in the new electrolyte. If in doubt as to whether the electrolyte contains impurities, submit a sample for test.

177. Sediment. The sediment which collects underneath the plates need not cause alarm unless it deposits too rapidly, in which case there is something wrong with the way the battery is operated. In a new battery there is always a thin layer at the start. As the battery wears, the sediment becomes higher, but for batteries which are floated, the plates usually wear out before the sediment space is filled.

178. Putting battery into storage

1. If the use of the battery is to be temporarily discontinued, give it a charge until all the cells gas and add water to the cells during this charge so that the gassing will ensure thorough mixing and prevent freezing in cold weather. Add enough water to raise the level of the electrolyte to the proper level. After the charge has been completed, remove all fuses to prevent the use of the battery during the idle period. Make sure all vent plugs are in place.
2. At certain periods the battery should be reconnected, water added, and the battery charged. These periods are every 2 months in climates averaging 70 to 80°F (21 to 27°C) and every 6 months in climates averaging 40°F (4.4°C).

179. Putting battery into commission again. Add water, if needed, and give a charge until the gravity of the electrolyte has ceased rising over a period of 3 h.

NICKEL-IRON-ALKALINE BATTERIES

180. The Edison storage battery is the result of an effort to avoid many of the disadvantages of the lead-sulfuric acid combination and is a radical departure from it in every detail of construction. The positive plate consists of hollow, perforated, sheet-steel tubes filled with alternate layers of nickel hydrate and metallic nickel. The hydrate is the active material, and the metal, which is made in the form of microscopically thin flakes, is added to provide good conductivity between the walls of the tube and the remotest active material. The negative plate is made up of perforated, flat, sheet-steel boxes or pockets loaded with iron oxide and a small amount of mercury oxide, the latter also for the sake of conductivity.

The grids which support these tubes and pockets are punchings of sheet steel. The cell terminals and container are likewise of steel, and all metallic parts are heavily nickel-plated. The electrolyte is a 21 percent solution of caustic potash containing also a small amount of lithium hydrate. All separators and insulating parts are made of rubber. The details of the construction of the Edison storage battery are shown in Fig. 4.197.

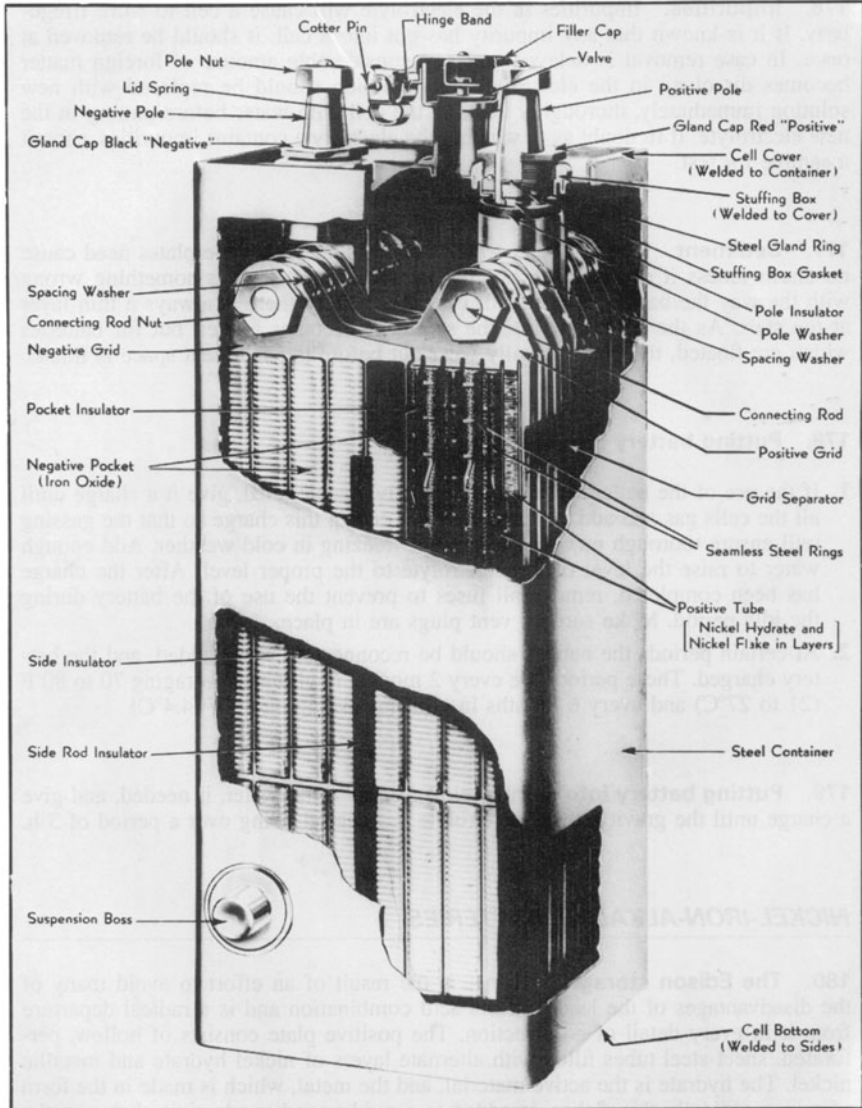

FIGURE 4.197 Edison nickel-iron-alkaline storage cell with container cut away to show construction detail. [Electric Storage Battery Co.]

The current used in charging causes an oxidation of the positive plate and a reduction of the negative, and these operations on discharge are reversed. The electrolyte acts merely as a medium and does not enter into combination with any of the active material as it does in the acid battery. Its specific gravity remains practically constant throughout the complete cycle of charge and discharge. The charge and discharge curves are shown in Fig. 4.198.

FIGURE 4.198 Charge and discharge curves of Edison battery.

The chief characteristics of the battery are ruggedness, due to its solid, steel construction; low weight, due to its stronger and lighter supporting metal; long life, due to the complete reversibility of the chemical reactions and the absence of shedding active material; and low cost of maintenance, due to freedom from the diseases, such as sulfation, so commonly met with in storage-battery practice and from the necessity of internal cleaning and plate renewals. The arguments against it are high first cost and high internal resistance. The importance of these must, of course, be weighed with the advantages and the resultant considered in each proposed installation. The battery has attained its chief prominence in vehicle propulsion, but its characteristics also recommend it for many other purposes.

181. Voltage characteristics. The voltage of each cell is approximately 1.5 V on open circuit, but it is higher than this when the battery is being charged and lower when being discharged. The voltage at any time depends upon state of charge or discharge, the temperature, and the density of the electrolyte. The average discharge voltage is approximately 1.2 V per cell. Typical voltage charge and discharge curves are shown in Fig. 4.198. Cells are generally discharged until the voltage drops from 1.0 to 0.9 V per cell. Further discharge is generally not satisfactory, since the voltage drops very rapidly if the discharge is continued past this point. The maximum voltage during charge will be between 1.80 and 1.90 V per cell. The voltage for any degree of discharge is affected slightly by the rate of discharge, as shown in Fig. 4.199.

182. Rating of nickel-iron-alkaline batteries. All batteries are given a normal ampere-hour capacity rating based on a certain rate of discharge to a final voltage of 1.0 V per cell. Some current ratings are based on a 5-h continuous discharge rate, and others on a 3¹/₃-h continuous rate.

FIGURE 4.199 Discharging at high rates: a four-cell battery, normal rate 30 A, discharged successfully at 30, 60, and 90 A, with comparison of continuous discharge at each of these rates. [Electric Storage Battery Co.]

The ampere-hour capacity for discharging continuously at a constant rate to a final voltage of 1.0 V per cell will be affected by the rate of discharge (Fig. 4.199). The higher the rate of discharge, the lower the capacity of the battery. The effect upon the capacity will not be so great, however, as it is for lead-acid batteries. After a high rate of discharge, the balance of the normal capacity of the battery can be obtained by continuing the discharge at a lower rate. If the battery is discharged intermittently, the normal capacity can be obtained unless the total elapsed time of discharge is excessively short. These batteries are very rugged and withstand very severe service. They are not harmed by occasional short-circuit discharges.

183. Charging. The best method of charging Edison batteries is by the average-constant-current method. The battery is connected in series with an adjustable resistance to a constant-potential dc supply, as shown in Fig. 4.200. The positive terminal of the battery should be connected to the positive terminal of the supply. The maximum voltage available at the batteries should be at least 1.85 times the number of cells in series. Throughout the charging period the rheostat should be periodically adjusted so that the average current will be maintained at its normal rated value. At each adjustment the current should be set a few amperes above the rated value so that by the time the next adjustment is made the current will not have dropped much below normal. The battery should be charged until a maximum voltage has been reached and maintained for 30 min. If an ampere-hour meter is used with the battery in charge and discharge, satisfactory charge is generally obtained by charging

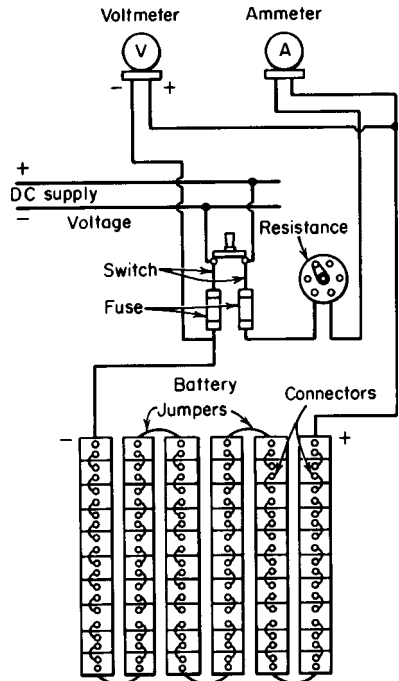

FIGURE 4.200 Correct connections for charging a battery at constant current through a variable resistor. [Electric Storage Battery Co.]

the battery at its rated current until the ampere-hours of charge is 125 percent of the ampere-hours of discharge. The condition of charge cannot be judged by means of specific-gravity readings. Automatic equipment for the control of the current during charge is being used to a greater extent.

Before starting to charge, see that the solution is at the proper level. If the solution is low, bring it to the proper level by adding pure distilled water as instructed in Sec. 169. If the battery is in a compartment, open the covers before starting a charge. If necessary, and if full capacity is not required, a battery can be taken off charge at any time and used.

184. Effect of temperature. Do not charge in a hot place or allow the temperature of the solution to exceed 115°F (46°C) on charge. High temperatures during charge or discharge will shorten the life of any kind of battery. Better efficiency is obtained if cells are charged at a temperature of 80 to 90°F (27 to 32°C). If the temperature of the solution exceeds 115°F while charging, allow the cells to cool before continuing the charge.

185. Charging at high rates. In an emergency, when time for a normal charge is not available, charging can be done at any higher rates than normal, provided there is no frothing and the temperature does not rise above 115°F (46°C).

186. Charging at low rates. If the discharge requirements are such that a low constant rate is used or if there is an intermittent rate of such value that for a given time period a low average rate will be had, then a charge rate of less than normal can be used, provided that this charge rate is approximately 120 percent of the constant or average discharge rate. The term *low discharge rate* is to be construed to mean a constant or average rate of less than 80 percent of normal.

When charging at low rates, it must be thoroughly understood that the required ampere-hour input must be put in and that, therefore, the time periods of charge must be correspondingly increased over that necessary to charge a cell fully at normal rate.

187. Boosting charge. An Edison battery can be boosted, i.e., given a supplementary charge, at high rates during brief periods of idleness, thereby materially adding to the available capacity. The principal limiting feature is that the temperature of the solution in the cells nearest the center or the warmest part of the battery does not exceed 115°F (46°C). A battery can be boosted whether it is entirely discharged or only partially discharged. The object of the boost is to supplement the remaining charge so that additional work can be done without waiting for regular charge.

The following table gives figures that can be used under average conditions, but values that will not cause excessive heating must be determined in each case by experience.

5 min at 5 times normal
15 min at 4 times normal
30 min at 3 times normal
60 min at 2 times normal

Frothing at the filler opening is an indication that the boosting has been carried too far (if the solution is at the proper height), and the boosting should be discontinued at once.

188. Overcharging is to be interpreted as charging a battery at the normal rate for periods in excess of the specified hours normal charge. For A, B, C, and N types, 12 h is considered an overcharge when the previous discharge has been taken only to an average of approximately 0.5 V per cell, and 15 h is considered an overcharge when the previous discharge has been taken to zero voltage and short-circuited. For G and L types these overcharge periods are, respectively, 8 and 10 h.

Overcharging in conjunction with proper discharges is used to compensate for either lack of work of battery or change of solution. In cases in which batteries have become sluggish owing to lack of work, as when a battery is seldom totally discharged in regular service, the battery should be periodically completely discharged to zero at normal rate and then short-circuited for 1 or 2 h. Follow with a regular overcharge.

With new Edison batteries better capacities will result if they are given plenty of work. It is, therefore, advisable to give new batteries additional work every 2 weeks for the first 2 months and every 2 months thereafter for 6 months. This should consist of a complete discharge to zero at normal rate with a short circuit of at least 2 h followed by an overcharge.

When an Edison battery does not give satisfactory capacity on discharge at rates several times normal, it is considered sluggish. This sluggishness or low capacity may result from persistent low-rate discharging, frequent low-rate charging, long stands, seldom discharging completely, or a weak solution. With the exception of the last named the primary cause is lack of work. Edison batteries thrive on work; therefore, the proper procedure is to discharge the battery completely at normal rate to zero and then short-circuit it for 2 h. Follow this by an overcharge. If the condition is rather pronounced, the cycle should be repeated. In the worst cases results can usually be obtained by several repetitions of the above. Ordinarily, this method will restore underworked batteries.

Completely discharge batteries before starting overcharges. Test for height of solution, and bring the solution to the proper height. Tests of solution height should be made before and after the battery has been completely discharged at normal rate, followed by a short circuit of at least 2 h and then an overcharge.

189. Nickel-Iron-Alkaline Batteries

^a Ratings are on basis of 5-hr rate for A, B, C, and N Type cells and 3½-hr rate for G and L Type, with average of 1.2 volts per cell and final of 1.0 volt per cell.

^b Weights are for completely assembled cells, including trays, connectors, etc.

^c The letter *H* indicates high-type cells; these cells have the same characteristics as the standard-type cells but are built higher so as to hold more electrolyte and are used in installations where frequent flushing is not convenient.

190. Maintenance of nickel-iron-alkaline batteries. The attention required by this battery is of the simplest character. It is chiefly important that the electrolyte be replenished from time to time with distilled water so that the plates will be entirely immersed and the outside of the cells be kept clean and dry, for if this is not done, leakage of current will occur with consequent corrosion of containers by electrolysis. Perhaps once or twice during the total useful life of the cell, the electrolyte may need renewal.

191. Cleaning. The cells, trays, and battery compartment must be kept dry, and care must be taken that dirt and other foreign substances do not collect at the bottom or between the cells.

Dirt and dampness are likely to cause current leakage, which may result in serious injury to the cells.

If protection of cell tops from moisture is required, they should be given a light coat of rosin or liquid Esbaline, this material being applied to the cover of the cell and sparingly to the outside of the filling aperture, care being taken not to get any great quantity on the lid hinge. Esbaline can be applied best with a small paintbrush, care being taken not to get any on the inside of lugs or on cell poles.

Rosin Esbaline must be applied warmed to approximately 170 to 190°F (77 to 88°C) and thinned to good paint consistency with benzine, etc.

A wet-steam jet or even an air blast will be found most satisfactory for cleaning but must not be used on cells while they are in the compartments. It has been found that a pressure of 70 lb with a 1-in rubber steam hose about 10 ft long into which has been inserted a piece of iron pipe about 12 in long with an orifice $\frac{1}{8}$ -in. in diameter will give wet steam with a velocity to clean the battery satisfactorily. (This orifice can be made by plugging one end of an iron pipe and drilling out with a $\frac{1}{8}$ -in drill.) When removing encrustations from the tops of cells, do not allow them to fall between or into the cells. Before reassembling, make sure that all poles, connectors, and jumper lugs are clean. Also cells, trays, and compartments must be dry before the battery is replaced.

Occasionally, cells and trays after being cleaned should be recoated with Esbalite, an alkaliproof insulating paint put out by the Electric Storage Battery Co.

The cells should be thoroughly cleaned of all grease, dirt, dried salts, and paint blisters or flakes and be perfectly free from all moisture. Painting may be done with a brush or, if the quantity is large, by dripping.

When cleaning and recoating with any cell coating be careful not to allow any of the materials to get into the cells.

192. Water or flushing. Do not allow the level of the solution to drop below the tops of the plates. Never fill higher than the proper level. If filled too high, solution will be forced out during charge.

For replenishing solution in Edison cells during operation use only pure distilled water or water which has been tested and approved by the Electric Storage Battery Co. Although pure distilled water is recommended for use in storage batteries generally, there are certain places in the United States where the local water supply is of such purity that it can be satisfactorily used. It is extremely important that no other water than pure distilled water be used unless it has received the approval of the Electric Storage Battery Co. after test at the factory's laboratories. The use of impure water will result in a slow poisoning of the electrolyte by an accumulation of impurities, the effect of which may not appear within a few months but will become apparent within the course of several years.

When solution has been spilled, use standard refill solution, which has a specific gravity of approximately 1.215 at 60°F (15.5°C).

FIGURE 4.201 Quick method of determining height of solution. [Electric Storage Battery Co.]

Battery compartments and trays must be kept dry and clean at all times; so take care when filling cells not to spill water over and around the cells and not to exceed specified height.

Test for height of solution before placing battery on charge. Do not test for solution height while battery is charging; the gassing during charge creates a false level.

A reasonably heavy-walled glass tube about 8-in (203 mm) long and of not less than $\frac{3}{16}$ in (4.8 mm) inside diameter with ends cut straight and fused enough to round the edges can be used as illustrated in Fig. 4.201 to find the level of electrolyte above plate tops. A short length of tightly fitting rubber tube forced over one end and projecting about $\frac{1}{8}$ in (3.2 mm) will prove a very good finger grip. Insert the tube until the tops of the plates are touched; close the upper end with the finger and withdraw the tube. The height of the liquid in the tube should be as specified by the manufacturer.

193. Specific gravity of nickel-iron-alkaline batteries. The density, or specific-gravity, reading of the electrolyte of an Edison cell has no value in determining the state of charge or discharge, as the specific gravity does not change during the charging or discharging of the cell to any marked extent. The small changes ordinarily observed are either due to large changes in temperature or loss of water from the electrolyte by evaporation or electrolysis in operating the cell. Therefore it is not necessary to take frequent readings to determine the specific gravity. The only time it is necessary to obtain a specific-gravity reading is to determine when a change of electrolyte would be advantageous. When making such readings, certain fundamental conditions must be observed. A suitable hydrometer must be obtained and used in accordance with the rules laid down in Sec. 172 on hydrometer readings. The glass container must be clean and must not contain acid or other impurities, as these tend to give lower readings than the true specific gravity.

Do not take a specific-gravity reading when the cell is charging, as the bubbles of gas contained in the electrolyte will cause a lower reading than the true one. Readings taken when the temperature of the electrolyte is either very high or very low will give results that will vary with the temperature. The specific gravities quoted in this section are for 60°F (15.5°C). Temperatures very much higher than this will give lower gravity readings, while temperatures very much lower than this will give higher readings.

Specific-gravity readings taken immediately after watering the cell are of no value, as the water has had no chance to be thoroughly mixed with the electrolyte and the resulting readings will be low. The specific gravity should be taken when the electrolyte is at the proper height after a complete charge. It is best to allow the cells to stand for a short period after the completion of the charge to permit free bubbles of gas to dissipate before taking readings. Corrections for temperature should be made by adding 0.0025 for each 10° above 60°F (each 5.5° above 15.5°C) to the observed reading or subtracting 0.0025 for every 10° below 60°F.

After taking a specific-gravity reading, return the solution to the same cell from which it was taken. Otherwise the gravity of the solution in the cell to which it is added will be

increased and the gravity of the solution in the cell from which it was taken will be decreased owing to the addition of water being made necessary.

The potash electrolyte in Edison cells has a normal specific gravity of approximately 1.200 at 60°F when at the normal level and thoroughly mixed by charging and when a sample is taken at least 1/2 h after charge to allow for dissipation of gas.

194. Solution renewal. Throughout the total useful life of the cell the electrolyte gradually weakens and may need renewal once or twice, depending on the severity of service, and in some cases, when maintenance and operation have been poor or when contamination has been allowed by the use of impure water, etc., a third time might be necessary.

The low-limit specific gravity beyond which it is inadvisable to run an electrolyte is 1.160. Operation at lower specific gravity than 1.160 should not be allowed, since such operation will produce sluggishness, loss of capacity, and rapid breakdown on severe service. Should the specific gravity be above 1.160 and at the same time sluggishness and loss of capacity be evident, do not immediately renew the electrolyte until it is found that an electrolyte sample sent to the factory shows a prohibitive accumulation of impurities and until the following treatment fails to produce marked improvement:

1. Discharge at normal rate to zero voltage. (When the current can no longer be kept up, either reverse the battery on the line with sufficient resistance in series or connect in series with another more nearly charged battery; then continue the discharge.) It is of prime importance that the rate be kept at normal throughout.
2. Short-circuit the battery in groups of not more than about five cells each for at least 2 h.
3. Charge at normal rate for 15 h for A, B, C, and N types and 10 h for G and L types.
4. Discharge at normal rate to approximately 1.0 to 0.9 V per cell.
5. Charge at normal rate for 7 h for A, B, C, and N types and 43/4 h for G and L types.
6. Discharge at normal rate to approximately 1.0 to 0.9 V per cell.

If the cells do not respond noticeably to this treatment, there is probably very marked contamination of the electrolyte, and the result of the analysis of a representative sample sent to the manufacturer's factory in accordance with instructions will show this. Therefore, regardless of the specific gravity, the electrolyte should be replaced as follows:

1. When previous electrolyte has reached approximately the low limit of 1.160, the new solution should be standard renewal.
2. When previous electrolyte is 1.190 or above, the new solution should be standard refill.

It is always advisable, in case the battery exhibits trouble of any sort, to communicate all details to the manufacturers or their representative, so that immediate advice may be obtained.

Do not use any other solution than Edison electrolyte. Do not pour out old solution until you have received new solution and are ready to use it. Never allow cells to stand empty. State type and number of cells when ordering Edison electrolyte for renewal.

When ready to renew solution, first completely discharge the battery at normal rate to zero and short-circuit for 2 h or more. This is done to protect the elements. Then empty cells completely. It is not necessary to shake or rinse cells, and under no circumstances should cells be filled with water.

Immediately after emptying each cell, pour in new solution. Do not allow to stand empty. Fill to exactly the proper height. For this purpose use a clean glass or enamelware funnel. A plain iron funnel can be used if it has no soldered seams, but do not by any means

use one of tinned or galvanized iron. A clean rubber tube can be used to siphon the solution directly from the container to the cell. If the tube is new, it should be thoroughly soaked in electrolyte for a couple of hours in such a position as to retain the solution. This is to remove thoroughly any impurities on the rubber. Fill to exactly the proper height, for if cells are filled too full when renewing the solution and allowed to remain that way, the specific gravity of the electrolyte will be too high when the level of the solution returns to proper height. This condition may lead to serious results and can easily be avoided by reasonable care.

Do not attempt to put in all solution received, as an excess is allowed to make up for any loss due to spilling. It may be necessary to add some more electrolyte after cells have stood a little time, as some electrolyte may be absorbed by the plates.

The specific gravity of the Edison electrolyte for renewal as shipped is about 1.250, but this will quickly fall to normal when put into a battery, owing to mixture with the old, weak solution remaining in the plates.

Do not attempt to use the electric filler for refilling cells. It was not designed for this purpose and will not work.

When the new electrolyte is in and the battery is again connected for service, give it an overcharge at the normal rate as outlined under Sec. 188, "Overcharging."

195. Cautions in operation of nickel-iron-alkaline batteries

1. Never put lead battery acid into an Edison battery or use utensils that have been used with acid; you may ruin the battery.
2. Never bring a lighted match or other open flame near a battery.
3. Never lay a tool or any piece of metal on a battery.
4. Always keep the filter caps closed except when necessary to have them open for filling.
5. Keep batteries clean and dry externally.
6. Edison electrolyte is injurious to the skin or clothing and must be handled carefully. Solution spilled on the person should be immediately washed away with plenty of water.

196. Laying up nickel-iron-alkaline batteries. If the battery is to be laid up for any length of time, be sure that the plates are covered to the proper height by solution or electrolyte. The battery should be stored in a dry place. Do not leave it in a damp place, as damage to the containers may result from electrolysis. Never let the battery stand unfilled.

Edison batteries are easy to lay up. Merely discharge to zero voltage and short-circuit. They can be left standing idle indefinitely in this condition without injury.

New Edison cells have received sufficient cycles of charge and discharge before shipment to give considerable capacity above that rated. However, Edison cells will increase still further in capacity if thoroughly worked in. Therefore it is best, if new cells are to stand for some time before being put into commission, to discharge them to zero at normal rate and short-circuit at least 6 h.

When putting the battery back into commission, go over each cell and see that all poles and connections are in good condition as for a new cell. See that the plates are properly covered with electrolyte and then charged as here instructed. First, if not already discharged, discharge cells to zero at normal rate and short-circuit. Follow this by an overcharge at normal rate, and then discharge at normal rate. Then charge at normal rate for normal hours of charge. If the battery shows signs of sluggishness, repeat the overcharge and carry the discharge down to zero until cells are fully active; then give regular charge.

NICKEL-CADMIUM BATTERIES

197. Nickel-cadmium batteries are a relatively new addition in the United States to the storage-battery family. These batteries consist of an interleaved assembly of positive and negative plates (Fig. 4.202).

Cell containers are made of nickel-plated steel. Active materials, nickel hydroxide (positive) and cadmium oxide (negative), are encased in finely perforated steel pockets. Plates consist of rows of pockets crimped together and locked into steel frames under many tons of pressure.

Positive and negative plates are welded or bolted to heavy steel busbars. Plate groups are interleaved and are separated by thin plastic rods.

The alkaline electrolyte is a solution of potassium hydroxide.

The active materials are converted on charging and discharging in accordance with the chemical reaction, which may be written as follows:

On discharge of the battery the reaction proceeds in the forward direction, while on charge the reaction is reversed. The system stores chemical energy when the battery is

FIGURE 4.202 Cutaway view of a nickel-cadmium battery. [Nicaid Division of Gould-National Batteries, Inc.]

charged, and this chemical energy is converted back to electrical energy on discharge. Reversibility of this reaction under extreme environmental conditions is one of the outstanding properties of the nickel-cadmium electrochemical system.

During charge or discharge of a nickel-cadmium cell there is practically no change in the specific gravity of the electrolyte. The sole function of the electrolyte is to act as a conductor for the transfer of hydroxide ions from one electrode to the other, depending on whether the cell is being charged or discharged.

198. Data for Nickel-Cadmium Batteries

199. Characteristics

Nominal voltage per cell. 1.2 V (a 6-V battery consists of 5 cells).

Temperature range. –60 to +200°F (–51 to +93°C).

Maximum discharge current. Up to 25 times rated ampere-hour capacity.

Capacity at –60°F (–51°C). Up to 90 percent at low rates.

Internal resistance very low. 0.001 Ω for 10-Ah-type cell.

Full charge. By constant potential in 1 h at 1.55 V per cell.

Full charge. By constant potential in 6 h at 1.43 V per cell.

Charge, trickle. 1.35 V per cell to maintain charged battery.

Gassing discharge. None.

Gassing charge. Virtually none below 1.47 V per cell.

Vibration resistance. Excellent.

Shock. 80 g.

Altitude. Pressure-release valve opens 25 psi (172,369 Pa) above ambient.

Cycle life. No known limit.

Storage life. No known limit in any state of charge.

Charge retention. Up to 70 percent after 1 year at room temperature.

Orientation. Any position on discharge.

200. Advantages of nickel-cadmium batteries as stated by Nicad Division of Gould-National Batteries, Inc.:

High surge currents. Good voltage maintenance under extremely high current discharge conditions.

Constant-voltage source. Close voltage regulation during discharge (see Figs. 4.203 and 4.204).

Rapid-charge acceptance. Can be completely recharged at high rates without damage.

Long life. Designed to give exceptionally long life under cycle and float service.

Extreme-temperature operation. Normal and high-rate discharge and charge possible at temperatures from -40 to $+165^{\circ}\text{F}$ (-40 to $+74^{\circ}\text{C}$).

Excellent charge retention. Charged cells filled with electrolyte will retain approximately 70 percent of their charge after 1 year of idle storage at normal temperature.

Storageability. Can be laid up in any state of charge for long periods without attention or fear of deterioration.

Discharge in any position. Can be discharged in any position.

Easy maintenance. Negligible loss of water during service. Records of specific gravity are not necessary.

Vibration and shock resistance. Capable of withstanding up to 50 g shock and severe vibration.

Alkaline electrolyte. The potassium hydroxide electrolyte does not give off corrosive fumes on charge or discharge.

Pressure sealing. The smaller cells are normally provided with pressure-sensitive sealed vents.

Economy. Low cost per year due to long life. Very low maintenance costs. Low-cost, high-rate performance.

Small size and light weight. Nicad sintered plate batteries are smaller and lighter than conventional batteries under high-current-drain conditions.

FIGURE 4.203 Typical discharge characteristics for a high-rate nickel-cadmium cell. [Nicad Division of Gould-National Batteries, Inc.]

FIGURE 4.204 Discharge-voltage characteristics of a nickel-cadmium cell. [Nicad Division of Gould-National Batteries, Inc.]

201. Installation and care of nickel-cadmium batteries. The following instructions for the installation and care of nickel-cadmium batteries are those recommended by the Nicad Division of the Gould–National Batteries, Inc.

202. Important precautions

1. Maintain the battery compartment, cells, and trays in a clean and dry condition. Dirt and moisture will cause self-discharge, corrosion, and eventual leakage of cell containers.
2. Check the electrolyte level *before* adding distilled water. Maintain correct electrolyte level, but do not add water in excess of the recommended maximum level. Do not spill water or electrolyte on the cells or trays.
3. The electrolyte is an alkaline solution of caustic potash—*not* sulfuric acid, as used in lead batteries.
4. Sulfuric acid or traces thereof will rapidly ruin the Nicad battery by corroding its steel plates and cell containers. Therefore, use only the hydrometer and level test tube furnished with the battery.
5. Do not discharge at normal rates below 1.10 V per cell. Repeated overdischarges will damage the battery.
6. Always keep the vent caps closed except when checking the electrolyte or adding water.
7. Never examine the cells with an open flame. Keep tools and other metal objects away from the battery.
8. Apply boric acid solution if electrolyte is splashed on person or clothing.

203. Installing the battery. Place the battery in a clean, dry room located so that it can be easily inspected and watered. On mobile equipment such as vehicles or ships it must be securely tied down.

Avoid placing the battery in a hot location (above 125°F, or 52°C) or where it will be exposed to corrosive gases or fumes.

It is not good practice to install Nicad batteries and lead-acid batteries in the same room unless there is ample ventilation to carry away fumes from the lead-acid batteries.

All battery rooms and compartments must have good ventilation and drainage, and at the same time cinders, road dirt, soot, dust, rain, snow, and seawater must be kept out.

Accumulations of dirt and moisture on cell tops and particularly between the cells will cause corrosion and leakage of cell containers.

Holes or gratings which permit ready entry of dust, water, etc., must be closed up. However, four small drainage holes (maximum diameter of holes $\frac{1}{4}$ in, or 6.35 mm) should be provided in the bottom, one at each corner of the compartment.

Compartments which have previously housed lead-acid batteries must be washed out, neutralized with ammonia or washing-soda solution, allowed to dry thoroughly, and then painted with Nicadvar asphalt paint. Wood liners must be removed and replaced by new ones. Ample space should be provided above the battery for inserting the electrolyte-level test tube and the hydrometer into the cells.

If the battery is to be serviced through the top of a compartment, allow a minimum clearance of 2 in (50.8 mm) between the top of the battery and the underside of the access cover.

If the battery is to be serviced from the side, the clearance between the battery and the ceiling of the compartment should be at least 8 in (203.2 mm).

Small stationary batteries can be placed directly on a clean, dry floor or on a suitable wall shelf. Large batteries should be placed on racks.

Check the electrolyte level and the specific gravity and be sure that the battery is thoroughly clean and dry before placing it in position.

Nothing should be placed or allowed to lodge in the open spaces between or underneath the cells. These air gaps serve as electrical insulation between the cells and are an essential part of the battery. For this reason they must be maintained open, clean, and unobstructed at all times.

Variation of specific gravity may be found between individual cells. A maximum variation of plus or minus 0.005 point is permissible. For example, if normal specific gravity called for is 1.210, a minimum of 1.205 and a maximum of 1.215 specific gravity is satisfactory.

The cell containers must not be grounded, and the bottoms of the cells must not be allowed to rest on any object. Battery trays should never be stacked directly on top of one another, nor should water or spilled electrolyte be allowed to accumulate under the battery.

All cables leading to the battery posts should be fitted with nickel-plated cable lugs. Do not use bare copper cable lugs or connectors. After connecting cable lugs to battery, cover lugs with Nicad petroleum jelly No. 32982.

All wiring to the battery should be properly spaced and firmly secured to prevent any chance of a short circuit.

Wires or cables should never be allowed to rest on top of the cells.

Never connect to the battery a device or instrument that might cause an unnecessary constant drain, however small, as it will ultimately discharge the battery when left standing on open circuit. Voltmeters, for instance, should be connected to the battery only by means of a normally open pushbutton switch.

If either side of a high-voltage battery is grounded, it will expose personnel and battery to hazardous conditions. The shock hazard to personnel is obvious. In such cases additional high-resistance grounds in any part of the circuit will cause trouble and possibly a serious short circuit. For example, an inductive surge from breaker operations can cause a slight ground to become larger and rapidly discharge the battery. When checking battery voltage, also take readings between each terminal of the battery and ground for possible leakage, as ground indicator lights may not show slight grounds.

Most storage batteries consist of a single series of cells of the same type and ampere-hour capacity. If the battery consists of more than one tray, be sure that the negative end terminal of each tray is connected to the positive end terminal of the following tray. Cells wrongly connected will receive a reverse charge and will be damaged if the condition is allowed to continue.

On completing the installation, make sure that no loose objects such as screws or tools have been accidentally left in the battery compartment.

Check and tighten all cell-post nuts, as loose electrical connections will heat up and can cause sparking.

Verify that every person who is going to take care of the battery has a copy of these instructions.

Mount the instruction card accompanying the battery in a conspicuous position for future reference.

204. Charging. The positive terminal post of every cell is identified by a plus mark on the cell container. When charging, always connect the positive terminal of the battery to the positive lead from the charger. Only direct current can be used for charging storage batteries. If only alternating current is available, a rectifier or a motor generator is necessary to convert the alternating into direct current. Information concerning various types of charging equipment is available from manufacturers.

When a battery is first placed in service, the charging rate may vary somewhat before it is stabilized. During the first week or two the adjustment should be checked every few days.

A reasonable amount of overcharging, particularly at low- or trickle-charge rates, has a beneficial effect on Nicad batteries. When in doubt at any time as to the state of charge, it is advisable to overcharge rather than to undercharge.

Variations in line voltage due to local conditions can be large enough to throw charge voltages off normal. A normal setting during the day may rise to a point of overcharge and excessive charging at night and on weekends. If such a condition exists, it is desirable to install a constant-voltage transformer ahead of the charger.

The open-circuit voltage is the voltage of a storage battery when standing idle, i.e., when it is neither on charge nor on discharge. All types of storage batteries standing idle for a period of time have an open-circuit voltage independent of the state of charge. It therefore cannot be used to indicate the state of charge of a battery.

The open-circuit voltage of a Nicad cell is approximately 1.30 V. Nicad batteries possess the characteristic common to all storage batteries that their voltage rises throughout the charge. Hence when the battery voltage ceases to rise and the charge current remains steady, it is an indication that the battery is fully charged. The voltage of a fully charged battery, still on charge, will depend upon the magnitude of the charge current; the heavier the current, the higher the battery voltage.

The accuracy of voltmeters and ammeters is of considerable importance. Temperature changes and even slight vibration can change their adjustment. Good storage-battery maintenance requires that meters, particularly panel-mounted ones, be checked periodically to an accuracy of 0.5 percent.

Several methods of charging batteries are described below.

205. Charging engine-starting batteries. The generator voltage regulator should be set so as to hold the battery voltage between 1.45 and 1.50 times the number of cells in the battery. Readings should be taken at the battery terminal posts with the voltage regulator at proper working temperature, with its cover in place, and only after the battery voltage has ceased to rise.

If the engine is started infrequently, as in emergency standby services, or if the engine is operated only for very short periods at a time (insufficient to keep the battery in a fully charged condition), it is recommended that the battery be maintained on constant trickle charge, preferably from a dry disk or plate, metallic rectifier, at a voltage equal to 1.40 to 1.45 times the number of cells in the battery. At this charge voltage the battery may require watering as often as every 6 to 9 months.

206. Trickle charging or floating. Fully charged batteries floated across the line should be maintained at a voltage equal to 1.40 times the number of cells in the battery. If the discharges, although momentary, are relatively heavy and frequent, the voltage should be raised to 1.45 times the number of cells in the battery to ensure that the total input will exceed the total output over a period of time.

Otherwise, the battery will become slowly discharged and require so-called equalization or overcharges from time to time to bring it back to a fully charged condition.

The recommended battery voltages will hold the individual cell voltages below 1.47 V. Above 1.47 V the cells will begin to gas and hence consume water. Variations in voltage up to a maximum of 0.05 V between the individual cells of a battery on float should be disregarded, as they are of no importance. One of the most valuable features of the Nicad battery is that its floating voltage is not critical, provided, of course, that it is high enough to compensate for the loads imposed on the battery from time to time. Floating at above 1.47 V per cell will not harm the battery, but its water consumption will be considerably increased, requiring additional attention.

Trickle charging is actually preservation charging and should be used only to keep a charged battery in a fully charged condition. It cannot be used as a substitute for normal charging of a discharged battery. Trickle chargers should be equipped with a variable resistance and a voltmeter of suitable range and accuracy. Information on suitable equipment for trickle and high-rate charging of Nicad batteries will be furnished by the manufacturer upon request.

207. Constant-current charging. This method consists of charging at a constant current, not for a definite length of time or to a definite end voltage, but until the battery voltage ceases to rise, indicating that the battery is fully charged.

The length of time required to charge the battery by this method depends on the magnitude of the charge current and the state of charge of the battery at the time it is put on charge.

It is usual to insert a variable resistance of suitable size between the dc line and the battery and to reduce the resistance from time to time by hand, during the charge, so as to hold the charge current reasonably constant.

A dc line voltage of 1.40 times the number of cells in the battery is necessary at the beginning of the charge and of 1.85 times the number of cells in the battery at the end of the charge. In theory, practically any rate of charge can be employed, provided that the electrolyte temperature, which is the limiting factor, is not allowed to exceed 145°F (63°C).

Too high a charge current, however, particularly if the electrolyte is above the maximum permissible level, may cause the electrolyte to be forced out of the cell vents.

When charged by the constant-current method at the normal (7-h) charge rate, Nicad batteries will commence to gas after about 4½ h, i.e., when the battery voltage has risen to about 1.47 V per cell. Therefore, if a period of more than 7 h between discharges is available, it is desirable to charge at a lower rate than normal. This will reduce gassing and consequently the amount of water required by the battery. For example, a 100-Ah battery has a "normal" charge rate of 20 A (for 7 h) but may conveniently be charged at 14 A for 10 h or 10 A for 14 h. The specific gravity of the electrolyte remains practically constant during charge and discharge; therefore, specific-gravity readings are not necessary.

208. Ascertaining state of charge. Open-circuit voltage readings (no current passing into or being delivered by the battery) *cannot* be used as an indication of the state of charge of any storage battery.

The density of the electrolyte of the Nicad battery does not change appreciably on charge or discharge, and specific-gravity measurements, therefore, do *not* indicate its state of charge at any time.

To determine the state of charge of a partially charged battery it becomes necessary to take simultaneous current and voltage readings. There are several ways of doing this, and for services in which it is necessary to determine the state of charge frequently a satisfactory method can generally be worked out.

For certain applications involving heavy rate discharges of short duration, such as switch tripping, it has been found advantageous to install a voltmeter and a fixed resistance near the battery to provide an artificial load equal in value to the normal load. Voltage readings obtained while the battery is connected momentarily to the artificial load indicate the ability of the battery to carry the normal load.

Information regarding methods and equipment can be obtained from manufacturers of nickel-cadmium batteries.

209. Discharging. Heavy discharges (such as engine starting) will not damage the Nicad battery. Do not, however, discharge the battery below 1.10 V per cell at from 3- to

10-h rates or below 1.20 V per cell at lower current rates. Overdischarging at low rates regularly continued below these end voltages will damage the battery and is an indication that the battery is too small for its work.

210. Maintenance. Keep the cells and trays clean and dry externally at all times. Moisture and dirt allowed to accumulate on top of and particularly between the cells will permit stray intercell currents, resulting in corrosion through electrolysis of the cell containers. For this reason any water or electrolyte spilled on the cells or the trays must be wiped off. Use compressed air or, better still, low-pressure steam to clean cells and trays. Do not allow dirt to enter the vents when cleaning cells. After cleaning, regrease the cell tops and connectors with Nicad petroleum jelly No. 32982 to protect the metal.

Batteries that are charged at high rates may gas heavily toward the end of charge, giving off minute quantities of potassium hydroxide. This combines with carbon dioxide in the air, forming potassium carbonate, which deposits a noncorrosive, inert white powder on the cell tops and connectors. Potassium carbonate is electrically conductive when damp and if allowed to build up can cause current leakage and possibly discharge the battery. Any accumulation should be removed with a brush or damp cloth.

Keep all vent caps closed to prevent air from entering the cells. Open caps only to check the electrolyte. Caps must be closed when the battery is charging.

Always check and service only one cell at a time.

Never place or drop any metal articles, such as post nuts, cable lugs, or tools, on or between the cells. These will cause heavy short circuits which may damage the cell containers.

Never permit sparks, open flame, or lighted cigarettes near a storage battery. All storage batteries when gassing give off a highly explosive mixture of hydrogen and oxygen. A nonmetallic flashlight is desirable for battery inspection. Keep all connections tight.

Use only spirit thermometers when taking temperature readings. Ordinary mercury thermometers may break. Mercury running into the cell between its plates will cause sparking and explosions.

Always keep the plates covered with electrolyte. Serious damage can be caused by exposing the tops of the plates to the air. If electrolyte has been spilled accidentally from the battery, proceed as described in Sec. 213.

211. Damage from impurities. Impurities of all kinds must be kept out of the cells, as they have a harmful effect and can eventually ruin the battery.

Even a trace of sulfuric acid can ruin a Nicad battery by attacking and corroding its steel plates and cell containers. To prevent contamination never use any tools or utensils such as hydrometers, funnels, rubber hoses, battery fillers, etc., which have been used at any time for servicing lead-acid batteries.

Any vegetable oil or grease accidentally introduced into the cells will cause them to froth on charge.

212. Electrolyte. The electrolyte (solution) in Nicad batteries is alkaline and consists of specially purified caustic potash (KOH, potassium hydroxide) dissolved in distilled water. The specific gravity of the electrolyte does not change with the state of charge but remains practically constant on charge and discharge.

The use of other than Nicad electrolyte can damage the battery. Ordinary commercial grades of caustic potash should never be used, as they are not sufficiently pure.

Nicad refill or renewal electrolyte of proper specific gravity is available in nonreturnable containers holding 5, 10, 15, 20, and 130 lb (2.3, 4.5, 6.8, 9, and 59 kg). Use an enamelware

or glass pitcher and funnel for filling cells with electrolyte or water. Earthenware, hard-rubber, and plastic utensils are also suitable.

Refill electrolyte is used to replace electrolyte accidentally lost in transit or otherwise, while renewal electrolyte is used when changing the electrolyte, as described in Sec. 216.

If electrolyte should be lost by accident from any of the cells, replace the lost quantity with Nicad refill electrolyte. If refill electrolyte is not available, take the battery out of service and add enough water to cover the plates (so as to prevent damage to the plates by exposing them to the air) and procure renewal electrolyte. Upon its arrival empty out all the old electrolyte and fill the cells with renewal electrolyte. Charge the battery and check that the specific gravity is correct and uniform in all the cells before putting the battery back into service.

213. Method of adjusting electrolyte specific gravity. Cells having lost their electrolyte in shipping or by accident should be filled immediately to the proper level with Nicad refill electrolyte, and no adjustment of electrolyte specific gravity will be needed. If, however, they have been filled with water pending the arrival of refill electrolyte, the following electrolyte adjustment treatment will be necessary.

Dump the weak electrolyte-water mixture from the cells and fill with refill electrolyte. Cells which have lost electrolyte in varying amounts need adjustment of electrolyte specific gravity. Adjustment should be made during charge and toward the end of the charge when the cells are gassing freely.

If electrolyte is too strong, add distilled water. If electrolyte is too weak, add special 1.400-specific-gravity electrolyte supplied by Nicad on request. Three adjustments may have to be made before the normal specific-gravity reading is obtained. Allow 30 min between each adjustment during charge.

The amount of distilled water or special 1.400-specific-gravity electrolyte required can be found only by trial. For example, one cell may need only half a syringe full to bring the electrolyte to normal specific gravity. Yet another cell may need several syringes full, depending on the size of the cell and the strength of the electrolyte in the cell.

Each time that electrolyte is withdrawn from a cell during this adjustment, it should be replaced with an equal amount of special electrolyte or water to maintain correct electrolyte level above the plate tops.

Once adjusted to the correct specific gravity at maximum level, the cell will need only distilled water to keep the electrolyte at maximum level.

The above-described method of adjusting the electrolyte specific gravity may seem slow and cumbersome but is necessary to ensure good performance and to maintain the capacity of the cells.

The electrolyte will readily absorb carbon dioxide from the air to form potassium carbonate, which has the effect of temporarily lowering the capacity of the battery. Electrolyte must therefore be stored in airtight containers. Cell vent caps should be kept closed at all times except when adding water or checking the electrolyte, and this should always be done as quickly as possible, opening only one vent cap at a time.

When handling electrolyte wear goggles and rubber gloves; avoid splashes. The electrolyte is injurious to skin and clothing and must therefore always be handled carefully. Particularly guard the eyes! A generous quantity of concentrated boric acid solution (5 oz of boric acid powder to each quart, or 0.14 kg/0.95 L, of water) should be kept handy in a bottle or open bowl for neutralizing any accidental splashes on person or clothing. Use an eyecup for eye injuries.

Boric acid powder will dissolve in warm water within 1 h. With cold water allow 24 h. Do not use the boric acid solution on cells or trays.

FIGURE 4.205 Application of hydrometer.
[Nicad Division of Gould-National Batteries, Inc.]

cell; then squeeze and release the bulb. This method will prevent Celoil (see Sec. 217) from being drawn up into the barrel. Draw up sufficient solution to permit the float to move freely, and then tap the glass barrel of the hydrometer gently with the finger to prevent the float from giving a false reading by sticking to the barrel wall.

The maximum level of the electrolyte is halfway between the tops of the plates and inside the cell covers (do not include vent height). At this level and down to the minimum level of $\frac{1}{2}$ in (12.7 mm) above the plate tops, the specific gravity of the electrolyte should be within the range specified on the wall card. These figures apply to normal temperatures. When extreme temperatures prevail and the observed hydrometer readings are outside these limits, it will be necessary to apply temperature- and electrolyte-volume-correction factors as described below.

To arrive at the true specific gravity of the electrolyte at 72°F (22°C), the temperature used as a base for purposes of calculation, observe and make a record of:

1. The electrolyte specific gravity
2. The electrolyte temperature
3. The electrolyte level above the plates

214. Checking the electrolyte.

Storage batteries normally lose water through natural evaporation and particularly when gassing freely on charge. While there are no corrosive or obnoxious gases given off by Nicad batteries, traces of the potassium hydroxide are lost with the gas, resulting in a gradual lowering of the specific gravity of the electrolyte over the years.

The level of the electrolyte as well as its specific gravity must therefore be checked periodically, as serious damage will be done to the plates if the electrolyte level falls below the top of the plates or the specific gravity is less than the minimum value stated on the wall card.

The electrolyte level is determined by inserting the $\frac{3}{16}$ -in- (4.8-mm-) bore plastic tube shipped with the battery through the vent until it rests on top of the plates, then placing the finger tightly over the end and withdrawing the tube for inspection. Be sure to return the electrolyte in the tube to the cell from which it was withdrawn.

A hydrometer (Fig. 4.205) is used to check the specific gravity of the electrolyte, which should be within the range specified on the wall card. The illustrations show the positions of the float in electrolyte which is too weak (Fig. 4.205B) and too strong (Fig. 4.205A).

Use only a Nicad hydrometer to take specific-gravity readings. First rest the tip of the nozzle firmly on top of the plates in the

If the electrolyte temperature is above 72°F, add to the specific gravity reading 0.001 for every 4° above 72°F (every 2.2° above 22°C).

If the temperature is below 72°F, subtract 0.001 from the specific-gravity reading for every 4° below 72°F.

For every $\frac{1}{4}$ in (6.35 mm) of electrolyte above the top of the plates add 0.005 to the specific-gravity reading.

The following examples show typical calculations:

EXAMPLE 1 Hydrometer reads 1.190. Electrolyte temperature is 96°F; add $0.001 \times (96 - 72) \div 4 = 0.006$. Specific gravity, corrected for temperature only, is 1.196. Electrolyte level is $\frac{3}{4}$ in; add $0.005 \times 1\frac{3}{4} \div \frac{1}{4} = 0.035$. Specific gravity, corrected for both temperature and volume, is 1.231.

EXAMPLE 2 Hydrometer reads 1.190. Electrolyte temperature is 40°F; subtract $0.001 \times (72 - 40) \div 4 = 0.008$. Specific gravity, corrected for temperature only, is 1.182. Electrolyte level is $\frac{3}{4}$ in; add $0.005 \times \frac{3}{4} \div \frac{1}{4} = 0.015$. Specific gravity, corrected for both temperature and volume, is 1.197.

A Nicad spirit thermometer part No. 91791 is necessary to apply proper temperature-correction factors to the hydrometer readings.

Gas bubbles in sample of electrolyte withdrawn from cells which are gassing must be allowed to disappear; otherwise false readings will be obtained.

Specific-gravity readings should not be taken on cells to which water or special 1.400-specific-gravity electrolyte has just been added, but deferred until they have had time to mix properly with the electrolyte during charge.

Always return the sample of electrolyte to the cell from which it was taken. After use wash out the hydrometer thoroughly with water to remove all traces of electrolyte as any electrolyte allowed to remain in the hydrometer will absorb carbon dioxide from the air to form a thin coating on the float, which will cause false readings.

215. Adding water. Always check the electrolyte level before adding any water to the cells. For maximum permissible level of the electrolyte refer to Sec. 214 or the wall card packed with the battery. Do not overflow.

Nicad batteries use very little water, particularly when they are on float or trickle charge. Batteries on float at a voltage equal to 1.40 times the number of cells in the battery will usually be found to require watering less than once a year.

If the cells are overfilled, the electrolyte will be forced out of the vents on charge and saturate the trays, causing electrolysis between the cells, corrosion of the cell containers, and troublesome grounds in the electrical circuit. Overfilling will also dilute the electrolyte to such an extent that the specific gravity will become too weak and the plates will be damaged.

Maintain the proper electrolyte level by the periodic addition of distilled water; do not add electrolyte. Do not use so-called distilled water for storage batteries, as it generally contains small amounts of sulfuric acid through being stored in carboys having contained sulfuric acid intended for use in lead batteries.

Some drinking water may be usable, but it is always advisable to forward to the manufacturer a laboratory analysis or a sample of the water to be used. Transportation should be prepaid. The minimum quantity of water to be sent is 2 qt (1.9 L), and the minimum quantity of electrolyte is 1 qt (0.95 L) for proper analysis. Ship in thoroughly cleaned glass or plastic bottles. Tag for easy identification. Do not send by mail. Send by express service. Label electrolyte "corrosive liquid."

Although the quantity of any impurities introduced into the battery each time the battery is watered may be insignificant, the cumulative destructive effect over a number of years will be considerable. Distilled water is so inexpensive and in most cases so easily procured that its use is easily justified in terms of battery life. Stills for producing distilled water at very low cost are available from a number of reliable manufacturers. Store distilled water in clean, airtight glass or plastic bottles or jars.

216. Change of electrolyte. Batteries which are charged at high rates for long periods and hence gas freely, with consequent loss of water and potassium hydroxide, may require change of electrolyte. Nicad batteries seldom if ever require change of electrolyte. However, it is desirable to check the specific gravity about once a year. When the specific gravity of the electrolyte, at a height of $\frac{1}{2}$ in (12.7 mm) above the tops of the plates, has fallen to the minimum specified, further operation of the battery will cause a rapid reduction in its life. At this point the battery should be discharged at the 7-h discharge rate to a voltage of 0.5 to 0.8 V per cell and have its electrolyte changed.

Remove the cells from their trays, and working on only one tray at a time, turn them upside down and empty out the electrolyte. Do not rinse the cells with water or electrolyte. Do not allow the cells to stand empty more than 30 min, as exposure of the plates to the air will damage the capacity. Fill immediately to the maximum height, i.e., halfway between the tops of the plates and inside the cell covers, with Nicad renewal electrolyte. The renewal electrolyte should, of course, always be procured in advance and be available before starting to empty the cells.

Avoid splashes. Protect the eyes! Wear goggles and rubber gloves.

While the above operations are performed, the trays or cells should not be stacked on top of one another, nor should the cell posts be allowed to touch anything except insulation. Any chance of short-circuiting the cells should be avoided. The trays should be examined for damage, and any broken parts replaced. Note that the trays are so designed that there is a clear space between the cells and the surface on which the trays rest.

After being thoroughly cleaned, preferably by steam or compressed air, the cells and the trays should be allowed to dry thoroughly and then painted or, preferably, dipped in Nicadvar, a specially prepared corrosion-resisting asphalt-base paint. After the battery has been reassembled, it should be given a 14-h charge at the 7-h charge rate before being put back into service.

217. Celoil. Nicad batteries normally contain a $\frac{1}{4}$ -in (6.35-mm) layer of Celoil floating on top of the electrolyte, which retards the natural evaporation of water from the electrolyte.

Celoil is a pure, acid-free, and nonsaponifying oil specially prepared for use in Nicad cells. Do not use anything but Nicad Celoil.

218. Laying up. When a Nicad battery is to be laid up for a few months, make sure that the specific gravity of the electrolyte is within the specified range and that the level is at least $\frac{1}{2}$ in (12.7 mm) above the tops of the plates.

Nicad batteries can be taken out of service in any state and left idle for years without deterioration.

Remove all the intertray connectors to break any stray currents, and store the battery in a cool place free from dust and moisture.

Regrease the cell tops to protect the metals with Nicad petroleum jelly No. 32982.

If the battery has been stored for some time, give it a freshening charge before placing it back in service. Charge battery for 7 h at normal rate or for 14 h at half normal rate.

219. Returning cells to factory. If a cell or battery appears to be abnormal in any respect or if an accident has occurred, it may be necessary to return it to the factory for test and repair.

Before a cell or battery is returned, a complete description of the unusual condition should be reported to the service department. If in the opinion of the company the return is indicated, full shipping instructions will be sent with return-material authorization.

Return shipments cannot be accepted without the company's authorization.

In case a cell has to be returned to the factory, it should be discharged at the 7-h rate to 0.5 to 0.8 V. The electrolyte must be left in the cell.

Tighten the post nuts, and drive a tapered rubber or wooden plug of suitable size into the vent hole. Turn the cell upside down. Leave it standing in this position for 1 h and then check that no electrolyte has leaked out.

Pack the cell, surrounded by a large quantity of liquid-absorbing material, such as sawdust, in a suitable container and ship prepaid in accordance with instructions which will be furnished by Nicad.

INSTALLATION OF STORAGE BATTERIES

220. In installing storage batteries, follow the rules of the National Electrical Code, which are given below.

221. Scope. The provisions of this section shall apply to all stationary installations of storage batteries.

222. Definition of nominal voltage. The nominal battery voltage shall be calculated on the basis of 2.0 V per cell for the lead-acid type and 1.2 V per cell for the alkali type.

223. Wiring and apparatus supplied from batteries. Wiring, appliances, and apparatus supplied from storage batteries shall be subject to the applicable provisions of the Code applying to wiring, appliances, and apparatus operating at the same voltage, however, overcurrent protection is not required for conductors from a battery rated less than 50 volts if the battery provides power for starting, ignition, or control of prime movers. The conductors are not required to be installed in a Chapter 3 wiring method (covered in Div. 9) and the normal grouping and system separation rules do not apply either. A disconnecting means is required for all ungrounded conductors fed from a stationary battery system operating over 30 volts. The disconnect must be readily accessible and within sight and not over 50 ft from the battery system.

224. Insulation of batteries of not over 250 V. The provisions of this section shall apply to storage batteries having the cells so connected as to operate at a nominal battery voltage not exceeding 250 V.

- 1. Vented lead-acid batteries.** Cells and multicompartiment batteries with covers sealed to containers of nonconductive, heat-resistant material shall not require additional insulating support.
- 2. Vented alkaline-type batteries.** Cells with covers sealed to jars of nonconductive, heat-resistant material shall require no additional insulation support. Cells in jars of conductive

FIGURE 4.206 Alkali-type battery with cells mounted in an insulating tray. [Electric Storage Battery Co.]

material shall be installed in trays of nonconductive material with not more than 20 cells (24 V) in the series circuit in any one tray (Fig. 4.206).

3. *Rubber jars.* Cells in rubber or composition containers shall require no additional insulating support if the total nominal voltage of all cells in series does not exceed 150. If the total voltage exceeds 150, batteries shall be sectionalized into groups of 150 V or less, and each group shall have the individual cells installed in trays or on racks.
4. *Sealed cells or batteries.* Sealed cells and multicompart ment sealed batteries constructed of nonconductive, heat-resistant material shall not require additional insulating support. Batteries constructed of a conducting container shall have insulating support if a voltage is present between the container and ground.

225. Insulation of batteries of over 250 V. The provisions of Sec. 224 shall apply to storage batteries having the cells so connected as to operate at a nominal voltage exceeding 250 V, and in addition the provisions of this section shall also apply to such batteries.

Cells shall be installed in groups having a total nominal voltage of not over 250 V on any rack. Insulation, which can be air, shall be provided between racks and shall have a minimum separation between live battery parts of opposite polarity of 50 mm (2 in) for battery voltages not exceeding 600 V.

226. Racks and trays. Racks and trays shall conform to the following:

1. **RACKS** Racks, as required in this section, refer to frames designed to support cells or trays (see Fig. 4.207). They shall be substantial and be made of any of the following:
 - a. Metal so treated as to be resistant to deteriorating action by the electrolyte and provided with nonconducting members directly supporting the cells or with continuous insulating material other than paint or conducting members
 - b. Other construction such as fiberglass or other suitable nonmetallic materials

FIGURE 4.207 Installation of lead-acid batteries in sealed glass jars mounted on a three-tier rack. [Electric Storage Battery Co.]

2. **TRAYS** Trays are frames, such as crates or shallow boxes usually of wood or other non-conductive material, so constructed or treated as to be resistant to deteriorating action by the electrolyte (see Fig. 4.208).

227. Battery locations. Battery locations shall conform to the following:

1. **VENTILATION** Provisions shall be made for sufficient diffusion and ventilation of the gases from the battery to prevent the accumulation of an explosive mixture.
2. **LIVE PARTS** Guarding of live parts shall comply with Sec. 110.27 of the NEC. Working clearance is to be measured from the edge of the battery rack.

FIGURE 4.208 Lead-acid battery of cells in sealed glass jars mounted in a supporting tray. [Electric Storage Battery Co.]

228. Vents shall conform to the following:

1. **VENTED CELLS** Each vented cell shall be equipped with a flame arrester designed to prevent destruction of the cell due to ignition of gases within the cell by an external spark or flame under normal operating conditions.
2. **SEALED CELLS** Sealed batteries or cells shall be equipped with a pressure-release vent to prevent excessive accumulation of gas pressure, or they shall be designed to prevent scatter of cell parts in the event of a cell explosion.

229. Danger from gas with storage batteries. The hydrogen and oxygen given off the battery during charge, when unmixed with a large amount of air, form a combination that will explode violently if ignited by an open flame or an electric spark. If the battery is in a compartment, open or ventilate the compartment while the battery is being charged so that these gases may become mixed with air. Do not bring exposed flame, match, cigar, etc., near the battery when charging or shortly afterward.

GENERAL CONSTRUCTION MATERIALS

230. Wire nails are formed from wire of the same diameter as the shank of the nail is to be. The wire from which nails are made, hence the nail diameter, is measured by the steel-wire gage (see Table 85, Div. 2), which is the same as the Washburn & Moen gage and is used by practically all nail manufacturers, though it is sometimes given a different name.

The size of nails is designated by the *penny system*, which originated in England. Two explanations are offered as to how this curious designation came about. One is that the six-penny, fourpenny, tenpenny, etc., nails derived their names from the fact that 100 cost six-pence, fourpence, etc. The other explanation, which is more probable, is that 1000 tenpenny nails, for instance, weighed 10 lb (4.5 kg). The ancient as well as the modern abbreviation for penny is *d*, which is the first letter of the Roman coin denarius; the same abbreviation in early history was used for the English pound in weight. At any rate, the penny has persisted as a term in the nail industry.

Ordinary nails are made of steel wire with a natural bright-steel finish. The following special coatings, finishes, and heat treatments can be obtained at some additional cost:

Galvanized (hot-process)	Brass-plated	Blued
Galvanized (electro)	Cadmium-plated	Annealed
Cement-coated (regular)	Nickel-plated	Oil-quench-hardened
Cement-coated (clear)	Chromium-plated	Japanned
Coppered	Painted	Parkerized
Tinned	Acid-etched	

Nails made of copper, aluminum, brass, or stainless-steel wire are also available.

Nails are made in several different forms to meet the requirements of different applications. The more common types are illustrated in Fig. 4.209 with dimensional data are given in the following sections, including actual sized drawings of 2d up through 60d nails in Figs. 4.210 and 4.211.

FIGURE 4.209 Casing, finishing, shingle, and fine nails.

40d	5	8	35						
2d ^a	1	17	1,560
3d ^a	1 ¹ / ₂	16	1,015

^a These sizes are called Extra Fine.

^b This nail is only 1¹/₂-in. long.

233. Dimensions of wood screws.

Roundheaded wood screws do not measure full-length but are from 1/16- to 3/16-in short. For example, a No. 4 by 1/2-in round-headed wood screw measures about 7/16-in long under the head, and a No. 20 by 2-in screw measures about 1⁷/₈ in under the head.

234. Wood screws.

Diameters are measured by the American Screw Co.'s gage and range in size from No. 0 to No. 30. They range in length from 1/4 to 6 in. The increase in length is by eighths of an inch up to 1 in, then by quarters of an inch up to 3 in, and by half inches up to 5 in. Manufacturers' standards vary, but generally the threaded portion is approximately seven-tenths of the total length. There is no standard number of threads per inch for the products of all manufacturers. The gage and diameter refer to the unthreaded portion of the screw. The screws are available in three types of head (Fig. 4.212): flat, round, and oval. The oval head (see illustration of machine screws, Fig. 4.213) is used for especially high-grade work such as cabinetwork, which must present a very neat appearance.

FIGURE 4.212 Wood screws.

The ordinary materials used for making wood screws are steel and brass. The flat-headed screws are regularly available in steel, with a natural bright finish or galvanized, and

Depth of hole - height of head A

in brass. The roundheaded screws are made of steel, with a blued or nickel-plated finish, and of brass. The oval-headed screws are regularly made of brass with a nickel-plated finish.

235. Machine screws. Diameters are designated by the American Screw Co.'s gauge and range in size from No. 2 to No. 34. They range in length from 1/8 to 4 in. The increase in length is by sixteenths of an inch up to 1 in, by eighths of an inch up to 2 in, and by quarters

of an inch up to 4 in. The threaded portion extends over either all or nearly all the total length. Machine screws are designated by their gage number and number of threads per inch. A No. 10-24 screw has a diameter corresponding to size No. 10 of the American screw gage and has 24 threads per inch. The gage number refers to the diameter over the thread. The screws are available with heads of four different types: flat, round, oval, and fillister (Fig. 4.213). The length of flatheaded screws is measured overall, the length of round-headed ones includes about one-half of the head, the length of oval-headed screws includes the countersinks, and the length of fillister-headed ones is measured from the rim of the head.

Standard machine screws are made of iron, aluminum, plastic, nylon, or brass. The iron screws may be provided with any one of the following finishes: natural bright, blued, nickel, brass- or silver-plated, silver- or copper-oxidized, various bronzes, japanned, lacquered, coppered, tinned, galvanized, Bower-Barff, gunmetal.

236. Data for Machine Screws

Screw gage No.	Diam, in.	Standard threads per in.	Screw gage No.	Diam, in.	Standard threads per in.

10	0.18944				

237. Machine bolts and nuts. Machine bolts are designated by the diameter of the shank of the bolt. They range in length from 1½ to 30 in. The increase in length is by half inches up to 8 in. and by inches up to 30 in. Bolts are regularly furnished with one nut. The standard number of threads per inch for the bolts and nuts is as follows:

Diameter in inches	¼	5/16	3/8	7/16	½	9/16	5/8	11/16	¾	7/8	1
Number of threads/in., NC	20	18	16	14	13	12	11	10	10	14	14
Number of threads/in., NF	28	24	24	20	20	18	18	16	16	14	14

Bolts are made with either square or hexagonal heads and may be furnished with nuts of the corresponding shape. They are made of iron and may be finished with a natural black or galvanized coating.

238. Dimensions and Strengths of Machine Bolts and Nuts

D	T	W	S	H	Q	U	R	V	Safe tensile strength of bolt at root of thread at 6,000 lb per sq in.	Safe shearing strength at 7,500 lb per sq in.	
										Full bolt	Root of thread

FIGURE 4.214 Machine bolts and nuts.

239. Data on carriage bolts are given in Div. 8.

240. Toggle bolts, which are used for fastening raceways and electrical devices to hollow tile or plaster-on-metal-lath surfaces, are of two general types. The screw type (Fig. 4.215) is the most frequently used but has the disadvantage that if it is ever necessary to remove the screw entirely, the toggle is lost within the wall. If the object fastened must

be removed and replaced, a nut-type toggle bolt (Figs. 4.216 and 4.217) can be used. When the type of Fig. 4.216 is used, it is usually necessary, after the device is in place, to cut off the part of the bolt that extends so as to give a neat appearance. The so-called plumbers' toggle bolt (Fig. 4.217) has a removable hexagonal cap so that the device can be inserted in the wall before the object to be fastened is slipped over the bolt. Then, on putting the cap in place, the whole bolt is backed into the wall, hiding the surplus thread from view. Cone-headed toggles (Fig. 4.218) are used principally for the erection of metal raceway and have the advantage that the toggle head will readily pass through the hole in the raceway backing. A spring-in type of toggle bolt is shown in Fig. 4.219. The wings are tempered spring steel having a cam action against the saddle which throws them to the open position. Toggle bolts are made in several diameters and lengths.

241. Lag screws are discussed in Div. 8.

242. Expansion sleeves, shields, and bolts are used for attaching equipment and devices to stonelike materials such as concrete, brick, tile, etc. They are made in a variety of types and consist of a lead sleeve or malleable-iron expansion shield which is inserted in a hole cut in the masonry. The equipment to be supported is attached to the sleeve or shield. As the screw is turned into the sleeve or shield, it expands the body of the sleeve or shield against the sides of the hole in the masonry so that it grips the masonry with considerable holding power. These devices are called by various trade names such as expansive anchors, expansion sleeves, expansion screws, or expansion bolts and anchors. Data and illustrations of some common types are given in the following sections.

FIGURE 4.220

243. Diamond multisize screw anchors

(Fig 4.220). These are designed to accommodate in one anchor several diameters of wood screws. The purpose is to reduce the number of anchors required to accommodate all sizes of screws. They are made in several lengths covering the majority of uses and are put up in boxes of 100.

For wood screws, No.	Length, in.	Size of drill, in.	Weight, lb per 100
6-8	$\frac{3}{4}$	$\frac{1}{4}$	1
6-8	$1\frac{1}{2}$	$\frac{1}{4}$	$1\frac{3}{4}$
10-14	$\frac{3}{4}$	$\frac{5}{16}$	$1\frac{1}{2}$
10-14	1	$\frac{5}{16}$	2
10-14	$1\frac{1}{2}$	$\frac{5}{16}$	$2\frac{3}{4}$
16-18	1	$\frac{3}{8}$	3
16-18	$1\frac{1}{2}$	$\frac{3}{8}$	$4\frac{1}{4}$
20-24	$1\frac{3}{4}$	$\frac{7}{16}$	$5\frac{1}{4}$

FIGURE 4.221

244. Diamond caulking anchors for use with machine screws (Fig. 4.221).

Caulking anchors are put up in standard packages of 100 for sizes No. 10-24 and smaller and in packages of 50 for sizes No. 12-24 and larger. One caulking tool is in each box. All suggested safe loads are based on ideal conditions.

Diam of bolt or screw	Hole size, in.		Suggested safe load, lb	Weight, lb per 100
	Diam	Depth		
6-32	$\frac{1}{4}$	$\frac{3}{8}$	80	1
8-32	$\frac{3}{16}$	$\frac{1}{2}$	90	$1\frac{1}{2}$
10-24	$\frac{3}{8}$	$\frac{5}{8}$	175	2
12-24	$\frac{7}{16}$	$\frac{3}{4}$	320	$3\frac{1}{2}$
$\frac{1}{4}$ -20	$\frac{1}{2}$	$\frac{7}{8}$	400	$4\frac{1}{2}$
$\frac{3}{16}$	$\frac{5}{8}$	1	480	11
$\frac{3}{8}$	$\frac{3}{4}$	$1\frac{1}{4}$	720	16
$\frac{7}{16}$	$\frac{7}{8}$	$1\frac{1}{2}$	950	24
$\frac{1}{2}$	$\frac{7}{8}$	$1\frac{1}{2}$	1,000	24
$\frac{5}{8}$	1	2	1,250	41

245. Ackerman-Johnson expansive screw anchors. The Ackerman-Johnson expansive screw anchor consists of a hard, biconoidal, internally threaded nut within a lead-composition expansive sleeve (Fig. 4.222). It is used for attaching fixtures or wiring to any stonelike material such as concrete, brick, tile, etc.

FIGURE 4.222

Method of Installing Anchor. When installed, the sleeve is driven farther toward the base of the tapered nut, being thereby expanded and swaged tightly against the sides of the hole, giving perfect holding contact throughout the length and circumference of the anchor.

To determine the anchor size best suited for the work, first select the screw or bolt to be preferred and then anchors of corresponding size number; for example, for work demanding No. 10-24 screws, specify No. 10-24 anchor; if 3/4-in bolts are required, use No. 3/4-in anchor.

A setting punch is included with every package of 50 or 1100 anchors.

Anchor size No.	Minimum dimensions of holes required, in.		Shipping weight, lb per 1000
	Diam	Depth	
6-32	1/4	3/8	7 1/2
8-32	5/16	1/2	15
10-24	3/8	5/8	22 1/2
12-24	7/16	3/4	34
1/4-20	1/2	7/8	50 1/2
5/16-18	5/8	1	95
3/8-16	3/4	1 1/4	162
7/16-14	7/8	1 1/2	221
1/2-13	7/8	1 1/2	231
5/8-11	1 1/8	2	512

Hammerless Setting Tool. Anchors are set perfectly, in tile or other thin materials in which the hole extends through or has a weak bottom, by means of the hammerless setting tool (see Fig. 4.223).

The stud is screwed into the anchor, which is then inserted in position; turning the wheel moves the threaded stud rearward, thus drawing the anchor nut into its ductile sleeve, expanding the latter to any degree required for safe anchorage. The tool is furnished in sizes to use with the following sizes of anchor: 8-32, 10-24, 12-24, and 1/4-20.

FIGURE 4.223 Hammerless setting tool.

FIGURE 4.224

246. Diamond lag-screw shield. The lag-screw shield (Fig. 4.224) is made of malleable iron in two wedge-shaped halves. The outer wedge slides forward when the screw is turned, creating a powerful expansion. The shield is galvanized by the Diamond hot-dip process.

248. Rawlplugs (Fig. 4.227) are made from stiffened strands of jute fiber. The fiber strands are compressed together by a patented process. Once in place, a Rawlplug can never crumble or pulp. It is unaffected by moisture or change in temperature.

The screw entering the Rawlplug automatically threads it, which permits removal and replacement of the screw as often as desired without stripping the threads so formed. The screw cannot be withdrawn by direct or indirect pulling.

Rawlplugs require only a small hole. This makes installation easy and assures a neat job. The Rawlplug is invisible when in position, as the diameter of the hole and Rawlplug is smaller than the head of the screw, giving the screw the appearance of being screwed into the masonry itself.

Owing to their composition, Rawlplugs resist and absorb shocks. They cannot work loose, slip, shear, or lose their viselike grip. When properly inserted, the Rawlplug should develop the entire strength of the screw or of the surrounding material, such as concrete, brick, stone, slate, marble, plaster, glass, hard rubber, gypsum block, wallboard, terracotta, composition walls and floors, wood, and metal.

Rawlplugs are made in the sizes listed below in lengths of $\frac{5}{8}$, $\frac{3}{4}$, 1, $1\frac{1}{4}$, $1\frac{1}{2}$, 2, $2\frac{1}{2}$, 3, and $3\frac{1}{2}$ in.

^c For $\frac{1}{4}$ -in. lag screw use No. 14 or No. 16 Rawlplug. For $\frac{5}{16}$ -in. lag screw use No. 20.

249. Rawl-Drives (Fig. 4.228) consist of a high-grade heat-treated steel pin with a flat head and split expanded central portion which, when driven in, grips the side of the hole with a spring action. They are easily and quickly installed, since they drive like a nail into a drilled hole no larger than the diameter of the pin itself. Rawl-Drives are for use only in

FIGURE 4.228 Principle of Rawl-drive.

solid masonry of brick, concrete, or stone. They should not be used in soft or brittle materials, such as plaster, wood, composition wood, glass, tile, etc. The manufacturer specifies that they have the following holding powers:

Holding Power of Rawl-Drives

Size Rawl-drive, in.	Average direct pull, lb	
	1-2-4 concrete	Common brick
$\frac{3}{16} \times 1\frac{1}{4}$	1,285	634
$\frac{1}{4} \times 1\frac{1}{2}$	2,050	1,183

252. Powder-actuated tools. A highly efficient method of attaching fasteners or materials to concrete or steel is the powder-actuated tool and fastening system. This integrated system (Fig. 4.229) permits fastening without drilling in one time-saving operation. It consists of a tool, a powder charge, and a fastener; and it fastens wood and steel to concrete of any compressive strength and to structural steel up to 1 in (25.4 mm) thick. A line of more than 100 drive pins, eye pins, and threaded studs meets the requirements for most jobs.

There are several major manufacturers of powder-actuated tool systems, and it is suggested that users be fully familiar with these tools and fastening materials. These manufacturers provide guidebooks on how to use the systems efficiently and safely. In some states and local areas mechanics who use power-actuated tools (Fig. 4.230) must be certified or licensed to indicate that they completely understand the use or proper applications of these systems.

CONSTRUCTION, TYPES, AND CHARACTERISTICS

1. A transformer is an apparatus for converting electrical power in an ac system at one voltage or current into electrical power at some other voltage or current without the use of rotating parts.

2. A constant-voltage transformer (Fig. 5.1) consists essentially of three parts: the primary coil which carries the alternating current from the supply lines, the core of magnetic material in which is produced an alternating magnetic flux, and the secondary coil in which is generated an emf by the change of magnetism in the core which it surrounds. Sometimes the transformer may have only one winding, which will serve the dual purpose of primary and secondary coils.

The high-tension winding is composed of many turns of relatively fine copper wire, well insulated to withstand the voltage impressed on it. The low-tension winding is composed of relatively few turns of heavy copper wire capable of carrying considerable current at a low voltage.

3. Transformer terminology. The *primary winding* is the winding of the transformer which is connected to the source of power. It may be either the high- or the low-voltage winding, depending upon the application of the transformer.

FIGURE 5.1 The elementary transformer.

The *secondary winding* is the winding of the transformer which delivers power to the load. It may be either the high- or the low-voltage winding, depending upon the application of the transformer.

The *core* is the magnetic circuit upon which the windings are wound.

The *high-tension winding* is the one which is rated for the higher voltage.

The *low-tension winding* is the one which is rated for the lower voltage.

A *step-up transformer* is a constant-voltage transformer so connected that the delivered voltage is greater than the supplied voltage.

A *step-down transformer* is one so connected that the delivered voltage is less than that supplied; the actual transformer may be the same in one case as in the other, the terms *step-up* and *step-down* relating merely to the application of the apparatus.

4. Transformer cores. Until recently, all transformer cores were made up of stacks of sheet-steel punchings firmly clamped together. One method of assembly and clamping of the sheets is shown in Fig. 5.2. Sometimes the laminations are coated with a thin varnish to reduce eddy-current losses. When the laminations are not coated with varnish, a sheet of insulating paper is inserted between laminations at regular intervals.

A new type of core construction consists of a continuous strip of silicon steel which is wound in a tight spiral around the insulated coils and firmly held by spot welding at the end. This type of construction reduces the cost of manufacture and reduces the power loss in the core due to eddy currents.

FIGURE 5.2 Assembly of transformer-core laminations.

5. Classification of transformers

1. According to method of cooling
 - a. Self-air-cooled (dry type)
 - b. Air-blast-cooled (dry type)
 - c. Liquid-immersed, self-cooled
 - d. Oil-immersed, combination self-cooled and air-blast
 - e. Oil-immersed, water-cooled
 - f. Oil-immersed, forced-oil-cooled
 - g. Oil-immersed, combination self-cooled and water-cooled
2. According to insulation between windings
 - a. Windings insulated from each other
 - b. Autotransformers
3. According to number of phases
 - a. Single-phase
 - b. Polyphase
4. According to method of mounting
 - a. Pole and platform
 - b. Subway
 - c. Vault
 - d. Special
5. According to purpose
 - a. Constant-voltage
 - b. Variable-voltage
 - c. Current
 - d. Constant-current
6. According to service
 - a. Large power
 - b. Distribution
 - c. Small power
 - d. Sign lighting
 - e. Control and signaling

- f. Gaseous-discharge lamp transformers
- g. Bell ringing
- h. Instrument
- i. Constant-current
- j. Series transformers for street lighting

6. Cooling of transformers. A certain amount of the electrical energy delivered to a transformer is transformed into heat energy because of the resistance of its windings and the hysteresis and eddy currents in the iron core. Means must be provided for removing this heat energy from the transformer and dissipating it into the surrounding air. If this were not done in a satisfactory manner, the transformer would operate at an excessively high temperature, which would destroy or harm the insulation of the transformer. The different methods of cooling employed are listed in Sec. 5 and described below.

In *self-air-cooled* transformers (Fig. 5.5), the windings are simply surrounded by air at atmospheric pressure. The heat is removed by natural convection of the surrounding air and by radiation from the different parts of the transformer structure. Air cooling has long been employed for transformers of very small capacity. The development of satisfactory coil insulation materials, such as porcelain, mica, glass, and asbestos, which will withstand higher temperatures than the more common insulating materials has made possible the application of air cooling to transformers of large capacity. Except in the smaller sizes, the sheet-metal enclosure is provided with louvers or gratings to allow free circulation of the air over and through the windings. Self-air-cooled transformers are commonly called *dry-type transformers*. The present-day use of self-air-cooled transformers has been extended to units of at least 3000-kVA capacity at 15,000 V.

In *air-blast-cooled transformers* (Figs. 5.6 and 5.7), the core and windings are enclosed in a metal enclosure through which air is circulated by means of a blower. This method has been used for large power transformers in ratings up to 15,000 kVA with voltages not exceeding 35,000.

In *liquid-immersed, self-cooled transformers*, the core and windings are immersed in some insulating liquid and enclosed in a metal tank. The liquid, in addition to providing

FIGURE 5.7 Exterior view of 1330-kVA air-blast transformer, showing the sheet-steel casing.

some of the required insulation between the windings, carries the heat from the core and windings to the surface of the tank. The heat is then removed into the surrounding atmosphere by natural convection of the surrounding air and by radiation from the tank. In the smaller sizes the tanks have a smooth surface (Fig. 5.8). In larger size, tanks are corrugated or finned or have external tubes (see Figs. 5.9 and 5.10), and in very large units the tanks must be supplied with external radiators (Fig. 5.11) through which the oil circulates by natural convection, owing to differences in temperature in the liquid. This method can be employed for units of any size or voltage rating, although large-capacity units become rather expensive and bulky. The common liquid employed is an insulating oil. Nonflammable and nonexplosive liquids have been developed for use as a cooling and insulating medium for electrical equipment. These liquids are used in transformers where their nonflammable and nonexplosive qualities warrant their additional expense. The use of such a liquid is particularly advantageous for transformers installed in buildings, since the transformer can then be installed in general areas without the use of a fireproof vault enclosure. Transformers insulated with such a liquid are designated as askarel-insulated transformers. Askarel has been banned by the U.S. Environmental Protection Agency and is being replaced in many instances by a listed less flammable nonpropagating liquid. See Sec. 450.23 of the National Electrical Code.

FIGURE 5.11 Liquid filled transformer utilizing silicone liquid listed by UL as a dielectric medium and less flammable per 450.23 of the NEC. [Dow Corning]

Large oil-immersed transformers are frequently cooled by means of a combination of *self-cooling* and *air-blast* (Fig. 5.12). The construction of the transformer is in general the same as for those which are oil-immersed and self-cooled, with the addition of a motor-driven blower or blowers mounted integrally with the transformer tank. The blowers provide a forced circulation of air up through the radiators to supplement the natural convection air currents. The blower motors are generally automatically controlled by means of a thermostat. When the oil temperature reaches a certain value, the thermostat closes the motor circuit. After the temperature has been reduced to a definite value, the thermostat opens the motor circuit, shutting off the fans.

Gas-vapor transformers (Fig. 5.13) are sometimes employed for large units. The transformer is insulated with a quantity of gas necessary for start-up, along with a vaporizable liquid which provides insulation and cooling during operation. During operation, a pump delivers a stream of this liquid from the sump to the upper part of the core and coils. Here, under low pressure, the liquid is evenly distributed over the core structure and all current-carrying parts. Enough of the liquid evaporates to absorb heat from the core and coils. The hot vapors, being heavy, flow downward and enter the cooler-tube headers near the bottom of the tank. Normally, the bottom of the cooling tubes will be hotter than the top. In the cooling tubes, the vapors condense back into liquid, thus releasing their heat to the cooler-tube surfaces. The liquid returns to the pump by gravity for recirculation.

7. The oil used in transformers (*Standard Handbook for Electrical Engineers*) performs two important functions. It serves to insulate the various coils from each other and from the core, and it conducts the heat from the coils and core to some cooler surfaces, where it is either dissipated in the surrounding air or transferred to some cooling medium. It is evident that the oil should be free from any conducting material, it should be sufficiently thin to circulate rapidly when subjected to differences of temperatures at different places, and it should not be ignitable until its temperature has been raised to a very high value. Although numerous kinds of oils have been tried in transformers, at the present time mineral oil is used almost exclusively. This oil is obtained by fractional distillation of petroleum unmixed with any other substances and without subsequent chemical treatment. A good grade of transformer oil should show very little evaporation at 100°C, and it should not give off gases at such a rate as to produce an explosive mixture with the surrounding air at a temperature below 180°C. It should not contain moisture, acid, alkali, or sulfur compounds.

It has been shown by C. E. Skinner that the deteriorating effect of moisture on the insulating qualities of an oil is very marked; moisture to the extent of 0.06 percent reduces the dielectric strength of the oil to about 50 percent of the value when it is free from moisture, but there is very little further decrease in the dielectric strength with an increase in the amount of moisture in the oil.

Dry oil will stand an emf of 25,000 V between two 0.5-in (12.7-mm) knobs separated by 0.15 in (3.8 mm). The presence of moisture can be detected by thrusting a red-hot nail in the oil; if the oil "crackles," water is present. Moisture can be removed by raising the temperature slightly above the boiling point of water, but the time consumed (several days) is excessive. The oil is subsequently passed through a dry-sand filter to remove any traces of lime or other foreign materials.

8. The insulating value of the oil, in oil-immersed transformers (*Standard Handbook for Electrical Engineers*), is depended on very largely to help insulate the transformer; this is done by providing liberal oil ducts between coils and between groups of

I. Liquid-filled transformer with standard and optional accessories.

II. Fan cooling is temperature-activated by a liquid temperature gage.

FIGURE 5.12 Liquid-filled transformer that is self-cooled, forced-air. [Siemens Energy & Automation, Inc.]

FIGURE 5.13 Gas-vapor substation-type transformer. [Westinghouse Electric Corp.]

coils, in addition to the solid insulation. The oil ducts thus serve the double purpose of insulating and cooling the windings.

Since the oil is a very important part of the insulation, every effort is made in modern transformers to preserve both its insulating and cooling qualities. Oxidation and moisture are the chief causes of deterioration. Oil takes into solution about 15 percent by volume of whatever gas is in contact with it. In the open-type transformer, oil rapidly darkens, owing to the effects of oxygen in solution in the oil and the oxygen in contact with the top surface of the hot oil.

1. *Expansion tank (or conservator).* One of the first devices used to reduce oxidation was the expansion tank (or conservator), which consisted of a small tank mounted above and connected with the main tank by means of a constricted connection so that the small tank could act as a reservoir to take up the expansion and contraction of the oil due to temperature changes and reduce the oil surface exposed to air.
2. *Inertaire transformer.* This transformer has the space above the oil in the tank filled with a cushion of inert gas which is mostly nitrogen. The nitrogen atmosphere is initially blown in from a cylinder of compressed nitrogen and is thereafter maintained by passing the inbreathing air through materials which remove the moisture and the oxygen, permitting dry nitrogen to pass into the case. A breathing regulator, which consists of a mercury U tube with unequal legs, allows inbreathing of nitrogen when the pressure in the case is only slightly below atmospheric, but prevents outbreathing unless the pressure in the case becomes 5 psi (34,474 Pa) higher than atmospheric pressure. The elimination of oxygen from within the transformer case eliminates the oxidation of the oil and prevents fire and secondary explosion within the case.

9. Insulation between windings. The great majority of transformers are constructed with two or more windings which are electrically insulated from each other. In some cases a single winding is employed, parts of the winding functioning as both primary and

secondary. These transformers are called *autotransformers*. They are frequently used when the voltage ratio is small. Autotransformers should never be used for high voltage ratios, as the low-voltage winding is not insulated from the high-voltage one, so that in case of trouble it would be dangerous to both life and equipment. Refer to Sec. 32 for further discussion.

10. Transformer insulation. The type of insulation used in dry-type-transformer design and construction has a definite bearing on the size and operating temperature of the unit. Currently four classes of insulation, each having a separate NEMA specification and temperature limit, are being used. A look at these will facilitate selection of the proper unit to meet prescribed installation and operating conditions.

1. *Class 130 insulation-system transformers.* When properly applied and loaded in an ambient not over 40°C, these transformers will operate at not more than a 60°C temperature rise on the winding. These units can be used as control-type transformers when higher temperatures might affect other temperature-sensitive devices in the enclosure or as distribution transformers in locations (textile mills, sawmills, etc.) where combustible flyings might be present in the surrounding atmosphere.
2. *Class 150 insulation-system transformers.* These units have a higher-temperature insulating system and are physically smaller and about half the weight of Class A units of corresponding rated capacities. When properly loaded to rated kilovolt-amperes and installed in an ambient not over 40°C, Class 150 units will operate at a maximum 80°C rise on the winding. For years dry-type distribution transformers have been of the Class 150 type.
3. *Class 200 insulation-system transformers.* These units also have a high-temperature insulating system and, when properly loaded and applied in an ambient not over 40°C, will operate at no more than 130°C rise on the winding. The units are smaller in size than similarly rated Class 150 units and currently are available from a number of manufacturers in ratings of 25 kVA and lower, both single- and three-phase design. One manufacturer designs in-wall, flush-mounted dry-type transformers as Class 200 units.
4. *Class 220 insulation-system transformers.* These units are insulated with a high-temperature system of glass, silicone, and asbestos components and are probably the most compact ones available. When properly loaded and applied in an ambient not over 40°C, Class 220 transformers will operate at a maximum 150°C rise on the winding. This class of insulation is used primarily in designs in which the core and coil are completely enclosed in a ventilated housing. Generally, this stipulation covers units with ratings of 30 kVA and larger. Some experts recommend that the hottest spot on the metal enclosure be limited to a maximum rise of 40°C above a 40°C ambient.

It should be noted that Class 150 insulation is being replaced with Class 200 or 220 insulation in transformers of recent design.

Another significant factor which concerns all dry-type transformers is that they should never be overloaded. The way to avoid this is to size the primary or secondary overcurrent device as close as possible to the full-load primary or secondary current for other than motor loads. If close overcurrent protection has not been provided, loads should be checked periodically. Overloading a transformer causes excessive temperature, which, in turn, produces overheating. This results in rapid deterioration of the insulation and will cause complete failure of the transformer coils.

11. Transformers are built in both single- and polyphase units. A polyphase transformer consists of separate insulated electric windings for the different phases,

FIGURE 5.14 Three-phase core-type transformer.

FIGURE 5.15 Interior view of a three-phase transformer.

wound upon a single core structure, certain portions of which are common to the different phases.

Three-Phase Transformers (*Standard Handbook for Electrical Engineers*). Although there are numerous possible arrangements of the coils and cores in constructing a polyphase transformer, it can be stated that a polyphase transformer generally consists of several one-phase transformers with separate electric circuits but having certain magnetic circuits in common. A three-phase transformer is illustrated in Fig. 5.14, together with the component one-phase transformer. It will be observed that a three-phase transformer requires 3 times as much copper as the one-phase component transformer but less than 3 times as much iron. Thus in comparison with three individual transformers, the three-phase unit is somewhat lighter and more efficient. Each component transformer operates as though the others were not present, the flux of one transformer combining with that of an adjacent transformer to produce a resultant flux exactly equal to that of each one alone. Figure 5.15 shows the interior of a Westinghouse three-phase transformer.

12. Application of three-phase transformers (A. D. Fishel). For central stations of medium size, three-phase transformers are rarely superior to single-phase, except when the large sizes can be applied, in which case the transformers are normally installed in substations or central stations. The chief reason for this is the nonflexibility of a three-phase transformer. It is usually purchased for a particular size and type of load, and if that load should be changed, the transformer, representing a comparatively heavy investment, remains on the hands of the central station, whereas a single-phase transformer of one-third the size could usually be adapted for some other service.

This feature becomes of less importance as the central station increases its size, and three-phase transformers for purely power service are now being used by a considerable number of the large central stations in the United States. The three-phase transformer costs less to install, and the connections are simpler, points that are of importance in connection with outdoor installations. The fact that a failure of a three-phase transformer would interrupt service more than the failure of one single-phase transformer in a bank of three is of little importance because of the comparatively few failures of modern transformers. On the

other hand, especially for 2200-V service, the single-phase transformer has been carried to a high degree of perfection and is manufactured in much larger quantities, so that better performance is usual and in some cases initial cost is lower. Three-phase distribution transformers are used extensively in underground city network service on account of the smaller space required by them in the manhole, their higher efficiency, and their lower initial cost. For overhead service for pole or platform mounting, three single-phase units are more common on account of the ease of handling and mounting the smaller-sized units.

13. Methods of mounting. Transformers are constructed with different types of metal enclosing structures to meet the requirements of different conditions of installation. One type of enclosure (Figs. 5.8 and 5.19) is designed for *mounting on poles*, either directly or with hanger irons, for use in overhead distribution work. Another type of enclosure, called the *platform type* (Figs. 5.10, 5.11, and 5.12), is suitable for installations in which the transformer stands upon its own base. It can be mounted on any flat horizontal surface having sufficient mechanical strength, such as a floor or a platform between poles. *Subway transformers* have watertight tanks which are designed primarily for underground installations when the transformer may be completely submerged in water. *Vault transformers* also have watertight enclosures so that they will not be injured by total submersion, but they are not designed to operate satisfactorily under such conditions. The vault transformers are intended for operation in underground vaults in which the transformer would not be required to operate for any considerable length of time while submerged. Small transformers for power and special application as listed in Sec. 5 (6c to 6j) are designed with special types of mounting to meet the requirements of installation for these types of service.

14. Purpose of transformers. Transformers can be classified as in Sec. 5 (5) according to the purpose of transformation for which they are employed.

The function of a *constant-voltage* transformer is to change the voltage of a system. It is designed to operate with its primary connected across a constant-voltage supply and to provide a secondary voltage which is substantially constant from no load to full load. It is the ordinary, common type of transformer. The currents of both primary and secondary vary with the load supplied by the transformer. A *variable-voltage* transformer is also intended for changing the voltage of a system but is so designed that when operated with its primary connected to a constant-voltage supply, the secondary voltage will vary widely with the load. Such transformers are necessary for the operation of many gaseous-discharge lamps.

A *current* transformer is one which is designed for changing the current of a system. The primary winding of such a transformer is connected in series with the circuit of which it is desired to change the current. The voltage of both primary and secondary will change with the value of the current of the system. Such transformers are used for instrument transformers and in some series street-lighting installations. *Constant-current* transformers are designed for supplying a constant value of secondary current regardless of the load on the transformer. The primary is connected to a constant-voltage source. The secondary voltage varies proportionally with the load, while the secondary current remains constant. The primary current and kilovolt-amperes will be constant for all loads, but the kilowatt input and power factor will vary with the load.

15. The most important application of constant-voltage transformers is raising the voltage of an electric transmission circuit so that energy can be transmitted for considerable distances with small voltage drop and small energy loss and then lowering the voltage for safe usage by motors, lights, and appliances.

16. Theory of operation of the constant-voltage transformer (see Fig. 5.1). It has been shown in Div. 1 that turns of wire wound on an iron core have self-induction. When an alternating voltage is applied to such turns, there flows through them a current that generates a countervoltage or emf that opposes the applied voltage. From formulas the transformer designer can compute just how many turns are necessary for a transformer of a given size so that it will generate a countervoltage equal to the applied voltage. So, in designing the primary winding of the transformer of Fig. 5.1, the designer would select such a number of turns for the primary winding that the countervoltage generated by it would be nearly 2400 V. Hence, when the primary winding is connected to a 2400-V circuit, it generates a countervoltage of practically 2400, and no appreciable current flows. A small current, the exciting current, just enough to magnetize the core, does flow, but it is so small that it can be disregarded in this discussion.

Since the primary and secondary windings are on the same core, the magnetic flux generated by the magnetizing or exciting current flowing in the primary winding also cuts the turns of the secondary winding and generates an emf in them. This emf will be, in accordance with a well-known law, opposite in direction to that impressed on the primary. If the secondary circuit is open, no current can flow in it, but if it is closed, a certain current, proportional to the impedance of the secondary circuit, will flow. This current, because of the direction of the emf generated in the secondary, will be in such a direction that the magnetic flux produced in the core by it will oppose the flux due to the primary winding. It will therefore decrease the effective or resultant flux in the core by a small amount which will decrease the counter-emf of the primary winding and permit more current to flow into the primary winding. As noted elsewhere, the ratio of the number of turns in the primary winding to the number of turns in the secondary winding determines the ratio of the primary to the secondary voltage.

If the voltage impressed on the transformer is maintained constant, the voltage of the secondary will be nearly constant also. When more current flows in the secondary, there will be a corresponding increase in primary current. As the load on a transformer increases, the impressed voltage remaining constant, there is actually a slight drop from the no-load voltage of the secondary, due to certain inherent characteristics of the transformer, but in a properly designed device this drop will be very small. Although the construction and elementary theory of the transformer are very simple, a theoretical explanation of all the phenomena involved in its operation is very complicated. Only the principal features have been described. Some minor, though very important, considerations that would complicate the explanation have not been treated.

17. Transformer ratios. The voltage ratio of a constant-voltage transformer, i.e., the ratio of primary to secondary voltage, depends primarily upon the ratio of the primary to the secondary turns. The voltage ratio will vary slightly with the amount and power factor of the load. For general work the voltage ratio can be taken as equal to the turn ratio of the windings.

The current ratio of a constant-voltage transformer will be approximately equal to the inverse ratio of the turns in the two windings. For example, for transforming or "stepping down" from 2400 to 120 V the ratio of the turns in the windings will be 20:1. The currents in the primary and the secondary windings will be, very closely, inversely proportional to the ratio of the primary and secondary voltages because, if the small losses of transformation are disregarded, the power put into a transformer will equal the power delivered by it. For example, for a transformer with windings having a ratio of 20:1, if its secondary winding delivers 100 A at 50 V, the input to its primary winding must receive almost exactly 5 A at 1000 V. The input and output are each practically equal, and each would equal almost exactly 5000 W.

18. The regulation of a transformer is the change in secondary voltage from no load to full load. It is generally expressed as a percentage of the full-load secondary voltage:

$$\text{Percent regulation} = \frac{\text{no-load secondary voltage} - \text{full-load secondary voltage}}{\text{full-load secondary voltage}} \times 100 \quad (1)$$

The regulation depends upon the design of the transformer and the power factor of the load. Although with a noninductive load such as incandescent lamps, the regulation of transformers is within about 3 percent, with an inductive load the drop in voltage between no load and full load increases to possibly about 5 percent. If the motor load is large and fluctuating and close lamp regulation is important, it is desirable to use separate transformers for the motors.

19. The efficiency of a transformer is, as with any other device, the ratio of the output to input or, in other words, the ratio of the output to the output plus the losses. As a formula it can be expressed thus:

$$\text{Efficiency} = \frac{\text{output}}{\text{input}} = \frac{\text{output}}{\text{output} + \text{copper loss} + \text{iron loss}} \quad (2)$$

Average efficiencies of transformers are given in Secs. 43 to 57.

20. The copper loss of a transformer is determined by the resistances of the high-tension and low-tension windings and of the leads. It is equal to the sum of the watts of I^2R losses in these components at the load for which it is desired to compute the efficiency.

21. The iron loss of a transformer is equal to the sum of the losses in the iron core. These losses consist of eddy- or Foucault-current losses and hysteresis losses. Eddy-current losses are due to currents generated by the alternating flux circulating within each lamination composing the core, and they are minimized by using thin laminations and by insulating adjacent laminations with insulating varnish. Hysteresis losses are due to the power required to reverse the magnetism of the iron core at each alternation and are determined by the amount and the grade of iron used for the laminations for the core.

22. Transformer ratings. Transformers are rated at their kilovolt-ampere (kVA) outputs. If the load to be supplied by a transformer is at 100 percent power factor (pf), the kilowatt (kW) output will be the same as the kilovolt-ampere (kVA) output. If the load has a lesser power factor, the kW output will be less than the kVA output proportionally as the load power factor is less than 100 percent.

EXAMPLE A transformer having a full-load rating of 100 kVA will safely carry 100 kW if the 100 kW is at 100 percent pf, 90 kW at 90 percent pf, or 80 kW at 80 percent pf.

Transformers are generally rated on the kVA load which the transformer can safely carry continuously without exceeding a temperature rise of 60°C for Class 130 insulation or 80°C for Class 150 insulation when maintaining rated secondary voltage at rated frequency and when operating with an ambient temperature of 40°C. (Ambient temperature is the temperature of the surrounding atmosphere.) The actual temperature of any part of the transformer is the sum

of the temperature rise of that part plus the ambient temperature. See Sec. 10 for an explanation of transformer insulation classifications.

The usual service conditions under which a transformer should be able to carry its rated load are:

1. At rated secondary voltage or not in excess of 105 percent of rated value.
2. At rated frequency.
3. Temperature of the surrounding cooling air at no time exceeding 40°C and average temperature of the surrounding cooling air during any 24-h period not exceeding 30°C.
4. Altitude not in excess of 3300 ft.
5. If water-cooled, temperature of cooling water not exceeding 30°C and average temperature of cooling water during any 24-h period not exceeding 25°C.
6. The load current shall be approximately sinusoidal. The harmonic factor shall not exceed 0.05 per unit.

GUIDE FOR LOADING OIL-IMMERSED DISTRIBUTION AND POWER TRANSFORMERS

23. The following sections on guidance for loading of transformers are excerpts from the American National Standards Institute's publication C57.92-1981.

The actual output which a transformer can deliver at any time in service without undue deterioration of the insulation may be more or less than the rated output, depending upon the ambient temperature and other attendant operating conditions.

24. Continuous loading on basis of average winding test temperature rise.

For each degree Celsius in excess of 5° that the test temperature rise is below the standard temperature rise of 55°C, the transformer load may be increased above rated kilovolt-amperes by the percentages shown in col. 3 of the accompanying table. Making use of this factor gives the kilovolt-amperes that the transformer can deliver with a 55°C temperature rise. The leeway of 5° provides for a negative tolerance in the measurement of temperature rise.

Loading on Basis of Ambient Temperature

Type of cooling	Percent of rated kVA	
	Decrease load for higher temperature each °C	Increase load for lower temperature each °C
Self-cooled	1.5	1.0
Water-cooled	1.5	1.0
Forced-air-cooled	1.0	0.75
Forced-oil-cooled	1.0	0.75

Some transformers are designed to have the difference between hottest-spot and average copper temperatures greater than the nominal allowance of 10°C. This will result in a temperature rise for average copper of less than 55°C, but the hottest-spot copper temperature rise may be at the limiting value of 65°C. Such transformers should not be loaded above rating as outlined under this heading. The manufacturer should be consulted to give information as to design of hottest-spot allowances.

25. Loading on basis of ambient temperature. For each degree Celsius that the average temperature of the cooling medium is above or below 30°C for air or 25°C for water, a transformer can be loaded for any period of time below or above its kilovolt-ampere rating as specified in the table of Sec. 24. Average temperature should be for periods of time not exceeding 24 h with maximum temperatures not more than 10°C greater than average temperatures for air and 5°C for water. On the basis used in this guide for calculating loss of life, life expectancy will be approximately the same as if the transformer had been operated at rated kilovolt-amperes and standard ambient temperatures over that period.

The use of transformers in cooling air above 50°C or below 0°C or with cooling water above 35°C is not covered by the table of Sec. 24 and should be taken up with the manufacturer.

26. Basic loading for normal life expectancy

Basic Conditions

1. The basic loading of a transformer for normal life expectancy is continuous loading at rated output when operated under normal service conditions.¹ It is assumed that operation under these conditions is equivalent to operation in a continuous ambient temperature of 30°C for cooling air or 25°C for cooling water. Normal life expectancy will result from operating with a continuous hottest-spot conductor temperature of 110°C (or equivalent variable temperature with 120°C maximum) in any 24-h period.
2. The hottest-spot conductor temperature determines loss of life due to loading. This temperature cannot be directly measured on commercial designs because of voltage hazard when placing a temperature detector at the proper location. The hottest-spot allowances are based on tests of laboratory models.
3. The hottest-spot temperature at rated load is usually taken as the sum of the average winding temperature and a 15°C allowance² for hottest spot. For mineral oil-immersed transformers operating continuously under the foregoing conditions with normal life expectancy, this temperature has been assumed to be a maximum of 110°C.

27. Continuous loading on basis of average winding test temperature rise.

For each °C in excess of 5° that the average winding test temperature rise is below 65°C, the transformer load may be increased above rated load by the percentages given in the table in Sec. 24. A 5° margin is used to provide a tolerance in the measurement of temperature rise. The loadability thus obtained is that which the transformer can carry at 65°C rise. Since this may increase the loading beyond that contemplated by the designer, the limitations should be checked before taking full advantage of this increased loadability. Among these limitations are: oil expansion, pressure in sealed units, bushings, leads, tap changers, and stray flux heating as well as the thermal capability of associated equipment such as

¹ When air cooled, the temperature of the cooling air (ambient temperature) shall not exceed 40°C and the average temperature of the cooling air for any 24-h period shall not exceed 30°C. The top liquid temperature of the transformer (when operating) shall not be lower than -20°C. Starting temperatures below -20°C are not considered as usual service conditions. When water cooled, the temperature of cooling water (ambient temperature) shall not exceed 30°C and the average temperature of the cooling water for any 24-h period shall not exceed 25°C. Minimum water temperature shall not be lower than 1°C, unless the cooling water includes antifreeze suitable for -20°C operation. The altitude shall not exceed 3300 ft (1000 m). The supply voltage wave shape shall be approximately sinusoidal, and the phase voltages supplying a polyphase transformer shall be approximately equal in magnitude and time displacement. The load current shall be approximately sinusoidal. The harmonic factor shall not exceed 0.05 per unit.

² If cooler inlet and outlet temperatures are available, a better estimate of the hottest-spot temperature is possible by making an adjustment in the 15°C allowance. Consult with the manufacturer.

cables, reactors, circuit breakers, disconnecting switches, and current transformers. High ambient temperatures will also restrict a transformer's loadability. Any of these items may limit loading, and manufacturers should be consulted for advice on such limitations.

Some transformers are designed to have the difference between the hottest-spot and average conductor temperatures greater than the 15°C allowance. This will result in an average winding temperature rise of less than 65°C, but the hottest-spot winding temperature rise may be the limiting value of 80°C. Such transformers should not be loaded above their rating as outlined in this section. The manufacturer should be consulted for information on the hottest-spot allowances used for these designs. This condition may exist in transformers with large differences (greater than 30°C) between top-and-bottom-oil temperatures. Whenever possible, data on hottest-spot and oil temperatures obtained from factory temperature should be used in calculating transformer loadability or when calculating temperatures for loads above rating.

28. Unusual temperatures and altitude service conditions. Transformers may be applied at higher ambient temperatures or at higher altitudes, but performance may be affected and special consideration should be given to these applications. The effect of the decreased air density due to high altitude is to increase the temperature rise of transformers since they are dependent upon air for the dissipation of heat losses. Transformers may be operated at rated kVA at altitudes greater than 3300 ft (1000 m) without exceeding temperature limits, provided the average temperature of the cooling air does not exceed the values of Table 28A for the respective altitudes. Transformers may be operated at altitudes greater than 3300 ft (1000 m) without exceeding temperature limits, provided the load to be carried is reduced below rating by the percentages given in Table 28B for each 330 ft (100 m) that the altitude is above 3300 ft (1000 m).

TABLE 28A Maximum Allowable Average Temperature* of Cooling Air for Carrying Rated kVA

Method of cooling apparatus	1000 m	2000 m	3000 m	4000 m
	(3300 ft)	(6600 ft)	(9900 ft)	(13,200 ft)
	Degrees C			
Liquid-immersed self-cooled	30	28	25	23
Liquid-immersed forced-air-cooled	30	26	23	20
Liquid-immersed forced-oil-cooled with oil-to-air cooler	30	26	23	20

*It is recommended that the average temperature of the cooling air be calculated by averaging 24 consecutive hourly readings. When the outdoor air is the cooling medium, the average of the maximum and minimum daily temperatures may be used. The value obtained in this manner is usually slightly higher, by not more than 0.3°C, than the true daily average.

TABLE 28B Rated kVA Correction Factors for Altitudes Greater than 3300 ft (1000 m)

Types of cooling	Derating factor (%)
Liquid-immersed air-cooled	0.4
Liquid-immersed water-cooled	0.0
Liquid-immersed forced-air-cooled	0.5
Liquid-immersed forced-liquid-cooled with liquid-to-air cooler	0.5
Liquid-immersed forced-liquid-cooled with liquid-to-water cooler	0.0

29. Effect of various factors existing at one time. When two or more of the following factors affecting loading for normal life expectancy exist at one time, the effects are cumulative and the increase in loads due to each can be added to secure the maximum suggested load (each increase must be based on rated kilovolt-amperes):

1. Loading on basis of test temperature rise
2. Loading on basis of ambient temperature
3. Either loading on basis of load factor or loading on basis of short-time overloads

Do not use both

30. Capacities of Transformers for Induction Motors

(General Electric Co.)

Size of motor, hp	kVA per transformer		
	Two single-phase transformers	Three single-phase transformers	One three-phase transformer
1	0.6	0.6	
2	1.5	1.0	2.0
3	2.0	1.5	3.0
5	3.0	2.0	5.0
7½	4.0	3.0	7.5
10	5.0	4.0	10.0
15	7.5	5.0	15.0
20	10.0	7.5	20.0
30	15.0	10.0	30.0
50	25.0	15.0	50.0
75	40.0	25.0	75.0
100	50.0	30.0	100.0

31. Capacities of transformers for operating motors (General Electric Co.).

For the larger motors the capacity of the transformers in kilovolt-amperes should equal the output of the motor in horsepower. Thus a 50-hp motor requires 50 kVA in transformers. Small motors should be supplied with a somewhat larger transformer capacity, especially if, as is desirable, they are expected to run most of the time near full load or even at slight overload. Transformers of less capacity than those noted in Table 30 should not be used even when a motor is to be run at only partial load.

32. The autotransformer (*Standard Handbook for Electrical Engineers*). The most efficient and effective method of operating a stationary transformer (when the ratio of transformation is not too large) is as an autotransformer, i.e., with certain portions of the windings used simultaneously as the primary and the secondary circuits. The electrical circuits of a one-phase autotransformer (sometimes called a *compensator* or a *balance coil*) are indicated in Fig. 5.16. The autotransformer has only one coil, a certain portion of which is used for both the high-tension and the low-tension windings. The number of turns of this coil is the same as would be required if it were used exclusively for the high-tension

winding and a separate additional coil were used for the low-tension winding. Moreover, when the ratio of transformation is 2:1 or 1:2, the amount of copper in the one coil is exactly the same whether it is used as an autotransformer or as a high-tension coil of a two-coil transformer of the same rating. Not only is less copper required for an autotransformer than for a two-coil transformer, but less iron is needed to surround the copper.

FIGURE 5.16 Electric circuits of a 1-kVA single-phase autotransformer.

Referring again to Fig. 5.16, note that the one-coil transformer is designed for 10 A throughout and for a total emf of 100 V. The voltage per turn is uniform throughout, so that to obtain 50 V it is necessary merely to select any two points on the continuous winding such that one-half of the total number of turns is included between them. The load current of 20 A (required for 1000 W at 50 V) is opposed by the superposed 10 A of primary current, so that even in this section of the coil the resultant current is only 10 A.

If an ordinary two-coil transformer had been used, the circuits would have been as noted in Fig. 5.17, while the required constructive material would have been approximately as indicated in Fig. 5.18, I. With respect to its constructive material, a 1-kW 2:1-ratio autotransformer is the equivalent of a 1:1-ratio 0.5-kW two-coil transformer as shown in Fig. 5.18, II. The latter transformer requires about 14 lb (6.35 kg) of copper and 28 lb (12.7 kg) of iron as compared to about 22 lb (10 kg) of copper and 34 lb (15.4 kg) of iron for the transformer of Fig. 5.18, I. Moreover, the losses of the autotransformer are correspondingly less than those of a two-coil transformer. Refer to Sec. 116 for limitations in the allowable use of autotransformers.

FIGURE 5.17 Electric circuits of a 1-kVA single-phase two-coil transformer equivalent to the autotransformer of Fig. 5.16.

FIGURE 5.18 Comparison of constructive material required for a two-coil transformer and for an autotransformer.

33. Constant-voltage transformers for the transformation of a large amount of power, more than 500 kVA, are called *power transformers*. Transformers for general constant-voltage power transformation, whose rating is 500 kVA or less, are called *distribution transformers*. All the methods of cooling are employed for power transformers. The choice depends upon which will result in the best overall economy, including first cost, operating expense, and space occupied. Distribution transformers generally are liquid-immersed, self-cooled. Power and distribution transformers are normally of the standard type with the windings insulated from each other, although those with autotransformer construction can be obtained for special applications in which the voltage ratio is small. Power

FIGURE 5.19 Distribution transformer for pole mounting.

FIGURE 5.20 Sectional view of CSP transformer. [Westinghouse Electric Corp.]

transformers are always of the platform type. Distribution transformers are made with tanks for pole and platform mounting and with tanks of the subway and vault types. The tanks of the platform-type transformers of 50-kVA capacity and smaller are equipped with lugs or brackets (Fig. 5.19) for direct pole mounting or for the attachment of hanger irons for crossarm pole mounting. A constant-voltage transformer maintains an approximately constant voltage ratio over the range from zero to rated output.

34. Network transformers are distribution transformers specially constructed and equipped with attached auxiliaries such as junction boxes and switches for disconnecting and grounding the high-voltage cable to meet the requirements of transformers for supplying low-voltage networks. A network transformer is designed for use in a vault to feed a variable capacity system of interconnected secondaries.

35. Self-protected distribution transformers are equipped with lightning and overload protective equipment built integrally with the transformers. They are made in two types: completely self-protecting (CSP), i.e., having both overload and lightning protection, and with only surge protection (SP). The connections of the lightning protective equipment can be made in different ways to satisfy any desired grounding practice. A sectional view of such a CSP transformer is shown in Fig. 5.20.

36. Voltage taps. It is frequently desirable on transformers to obtain a voltage ratio which is slightly different from the standard ratio obtained with the complete winding. Most transformers are provided with two 5 percent taps on the high-voltage winding for this purpose. The taps are for reduced voltage and allow the rated secondary voltage to be obtained when the supply voltage is below the rated value. Many transformers are equipped with a ratio adjuster (Fig. 5.21). The ratio adjuster provides a means of changing taps on the transformer simply by turning an operating handle without having to take down and remake connections. The diagram of connections of a ratio adjuster is shown in Fig. 5.22. The transformer of the illustration is provided with two primary coils instead of one, as would be the more general practice. The transformer should be disconnected from the line before the taps are changed with the ratio adjuster, as the device is not intended for operation under load.

FIGURE 5.21 Core and coils for a 6600-V distribution transformer showing ratio adjuster. [General Electric Co.]

The standard taps for distribution transformers are given in Secs. 38 and 39. A rated kilovolt-ampere tap is a tap through which the transformer can deliver its rated kilovolt-ampere output without exceeding its rated temperature rise. A reduced kilovolt-ampere tap is a tap through which the transformer can deliver only a kilovolt-ampere output less than its rated value without exceeding its rated temperature rise.

Large power transformers frequently are equipped with load-ratio control equipment by means of which the connections to taps of the transformer can be changed under load.

Position	Connecting	% of winding
I	C to D	100
II	B to D	97.5
III	A to E	95

†See Figs. 1 and 2 for L dimension.

‡Tolerance for slot dimensions shall be ± 0.016 in (± 0.4 mm).

NOTES:

1. Support lugs are spaced $\frac{3}{4}$ in less than pole bolt spacing.
2. "A" lugs to use $\frac{5}{8}$ -in bolts.
"B" lugs to use $\frac{3}{4}$ -in bolts.
3. The dimensions shown must be maintained to obtain a standard mounting and are not intended to show construction details, except for slot dimensions.
4. Tolerance for all dimensions, except where indicated, shall be ± 0.063 in (± 1.6 mm).

FIGURE 5.23 Transformer support lugs A and B. [American National Standards Institute]

NOTES:

1. Support lugs attached to transformer and intended for bolting to adapter plates for direct pole mounting or to conventional crossarm hangers.
2. Slots or holes shall be suitable for $5/8$ -in bolts.
3. Support-lug faces are to be in one plane.
4. For L dimension see ANSI Figs. 24A and 24B.
5. The dimensions shown must be maintained to obtain a standard mounting and are not intended to show details of construction.

High-voltage rating (kV)	kVA	Support lug-type	L		Z^*	
			in	mm	in	mm

	500	C	36	914	15 ± 3	381 ± 76
13.2/22.86Y to 14.4/24.94Y, 24.94GrdY/14.4, 34.5GrdY/19.92, and 16.34	10-50	A	$11\frac{1}{4}$	286	$16\frac{1}{2} \pm 3$	419 ± 76
	75-167	B	$23\frac{1}{4}$	591	$16\frac{1}{2} \pm 3$	419 ± 76
	250-333	C	24	610	$19\frac{1}{2} \pm 3$	495 ± 76
	500	C	36	914	$19\frac{1}{2} \pm 3$	495 ± 76

*Z dimension applies only to high-voltage cover bushing transformers.

FIGURE 5.24A Segment designations and interchangeability dimensions for single-phase transformers.

High-voltage rating (kV)	kVA	Support lug-type	L		Z ^a	
			in	mm	in	mm
19.92 and below	15-30	A	23 1/4	591	14 ± 2	356 ± 51
	45-75	B	23 1/4	591	14 ± 2	356 ± 51
	112 1/2-300	C	36 [†]	914	14 ± 2	356 ± 51

^aThe Z dimension applies only to high-voltage cover bushing transformers.

[†]A spacing of 24 in (610 mm) may be used when tank height will not permit the 36-in (914-mm) dimension.

FIGURE 5.24B Segment designations and interchangeability dimensions for three-phase transformers.

NOTES:

1. Support lugs attached to transformer and intended for bolting to adapter plates for direct pole mounting or to conventional crossarm hangers.
2. Slots or holes shall be suitable for 5/8-in bolts.
3. Support-lug faces are to be in one plane.
4. For L dimension see ANSI Figs. 24A and 24B.
5. The dimensions shown must be maintained to obtain a standard mounting and are not intended to show details of construction.

FIGURE 5.25 Transformer support lug C. [American National Standards Institute]

NOTES:

1. Upper and lower adapter plates are identical, except that bolt slot is $\frac{3}{4}$ in longer and jumpproof lips are omitted on lower plate and bottom of bolt slot is chamfered.
2. Use $\frac{5}{8}$ -in bolts to bolt adapter plates to transformer support lugs. Use $\frac{3}{4}$ -in bolts to bolt adapter plates to pole.
3. For ease of inserting pole bolts in adapter-plate slots and for tolerance in boring pole-bolt holes, the distance between the tops of bolt slots is $\frac{3}{4}$ in less than bolt spacing, and lower edges of slots are chamfered on lower adapter plate.
4. Tolerances, except where indicated otherwise, shall be $\pm\frac{1}{16}$ in, except that adapter-plate bolt slot tolerances shall be $\pm\frac{1}{64}$ in.
5. Adapter plates, nuts, and bolts shall be hot-dip-galvanized.
6. Not suitable for use with transformers in excess of 2000 lb.

Hanger crossarm size	Kicker size	Number of 5/8-in bolts and nuts		Number of 3/4-in bolts and nuts	
		Hanger	Kicker	Hanger	Kicker
T1	K1	2	1
T2	2K	2	1

NOTES:

1. Tolerances, except where indicated otherwise, shall be $\pm 1/16$ in, except that bolt hole and slot tolerances shall be $\pm 1/64$ in.
2. All bolts and nuts to be square-headed NC threads.
3. 5/8-in bolts, 2 1/2 in long, and threaded within 3/16 in or less of bolt head.
4. 3/4-in bolts, 2 1/2 in long, and threaded within 3/8 in or less of bolt head.
5. All T-crossarm hangers, kickers, nuts, and bolts shall be hot-dip-galvanized.

FIGURE 5.27 T-crossarm hangers and kickers for the mounting of transformers. [American National Standards Institute]

Crossarm Hanger C1
For use with 75-100 kVA
single-phase

Crossarm Hanger C3
For use with 75-150 kVA three-phase
and 167 kVA single-phase

NOTES:

1. Crossarm hangers shall be hot-dip-galvanized.
2. C1- and C3-crossarm hangers each to be equipped with four square-head bolts and square nuts having NC threads, 2 1/2 in long, threaded to within 3/8 in or less of bolt head.
3. Tolerances, except where indicated otherwise, shall be $\pm 1/16$ in, except that bolt hole and slot tolerance shall be $\pm 1/64$ in.

57. Small power transformers (Figs. 5.5 and 5.29) are constant-voltage, self-air-cooled transformers for industrial purposes. The windings are completely enclosed in metal casings. The transformers are available in single- and three-phase construction of conventional or autotransformer types with cases designed for open or conduit wiring.

FIGURE 5.29 Small power transformers, self-air-cooled.
[General Electric Co.]

Single-phase units are available in sizes up to 50 kVA, while three-phase units are made as large as 150 kVA. Primary voltage ratings range from 125 to 2400 V. Standard secondary voltages are 115/230 or 230/460 V.

58. Small power transformers are available for taking power from motor disconnecting switches for localized lighting at the machine. Types are available for operating 115-, 64-, 32-, or 6-V lamps from 115-, 230-, 460-, or 575-V power circuits. Standard sizes are 75, 150, 225, and 300 W. Another type of small power transformer is the one designed for domestic oil-burner ignition (see Fig. 5.30).

FIGURE 5.30 Replacement-type domestic oil-burner ignition transformers. [General Electric Co.]

59. Sign-lighting transformers are single-phase, constant-voltage, self-air-cooled transformers for stepping down from 115 or 230 V to the proper voltage for low-voltage incandescent lamps in signs. They are made in sizes up to 5 kVA with the windings completely enclosed in metal casings.

60. Control and signal transformers are constant-voltage, self-air-cooled transformers for the purpose of supplying the proper voltage for control circuits of electrically operated switches or other equipment and for signal circuits. They may be of the open type with no protective casing over the windings or of the enclosed type with a metal casing over the windings. Some of the available mounting types are shown in Figs. 5.31 and 5.32.

61. Transformers for many gaseous-discharge lamps must be of the variable-voltage type. These transformers are designed so that the secondary voltage drops rapidly with load. This voltage characteristic is accomplished by means of a three-winding transformer with magnetic leakage paths between the primary and each secondary, as shown in Fig. 5.33. As the load increases, the leakage flux of the primary produces a greater voltage drop in the primary winding, thereby reducing the secondary voltage. Some of these transformers are equipped with a capacitor mounted inside the same enclosing case for power-factor improvement. The transformers are of the self-air-cooled type. Various mounting types for luminous-tube work are shown in Fig. 5.34.

I. Enclosed type with flexible terminal leads.

II. Open type with lug terminals.

III. Enclosed type with flexible terminal leads, encapsulated core and coil.

FIGURE 5.34 Luminous-tube transformers rated 3000 to 15,000 V, 30 to 120 mA, showing low- and high-voltage terminals. [General Electric Co.]

62. Bell-ringing transformers are especially designed small-capacity constant-voltage transformers for applications such as the operation of doorbells, buzzers, door openers, and annunciators. They are self-air-cooled units enclosed in metal cases. They can be obtained for primary voltages of 120 or 240 with a single secondary voltage of 10 or with three secondary voltages of 6, 12, and 18.

63. Instrument transformers are employed for the purpose of stepping down the voltage or current of a circuit for the operation of instruments, such as ammeters, voltmeters, wattmeters, etc., and relays for various protective purposes. It would be practically impossible to build delicate devices such as instruments and relays so that they would have satisfactory insulation for high voltages. Frequently such devices while energized must be accessible to operators, so that it is necessary to have the devices insulated from the high-voltage circuit. Instrument transformers are of two types: voltage and current. They are made in various types, depending upon the voltage of the circuits, requirements of installations, and accuracy required. Instrument transformers will always introduce a certain amount of error into the readings obtained on instruments supplied by them. The transformers are not rated on a thermal basis of the load which they can safely carry but upon an accuracy basis. The voltampere rating is the load which the transformer will carry without exceeding the specified accuracy limit. If accuracy can be sacrificed, the transformers can be used for loads considerably above their rated values. Instrument transformers are made in indoor, outdoor, and portable types for test purposes. Voltage transformers have a normal secondary voltage of 120 V. Current transformers have a normal secondary current of 5 A. Typical instrument transformers are shown in Figs. 5.35 and 5.36.

FIGURE 5.36 Typical voltage transformers. [General Electric Co.]

64. The current transformer (*Standard Handbook for Electrical Engineers*), considered electrically and without any reference to the change in its design to accomplish its specific duty, differs from the shunt or voltage transformer merely in the method of use. The latter transformer is ordinarily supplied with a constant impressed voltage, the load being changed by varying the impedance (load) of the total secondary circuit, while the total impedance of the secondary circuit of the former transformer is normally held constant, and the change in load is due to a simultaneous change in the primary current and emf. In the voltage transformer the actual ratio of the primary to the secondary current is of minor importance, while every effort is made to design the apparatus so that the ratio of the secondary power to the primary power is as nearly unity as possible. In the design of a series transformer no thought whatsoever is given to the ratio of the primary and secondary watts, but attention is concentrated on the endeavor to obtain a definite ratio of secondary to primary amperes.

The electric and magnetic circuits of a current transformer can conveniently be represented by the diagram shown in Fig. 5.37, in which it is used for reducing the line current to a value suitable for measurement by a low-reading ammeter, which can be thoroughly insulated from

the main circuit. If the small transformer loss is neglected, the current through the ammeter A is, since the ratio of turns $M = 2:5$, equal to two-fifths of the line current I_L .

65. Application of the current instrument transformer.

When an alternating current is so large that to connect measuring or operating instruments directly in the circuit would be impracticable or when the voltage is so high that to do so would be unsafe, the current transformer provides a means of reproducing the effect of the primary current on a scale suited to the instrument and of insulating the instrument from the main circuit. It is a special development of the transformer principle in which a constant ratio of primary to secondary current is the important consideration instead of the usual constant ratio of primary to secondary voltage.

Current transformers are used with ac ammeters, wattmeters, power-factor meters, watt-hour meters, compensators, protective and regulating relays, and the trip coils of circuit breakers. It is a standard practice in the United States to design current transformers (regardless of their capacity or ratios of transformation) to supply a rated secondary current of 5 A.

EXAMPLE A 600-A current transformer has a ratio of 120:1, i.e., when a current of 600 A flows in the primary circuit, $600 \div 120 = 5$ A will flow in the secondary circuit.

Measuring instruments for use with these transformers are so designed and are provided with scales such that they give a normal scale deflection when 5 A flows through them.

FIGURE 5.37 Elementary series transformer.

66. It is unsafe to open the secondary circuit of a current transformer when there is any current in the primary.

When the secondary circuit is closed, the current in this circuit creates a magnetomotive force (mmf) which is in opposition to the mmf of the primary current, and the core flux is thereby limited to the value necessary to generate in the secondary coil an emf sufficient to produce therein a current only slightly less than the primary current in magnetizing effect. When the secondary is open, there is no opposing mmf for limiting the core flux, which may reach a high value. Thus, even a small value of primary current produces an excessive value of core flux and a correspondingly large secondary emf. The secondary voltage under these conditions reaches a value which may both damage the insulation and prove dangerous to life. Absolutely no harm can come from short-circuiting the secondary terminals of the current transformer, and this method is used when it is necessary to insert or disconnect instruments in the secondary circuit.

67. The constant-current transformer (*Standard Handbook for Electrical Engineers*).

The operation of low-voltage lamps in parallel on a constant-voltage system necessitates a prohibitive expenditure for conducting material when the area to be lighted is extensive and the lamps are widely separated. For such service it is the common practice to operate the lamps, which are connected in series, with a constant current. The constant-current transformer is a special form of transformer which converts alternating current at a constant voltage to a constant (alternating) current with a voltage varying with the load. It consists of a primary coil upon which the constant voltage is impressed, a secondary coil (or coils) movable with respect to the primary, and a core of low magnetic reluctance. It depends for its regulation upon the magnetic leakage between the primary and secondary coils.

Consider first the primary coil; with the constant emf impressed upon this coil the total magnetism within the coil will be practically constant under all conditions. The emf generated in the secondary will depend upon the strength of the field which it surrounds. In all types of stationary transformers the secondary current is opposite in general time direction to the primary, so that there is not only a repulsive thrust between the two coils but also a considerable tendency for the magnetic lines from the primary to be forced out into space without penetrating the secondary. In the ordinary constant-voltage transformer the repelling action between the two currents is prevented from producing motion of the coils by the rigid mechanical construction, while the proximity of the primary and secondary coils limits the magnetic leakage.

In the constant-current transformer, however, the repelling action is utilized to adjust the relative positions of the primary and secondary coils; when the coils are widely separated, the paths for the leakage lines are increased and the lines which the secondary surrounds are fewer than when the coils are quite close together. The counterweights mechanically attached to the movable coil (or coils) are so arranged that when the desired current exists in the secondary coil (independent of its position along the core), the weights are just balanced. An increase in the current increases the repulsion and causes the coils to separate. With any current less than normal, the repelling force diminishes, and the primary and secondary coils approach each other, thereby restoring the current to normal. The primary can be wound for any reasonable voltage (say, as high as 10,000 V), while the secondary can be wound for the voltage required for operating the number of lamps in the circuit—from 15 to 200 or more lamps.

FIGURE 5.38 Constant-current transformer.

arranged to be equal to the variable repulsive thrust corresponding to a constant value of current in the coils at all positions of the movable coils. In fact, the transformer can be adjusted to regulate for a current of constant value at all loads or for one which either increases or decreases with increase of loads, while both the real value of the load current and its rate of change with the variation in load can be adjusted at will. To prevent any "hunting" action of the movable coils, each transformer is sometimes equipped with a dashpot (see Fig. 5.38).

68. Mechanical construction of the constant-current transformer.

The magnetic circuit of a constant-current transformer is usually of the *shell* type, the three limbs being placed vertically. In small sizes (Fig. 5.38) one of the coils is arranged in a fixed position, while the other is movable. In some of the larger sizes there are two fixed primary coils and two movable secondary coils, while in others both the primary and secondary coils are movable. In any event the gravitational action on the movable coil or the gravitational action of one movable coil against another to which it is mechanically interconnected is counterbalanced accurately with an excess or deficiency just equal to the repulsive thrust of the primary and secondary coils at the desired load current. By the use of cam mechanisms for the counterweights or of eccentrically placed extra weights, the excess force of the counterweights can be

69. Commercial constant-current transformers are built for natural air cooling or for immersion in oil. Oil has proved an excellent medium for insulation, cooling, and

lubrication. This type of transformer is extensively used for series street-lighting service with either gaseous-discharge or incandescent lamps. The efficiency of a constant-current transformer is high, being about 96 percent at full load for a 100-lamp transformer. The power factor, which depends upon the magnetic leakage, is low at all loads; it reaches from 75 to 80 percent at full load and decreases therefrom in almost direct proportion to the decrease in load.

Constant-current transformers are made in outdoor-pole-mounting, subway-mounting, and indoor-station types. A primary voltage of 2400 is standard. The secondary current may be 6.6 or 20 A. The standard ratings are 5, 10, 15, 20, 25, 30, 35, 40, 50, 60, and 70 kVA.

70. Series transformers are for use with series incandescent street lamps for operation of lamps at a different value of current from that of the main series circuit or for isolation of a lamp of the same current value as the main circuit from the main circuit, which operates at a high voltage. The principle of operation is the same as for instrument current transformers. The primary is connected in series with the main series circuit. The lamp or lamps are connected to the secondary. These transformers are made in single-lamp types for operating one 6.6-, 15-, or 20-A series lamp from a 6.6-A main circuit; in two-lamp series type for operating two 6.6-, 15-, or 20-A series lamps connected in series to the secondary; in two-lamp multiple type for operating two 6.6-, 15-, or 20-A series lamps connected to two separate secondaries; in group series type for operating a group of 6.6-A series lamps connected in series to the secondary; and in single-lamp type for operating a single 115-V lamp from a series 6.6-A main circuit. The group series type is made in ratings of 0.25, 0.5, 1.0, 2, 3, 4, 5, 7.5, and 9.0 kVA. The single-lamp type for a 115-V lamp is made in sizes to accommodate one lamp of any watt size from 40 to 1000 W. These are made in types for vault or subway mounting, for mounting in bases of ornamental lighting poles, and for pole mounting (Figs. 5.39 and 5.40).

FIGURE 5.40 Series transformers for operation of a group of lamps from series street-lighting circuits. [General Electric Co.]

FIGURE 5.41 Section through a single-phase induction-type voltage regulator.

71. The induction regulator (Fig. 5.41) is a special type of transformer, built like an induction motor with a coil-wound secondary, which is used for varying the voltage delivered to a synchronous converter or ac feeder system. In comparison with a variable-ratio transformer it possesses the advantage of being operated without opening the circuit and without short-circuiting any transformer coil. The primary of the induction regulator is subjected to the constant voltage of the supply system, the delivered voltage obtained from the secondary winding being varied by rotating the primary structure through a certain number of degrees with reference to the secondary structure. The primary structure is normally stationary, although it is movable either automatically or by hand for the purpose of varying the secondary voltage.

FIGURE 5.42 Single-phase step-by-step voltage regulator.

72. The step-by-step voltage regulator is merely a stationary transformer provided with a large number of secondary taps and equipped with a switching mechanism for joining any desired pair of these taps to the delivery circuit, according to the emf required. A diagram of this type is shown in Fig. 5.42. In comparison with the induction type of regulator the step-by-step type is less noisy in operation, requires less magnetizing current, and is more rapid in action. However, it provides only a limited number of voltage steps and may give trouble from arching at the switch contacts.

CONNECTIONS: POLARITY

73. Polarity of transformers (Line Material Co.). The polarity of a transformer is simply an indication of direction of flow of current from a terminal at any one instant. The idea is quite similar to the polarity marking on a battery.

As you face the high-voltage side of a transformer, the high-voltage terminal on your right is always marked H_1 and the other high-voltage terminal is marked H_2 . This is an established standard.

By definition, the polarity is additive if when you connect the adjacent high-voltage and low-voltage terminals (Fig. 5.43a) and excite the transformer, a voltmeter between the other two adjacent terminals reads the sum of the high-voltage and low-voltage winding voltages. For additive polarity, the low-voltage terminal on your right when facing the low-voltage side should then be marked X_1 and the other low-voltage terminal X_2 .

For subtractive polarity, the voltmeter in Fig. 5.43b reads the difference between the two winding voltages. In other words, the voltages subtract. In the case of subtractive polarity, the low-voltage terminal on your left when facing the low-voltage side is marked X_1 .

In making transformer connections, particularly bank connections, polarity of individual transformers must be checked. In making such connections it is necessary to remember that all H_1 terminals are of the same polarity and all X_1 terminals are of the same polarity. Thus, if you were connecting two single-phase transformers in parallel, you should connect the two H_1 terminals together, then the two H_2 terminals together, the two X_1 terminals together, and the two X_2 terminals together. By following this procedure, you can satisfactorily parallel transformers regardless of whether they are both of the same polarity or one is of additive and the other is of subtractive polarity.

FIGURE 5.43 Transformer polarity. [Line Material Co.]

74. Tests for polarity of single-phase transformers. If a standard transformer of known correct polarity and of the same ratio and voltage as the transformer to be tested is available, the following simple method can be used. Connect together (Fig. 5.44, I) the high-tension and low-tension leads as if for parallel operation, inserting a fuse in one of the secondary leads. If both transformers are of the same polarity, no current will flow in the low-tension windings and the fuse will not blow. If the transformers are of opposite polarities, the low-tension windings will short-circuit each other and the fuse will blow. The fuse should be sufficiently small so that there can be no possibility of injuring the transformers.

A method of testing for polarity of single-phase transformers with a voltmeter is shown in Fig. 5.44, II. Connect the transformer as shown. Make, successively, voltmeter readings V , V_1 , and V_2 . If the transformer has what is called additive polarity, $V + V_1$ will equal V_2 .

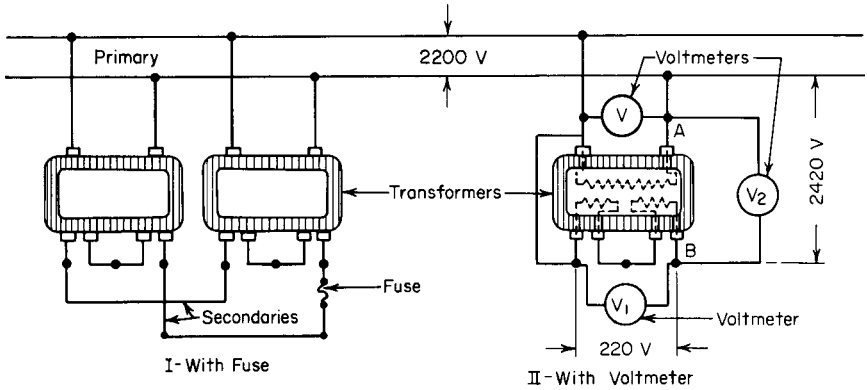

FIGURE 5.44 Testing transformers for polarity.

If the transformer has what is called subtractive polarity, V_2 will equal $V - V_1$. For example, in Fig. 5.44, II, the transformer has additive polarity, and the primary line voltage V (2200 V) plus the secondary transformer voltage V_1 (220 V) equals the voltage between A and B, or 2420 V. With subtractive polarity the voltmeter V_2 would read $(2200 - 220)$, or 1980 V.

SINGLE-PHASE CONNECTIONS

75. Connections for standard distribution transformers are shown in Figs. 5.45 and 5.46. Distribution transformers of medium and small capacity are almost invariably arranged with two secondary coils, which can be connected in series or parallel with each other so that the same transformer can be used to supply either of two different secondary

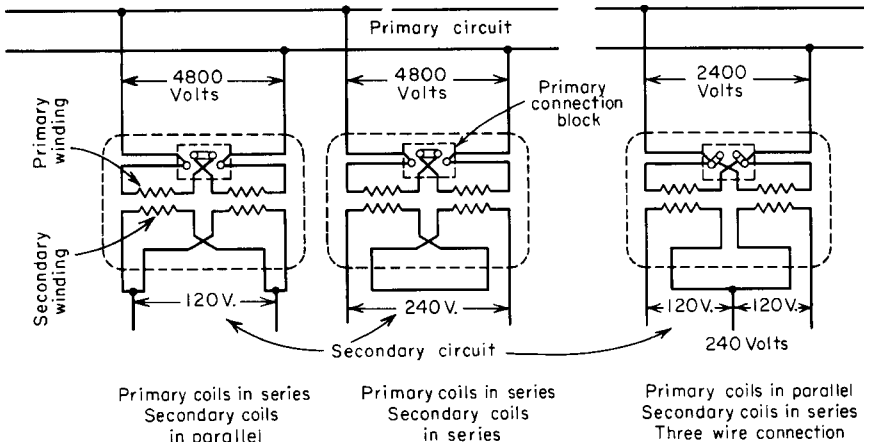

FIGURE 5.45 Connections of standard distribution transformers.

FIGURE 5.46 Method of interconnecting transformer secondaries with connectors.

voltages or a three-wire system. In transformers of the 120/240-V type their secondary windings can be so connected as to deliver 120 or 240 V or for a 120/240-V three-wire circuit. The connections of the secondary coils are made, either by splicing the secondary leads or with connectors, outside the transformer case. Some transformers are constructed with two primary coils as shown in Fig. 5.45. If the necessary primary-coil connections are made, they can be used on primary circuits of either of two voltages. Standard practice with respect to number of coils and voltage ratings is given in Secs. 38 and 39.

76. Transformer connections for three-wire secondary service are shown in Figs. 5.45, 5.46, and 5.47. In the arrangement in Figs. 5.45 and 5.46, only one transformer is used. Its secondary windings are connected in series, and a tap is made to the point of

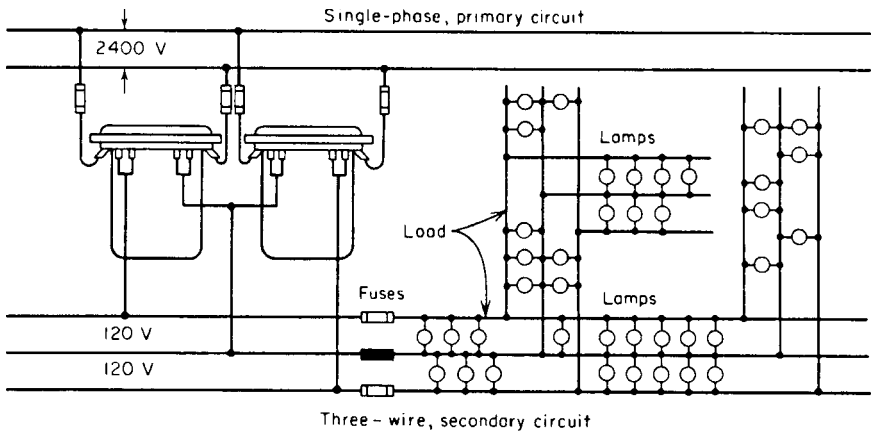

FIGURE 5.47 Two transformers serving a three-wire circuit.

connection between the two windings, providing 240 V between the two outside wires and 120 V on each of the side circuits. The transformer should have a capacity equal to the load to be supplied, and the three-wire circuits should be carefully balanced. If the three-wire circuits are decidedly unbalanced, the transformer should have a capacity equal to twice the load on the more heavily loaded of the two side circuits.

In Fig. 5.47, two transformers are shown connected to serve a three-wire circuit. The three-wire load should be balanced as nearly as possible, and if it is very nearly balanced, each transformer should have a capacity equal to one-half of the total load. If the load is badly unbalanced, each transformer should have a capacity equal to the load on its side of the circuit. See "Parallel Operation" shown in Fig. 5.47.

TWO-PHASE CONNECTIONS

77. Transformers connected to four-wire two-phase circuits are shown in Fig. 5.48. As a rule, two-phase primary lines are four-wire as shown, and to such a four-wire line the transformers are connected to each of the side circuits, as if each side circuit were a single-phase circuit not having any connection with the other. The total load should be so divided between the phases that the loads on each will be as nearly equal as possible. Each transformer should be designed for line voltage and will carry line current. Each transformer should have a kilovolt-ampere capacity equal to one-half of the kilovolt-ampere load that is served by the two transformers.

FIGURE 5.48 Transformers with two-phase to two-phase four-wire connection.

78. Transformers connected to three-wire two-phase circuits are shown in Fig. 5.49. The current in the center line wire AA for balanced load is 1.41 times the current in either of the outer wires. Each transformer has line voltage impressed on it and carries one-half the total load. A General Electric Co. publication comments thus: "Considerable unbalancing of voltage at the end of a transmission line or cable is experienced with the three-wire, two-phase system owing to the mutual induction between phases. Where the power factor is low, a still worse regulation is obtained, making satisfactory operation

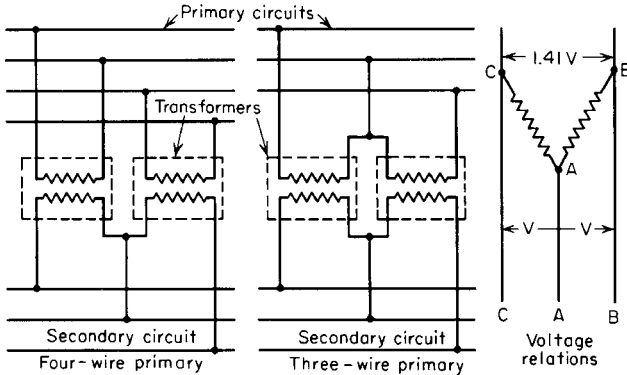

FIGURE 5.49 Connections for transformers on three-wire two-phase circuits.

difficult. Very few systems now operate on this plan, and practically all of them could be improved by the use of some other system.”

79. Mixed connections are sometimes made with two-phase transformers, as shown in Fig. 5.50. With improper connections such as those shown, difficulty will be experienced in the operation of motors, and they may not run at all.

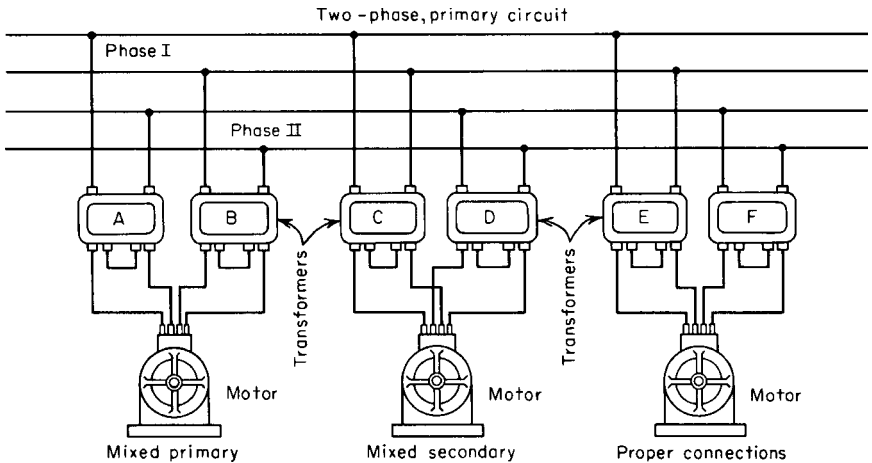

FIGURE 5.50 Correct and incorrect connections for transformers serving two-phase motors.

THREE-PHASE CONNECTIONS

80. Comparison of one three-phase transformer with a group of single-phase transformers (*Standard Handbook for Electrical Engineers*) that can be employed for obtaining the same service has been summed up by J. S. Peck as follows.

The advantages of the three-phase transformer are (1) lower cost, (2) higher efficiency, (3) less floor space and less weight, (4) simplification in outside wiring, and (5) reduced transportation charges and reduced cost of installation. The disadvantages of the three-phase transformer are (1) greater cost of spare units, (2) greater derangement of service in the event of breakdown, (3) greater cost of repair, (4) reduced capacity obtainable in self-cooling units, and (5) greater difficulties in bringing out taps for a large number of voltages. It is considered that the three-phase transformer has certain real and positive advantages over the one-phase type, while its disadvantages are chiefly those which result in the event of breakdown—an abnormal condition which occurs at rarer and rarer intervals as the art of transformer design and manufacture advances.

81. Connections of transformers for the transformation of three-phase power are given in Figs. 5.51 to 5.58 inclusive. In all these figures the polarity of the transformer units is additive. If the transformers had subtractive polarity, the interconnections between transformers would be made in exactly the same manner as shown in the figures insofar as terminal marking is concerned. The interconnections for subtractive polarity would be different with respect to the relative location of terminals. The connections shown in these figures result in standard angular displacements.

Much of the material in the following sections has been taken from a publication of the Line Material Company.

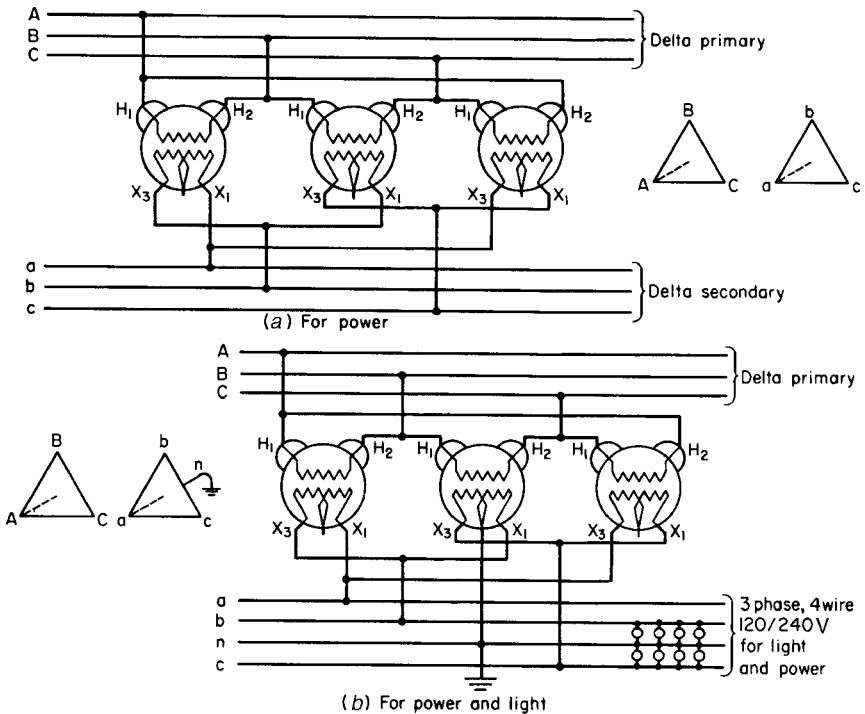

FIGURE 5.51 Transformers delta-connected on both primary and secondary.

82. Transformers with both primary and secondary coils delta (Δ) connected are shown in Fig. 5.51*a*. All three of the transformers are connected in series in a closed circuit, and each line wire is connected to the connection between two of the transformers. The voltage imposed on either the primary or the secondary winding is the primary or the secondary line voltage, respectively. The current in either winding = line current $\div \sqrt{3}$, or line current $\times 0.58$. The kilovolt-ampere capacity of each transformer should be equal to one-third the total kilovolt-amperes of the load to be served. The total kilovolt-ampere load transmitted by a balanced three-phase line = $1.73IE$ (where I is the line current in each line wire and E is the voltage between wires). Therefore, the kilovolt-ampere capacity of each transformer should be $1.73IE \div 3 = 0.58IE$. This type of three-phase transformation has been the one most commonly used in the past. The ungrounded primary system will continue to supply power even though one of the lines is grounded owing to a fault. If one of the transformers in the bank should fail, secondary power can be supplied from the two remaining units by changing to the open-delta connection. Thus this type of connection is ideal from the standpoint of service continuity.

When light and power are to be supplied from the same bank of transformers, the mid-tap of the secondary of one of the transformers is grounded and connected to the fourth wire of the three-phase secondary system as shown in Fig. 5.51*b*. The lighting load is then divided between the two hot wires of this same transformer, the grounded wire being common to both branches.

83. Transformers with both primary and secondary coils, star-connected, from a three-wire primary circuit are shown in Fig. 5.52. The current in each transformer winding is the same as the line current, and the voltage imposed on each winding = line voltage $\div \sqrt{3}$ = line voltage $\times 0.58$. The kilovolt-ampere capacity of each transformer should be equal to one-third the total kilovolt-amperes of the load to be served. The total kilovolt-ampere load transmitted by a balanced three-phase line = $1.73IE$ (where I is the line current in each line wire and E is the voltage between wires). Therefore, the kilovolt-ampere capacity of each transformer should be $1.73IE \div 3 = 0.58IE$.

It is necessary that the primary neutral be available when this connection is used, and the neutrals of the primary system and of the bank are tied together as shown. If the three-phase load is unbalanced, part of the load current flows in the primary neutral. Also the third-harmonic component of the transformer exciting current flows in the primary neutral. For these reasons, it is necessary that the neutrals be tied together as shown. If this tie were

FIGURE 5.52 Transformers star-connected on both primary and secondary (four-wire primary circuit).

omitted, the line to neutral voltages on the secondary would be very unstable. That is, if the load on one phase were heavier than on the other two, the voltage on this phase would drop excessively and the voltage on the other two phases would rise. Also, large third-harmonic voltages would appear between lines and neutral, both in the transformers and in the secondary system, in addition to the 60-Hz component of voltage. This means that for a given value of rms voltage, the peak voltage would be much higher than for a pure 60-Hz voltage. This overstresses the insulation both in the transformers and in all apparatus connected to the secondaries.

84. Transformers delta-connected to the primary circuit and star-connected to the secondary circuit are shown in Fig. 5.53. Any group of transformers can have either their primary or their secondary coils connected in either star or delta. With the primary delta-connected and the secondary star-connected as shown, the secondary voltage will be 1.73 times what it would be if it were delta-connected. The neutral of the secondary three-phase system is grounded. The single-phase loads are connected between the different phase wires and neutral while the three-phase power loads are connected to the three-phase wires. Thus, 120 V is supplied to the lighting loads and 208 V to the power load. Advantages of this type of bank are the fact that the single-phase load can be balanced on the three phases in each bank by itself and the fact that the secondaries of different banks can be tied together.

FIGURE 5.53 Transformers delta-connected primary and star-connected secondary.

85. Transformers star-connected primary and delta-connected secondary are shown in Fig. 5.54. This is the reverse of the grouping described in Sec. 84, and the secondary voltage will be only 0.58 times as great as if both secondary and primary were star-connected.

The present tendency in utilities is to replace the 2400 delta system with the 4160Y/2400-V three-phase four-wire system. This change in effect raises the distribution voltage from 2400 to 4160 without any major changes in connected equipment. The same transformers that were previously connected between lines on the 2400-V delta system are now connected between lines and neutral on the new 4160Y/2400-V system. Three-phase banks that had previously been connected delta-delta are now connected Y-delta as shown.

FIGURE 5.54 Transformers star-connected primary and delta-connected secondary.

When service for both light and power is to be supplied, the Y-delta bank takes the form shown in Fig. 5.54b.

If one unit of a Y-delta bank goes bad, service can be maintained by means of the connection of Fig. 5.55. In the regular Y-delta bank with three units, the neutral of the primaries of the transformers is not ordinarily tied in with the neutral of the primary system. In fact,

FIGURE 5.55 Y-delta connection with one unit missing.

this bank can be used even when the primary neutral is not available. In the bank with two units, however, it is necessary to connect to the neutral as shown. The main disadvantage of this hookup is the fact that full-load current flows in the neutral even though the three-phase load may be balanced. In addition to maintaining service in an emergency, this type of bank is satisfactory if the main part of the load is lighting and the three-phase load is small.

86. The three-phase V, or open-delta, connection (Fig. 5.56). Line voltage is impressed on each transformer, and line current flows in each transformer coil. This method is often used for motors but has the objection that if one of the transformers becomes inoperative, the three-phase circuit served will be fed by only one transformer and hence will be inoperative.

The combined capacity of two transformers (Harry B. Gear and Paul F. Williams, *Electric Central Station Distributing Systems*, D. Van Nostrand Co.) connected by this method and serving a given load should be 15.5 percent greater than the combined capacity of three transformers delta- or star-connected and serving the same load. For instance, if three 5-kVA transformers (total capacity, 15 kVA) are required for a certain installation and they are replaced by two 7½-kVA transformers (total capacity, 15 kVA), the two transformers will be overloaded by 15.5 percent at a full load of 15 kW at 100 percent pf.

FIGURE 5.56 Three-phase V, or open-delta, connection of two transformers.

For example, assume that in a three-transformer installation the current in the secondary line is 17.3 A. This imposes a load of 10 A on the transformer secondary coils. At 200 V this is 2 kW per transformer, or 6 kW in all. If two 3-kW transformers are put in to replace the three 2-kW units, the capacity of the secondary coils would be 15 A. But, as noted above, with the open-delta connection the current in the secondary coil is the same as the current in the line, and the 15-A winding must carry 17.3 A, or 15.5 percent overload.

In the grouping of Fig. 5.56, to reverse the direction of a motor served by the group, interchange any two of the primary phase wires or reverse any two of the secondary wires.

In some cases two transformers for open-delta grouping of proper aggregate capacity to serve a given load will be cheaper than three transformers for star or delta grouping to serve the same load, but this is not always the case.

The open-delta connection can be used in an emergency if one of the transformers in a delta-delta bank fails. This type of bank is also used to supply power to a three-phase load which is temporarily light but which is expected to grow. When the load increases to a point at which the two transformers in the bank are overloaded, an increase in capacity of 1.732 times can be obtained by adding another unit of the same size and using the delta-delta connection.

When the secondary circuits are to supply both light and power, the open-delta bank takes the form shown in Fig. 5.56*b*. In addition to the applications listed above for the open-delta bank for power, this type of bank is used when there is a large single-phase load and only a small three-phase load. In this case, the two transformers would be of different kVA sizes, the one across which the lighting load is connected being the larger.

87. Disadvantages of the V, or open-delta, connection (*Standard Handbook for Electrical Engineers*). For normal operation not only must each of the V-connected transformers be larger than each of the delta-connected transformers, but the two transformers must have a combined rating 15.5 percent greater than the three transformers. This fact taken alone does not represent a disadvantage of the V connection, because the two larger transformers are exactly equal in constructive material and operating efficiency to the three smaller transformers. The real objection to the V connection for serious work resides in the tendency for the local impedance of the transformers to produce an enormous unbalance of the secondary voltages and of the primary currents. In spite of this disadvantage (which is really of little consequence in 2200-V primary distribution work), many V-connected groupings are in satisfactory operation.

88. Comparison between the delta, the star, and the open-delta methods of connection (*Standard Handbook for Electrical Engineers*). The choice between the methods would be governed largely by the service requirements. When the three transformers are delta-connected, one can be removed without interrupting the performance of the circuit, the two remaining transformers in a manner acting in series to carry the load of the missing transformer. The desire to obtain immunity from a shutdown due to the disabling of one transformer has led to the extensive use of the delta connection of transformers, especially on the low-potential delivery side. It is to be noted that if one transformer is crippled, the other two will be subjected to greatly increased losses.

Thus, if three delta-connected transformers are equally loaded until each carries 100 A, there will be 173 A in each external circuit wire. If one transformer is now removed and 173 A continues to be supplied to each external circuit wire, each of the remaining transformers must carry 173 A, since it is now in series with an external circuit. Therefore, each

transformer must now show 3 times as much copper loss as when all three transformers were active, or the total copper loss is now increased to a value of 6 relative to its former value of 3. An open-delta installation is made frequently when considerable future increase in load is expected. The increase can be accommodated by adding the third transformer to the bank at a later date and thus increasing the capacity of the load that can be carried by about 75 percent.

A change from delta to Y in the secondary circuit alters the ratio of the transmission emf to the receiver emf from 1 to $\sqrt{3}$. On account of this fact, when the emf of the transmission circuit is so high that the successful insulation of transformer coils becomes of constructive and pecuniary importance, the three-phase line sides of the transformers are connected in "star" and the neutral is grounded. The windings of most transformers operating on systems of 100,000 V or more are star-connected.

See also Sec. 87 regarding properties of an open-delta-connected group.

89. Comparative cost of transformers for different grouping for three-phase service. The accompanying table shows the costs of the single-phase transformers, of proper capacities for either a delta or an open-delta grouping, and of a three-phase transformer to serve a 75-kVA installation. The relative costs will be the same for the present date.

Method of connection or grouping	Number of transformers required	Capacity of each transformer, kVA	Aggregate capacity	Cost per transformer, \$	Aggregate cost, \$
Delta (Δ)	3	25	75	500	1500
Open-delta (V)*	2	50	100	800	1600
Three-phase transformer	1	75	75	1400	1400

*The theoretical aggregate capacity of two single-phase transformers for open-delta grouping for a 75-kVA three-phase load (see Sec. 86) would be $75 \times 1.15 = 86.3$ kVA or $86.3 \div 2 = 43.2$ kVA per transformer. The nearest commercial capacity to 43.2 kVA is 50 kVA, which gives an aggregate capacity of 100 kVA.

90. Nonstandard angular displacement. All the transformer connections shown in Figs. 5.51 to 5.56 inclusive are made to give the standard angular displacement or vector relation between the primary and secondary voltage systems as defined by the different standards publications, including those of the ANSI. These standard angular displacements are 0° for delta-delta or Y-Y connected banks and 30° for delta-Y or Y-delta banks.

Angular displacement becomes important when two or more three-phase banks are interconnected into the same secondary system or when three-phase banks are paralleled. In such cases it is necessary that all the three-phase banks have the same displacement.

If subtractive-polarity transformers are used in the connections illustrated in Figs. 5.51 to 5.56, it is found that the secondary connections are much simplified from those shown for the additive-polarity units. The additive-polarity connections for standard angular displacement are somewhat complicated, particularly in cases with a delta-connected secondary, by the crossed secondary interconnections between units.

For this reason simplified bank connections which give nonstandard angular displacement between the primary and secondary systems are sometimes used with additive-polarity units. The diagrams of Figs. 5.57 and 5.58 cover these simplified bank connections for three additive-polarity units for the more common three-phase connections with the delta-connected secondary.

FIGURE 5.57 Delta-delta connections with nonstandard angular displacements.

FIGURE 5.58 Y-delta connections with nonstandard angular displacements.

SPECIAL TRANSFORMER CONNECTIONS

91. Transformers connected for transforming from three-phase to two-phase or the reverse are illustrated in Fig. 5.59, which shows what is known as the *Scott connection*. The transformers required are special, and each has a lead brought out from the middle point of the high-tension winding, and a special voltage tap giving 86.6 percent of the high-tension winding is arranged. Usually two transformers just alike are purchased so that they will be interchangeable. These special transformers can be purchased from any of the large manufacturers. Those shown are Westinghouse transformers. Two standard single-phase transformers for such service should have an aggregate kilovolt-ampere rating $15\frac{1}{2}$ percent greater than their group or nominal rating.

92. Explanation of the transformation from three-phase to two-phase (*Standard Handbook for Electrical Engineers*). Assume the simple case of a total power of 30,000 W, 1.0 pf, at 100 V, three-phase to be transformed (without loss) to 30,000 W, 100 V, two-phase (see Fig. 5.60). If the load is balanced on the two-phase side, there will be 15,000 W per phase, or 150 A at 100 V. Since the three-phase power is represented as

FIGURE 5.59 Transformers connected for three-phase to two-phase transformation.

FIGURE 5.60 Three-phase to two-phase transformation.

$IE = 30,000$, where I is the current per line wire and E is the emf between line wires, I must equal 173.2 A, because E has been taken as 100 V.

As shown in Fig. 5.60, the three-phase coils of one transformer must be designed for 100 V and 173.2 A, while the three-phase coils of the other transformer must be designed for 86.6 V and 173.2 A. The current through the coil CD divides equally. A part (86.6 A) goes through DA and an equal part (86.6 A) passes differentially through DB ; thus the mmf

of these two currents has a resultant of zero, and it has no effect upon the core flux insofar as transformer T^1 is concerned. The coil ADB carries a total value of current of 173.2 A throughout all its turns, but the current in one half is 60 time degrees out of phase with that in the other half. That is to say, the 173.2 A in one half is made up of a load current of 150 A, in leading time quadrature with which is 86.6 A of superposed current, while that in the other half is made up of a load current of 150 A, in lagging time quadrature with which is a superposed current of 86.6 A. The magnetizing effect of the 173.2 A is, therefore, 150 A, and the current in the two-phase side of transformer T^1 is 150 A. In the T^1 transformer the mmf of 173.2 A in 86.6 percent turns is just equal to that of 150 A in 100 percent turns; these two currents are directly in time-phase opposition, and the apparatus operates in all respects like a one-phase transformer. The phase relations and the relative values of the several components of currents are shown in the vector diagram of Fig. 5.60.

93. Kilovolt-ampere ratings of transformers for Scott connection (three-phase to two-phase) for serving a given horsepower load. The accompanying table gives the ratings recommended by the Westinghouse Electric Corp. for transformers serving squirrel-cage induction motors and indicates the efficiency of the installation. The temperature guarantee with performance as shown is a 50°C rise.

Hp of motor	Number of transformers	kVA capacity of each transformer	Total kVA load imposed on the group of two transformers when motor is operating at full load	Efficiency of bank of transformers with full load on motor
1/2	2	1/2	0.75	92.8
1	2	1/2	1.35	94.5
2	2	1	2.40	95.2
3	2	1 1/2	3.4	95.9
5	2	2 1/2	5.5	96.4
7 1/2	2	4	8.1	97.0
10	2	5	10.7	97.2
15	2	7 1/2	15.7	97.4
20	2	10	20.9	97.6
30	2	15	31.5	97.8
40	2	20	42.0	98.0
50	2	25	51.0	98.0
75	2	37 1/2	77.0	98.3

$$\text{kVA on each transformer} = \frac{\text{hp} \times 0.746 \times 0.59}{(\text{efficiency} \times \text{pf of motor})}$$

$$\text{Efficiency} = \frac{\text{kW on transformer}}{\text{kW transformer loss} + \text{kW on transformer}}$$

94. T-connected transformers for transforming from three-phase to three-phase (*Standard Handbook for Electrical Engineers*). A method of employing two transformers in three-phase transformation which practically overcomes the disadvantages of the V connection and possesses considerable merit is found in the T connection. As indicated in Fig. 5.61, one transformer is connected across between two of the line wires, while

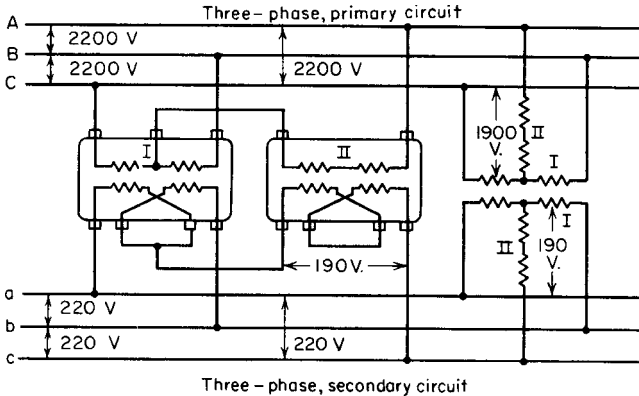

FIGURE 5.61 Transformers, T-connected for three-phase transformation.

the other is joined between the third line wire and the middle point of the first transformer. The current in the primary coil of each transformer is the same in value as that in the primary coil of the other, and the secondary currents in the two transformers are likewise equal in value. The voltage impressed across one transformer is only 86.6 percent of that across the other, so that if each transformer is designed especially for its work, one will have a rating of EI and the other a rating of $0.866EI$, where I is the current in each line wire and E is the emf between lines. The combined rating will therefore be 1.866, as compared with $1.732EI$ for three one-phase transformers connected either Δ or Y , or with $2.0EI$ for two V -connected transformers.

95. Requisites for transformers for T connection. The two transformers should possess the same ratio of primary to secondary turns, and a tap should be brought out from the central point of one of the transformers. It is not essential that the former transformer be designed for exactly 86.6 percent of the voltage of the latter; the normal voltage of one can be 90 percent of the other without producing detrimental results. Moreover, transformers designed for the same normal emf and intended for V connection can be T-connected with considerable improvement in service.

96. In comparing the T connection with the Δ or the Y connection (*Standard Handbook for Electrical Engineers*), it is to be noted that each connection accomplishes the transformation without sensible distortion of phase relations. The T connection allows the neutral point to be reached equally as well as does the Y connection. The Δ connection, however, is the only one capable of transforming in emergencies with one disabled transformer. With reference to its ability to maintain balanced phase relations, the T connection is much better than the V connection. The aggregate kilovolt-ampere rating of two T-connected transformers should be $15\frac{1}{2}$ percent greater than the nominal kilovolt-ampere rating of the group.

97. Booster transformers (Harry B. Gear and Paul F. Williams, *Electric Central Station Distributing Systems*). Ordinary distributing transformers applied as illustrated (Fig. 5.62) are used when it is necessary to raise, by a fixed percentage, the voltage

FIGURE 5.62 Boosting transformers.

delivered by a line, as it is when transformer ratios do not give quite the right voltage or when line drop is excessive. A booster raises the voltage of any primary circuit in which it may be inserted by the amount of the secondary voltage of the booster (see Fig. 5.62).

EXAMPLE On a long single-phase 2080-V lighting branch so heavily loaded that the pressure drops more than the amount for which the normal regulation of the feeder will compensate, a 110-V transformer inserted in the line as a booster will raise the pressure of the primary branch on the load side of the booster by 110 V. This raises the secondary pressure 5.5 percent on all the transformers beyond the booster.

With 440-V service supplied by star-connected 230-V transformers, a 10 percent booster in each phase raises the normal pressure of 230/400 V to 253/440 V.

The connections for a simple booster are shown in Fig. 5.62, I, the line pressure being raised from 2080 to 2184 V, or 5 percent. The connection at II is that for an augmented booster in which the line pressure is raised from 2080 to 2190 V, because the primary of the booster is connected across the line on the far side and the booster is boosted as well as the line. This gives an increase of 5.5 percent in the line pressure.

Figure 5.62, II, shows a 10 percent simple booster and IV an augmented 11.1 percent booster.

The transformers shown in Fig. 5.62 have a 10:1 or 20:1 ratio, and the percentages shown apply only to transformers of this ratio. If boosters having a ratio of 2080 to 115/230 are used, the percentages are increased by about 10 percent. Figure 5.62, I, would then become 5.5 percent; II, 6.05 percent; III, 11.1 percent; and IV, 12.2 percent.

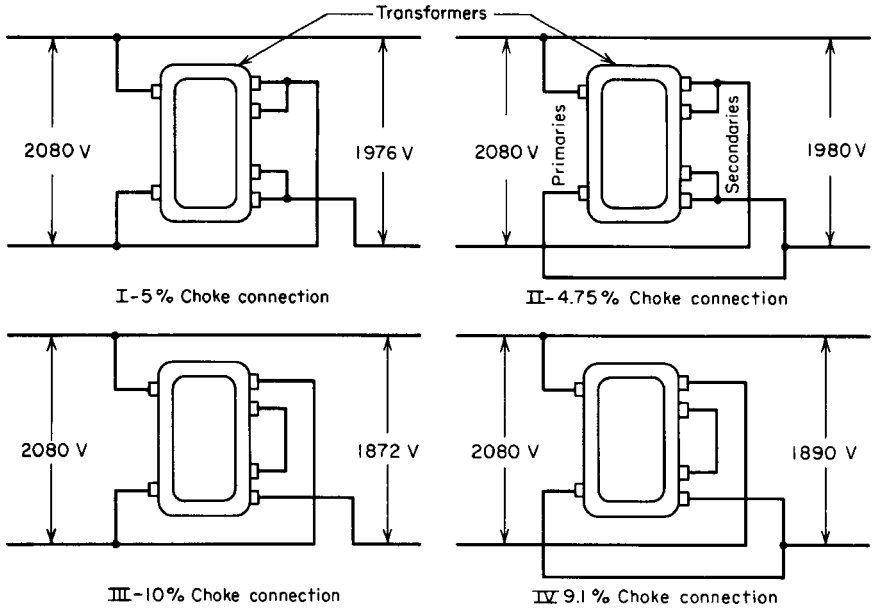

FIGURE 5.63 Bucking (choking) transformers.

98. The proper connection of the secondary for a booster or bucking transformer must usually be determined by trial for a transformer of any given type, but once it has been determined, the same connection can be used for any transformer of the same type. The connections shown in Figs. 5.62 and 5.63 are correct for transformers of the principal makers. Boost and buck transformers are also used in circuits of 600 V and less. See Sec. 108.

99. Boosters are connected in a two-phase circuit in a manner similar to that shown in Fig. 5.62 for a single-phase circuit. In three-wire two-phase feeders the boosters (secondary windings) are cut into the outer wires, and the primary windings are connected between the middle and the outside wires.

100. Booster transformers in three-phase circuits are connected as shown in Fig. 5.64 (*Electric Central Station Distributing Systems*). The insertion in any phase wire of the booster voltage affects two phases. The boosting and bucking effects, with transformers of various ratios, with the boosting transformers used in one, two, or three phases, are expressed in percentage of the primary voltage in the tables of Sec. 101.

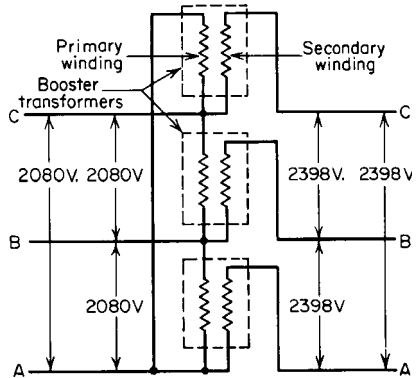

FIGURE 5.64 Booster transformers in a three-wire, three-phase circuit.

101. Voltage boosting and bucking effect of transformers connected in three-phase circuits (*Electric Central Station Distributing Systems*). Values in the body of the tables are the percentages that the voltages will be increased or decreased, respectively, by the insertion of booster or bucking transformers, of different ratios, in one, two, or three of the phase wires. Transformers are connected for boosting as shown in Fig. 5.64. *AB*, *BC*, and *CA* refer to the three phases of Fig. 5.64.

BOOSTING												
Ratios	10:1			20:1			9:1			18:1		
Booster in	<i>AB</i>	<i>BC</i>	<i>CA</i>	<i>AB</i>	<i>BC</i>	<i>CA</i>	<i>AB</i>	<i>BC</i>	<i>CA</i>	<i>AB</i>	<i>BC</i>	<i>CA</i>
A phase	10.0	10.0	5.3	5.00	0.00	2.65	11.0	0.0	5.8	5.5	0.00	2.9
A and B	15.3	10.0	5.3	7.65	5.00	2.65	16.8	5.5	5.8	8.4	2.75	2.9
A, B, and C	15.3	15.3	15.3	7.65	7.65	7.65	16.8	16.8	16.8	8.4	8.40	8.4
BUCKING												
A phase	10.0	0.0	4.6	5.0	0.0	2.3	11.00	0.00	5.06	5.5	0.00	2.53

102. Bucking transformers (*Electric Central Station Distributing Systems*). When the secondary is connected in reverse order, the transformer becomes a “choke,” reducing the line pressure instead of raising it.

EXAMPLE A 5 percent choke connection is shown in Fig. 5.63, I, a 4.75 percent choke in II, a 10 percent choke in III, and a 9.1 percent choke in IV.

The transformers shown in Fig. 5.63 have a ratio of 10:1 or 20:1, and the percentages shown are only for transformers of that ratio. If bucking transformers having a ratio of 2080 to 115/230 are used, the choking percentages would be changed to the following values: Fig. 5.63, I, 5.5 percent; II, 5.24 percent; III, 11 percent; and IV, 10 percent.

103. The capacity of a transformer that is to be used as a booster (Fig. 5.65) will be determined by (1) the current *I* which will flow in the ac line and (2) the voltage *E* by which the emf on the line will be boosted. If, for example, the current in the line is 20 A and it is desired to raise the voltage (Fig. 5.65) by 110 V, then required capacity of the boosting transformer = 20 A × 110 V = 2200 VA = 2.2 kVA. Hence, for these conditions it would be necessary to use at *I* a standard 2½-kVA transformer. The secondary coils of this transformer would be connected in multiple so that they would develop 110 V.

If it is desired to boost the voltage by 220 V, then 20 A × 220 V = 4400 VA = 4.4 kVA. Hence, theoretically a 4.4-kVA transformer would be required. Note that in any case the secondary winding of the boosting transformer must be capable of carrying the primary line current (20 A, in Fig. 5.65). Furthermore, the secondary coils of the boosting transformer must be so designed and connected that they will produce at their terminals the voltage by which it is desired to boost the emf which is impressed on the line by the generator in the station.

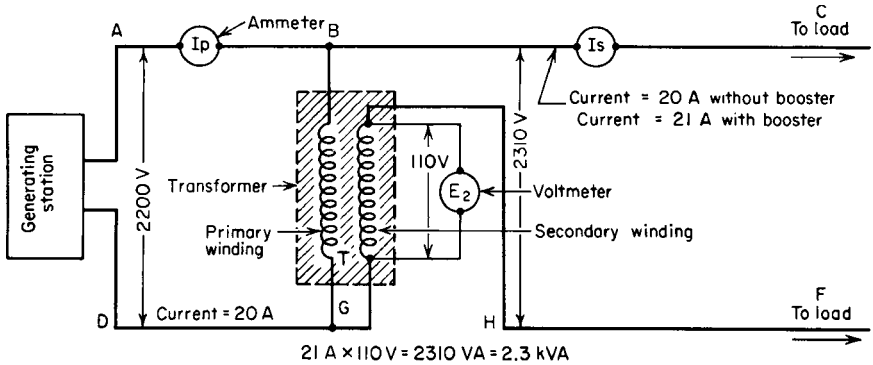

FIGURE 5.65 Example of computing capacity required for a booster transformer.

104. As a practical proposition it is usually desirable to select for the boost voltage one of the voltages for which the secondaries of distributing transformers are regularly designed or for which they can be connected. That is, the boosting voltage should, ordinarily, be either 110, 220, or 440. If a boosting voltage other than one of these standard voltages is necessary, it will then probably be necessary to obtain a specially designed transformer or a transformer which has taps on the secondary coils.

105. In every case the line current will be increased somewhat by the boosting transformer. If the load remains constant, the increase in that portion of the circuit *HFCB* (Fig. 5.65) will be in the ratio by which the voltage impressed on this portion of the circuit has been boosted. For example, if the current in the ac line *HFCB* of Fig. 5.65 was 20 A before the boosting transformer was inserted, the current after its insertion would be computed in this way:

$$\frac{I_2}{I_1} = \frac{E_2}{E_1} \tag{3}$$

$$I_2 = \frac{E_2 \times I_1}{E_1} \text{A} \tag{4}$$

where I_1 = the line current, in amperes, before inserting the booster transformer; E_1 = emf, in volts, across *BH* (Fig. 5.65) before inserting the booster transformer; I_2 = current, in amperes, in *HFCB* after the booster is inserted; and E_2 = emf, in volts, across *BH* after the booster is inserted.

EXAMPLE If we substitute the values from Fig. 5.65 in Eq. (4), the current in *HFCB* after inserting the booster = $I_2 = (E_2 \times I_1) \div E_1 = (2310 \times 20) \div 2200 = 21$ A. After inserting the booster, the current I_p in *ABCD* will be 21 A + the current carried by the primary winding. The value of 20 A in Sec. 103 is not strictly correct, but this relatively small difference will not appreciably affect the kilovolt-ampere rating of the booster transformer which would be used.

106. There are certain precautions that should be observed in the installation of boosters (*Electric Central Station Distributing Systems*) to protect them from injury. The booster secondary is in series with the line, and current is drawn through its primary windings in proportion to the load on the line. If the primary of the booster is opened

while the secondary is carrying the line current, the booster acts as a choke coil in the main circuit. This causes a large drop of pressure in the booster, imposing upon its secondary windings a difference of potential of 2 to 5 times normal. Under these conditions the insulation of a 2000-V transformer can be subjected to a pressure of 10,000 to 20,000 V or more, depending upon the load carried by the main circuit at the time.

If a fuse is used in the primary, its blowing creates the above condition, and the arc holds across the terminals of the fuse block until it burns itself clear. It has often been observed that if boosters have been "protected" by fuses in this way, the transformer has burned out shortly after the blowing of its primary fuses if not at the time.

Also, in using ordinary static transformers as boosters, it should be remembered that the service is different from that for which the transformer is designed. If this feature is neglected, the insulation may be subjected to excessive voltage or dielectric stresses, thus causing breakdown. The standard distributing transformer is designed to withstand a pressure of about 10,000 V between the high-voltage coils and the case, while the low-voltage coils (the 220-V coils) are designed to withstand a test pressure of 4000 V between coils, core, and case for a period of 1 min.

When a 2200–110/220-V transformer is used as a booster, the low-voltage coils are subjected to a continuous pressure of about 2300 V above ground. This sustained voltage will, if the case is grounded, be likely to destroy the insulation of the low-voltage coils. Therefore the transformer case should, if feasible, be insulated from the ground, although this may involve life hazard. When the transformer is installed on a pole, the insulation is automatically provided, since the pole acts as the insulating medium.

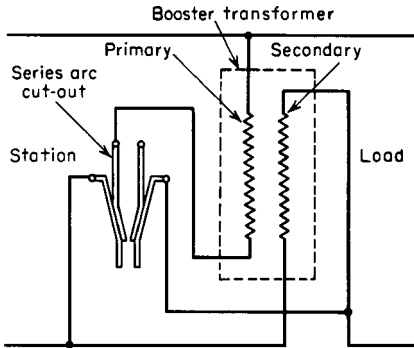

FIGURE 5.66 Series arc cutout for a booster.

107. Booster cutout (Gear and Williams). In connecting or disconnecting a booster, the main line should be opened before putting it in or out. If service on the line cannot be interrupted or if it is desired to switch the booster in or out at certain times, it can be done with a series arc cutout as in Fig. 5.66. The operation of the cutout simultaneously opens the primary and short-circuits the secondary of the booster. The switch must be of a type having a positive action so that arcing will not damage its contacts at the moment when the secondary is short-circuited. The arc cutout must have sufficient carrying capacity to carry the

main-line current when the booster is shunted out, and standard series cutouts should not be used if the line current is likely to exceed 20 to 25 A.

When the augmented booster is used, the terminals of the primary winding of the transformer which goes to the cutout should be connected to the terminal of the cutout which is shown as not being in use in Fig. 5.66.

108. Boost-buck transformers in low-voltage circuits. For circuits of 600 V or less, the most common application for a boost-buck transformer is boosting 208 to 230 or 240 V and vice versa for industrial and commercial air-conditioning systems, boosting 110 to 120 V, and 240 to 277 V for lighting systems, and voltage correction for heating systems and all types of induction motors.

In such cases a buck-boost transformer raises or lowers a supply line voltage by as much as 20 percent. A typical transformer has two primary (input) windings, both rated at either

120 or 240 V, and two secondary (output) windings, both rated at 12, 16, or 24 V. With this arrangement the primary and secondary windings can be connected together so that the electrical characteristics are changed from those of an insulating transformer to those of a boosting or bucking autotransformer.

Connections are quite similar to those shown in Figs. 5.62 and 5.63, and complete literature on boost and buck transformers can be obtained from Acme Electric Corp.

CONNECTIONS FOR THREE-PHASE TRANSFORMERS

109. Methods of connecting the windings of three-phase transformers (*Standard Handbook for Electrical Engineers*). The windings of each component transformer are connected to the external circuits just as though this component were a one-phase unit; i.e., the primaries can be connected either Y or delta. Moreover, the relative advantages of the Y connection and the delta connection are quite the same with one three-phase transformer as with three one-phase transformers. The delta connection is advantageous in some cases, in that if the windings of one phase become damaged by short circuiting, grounding, or any other defect, it is possible to operate with the other phase windings V-connected.

110. In operating a damaged three-phase transformer on two coils, it is necessary to separate the damaged transformer windings electrically from the other coils, as indicated in Fig. 5.67. The high-potential winding of the damaged phase should be short-circuited upon itself, and the corresponding low-potential winding should also be short-circuited upon itself. The winding thus short-circuited will choke down the flux passing through the portion of the core surrounded by the windings without producing in any portion of the winding a current greater than a small fraction of the current which would normally exist in such portion at full load.

FIGURE 5.67 Operating a damaged three-phase transformer.

PARALLEL OPERATION

111. Parallel operation of transformers. Transformers will operate satisfactorily in parallel (Fig. 5.68), i.e., with their high- and low-tension windings respectively connected directly to the same circuits, provided that they have (1) the same ratio of transformation, (2) the same voltage ratings, and (3) approximately the same regulation. If the low-tension voltages are different, the transformer having the highest voltages will circulate current to those of lower voltage and cause a continuous loss. If transformers connected in parallel do not have the same regulation, they will not share the total load in proportion to their ratings. The greater share of the load will be taken by the transformer having the best regulation.

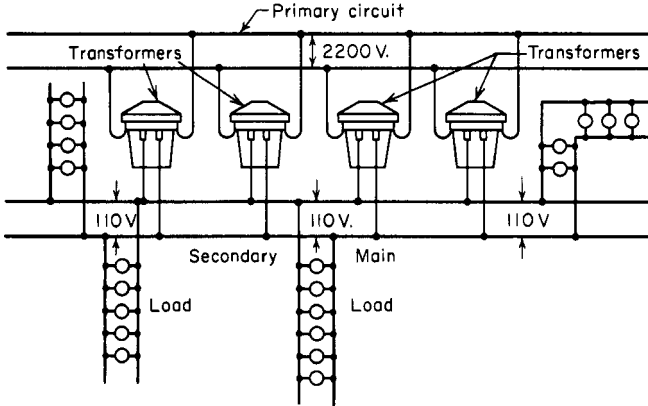

FIGURE 5.68 Transformers banked or operating in parallel.

In connecting large transformers in parallel, especially when one of the windings is for a comparatively low voltage, it is necessary that the resistance of the joints and interconnecting leads does not vary materially for the different transformers, or it will cause an unequal division of load.

112. With transformers of the same general voltage and capacity characteristics connected in multiple in a secondary network (A. D. Fishel, *Distributing Transformers*), little trouble will be encountered, as the impedance of the line between two transformers on separate poles spaced about 100 or 200 ft (30.5 or 61 m) apart will normally neutralize any difference in the transformer impedances. When transformers operated in multiple are placed on the same pole, the question of equal sharing of the load may be of some importance. The standard transformers of reliable manufacturers do not differ very widely in impedance characteristics, however, and it is usually practicable to operate transformers of

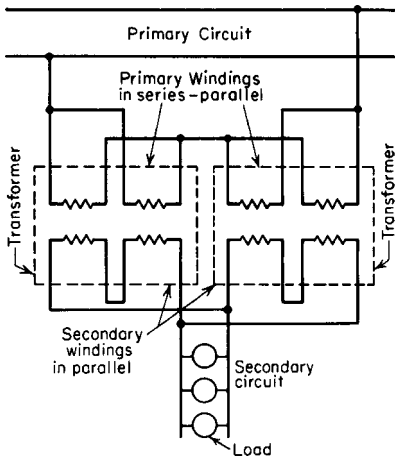

FIGURE 5.69 Connection for forcing parallel operation of transformers which have different impedance characteristics.

the various standard types in parallel. Often the commercial desirability of paralleling transformers of different sizes will overbalance the undesirability of some inequality in the sharing of the load which might result.

113. A method of forcing equal division of load between transformers having considerably different impedance characteristics (A. D. Fishel, *Distributing Transformers*) is shown in Fig. 5.69. Standard 2200-V distributing transformers are usually provided with arrangements for the series-parallel connecting of both the high-tension and the low-tension windings, and therefore the connections shown can be used. As the high-tension windings are in series, the currents in the primary windings will be the same; hence, the transformers will be equally loaded.

114. Some three-phase transformers can be paralleled, and some cannot (W. M. McConahey, *Electric Journal*). A transformer having its coils connected in delta on both high-tension and low-tension sides cannot be made to parallel with one connected either in delta on the high-tension and star on the low-tension or in star on the high-tension and delta on the low-tension side. However, a transformer connected in delta on the high-tension and in star on the low-tension side can be made to parallel with transformers (having their coils joined in accordance with certain schemes) connected in star on the high-tension side and in delta on the low-tension side. Some three-phase transformers cannot be made to parallel (without changing the internal connection arrangement of their coils) with others using the same type of connections for the two windings. For example, a transformer connected delta to delta may have its coils so interconnected that it will not parallel with another transformer, connected delta to delta. By changing the internal connections between the coils, however, it will be possible to bring out the terminals in such a way that parallel operation can be obtained.

115. How to determine whether or not three-phase transformers will operate in parallel. If the transformers are available, connect them as indicated in Fig. 5.70, leaving two leads on one of the transformers unjoined. Test with a voltmeter across the unjoined leads. If there is no voltage between E and e or between F and f of transformer 2, the polarities of the transformers are the same, the connections can be completed, and the transformers put in service.

If a voltage difference is found between E and e or between F and f or between both, the polarities of the transformers are not the same. Then connect transformer lead A successively to mains 1, 2, and 3 and at each connection test with the voltmeter between e and f and the legs of the main to which lead A is not connected. If with any trial connection the voltmeter readings between f and e

and either of the two legs is found to be zero, the transformer will operate with leads f and e connected to those two legs. If no system of connections can be found that will satisfy this condition, the transformer will not operate in parallel without changes in its internal connections, and it may be that it will not operate in parallel at all (see Sec. 114).

FIGURE 5.70 Testing three-phase transformers for parallel operation.

CONNECTIONS AND APPLICATIONS OF AUTOTRANSFORMERS

116. Use of autotransformers. The National Electrical Code allows the use of autotransformers for supplying interior-wiring systems under certain conditions.

A branch circuit may be supplied through an autotransformer only if the system supplied has a grounded conductor which is electrically connected to a grounded conductor of the system supplying the autotransformer, with the following exceptions.

1. An autotransformer can be used to extend or add a branch circuit for an equipment load without the connection to a similar grounded conductor when transforming from a nominal 208 V to a nominal 240-V supply or similarly from 240 to 208 V.
2. In industrial occupancies, where conditions of maintenance and supervision ensure that only qualified persons will service the installation, autotransformers can be used to supply nominal 600-V loads from nominal 480-V systems, and 480-V loads from nominal 600-V systems, without the connection to a similar grounded conductor.

This transformation is commonly employed to connect 480-V equipment in a factory with a 600-V distribution, or vice versa. A 480- to 120-V two-winding transformer is connected with its windings in series so it functions as an autotransformer, as shown in Fig. 5.71. There is an easy way to determine how to size the two-winding transformer that will be connected in this way.

Let C = transformation capacity as an autotransformer

X = rated transformation capacity as a two-winding transformer

and R = the voltage ratio of the two windings

$$X = \frac{C}{(R + 1)} \quad (5)$$

This formula is derived as follows:

Look at both sides of the transformer. When the transformer is connected as shown the current taken at point C is the sum of the currents in the shunt and series windings, but the voltage between points A and C (the low side) is simply the shunt winding voltage. On the other (high) side, the voltage between points A and B is the sum of the voltages in the shunt and series windings, but the current is simply the series winding current since all of the

FIGURE 5.71 A 480- to 120-V two-winding transformer (or, perhaps more likely, a 480 to 120/240 center-tapped secondary with the two 120-V connections connected in parallel) connected as an autotransformer to run 465-V motors on a 575-V distribution.

current at point B must pass through that winding. Transformers are not assumed to consume power, so the power on both sides must be the same. Therefore:

$$(E_{sh} + E_{se})I_{se} = C = E_{sh}(I_{se} + I_{sh}) \text{ Note also that:}$$

$$E_{se}I_{se} = X = E_{sh}I_{sh} \text{ and that:}$$

$$\frac{E_{sh}}{E_{se}} = R \text{ which means that } R \times E_{se} = E_{sh}$$

We need only work with the left side of the first two equations, as follows:

$$(E_{sh} + E_{se})I_{se} = C$$

$$E_{sh}I_{se} + E_{se}I_{se} = C \text{ (substituting for } E_{sh} \text{ and } E_{se}I_{se}\text{):}$$

$$R(E_{se})I_{se} + X = C \text{ (substituting again for } E_{se}I_{se}\text{):}$$

$$RX + X = C \text{ (rearranging terms):}$$

$$X(R + 1) = C \text{ (solving for } X\text{):}$$

$$X = \frac{C}{R + 1}$$

EXAMPLE Suppose a 50-hp and a 3-hp motor, both rated 460-V load will be connected to a 575-V 3-phase system. If two 480-V/120-V–two-winding transformers will be connected in open delta to service the loads, what size transformers should be purchased?

The full-load ratings of the motors must be evaluated using the NEC Table 430.250, reproduced in this book in Div. 12, Table 10. The 50-hp motor draws 65 A and the 3-hp motor 4.8 A. Converting to kilovolt-amperes, $65 \text{ A} \times 465\sqrt{3}/(1000) = 52 \text{ kVA}$ and $4.8 \text{ A} \times 465\sqrt{3}/(1000) = 4 \text{ kVA}$.

Add 13 kVA (25 percent of the largest motor) to get 69 kVA total.

In the formula, R will be $480 \text{ V} \div 120 \text{ V} = 4$, and C will be 69 kVA.

Then the capacity required will be $69 \text{ kVA} \div 5$ or 14 kVA.

Remember that the capacity of an open-delta transformer bank is not the sum of the two transformers; instead, the capacity is that of the two transformers multiplied by half the square root of three. Two 10-kVA–two-winding transformers would be a good choice in this case. The final capacity would be $(10 \text{ kVA} + 10 \text{ kVA})(1/2\sqrt{3}) = 17 \text{ kVA}$.

Note that this 480-V transformer (120-V secondary) will be connected to a 600-V supply voltage. The NEC requires that field-connected autotransformers be identified for use at the elevated voltage because the dielectric withstand test is often done at a lower level for windings rated 250 V or less, and in this case the 120-V winding must be tested as though it were a 600-V winding. Transformer manufacturers are very familiar with this application and appropriate products are readily available.

Autotransformers may be used as part of the ballast for lighting units. In these applications an autotransformer which raises the voltage to more than 300 V shall be supplied only by a grounded system.

Autotransformers may be used as starting compensators for ac motors. The compensator supplies a reduced voltage to the motor circuit while the machine is accelerating from rest. Ordinarily each autotransformer used for this purpose is provided with several taps so that a number of low voltages can be obtained.

117. A starting-compensator arrangement for a two-phase induction motor (*Standard Handbook for Electrical Engineers*) is shown in Fig. 5.72. There are two autotransformers, the two separate phase lines being connected to the ends of the separate autotransformer windings. During the starting period the motor is connected between two of the ends and two intermediate taps. Figure 5.73 shows a starting-compensator arrangement for a three-phase induction motor. The three autotransformer windings are Y-connected, and low-voltage points are permanently selected along each leg of the Y. It is not necessary to employ three autotransformers for starting a three-phase

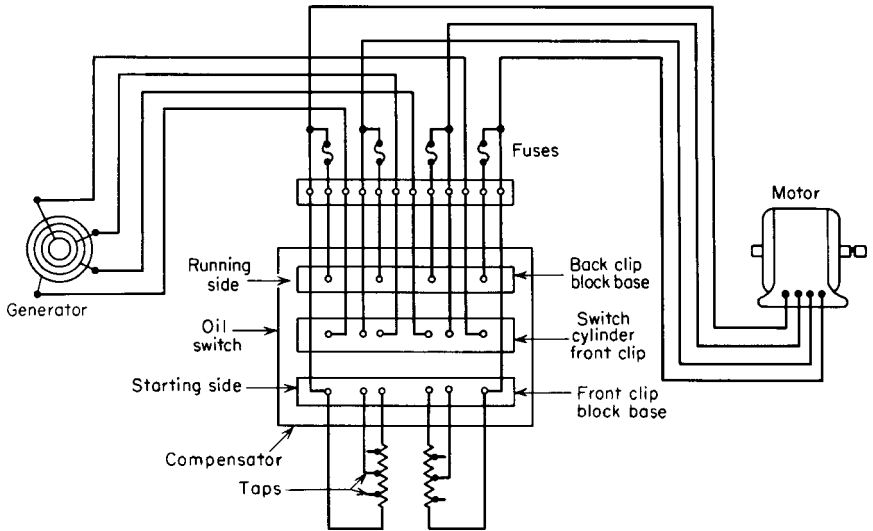

FIGURE 5.72 Two-phase starting compensator.

FIGURE 5.73 Three-phase starting compensator.

FIGURE 5.74 An autotransformer three-phase starting compensator.

motor; two V-connected autotransformers are quite satisfactory for this purpose. Figure 5.74 shows two V-connected autotransformers for starting a three-phase induction motor and operating it at four different voltages.

FIGURE 5.75 Y-connected three-phase autotransformer.

118. The coils of a three-phase transformer can be connected for operation as an autotransformer equally as well as can those of a one-phase transformer. The interconnections would ordinarily be by the Y method, although the delta method or a combination of the Y and delta methods may be used. Figure 5.75 represents a Y connection for auto-transformer operation.

INSTALLATION, CARE, AND OPERATION

119. The successful operation of transformers (Allis-Chalmers Corporation) is dependent upon proper installation and operation as much as upon proper design and manufacture. Although a transformer requires less care than almost any other type of electrical apparatus, neglect of certain fundamental requirements may lead to serious trouble, if not loss of the transformer.

120. The following sections (122 to 148) give the requirements of the National Electrical Code for the installation of transformers. For further information see Article 450 of the NEC.

121. Application. Article 450 of the NEC applies to the installation of all transformers, except (1) current transformers, (2) dry-type transformers which constitute a component part of other apparatus and which conform to the requirements for such apparatus, (3) transformers which are an integral part of an x-ray, electrostatic-coating, or high-frequency apparatus, (4) transformers used with Class 2 or Class 3 circuits that comply with Article 725

of the Code, (5) transformers for sign and outline lighting that comply with Article 600 of the Code, (6) transformers for electric discharge lighting that comply with Article 410 of the Code, (7) transformers used for power-limited fire alarm circuits that comply with Part III of Article 760, and (8) transformers used for research, development, or testing, where effective arrangements are provided to safeguard persons from contacting energized parts.

Article 450 applies to the installation of transformers to fire pumps and in hazardous locations, except as modified by Articles 501 through 504 of the NEC. Throughout this part of the NEC, the following definition of a transformer applies: “an individual transformer, single- or polyphase, identified by a single nameplate, unless otherwise indicated in this article.”

122. Overcurrent protection. Overcurrent protection shall conform to the following requirements. As used in this section, the word *transformer* means a transformer or a polyphase bank of two or more single-phase transformers operating as a unit.

TABLE 450.3(A) Maximum Rating or Setting of Overcurrent Protection for Transformers Over 600 V (as a Percentage of Transformer-Rated Current)

Location Limitations	Transformer Rated Impedance	Secondary Protection (see Note 2)				
		Primary Protection Over 600 V		Over 600 V		600 V or Less
		Circuit Breaker (see Note 4)	Fuse Rating	Circuit Breaker (see Note 4)	Fuse Rating	Circuit Breaker or Fuse Rating
Any location	Not more than 6%	600% (see Note 1)	300% (see Note 1)	300% (see Note 1)	250% (see Note 1)	125% (see Note 1)
	More than 6% and not more than 10%	400% (see Note 1)	300% (see Note 1)	250% (see Note 1)	225% (see Note 1)	125% (see Note 1)
Supervised locations only (see Note 3)	Any	300% (see Note 1)	250% (see Note 1)	Not required	Not required	Not required
	Not more than 6%	600%	300%	300% (see Note 5)	250% (see Note 5)	250% (see Note 5)
	More than 6% and not more than 10%	400%	300%	250% (see Note 5)	225% (see Note 5)	250% (see Note 5)

Notes:

1. Where the required fuse rating or circuit breaker setting does not correspond to a standard rating or setting, a higher rating or setting that does not exceed the next higher standard rating or setting shall be permitted.

2. Where secondary overcurrent protection is required, the secondary overcurrent device shall be permitted to consist of not more than six circuit breakers or six sets of fuses grouped in one location. Where multiple overcurrent devices are utilized, the total of all the device ratings shall not exceed the allowed value of a single overcurrent device. If both circuit breakers and fuses are used as the overcurrent device, the total of the device ratings shall not exceed that allowed for fuses.

3. A supervised location is a location where conditions of maintenance and supervision ensure that only qualified persons will monitor and service the transformer installation.

4. Electronically actuated fuses that may be set to open at a specific current shall be set in accordance with settings for circuit breakers.

5. A transformer equipped with a coordinated thermal overload protection by the manufacturer shall be permitted to have separate secondary protection omitted.

TABLE 450.3(B) Maximum Rating or Setting of Overcurrent Protection for Transformers 600 V and Less (as a Percentage of Transformer-Rated Current)

Protection Method	Primary Protection			Secondary Protection (see Note 2)	
	Currents of 9 A or More	Currents Less than 9 A	Currents Less than 2 A	Currents of 9 A or More	Currents Less than 9 A
Primary only protection	125% (see Note 1)	167%	300%	Not required	Not required
Primary and secondary protection	250% (see Note 3)	250% (see Note 3)	250% (see Note 3)	125% (see Note 1)	167%

Notes:

1. Where 125 percent of this current does not correspond to a standard rating of a fuse or nonadjustable circuit breaker, a higher rating that does not exceed the next higher standard rating shall be permitted.

2. Where secondary overcurrent protection is required, the secondary overcurrent device shall be permitted to consist of not more than six circuit breakers or six sets of fuses grouped in one location. Where multiple overcurrent devices are utilized, the total of all the device ratings shall not exceed the allowed value of a single overcurrent device. If both breakers and fuses are utilized as the overcurrent device, the total of the device ratings shall not exceed that allowed for fuses.

3. A transformer equipped with coordinated thermal overload protection by the manufacturer and arranged to interrupt the primary current, shall be permitted to have primary overcurrent protection rated or set at a current value that is not more than six times the rated current of the transformer for transformers having not more than 6 percent impedance, and not more than four times the rated current of the transformer for transformers having more than 6 percent but not more than 10 percent impedance.

Voltage Transformers. When voltage transformers are installed indoors or enclosed, they shall be protected with primary fuses.

123. Autotransformers. Each autotransformer rated 600 V, nominal, or less shall be protected by an individual overcurrent device in series with each ungrounded conductor, rated or set at not more than 125% of the rated full-load input current of the autotransformer. If this calculation does not correspond to a standard rating and the rated input current is 9 A or more, the next higher standard device is permitted. No overcurrent device shall be placed in series with the shunt winding.

Referring to Fig. 5.71, no overcurrent device should be placed between points *A* and *C*. If the overcurrent device opened and the load impedance were low, the input 600 V would return to the autotransformer at some voltage approaching 600 V across the series winding (between *B* and *C* in Fig. 5.71). Given the 1:4 winding ratio, that could result in a voltage on the 480 V side of the autotransformer exceeding 2000 V.

As an example of an overcurrent protective device sizing calculation, the two 10-kVA transformers used in Sec. 116 analysis can supply 17.3 kVA of load transformation. In the formula, rearrange the terms to solve for *C*: $C = X(R + 1)$ or in this case 17.3 kVA $(4 + 1) = 87$ A. This arrangement of autotransformers must be protected at not more than 125% of this number, or 108 A, with the next higher standard size protective device (110 A) permitted.

Autotransformers field connected for this purpose must be identified for use at the elevated voltage. Refer to the discussion on this point in Sec. 116 for more information.

124. Grounding autotransformers. Grounding autotransformers covered in this section are zigzag or T-connected transformers connected to 3-phase, 3-wire ungrounded systems for the purpose of creating a 3-phase, 4-wire distribution system or providing a neutral point for grounding purposes. Such transformers shall have a continuous per-phase current rating and a continuous neutral current rating. Zigzag-connected transformers shall not be connected on the load side of any system grounding connections, including those made in accordance with 250.24(B), 250.30(A)(1), or 250.32(B) Exception.

NOTE Zigzag grounding autotransformers are comprised of two three-phase wye connections in series. Figure 5.76 shows most of the requirements as well as the angular displacements that give the transformation its name. The inner connections are a straightforward wye, and close inspection of the three outer segments of the pinwheel shows that they are also oriented in a wye configuration. In fact, at least one major transformer manufacturer now sells zigzag customers three two-winding transformers (thus, six windings) along with instructions as to how to connect them to achieve this result. The simultaneous disconnection rule is crucial because if a single-pole overcurrent device were to open, the grounding transformer will no longer function as intended, including a strong likelihood of dangerous transient overvoltages on its load side. A properly functioning zigzag connection will derive a fully functional neutral for 277-V circuits, and return one-third of the total neutral current equally to each phase. The balance of this code section is primarily divided into two parts, one for an actual neutral for a distribution system, and the other for a neutral reference for an impedance grounding connection.

FIGURE 5.76 A zigzag-connected grounding autotransformer used to derive a 277-V neutral from an ungrounded 480-V delta distribution, showing NEC required safeguards in place.

A grounding autotransformer used to create a 3-phase 4-wire distribution system shall comply with the following four requirements:

1. The transformer shall be directly connected to the ungrounded phase conductors and shall not be switched or provided with overcurrent protection that is independent of the main switch and common-trip overcurrent protection for the 3-phase 4-wire system. A transformer used to limit transitory overvoltages shall be of suitable rating and shall be connected in accordance with this rule.
2. An overcurrent sensing device shall be provided that will cause the main switch or common-trip overcurrent protection previously referred to open if the load on the autotransformer reaches or exceeds 125 percent of the continuous current per phase or neutral rating. Delayed tripping for temporary overcurrents sensed at the autotransformer overcurrent device shall be permitted for the purpose of allowing proper operation of branch or feeder protective devices on the 4-wire system.
3. A fault-sensing system that causes the opening of a main switch or common trip overcurrent device for the 3-phase 4-wire system shall be provided to guard against single phasing or internal faults. An explanatory note advises that this can be accomplished by the use of two subtractive-connected donut-type current transformers installed to sense and signal when an unbalance occurs in the line current to the autotransformer of 50 percent or more of rated current.
4. The autotransformer shall have a continuous neutral-current rating that is sufficient to handle the maximum possible neutral unbalanced load current of the 4-wire system.

NOTE Zigzag connections are never a substitute for running a neutral to a load, regardless of how remote. If the supply system is grounded at any point, then a parallel neutral return path will exist and this will desensitize the protective controls for the transformer. The NEC now expressly prohibits the use of grounding transformers on the load side of any system grounding connection. The remainder of this section covers grounding autotransformers that do not supply utilization loads, but instead merely provide a ground reference and a specified magnitude of ground-fault current for the operation of ground-responsive protective devices, typically so an ungrounded system can be grounded through an impedance. Refer to Sec. 356 of Div. 9 for details. Insert the grounding impedance as indicated and eliminate all load connections to the neutral. There are three requirements:

1. The autotransformer shall have a continuous neutral current rating sufficient for the specified ground-fault current.
2. An overcurrent device having an interrupting rating suitable for the fault current available at its supply terminals and that will open simultaneously all ungrounded conductors when it operates shall be applied in the grounding autotransformer branch circuit.
3. The overcurrent protection covered immediately above shall be rated or set at a current not exceeding 125 percent of the autotransformer continuous per phase current rating or 42 percent of the continuous-current rating of any series-connected devices in the autotransformer neutral connection. Delayed tripping for temporary overcurrents to permit the proper operation of ground-responsive tripping devices on the main system shall be permitted but shall not exceed values that would be more than the short-time current rating of the grounding autotransformer or any series connected devices in the neutral connection thereto.

NOTE The 42 percent rule reflects the fact that the current in each phase is 33 percent of the neutral return current, and 125 percent of this is about 42 percent. An exception follows

for high-impedance grounded systems, for which the 125 percent rule is impracticable because the neutral current through the impedance is so low that 125 percent of this current does not come close to a conventional overcurrent device setting or rating.

For high-impedance grounded systems covered in NEC 250.36, where the maximum ground-fault current is designed to be not more than 10 A, and where the grounding autotransformer and the grounding impedance are rated for continuous duty, an overcurrent device rated not more than 20 A that will simultaneously open all ungrounded conductors shall be permitted to be installed on the line side of the grounding autotransformer.

125. Secondary ties. As used in this section, the word *transformer* means a transformer or a bank of transformers operating as a unit. A *secondary tie* is a circuit operating at 600 V or less between phases which connects two power sources or power supply points, such as the secondaries of two transformers. The tie may consist of one or more conductors per phase.

A. Tie Circuits. Tie circuits shall be provided at each end with overcurrent protection *according to the ampacity of the conductors*, except under the conditions described in Subparas. A1 and A2 of this section, in which cases the overcurrent protection may be in accordance with Subpara. A3 of this section.

1. *Loads at transformer supply points only.* If all loads are connected at the transformer supply points at each end of the tie and overcurrent protection is not provided, the rated ampacity of the tie shall be not less than 67 percent of the rated secondary current of the largest transformer connected to the secondary tie system.
2. *Loads connected between transformer supply points.* If a load is connected to the tie at any point between transformer supply points and overcurrent protection is not provided, the rated ampacity of the tie shall be not less than 100 percent of the rated secondary current of the largest transformer connected to the secondary tie system, except as otherwise provided in Subpara. A4.
3. *Tie-circuit protection.* Under the conditions described in Subparas. A1 and A2 of this section, both ends of each tie conductor shall be equipped with a protective device which will open at a predetermined temperature of the tie conductor under short-circuit conditions. This protection shall consist of one of the following: (1) a fusible-link cable connector, terminal, or lug, commonly known as a *limiter*, being of a size corresponding with that of the conductor and of construction and characteristics, according to the operating voltage and the type of insulation on the tie conductors, or (2) automatic circuit breakers actuated by devices having comparable current-time characteristics.
4. *Interconnection of phase conductors between transformer supply points.* If the tie consists of more than one conductor per phase, the conductors of each phase shall be interconnected to establish a load supply point, and the protection specified in Subpara. A3 shall be provided in each tie conductor at this point, except as follows:

Loads can be connected to the individual conductors of a paralleled conductor tie without interconnecting the conductors of each phase and without the protection specified in Subpara. A3 at load connection points, provided the tie conductors of each phase have a combined capacity not less than 133 percent of the rated secondary current of the largest transformer connected to the secondary tie system; the total load of such taps does not exceed the rated secondary current of the largest transformer, and the loads are equally divided on each phase and on the individual conductors of each phase as far as practicable.

5. *Tie-circuit control.* If the operating voltage exceeds 150 V to ground, secondary ties provided with limiters shall have a switch at each end which when open will deenergize the associated tie conductors and limiters. The current rating of the switch shall be not less than the rated current of the conductors connected to the switch. It shall be capable of opening its rated current, and it shall be constructed so that it will not open under the magnetic forces resulting from short-circuit current.

B. Overcurrent Protection for Secondary Circuits. When secondary ties are used, an overcurrent device rated or set at not more than 250 percent of the rated secondary current of the transformers shall be provided in the secondary connections of each transformer, and in addition an automatic circuit breaker actuated by a reverse-current relay set to open the circuit at not more than the rated secondary current of the transformer shall be provided in the secondary connection of each transformer.

126. Parallel operation. Transformers can be operated in parallel and switched as a unit if the overcurrent protection for each transformer meets the requirements of Sec. 122.

127. Guarding. Transformers shall be guarded as follows:

A. Mechanical Protection. Appropriate provisions shall be made to minimize the possibility of damage to transformers from external causes if the transformers are located where they are exposed to physical damage.

B. Case or Enclosure. Dry-type transformers shall be provided with a noncombustible moisture-resistant case or enclosure which will afford reasonable protection against the accidental insertion of foreign objects.

C. Exposed Energized Parts. The transformer installation shall conform with the Code provisions for guarding live parts.

D. Voltage Warning. The operating voltage of exposed live parts of transformer installations shall be indicated by signs or visible markings on the equipment or structures.

128. Ventilation. The ventilation shall be adequate to dispose of the transformer full-load losses without creating a temperature rise that is in excess of the transformer rating. Transformers with ventilating openings shall be installed so that the ventilating openings are not blocked by walls or other obstructions. The required clearances shall be marked on the transformer.

129. Grounding. Exposed noncurrent-carrying metal parts of transformer installations, including fences, guards, etc., shall be grounded and bonded where required under the conditions and in the manner specified for electrical equipment and other exposed metal parts in Parts V, VI, and VII of Article 250.

130. Marking. Each transformer shall be provided with a nameplate giving the name of the manufacturer, rated kilovolt-amperes, frequency, primary and secondary voltage, impedance if the transformer rating is 25 kVA or larger, required clearances for transformers with ventilating openings, and the amount and kind of insulating liquid where

used. In addition, the nameplate of each dry-type transformer shall include the temperature class of the insulation system.

131. Terminal wiring space. The minimum wire-bending space at fixed, 600-V and below terminals of transformer line and load connections shall be as required in cabinets as tabulated in Div. 12, Tables 33 and 34. Wiring space for pigtail connections shall comply with the requirements for box volumes discussed in Div. 9, Sec. 345 and tabulated in the NEC, Table 314.16(B).

132. Accessibility. All transformers and transformer vaults shall be readily accessible to qualified personnel for inspection and maintenance or they shall meet one of the following two conditions:

1. Dry-type transformers 600 V, nominal, or less, located in the open on walls, columns, or structures, shall not be required to be readily accessible.
2. Dry-type transformers 600 V, nominal, or less and not exceeding 50 kVA shall be permitted in hollow spaces of buildings not permanently closed in by structure, provided they meet the ventilation requirements of Sec. 128 and the separation from combustible materials requirements covered in Sec. 133.

PROVISIONS FOR DIFFERENT TYPES OF TRANSFORMERS

133. Dry-type transformers installed indoors. Transformers rated 112½ kVA or less shall have a separation of at least 300 mm (12 in) from combustible material unless separated therefrom by a fire-resistant heat-insulating barrier or unless of a rating not exceeding 600 V and completely enclosed with or without ventilating openings.

Transformers with a rating of more than 112½ kVA shall be installed in a transformer-room of fire-resistant construction unless they are constructed with class 155 or higher insulation systems and are separated from combustible material by not less than 1.83 m (6 ft) horizontally and 3.7 m (12 ft) vertically or are separated therefrom by a fire-resistant heat-insulating barrier; or are constructed with class 155 or higher insulation systems and completely enclosed, except for ventilating openings.

Transformers rated more than 35,000 V shall be installed in a vault.

134. Dry-type transformers installed outdoors. Dry-type transformers installed outdoors shall have a weatherproof enclosure. Transformers exceeding 112½ kVA shall not be located within 300 mm (12 in) of combustible materials of buildings unless the transformer has Class 155 insulation systems or higher and is completely enclosed, except for ventilating openings.

135. Less-flammable liquid-insulated transformers. Transformers insulated with listed less-flammable liquids that have a fire point of not less than 300°C shall be permitted to be installed in accordance with A or B below.

A. Indoor Installations. Indoor installations shall be permitted under any of the following three conditions:

1. In Type I or Type II buildings where the transformer is rated 35,000 V or less, no combustible liquids are stored, a liquid confinement area is provided, and the installation complies with all restrictions provided for in the listing of the liquid.
2. With an automatic fire extinguishing system and a liquid confinement area, provided the transformer is rated 35,000 V or less.
3. The installation meets the requirements for oil-insulated transformers installed indoors, as covered in Sec. 138.

B. Outdoor Installations. Less-flammable liquid-filled transformers shall be permitted to be installed outdoors, attached to, adjacent to, or on the roof of buildings, where installed in accordance with either 1 or 2 below.

1. For Type I or Type II buildings, the installation shall comply with all restrictions provided for in the listing of the liquid.
2. The installation meets the requirements for oil-insulated transformers installed outdoors, as covered in Sec. 139.

NOTE A listed less-flammable liquid is one which, when subjected to a source of ignition, may burn but the flame of which will not spread from the source of ignition. These liquids were developed to replace askarel. Askarel contains polychlorinated biphenyls (PCBs), and has been banned by the U.S. Environmental Protection Agency as a carcinogen.

136. Nonflammable fluid-insulated transformers. Transformers insulated with a dielectric fluid identified as nonflammable shall be permitted to be installed indoors or outdoors. Such transformers installed indoors and rated over 35,000 V shall be installed in a vault. Such transformers installed indoors shall be furnished with a liquid confinement area and a pressure relief vent. The transformers shall be furnished with a means for absorbing any gases generated by arcing inside the tank, or the pressure-relief vent shall be connected to a chimney or flue that will carry such gases to an environmentally safe area. For the purposes of this section, a *nonflammable dielectric fluid* is one that does not have a flash point or a fire point and is not flammable in air.

137. Askarel-insulated transformers installed indoors. Askarel-insulated transformers installed indoors and rated in excess of 25 kVA shall be furnished with a pressure-relief vent. If installed in a poorly ventilated place, they shall be furnished with a means of absorbing any gases generated by arcing inside the case, or the pressure-relief vent shall be connected to a chimney or flue which will carry such gases outside the building. Askarel-insulated transformers rated more than 35,000 V shall be installed in a vault.

138. Oil-insulated transformers installed indoors. Oil-insulated transformers shall be installed in a vault constructed as specified in Article 450 of the Code, except as follows:

A. Not over 112^{1/2}-kVA Total Capacity. The provisions for transformer vaults specified below apply, except that the vault may be constructed of reinforced concrete not less than 100 mm (4 in) thick.

B. Not over 600 V. A vault is not required, provided suitable arrangements are made when necessary to prevent a transformer oil fire from igniting other materials, and the

total transformer capacity in one location does not exceed 10 kVA in a section of the building classified as combustible or 75 kVA in a section classified as fire-resistant.

- C. *Electric-Furnace Transformers.*** Transformers of a total rating not exceeding 75 kVA may be installed without a vault in a building or room of fire-resistant construction if arrangements necessary to prevent a transformer oil fire from spreading to other combustible material are provided.
- D. *Charged Particle Accelerating Equipment.*** A transformer that has a total rating not exceeding 75 kVA and a supply voltage of 600 V or less that is an integral part of charged particle accelerating equipment shall be permitted to be installed without a vault in a building or room of noncombustible or fire-resistant construction, provided suitable arrangements are made to prevent a transformer oil fire from spreading to other combustible material.
- E. *Detached Buildings.*** Transformers may be installed in a building that does not conform with Code provisions for transformer vaults provided that neither the building nor its contents present a fire hazard to any other property and that the building is used only in supplying electric service and the interior is accessible only to qualified persons.
- F. *Portable and Surface Mining Equipment (Such as Electric Excavators).*** Oil-insulated transformers may be used without a vault if (1) provisions are made to drain leaking fluid to the ground, (2) safe egress is provided for personnel, and (3) personnel are protected with at least a 6.36-mm (1/4-in) steel barrier.

139. Oil-insulated transformers installed outdoors. Combustible material, combustible buildings and parts of buildings, fire escapes, and door and window openings shall be safeguarded from fires originating in oil-insulated transformers installed on roofs, or attached or adjacent to a building or combustible material. Space separations, fire-resistant barriers, automatic water-spray systems, and enclosures which confine the oil of a ruptured transformer are recognized safeguards. One or more of these safeguards shall be applied according to the degree of hazard involved where the transformer installation presents a fire hazard. Oil enclosures may consist of fire-resistant dikes, curbed areas or basins, or trenches filled with coarse crushed stone. Oil enclosures shall be provided with trapped drains if the exposure and quantity of oil are such that removal of oil is important.

140. Modification of transformers. When modifications are made to a transformer in an existing installation that change the type of the transformer with respect to this part of the article, such transformer shall be marked to show the type of insulating fluid installed, and the modified transformer installation shall comply with the applicable requirements for that type of transformer.

PROVISIONS FOR TRANSFORMER VAULTS

141. Location. Vaults shall be located where they can be ventilated to the outside air without using flues or ducts wherever such an arrangement is practicable.

142. Walls, roofs, and floors. The walls and roofs of vaults shall be constructed of reinforced concrete, brick, load-bearing tile, concrete block, or other fire-resistive

constructions, which have adequate structural strength for the conditions and a minimum fire resistance of 3 h according to Method for Fire Tests of Building Construction and Materials, ANSI/ASTM E119-1995, Standard Methods of Tests of Fire Endurance of Building Construction and Materials, NFPA 251-2006. The floors of vaults in contact with the earth shall be of concrete not less than 100 mm (4 in) thick, but where the vault is constructed with a vacant space or other stories below it, the floor shall have adequate structural strength for the load imposed thereon and a minimum fire resistance of 3 h. If transformers are protected with an automatic sprinkler, a water spray, halon, or carbon dioxide, construction may have a 1-h rating.

143. Doorways. Vault doorways shall be protected as follows:

- A. Type of Door.** Each doorway leading into a vault from the building shall be provided with a tight-fitting door of a type as defined in the National Fire Protection Association *Standard for the Installation of Fire Doors and Windows*, No. 80, 2007 with a minimum fire rating of 3 h. The authority enforcing the Code may require such a door for an exterior-wall opening when conditions warrant. If transformers are protected with an automatic sprinkler, a water spray, halon, or carbon dioxide, construction may have a 1-h rating.
- B. Sills.** A door sill or curb of sufficient height to confine within the vault the oil from the largest transformer shall be provided, and in no case shall the height be less than 100 mm (4 in).
- C. Locks.** Entrance doors shall be equipped with locks, and doors shall be kept locked, access being allowed only to qualified persons. Personnel doors shall swing out and be equipped with panic bars, pressure plates, or other devices that are normally latched but open under simple pressure.

144. Ventilation openings. When required by Sec. 129, openings for ventilation shall be provided in accordance with the following:

- A. Location.** Ventilation openings shall be located as far as possible from doors, windows, fire escapes, and combustible material.
- B. Arrangement.** Vaults ventilated by natural circulation of air may have roughly half the total area of openings required for ventilation in one or more openings near the floor and the rest in one or more openings in the roof or in the sidewalls near the roof, or all the ventilation area may be provided in one or more openings in or near the roof.
- C. Size.** In vaults ventilated to an outdoor area without using ducts or flues, the combined net area of all ventilating openings after deducting the area occupied by screens, gratings, or louvers shall be not less than 1900 mm^2 (3 in^2)/1 kVA of transformer capacity in service, except that the net area shall be not less than 0.1 m^2 (1 ft^2) for any capacity under 50 kVA.
- D. Covering.** Ventilation openings shall be covered with durable gratings, screens, or louvers, according to the treatment required to avoid unsafe conditions.
- E. Dampers.** All ventilation openings to the indoors are to be provided with automatic-closing dampers that operate in response to fire. Such dampers shall have a fire rating of not less than $1\frac{1}{2}$ h.
- F. Ducts.** Ventilating ducts shall be constructed of fire-resistant material.

145. Drainage. If practicable, vaults containing more than 100-kVA transformer capacity shall be provided with a drain or other means which will carry off any accumulation of oil or water that may collect in the vault unless local conditions make this impracticable. The floor shall be pitched to the drain where provided.

146. Water pipes and accessories. Any pipe or duct systems foreign to the electrical installation shall not enter or pass through a transformer vault. Piping or other facilities provided for vault fire protection or for water-cooled transformers are not deemed to be foreign to the electrical installation.

147. Storage in vaults. Materials shall not be stored in transformer vaults.

148. The following instructions (Secs. 150 to 177) are for procedures in installing, caring for, and operating transformers.

149. Location. Accessibility, ventilation, and ease of inspection should be given careful consideration in locating transformers. *Water-cooled transformers* depend almost entirely upon the flow of water through the cooling coils for carrying away heat, so that the temperature of the surrounding air has little effect upon that of the transformers. For this reason air circulation is of minor importance, and water-cooled transformers can be located in any convenient place without regard to ventilation.

150. Self-cooled (dry-type) transformers depend upon surrounding air for carrying away their heat. For this reason care must be taken to provide adequate ventilation. For indoor installation the room in which the transformers are placed must be well ventilated so that heated air can escape readily and be replaced by cool air from outside. Inlet openings should be near floor level and distributed to be most effective. The outlet or outlets should be as high above the apparatus as construction of the building will permit. The number and size of air outlets required will depend on their distance above the transformer and on the efficiency and load cycle of the apparatus. In general, about 20 ft² (1.86 m²) of outlet opening or openings should be provided for each 1000 kVA of transformer capacity. Air inlets should be provided with the same total area as the outlets. If the transformer must operate for considerable periods at continuous full load, areas of the inlet and outlet openings should be increased to about 60 ft² (5.57 m²)/1000 kVA of transformer capacity.

151. Storage. When a transformer can be set up immediately in its permanent location and filled with oil, it is advisable to do so even though it will not be put into service for some time. If this is not convenient, it should be stored in a dry place having no rapid or radical temperature changes and, if possible, filled with dry transformer oil. The transformer should not be stored or operated in the presence of corrosive gases such as chlorine. If an indoor transformer is stored outdoors, it should be thoroughly covered to keep out rain.

152. Handling. When a transformer is being lifted, the lifting cables must be held apart by a spreader to avoid bending the lifting studs or other parts of the structure.

If a transformer cannot be handled by a crane, it may be skidded or moved on rollers, but care must be taken not to damage the base or tip the transformer over. A transformer should never be lifted or moved by placing jacks or tackle under the drain valve, cooling-coil outlets, radiator connections, or other attachments. When rollers are used under large transformers, skids must be employed to distribute the stress over the base.

When working about a transformer, particular care must be taken in handling all tools and other loose articles, since anything metallic dropped among the windings and allowed to remain there may cause a breakdown.

153. Inspection preliminary to installation. Transformers are in first-class operating condition when shipped by the manufacturer; i.e., they have been thoroughly tested for defects and are perfectly dry. When received, they should be examined before removing the shipment, and if any injury is evident or any indication of rough handling is visible, a claim should be filed at once and the manufacturer notified.

Moisture may condense on any metal if the metal is colder than the air, and if present, it lowers the dielectric strength and may cause a failure of the transformer. Therefore, if transformers or oil drums are brought into a room warmer than they are, they should be allowed to stand before opening until there is no condensation on the outside and they are thoroughly dry.

Before installation, each individual transformer should be thoroughly examined for indications of moisture and inspected for breakage, injury, or displacement of parts during shipment. In addition, all accessible nuts, bolts, and studs should be tightened if necessary. Before being placed in service, transformers having a plurality of voltage connections should be carefully checked to ensure that they are connected for operation at the required voltage and on the proper tap.

It is a standard practice to ship transformers connected for their maximum voltage.

If transformers are water-cooled, the cooling coils should be tested for leaks at a pressure of 80 to 100 psi (551,581 to 689,476 Pa). Water, oil, or preferably air may be used in the coil for obtaining the pressure. The coil must be outside the tank, i.e., away from the winding insulation, if water is used for the pressure test. When pressure is obtained, the supply should be disconnected, and after 1 h it should be determined whether any fall in pressure is due to a leak in the coil or a leak in the fittings at the ends of the coil.

154. Transformers shipped filled with oil. Each transformer shipped filled with oil should be inspected to see whether there is any condition indicating the entrance of moisture during shipment.

If the transformer is received in damaged condition, so that water or other foreign material has had a chance to enter the tank, the transformer should be emptied of oil and treated as though not shipped in oil, and in no case may drying be omitted.

In all cases samples of oil should be taken from the bottom and tested. The dielectric strength of the oil when shipped is at least 22 kV between 1-in (25.4-mm) disks spaced 0.1 in (2.54 mm) apart. A new transformer should not be put into service with oil which tests below this value.

155. Transformers shipped assembled without oil. Each transformer shipped assembled but not filled with oil should be carefully inspected for damage in shipment. A thorough inspection can be made only by removing core and coils from the tank. All dirt should be wiped off and parts examined for breakage or other injuries. All conductors and terminals should be examined to check their proper condition and position. The coil and core clamps should be tightened if necessary.

The tank should be inspected and, if necessary, cleaned.

When a transformer is shipped assembled but not filled with oil, moisture may be absorbed during transportation. For this reason it is a good practice to dry out all such transformers, especially transformers above 7500 V, before putting them into service.

156. Transformers shipped disassembled. Only very large transformers are shipped in this way, and special instructions covering features incident to this method of shipping are supplied by the manufacturer. These instructions should be carefully followed.

157. Drying core and coils. There are a number of approved methods of drying out transformer core and coils, any one of which will be satisfactory if carefully performed. However, too much stress cannot be laid upon the fact that if the drying is carelessly or improperly performed, great damage may result to the transformer insulation through overheating.

The methods in use may be broadly divided into two classes:

1. Drying with the core and coils in the tank with oil.
2. Drying with the oil removed. The core and coils may or may not be removed from the tank.

158. Drying with oil in tank. Under the first class, the moisture is driven off by sending current through the winding while immersed in oil, with the top of the tank open to the air or with some other arrangement made for adequate ventilation. The current necessary for this class can be secured by the short-circuit method.

This method consists in heating the windings and oil up to a high temperature for a limited time under short circuit with a partial load on the windings, the high oil temperature being obtained by blanketing the tank (or by reducing the flow of water for water-cooled transformers).

When a transformer is short-circuited in this manner, only a fraction of the normal voltage should be applied to one winding. When this method is used, the load current and maximum top-oil temperature should be in accordance with the following tabulation.

During the drying run, ventilation additional to that ordinarily provided should be maintained by slightly raising the manhole cover and protecting the opening from the weather. With good ventilation, the moisture, as it is driven off in the form of vapor, will escape to the outside atmosphere, and no condensation of moisture will take place on the underside of the cover or elsewhere, provided these parts are lagged with heat-insulating material to prevent condensation of moisture within.

The accompanying table shows the short-circuit current in percentage of full-load current which can be used for this method of drying transformers, with the corresponding maximum allowable top-oil temperature in degrees Celsius. Less than 5 percent of normal voltage will usually be required to circulate the current in the windings.

Self-cooled transformers	Water-cooled transformers	Maximum top-oil temperatures, °C
Short-circuit ampere in percentage of full load		
50	50	85
75	60	80
85	75	75

These temperature limits and loads must be adhered to strictly to obtain the desired results without danger to the transformers.

It should be noted that the higher allowable temperatures go with the smaller loads; i.e., more blanketing or less water will be required for the smaller loads than for the higher to bring the oil temperature up to the point shown in the table.

159. When to discontinue drying. Drying should be continued until oil from the top and bottom of the tank tests 22 kV or higher for seven consecutive tests taken 4 h apart with the oil maintained at maximum temperature for the load held and without filtering. The testing of the oil for dielectric strength should be made between parallel 1-in- (25.4-mm-) diameter disks, spaced $\frac{1}{10}$ in (2.54 mm) apart. All ventilating openings should then be closed, the transformer kept at the same temperature for another 24 h without filtering the oil, and as before the oil should be tested at 4-h intervals. A decrease in the dielectric strength of the oil indicates that moisture is still passing from the transformer into the oil, and drying should be continued. The temperature of the oil samples when tested should preferably be at room temperature and not in excess of 40°C.

Unless constant or increasing dielectric strength as shown by these tests indicates that drying is complete, the ventilators should be opened, the oil filtered, and the drying process continued.

After the short-circuit run has been discontinued, the transformer should be operated for 24 h at approximately two-thirds voltage, and at the same high temperature, similar tests of oil samples should be made, and the oil filtered if necessary. After a satisfactory two-thirds-voltage test, full voltage should be applied for 24 h and the same tests repeated. Water-cooled transformers may require some water to hold the top-oil temperature within the 85°C limit during this test.

160. Drying with oil removed. Typical of the second class, i.e., drying with the oil removed, are the following three methods:

1. By internal heat
2. By external heat
3. By internal and external heat

1. By Internal Heat. For this method alternating current is required. The transformer should be placed in its tank without the oil and with the cover left off to allow free circulation of air. Either winding can be short-circuited, and sufficient voltage should be impressed across the other winding to circulate enough current through the coils to maintain the temperature at from 75 to 80°C. About one-fifth of normal full-rated current is generally sufficient to do this. The impressed voltage necessary to circulate this current varies within wide limits among different transformers but will generally be approximately 0.5 to 1.5 percent of normal voltage at normal frequency.

The end terminals of the winding, not taps, must be used so that current will circulate through the total winding. The amount of current can be controlled by a rheostat in series with the exciting winding. Proper precautions should be taken to protect the operator from dangerous voltage.

This method of drying out is superficial and slow and should be used only with small transformers and then only when local conditions prohibit the use of one of the other methods.

2. By External Heat. The transformer should be placed in a box with holes in the top and near the bottom to allow air circulation. The clearance between the sides of the transformer and the box should be small so that most of the heated air will pass up through the ventilating ducts among the coils and not around the sides. The heat should be applied at the bottom of the box. With some types of transformers it is better to distribute the heat evenly around the lower coils.

The best way to obtain the heat is from grid resistors, using either alternating or direct current. The temperature limits of ingoing air are 85 to 90°C. The transformer must be carefully protected against direct radiation from the heaters. Care must also be taken to see that there is no flammable material near the heaters, and to this end it is advisable to line the wooden box completely with asbestos. Also, when forced air is used, suitable baffles should be placed between heater and inlet to the transformer enclosure.

Instead of the heater being placed inside the box containing the transformer, it can be placed outside, the heat being carried into the bottom of the box through a suitable pipe. When this plan is followed, the heat may be generated by the direct combustion of gas, coal, or wood, provided that none of the products of combustion are allowed to enter the box containing the transformer. Heating by combustion is not advocated, except when electric current is not available.

This method, although effective, requires a much longer time than Method 3.

3. By Internal and External Heat. This is a combination of Methods 1 and 2. The transformer should be placed in a box and external heat applied as in Method 2, and current circulated through the windings as in Method 1. The current should, of course, be considerably less than when no external heat is applied.

This method is used occasionally when direct current only is available, a certain amount of current being passed through the high-voltage winding only, as the cross-sectional area of the low-voltage conductor is generally too large for it to be heated with an economical amount of direct current. The use of direct current for drying out is not recommended except when alternating current cannot be obtained. When this method of drying is used, the temperature should be measured by the increase-in-resistance method.

Method 3 requires technically skilled supervision.

161. Time required for drying. There is no definite length of time for drying. Up to 3 weeks may be required, depending upon the condition of the transformer, the size, the voltage, and the method of drying used.

162. Insulation resistance. The measurement or determination of insulation resistance is of value in determining the course of drying only when the transformer is without oil. If the initial insulation resistance is measured at ordinary temperatures, it may be high although the insulation is not dry, but as the transformer is heated up, it will drop rapidly.

As the drying proceeds at a constant temperature, the insulation resistance will generally increase gradually until toward the end of the drying period, when the increase will become more rapid. Sometimes the resistance will rise and fall through a short range one or more times before reaching a steady high point. This is caused by moisture in the interior parts of the insulation working its way out through the outer portions which were dried at first.

As the temperature varies, the insulation resistance also varies greatly; therefore the temperature should be kept nearly constant, and the resistance measurements should all be taken at as nearly the same temperature as possible. The insulation resistance in megohms varies inversely with the temperature, and, for a 10°C change of temperature, the megohms change by a ratio of 2:1. Measurements should be taken every 2 h during the drying period.

163. Resistance curve. A curve of the insulation-resistance measurements should be plotted with time as abscissa and resistance as ordinate. By observation, the knee of the curve (the point where the insulation resistance begins to increase more rapidly) can be determined, and the run should continue until the resistance is constant for 12 h.

The Allis-Chalmers Corporation further recommends that the insulation resistance should be as great or greater than that given by the following formula and that the megohm resistance should be taken with all windings grounded, except the winding being tested.

Megohms at 85°C in air or at 40°C in oil are equal to

$$\frac{kV \times 30}{\sqrt{kVA/cycles}}$$

where kV = kilovolts of winding involved and kVA = kilovolt-amperes of transformer per phase.

The megohms vary inversely with the temperature, and for a 10°C change of temperature the megohms change in the ratio of 2:1. For example,

Megohms at 85°C = 300

Megohms at 75°C = 600

Megohms at 55°C = 1200

Megohms at 55°C = 2400

164. Precautions to be observed in drying without oil. As the drying temperature approaches the point at which fibrous materials deteriorate, great care must be taken to see that there are no points at which the temperature exceeds 85°C. Several thermometers should be used, and they should be placed well in among the coils near the top and screened from air currents. Ventilating ducts offer particularly good places in which to place some of the thermometers. As the temperature rises rapidly at first, the thermometers must be read at intervals of about 1/2 h. To keep the transformer at a constant temperature for insulation-resistance measurements, one thermometer should be placed where it can be read without removing it or changing its position. The other thermometers should be shifted about until the hottest points are found and should remain at these points throughout the drying period. Whenever possible, the temperature should be checked by the increase-in-resistance method.

165. Caution in drying out. It is well to have a chemical fire extinguisher or a supply of sand at hand for use in case of necessity.

It is not safe to attempt the drying out of transformers without giving them constant attention.

166. Sampling and testing of oil. The sample container should be a large-mouthed glass bottle. All bottles should be cleaned and dried with gasoline before being used. A cork stopper should be used.

The sample for dielectric tests should be at least 16 oz (0.473 L); if other tests are to be made, 1 qt (32 oz, or 0.946 L).

Test samples should be taken only after the oil has settled for some time, varying from 8 h for a barrel to several days for a large transformer. Cold oil is much slower in settling

and may hardly settle at all. Oil samples from the transformer should be taken from the oil-sampling valve at the bottom of the tank. Oil samples from a barrel should be taken from the bottom of the drum. A brass or glass "thief" can be conveniently used for this purpose. The same method should be used for cleaning the thief as is used for cleaning the container.

When samples of oil are drawn from the bottom of the transformer or large tank, sufficient oil must first be drawn off to make sure that the sample will comprise oil from the bottom of the container and not from the oil stored in the sampling pipe. A glass receptacle is desirable so that if water is present, it can be readily observed. If water is found, an investigation of the cause should be made and a remedy applied. If water is not present in sufficient quantity to settle out, the oil may still contain considerable moisture in a suspended state. It should, therefore, be tested for dielectric strength.

For *testing oil for dielectric strength*, some standard device for oil testing should be used. The standard oil-testing spark gap has disk terminals 1 in (25.4 mm) in diameter spaced 0.1 in (2.54 mm) apart. The testing cup should be cleaned thoroughly, to remove any particles of cotton fiber, and rinsed out with a portion of the oil to be tested.

The spark-gap receptacle should be filled with oil, both oil and spark gap being at room temperature or approximately 25°C. After filling the receptacle, allow 1/2 to 1 min for air bubbles to escape before applying voltage.

The rate of increase in voltage should be about 3000 V/s. Five breakdowns should be made on each filling, and then the receptacle emptied and refilled with fresh oil from the original sample. The average voltage of 15 tests (5 tests on each of three fillings) is usually taken as the dielectric strength of the oil. It is recommended that the test be continued until the mean of the averages of at least three fillings is consistent.

The dielectric strength of oil when shipped is at least 22 kV tested in the standard gap. If the dielectric strength of the oil in a transformer in service tests at less than 17,500 V, it should be filtered. New oil of less than the standard dielectric strength should not be put in a transformer.

167. Drying oil and filling transformer. In removing moisture from transformer oil, it is preferable to filter from one tank and discharge into another, although if necessary oil may be drawn from the bottom of a tank and discharged at the top. When there is much water in the oil, it should be allowed to settle and then be drawn off and treated separately.

Before the transformer is filled with oil, all accessories, such as valves, gages, thermometers, plugs, etc., must be fitted to the transformer and made oiltight. The threads should be filled in accordance with instructions from the manufacturer before putting them in place. The transformers must be thoroughly cleaned.

Metal hose must be used for filling instead of rubber hose, because oil dissolves the sulfur found in rubber and may cause trouble if the sulfur attacks the copper.

The oil used should be clean, dry oil of the grade recommended by the manufacturer.

The use of a filter press is recommended, and if one is not available, some precaution should be taken to strain the oil before putting it in the transformer.

After filling the transformer, the oil should be allowed to settle at least 12 h, and then samples taken from the bottom should again be tested before voltage is applied to the transformer.

It is very important that the surfaces of the oil when cold (25°C) be at the oil level indicated by the mark on the oil gage. When the transformer is not in service, the oil level must never be allowed to fall to a point at which it does not show in the gage. When it is necessary to replenish the oil, care must be taken to see that no moisture finds its way into the tank. As the oil heats up with the transformer under load, it will expand and rise to a higher level.

168. Putting into service. When the voltage is first applied to the transformer, it should, if possible, be brought up slowly to its full value so that any wrong connection or other trouble can be discovered before damage results. After full voltage has been applied successfully, the transformer should preferably be operated in that way for a short period without load. It should be kept under observation during this time and also during the first few hours that it delivers load. After 4 or 5 days' service it is advisable to test the oil again for moisture.

If the transformer is *water-cooled*, the main water valve should be opened as soon as the oil temperature reaches 45°C. If there are two or more sets of cooling coils in parallel, the valves of all sections should be adjusted for equal rates of flow. This can be estimated by feeling the weight of the discharge streams from the different sections. It can be determined best, however, by noting the difference in temperature between ingoing and outgoing water from each section. A careful measure should be taken of the total amount of water flowing through all sections, and the total rate of flow should be adjusted to a value not less than that specified.

169. Care. The idea that a transformer in service needs no attention may lead to serious results. Careful inspection is essential, and the directions given in this section should be followed.

In spite of all precautions, moisture may be absorbed by the transformer if it is of the open type, and during the first few days of operation it is well to inspect the inside of the manhole cover for moisture. If sufficient moisture has condensed to drip from the cover, the transformer should be taken out of service and dried. The oil should be tested and dried if necessary.

Closed-type transformers should have their oil tested at top and bottom after the first few days of operation to make sure that no moisture is being given off from the transformer into the oil.

Samples of oil from all transformers should be drawn and tested at least once every 6 months or according to the manufacturer's recommendations.

During the first month of service of transformers having a potential of 40,000 V or over, samples of oil should be drawn each week from the bottom of the tank and tested.

If at any time the oil should test below 17,500 V, it should be filtered.

Closed-type transformers when properly dried out and installed will need thorough inspection only infrequently, i.e., only when there are specific indications of trouble. Other types of transformers should be taken out of service periodically for a thorough inspection. The inside of the cover and the tank above the oil should be regularly inspected to see that they are clean, dry, and free from moisture and that the thermometer bulb is clean. If an appreciable amount of dirt or sediment is found inside the case, it is best to untank the transformer and remove the oil from the tank. The transformer and the tank should then be cleaned thoroughly and the oil filtered and tested. In cleaning, only dry cloths or waste should be used. Care should be taken to see that all nuts are tight and that all parts are in their proper places. If the transformer is water-cooled, the cooling coils should be cleaned thoroughly. The transformer and the oil should be replaced in the tank, and when the cover is put on, all cracks and openings should be closed tightly.

In the case of water-cooled transformers the rate of flow should be checked from time to time, and if it is found to have diminished, the cause should be looked for and remedied. The most frequent cause of clogging of cooling coils is the presence of air in the water, resulting in the formation of a scaly oxide.

170. Removing scale from cooling coils. Scale and sediment can be removed from a cooling coil without removing the coil from the tank. Both inlet and outlet pipes should be disconnected from the water system and temporarily piped to a point a

number of feet away from the transformer where the coil can be filled and emptied safely. Special care must be taken to prevent any acid, dirt, or water from getting into the transformer.

All the water should be blown or siphoned from the cooling coils, which should then be filled with a solution of hydrochloric (muriatic) acid (specific gravity, 1.10). Equal parts of commercially pure concentrated hydrochloric acid and water will give this specific gravity.

It may be found necessary to force this solution into the cooling coils. When this is done, one end of the coil should be partially restricted, so that the solution will not be wasted when the coil is full. After the solution has stood in the coil about 1 h, the coil should be flushed out thoroughly with clean water. If all the scale is not removed the first time, the operation should be repeated until the coil is clean, using new solution each time. The number of times it is necessary to repeat the process will depend on the condition of the coil, though ordinarily one or two fillings will be sufficient.

As the chemical action which takes place may be very violent and may often force acid, sediment, etc., from both ends of the coil, it is advisable to leave both ends partially open to prevent abnormal pressure.

171. Idle cooling coils. When a water-cooled transformer is idle and exposed to freezing temperatures, the water must be blown out of the cooling oil. In addition to blowing out the water, the cooling coils should be dried by forcing heated air through them. If it is not convenient to do this, the coil should be filled with transformer oil.

172. Stopping oil leaks (Allis-Chalmers Corporation). Oil leaks at gasketed joints can often be stopped by tightening the bolts, but if this is not effective, new gaskets must be installed. Special cork is available for this purpose. An adhesive such as shellac, Bakelite varnish, or other suitable material should be used.

Oil leaks at welds can be stopped by peening, soldering, or welding. Peening is often effective for small stains, and soldering alone or a combination of peening and soldering will usually be effective with larger leaks. For this purpose a hard solder having a high melting point (about 365°F, or 185°C) can be used.

Leaks which cannot be stopped by any of these methods must be welded. When transformer tanks are welded with the core and coils in place, the oil should not be removed.

173. General operation. An artificially cooled transformer should not be run continuously, even at no load, without the cooling medium. Therefore, it is essential to maintain a proper circulation in the cooling system.

If the water circulation in a water-cooled transformer is stopped for any reason, the load should be immediately reduced as much as possible and close watch kept of the temperature of the transformer. When the oil at the top of the tank reaches 80°C, the transformer must be cut out of service at once. This temperature should be recognized as an absolute limit and must not be exceeded. It should be held only during an emergency period of short duration.

Nearly all cooling water will in time cause scale or sediment to form in the cooling coil. The time required to clog up the cooling coils depends on the nature and amount of foreign matter in the water. The clogging materially decreases the efficiency of the coil and is indicated by a high oil temperature and a decreased flow of water, load condition and water pressure remaining the same.

174. Temperature. Thermometers should be read daily or more often. If, at rated load or less, the oil temperature reaches 80°C for an oil-immersed, self-cooled transformer

or an oil-immersed, forced-air-cooled transformer or 65°C for an oil-immersed, water-cooled transformer, it is advisable to check operating conditions.

Oil-immersed, self-cooled transformers or oil-immersed, forced-air-cooled transformers should not be operated for long periods of time at oil temperatures in excess of 80°C on account of the increased rate of deterioration of the insulations. The oil temperature in these transformers should not be allowed to exceed 90°C even for short periods of time.

If the oil temperature in oil-immersed, water-cooled transformers should exceed 65°C at rated load or less, the cooling coils need cleaning, an insufficient amount of cooling water is being used, or the temperature of the cooling water is higher than 25°C. The oil temperature in oil-immersed, water-cooled transformers should not be allowed to exceed 75°C even for short periods of time. A lower oil temperature is recommended for oil-immersed, water-cooled transformers on account of the greater difference between the temperatures of the windings and of the oil than in oil-immersed, self-cooled transformers.

Regardless of oil temperatures as indicated by thermometers, transformers should not be operated continuously at overloads in excess of 1 percent for each degree that the ambient is below 30°C for air and 25°C for water. In no case should the overload exceed 30 percent for self-cooled transformers and 25 percent for water-cooled transformers unless stipulated by the specification or contract. During overloads the transformer should be watched with special care.

Moisture may get into an open-type transformer owing to the fact that as oil is heated and cooled, it expands and contracts, causing air to be expelled from and drawn into the transformer. If the air which enters the transformer is at the same time cooled by contact with the cover to below its dew point, moisture will condense.

It is therefore a good practice to operate transformers at several degrees above air temperatures at all times. This will largely prevent condensation.

175. Recommendations relative to pole-mounted transformers. In pole mounting, convenient lugs or eyebolts are provided on the side of the case to which the rope lifting the transformer may be attached. It will be found convenient to fasten the hanger irons to the case before the transformer is raised to the crossarm. The transformer can then be raised up to and slightly above the crossarm, and the hooks on the hanger irons can then be made to engage the crossarm by lowering the transformer.

Pole-mounted transformers may be filled with oil either before or after mounting, as desired. It is sometimes necessary to add oil a short time after the transformer has been installed, owing to the fact that the insulation will absorb a certain amount of oil. It may be found necessary to replenish the oil from time to time during actual operation so that the normal oil level is kept constant. When the transformer oil is replenished, care should be taken that no moisture finds its way inside the case.

Great care should be exercised in putting on the cover. If the gasket is not properly in place or the cover not securely bolted to the case, moisture in the form of snow or rain may be driven into the transformer tank.

It is very important that the surface of the oil when cold (25°C) be at the oil level indicated on the inside of the tank or on the oil gage.

The following practice is recommended for the care of pole-mounted distribution transformers in service:

1. The oil level should be inspected once every year, and enough oil added to bring the level up to the mark inside the tank or on the oil gage.
2. Periodically the condition of the oil should be inspected, and if necessary the oil should be removed and replaced with good clean oil.
3. A periodic check of the load should be made to ensure that the transformer is not being overloaded.

176. Care and operation of transformers immersed in nonflammable, non-explosive liquids are, in general, the same as for those which are oil-immersed. The liquid may be dehydrated and filtered by means of special equipment designed for the purpose. Regular oil-filtering equipment cannot be used. The same great care with respect to moisture must be taken with these transformers as with the regular types. The transformer cover should not be taken off in a manhole.

Precautions should be taken in handling the liquid, as it has an irritating effect upon the skin, more so to some persons than to others. Especially the eyes, nose, and lips are affected when coming in contact with the liquid, and safety precautions must be observed when handling it.

When a person handles the liquid or works on a transformer filled with the liquid, an application of castor oil is recommended for the eyes and castor oil or cold cream for the nose and lips. In case the liquid comes in contact with the skin, the part should be thoroughly washed and cleaned.

A person should be careful about looking down into the transformer case, as the liquid gives off a gas at 80°C which causes irritation to eyelids, nostrils, and lips. When a person works around one of these transformers, the hands should be coated with grease and the eyes, nose, and lips protected as advised above.

THE NOISE PROBLEM

177. Transformer noise. Transformers create noise when energized. Actually, the noise is a characteristic hum that is generated by vibrations in the laminated core structure. This hum has a fundamental frequency about twice that of the applied frequency. Its relative loudness to the ear is a function of transformer design and construction characteristics, the ambient noise level of the area where it is located, and the manner in which it is installed. In some applications, such as factories, transformer noise is masked by the higher level of surrounding noise, and it poses no problem. In low-noise-level or quiet areas (hospitals, schools, libraries, apartment buildings, office interiors, churches, etc.), transformer hum can be quite objectionable and cause serious concern. In fact, this became such an application problem that manufacturers improved transformer design and construction so that they now provide low-noise-level standard units and give them a definite sound rating in decibels.

178. Selection. The decibel (dB), a unit of measure of sound level, has become a key factor in the selection of transformers in areas where noise considerations are important. The following table of average ambient noise levels in common installation areas is the starting point:

Area	Average sound level, dB
Average home	30–45
Retail store	45–55
Office area (without machines)	45–70
Office area (with machines)	50–75
Average factory	75–95

To facilitate comparison, transformer manufacturers publish the sound-level ratings in decibels of their units as determined by prescribed standard test procedures.

179. Typical ratings are listed in the following table:

Transformer rating, kVA	Average sound level, dB
0–9	40
10–50	45
51–150	50
151–300	55
301–500	60

The tables in Secs. 179 and 180 comprise a handy reference when audible-noise considerations are a factor in transformer applications. It is a simple matter of comparing transformer noise with ambient noise. Knowing the average ambient sound level of the installation area, one can select a transformer with the proper sound rating (from the table or manufacturer's data). A basic selection rule is to choose a transformer with a decibel rating lower than the average decibel level of the area in question. Otherwise, the installed results might be disappointing.

One point must be kept in mind. The sound level of a specific transformer, measured and recorded under established test conditions at the factory, may be quite different after the unit has been installed. Because of location, mechanical and/or acoustical conditions, and mounting methods, the audible sound level may be considerably higher. The ultimate objective must be to keep the job-installed noise level of the unit below the area ambient noise level.

180. Carefully check the sound-level ratings of standard transformers, particularly when applications are to be made in areas of medium and low ambient levels. If ambient noise will be considerably higher than the transformer decibel ratings in the table in Sec. 179, there should be no problem. If the spread between transformer and ambient noise is not so great, careful attention must be given to installation. Often the combination of a sufficiently quiet standard unit and recognized noise-attenuating mounting methods will resolve the problem. However, if audible noise in specific areas is especially critical, it may be necessary to order special quiet-type transformers from the factory.

181. Noise attenuation. The manner in which a transformer is located and installed has a definite bearing on the overall audible noise level in the area. If the unit is mounted in such a way that the noise vibrations are transmitted to a large vibrating surface such as sheet metal or wood, the sound can be amplified to a higher level than the unit's decibel rating. Similar amplification occurs when the unit is located in the corner of a room or close to large reflecting surfaces which act like a megaphone and give the transformer hum an acoustical level boost. In some cases of poor mounting, a special quiet-type transformer can produce a louder sound output than that of a carefully mounted standard transformer.

Some experts claim that improper location and installation can increase transformer sound levels from 10 to 20 dB. Such a condition might easily become intolerable because a 3-dB increase in sound level reportedly has the effect of almost doubling the sound volume as detected by the human ear.

182. There are a number of basic installation precautions and mounting techniques which, if carefully noted and followed, will minimize the audible sound level of energized transformers. Some of the major considerations are:

1. **Proper Location.** This is the first consideration in a low-sound-level installation. To keep within or below prescribed area decibel limits:
 - a. Keep the transformer as far as possible from the area in which its noise would be most objectionable.
 - b. Avoid mounting the unit in a room corner up near the ceiling. Three-sided corners act as megaphones and amplify the sound.
 - c. Avoid installations in narrow halls and corridors or in corners of stairwells. The transformer sound reflected from the walls can become additive to the primary sound of the transformer and cause additional decibel buildup.
 - d. If feasible, experimental temporary operation and positioning of a free-standing transformer in a room or area will quickly indicate the best location and orientation of the unit.
 - e. If necessary, cover the walls of the transformer room with acoustical dampening material (fiberglass, acoustical tile, or similar absorbent materials), to reduce propagation of transformer noise from the room to any adjacent areas. It should be noted, however, that such material has a major effect on the high harmonics of transformer noise but little, if any, effect on the fundamental hum. Although there are special sound-insulating materials available for the 120-cycle frequency range, their present form and cost make them impractical for the above application.
2. **Transformer Mounting.** Mounting methods play an important role in control and reduction of the audible sound coming from the unit. The prime objective is to isolate the noise, that is, to prevent its mechanical transmission to the supporting structure and connected raceway system. This can be accomplished with one or a combination of the following installation techniques:
 - a. Use solid mounting when the transformer can be secured to a heavy, solid mass which cannot vibrate audibly. Such would be reinforced concrete for floor or wall.
 - b. For installation on a structural frame, wall, ceiling, or column, use the flexible-mounting technique, employing special vibration isolating pads called *flexible mounts* or vibration dampeners. There must be no solid-metal contact between the transformer and supporting surface; otherwise the vibration of the pads would be “short-circuited.” These external pads are furnished and installed by the installer. Internal vibration dampeners between the core-coil assembly and enclosure are or can be furnished by the manufacturer.
 - c. Use flexible connections between the raceway system and the transformer enclosure to prevent transmission of noise vibrations from the enclosure to the raceway system, panels, and other mechanical parts. Flexible metal conduit and liquidtight flexible metal conduit are frequently used for these relatively short coupling sections.

POLE AND PLATFORM MOUNTING

183. Mounting distributing transformers. Units of the smaller capacities are supported either directly on the poles or on crossarms in accordance with instructions furnished by their manufacturers. Refer to Sec. 40 and Figs. 5.23 to 5.28 for details of transformer mounting lugs, adapter plates, crossarm hangers, etc.

With some of the newer transformer designs single transformers up to 167 kVA can be mounted satisfactorily directly on a pole (see Figs. 5.77, 5.78, and 5.80). Three 50-kVA transformers of the proper design can be safely supported from the crossarm on a single pole. In crossarm mounting of transformers Gear and Williams recommend that for transformers of capacities larger than 20 kVA double crossarms should be used at the top, as the top arms carry most of the weight. “Where the installation consists of three 15-kVA or

FIGURE 5.77 Overhead-type conventional 25-kVA transformer with two high-voltage cover bushings. [Cooper Power Systems]

FIGURE 5.78 Overhead-type single-phase conventional transformer with two high-voltage sidewall bushings. [Cooper Power Systems]

FIGURE 5.79 Platform for large transformers.

FIGURE 5.80 Pole-mounted 30-kVA distribution transformer protected with conventional surge arrester and separate current-limiting fuse. [Cooper Power Systems]

larger transformers it is advisable to use a larger-sized crossarm than the standard. An arm having a cross section of 4 by 5½ in has been found ample for installations aggregating 90 to 100 kVA.” Gear and Williams state: “Where a large amount of power is needed which requires a number of 50-kVA units which cannot be conveniently installed inside the building, they can be safely and conveniently installed on a platform between two or more poles,” as shown in Fig. 5.79. A platform for supporting three 50-kVA units can be built by bolting in gains, between two poles, two 3- by 10-in planks and nailing to them a floor of 2-in plank. Transformers have standardized mounting bracket provisions to assure consistent mounting practices, as illustrated in Fig. 5.23 to 5.28.”

of the Pennsylvania Electric Association. The practices outlined were those followed by the Allegheny County Light Co. The methods provide ample clearances for persons climbing the poles and assure that the wiring will remain in place and not give trouble from short circuits. Platforms are recommended for supporting the larger transformers because of the accessibility for repairs or replacements that they provide.

184. Methods of crossarm and platform mounting of transformers.

The methods of mounting transformers described and illustrated in the following paragraphs were taken from *Report of the Committee on Overhead Line Construction*

185. Crossarm method of mounting single transformers of from 1- to 4-kVA capacity. The transformer should be supported by the iron hangers furnished by the manufacturer and hung at the central point on the crossarm and not out on the arm away from the pole. At the bottom of the hanger a section of an arm, not longer than the diameter of the pole, should be fastened to the pole with two lag bolts. The transformer can be hung on the bottom arm, if one is in place and supports lines, provided this arm is in the second gain or a lower one. The primary mains feeding the transformer should be on an upper arm.

In installations in which the transformers are more than 4 ft (1.2 m) below the arm supporting the primary mains, it is advisable to mount Western Union pins horizontally in the line arms. On these pins the primary wires can be tied to maintain them rigid. Iron pins should also be mounted in the transformer arm to take the stress imposed on the primary conductors by the fuse terminal screws.

186. Method of mounting transformers of from 5- to 10-kVA capacity (Fig. 5.81). The same rules should be followed as outlined in the preceding paragraph with the following additions. The transformers, on account of their increased weight and dimensions, should not be hung on a line arm. A specially placed arm should be used underneath existing arms and other apparatus. In addition to using the regular hangers which accompany transformers, a pair of iron braces 24 by 2 by ¼ in (610 by 51 by 6.35 mm)

FIGURE 5.81 Method of supporting a 5- to 10-kVA transformer.

should be placed between the transformer lugs and the hanger with the hanger bolts passing through one of the holes in the braces. These braces are to be run in an upward direction and fastened to the pole with a standard through bolt (see Fig. 5.81). If the arm weakens or entirely rots away, these two braces are of sufficient strength to support the transformer and permit crossarm replacement.

187. Method of mounting two 5-kVA or two 10-kVA transformers (Fig. 5.82). Construction similar to that described above should be used, except that a standard arm on which the hanger irons can rest should be placed at the bottom. Also, only one special brace (24 by 2 by 1/4 in) per transformer should be placed between the lug and hanger iron next to the pole.

FIGURE 5.82 Method of supporting two 5-kVA or two 10-kVA transformers.

FIGURE 5.83 Method of supporting three 5-kVA transformers.

188. Method of mounting three 5-kVA transformers (Fig. 5.83). The construction should be similar to that outlined in the preceding paragraphs, except that the special braces supporting the outside transformers are 33 in (838 mm) between centers of holes. It is also advisable to place an additional crossarm on the rear side of the pole. This arm braces the front arm and provides a place where fuse blocks can be mounted.

189. Method of mounting three 10-kVA transformers (Figs. 5.84 and 5.85). The construction is similar to that for three 5-kVA transformers with the following addition. The top arm supporting the transformers should be reinforced over its entire length with a piece of 5- by 3-in (127- by 76-mm) angle iron, which should be placed with the 3-in (76-mm) leg on the top of the arm.

190. Method of mounting two 20-kVA, two 30-kVA, or one 50-kVA transformer (Fig. 5.86). For transformers of these capacities a single-pole platform is recommended. The beams for the platform should be 4-in (101-mm) by 6-lb (2.7-kg) channel iron 8 ft (2.4 m) long. The braces used are a single piece of angle iron 3 by 3 by $\frac{3}{8}$ in (76.2 by 76.2 by 9.5 mm) bent in a V shape. Pine or oak planks 2 by 12 by 24 in (51 by 305 by 610 mm) are to be laid across the channel irons for the transformers to rest upon. The wooden platform is to be held together by a 2- by 2-in (51- by 51-mm) strip of wood running on the outside of the channel iron, to which the planks are secured by 4-in wood screws or 20-penny nails.

FIGURE 5.84 Method of supporting three 10-kVA transformers.

FIGURE 5.86 Single-pole platform for two 20-kVA, two 30-kVA, or one 50-kVA transformer.

191. Method of mounting three 20-kVA, three 30-kVA, two 50-kVA, or three 50-kVA transformers (Fig. 5.87). The poles should be spaced 10 ft (3 m) apart on centers. The main channel irons are 6 in (152 mm) by 10 lb (4.5 kg) by 10 ft 6 in (3.2 m) overall. Braces are of 3-in (76-mm) by 4-lb (1.8-kg) channel.

SATURABLE-CORE REACTOR

192. Saturable-core reactor. In many control circuits it is desirable to be able to control the value of the inductive reactance. This can often be accomplished advantageously by means of a device called a *saturable-core reactor*. A saturable-core reactor consists of a magnetic core associated with dc and ac windings. A common form of construction is shown in Fig. 5.88. When there is no current in the dc winding, the inductive reactance of the ac winding will be high, since there will be a high rate of change of flux with current. If sufficient direct current is passed through the dc winding to saturate the magnetic core, then the changing current in the ac winding will produce only very small changes in the flux of the core, and the inductive reactance of the ac winding will be very small. If the current of the dc winding is adjusted, the inductive reactance of the ac winding can be varied smoothly from practically zero to its maximum value. It might appear that a saturable-core reactor could be constructed with one ac and one dc winding on a common core. This simple construction would not be satisfactory, since the variations of the flux produced by the alternating flux would induce large voltages of changing magnitude in the dc winding. To be satisfactory, the reactor must be so constructed that the flux linked with the dc winding is not affected by the alternating current in the ac winding. This can be accomplished by the construction of Fig. 5.88. The currents in the two ac coils tend to produce flux in opposite directions through the central core on which the dc winding is wound. Therefore, the currents in the ac windings neutralize each other with respect to the production of flux linking with the dc winding.

FIGURE 5.88 Saturable-core reactor.

193. Transformer losses and the effect of harmonic currents on these losses (ANSI/IEEE C57.110-1986 Appendix). Power transformers with ratings up to 50 MVA are almost always of core form construction. High-voltage and low-voltage windings are concentric cylinders surrounding a vertical core leg of rectangular or circular cross section. The vertical core legs and the horizontal core yoke members that constitute the magnetic circuit are made up of thin steel laminations. In the top and bottom yoke regions there are usually external clamping structures (clamps) that may be made of either metallic or insulating materials. Oil-immersed transformers may be either free-standing or surrounded by a metal enclosure.

If direct current is passed through the transformer winding conductors, a simple I^2R loss will be produced, where R is the dc resistance of the winding. However, if an alternating current (ac) of the same magnitude is passed through the winding conductors, an additional loss is produced. This can be explained as follows.

When transformer windings carry the ac current, each conductor is surrounded by an alternating electromagnetic field whose strength is directly proportional to the magnitude of the current. Each metallic conductor linked by the electromagnetic flux experiences an

internal induced voltage that causes eddy currents to flow in that conductor. The eddy currents produce losses that are dissipated in the form of heat, producing an additional temperature rise in the conductor over its surroundings. This type of extra loss beyond the I^2R loss is frequently referred to as *stray loss*. Although all of the extra loss is an eddy-current loss, the portion in the winding is usually called *eddy-current loss* (P_{EC}), and the portion outside the windings is called *other stray loss* (P_{OSL}).

Eddy-current loss in winding conductors is proportional to the square of the electromagnetic field strength (or the square of the load current that produces the field) and to the square of the ac frequency. Other stray losses are generally proportional to current raised to a power slightly less than 2, because the depth of penetration of the electromagnetic flux into the other metallic parts (usually steel) varies with the field strength. (For very high frequency harmonic currents the electromagnetic flux may not totally penetrate winding conductors either, but it is conservative to assume that the eddy-current loss, P_{EC} , is proportional to the square of the harmonic current magnitude.)

When a transformer is subjected to a load current having significant harmonic content, the extra eddy-current loss in winding conductors and in other metallic parts will elevate the temperature of those parts above their normal operating temperature under rated conditions. Experience has shown that the winding conductors are the more critical parts for determination of acceptable operating temperature, so that objective should be to prevent the losses in winding conductors under harmonic load conditions from exceeding the losses under rated 60 Hz operating conditions.

The inner winding of a core form transformer typically has higher eddy-current loss than the outer winding, because the electromagnetic flux has a greater tendency to fringe inwardly toward the low reluctance path of the core leg. Furthermore, the highest local eddy-current loss usually occurs in the end conductors of the inside winding. This is a result of the fact that this is the region of highest radial electromagnetic flux density (closest spacing of the radially directed flux lines) and the radial flux passes through the width dimension of the rectangular winding conductor. Since the width dimension of a conductor is typically 3 to 5 times the thickness dimension, the thickness dimension and eddy-current loss is produced in the end conductors.

Harmonic currents flowing through transformer leakage impedance and through system impedance may also produce some small harmonic distortion in the voltage waveform at the transformer terminals. Such voltage harmonics also cause extra harmonic losses in the transformer core. However, operating experience has not indicated that core temperature rise will ever be the limiting parameter for determination of safe magnitudes of nonsinusoidal load currents.

194. Underwriters Laboratories transformer ratings.³ A K-factor rating is optionally applied to a transformer indicating its suitability for use with loads that draws nonsinusoidal currents. A transformer intended for use with loads drawing nonsinusoidal currents may be marked "Suitable for nonsinusoidal current load with K-factor not to exceed _____." The blank shall be filled in with K-factor rating of 4, 9, 13, 20, 30, 40, or 50.

(The following analysis is adapted from *Practical Electrical Wiring*, 20th edition, © Park Publishing, 2008, all rights reserved.) The K factor required is based on an analysis of how much current is flowing at each harmonic frequency. Look at the per-unit rms current at each given harmonic h and square it, and then multiply each result by the square of the harmonic order involved. The K factor is the summation of those results over the range of applicable harmonic orders. For example, suppose for a unit 1 A rms load, a harmonic analysis shows that it

³ This material is reproduced with the permission of Underwriters Laboratories, Inc.[®], Copyright ©1995.

comprises 0.91 A at 60 Hz (first order), 0.34 A at 180 Hz (third order), 0.22 A at 300 Hz (fifth order), 0.11 A at 420 Hz (seventh order), and 0.05 A at 540 Hz (ninth order). The even order harmonics generally cancel. Remember that these currents are not in phase, and do not add arithmetically (hence seeming to add to more than 1). Square each of these numbers, multiply each one by the square of the harmonic order (1, 9, 25, 49, 81, respectively), and add the results together. The result (3.97) points to a K-4 rating for this application.

195. Measurement of harmonics. The measurement of nonsinusoidal voltages and currents may require equipment different from the conventional meters used to measure sinusoidal waveforms. Many voltage and current meters respond only to the peak value of a waveform, and indicate a value that is equivalent to the rms value of a pure sine wave. For a sinusoidal waveform, the rms value will be 0.707 times the peak value. Meters of this type are known as *average responding meters* and will only give a true reading if the waveform being measured is sinusoidal. Both analog and digital meters may be average responding instruments. Voltages and currents which are nonsinusoidal, such as those with harmonic frequencies, cannot be accurately measured using an average responding meter. Only a meter (see Fig. 5.89 for an example) that measures “true rms” can be used to correctly measure the rms value of a nonsinusoidal waveform.

When measuring a nonsinusoidal waveform, it is often desirable to also know the magnitude of each frequency present. To accomplish this, a *harmonic analyzer* is necessary. An *analog harmonic analyzer* is a voltage measurement instrument that uses selective filtering to tune out all frequencies, except the one being analyzed.

With the widespread use of microprocessors, and recent advances in digital data acquisition, the analog analyzers have been superseded by analyzers capable of digital harmonic analysis. The most popular harmonic analyzers today use a Fast Fourier Transform (FFT) technique to break down a complex waveform into its individual frequency components. The FFT is a useful tool for quickly performing a Fourier analysis on a block of sampled data. FFT-based harmonic analyzers also have the ability to display the phase as well as magnitude of each frequency present. Current transformers and clamp-on ammeters easily adapt to digital harmonic analyzers, making current as well as voltage harmonic measurements a simple procedure.

FUNDAMENTALS OF ELECTRONICS

1. From vacuum tubes to transistors. The *science of electronics* was founded on the ability of the electron tube (most importantly, the vacuum tube) to generate, amplify, and control an electric signal to accomplish a wide variety of functions. During its half-century dominance of the electronics art, the vacuum tube fostered the invention of radio, television, and radar, of factory automation and computers, and indeed of all the phenomena that we associate with electronics even today. Yet, with the invention of the transistor by Bell Laboratories in 1948, the tube was headed for extinction. Today, except for a few special functions, it no longer occupies an important place in electronic technology.

In place of the electron tube, the transistor has emerged as the cornerstone of modern electronics. Based on the theory of electron conduction in a solid crystalline material rather than in a vacuum or a gaseous environment, the transistor not only can perform virtually all the functions formerly associated with the tube, it can do them faster, more cheaply, and more reliably. Moreover, it occupies an infinitesimally small amount of space and, unlike the tube, requires no power-wasting filament that ties large equipment to the commercial power lines.

The dramatic effects of these advantages are most readily evident in the field of computers. The most advanced computer in the vacuum-tube era costs millions of preinflation dollars; consisted of an entire roomful of equipment utilizing tens of thousands of vacuum tubes; required a power plant just to heat the filaments and an air-conditioning plant to keep the computer cool; was difficult to keep in operation owing to vacuum-tube failures; and had less capability than today's simple calculator, which fits into a vest pocket, requires only an occasional battery replacement, and is thrown away at the first sign of trouble because of its low replacement cost.

But while the transistor is the cornerstone of today's electronics technology, it is not, in itself, the means for accomplishing the exponential expansion of electronic-capabilities

since the mid-1970s. That distinction is reserved for the invention and development of integrated circuits.

2. Integrated circuits. There are two types of integrated circuits (IC) in use today: monolithic and hybrid.

A monolithic IC consists of a semiconductor substrate, called a *chip* or *die*, in which all necessary active and passive components are formed and interconnected to perform a desired circuit function (Fig. 6.1*a*). The chip is then encased in a suitable package, which may subsequently be interconnected on a printed-circuit board with other monolithic ICs and/or discrete components to form circuits of greater scope and complexity.

A hybrid IC (Fig. 6.1*b*) consists of an insulating substrate with deposited passive elements (resistors and capacitors) and metallized interconnected patterns, to which active elements are

(a)

(b)

FIGURE 6.1 (a) A modern monolithic microprocessor integrated circuit contains upward of 70,000 transistors on a tiny silicon die. (b) An example of a hybrid circuit utilizes power transistor chips and integrated circuits with deposited passive elements on an insulating substrate in a radio-frequency amplifier module. [Motorola Inc.]

added in uncased chip form either by wire bonding or by other die-attachment techniques. The active elements may be discrete devices or monolithic ICs. Hybrid circuits can be considerably smaller than circuits of equivalent complexity made by interconnecting the same components in encapsulated form on a more conventional printed-circuit board. However, they do not have most of the major attributes of monolithic ICs and are utilized principally where size reduction is required but where the required performance cannot be built into a monolithic structure.

3. Characteristics of monolithic integrated circuits

Size and Weight Reduction. Monolithic integrated circuits consist of a number of transistors and associated resistors fabricated and interconnected within the same monolithic piece of solid semiconductor material. Since these functional elements are fashioned by a slight change in the atomic structure of the material rather than by the addition of actual physical elements, the dimensions of these elements are so small that it is possible today to fabricate and interconnect tens of thousands of individual components within a piece of material no larger than the fingernail of a small child. And researchers are already anticipating circuits of million-transistor complexity within a single monolithic building block of similar dimensions.

Obviously, it is the size and weight reduction of integrated circuits, compared with equivalent vacuum-tube circuits (or even those made from individual discrete transistors), that has put the power of a full-scale computer into a pocket or purse. But size and weight reduction have long ceased to be the principal objectives on integrated circuits. Though vitally important in certain applications such as medical electronics and space apparatus, the physical characteristics of equipment are dictated more by the dimensions of the peripherals—the display and keyboard of calculators and computers, the loudspeakers and picture tubes of radio and TV, etc.—than they are by the associated electronics. Indeed, the size and weight advantages of integrated circuits would be of limited importance if they were not paced by corresponding reductions in cost and the improvements in component reliability and circuit performance.

Cost Reduction. The cost of the active elements associated with transistors, particularly transistors within complex integrated circuits, borders on the insignificant. This is so because semiconductor devices are made by batch processing, in which individual manufacturing processes operate not on a single device but simultaneously on a batch of devices ranging from hundreds of integrated circuits to thousands of discrete transistors. The basic cost of such devices therefore reflects primarily the packaging, testing, and marketing such devices rather than the raw materials or manufacture of the basic element. As a result, discrete small-signal transistors can be purchased for only pennies (in large quantities), and complex ICs housing up to thousands of fully interconnected transistors are available for only a few dollars. Each transistor serves the function of an erstwhile vacuum tube, whose individual cost equaled or exceeded that of many of today's complex ICs. It is clear therefore that an attempt to duplicate the functions of today's very-large-scale integrated circuits (VLSI circuits) before the era of semiconductor technology would have priced the resulting equipment out of the market.

Improved Reliability. Semiconductor electronics is based on the movement of free electrical particles (electrons and holes) within a loop of solid materials. Once such particles have been introduced into the material during manufacture, their movement can be controlled but the particles themselves cannot be destroyed. The basic semiconductor device therefore has no inherent wear-out mechanism. While the packaging of semiconductor devices does introduce some potential failure modes and while such devices can be damaged

through overvoltage and excessive heat, modern manufacturing technology and circuit design techniques have reduced such failures almost to the vanishing point. It is this attribute of semiconductors that makes possible today's highly complex electronic equipment utilizing millions of transistors.

Improved Performance. While transistors have replaced vacuum tubes in most applications, there are a few application areas in which tubes still dominate. Primarily, these are the areas of very high power and very high (microwave) frequencies. Since ICs are based on transistor technology, it is clear that they have not yet penetrated these applications to a significant degree. In all other applications, particularly those involving complex circuitry utilizing many transistors, the IC not only represents the most cost-effective component but also provides the best performance.

This performance advantage is the result of the close spacing between transistors within the monolithic substrate of the IC, which greatly reduces signal-propagation delay within a large system. Propagation-delay time is composed of two constituents: (1) the time required for a circuit stage (transistor) to perform its operation and (2) the time required for the signal to travel to the succeeding stage or stages. In the early days of transistors, the reaction time of the transistor was relatively slow so that interstage travel time was not a significant factor in total propagation delay. Today's transistors, however, can operate at subnanosecond speeds. Thus, even if we assume that a signal travels along its conductive path between transistors with the speed of light (approximately 1 ft/ns), signal travel time through large systems composed of discrete transistors can become a significant part of the total delay. Within ICs, the spacing between transistors can be held to a few micrometers, eliminating travel time as a major factor of overall operating speed for most electronic applications.

DISCRETE SOLID-STATE COMPONENTS

Integrated circuits have penetrated all digital electronic equipment. They are still limited, however, in the amount of power they can produce, and their uses in linear applications have not yet been fully exploited. Discrete solid-state components therefore are still very much in evidence, and there is no indication that their use rate will diminish significantly in the immediate future.

Among the most prevalent discrete components are transistors themselves (both signal transistors and power transistors), as well as zener diodes and rectifiers, thyristors, and a growing family of transducers such as light-, temperature-, and pressure-activated devices. Most of the nontransistor components had counterparts in the electron-tube era, but they are subject to the same benefits of smaller size, improved performance, greater reliability, and lower cost when converted to the solid state.

4. Fundamentals of solid-state devices. Solid-state devices, whether discrete or IC, are fabricated from semiconductor materials, so named because their conductivity lies somewhere between that of a conductive material and that of an insulator. While a variety of semiconductor materials (germanium, selenium, copper oxide, etc.) have been used to fabricate solid-state devices in the past and still others (notably gallium arsenide) are coming into limited use for special purposes, the most common material in current use is silicon. This material is used for both discrete components and integrated circuits. A basic understanding of its properties therefore is essential to an understanding of today's solid-state devices.

The Silicon Atom. From an electrical standpoint, the silicon atom (Fig. 6.2) consists of a nucleus containing 14 protons (each with an electrical charge of +1) and three orbital rings

FIGURE 6.2 (a) A diagram of a silicon atom shows a nucleus of 14 protons and 14 neutrons and three orbital rings containing a total of 14 electrons. (b) The electrical equivalent of the silicon atom.

housing a total of 14 electrons (each with a charge of -1), which electrically neutralize the protons of the nucleus. The outermost ring contains four electrons. Since the electrons in the two inner rings are tightly bound to the nucleus, they contribute nothing to the electrical properties of the atom and therefore can be disregarded. The four outer-ring electrons, however, are loosely bound to their neutralizing protons and can easily be dislodged from their orbits by some external force.

The Crystal Structure. The atoms of silicon tend to arrange themselves into a crystal structure. With proper processing, the material can be of single-crystal form, in which all the atoms are arranged in a continuous, well-ordered lattice (Fig. 6.3), whereby each of the four outer-ring electrons associated with one atom forms a bond with one of the electrons

FIGURE 6.3 Symbolic diagram (a) and schematic representation (b) of a pure silicon lattice structure. Covalent bonds between adjacent atoms firmly fix all electrons in their respective orbits, rendering the structure nonconductive at very low temperatures.

of a neighboring atom so that every electron of every atom is tightly bound within the crystal lattice. Thus, while the four outer electrons of an individual silicon atom can easily be removed by an external force, once they have been bound in the lattice, they are very difficult to dislodge. Intrinsic (pure) single-crystal silicon therefore behaves like an insulator at very low temperatures.

Electrons and Holes. As temperature is raised, however, thermal energy is imparted to the lattice structure, causing it to vibrate. When this occurs, electrons at random points throughout the crystal gain enough energy to break their bond and become free to wander through the lattice. Wherever such a bond is broken, a hole is left in the lattice. And because a hole is caused by an electron leaving the orbit of a particular atom, that atom becomes a positive ion with an electrical charge of +1.

At any given temperature above absolute zero, there will be a given number of electrons that gain enough energy to break the covalent bond. The higher the temperature, the greater the number of broken bonds; hence the greater the number of electron-pole pairs scattered throughout the crystal. These electrons and holes can be regarded as charge carriers which are free to move through the crystal lattice. The electrons represent negative charges; the holes, positive charges.

Once liberated from its covalent bond, an electron moves at random through the lattice until it happens to land in the vicinity of a hole in the structure. Now the hole, having a positive charge, will have an attracting influence on the negative electron, which, when sufficiently close, will jump into the hole. As a result, both the hole and the electron will disappear as free charges within the crystal.

A hole, too, is free to move through the crystal lattice. When a hole is formed, it will affect an attracting force on electrons in covalent bonds in the immediate vicinity because of its positive charge. Since, in a vibrating lattice, these bonds are none too tight, the energy gained by an electron in an adjacent bond, coupled with the attracting force of the hole, will cause the electron to break its bond in order to fill the hole. Note that the hole itself has not disappeared; it has merely moved to an adjacent atom. In this way, the hole, too, can move at random throughout the crystal. Not until the hole meets a free electron recombination will take place and cause both hole and electron to disappear as free charges.

For every hole-electron pair that is generated at one point in the lattice, there will be recombination of a free hole and electron at another point; and for every recombination, another hole-electron pair will be generated elsewhere. At any given temperature, therefore, there will always be a predictable number of carriers, both positive and negative, within the lattice, and the higher the temperature, the greater the number of free charges in the material. But it is interesting to compare the number of free charges with the total number of atoms in the silicon material. Intrinsic silicon has 5×10^{22} atoms per cubic centimeter. At room temperature (25°C), approximately 1.5×10^{10} of these atoms are ionized. Therefore, there is only one hole and one free electron for approximately every 3 trillion atoms in the crystal structure.

As the temperature is increased, the number of free carriers increases proportionally and the silicon's electrical resistivity is decreased proportionally.

5. Impurity concentrations in silicon. The only major electrical characteristic of intrinsic silicon is a temperature-sensitive resistance which (except, perhaps, as a temperature-sensing element) is undesirable in any actual use. To utilize the properties of a semiconductor material, it is necessary to introduce additional charge carriers deliberately into the intrinsic semiconductor lattice. This is done by introducing impurity atoms into the structure. If the number of charge carriers introduced by these impurity atoms is much

larger than the number of charge carriers resulting from thermal agitation of the lattice, the temperature sensitivity of the material is reduced to practical limits.

Two types of impurity atoms are of primary importance: those with three electrons in their outer rings, such as boron; and those with five electrons in their outer rings, such as phosphorus.

P-Type Material. If an atom of boron is substituted for a silicon atom in the lattice structure, the electrons of the boron atom can form covalent bonds with only three adjacent silicon atoms. Since the fourth silicon atom of the crystal structure is not symmetrically bound in the lattice, a defect exists in the lattice structure. This defect takes on the characteristics of a hole. This hole, by virtue of capturing an electron from another adjacent silicon atom, will move through the lattice in the form of a positive charge.

Impurity atoms having three electrons in the outer ring are called *acceptor atoms*, because such impurities will accept electrons from the silicon lattice. Silicon doped with acceptor atoms is called *p*-type silicon, indicating that the resulting charge carriers are holes having a positive charge.

Although the thermally generated holes in heavily doped *p*-type material have a negligible effect on the characteristics of the material, their number being small in comparison with the impurity-caused holes at normal temperatures, the thermally generated electrons do play an important part in semiconductor devices. Because their number is small compared with the number of holes, free electrons in *p*-type materials are called *minority carriers*. The holes, for obvious reasons, are called *majority carriers*.

Now if an electrical force, e.g., a battery, is applied across a *p*-type material, the holes will appear to drift toward the negative terminal of the battery and the free electrons will drift toward the positive terminal. Because the number of majority carriers predominates, conduction in doped semiconductor material is majority-carrier conduction or, in this case, *p*-type conduction.

N-Type Material. If an intrinsic piece of silicon is doped with an impurity atom having five electrons in its outer ring, only four of the impurity atom's electrons can form covalent bonds with the silicon atoms; the fifth, being very loosely bound in the lattice, is free to detach itself from the impurity atom and wander through the lattice as a negative charge. In this case, however, the free electron is not balanced by a corresponding hole because the crystal lattice is unbroken. Under this condition, the material has an excess of free negative-charge carriers and is called *n*-type material. Still, the material remains electrically neutral because the detached electron leaves a positive phosphorus ion in its wake. Impurity atoms that produce *n*-type material are called *donor atoms*.

The *n*-type material behaves very similarly to the *p*-type material just described. The majority carriers in this case are, of course, electrons. The minority carriers are holes generated by thermal excitation.

6. *P-n* junctions and their characteristics. When two oppositely doped materials are fused to form a *p-n* junction, free electrons from the *n* side and free holes from the *p* side of the junction migrate across the junction to combine with the oppositely charged carriers in the regions near the junction. Since both materials are originally electrically neutral, this migration and subsequent combination create a small electrical potential across the junction, the *p* side becoming slightly negative and the *n* side becoming slightly positive (Fig. 6.4a). This "space charge" in the vicinity of the junction quickly reaches an equilibrium condition in which the acquired negative charge on the *p* side prohibits any further migration of electrons from the *n* region and the acquired positive charge on the *n* side repels any further incursion of holes from the *p* side.

FIGURE 6.4 Junction characteristics. (a) An unbiased junction. (b) A forward-biased junction permits nearly unrestricted current flow. (c) A reverse-biased junction represents high resistance to majority carriers.

When an external voltage is applied across the junction, the equilibrium condition is altered. With the voltage connected as shown by the battery in Fig. 6.4*b* (positive to the *p* side, negative to the *n* side), some of the excess electrons that originally migrated from *n* to *p* are drawn out of the material and the voltage barrier at the junction is reduced. As a result, majority carriers from both sides can move freely and continuously across the junction. Under this condition, the junction is *forward-biased* and represents little resistance to the flow of current.

Conversely, if the potential of the battery is reversed (negative to the *p* side, positive to the *n* side; Fig. 6.4*c*), electrons from the battery enter the *p* region and fill in more of the holes in that region. This increases the potential across the junction and prevents the migration of majority carriers across the junction. The junction is then *reverse-biased* and represents a very high resistance to the flow of current.

But while a reverse-biased junction is a high resistance to majority carriers, it is a very low resistance to minority carriers. These can cross the junction quite easily and form a *leakage current*. Since the number of minority carriers in doped semiconductor material is quite small, the leakage current is correspondingly small.

Rectification. From the foregoing, it is evident that a semiconductor junction has the properties of a rectifier, permitting a current flow when biased in one direction and prohibiting a

FIGURE 6.5 Junction current versus voltage characteristics. Note that the reverse bias is measured in microamperes and is virtually independent of voltage until breakdown V_B is reached.

current flow (except for leakage) when biased in the other direction. The voltage-current characteristics of such a junction are shown in Fig. 6.5. Here it is seen that, when biased in the forward direction, the current rises quickly as the applied voltage is raised. The bend in the curve at low voltage is due to the fact that the externally applied voltage must neutralize the space charge before full current is permitted to flow. Thereafter, however, the current flow is directly proportional to the applied voltage, being limited only by the bulk resistivity of the material itself.

Biased in the reverse direction, the current is seen to be extremely small (leakage) until a breakdown point is reached. At that point, current flow increases greatly for any small increase in voltage. Unless current is limited by an external resistance, the junction can be destroyed.

Capacitance Effect. A capacitor is formed when two conductors are separated by an insulator (dielectric) across which a difference of potential can exist. For a p - n junction, with no applied external voltage, the region in the immediate vicinity of the junction is depleted of free current-carrying charges. This is so because any mobile electrons near the junction in the n region have migrated across the junction to combine with the mobile holes in the p region. With the junction area thus depleted of free-charge carriers, the region can be considered to be an insulator. This region, however, is bounded at each end by a conductive region of p - and n -type material in which there are numerous free charges (holes and electrons, respectively), so that the structure fits the definition of a capacitor.

The value of the capacitance is a function of the area of the junction (die size), the resistivity of the material (determined primarily by the doping level of the high-resistivity side of the structure), and the voltage applied across the junction. For a reverse-biased junction, this capacitance decreases as the reverse voltage is increased. This is so because an increase in reverse bias increases the width of the depletion area near the junction, thereby widening the dielectric region between the two conductive regions of the structure.

The capacitance associated with a p - n junction represents a limiting factor on the frequency response of semiconductor devices. However, in some devices, such as varactor diodes, it is utilized for constructive purposes.

7. Practical applications for *p-n* junctions. A simple *p-n* junction forms the nucleus of a number of practical semiconductor components. Among the most prevalent are signal and rectifier diodes, zener and reference diodes, and varactor diodes.

Rectifier Diodes. The characteristics of a *p-n* junction are utilized most extensively in the half-wave rectifier diode to convert an ac voltage (or current) into pulsating direct current (Fig. 6.6). This characteristic is used in power supplies, demodulator circuits of AM radios, signal clippers, square-wave generators, and a variety of other applications. Many of these functions, particularly those associated with small-signal applications, are currently being combined with other circuit functions in integrated circuits, so that the use of such diodes in discrete form is diminishing. The primary exception is the rectifier diode for power supplies, which is required to pass relatively high currents and is not yet replaceable with ICs. The selection of such rectifiers, in both capabilities and packaging, continues to expand.

The use of silicon rectifiers in the most popular power supply configurations, as well as the more important circuit characteristics, is shown in Fig. 6.7.

FIGURE 6.6 Schematic diagrams and waveforms of diodes used as (a) rectifiers and (b) clippers.

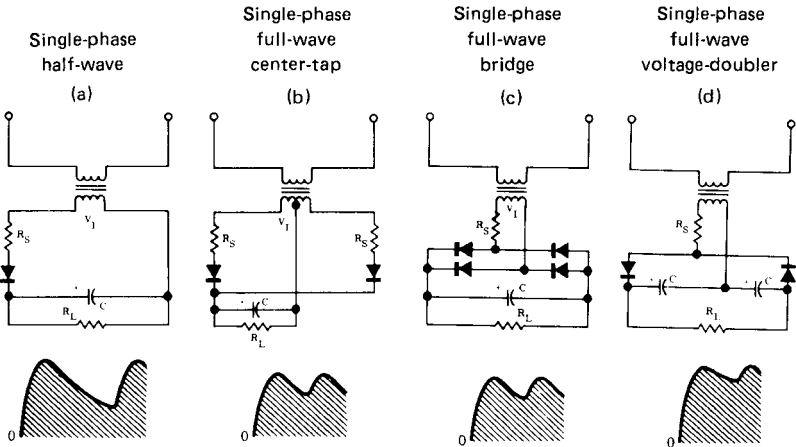

FIGURE 6.7 Practical power supply circuits and their characteristics.

Schottky Rectifiers. When a metal is brought into contact with a highly doped (low-resistivity) semiconductor material, an ohmic contact is formed. The resulting junction is highly conductive, exhibiting linear voltage-current relationships with little series resistance. Such junctions are used for the connection of metal leads to semiconductor devices. However, when a metal is brought into contact with a lightly doped (high-resistivity) semiconductor material, the resulting junction exhibits rectifying properties similar to those of a $p-n$ junction. Alternatively known as Schottky rectifiers (diodes), surface-barrier diodes, and hot-carrier diodes, such structures are commonly employed as VHF-UHF mixers, as which they offer faster response time and lower noise than other types of devices and as high-speed rectifiers in power supply circuits, for which they have a number of advantages over standard $p-n$ junction rectifiers. Among these advantages are:

1. Virtually nonexistent offset voltage at low current and substantially lower forward voltage drop than comparable silicon rectifiers at high currents (Fig. 6.8)
2. Substantial improvement in rectification efficiency
3. Significantly higher switching speed owing to the absence of storage time as a speed-limiting parameter

This combination of features makes Schottky rectifiers highly useful in low-voltage, high-current power supplies, in switching power supplies, and in switching circuits associated with integrated circuits.

FIGURE 6.8 Typical offset voltage and forward voltage drop of standard and Schottky rectifiers with similar current ratings.

Condition: $R_{L(\min)} = 50 R_s$.

The primary disadvantage of a Schottky rectifier is its substantially higher reverse-bias leakage current, which may be of an order of magnitude greater than that of p - n junctions. Total power dissipation with symmetrical signals, however, favors the Schottky diode because of its low voltage drop in the on condition.

The lower turn-on potential of Schottky diodes is used to increase the switching speed of conventional saturated-logic circuits by keeping the switching transistor out of deep saturation while in the on condition. This circumstance increases the turn-off speed by eliminating storage time as a factor of turn-off time. This is accomplished by connecting a reverse-biased Schottky diode across the collector-base junction of the transistor. As a positive-going base signal drives the transistor toward saturation, resulting in a collector voltage lower than the base voltage (tending to forward-bias the collector-base junction), the lower turn-on potential of the Schottky diode causes the diode to conduct before the normally reverse-biased collector-base junction of the transistor goes into conduction. Thus, the collector-base forward voltage is clamped by the low on voltage of the diode to a value that is less than required to cause reverse conduction in the collector-base junction.

Zener Diodes. Operated as a rectifier, a p - n junction utilizes the forward-conduction–reverse-blocking action of the structure. As a zener diode, it employs the “breakdown” region of the diode.

Figure 6.9 shows that, for an applied reverse voltage, the diode current is very small (leakage current) until the breakdown point is reached, at which point the reverse current increases very rapidly. This breakdown voltage is usually called *zener voltage* (V_z). A zener diode differs from a rectifier diode in that the breakdown-voltage point V_z is very precisely controlled during design and manufacture.

When used as a zener diode, the device is operated in the breakdown region, where it acts as a constant-voltage device and can be utilized as a voltage regulator in power supplies. The simple circuit in Fig. 6.10 illustrates this application. Here, when the applied unregulated dc potential is low (below the breakdown point of the diode), the diode current is very small and the device acts essentially as an open circuit. Therefore, its effect on the load circuit is virtually zero. If the applied dc voltage exceeds V_z , however, the junction breaks down and its voltage drop remains essentially constant. Therefore, the voltage available to the load remains approximately constant and equal to the zener voltage regardless of variations in source voltage or load-current requirements. Of course, if the applied voltage should drop below the point where diode breakdown is maintained or if the load resistance R_L were to decrease to the point where it could no longer sustain the voltage required for zener breakdown, the diode would come out of conduction and voltage regulation would be lost. With proper design, the value of the applied dc voltage and

FIGURE 6.9 Typical zener-diode characteristics and major parameters. V_Z = zener breakdown voltage; I_{ZT} = zener test current at which V_Z is specified; I_{ZM} = maximum permissible zener current.

FIGURE 6.10 Simple power supply voltage regulator.

the value of the series resistance R_s are chosen so that the voltage drop across R_L in the absence of the zener diode would be greater than V_Z under any anticipated load-resistance variations.

Zener diodes are also used for a variety of other applications, including clipper circuits (by replacing the batteries utilized in the circuits of Fig. 6.6), overvoltage-protection circuits (similar to the voltage-regulator circuit of Fig. 6.10), and surge-protection circuits for all sorts of electrical equipment as exemplified by the circuit of Fig. 6.11, where the zener is used to protect against excessive fuse burnout due to prolonged periods of operation near the melting point of the fuse. The zener provides a sudden burst of current at voltages beyond V_Z so that a more tolerant fuse may be selected.

Commercial zener diodes are available with zener voltages ranging from about 2.4 to 200 V and with power ratings from milliwatts to 50 W or more so that a great many power supply regulation requirements can be satisfied. Manufacturers' data sheets usually provide a minimum current (I_{ZK}), which will assure reasonable regulation, as well as a maximum current (I_{ZM}) beyond which the diode is subject to damage.

FIGURE 6.11 Zener-diode protection permits the use of fuses with higher current ratings by generating a sudden burst of current at the pre-determined fault point.

Reference Diodes. The forward and reverse characteristics of a typical zener diode are affected by temperature. This is shown in the graph of Fig. 6.12, where it is seen that a change in temperature from 25 to 100°C causes a decrease in voltage of approximately 150 mV in the forward-biased region of the diode. This corresponds to a negative temperature coefficient (TC). In the zener region, the voltage increases as temperature is increased, resulting in a positive TC.

For many applications this change in zener voltage with temperature can be tolerated. Critical applications, however, require temperature-compensated diodes, or reference diodes, whose breakdown voltage remains constant under varying temperature conditions.

A reference diode can be formed by combining one or more forward-biased diodes with a reverse-biased diode, as shown in Fig. 6.13. Here it is seen that the increase in voltage across the reverse-biased zener junction is counterbalanced by the decrease in voltage across the forward-biased junction at 7.5 mA. By judicious selection of diode junctions and proper operation, excellent temperature compensation can be achieved. It is important, however, to operate the TC device at a current level specified in the data sheet. Otherwise, voltage compensation is not obtained because the ΔV 's at different current levels are not necessarily equal.

The Transistor. The transistor is the most versatile component in the semiconductor family. Its most important characteristic is current and/or voltage amplification. Because of this capability it is the heart of most electronic circuits involving signal amplification and switching.

FIGURE 6.12 Typical forward and reverse diode characteristics as a function of temperature.

FIGURE 6.13 The temperature effect on zener breakdown voltage can be compensated for by a series-connected forward-biased diode with an equal temperature change of opposite polarity.

There are two basic kinds of transistors: *unipolar transistors*, usually referred to as field-effect transistors (FETs), and *bipolar transistors*. The FET was first described in the early 1930s but was not exploited commercially at that time. The bipolar transistor was invented in the late 1940s and rapidly became a commercial product. The FET was finally developed as a commercial product early in the 1960s, long after the bipolar transistor had established itself. FETs, especially MOSFETs, are now widely used in the front ends of low-noise radio and TV equipment, and they are the dominant devices in digital integrated circuits.

8. Bipolar transistors. The basic element of any bipolar transistor is the p - n junction. When the junction (diode) is forward-biased (p layer positive, n layer negative), current through the device increases rapidly as the voltage is increased. Under reverse bias, only a very small leakage current can flow until the reverse voltage becomes high enough to cause breakdown.

A bipolar transistor is formed by sandwiching a very thin layer of n -doped material between two layers of p -type material (p - n - p) or a thin layer of p -type material between two n -doped layers (n - p - n). The characteristics of such a structure are varied by varying the geometries and resistivities of the three layers.

The three layers of a bipolar transistor (Fig. 6.14) are the *emitter*, the *base*, and the *collector*. The emitter represents the current source, where the current carriers originate. The base is the control element, and the collector is the element through which the current carriers are transferred to an external circuit.

FIGURE 6.14 Physical representation of bipolar transistors.

The main difference between a p - n - p and an n - p - n transistor is that the former operates with a negative voltage on the collector while the latter operates with a positive collector voltage (with respect to the emitter). This makes it possible to have complementary circuits that often provide improved performance over single-ended circuits, which can be implemented with only one type of transistor.

Transistor action can be understood by analyzing the current flow through an n - p - n transistor under the influence of externally applied voltages (Fig. 6.15). For the normal case,

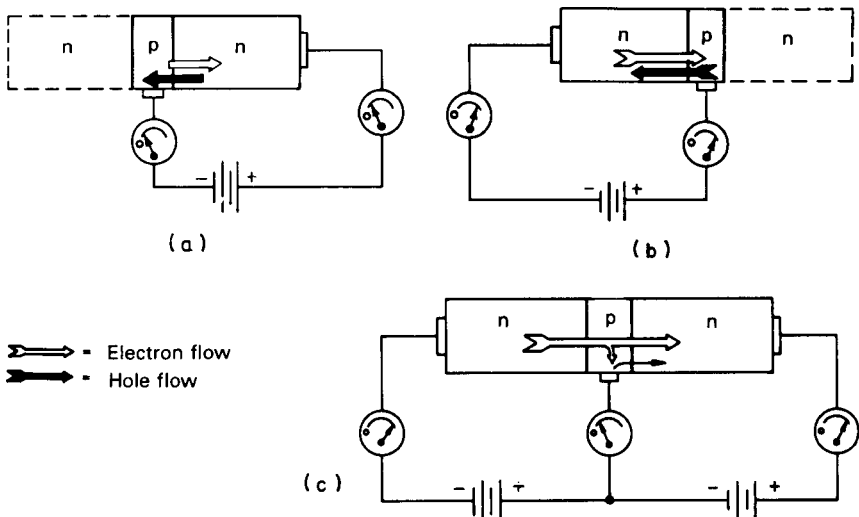

FIGURE 6.15 Transistor action. With the collector junction reverse-biased (a), only minority carriers can cross the junction, and the resulting current flow is small. A forward-biased emitter junction (b) permits a heavy flow of majority carriers. With both junctions properly biased (c), emitter-injected electrons cross the thin base region and flow out of the collector lead.

the external voltages are applied so that the emitter junction is forward-biased and the collector junction is reverse-biased. By examining first the collector junction with the emitter open (a), it is obvious that only minority carriers from the base and collector can cross this junction. If the number of minority carriers in these regions is assumed to be relatively small, the total current across this junction is correspondingly small and is referred to as leakage current (I_{CBO}).

If the collector circuit is opened and a forward bias is applied to the emitter-base junction (b), majority carriers from the emitter and the base (electrons and holes, respectively) find it quite easy to cross this junction, causing a heavy base current.

With both junctions properly biased (c), if the base region were quite thick, the electrons from the emitter would combine with abundantly available holes in the base and cause an equivalent and compensating flow of current out of the base lead. In that case, the current in the collector would not be greatly affected by the emitter-injected carriers and would remain at its leakage-current value while the base current would be quite high.

However, for a very thin base region, the *lifetime* of the electrons injected into the base (before recombination takes place) is long enough so that most of them can traverse the entire base region toward the collector. Since these electrons represent minority carriers in the base region, the reverse-biased collector-base junction is actually forward-biased for the minority carriers, and the electrons will be swept across the junction into the collector region and from there into the collector power source. Therefore, the collector current equals the leakage current plus most of the injected current, while the base current is very small.

The above action gives rise to the most commonly used expressions for transistor current gain, beta (β), which is the ratio I_C/I_B and is called the *common-emitter current gain*. Beta can be quite high since, for a very thin, high-resistivity base region, almost all of the injected carriers diffuse into the collector, with very few exiting via the base lead.

Circuit configurations. There are three basic transistor circuit configurations: common-emitter, common-base, and common-collector. They differ principally in the manner in which the signal is applied to the transistor and where the load is attached. Figure 6.16 shows these basic circuits. Since the common-emitter circuit is by far the most prevalent, data sheets normally characterize the transistor in terms of this circuit.

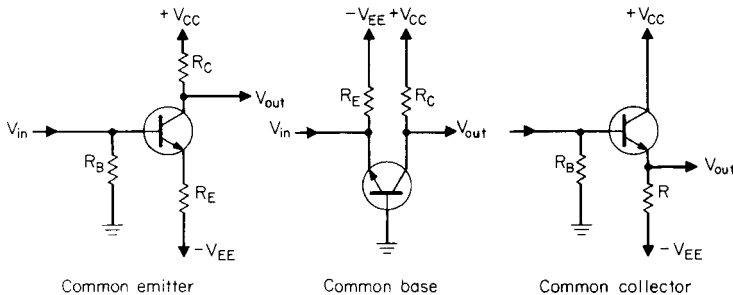

FIGURE 6.16 Basic transistor circuit configurations and their relative characteristics.

Circuit	Current gain	Voltage gain	Input resistance	Output resistance
Common emitter	High	High	Low	High
Common base	<1	High	Very low	Very high
Common collector	High	<1	High	Low

FIGURE 6.17 Typical input-output characteristic curves of a bipolar transistor in a common-emitter circuit. (a) Emitter current versus base voltage (input characteristics). (b) Collector current versus base current. (c) Collector current versus collector voltage for various values of base current (output characteristics).

Bipolar-Transistor Characteristics. Figure 6.17 shows the characteristics of a typical small-signal transistor in a common-emitter circuit. The input circuit, curve *a*, shows that a base-emitter voltage V_{BE} of less than approximately 0.5 V (for silicon) causes virtually no emitter current I_E to flow, thereby keeping the transistor cut off. Above 0.5 V, I_E rises sharply, limited only by the ohmic resistance of the emitter region. Since the latter is very small, a very small rise in V_{BE} , beyond the threshold voltage V_T , causes a large injection of emitter current into the base and from there into the collector, with a small portion flowing out of the base lead.

A typical plot of the division of emitter current between base and collector is shown in Fig. 6.17*b*. The numbers vary considerably for different transistors, but the shape of the curve remains similar. This shows that the β of the transistor can vary considerably over the range of the curve and that, for large signals, distortion can be quite high.

The collector curves in Fig. 6.17*c* are the most significant. They can be used to determine the relationship between the input and output signals of a transistor.

When the transistor is cut off ($I_B = 0$), a residual current I_{CES} flows in the collector circuit. This leakage current can be reduced somewhat (but not to zero) by applying reverse bias to the emitter junction. The limiting value, with reverse bias applied to the emitter-base junction, is I_{CBO} . This is equivalent to the collector-base leakage current when the emitter is open-circuited.

Collector current increases rapidly as the base is energized. The maximum I_C , $[I_{C(max)}]$, is that which would damage the internal transistor structure. This value of collector current is given as a maximum rating on data sheets. Thus, the output current could range from $I_{C(max)}$ to I_{CES} (or I_{CBO} in the event of reverse bias), but in practice I_C is limited to a value far less than $I_{C(max)}$.

Power Dissipation. Power dissipation P_D is the product of V_{CE} and I_C , and it causes the collector junction to heat up. Beyond a critical junction temperature $T_{J(max)}$, the device could be damaged. Thus, the $P_{D(max)}$ rating of a transistor limits the maximum V_{CE} and I_C that can be applied simultaneously. The locus of a $P_{D(max)}$ rating is the parabolic curve on the V_{CE}/I_C

plot of Fig. 6.17. A load line, XQY , must be chosen to maintain steady-state operation to the left of the locus.

Switching Action. From the above it is evident that when the voltage applied between base and emitter is less than approximately 0.5 V, there is only a very small current flow through the transistor. Between collector and emitter, therefore, the transistor represents a very high resistance, or open switch. When V_{BE} is raised significantly above the threshold voltage, the internal resistance of the transistor drops to a very small value so that the device approximates a closed switch. As shown in Fig. 6.17, it takes a change of only 7 mA of I_B along the load line XQY to cause V_{CE} to cause the voltage across this particular transistor to change from V_{CC} to near zero, that is, from an open switch to a closed switch. The switch action is accomplished by a V_{BE} of only a few tenths of a volt.

Biasing. When operated as an amplifier, the transistor must first be biased to some quiescent value of collector current, so that both positive- and negative-going input-voltage excursions will cause corresponding changes in output voltage and current. The ideal bias point is represented by Q on the load line because this permits approximately equal excursions in I_C and V_{CE} without signal clipping. The bias point is established by a quiescent base current that results in a dc collector voltage of approximately $V_{CC}/2$.

Several circuits are used for establishing the bias point. Among the most familiar are those in Fig. 6.18. The basic performance difference is in the bias-point stability.

I_C	$\beta \frac{V_{CC}}{R_B}$	$\frac{V_{CC}}{R_C + R_B/\beta}$	$\frac{R_2}{R_1 + R_2} \times \frac{V_{CC}}{R_C}$
S	1	$\frac{1}{1 + \beta R_C/R_B}$ for $R_B = \beta R_C$ $S = 0.5$	$\frac{1}{1 + \beta R_E \frac{R_1 R_2}{R_1 + R_2}}$
To make			
$I_C = \frac{I_{C(sat)}}{2}$	$R_B = 2\beta R_C$	$R_B = \beta R_C$	$\frac{R_1}{R_2} = 1 + 2 \frac{R_1}{R_E}$

At point Q on the load line in Fig. 6.17, the transistor has a beta (I_C/I_B) of approximately 20. If a transistor with a β of 40 were substituted (simulated by dividing all I_B values by 2) and if I_B were held by the bias circuit to 2.5 mA as before, the operating point would move up the load line to point Q' , a much higher value of I_C . As a result, considerable distortion would occur for high-value input signals.

The bias-point stability factor S is defined as the percent change in I_C for a percent change in β , or $\Delta I_C/I_C = S \Delta \beta/\beta$. If a percent change of β causes a corresponding percent change in I_C (the least desirable condition), then $S = 1$. If I_C is independent of β (corresponding to a zero change in I_B when β is varied), then $S = 0$. The

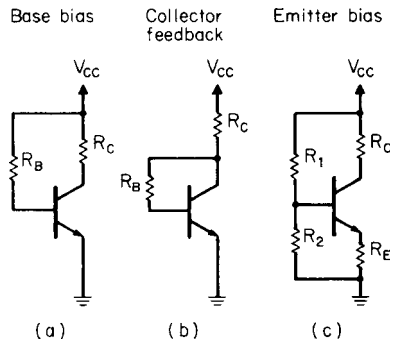

FIGURE 6.18 Conventional common-emitter bias circuits. The following table gives approximate characteristic expressions.

formulas accompanying Fig. 6.18 give I_C and S as functions of β and assign values for S under specific operating conditions. The bias arrangement in Fig. 6.18c, using emitter degeneration, is preferred because, by proper choice of resistor values, the effect of β on I_C can be made almost negligible.

9. Field-effect transistors (FETs). There are two types of field-effect transistors: the junction field-effect transistor (JFET) and the metal-oxide-semiconductor field-effect transistor (MOSFET). Of these, the MOSFET is by far the more popular and forms the basis for most digital large-scale and very-large-scale integrated circuits (LSI and VLSI). JFETs, because of their low-noise advantages, are utilized extensively in TV and radio front ends as well as in input circuitry for integrated operational amplifiers, etc.

Junction Field-Effect Transistors. In its simplest form, a JFET starts with a bar of n - or p -doped silicon which behaves as a resistor (Fig. 6.19a). By convention, the terminal into which current is injected is called the *source*; the other terminal is the *drain*. Current flow between source and drain is dependent on the drain-source voltage and on the resistivity of the material.

In Fig. 6.19b, p -type regions have been diffused into an n -type substrate, leaving an n channel between source and drain. (A complementary p channel is made by reversing the dopants in all regions of the structure.) The p regions control the current flow between source and drain and are called *gates*.

When the gates are connected to the source and a positive voltage is applied between drain and source (Fig. 6.19c), current flow in the channel creates a voltage gradient along the length of the channel. This voltage reverse-biases the gate-substrate junctions and creates the usual depletion layer in the vicinity of the junction. The depletion layer, being devoid of mobile charges, is in effect an insulating region which cannot be penetrated by the channel current. This reduces the channel width, thereby increasing its resistance.

The overall effect is shown in Fig. 6.20a, where an increase in V_{DS} causes a corresponding increase in drain current I_D , but the rate of change of current tapers off as the increasing voltage drop in the channel increases the spread of the depletion region into the channel. At V_p (pinch-off voltage) an equilibrium condition is reached whereby an increase in V_{DS} generates a neutralizing increase in channel resistance, and drain current remains essentially constant until the breakdown condition is reached.

By applying a reverse-bias voltage between the gates and the substrate (Fig. 6.20b), the channel width is reduced by the gate voltage and the maximum drain current is lowered. Further increases in gate voltage correspondingly reduce the channel width and produce successive reductions in maximum drain current.

It will be noted that current flow in an FET is made of majority carriers only and that, unlike in a bipolar transistor, the current does not cross a junction. Hence, an FET is sometimes called a *unipolar transistor*.

FIGURE 6.19 Development of junction field-effect transistors.

FIGURE 6.20 Drain-current characteristics.

FIGURE 6.21 Cross section of a JFET structure.

A more practical structure for a junction FET is illustrated in Fig. 6.21. In this single-ended geometry, the *p*-type substrate takes the place of gate 2 in Fig. 6.20. An *n*-type layer is epitaxially grown on top of this substrate, and a *p*-type gate diffusion into the epitaxial layer forms the second gate and creates the channel.

MOS Field-Effect Transistors. The MOSFET operates on a somewhat different control mechanism. Figure 6.22 shows the development. Two separate low-resistivity *n*-type regions (source and drain) are diffused into a high-resistivity substrate, as shown in Fig. 6.22*a*. Next, the surface of the structure is covered with an insulating oxide layer (Fig. 6.22*b*), and holes are cut into the layer, allowing metallic contact to source and drain. Then, a metal area is overlaid on the oxide, covering the entire region between source and drain, and simultaneously metal contacts to drain and source are made as shown in Fig. 6.22*c*. The metal area between source and drain is the gate terminal. Note that there is no physical penetration of the gate metal through the oxide into the substrate. Since drain and source are isolated by the opposite-polarity substrate, the structure is analogous to two diodes connected back to back (Fig. 6.22*d*). If a voltage were to be applied between source and drain (in the absence of a gate voltage), the resulting current flow would be very small because one of the back-to-back diodes would be reverse biased regardless of the polarity of the applied voltage.

FIGURE 6.22 Development of a MOSFET.

The metal gate area, in conjunction with the insulating oxide layer and the semiconductor layer underneath, forms a capacitor. The metal area is the top plate; the substrate material, the bottom plate. When a positive potential is applied to the gate metal, the positive charge at the metal side of the capacitor induces a corresponding negative charge at the semiconductor side. As the positive charge at the gate is increased, the negative charge “induced” in the semiconductor increases until the region beneath the oxide is changed from *p*-type to *n*-type (Fig. 6.23), and current can flow between drain and source through the induced channel. In other words, drain-current flow is “enhanced” by the gate potential. Thus, drain-current flow can be modulated by the gate voltage; i.e., channel resistance is inversely proportional to gate voltage. (The *n*-channel structure may be changed to a *p*-channel device by reversing conductivity of the semiconductor regions.)

FIGURE 6.23 A typical MOSFET operation. A positive voltage applied to the gate converts the *p*-type material underneath the gate insulation to *n*-type material and creates a conductive channel between source and drain.

The FET just described is called an enhancement-type MOSFET. A depletion-type MOSFET can be made by diffusing a low-resistivity *n* channel into the space between source and drain so that considerable drain current will flow when the gate potential is at zero volts. In this manner, the MOSFET can be made to exhibit depletion characteristics by applying a negative voltage to the gate.

For a moderate-resistivity induced channel, the FET will exhibit both enhancement and depletion characteristics. Typical performance curves for such structures are illustrated in Fig. 6.24.

Comparison of Small-Signal Bipolar and MOS Transistors. The MOSFET enjoys several clear-cut advantages over its bipolar counterpart. First, it has an extremely high input resistance, making it more adaptable to many circuit applications. Second, it is a low-noise

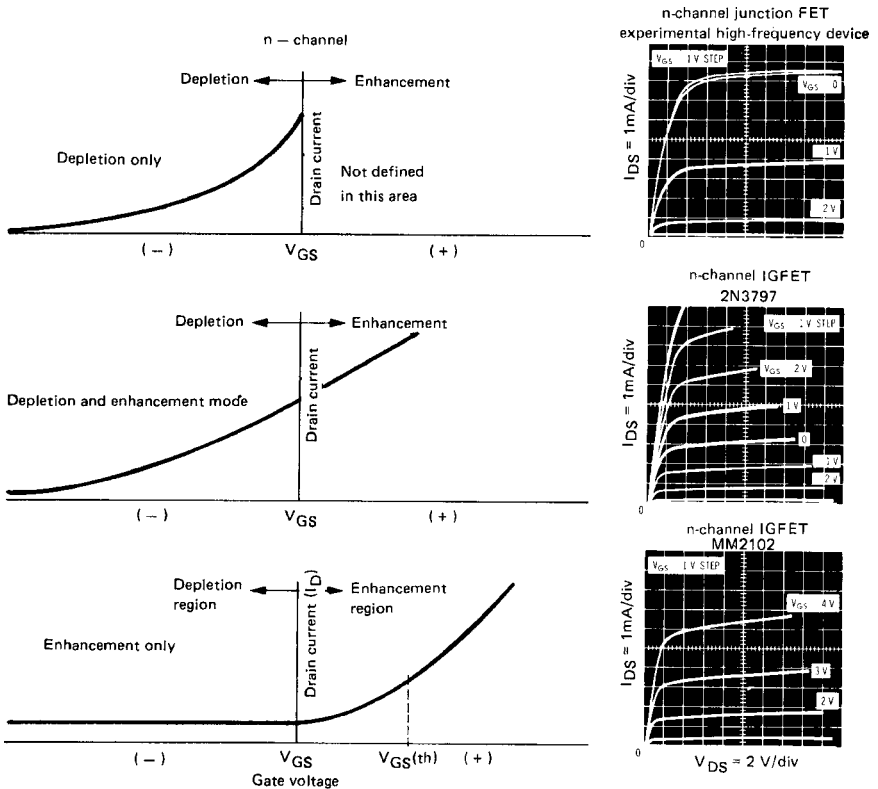

FIGURE 6.24 Gate-voltage-transfer characteristics and associated scope traces for different types of FETs.

device and is often preferred for front-end communications circuits. Third, it is extremely compatible with integrated-circuit processing, particularly for LSI and VLSI circuits, for which its smaller geometry, lower power consumption, and simpler processing make it the preferred basic device for many applications.

On the other hand, bipolar transistors are capable of operating at higher speeds and higher power. In discrete form, they are generally available with a wider range of specifications and often at considerably lower cost for applications for which both types of devices are suitable.

Power MOSFETs. While MOSFETs for small-signal applications have been widely used for some years, their performance in power circuits has been limited. The limiting factor of the conventional small-signal MOSFET structure has been the lateral channel, which has an inherently low current-carrying capacity and a relatively high on resistance coupled with a low reverse breakdown voltage.

The disadvantages of the lateral FET from a power standpoint were overcome with the development of a structure that permits the control of a vertical current flow by means of a gate field. The structure utilizes thousands of “source” sites interconnected in parallel on a single die (Fig. 6.25). A common drain at the bottom of the die minimizes the geometry of the structure to make such a multicell architecture practical. Moreover, it permits very short channel lengths to reduce the on resistance of each cell to a minimum. The overall result is a device which allows current and voltage ratings to meet virtually any desired electronic application while maintaining the higher speed and circuit-simplification advantages of MOSFETs in comparison with bipolar transistors.

The power MOSFET has made great strides, but emphasis on cost reduction is continuing. Improvements of present devices over the early double-diffused MOS structure have been significant, and prices are now approaching those associated with bipolar power transistors for medium voltage and current applications.

FIGURE 6.25 A power MOS transistor. The cross section (a) illustrates overall interaction of source sites, while (b) shows the details of a single transistor element in the structure.

10. Thyristors. Thyristors and their trigger devices can take numerous forms, but they share these characteristics:

1. They are “open circuits,” capable of withstanding rated voltage until triggered.
2. They become low-impedance current paths when triggered and remain so, even after the trigger source has been removed, until current through that path is interrupted or is reduced below a minimum “holding” level.

The regenerative action which holds a thyristor in the on state is due to multiple layers of opposite *p*- and *n*-doped silicon which result in the two-transistor-equivalent circuit

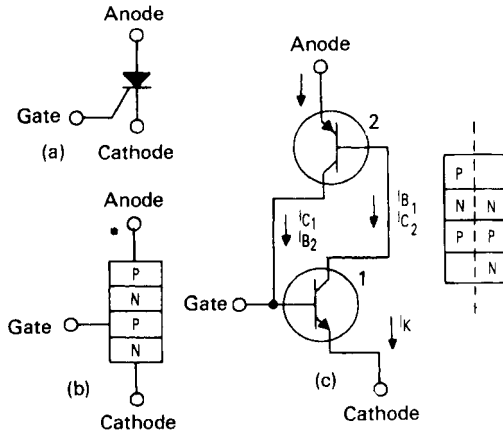

FIGURE 6.26 Two-transistor analogy of an SCR. (a) Schematic symbol of SCR. (b) A $p-n-p-n$ structure represented by a schematic symbol. (c) A two-transistor model of an SCR.

structure shown in Fig. 6.26. Here, part of the current through transistor 2 is injected back into transistor 1 to supplement the trigger current and sustain conduction when the trigger is removed. This characteristic, coupled with the thyristor's low on resistance, makes it possible to control a portion of each cycle of an ac power waveform into a load, for low-dissipation "dimming" or motor-speed-control applications, to switch capacitive discharge currents precisely in electronic pilot ignition systems, and to fulfill innumerable other control purposes.

There are a number of semiconductor devices under the title of thyristor; the most important of these are silicon-controlled rectifiers (SCRs) and triacs.

SCRs. As a rectifier, the SCR conducts current in only one direction. But unlike a two-layer rectifier, which begins conduction when its anode becomes slightly positive with respect to its cathode, the SCR will remain nonconductive even in the forward direction until the anode voltage exceeds a certain minimum value called the *forward breakover voltage* (V_{DRM}). Moreover, the value of V_{DRM} can be varied through the injection of a small current into a third, or *gate*, element, which governs the amplitude of the anode voltage needed to cause conduction, or firing.

The current-voltage relationship of an SCR is shown in Fig. 6.27. With the gate terminal open or shorted to the cathode and an external voltage applied only between anode and cathode, the reverse-bias characteristics (anode negative with respect to cathode) are identical to those of a conventional $p-n$ junction, or rectifier. Under forward-bias conditions, however, current flow does not begin (except for a small leakage current) until V_b is reached. At that point current flow begins to increase very rapidly until, at the *forward-breakover-current point*, a switchback effect takes place and the voltage across the device suddenly drops to a very low value. At that point, the voltage-current relationship becomes similar to that of a conventional forward-biased diode.

It is important to recognize the difference between the reverse-bias breakdown and the forward-bias-breakover effect. In the former, the voltage across the junction remains at its breakdown value so that power dissipation in the device is high and care must be taken to keep the maximum current at a relatively low value to prevent device damage. In the forward breakover region, owing to the switchback effect, the voltage across the device is very

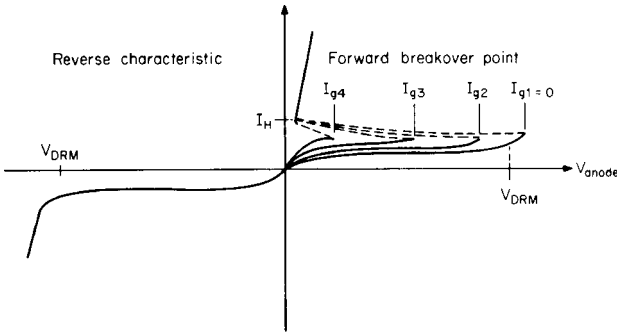

FIGURE 6.27 Thyristor characteristics illustrating breakover as a function of gate current.

low, and it can carry large amounts of current without exceeding the power-dissipation rating of the device. Hence, the device with its gate open (or shorted to the cathode) acts like a voltage-operated switch. The switch is turned on when the applied anode voltage exceeds the breakover voltage and is turned off when the anode current through the device is reduced to the *holding current* I_H , at which point the device returns to its high-resistance state and the switch is turned off.

The switching action of the SCR is greatly enhanced by employing its gate characteristics. When a current is injected into the gate, the breakover voltage of the device is reduced. As this current is increased, the breakover point becomes less and less until the barrier to forward conduction is removed entirely and the device acts as a forward-biased rectifier. The amount of gate current required to reduce breakover voltage from its open-gate value (open switch) to virtually zero (closed switch) is extremely small, so that a small amount of gate current can control a large amount of anode current. In this respect, the SCR acts very much like a sensitive relay, in which a small current through the relay coil can control a much larger current through the relay contact circuit.

A simplified SCR circuit is shown in Fig. 6.28, where the SCR is connected in series with the load R_L and an applied voltage V_{ac} . V_{ac} is less than the breakover voltage of the SCR, so that the SCR is an open circuit until a gate signal is applied. If a gate-signal pulse is applied at the beginning of the positive-going cycle of V_{ac} , the SCR is turned on and the current through the load follows the positive half cycle of the applied voltage until that voltage approaches the point *A* where it can no longer sustain a current above the holding-current value. The SCR is then turned off.

It must be noted that the SCR can be turned on only during the positive-going portion of the applied voltage. No amount of gate current can turn it on during the negative portion of the cycle, so that a single SCR acts like a triggered half-wave rectifier.

Various techniques can be used to permit SCRs to function during both halves of an applied ac voltage. This can be accomplished by connecting two SCRs in an inverse-parallel configuration so that one device is turned on during the positive-going half cycle and the other during the negative portion (Fig. 6.29*a*). Another is to utilize a triac in place of an SCR (Fig. 6.29*b*).

Triacs. A triac is a device which operates exactly like an SCR, except that it can be triggered on during both the positive-going and the negative-going half cycles of an applied voltage. Thus, it acts like a triggered full-wave rectifier or, as indicated by its schematic symbol, like a pair of inverse-parallel-connected SCRs. In application, the triac offers circuit

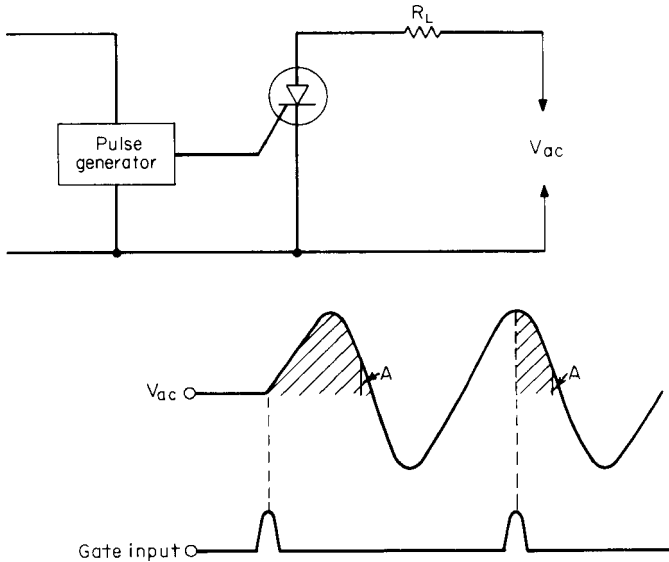

FIGURE 6.28 A simple control circuit indicates the amount of current control available with SCRs.

FIGURE 6.29 Full wave power control achieved by two inverse-parallel-connected SCRs (a) and through the use of a triac to replace the SCRs (b).

simplification and a reduction in component requirements where full-wave power control is required.

A triac may be triggered into conduction by either a positive- or a negative-going gate signal, but sensitivity varies considerably. The recommendations given in manufacturers' data sheets should be followed for best performance.

Gate-Turnoff Thyristors (GTOs). A gate-turnoff thyristor (GTO) combines the most desirable characteristics of SCRs and bipolar power transistors. Like a transistor, the GTO can be switched on and off by a low-power gate drive signal; like an SCR, it can pass high forward currents when turned on and block high forward voltages when turned off. But unlike the power transistor, which requires a constant drive source to keep it turned on, the GTO is turned on by a momentary pulse and remains in the on condition until the anode voltage is reduced below the level that sustains a holding current or until it is turned off by a reverse-polarity gate-turnoff pulse. In this way, it differs, too, from more conventional

thyristors (SCRs, triacs), which cannot be turned off by a gate signal. Present devices have voltage ratings up to 1400 V and current ratings on the order of 20 A. Gate current trigger requirements are 300 mA. Devices will withstand surge currents as high as 200 A.

Triggers for Thyristors. The most common form of power control using SCRs (or triacs) is phase control of alternating current. Power control is achieved by controlling the timing of the gate trigger pulse. If the trigger pulse is applied at the beginning of the positive-going anode cycle, the thyristor is turned on for virtually the entire positive half of the cycle, allowing the maximum load current to flow. As the trigger pulse is delayed, correspondingly less of the positive-going anode voltage waveform is applied to the load. Figure 6.28 explains visually how this phase control of alternating current is achieved.

There are some instances when a thyristor can be adequately triggered by the slowly rising voltage or current from the 60-Hz line without a separate trigger device, e.g., the simple motor-speed-control circuit in Fig. 6.30. Here the setting of R_3 determines the point of the applied-voltage cycle at which the gate voltage will be high enough to trigger the SCR. The circuit offers control over almost the entire half of the positive portion of the applied voltage. Much better control can be achieved, however, by employing a separate trigger device to provide reliable turn-on pulses timed to trigger the SCR at any desired point during the cycle.

FIGURE 6.30 Half-wave motor-speed-control circuit. The thyristor is triggered directly from the 60-Hz line.

The most common trigger circuit is a relaxation oscillator (Fig. 6.31) using one of a variety of semiconductor switching devices. As shown, when the voltage on the capacitor rises to a point where the electronic switch turns on, the discharge of the capacitor produces a trigger pulse to the load. The charge time of the capacitor can be varied by the setting of R_T , so that pulse spacing can be varied at will.

A number of trigger devices serve the purpose of the electronic switch. Among them are unijunction transistors (UJTs), three- and four-layer diodes, and sidacs.

Unijunction transistors. The UJT is a three-terminal device having only a single semiconductor junction. Its basic structure and equivalent circuit are shown in Fig. 6.32a and b.

In the physical structure, when a positive voltage is applied between base 2 (B_2) and base 1 (B_1) and the emitter is shorted to B_1 , the current through the device sets up an internal voltage drop. The voltage at the p - n junction, being slightly positive, reverse-biases the diode junction, and there is a small reverse-bias (leakage) current through the diode. The diode represents a high resistance in parallel with R_{b1} and has no effect on the internal voltage distribution.

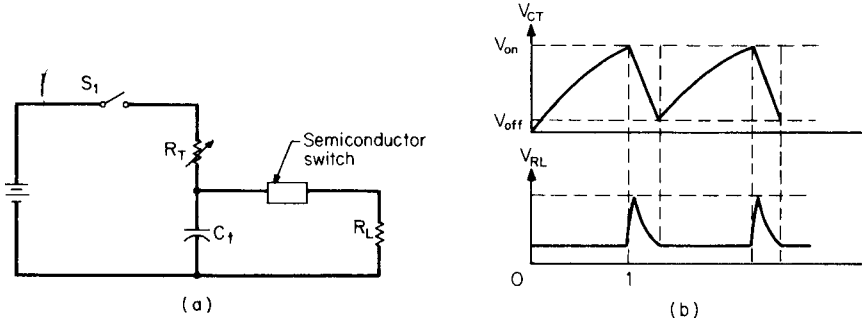

FIGURE 6.31 Basic relaxation-oscillator circuit and associated waveforms.

FIGURE 6.32 A unijunction transistor: basic construction (a) and equivalent electrical circuit (b).

FIGURE 6.33 *I-V* characteristics of a unijunction-transistor input (emitter- B_1) circuit.

If a positive-going voltage is applied between the emitter and B_1 , a point will be reached where the voltage overcomes the internal reverse-bias voltage on the $p-n$ junction and the junction becomes forward-biased, representing a very small resistance in parallel with R_{b1} . At that point, the voltage at point A drops to that of a forward-biased junction.

The emitter *I-V* characteristic curve of a UJT is shown in Fig. 6.33. To an external circuit, it appears that the UJT has a negative resistance to applied emitter voltage between V_p , the diode turn-on point (peak-point voltage), and V_v , the point where the diode becomes fully conductive and its voltage drops to its forward-biased value (valley point).

A relaxation oscillator utilizing a UJT (Fig. 6.34) provides an output across R_L after capacitor C_1 has charged up through R_1 to reach the peak-point voltage of the UJT. Subsequently, C_1 discharges through R_L and the UJT to generate a positive pulse across R_L . The frequency of the pulsed output can be varied by varying the resistance of R_p , which permits triggering the thyristor load at any desired point of the positive-going anode cycle.

Unijunction transistors are highly stable devices for general-purpose trigger applications and as pulse generators and timing circuits at frequencies ranging from 1 Hz to 1 MHz.

A number of other trigger devices are available. All take advantage of the phenomenon of negative-resistance characteristics to produce switching action. The *V-I* characteristic curves of some of the more popular devices are illustrated in Fig. 6.35.

FIGURE 6.34 Basic relaxation-oscillator circuit using a UJT trigger device.

Basic thyristors

Trigger devices

FIGURE 6.35 Voltage-current characteristics of various popular thyristor devices.

Programmable unijunction transistors (PUT). Programmable unijunction transistors are similar to UJT's except that their basic characteristics are programmable (adjustable) by means of external voltage dividers. This ability stabilizes circuit performance for variations in device parameters. The general operating frequency range is from 0.01 Hz to 10 kHz, making PUTs suitable for long-duration timer circuits.

Bilateral triggers: DIACs. Specifically designed as low-cost triggers in line-operated triac control circuits such as light dimmers, motor controls, and temperature controls, these devices exhibit symmetrical bidirectional characteristics with defined switching voltage and current points. The negative-resistance region extends over the full range of operating current, so that the concept of holding current is not applicable. Switching voltages on the order of 35 V or greater are achievable.

Silicon bidirectional switches (SBS). These devices are actually integrated circuits as opposed to the four layer discrete structures of other thyristors. They offer greater accuracy than conventional triggers, the difference between positive and negative breakover voltage being less than 0.5 V. A third lead, designated the gate, permits variations in characteristics such as breakover voltage. Switching voltages up to 10 V are achievable.

Sidacs. These components extend trigger capabilities to significantly higher voltages and currents than are achievable with other devices. With voltage ratings up to 300 V and a steady-state rms current rating of 1 A, they can replace triacs in numerous low-power applications.

11. Optoelectronics devices. The field of optoelectronics deals mainly with the phenomena of converting light into electric current and, conversely, turning electric current into light. Phototubes, followed by solid-state cadmium sulfide photocells, have been early and successful examples of light-to-current conversion, while tungsten-filament and gas-filled bulbs have been serving current-to-light conversion for many years. Their applications, however, have been restricted to direct current and low frequencies. Semiconductor light sources (LEDs and lasers) and detectors have brought about significant changes in optoelectronic applications.

Light sources basically consist of injection laser diodes (ILDs) and light-emitting diodes (LEDs). Both are semiconductor chips made of gallium arsenide (GaAs) or related III-V compounds.

Detectors consist primarily of silicon *p-n* junctions that perform the conversion function, but these may be combined (on the same chip) with other semiconductor devices such as transistors or integrated circuits to improve sensitivity and resulting output.

Light Sources. One basic characteristic of semiconductor *p-n* junctions is their sensitivity to light. Specifically, in the cutoff region the leakage current of such a diode increases with light intensity, while in the avalanche breakdown region it actually emits light. A diode therefore can be operated both as a light detector and as a light source.

The important characteristics of light sources are *spectral width*, the portion of the spectrum covered by the emitted light; *peak wavelength*, the wavelength at which maximum output is achieved; *emission pattern*, the "spread" of the light beam as it leaves the emission point; *power output*, the amount of light emitted by the device at its peak wavelength; *speed*, usually determined by the time it takes for the output to rise from 10 to 90 percent of peak power in response to an applied signal pulse; and *reliability and lifetime*, the anticipated mean time between failures of a component.

In electronic applications, the ILD is usually considered for long-distance communications in the fiber-optic transmission of CATV and telephone signals. It has a very narrow optical beam (Fig. 6.36) and can launch a greater amount of power into small-diameter fiber cores than an LED. And, because of its significantly higher speed, it has greater frequency-modulation

FIGURE 6.36 Typical spectral width of laser diodes and LEDs.

rates. The LED is normally preferred for short-distance communications and for other electronic functions such as optocoupling (isolation) and light-control applications. This preference is due to its substantially lower cost, its spectral match with a wide variety of detectors, its comparatively long life, and its general compatibility with most short-distance communications requirements.

The spectral response of an LED depends on the material used in its manufacture. Gallium arsenide is used primarily for LEDs with outputs in the infrared region of the spectrum between 900 and 1000 nm. Gallium arsenide phosphide produces a visible red light at about 660 nm, and gallium phosphide yields green at about 560 nm.

Visible-light diodes are widely used in panel lights, circuit-condition indicators, light modulators, displays, and the like. Infrared emitters are employed in fiber-optics communications, in card and tape readers, for shaft and position encoders, and in other applications requiring the use of photodetectors in place of the human eye because, as shown in Fig. 6.37, the detector response is much greater to infrared than to the visible-light spectrum.

FIGURE 6.37 Spectral output of various LED materials and spectral response of two common detectors, the human eye and silicon photodetectors.

Packaging has a substantial effect on the characteristics of an LED. It affects not only the power output but the spatial response as well. Figure 6.38 shows variation of output power and light intensity to be linear functions of current for typical LEDs. One limiting value is the current limit set by the package in which the die is housed. Spatial response is a function of the placement of the die within the package (with respect to the lens) and of the shape of the lens.

Spatial distribution is also a function of the basic chip design. A simple *p-n* junction yields a lambertian emission pattern which radiates in all directions. While this is desirable for some applications, it is undesirable in others. A number of techniques have been developed to control the emission pattern of the junction. Some of the prevalent chip structures and packaging methods are illustrated in Fig. 6.39.

FIGURE 6.38 Typical characteristics of commonly available LEDs. Graph, upper left, shows typical output as a function of drive current. Spatial-response curves are functions of package and lens designs.

(a)

(b)

FIGURE 6.39 Chip design (a) and packaging methods (b) affect the radiation pattern of LEDs.

Photodetectors. All semiconductor materials are light-sensitive. An increase of light within a specific range of frequencies, like an increase in temperature, imparts energy to the crystal lattice, causing some of the electrons to break their covalent bonds and become free. In a homogeneous semiconductor material or in a forward-biased p - n junction, the number of light-generated carriers is relatively small compared with the normally available free carriers and add little to the overall current flow. In a reverse-biased junction, however, the increase in current due to light-induced carriers becomes significant.

Photodiodes. If a near-intrinsic layer of silicon is interspersed between oppositely doped layers, a *PIN diode* is formed. The *I* (intrinsic) layer, being nearly devoid of free carriers, adds significantly to the width of the depletion region, making the structure far more light-sensitive than the ordinary p - n junction.

If the reverse bias on a p - n junction is increased to a point near the reverse breakdown point, the electric field within the depletion region will be high enough to give any light-liberated carrier enough energy to liberate additional carriers through collision with other atoms in the lattice. This avalanche effect actually multiplies the current generated by the impinging light and greatly increases the sensitivity of the diode.

Phototransistors. When one of the junctions of a transistor, e.g., the normally reverse-biased collector-base junction, is exposed to light, a phototransistor is created. Such a device adds gain to a photodiode and therefore increases sensitivity considerably. It pays for this, however, with a decrease in response time. Whereas the response time of diodes is measured in nanoseconds, that of phototransistors is specified in microseconds. Even greater gain and correspondingly slower response time are achieved with photodarlington devices.

Virtually any semiconductor device can be made photosensitive. Thus, manufacturers are now providing phototriacs and photo SCRs in order to reduce the component count in light-sensitive equipment requiring such devices.

With the advent of integrated circuits, optodetectors are being combined with complete preamplifiers to provide an amplified low-impedance output that is far less noise-sensitive than that of a discrete detecting device.

Optocouplers. An excellent example of optoutilization to replace conventional electronic components is the optical coupler. Consisting of an infrared-emitting diode coupled to a phototransistor in a single package, the device advantageously replaces such components as interstage transformers and relays as well as coupling and feedback networks.

The diagrams in Fig. 6.40 show such a unit being used as a linear-signal coupler and as a pulse coupler. In the former mode a constant current supplied to the emitter biases this diode, and since the output (infrared) is directly proportional to the diode current, any increase or decrease of diode bias current resulting from an applied modulation input causes corresponding variations in light output. These are coupled to the detector, which provides an equivalent linear current output. Devices with current transfer ratios (I_F/I_C) ranging from 2 to 1000 percent (depending on detector gain) are currently available.

As pulse couplers, the devices are equally interesting. The principal operating difference is that in the switching mode they require no bias current. The detector is either off (with a dark current of typically less than 20 nA) or on (with a maximum continuous forward current of around 50 mA).

Used as an electronic relay, the coupler is fast (much faster than a mechanical relay), and it has no contacts to bounce, pit, or corrode. It is small and insensitive to vibration, and, in contrast to other forms of electronic relays, its output is completely isolated from its input.

Couplers of this type could be produced with an almost infinite variety of gain, sensitivity, and output current. Currently they are available with transistor output, Darlington

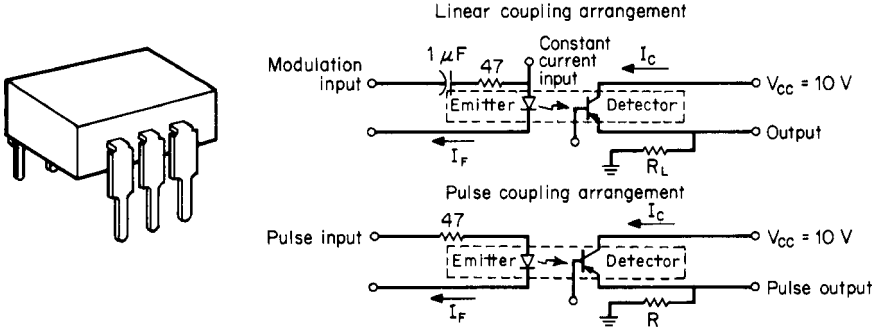

FIGURE 6.40 An optoelectronic coupler consists of an LED and a photodetector with similar spectral-response characteristics coupled to each other in a single package. It permits efficient transfer to linear or pulse signals between circuits where impedance matching is difficult.

output, SCR output, triac driver output, and Schmitt trigger output. They are even being combined with on-chip amplifiers. This is a case of matching design to a required application, and the couplers clearly lend themselves ideally to custom fabrication when end-use quantities are high enough to permit economical production.

12. Varactor diodes. Normally, a *p-n* junction (diode) is operated in the forward conduction region, as a rectifier, or in the reverse breakdown (avalanche) region, as a zener. There is, however, a third region, the region between forward conduction and reverse breakdown (Fig. 6.41), in which the junction is nonconductive and acts as a capacitor. This junction capacitance is an undesirable parasitic in most applications but becomes the mechanism whereby the junction can act as a variable-capacitance (tuning) diode or frequency multiplier.

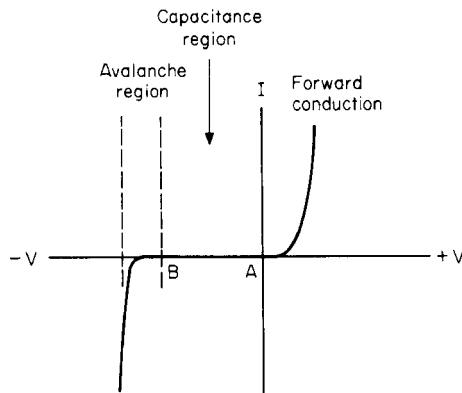

FIGURE 6.41 The three regions of a junction *I-V* characteristic curve are used for various applications: the forward conduction region for rectification, the capacitance region for voltage-variable capacitance diodes, and the avalanche region for zener diodes.

FIGURE 6.42 Typical capacitance versus reverse-voltage variations of one commercial line of hyper-abrupt junction diodes.

An unbiased semiconductor junction simulates a slightly charged capacitor, with the depletion region representing the dielectric and the n - and p -type regions adjacent to the junction representing the two conductive plates. If an external voltage is connected across the diode so as to reinforce the contact potential (reverse bias), the depletion-layer width increases, resulting in a decrease in capacitance. Conversely, if an external forward bias is applied, the depletion region narrows and capacitance increases. However, if the forward voltage is made large enough to overcome the contact potential, forward conduction occurs and the capacitance effect is destroyed. By applying a variable dc voltage of a magnitude between points A and B of Fig. 6.41, the capacitance of the junction can be varied to cover the tuning requirements of radio and television receivers.

Three parameters are of particular importance with varactor diodes: nominal capacitance, capacitance ratio, and Q . The nominal capacitance C is normally specified on data sheets at a particular value of reverse-bias voltage. This serves as a reference point for comparing the capacitance values of various varactor diodes. Capacitance ratio is the ratio C_{\max}/C_{\min} for a specified reverse-bias voltage range. Q is the figure of merit that defines the quality of the device as a capacitor. As a reference, mechanical tuning capacitors that are being largely replaced by varactor tuning diodes often have Q 's on the order of 1000 or greater. Tuning-diode Q 's are generally considerably lower but still are adequate to achieve the desired performance.

The capacitance change over a specific voltage range for a commercial line of tuning diodes is shown in Fig. 6.42.

Varactors can be applied to most sections of a receiver or transmitter where variable capacitors are required. Usable frequencies range to several thousand megahertz, and nominal capacitance values range from about 6 to 500 pF or greater. Capacitance ratios run from approximately 15, for AM broadcast-band tuning diodes, to as low as 2.5 for diodes used for general tuning and control purposes.

Varactor diodes are useful for a variety of radio-frequency applications, including electronic tuning, harmonic generation, and parametric amplification.

13. Transducers (sensors). Transducers are representative of a class of device that converts one form of energy into another. Sensors are often defined as the basic element within a transducer in which the actual conversion takes place. This may be followed by

additional circuitry that provides signal conditioning and amplification to accomplish an end result.

Semiconductor devices, owing to their low cost and high reliability, are being adopted in increasing numbers to accomplish the basic sensing functions. Optoelectronic devices in the form of light emitters and detectors (Sec. 11) are examples of semiconductor applications for sensing purposes. Other categories include temperature sensors and pressure sensors.

Pressure Sensors. One form of pressure sensor employs the piezoresistive effect in silicon to convert a change in pressure into a change in electric current. A commercial structure of this type is illustrated in Fig. 6.43. Here a cavity, or chamber, is etched into one side of a bar of silicon, leaving a thin, flexible bridge of silicon that acts as a diaphragm. A resistive element is diffused into this diaphragm at a point where it is most susceptible to stress when the diaphragm is flexed. A pair of contacts is placed at a point of the resistor to measure the transverse voltage at that point when a current flows through the resistor.

FIGURE 6.43 Top view and cross section of a commercial pressure-sensor chip. [Motorola Inc.]

FIGURE 6.44 Absolute-pressure measurement.

depending on the polarity of the external pressure, whether positive or negative (Fig. 6.44).

For differential-pressure measurements, the chamber is left unsealed so that an external positive (downward) pressure applied to the “pressure” side of the diaphragm acts against existing atmospheric pressure at the underside to create a differential voltage. Alternatively, the difference between two external pressures can be measured by applying these simultaneously to opposite sides of the diaphragm, through pressure ports associated with the package (Fig. 6.45).

While piezoresistive techniques in silicon provide a very accurate and linear output, they are temperature-sensitive and generate an initial offset voltage. Both effects can readily be compensated for with external circuitry, but integrated-circuit technology has been

FIGURE 6.45 Packaged pressure sensor with ports for the application of external pressure.

The resistance value is subject to change as the resistor is stressed as a result of pressure being applied to the diaphragm (piezoresistive effect). This causes a change in voltage at the points of contact that is available for measurement or control purposes by means of the package pins.

The device can measure absolute pressure with respect to a vacuum or differential pressure with respect either to atmospheric pressure or to two different pressures applied to opposite sides of the diaphragm. For absolute-pressure measurements, the chamber is sealed off in an evacuated atmosphere to create a vacuum on the underside of the diaphragm. This flexes the diaphragm and generates a reference offset voltage equal to 14.5 psi (1 atm). When an external pressure is applied to the opposite side of the diaphragm, the output voltage varies linearly above or below the reference point,

FIGURE 6.46 Schematic diagram of a fully compensated monolithic pressure sensor (a) and output characteristics of compensated and uncompensated devices (b).

employed to put temperature compensating and calibrating directly on the chip during the fabrication process. The compensating thin-film resistor network is laser-trimmed during the computer-controlled manufacturing process to provide good temperature stability and to eliminate the offset (Fig. 6.46). The more advanced devices feature on-chip amplification to increase the output-voltage span from millivolts to volts.

INTEGRATED CIRCUITS

The evolution of integrated circuits has initiated tremendous innovations in the conception, design, and manufacture of electronic equipment. The individual components such as resistors, capacitors, and inductors, which once were the building blocks of all electronic equipment, are being relegated to relatively minor peripheral functions. Circuit designs are being implemented without the benefit of capacitors and inductors, which are difficult to combine with active components on a practically sized silicon chip. Even the resistor is losing its battle against active devices, such as transistors, which can often serve the resistive function more compatibly and in much less space. Digital techniques are replacing analog functions in communications circuitry. The computer is replacing the time-honored "breadboard" for developing, testing, and evaluating new circuit and system designs; and in the factory the microscope is replacing the soldering iron as the basic manufacturing tool in many instances.

But there still remains a large number of applications for which ICs are not yet adaptable. Integrated circuits are not able to produce high power output; they are uncomfortable in VHF-UHF applications, and they are not particularly well suited to very simple electronic equipment that might have special requirements outside the realm of standard off-the-shelf ICs. Indeed, while ICs are expanding into ever larger subsystem functions, they will continue to need discrete-component supplements for some time to come.

All integrated circuits have a common goal of reducing equipment size and cost and improving reliability and performance. There are many different paths toward achieving these goals. The more important of these are listed in Table 1.

TABLE 1 Integrated-Circuit Classifications

Technology	Applications	Complexity	Selection
Monolithic	Digital	SSI	Standard
Bipolar	Linear	MSI	Semicustom
MOS		LSI	Custom

Thin film			
Thick film			

14. Integrated-Circuit Technology

Monolithic Circuits. Monolithic circuits are those in which all associated components are fabricated and interconnected on or within a single chip of silicon. Processes employed are basically separated into *bipolar*, using the two-junction transistor as its basic element, and *MOS*, using the unipolar field-effect structure as its building block.

Bipolar processing generally yields greater speed and permits the design of higher-voltage and higher-power circuits. MOS processing, including the widely implemented complementary MOS (CMOS) structure, offers greater component density and much lower internal power dissipation. Therefore, bipolar circuits are widely used in linear circuits, in small-scale-integration (SSI) and medium-scale-integration (MSI) logic circuits, where they are so well entrenched that they cannot be economically replaced, and in circuits where state-of-the-art speed is required.

MOS circuits, particularly CMOS circuits, are utilized primarily in digital LSI and VLSI designs, where their small geometries and extremely low power requirements permit implementation of circuit complexities that cannot readily be achieved by other means.

Progress is being made in combining bipolar and MOS technologies, each to its own advantage, within a single chip, and some such circuits are being marketed. Generally, however, the two technologies are being used independently.

Hybrid Circuits. Hybrid circuits utilize a combination of monolithic integrated circuits and discrete components attached to and interconnected by a thin- or thick-film conductive pattern deposited on an insulating glass or ceramic substrate (Fig. 6.47). They are used basically for size and weight reduction of complex circuitry whose component complement does not permit monolithic fabrication. High-power circuits and radio-frequency circuits which require capacitors and inductors are typical candidates for thin-film construction techniques.

The advantages of thin-film circuits over conventionally wired circuits using printed-circuit boards lie in the fact that most of the passive elements of a complete circuit, such as resistors and capacitors, can be fabricated directly and simultaneously on the insulating substrate. Similarly, all interconnections can be made at one time, often in conjunction with one of the deposition steps of the passive elements. Then the active components (or monolithic ICs) are added separately and interconnected with the previously deposited pattern on the substrate. To save space, active elements are often utilized in chip form and wire-bond

FIGURE 6.47 Hybrid UHF power amplifier module capable of 2.2-W output at frequencies up to 900 MHz. It is designed for portable cellular radio applications.

FIGURE 6.48 Tiny surface-mounted packages now replace unencapsulated chips in hybrid-circuit designs because of their simpler installation and testing.

techniques are employed for subsequent interconnections. This practice, however, introduces manufacturing and testing complications. The recent proliferation of surface-mounted packages for both discrete active components and ICs (Fig. 6.48) greatly simplifies hybrid-circuit manufacturing with little penalty on space utilization.

Digital Circuits. Digital circuits are those dealing exclusively with the technology of *ones* and *zeros*. Their active elements, predominantly transistors, are used as switches which are either on or off. These circuits are used as digital logic elements in computer and control applications. They are composed primarily of basic building blocks, called *gates*, which are interconnected in a variety of ways to form more complex functions such as flip-flops, counters, and a myriad of other circuit entities. In all instances, however, the basic

circuit is driven by a signal whose voltage level is either high or low (one or zero), causing the circuit to be turned on or off and the output voltage to be either high or low, or true or false, depending on the terminology associated with a particular application. Generally, digital circuits, no matter how complex, are operated at low voltages, normally ranging between 3 and 10 V.

Linear Circuits. Linear circuits are not as clear-cut in definition. Generally, they encompass analog functions, such as amplifiers, whose output is *proportional* to the *level* of the input signal. Also included in the linear category are analog-to-digital (A/D) and digital-to-analog (D/A) converters, comparators, voltage regulators, and even interface circuits whose functions are more digital than analog in nature.

In recent years, the proliferation of circuits and the increasing complexity which permits the combination of digital and linear functions in a single chip have made these classifications virtually obsolete. The present trend is toward definitions that classify circuits in terms of their primary intended applications. Categories such as logic circuits, microcomputer circuits, voice-data circuits, analog circuits, power-conversion circuits, etc., are becoming more commonplace. While such definitions also have limitations and while there is as yet no standardization of such classifications, they serve as the basic subsections for the following discussions. These discussions, moreover, will be limited primarily to standard circuits, available off the shelf from IC manufacturers and distributors as the basic building blocks for system designs. A brief discussion of the growing trend toward semi-custom and custom approaches is included.

15. Integrated-circuit complexity. Integrated circuits in general and logic circuits in particular are classified within four basic categories: small-scale integration (SSI), medium-scale integration (MSI), large-scale integration (LSI), and very-large-scale integration (VLSI). Initially, each of these encompassed a degree of chip complexity involving a specified number of equivalent gate circuits (gate equivalents). The rapid progress in IC technology has rendered this practice virtually obsolete, since the VLSI circuit of only a decade ago would hardly be classified as more than MSI today. Nevertheless, the terms still apply on a relative basis, although the judgment of where one classification ends and the other begins is largely a matter of personal interpretation.

16. Integrated-Circuit Selection

Standard versus Custom Circuits. From the very beginning of the technology, the development and production of state-of-the-art ICs has been a time-consuming and expensive endeavor. For IC manufacturers, each new circuit represented a gamble on whether the device would sell in large enough quantities to permit recovery of the development cost and, subsequently, to produce a profit. In the earliest days, the odds were good because there were enough universally required circuits to assure large-scale acceptance. Gates and flip-flops for digital equipment, operational amplifiers, and voltage regulators in the linear field were certain to find ready markets. IC manufacturers found it easy to identify such circuits and rapidly built up inventories of a large variety of “standard” off-the-shelf devices that were sold to all comers.

Even then, however, some equipment manufacturers opted to have special proprietary circuits designed on a custom basis if their volume requirements were large enough to amortize development costs. In many instances, these custom circuits, after an agreed-upon time, became standard circuits offered on the open market.

As the technology advanced, it became more difficult to identify increasingly complex circuits that would find a large general market. Accordingly, the development of standard circuits has become a greater gamble for the manufacturer. And as the demand for ever-increasing device complexity has increased, the number of original-equipment manufacturers (OEMs) able to afford the cost of designing such proprietary VLSI circuits is dwindling. As a result, an intermediary technology has emerged that permits the development of very complex semicustom circuits, utilizing a library of predefined basic circuits.

Called applications-specific integrated circuits (ASICs), these devices sacrifice some custom-design flexibility, by being constrained to the basic-circuit library, but are much less costly and less time-consuming to produce.

ASIC technology is applicable largely to circuits so complex that they can be implemented only through computer-aided-design (CAD) techniques. Currently, two types of ASIC techniques have reached production status: gate arrays and standard cells.

Gate Arrays. The most complex digital logic circuits can be designed through the interconnection of basic gate circuits in various unique arrangements and sequences. IC manufacturers take advantage of this fact by producing complete wafers full of identical basic gate circuits. Then they provide a computer-stored program for interconnecting the gates into circuits of increasing complexity. During the design cycle, the system designer formulates a complex design by using the library of subcircuits issued by the IC manufacturer. The computer-stored program is then utilized to develop an interconnect system that converts the network of gates on the wafer into an exact duplication of the complex design. Use of prefabricated gate arrays and a proven CAD program saves months of time compared with custom design of VLSI circuits.

Macrocell Arrays. Macrocell arrays are similar to gate arrays, except that the prediffused wafers do not contain prewired basic gates but rather a pattern of islands each of which contains a number of prediffused transistors and resistors (Fig. 6.49). The IC manufacturer issues a library of predefined functions called *macros* that the computer program can produce from the discrete parts within each island and subsequently interconnect into a custom IC. In theory, the macrocells—flip-flops, counters, registers, and a wide variety of additional digital building blocks—can be designed more efficiently from discrete components than from basic gates, yielding smaller geometries (equivalent to lower cost) and improved performance. As with gate arrays, the designer develops VLSI circuits with the macros contained in the library, and the computer develops the necessary mask patterns that convert the prediffused macrocell wafers into functional VLSI circuits.

Commercial Implementation. The efficiency of the gate-array-macrocell-array concepts depends upon the availability of arrays that closely match the needs of the designer. For example, a prediffused array with fewer on-chip gates (or islands) than required for the envisioned VLSI circuit would increase the number of IC packages; an array with too many on-chip gates would result in unused wafer space. IC manufacturers therefore offer a variety of array sizes (Table 2) that permit a close match between need and availability. Moreover, such arrays are available for a variety of technologies (bipolar and MOS) to offer a number of performance options.

Standard Cells. Standard-cell concepts go one step further toward true custom designs than gate or macrocell arrays do. These too start with a computer-stored catalog of basic circuits (standard cells) that form the building blocks for VLSI designs. Rather than using prediffused wafers of basic cells, with each cell requiring an equal

FIGURE 6.49 A typical macrocell-array chip layout (a) illustrates cell placement and routing channels. Component content (b) represents one-half of the complement within each major cell. *M* = major cell; *I* = input cell; *O* = output cell.

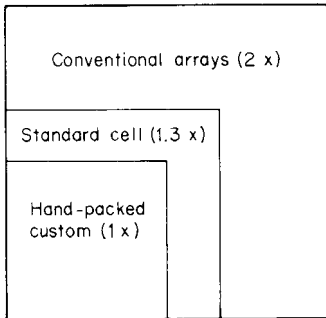

FIGURE 6.50 Relative comparison of die size between full-custom and semi-custom circuits.

amount of chip space, a standard cell is designed to provide maximum efficiency with a layout requiring a minimum amount of space. The computer then provides the necessary mask patterns for the fabrication of the complete circuit, not just the interconnect patterns for the prediffused arrays. The use of custom-designed standard cells, compared with equivalent cells made from array components, can save a significant amount of chip space (Fig. 6.50) and produce end results that closely rival those of true custom circuits. Yet, because these end circuits are fashioned from predefined building blocks with the computer doing much of the design, development time is substantially reduced.

TABLE 2 Macrocell Arrays*

Technology:	ECL			TTL			ECL-TTL		
Bipolar array number:	MCA 600 ECL	MCA 1200 ECL	MCA 2500 ECL	MCA 500 ALS	MCA 1300 ALS	MCA 2800 ALS	MCA 2900 ETL

*These arrays run the gamut of technologies and offer a variety of cell configurations. Comparative speed-power specifications are given. [Motorola Inc.]

INTEGRATED-CIRCUIT LOGIC FUNCTIONS

Logic circuits are implemented with either bipolar or MOS technologies. Bipolar logic circuits encompass a variety of different basic “families,” each with its unique advantages and limitations. These various families are divided into two generic categories: saturated logic and nonsaturated logic. In saturated-logic designs, the transistor (acting as a switch) is driven from the cutoff condition to the saturated condition by the input signal. In nonsaturated logic, the transistor is not switched from full off to full on but swings above and below a specified reference level. Thus, nonsaturated logic avoids some of the inherent transistor time delays associated with saturated-mode switching but pays for the resulting improvement in switching speed with increased power consumption.

Integrated logic circuits have gone through a number of iterations. The early forms, carryovers from discrete designs, were bipolar resistor-transistor-logic (RTL) and diode-transistor-logic (DTL) circuit designs, all utilizing saturated-logic forms. These have been largely replaced with a variety of transistor-transistor-logic (TTL) designs utilizing bipolar technology, with bipolar nonsaturated emitter-coupled-logic (ECL) designs where maximum speed is required, and with CMOS (complementary MOS) designs using MOS technology where low power consumption is a basic requirement. In general, SSI and MSI circuits are being implemented with bipolar and CMOS technologies, both of which offer a wide selection of standard circuits as building blocks. LSI and VLSI designs utilize CMOS technology to an ever-increasing degree.

17. Transistor switching characteristics. While the performance of a logic family is judged on a number of characteristics, the most important of these is switching speed. *Switching speed* defines the time it takes for a transistor, or gate, to change its output from one state to another in response to a change in the input signal.

Figure 6.51 shows a typical switching transistor and its associated input and output waveforms. In a “perfect” switch, the output current would follow the input-voltage waveform exactly. The practical circuit involves a number of delays. Note that collector current

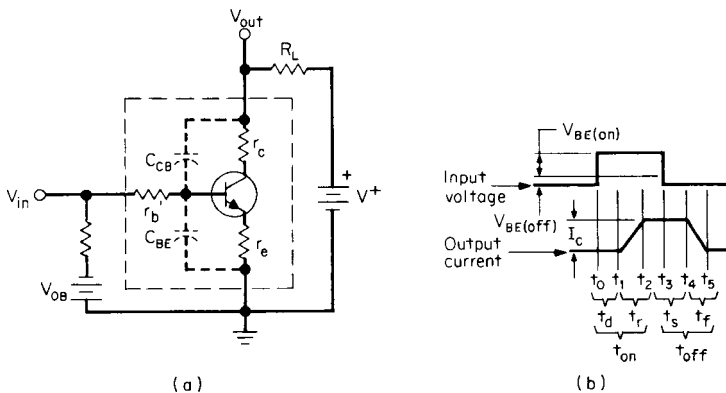

FIGURE 6.51 A typical saturated-mode switching circuit (a) and its input and output waveforms (b).

does not begin to flow until time t_1 , some time after t_0 , where the base voltage rises to its maximum value. The difference between t_0 and t_1 is the *turn-on delay time* (t_B), caused by the need to charge or discharge the transistor interelectrode capacitances (C_B and C_C) before current flow can begin.

At t_1 collector current begins to flow but cannot rise instantly to its maximum value because of the finite time required for charge carriers to traverse the base region of the transistor between the emitter and the collector. The time required for the current to rise from 10 to 90 percent of its maximum value (from t_1 to t_2) is called *rise time* (t_B).

When the transistor is driven into saturation, both the emitter and the collector junctions are forward-biased and dump minority carriers (electrons, in the case of an n - p - n transistor) into the base region. When the base voltage suddenly drops to zero, at t_3 , these carriers must be ejected through the collector circuit. Hence, current continues to flow until all these carriers have been pulled out of the base region. The time difference between t_3 (the drop of the base signal to zero) and the point where collector current begins to drop at t_4 is called *storage time* (t_s). Even then, collector current cannot drop instantly to zero because the interelectrode capacitances cannot discharge instantly. The gradual decay of collector current between t_4 and t_5 is the *fall time* (t_f).

From the above, it is clear that a practical transistor switch involves both a turn-on delay time (t_{on}) and a turn-off delay time (t_{off}). Of these, t_{off} is by far the greater and is significantly influenced by t_s , which in turn results from driving the transistor into saturation.

The Gate Function. The basic circuit of all logic elements is the gate circuit. Virtually all building blocks associated with digital equipment, flip-flops, counters, shift registers, etc., can be made by interconnecting a series of gate circuits. Hence, the complexity of any given logic circuit is specified by the number of equivalent individual gate functions it encompasses. The electrical characteristics of a basic gate circuit within a given logic family (TTL, ECL, CMOS, etc.) are often used for comparing the capabilities of various logic families.

A gate is simply an electrical or electronic switching circuit, with two or more inputs, through which power is applied to a load. The mechanical equivalent (Fig. 6.52a) shows an OR gate consisting of two switches (relays) connected in such a way that power is applied to the lamp (load) when either switch *A* or switch *B* is closed. Figure 6.52b shows an AND gate which applies power to the load only when switch *A* and switch *B* are closed.

In Fig. 6.52c, an additional relay is connected to the OR circuit so that power is applied to the load only when switch *A* and switch *B* are *not* closed. This is a NOT OR, or NOR, gate.

Similarly, an AND circuit connected in such a way that the load is powered only when switch *A* and switch *B* are *not* closed simultaneously (Fig. 6.52d) is a NAND gate.

The additional relays perform the function of an *inverter*; i.e., they invert a normally high (or 1) output of an OR or AND gate into a low (or 0) output, and vice versa. Hence, an OR or AND gate can be converted to the NOR or NAND function by running the outputs through an inverter.

In Fig. 6.53, the switching relays of Fig. 6.52 have been replaced by diodes which serve similar functions. In the OR gate (*a*), the output is high (or 1) when the input to diode *A* or diode *B* is high. In the two-input AND gate (*b*), the output is high only when both diode inputs are high. If either input were low, the corresponding diode would conduct and the output would be equal to the very low (0) voltage drop of the conducting diode.

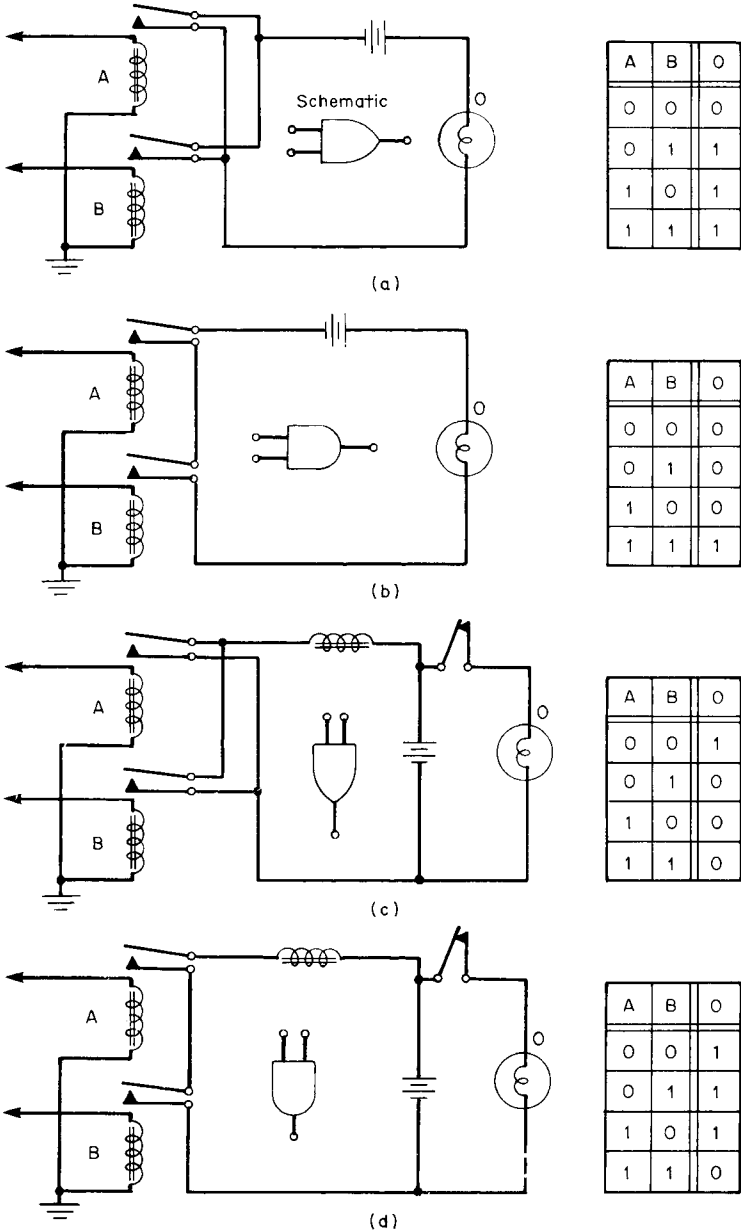

FIGURE 6.52 Basic mechanical gate functions. (a) Mechanical equivalent of a two-input OR gate and its representative functional truth table which illustrates the status of the output *o* as a function of the status of inputs *A* and *B*. (b) Mechanical AND gate and its accompanying truth table. (c) NOR gate and its truth table. (d) NAND gate and its truth table.

FIGURE 6.53 Diode logic OR (a) and AND (b) gates.

FIGURE 6.54 Basic NAND function.

When a common-emitter transistor circuit is added to the above circuits (Fig. 6.54), the transistor automatically converts a low-level input into a high-level output (and a high-level input into a low-level output), thereby acting as an inverter. Thus, a transistor added to a diode AND gate results in a NAND gate, and a transistor added to a diode OR gate results in a NOR gate.

18. Saturated-logic gates. In many switching-circuit families the transistors are driven from deep-in cutoff, where the collector voltage is equal approximately to the supply voltage, to a high level of conduction (saturation), where the collector junction becomes forward-biased, resulting in a very low collector voltage, $V_{CE(\text{sat})}$, that remains relatively constant even if the base-drive voltage is further increased. In this latter condition, virtually all the power supply voltage is dropped across the collector load resistor—a limiting condition that prevents any further increase in collector current even if the charge injected into the base is increased by a further rise in base voltage. This is called *saturated-mode switching*.

Diode-Transistor Logic (DTL). The basic DTL gate circuit is the DTL NAND gate shown in Fig. 6.55. Note that it uses the NAND circuit of Fig. 6.54 plus an offset-voltage diode circuit. The offset-voltage diode circuit, being returned to a negative bias voltage through resistor R_3 , improves noise immunity and transistor turn-off time.

FIGURE 6.55 Basic DTL NAND gate. Operation: With a low-state voltage, say $V_{CE(sat)} = 0.1$ V, applied to input diode D_1 or D_2 , current I_1 will flow through the diode, causing the voltage at point A to equal one diode drop, or approximately 0.7 V. At the same time, current I_2 will flow through diodes D_3 and D_4 , causing the voltage at point B to be two diode drops less than that at point A, or approximately -0.7 V. With a negative voltage thus applied to the base of transistor Q_1 , the transistor will be cut off and its collector voltage V_{out} is equal to V^+ , or 4 V (neglecting leakage current). If we now apply a high-state voltage, say 4 V, to both input diodes, they will be reverse-biased and become nonconductive. The base of Q_1 therefore “sees” a relatively high positive voltage, and the transistor will be driven into saturation. Its output voltage then is $V_{CE(sat)}$. Therefore, V_{out} swings from $V_{CE(sat)}$ to nearly V^+ .

Transistor-Transistor Logic (TTL). The DTL circuit just described was the basis of a more advanced logic line currently in use. Known as transistor-transistor logic (TTL), this logic is considerably faster than other forms of saturated logic.

The basic diagram of a typical TTL gate circuit is shown in Fig. 6.56. The principal difference between DTL and TTL is that the latter uses the collector-base junctions of a multiple-emitter transistor Q_1 as the input diodes and the collector-base junction as the off-set diode. This, however, has a considerable effect on the operation, as follows:

FIGURE 6.56 Basic TTL gate circuit.

When the input voltage to one or more of the Q_1 emitters is very low, say, zero, the base-emitter junction is forward-biased, through R_1 , to a high positive voltage. Current flow through this junction, therefore, establishes approximately 0.7 V at the base. The collector of Q_1 is returned to ground through the base-emitter junctions of Q_2 and Q_3 . Thus, the

collector-base junction is also forward-biased, and it would appear that there should be a current flow through the emitter-base junctions of Q_2 and Q_3 . This cannot occur, however, because it would require a Q_1 base voltage of at least three junction drops [$V_{BE(Q_3)} + V_{BE(Q_2)} + V_{CB(Q_1)}$], or 2.1 V, to turn both Q_2 and Q_3 fully on. Therefore, Q_2 and Q_3 remain cut off and the output voltage V_{out} is equal to V^+ (minus a small leakage drop).

Now if the input voltage is increased to approximately 0.6 V, the Q_1 base voltage rises to 1.3 V, and the collector junction of Q_1 and the base junction of Q_2 will be brought to the threshold of conduction through R_2 . As input voltage increases still further to about 1.3 V, Q_1 base voltage rises to 2.0 V, the collector and Q_2 base junctions become fully conductive, and the voltage across R_2 rises to 0.6 V. This brings Q_3 to the threshold of conduction, so that any additional increase in input voltage causes Q_3 to turn on and the output voltage drops to $V_{CE(sat)}$.

For most of the operating cycle the multiple-emitter input transistor acts as though it were a pair of back-to-back diodes. During one small part of the turn-off operation it does act like a transistor, thereby improving circuit speed. Specifically, when the input is in the high state and both Q_2 and Q_3 are conducting, the voltage at the base of Q_1 is 2.1 V while the base voltage of Q_2 is 1.4 V. Thus, Q_2 is in saturation, and a heavy charge is built up in its base region. Now the input suddenly drops to zero and the Q_1 base voltage drops to 0.7 V (the forward voltage drop of the input diode). If the Q_1 collector-base junction were an ordinary diode, it would be reverse-biased and Q_2 would be suddenly cut off. As a result, the stored charge in the Q_2 base would have to be dissipated by recombination, and Q_2 would continue to conduct until equilibrium was restored. Storage time, therefore, would be relatively long.

With the transistor, however, for the conditions existing at Q_2 turn-off, the emitter of Q_1 quickly drops to nearly zero volts. The base drops to 0.7 V, but the collector remains near 1.4 V because of the charge in the base of Q_2 . These are the proper biases for transistor action and cause a sudden surge of Q_1 collector current that quickly clears Q_2 of its stored charge. Thus, storage time of Q_2 is drastically reduced.

19. Nonsaturated-logic gates.

See Secs. 20, 21, and 22.

20. Schottky TTL. The basic TTL family has been substantially improved by a number of variations, involving the use of Schottky diodes to keep the transistors out of saturation during turn-on. Since the switching time delay associated with transistor *storage time* is the result of driving the device into saturation, nonsaturated logic can considerably improve switching speed.

Schottky TTL simply involves the use of a Schottky diode between collector and base of a transistor, as shown in Fig. 6.57. Since this configuration can be achieved during the fabrication of the transistor without the use of a separate diode, it adds little to the device cost, but it has a great effect on performance.

Specifically, since the turn-on voltage for the diode is considerably less than that for a conventional junction diode (in this case, the collector-base junction of the transistor), diode conduction occurs before the $V_{CE(sat)}$ region of the transistor is reached. Therefore, the collector voltage will be clamped at a value that prevents the collector-base junction from becoming forward-biased, and storage-time delay during turn-off is avoided (see Secs. 17 to 23).

FIGURE 6.57 A representative Schottky-clamped transistor (a) is normally indicated by the schematic symbol in (b).

FIGURE 6.58 A simple RTL inverter circuit is used here to demonstrate the concept of noise immunity and the fanout effect on noise immunity.

By raising the minimum achievable collector voltage somewhat, the maximum output voltage of the transistor is correspondingly reduced. This lowers the noise margin slightly, but not enough to be seriously detrimental for most applications.

Noise margin can be simply described with the aid of the basic RTL inverter circuit and transfer characteristics in Fig. 6.58. From the transfer characteristics it is seen that when the input to the transistor is low (say, 0 to 0.6 V in this instance), the output voltage is high and current is delivered to the load. As the input voltage rises to approximately 0.6 V, the transistor begins to conduct and its output rapidly drops toward $V_{CE(sat)}$ (approximately 0.1 V). For any input voltage greater than 0.9 V, the output remains at $V_{CE(sat)}$. The output voltage swing therefore is from 0.1 to 1.65 V.

Under low-input conditions, if a noise pulse of 0.5 V or higher were to appear at the input of the gate, the noise voltage would add to the 0.1-V input voltage and the gate would tend to change its output from high to low. Therefore, the gate is immune to noise signals up to 0.5 V, or it has a high-state noise margin of 0.5 V.

The RTL circuit is used in the above example because it permits a simple discussion of noise immunity (it is no longer a popular logic format). It also offers a simple demonstration of the effect of fanout (FO) on noise immunity. In this instance, if the output voltage were applied simultaneously to five succeeding stages, the high-state voltage would drop to approximately 1 V and the low-state noise immunity would approach zero.

Schottky TTL logic families now include a variety of circuit innovations. All are based on the familiar 54/74 TTL series, which for years has been the dominant logic family for general-purpose applications. Only within the last few years has the Schottky LSTTL series made significant inroads, replacing the original 7400 series with lower power requirements and higher speed. The latest in this progressive logic series are the advanced low-power Schottky (ALSTTL) family and the FAST Schottky TTL series.

The *low-power Schottky (LSTTL) family* combines an improvement in current and power reduction over the standard 7400 TTL by a factor of 5. This is accomplished by advanced processing and by using Schottky diode clamping to prevent saturation.

The *advanced low-power Schottky TTL family (ALSTTL)* provides a 50 percent power reduction compared with the standard 54/74 LSTTL and yet offers improved circuit performance over the standard LS owing to a state-of-the-art oxide-isolated process (MOSAIC).

ALS also differs from LS in that p - n - p transistors on the input stage are utilized to lower input currents and raise thresholds.

The *FAST Schottky TTL family* provides a 75 to 80 percent power reduction compared with the standard Schottky 54/74S TTL and yet offers a 20 to 40 percent improvement in circuit performance over the standard Schottky owing to the MOSAIC process. Also, FAST circuits contain additional circuitry to provide a flatter power-frequency curve. The input configuration of FAST uses a lower input current, which translates into higher fanout.

Speed-power comparisons of these three families are indicated in Table 3.

TABLE 3 Speed-Power Characteristics for Schottky TTL Logic*

Characteristics	Symbol	LS	ALS	FAST	Units
Quiescent supply current or gate	I_G	0.4	0.2	1.1	mA
Power or gate (quiescent)	P_G	2.0	1.0	5.5	mW
Propagation delay	t_p	9.0	5.0	3.7	ns
Speed-power product	...	18	5.0	19.2	pJ

Clock frequency (counter)	f_{\max}	40	45	125	MHz

*All typical ratings.

21. Emitter-coupled logic (ECL). Emitter-coupled logic is the fastest form of logic currently available. It is nonsaturated logic which is extremely flexible, with both OR and NOR logic outputs available from the same basic gate configuration.

ECL utilizes a pair of input transistors, one of which is in a conductive state while the other is nonconductive. Switching is accomplished by means of a signal appearing across a common-emitter resistor. The basic gate circuit of an emitter-coupled logic circuit is shown in Fig. 6.59. It consists principally of a switching circuit, followed by an emitter-follower output circuit. The switching circuit consists of transistors Q_1 and Q_2 , which are connected in a differential amplifier configuration. Operation is as follows:

Assume for a moment that all input transistors Q_1 are cut off owing to logical 0 being applied to their gates. Q_2 has its base connected to a fixed stable bias source V_{BB} of -1.15 V, which causes Q_2 to conduct heavily since its emitter is connected, through R_{E2} , to -5.2 V. Under these conditions the voltage drop across the base-emitter junction of Q_2 is approximately 0.75 V, and the current through Q_2 is

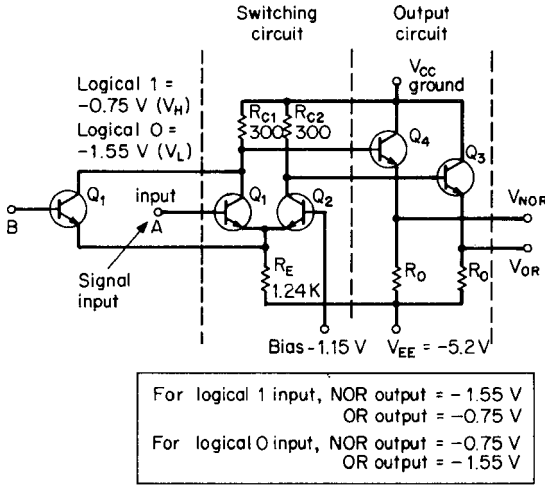

$$\begin{aligned} I_{Q_2} &= [V_{EE} + V_{BE(Q_2)} + V_{BB(Q_2)}]/RE \\ &= (-5.2 + 0.75 + 1.15)/1.24 \\ &= -2.66 \text{ mA} \end{aligned}$$

and $V_{C_2} = I_{Q_2}R_{C_2} \approx -0.8$ V

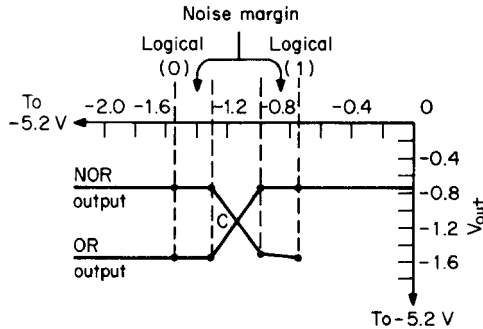

In the on condition, therefore, Q_2 is not in the saturated mode because the voltage across the collector-base junction is still positive ($V_C - V_B$), keeping this junction reverse-biased.

Transistor Q_3 , seeing -0.8 V on its base compared with -5.2 V as an emitter source, goes into heavy conduction, yielding the OR output of

$$V_{OR} = V_{C(Q_2)} - V_{BE(Q_2)} = -(0.8 + 0.75) = -1.55 \text{ V}$$

(a)

(b)

FIGURE 6.59 (a) Basic ECL gate circuit. (b) Typical transfer characteristic curve.

which represents the output-low condition.

At the same time, the base of Q_4 , being connected to the collector of Q_1 (which is nonconductive), sees a voltage of zero, causing this transistor to conduct even more heavily. Its output voltage is

$$V_{NOR} = V_{C(Q1)} - V_{BE(Q4)} = -0.75\text{V}$$

which represents the output-high condition indicative of the NOR function.

If a positive-going signal is now applied to one or more of the Q_1 transistors, the transistors begin to conduct, tending to increase the emitter voltage of Q_1/Q_2 . In turn, this reduces the forward bias on Q_2 , causing a nearly equivalent decrease in Q_2 collector current. Thus, it is clear that emitter current remains essentially constant but is switched from Q_2 to Q_1 . At the same time, the output-voltage levels of Q_3 and Q_4 reverse from their

previous states, which again is consistent with their respective OR/NOR functions. The transfer characteristics illustrated in the graph of Fig. 6.59*b* indicate the following:

1. When an ECL gate is driven by another ECL gate, it provides two output signals: one identical to the input, the other equal to the inverted input.
2. The fixed logic levels are -0.75 (logical 1) and 1.55 (logical 0) V, resulting in a difference of 800 mV between the on state and the off state.
3. The transistors are never driven into saturation; therefore, storage time is eliminated.
4. The noise margin is approximately 250 mV.
5. The total current flow in the circuit remains relatively constant, thereby maintaining a relatively constant drain on the power supply and preventing internally generated noise spikes.

The circuit, furthermore, has a very high input impedance and a very low output impedance, which makes high fanout possible. Thus, ECL not only is the highest speed logic available but provides other features that make it highly desirable for advanced systems. Its principal detriment is its limited (800-mV) logic swing, which makes it somewhat more sensitive to externally generated noise than some other logic forms. In addition, power consumption is considerably higher than for other logic forms.

Like TTL, emitter-coupled logic also comprises a number of families with progressively improved performance. Three families are in popular use: ECL 10K, ECL 10KH, and ECL III.

The ECL 10K series has become the industry standard for high-speed applications. To make the circuits comparatively easy to use, edge speed (rise and fall times) are deliberately slowed to 2.0 ns while the important propagation delay is held to 2.0 ns. The slow edge speed permits use of wire-wrap and standard printed-circuit lines; however, the circuits are specified to drive transmission lines for optimum performance.

The newer ECL 10KH family features 100 percent improvement in propagation delay and clock speeds while maintaining a power supply current equal to that of the ECL 10K. This ECL family is voltage-compensated, which allows guaranteed dc and switching parameters over a ± 5 percent power supply range. Noise margins of ECL 10KH are 75 percent better than those of the ECL 10K series. ECL 10KH is compatible with ECL 10K and ECL III, a key element in allowing users to enhance existing systems by increasing the speed in critical timing areas.

ECL III, with its 1-ns gate propagation delays and greater than 1-GHz flip-flop toggle rates, is the industry speed leader. The 1-ns rise and fall times require a transmission-line environment for all but the smallest systems. For this reason, all circuit outputs are designed to drive transmission lines, and all output logic levels are specified when driving 50- Ω loads. Because of ECL III's fast edge speeds, multilayer boards are recommended above 200 MHz. ECL III's popularity is with high-speed test and communications equipment.

Speed-power comparisons for Motorola ECL families are given in Table 4.

TABLE 4 ECL Family Comparisons

Parameter	MECL 10KH	MECL 10K		MECL III
		10,100 series 10,500 series	10,200 series 10,600 series	
Gate propagation delay	1.0 ns	2 ns	1.5 ns	1 ns
Output edge speed	1.2 ns	2.2 ns	2.0 ns	1 ns
Flip-flop toggle speed	250 MHz min	125 MHz min	200 MHz min	300–500 MHz min
Gate power	25 mW	25 mW	25 mW	60 mW
Speed-power product	25 pJ	50 pJ	37 pJ	60 pJ

22. CMOS logic. While individual p -channel and n -channel MOS devices have certain performance advantages over bipolar structures and while a p -channel logic line did gain some popularity for a short time, these advantages were not sufficient to displace bipolar logic. Not until processing technology permitted *complementary* MOS cells to become space-competitive with individual bipolar cells did MOS become a serious challenge. Now, CMOS logic families promise to become the dominant logic form over the next few years, particularly in the areas of general-purpose logic, where speed is not an overriding consideration, and in VLSI circuitry, where high chip density demands the lowest possible dissipation.

Some of the features of CMOS are attributable directly to the basic MOS transistor structure, while others are the result of (or are enhanced by) the complementary symmetry configuration. For example, the MOS transistor inherently has a very high input resistance, thereby eliminating dc fanout restrictions and providing low power dissipation. The CMOS configuration reduces power dissipation even more and increases speed, noise immunity, and logic swing.

A simple p -channel MOSFET inverter and its transfer characteristics are shown in Fig. 6.60a. (The use of a second [fixed-bias] MOSFET in place of a conventional load resistor is particularly beneficial since a resistor would require far more chip area. Thus, MOS is cost-effective by increasing the permissible number of circuits on a wafer.)

As indicated by the transfer characteristic curve, for an input voltage V_{in} between ground and V_{to} , transistor Q_s is off, so the output voltage V_o approaches the V^- state. As the input voltage approaches threshold voltage V_{to} , Q_s begins to conduct, and for further increases of V_{in} the output voltage is reduced. Note, however, that for a fixed MOSFET load resistance V_o can never reach zero because the resistance of Q_o never reduces to zero regardless of the value of V_{in} . In fact, its on resistance is substantially higher than that of bipolar transistors. Therefore, the total output-voltage swing is always less than the supply voltage V^- .

The complementary configuration (Fig. 6.60b) results in far more satisfactory performance. In this connection, the signal is applied simultaneously and in phase to both transistors so that when the signal value is zero, Q_1 is off and Q_2 is on. Under this condition, the output voltage is very nearly the full supply voltage. When the gate voltage goes high (positive), transistor Q_1 is turned on while Q_2 is turned off. This causes V_o to go virtually to zero because the current flowing through Q_1 is the leakage current of Q_2 , which is very, very low. (The resistance of an MOSFET in cutoff is approximately 5000 M Ω , resulting in a leakage current of less than 1 nA.)

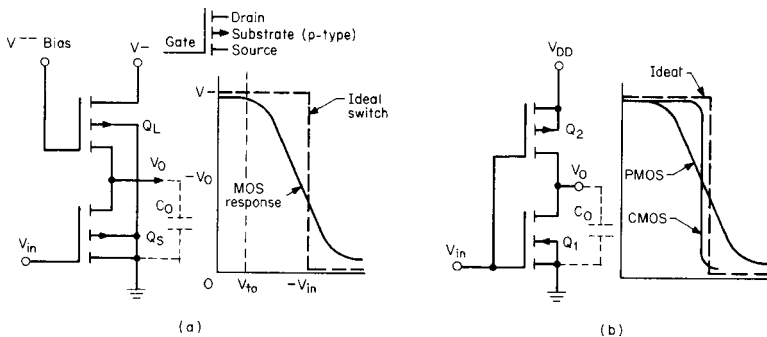

FIGURE 6.60 Inverter circuits and their response characteristics. (a) Typical PMOS inverter circuit using a fixed-bias MOSFET as a load. Transfer characteristics compare response with a “perfect” switch. (b) Typical CMOS inverter circuit with p - and n -channel MOSFETs. Characteristics closely approach an “ideal” switch.

The transfer characteristic curve for the complementary circuit is shown in comparison with that of a single-ended circuit. Observe that the slope of the complementary circuit curve is much steeper in the transition region, thus providing much greater noise immunity. This is caused by the input signal acting on both transistors in opposition, turning one device on and the other off.

In addition, it is evident that the circuit conducts current only during a very short time after turn-off (Fig. 6.61), as required to charge capacitor C_o through the load (the load is assumed to be another CMOS inverter circuit). This reduces power dissipation of the structures to such a low value that thousands of them can be fabricated within a tiny chip of silicon without special heat-sinking techniques.

Progressive improvements in technology have resulted in the current availability of two CMOS logic families: a standard metal-gate family and a high-speed silicon-gate family. In silicon-gate CMOS, the metal (aluminum) gate associated with standard CMOS is replaced by a heavily doped silicon layer which serves a similar function but has the following advantages:

1. It reduces the threshold voltage required to turn the transistor on.
2. It provides self-alignment of the gate electrode, thereby simplifying manufacture and improving fabrication accuracy.
3. It reduces gate-to-drain capacitance, thereby increasing circuit speed.
4. It permits improved space utilization, thereby increasing packing density.

General comparisons of speed and power requirements for the two CMOS families are indicated in Table 5.

FIGURE 6.61 A comparison of current flow in a PMOS and a CMOS inverter during a full on-off cycle of V_{in} .

TABLE 5 Speed-Power Characteristics for CMOS Logic*

Characteristic	Symbol	Standard CMOS	High-speed CMOS	Units
Quiescent supply current or gate	I_G	0.0001	0.0003	mA
Power or gate (quiescent)	P_G	0.0006	0.001	mW
Propagation delay	t_p	125	8.0	ns
Speed-power product	. . .	0.075	0.01	pJ
Clock frequency (D-F/F)	f_{max}	4.0	40	MHz
Clock frequency (counter)	f_{max}	5.0	40	MHz

23. Comparison of logic-family characteristics. The variety of established and newly introduced logic families challenges the system designer with choosing the best available technology for each design. Each family offers distinct advantages and limitations.

The three most often used characteristics for determining family selection are propagation delay, operating frequency, and power consumption. For the logic families described here, these characteristics are displayed and compared in the graphs of Fig. 6.62. Graph *a* illustrates the tradeoffs between power dissipation and propagation delay at low operating frequencies. As frequency increases, the changes in power-dissipation characteristics of the various families vary considerably, as shown in graph *b*. These factors, plus the ever-changing impact of economics, must be considered in the selection of the most suitable logic line.

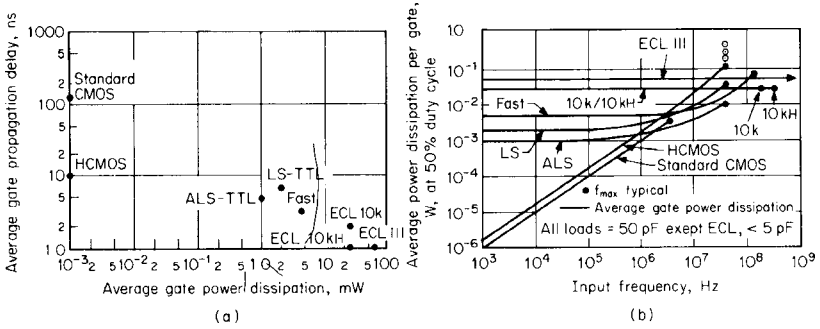

FIGURE 6.62 A comparison of major characteristics of various logic families. (a) General comparison of speed-power characteristics. (b) Variations in power dissipation as a function of operation frequency.

Linear-Circuit Families. Linear (analog) integrated circuits are as pervasive and as unique as the markets they serve. They do not lend themselves readily to classification by building-block families, as do digital circuits for which standardized basic circuits can be used repetitively in various combinations to build highly complex end systems. Linear circuits tend to be complete functional circuits applicable to a wide variety of specific unique functions. And as circuit and chip complexity increases, this situation will become even more prevalent.

There are, however, a number of linear classifications that do encompass the family approach. Chief among these are operational amplifiers and voltage regulators. These represent basic circuits utilized in many different pieces of equipment, each of which requires some variation in performance specifications.

24. Operational amplifiers. Throughout history, there has been a continuous goal to develop the “ideal” device for a particular class of application: one that would satisfy all necessary requirements, thereby eliminating the need for any other product. In the field of signal amplifiers, the operational amplifier comes close to approaching that ideal.

Originally, the operational amplifier was designed principally for performing arithmetic operations. In such applications, high amplifier gain was not of critical importance, but absolute stability and accuracy were. These were achieved through the design of a high-gain amplifier that permitted the application of a large amount of negative feedback to provide the necessary accuracy.

This is still the basic design criterion for operational amplifiers. But while virtually any operational amplifier will serve a tremendous number of amplifier functions, the ideal device still remains to be invented. Hence, while the basic operational amplifier exhibits tremendous versatility, the operational-amplifier classification probably contains more type numbers than any other single applications category.

Basically, the operational amplifier is a multistage low-level amplifier with an open-loop gain (A_{VOL} , before the application of negative feedback), ranging from a low of, say, 25,000 (25 V/mV) to 1 million or more. With such high gain levels readily available, further gain increases are apt to be by-products of improvements in other parameters rather than specific design goals. This is evident from Fig. 6.63, which shows the percent of amplifier gain error as a function of open-loop gain. It is clear that for a reasonable closed-loop-gain requirement, say, 100 or less, an open-loop gain of 1×10^6 will permit sufficient feedback to hold gain error to negligible levels.

Since integrated circuits are intolerant of capacitors, analog functions are achieved with dc amplifier configurations. This usually involves *differential* amplifier input circuits which provide stable, direct-coupled amplification with very high circuit gain.

FIGURE 6.63 When operational amplifiers are used at modest closed-loop gains, closed-loop-gain error can be held to negligible levels.

The block diagram for a typical operational amplifier is shown in Fig. 6.64a. Most integrated-circuit operational amplifiers follow this format. The primary differences are those of the circuits within each of the blocks that give the amplifier its ultimate performance specifications.

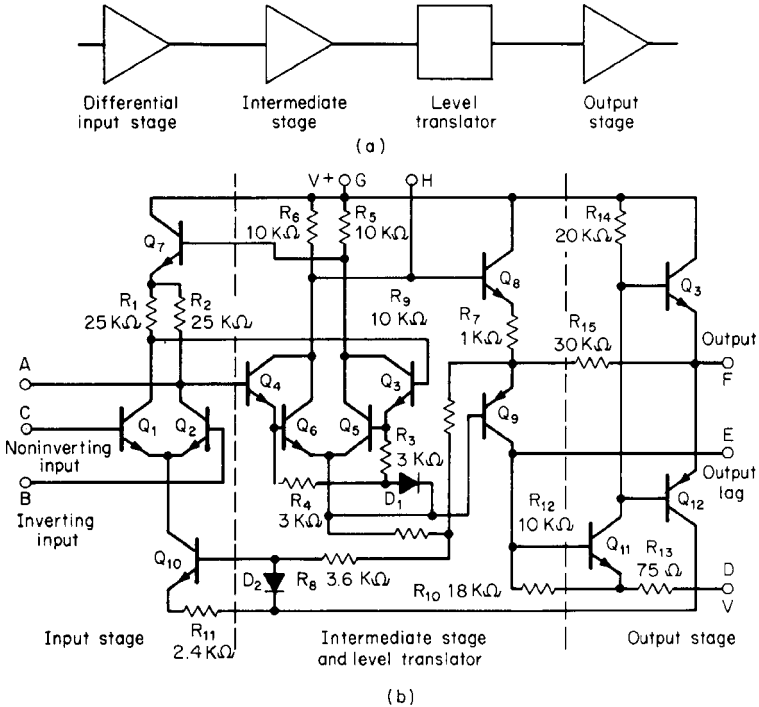

FIGURE 6.64 A block diagram of a typical operational amplifier (a) and schematic diagram of an MC1709 circuit (b).

The first stage of an operational amplifier is a differential amplifier that provides most of the circuit gain. It is desirable to have high gain in this section so that any imperfections in succeeding stages (offset voltage, etc.) have little or no effect on the output. The first stage, too, should employ a current source at the common-emitter node for good common-mode rejection.

The second stage does not require a current source in the emitter because common-mode rejection and other matching-dependent characteristics of the total amplifier are determined primarily by the specifications of the first stage. It is needed primarily to provide additional gain. Its input resistance should be relatively high to prevent excessive loading of the first stage. Therefore, an emitter-follower or Darlington-amplifier stage is often employed.

Since a single-ended output is normally employed for the second stage, it follows that a dc voltage is present at its output. In a direct-coupled system, this dc level is propagated through the amplifier chain so that the amplifier output voltage would have a dc component in addition to a desired ac output signal. Therefore, some means of level translation is employed between the second and final stages. By eliminating the dc level at the final stage, the output voltage will vary about a zero reference level, thus preventing any undesired dc current in the load and also increasing the permissible output-voltage swing.

Differential Amplifier. The differential amplifier is the ideal circuit for direct coupling because of its versatility, its excellent stability, and its high immunity to interfering signals.

From the standpoint of stability, the circuit can be made virtually insensitive to temperature changes, which often cause excessive drift in other configurations. It is versatile in that it may be adapted for applications requiring floating inputs and outputs, as in the case of some sense amplifiers, or for applications in which grounded inputs and/or outputs are more desirable. In both cases, it exhibits the same drift-free interference-rejection capabilities.

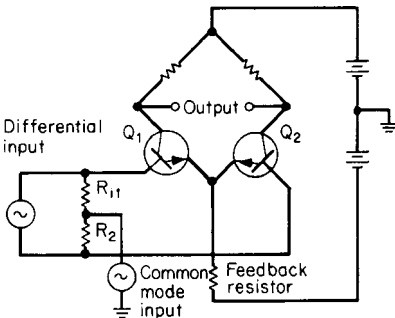

FIGURE 6.65 A basic differential amplifier circuit.

the input signals to each transistor will be equal in amplitude and in phase. The bridge will remain balanced, and the voltage between the output terminals will remain zero. Thus, the circuit provides high gain for differential-mode signals and no output at all for common-mode signals.

In applications in which output must be taken between one output terminal and ground, the common-mode signal will produce some output voltage, although there will be a very substantial reduction of gain for the common-mode signal as compared with the gain for the differential-mode input.

If, for example, a common-mode signal causes the current through the transistors to rise, the voltage drop across the common-emitter resistor also rises. This represents

To illustrate these capabilities, examine the schematic diagram of a simple differential amplifier shown in Fig. 6.65. Note that the two transistors with their respective collector resistors form a bridge which, if the transistor and resistor characteristics are identical, is perfectly balanced. Thus, the voltage across the output terminals is zero. If we now apply a differential-mode input signal and if R_{11} equals R_{12} , so that the input voltages are equal in amplitude but opposite in phase, there will be a difference in voltage between the two output terminals which is proportional to the gain of the transistors.

If a common-mode input signal is applied (caused by line pickup or other interference),

FIGURE 6.66 A differential amplifier operating from a constant-current source. With a fixed voltage at the base of Q_3 , this transistor provides a constant current regardless of load because its collector current is relatively independent of collector voltage.

degeneration, and the gain of the transistors is very low. For differential-mode signals, the current through one transistor rises while that through the other transistor drops by an equal amount. Thus, the current through the emitter resistor remains constant and no degeneration occurs. The gain for the differential-mode signal, therefore, with matched conditions assumed, is unaffected whereas that for the common-mode signal is substantially reduced.

A modified version of the basic differential amplifier, using a constant-current source in place of an emitter resistor (Fig. 6.66), represents the most common basic amplifier not only for operational-amplifier input stages but for virtually all low-power amplification purposes.

Darlington Circuit. In many applications for which an amplifier is used with a high-impedance signal source, it is desirable to have a higher input resistance than is available with conventional bipolar transistor circuits. In such cases, today's technology offers field-effect transistors and Darlington (bipolar) transistor configurations. The Darlington circuit, used as the intermediate amplifier stage in Fig. 6.64, is shown in its simplistic form in Fig. 6.67.

The input resistance of a transistor is a function of its emitter resistance r_e and its β such that $R_{in} = \beta r_e$. In the Darlington circuit shown, the input resistance of Q_2 becomes the emitter resistance (approximately) of Q_1 , and the input resistance of the circuit is

$$R_{in} = \beta r_{e(Q1)}$$

$$\text{but } r_{e(Q1)} = \beta r_{e(Q2)}$$

FIGURE 6.67 A simplified circuit of a Darlington transistor pair.

$$\begin{aligned} \therefore R_{in} &= \beta_{(Q1)} \times \beta_{(Q2)} r_{e(Q2)} \\ &= \beta^2 r_{e(Q2)} \text{ for transistors with equal betas} \end{aligned}$$

Thus the input resistance of the Darlington transistor pair is extremely high, and its loading effect on the driving source is negligible. The total β of the Darlington is also the square of the individual betas so that extremely high current gain can be obtained.

On the other hand, the ac input resistance of the pair is dependent on the input capacitance, which now shunts a much higher input resistance. Therefore, the frequency response curve of a Darlington drops off very rapidly as frequency is increased. In operational amplifiers, which are primarily intended for low-frequency applications, this is not a serious limitation, particularly since the high open-loop gain of such devices permits large amounts of negative feedback to compensate.

Operational-Amplifier Specifications. Operational-amplifier specifications, as listed on manufacturers' data sheets, cover a wide range of characteristics. Among the most important are the following:

Open-Loop Voltage Gain (A_{VOL}). This is normally specified in volts (output) per millivolts (input). This specification defines the maximum available voltage gain, without feedback, and gives an indication of the eventual accuracy that can be obtained when feedback is applied (see Fig. 6.63).

Common-Mode Rejection Ratio (CMRR). CMRR is defined as the ratio of common-mode input voltage to differential-mode input voltage that will yield the same differential-mode output voltage. With well-designed monolithic integrated circuits, common-mode rejection ratios can be as high as 100 dB.

Input Offset Voltage (V_{IO}). Although IC technology permits close matching of adjacent transistors, perfect matching is not achievable. A slight mismatch in gain between the two differential-amplifier transistors will result in an undesirable dc voltage across the differential output terminals. V_{IO} is defined as the offsetting base-emitter voltage required for equal emitter currents in the two transistors.

Input Offset Current (I_{IO}). I_{IO} is the difference in base currents required to produce equal emitter currents in differential-amplifier transistors.

Input Bias Current (I_B). I_B refers to the amount of current flowing in input terminals under no-signal conditions. When an amplifier is required to respond to extremely small input signals, the input bias current limits the response. Today's standard operational amplifiers have normal I_o 's on the order of only a few nanoamperes, and even this can be substantially reduced through the use of FET input devices to the picoampere range.

Slew Rate (SR). Slew rate refers to the maximum time rate of change of closed-loop-amplifier output voltage. It is determined by applying a step-function input signal and measuring the slope of the output pulse, as shown in Fig. 6.68a. Obviously, if an applied signal voltage varies more rapidly than the slew rate of the amplifier, the amplifier cannot respond exactly and the output signal is distorted. This can occur on a sine-wave signal, as illustrated in Fig. 6.68b, as well as on a pulsed signal.

Slew rate is specified in terms of the maximum signal-voltage change per microsecond that can be tolerated without signal distortion.

Other Parameters. Among other parameters normally specified for operational amplifiers are *power supply voltage*, which indicates the maximum output voltage obtainable; *bandwidth*, which indicates frequency response; and *temperature coefficient* of the input offset voltage, which describes the effect of temperature on operational-amplifier operation.

(a)

(b)

FIGURE 6.68 The effect of slew-rate limiting on a pulse input (a) and on a sine wave (b).

25. Power supply circuits. The power supply, which converts ac to dc operating voltages, is the one circuit that is universally required for all ac line-operated electronic equipment. In addition, the sensitivity of active components to changes in operating voltage and the potentially large variations in applied ac source voltage and load currents demand that power supplies for most equipment be well regulated in order to maintain stable operation under these variable conditions. Voltage-regulator circuits therefore are important functions for most power supplies.

Voltage regulators can be designed with discrete components to match the specific requirements of any equipment. However, the prevailing need for such circuits has resulted in a large variety of monolithic IC regulators to approximate most ideal requirements closely at a small fraction of the cost of equivalent discrete circuits.

26. Voltage regulators. A voltage regulator operates on the principle that a variable resistance in series or in shunt with the load resistance of an unregulated power supply can be used to compensate for any variation in output voltage or load resistance to keep the voltage across the load at a “constant” value.

The simplest shunt voltage regulator (Fig. 6.69a) is that of a zener diode in series with a voltage-dropping resistor R_s . Operated in the breakdown region, the zener acts much like

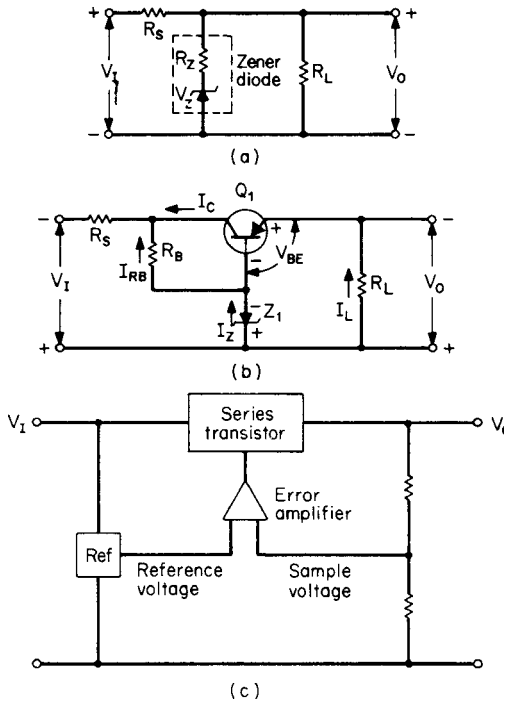

FIGURE 6.69 Progression of voltage regulators. The circuit in *c* forms the basis of today's more complex regulator ICs. (a) Basic zener shunt regulator. The internal zener resistance R_Z is very small compared with R_S and R_L . (b) A simple series-pass regulator improves efficiency and performance. (c) An improved series regulator uses the gain of a differential amplifier to increase regulator sensitivity and provide additional functions.

a voltage-activated variable resistor, in that the voltage across its terminals tends to remain constant while the current through the device varies in accordance with an applied voltage. Thus, in the simple circuit of Fig. 6.69a, if the input voltage to the circuit V_I were to increase (for a constant load resistance) or if the load resistance were to increase (for a constant input voltage), the output voltage V_O would tend to increase. As a result, the current through the zener would increase, and this increased current, flowing through R_S , counteracts the initial increase in V_O , thereby keeping this voltage close to its original value.

An improved regulator circuit is the series regulator of Fig. 6.69b. Here, the series resistance R_O of the previous circuit is replaced with the collector-emitter resistance of a power transistor. The collector-base feedback resistor, in conjunction with the zener diode, varies the bias on the transistor, thereby causing a change in its internal resistance to compensate for any change in output voltage.

A further improvement in performance results from the circuit configuration in Fig. 6.69c, in which a differential amplifier (or operational amplifier) is used to control the resistance of the series-connected transistor. The differential amplifier continuously samples the output voltage, compares it with a fixed reference voltage, and produces an "error voltage" to control the bias on the series transistor. Because the differential amplifier has considerable gain, even very small changes in output voltage will be detected and compensated for. The circuit in Fig. 6.69c forms the basis of most IC voltage regulators in use today.

IC voltage regulators are available in a variety of configurations to meet the specific needs of the system designer. These configurations include the following:

1. Three-terminal fixed-output regulators with either positive or negative output
2. Three-terminal adjustable-output regulators with positive or negative output
3. Floating regulators for increased voltage range
4. Tracking regulators with a combination positive and negative output voltage
5. Switching regulators for use in switching power supplies

Three-Terminal Fixed-Output Regulators. Such regulators are available with a variety of fixed-output voltages in a range from approximately 2 to 40 V. Permissible output currents run the gamut from 100 mA to approximately 3 A, and both positive and negative output regulators are readily obtainable. The diagram in Fig. 6.70 illustrates the simple application and the range of voltage and current available for one commercial line of regulators, but even this wide variety of capabilities is expandable through the addition of external components. Paralleling the regulator with an external series-pass transistor (Fig. 6.71) can increase current-handling capacity; adding an external preregulator (Fig. 6.72) permits operation with higher input voltage than the maximum of 35 to 40 V for which this series of regulators was designed.

FIGURE 6.70 Basic circuit configurations for positive fixed-output three-terminal regulators. C_{in} : Required if regulator is located more than a few (about 2 to 4) inches away from input supply capacitor; for long input leads to regulator up to 1 μ F may be needed for C_{in} . C_{in} : should be a high-frequency type of capacitor. C_o : improves transient response. XX: these two digits of the type number indicate nominal output voltage. Available voltages are 5, 6, 8, 12, 15, 18, 20, and 24 V.

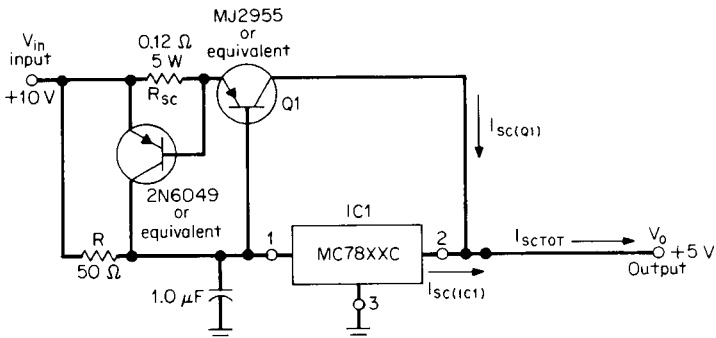

FIGURE 6.71 A current-boost configuration for positive three-terminal regulators. R : used to divert IC-regulator bias current; determines at what output-current level Q_1 begins conducting. Values shown are for a 5-V, 5-A regulator using an MC7805CK on a 2.5°C/W heat sink and Q_1 on a 1°C/W heat sink for T_A up to 70°C. [Motorola Inc.]

$$R1 = \frac{V_{in} - 30}{1.5} \times h_{FEQ1}; V_{CE0Q1} \geq V_{in}$$

FIGURE 6.72 A preregulator for input voltages above the specified maximum input voltage of the regulator. Values shown are for $V_{in} = 60\text{ V}$. Q_1 should be mounted on a 2°C/W heat sink for operation at T_A up to $+70^\circ\text{C}$. IC_1 should be appropriately heat-sinked for the package type used. [Motorola Inc.]

FIGURE 6.73 An adjustable three-terminal regulator circuit.

The simplicity of obtaining the exact output voltage required with an adjustable three-terminal output-voltage regulator is shown in Fig. 6.73. As in the previously used series, maximum output voltage is approximately 40 V, but any value from 1.2 V to the maximum limit can be obtained through the adjustment of R_2 . Current values from 100 mA to 3 A are available.

Floating Regulators. When wide flexibility in output voltage and current is required, a floating regulator can be employed. In the configuration illustrated

in Fig. 6.74 the regulator is isolated from the main power supply by a dedicated power

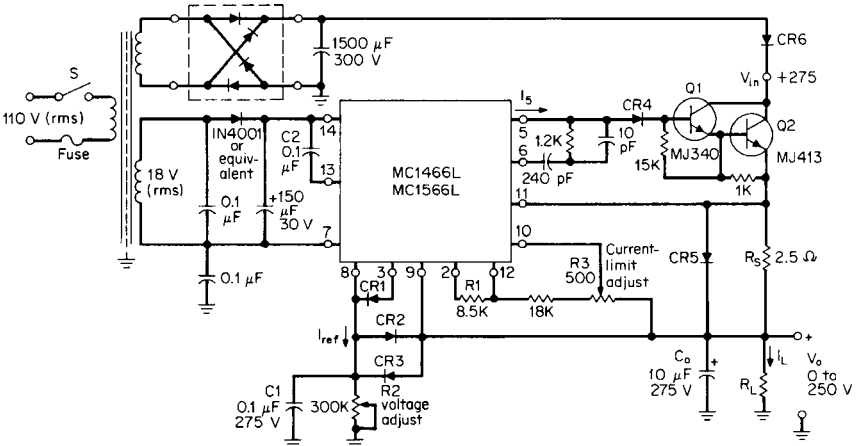

FIGURE 6.74 An MC1566, MC1466 floating-regulator configuration. For constant-voltage operation, output voltage V_o is given by $V_o = (I_{ref})(R_2)$, where R_2 is the resistance from pin 8 to ground and I_{ref} is the output current of pin 3. The recommended value of I_{ref} is 1.0 mA dc. Resistor R_1 sets the value of I_{ref} at $8.5/R_1$, where R_1 is the resistance between pins 2 and 12. For constant-current operation, (a) select RS for a 250-mV drop at the maximum desired regulated output current I_{max} ; and (b) adjust potentiometer R_3 to set constant-current output at the desired value between zero and I_{max} . Values shown are for a 0- to 250-V, 100-mA regulator using an MC1486L with Q_1 and Q_2 mounted on a 1°C/W heat sink for $T_A \leq 70^\circ\text{C}$. [Motorola Inc.]

source of its own. Its output-voltage and -current capabilities are limited only by the choice of external series-pass transistors.

Tracking Regulators. Applications requiring a dual polarity (+ and -) power supply, such as operational-amplifier circuits, can be served with tracking regulators. These consist of two regulators, interconnected so that the positive and negative regulators have the same output-voltage levels, which track each other in the event of parameter changes.

The circuit of Fig. 6.75 uses an MC1568 or MC1468 monolithic dual regulator for this purpose. Its outputs are set internally for ± 15 V, but an external adjustment can change both outputs simultaneously from 8.0 to 20 V through the use of two balancing resistors.

Alternatively, tracking regulators can be developed by interconnecting two separate regulators, one positive and the other negative, in such a way that the output of one drives the input of the other.

FIGURE 6.75 A dual-tracking regulator provides equal but opposite polarity outputs where both positive and negative voltages are required.

Switching Regulators. Switching power supplies, or “switchers,” are making rapid inroads into the power supply market. Compared with linear supplies, they have significant advantages in efficiency, size, and weight. They are, however, more complex and in the past have been considered principally for high-power applications. With the advent of IC regulators and improvement and cost reductions of other solid-state components, the cost-performance tradeoffs are no longer severe even for medium- and low-power requirements. As anticipated, therefore, switching power supplies are rapidly increasing their market share.

The basic circuit configuration of a typical flyback switcher is shown in Fig. 6.76. In this off-line circuit, the ac line voltage is rectified by a bridge rectifier and filtered by capacitor C_1 . The resulting dc voltage is then “chopped” by high-frequency square-wave pulses applied to the transistor in series with the primary-transformer winding. The resulting square wave is then passed through a high-frequency transformer. This provides the required step up or step down to produce the desired dc output after a second rectification and filtering process.

The output voltage is regulated by varying the width of the pulses applied to the chopper transistor. This is done through a pulse-width-modulator control circuit consisting of a triangular-wave generator, a pulse-width modulator, a dc reference source, and a comparator. The comparator senses the dc output voltage of the supply and compares it with the reference source. Any deviation of the output voltage from its design value will cause a control voltage from the comparator to provide a compensating pulse-width compression or expansion by the pulse-width modulator.

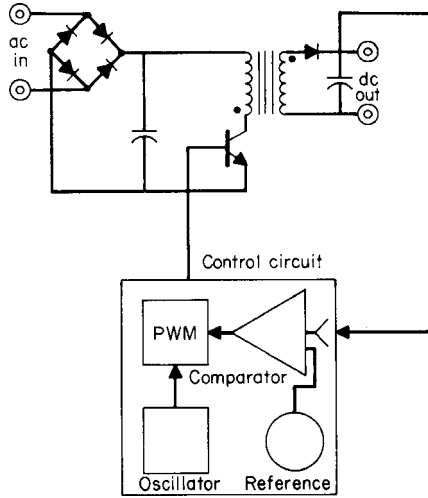

FIGURE 6.76 A representative block diagram of a typical flyback switching power supply.

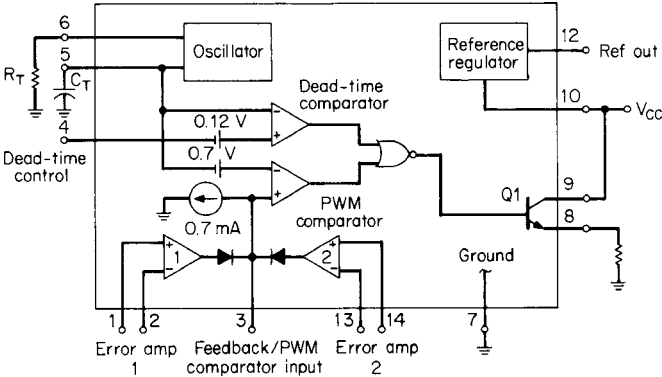

FIGURE 6.77 A block diagram of an MC34060 pulse-width-modulation control circuit incorporating the primary building blocks for the control of a switching power supply. [Motorola Inc.]

The control circuits are quite complex, as indicated by the block diagram of a typical unit in Fig. 6.77. Monolithic IC processing, however, has reduced the cost to a point at which switching power supplies are cost-competitive with series-regulated supplies for many applications. This is particularly true in view of the cost savings accruing from lower-cost transformer and filtering requirements.

MICROCOMPUTERS

Computer concepts in the 1940s were credited with revolutionizing the scientific and engineering fields by replacing people power with electronic power for computational purposes. In the 1950s, by using vacuum tubes, large computer installations performed rather primitive

routines and proved the value of these concepts in actual practice. In the early 1960s, widespread use of the transistor and its attending improvement in reliability, performance, and size expanded the influence of the computer to include business and process control applications. In the 1970s, integrated-circuit technology, with its attending cost reductions, spawned the microprocessor, which broadened computer applications to affect virtually every human endeavor and practice. From the laboratory to the factory floor, from the office to the warehouse, from the kitchen to the automobile, the invasion of the microprocessor has created dramatic changes in equipment architecture and its use.

Computers, whether mainframe, mini, or micro, all have essentially the same basic organization; that is, they all consist of a central processing unit (CPU) which performs the basic arithmetic and logic operations in response to a sequential series of instructions (program), a memory section which stores the program, and an input/output section (I/O) which communicates with external equipment. The principal difference between the three classes of computers is in the word length that can be processed and in the memory capacity, being largest for mainframe and smallest for microcomputers. The larger the word size and the internal the memory, the faster the operation of the computer and the larger and more powerful the program which can be sorted and executed.

Additionally, mainframe computers and minicomputers are usually made with bipolar components (TTL or ECL), which are inherently faster than the MOS technology employed for microprocessor units (MPUs), the CPUs associated with microcomputers. But the distinction between the various computer classifications is blurring as the latest microcomputers exceed the capabilities of today's minicomputers and approach those of existing mainframes. That is, microcomputers utilizing the latest 32-bit MPUs can serve applications formerly in the domain of the more powerful minis and mainframes, depending on the amount of memory and other peripheral circuitry used in association. It is likely that in the future the distinction between computers will be based more on the amount of circuitry crammed into a computer's architecture than on the inherent capability of the technology employed.

The pervasiveness of the microcomputer, however, depends not so much on the upper limit of its speed and processing power as it does on its miniscule size and its incredibly low cost. It is this combination that makes a microcomputer suitable not only as a general-purpose machine which must be reprogrammed for each specific end use but also as a pre-programmed and dedicated "engine" that loses its identity as a computer and becomes an electronic ignition system, a smart cash register with built-in inventory control, a control system for home appliances, or one of countless other machines in everyday use.

27. Computer architecture. The diagram in Fig. 6.78 shows the basic components of a typical computer. The heart of the system is the central processing unit (CPU), which consists of an arithmetic-logic unit (ALU) and a control unit. In a microcomputer, these two entities are normally processed on a single chip called a *microprocessor unit* (MPU). Together, these two sections provide all the action within the computer: the control unit "fetches" the instructions and the data from the memory section in the proper sequence and feeds these to the ALU; the ALU performs the actual arithmetic and logic operations in accordance with the instructions it receives from the control unit and passes the results onto the output section. The output section converts the results into the corresponding electrical stimulus needed to activate the peripheral equipment associated with the computer. This equipment may be a printer, a display terminal, a control mechanism such as a motor or relay, a modem (for transmission to a remote location over telephone lines), or any other electronic or electromechanical system.

The memory system represents the brain of the computer. The main memory stores all the instruction (program) to be run and all the data which are to be manipulated. In a dedicated microcomputer, the memory section is invisible to the user. It consists of an electronic

FIGURE 6.78 Basic components of a typical computer.

read-only memory (ROM), which stores the code sequence for the particular program that is to be run. In a general-purpose computer, much of the internal memory is random-access (RAM), often called a *read-write memory* because it can be programmed and reprogrammed at will. With such computers, the specific program to be run must first be loaded into the RAM from an external source through the input section.

The main-memory system shown in the diagram represents that portion of the system which is an integral part of the microcomputer itself. In a microcomputer dedicated to one specific application, this is all the memory needed. General-purpose computers operate in conjunction with associated mass memory, which is external to the computer. Such memories are in the form of disks, tapes, and cassettes which represent permanent storage for the various programs that the computer may be called upon to run at different times. These programs must be transferred from the external memory to the computer's internal main memory before they can be used effectively.

The input section converts the output of a signal source into a format acceptable to the microprocessor and memory. The signals from such input peripherals as the keyboard, disk and tape readers, etc., may already be in the proper format. Other potential input systems such as pressure and temperature sensors, modems, and light or presence detectors have output signals that are incompatible with either the computer memory or the MPU. These must first be converted into the proper format by the input section.

28. Computer language. The language of the modern computer is *binary*. That is, all data and all instructions processed by the computer consist of a series of binary digits (bits) representing either a zero (0) or a one (1).

A zero is normally represented by a low voltage level, while a one is represented by a high voltage level. The actual voltage value representing a 1 or a 0 depends upon the type of logic employed.

The basic computer word consists of eight bits, called a *byte* (Fig. 6.79). A single byte can represent decimal numbers from 0 to 256 (2×10^8); 2 bytes (16 bits) can represent

numbers up to $65,536 (2 \times 10^{16})$, etc. Similarly, a 2-byte (16-bit) word can encompass over 65,000 memory addresses or program instructions.

Within the computer, information is processed in blocks of parallel bits (bytes or multiple bytes) which are transferred from one section to another along parallel paths called *buses*. A microcomputer generally has three distinct buses: a data bus, an address bus, and a control bus (Fig. 6.80).

The data bus carries the data words between the ALU and the main memory. It is therefore bidirectional and usually has as many lines as the number of data bits which the ALU is able to process in one operation. Thus, an 8-bit MPU has an 8-bit data bus; a 16-bit machine has a 16-bit data bus, etc. An 8-bit machine could be used to process a 16-bit data work, but it would require two cycles of operation and would be considerably slower than a 16-bit machine.

FIGURE 6.79 An 8-bit computer word (byte) can be implemented by eight parallel-connected transistors, or memory cells, each programmed to either a high level (1) or a low-level (0) state. The word can represent a letter, a number, a symbol, or an instruction code.

FIGURE 6.80 A typical MPU bus system uses three separate interconnect paths to carry signals between the MPU and its peripheral chips. PIA = peripheral interface adapter; ACIA = asynchronous communications interface adapter.

The address bus is used by the control unit to fetch data and instructions from specific locations in the main memory and transport it to the ALU for processing. The most popular 8-bit machines utilize 16-bit address buses to access in excess of 65,000 memory address locations.

The control bus accesses all portions of the microcomputer. It controls the sequence of events that carries out a particular instruction, activating the read and write lines of the memory, as needed, initiating the transfer of instructions and data to various parts of the CPU in the proper sequence, and generally controlling the entire sequence of program execution.

29. Microcomputer hierarchy. The first major component of the microcomputer era was a PMOS 4-bit microprocessor introduced by Intel Corp. in 1971. This limited-capability chip was soon joined by 8-bit NMOS MPUs from a number of manufacturers. As processing technology improved to permit increased component density, processor power increased first to 16-bit and, most recently, to 32-bit data manipulation on a single chip of silicon. The latter utilize CMOS technology, which, owing to its extremely low power requirements, permits the operation of tens of thousands of transistors in such a small area without demanding extraordinary measures of heat dissipation.

While microprocessor power was expanding from 4 to 32 bits, microcomputer-chip architecture was expanding in other directions as well. Recall that a microprocessor consists of a single chip housing the ALU and control-unit functions. A complete microcomputer requires memory and I/O circuitry as well. Understandably, as increasing component densities facilitated the increase of on-chip componentry, designers began to utilize the excess chip space to place memory and I/O functions on the same chip with the MPU. This resulted in a diversified series of components called *microcomputer units* (MCUs), which provide virtually complete microcomputer capabilities on a single chip. The repertoire of MCUs is necessarily large because of the many different applications in which microcomputers are employed. These varying applications require different amounts of memory and, in many instances, different I/O functions. Thus, with a basic MPU structure as a core, semiconductor manufacturers are offering MCUs that are tailor-made for different end-use functions by surrounding the MPU with differing complements of on-chip peripheral circuits (Table 6). This capability is becoming so commonplace that some manufacturers are including microprocessor cores and associated peripheral choices as basic cells to be used in the design of semicustom (ASIC) microcomputers.

TABLE 6 On-Chip Peripheral Variations Available with a Basic MC6805 MPU Core

Features	Suffix	CMOS MC146805				
		C4	E2	F2	G2	H2
Number of pins		40	40	28	40	40
RAM (bytes)		176	112	64	112	112
User ROM (bytes)		4160	0	1089	2106	2106
I/O lines, bidirectional		24	16	16	32	24
I/O lines, unidirectional		0	4	0	4	0
Timer (bits)		16	8	8	8	8
Special features	SPI, SCI	Bus expander	COP, synthetic audio output tone generator
EPROM version		MC1468705F2	MC1468705G2	

NOTE SPI = serial peripheral interface; SCI = serial communications interface; COP = computer-operating-properly reset timer which acts as a watchdog to reset the CPU automatically if it is not reset by a program sequence within a given time.

30. Product availability. The proliferation of microcomputer applications has spawned a large array of component building blocks with which to implement microcomputer systems. Fundamental, still, for low-level applications are the 8-bit MPUs with their wide assortments of associated memory and I/O chips. These have recently been joined by increasing numbers of 8- and 16-bit MCUs which can be selected for

dedicated applications without the need for additional peripheral chips except, perhaps, for interface circuits to match an MCU to the voltage and current requirements of specific input and output equipment.

For more sophisticated computer applications, 32-bit microprocessors have become commonplace, and 64-bit MPUs are in the early stages of implementation. These circuits are so complex that manufacturers have not yet combined them with memory and I/O peripherals on the same chip, but associated peripheral chips to match the characteristics of the MPUs are being introduced in considerable numbers. These peripherals are often as complex as the MPUs themselves and greatly reduce design time as well as the size of the resulting equipment.

Implementation of microcomputers in a wide range of personal computers as well as dedicated machines is further aided by the availability of increasing numbers of board-level products. These predesigned boards greatly speed up the equipment design cycle. They are being offered not only by the chip manufacturers themselves but also by other manufacturers. Regardless of manufacturer, the boards are designed in families that work together to form complete systems. They offer a choice of basic single-board-microcomputer modules as well as additional peripheral modules that provide a variety of memory capacity and interface choices.

Board families are defined in terms of the bus structure they support; that is, all boards within a given bus family, say, the VMEbus family, have identical pin assignments so that they will be properly interconnected when plugged into a backplane. It is possible, therefore, to purchase VMEbus boards (modules) from different vendors and be assured that they will be compatibly interconnected when plugged into a VMEbus chassis. The large variety of modules available for some bus structures has given rise to the open-system philosophy which permits rapid assembly of complete functional systems with tailor-made capabilities by choosing the appropriate modules and plugging them into the slots (sockets) of a prewired chassis (Fig. 6.81).

FIGURE 6.81 A prewired chassis and board assortment simplifies microcomputer design and assembly.

ELECTRONIC MEMORIES

While MCUs normally have on-chip memory sections with a memory capability deemed adequate (by the manufacturer) for the intended application, the MPUs implement their memory sections with peripheral chips. Since all microcomputers require some sort of memory, these devices are the most prevalent of the microprocessor peripherals.

There are many different types of memories. They are classified in a variety of ways, as shown in Table 7. These memories are electronic memories associated with the actual operation of the computer, not with the permanent mass storage of operating programs or large files of data. The mass-storage memories, such as disks, tapes, and cassettes, are separate from the microcomputers and are used only as sources of information to be entered into the computer when required. They are *nonvolatile*, meaning that the information they contain is “permanent” (unless deliberately removed), and they store large amounts of data in a serial fashion. This means that access time is relatively slow.

TABLE 7 Memory Descriptors*

By function	RAM, ROM, PROM, EPROM, EEPROM
By capacity (number of bits)	1K (1000), 16K, 64K, 256K, 1M (1,000,000)
By organization	$4K \times 1$, $4K \times 4$, $2K \times 8$, etc.
By technology	NMOS, CMOS, bipolar (TTL, ECL)
By operation	Dynamic, static (RAM only)

*A representative description might be: a 256K \times 1-bit NMOS dynamic RAM.

On the other hand, the so-called main memory, or operating memory, within the computer is electronic in nature, and information is stored in a matrix of cells that are accessed in a parallel manner, so that information transfer to and from such memories is relatively fast.

As with logic circuits, memory characteristics are determined by the technology employed. Bipolar ECL and TTL memories are the fastest, NMOS memories have the highest chip density and therefore the highest storage capacity, and CMOS memories have the lowest power dissipation.

31. Memory organization. An electronic memory consists of a number of storage units called *cells*. Each cell is a transistor circuit that can be charged to either of two binary states: a high (voltage) level or a low level. A high level is designated as 1, and the low level is designated as 0. In practice, the cells are operated in groups called *words* which store information in binary coded form. The content of a memory word can be the binary code for a number, a letter, or an instruction for manipulating data.

A memory is specified by two numbers that indicate the total number of cells (bits) in the memory and the manner in which these cells are grouped. A 1024×1 -bit memory (commonly called 1K memory) contains 1024 cells, each of which is separately addressable and programmable. A 128×8 -bit memory also contains 1024 cells. Each one of these is also individually programmable, but each is accessible only with a group of seven other cells with which it is permanently associated.

32. Memory capacity. Memory chips are available in a variety of sizes and cell organizations. Capacity has been increasing rapidly as computer power and processing technology have increased.

Early memories had a capacity of only 128 bits, or 16 bytes. The subsequent 1K-bit memory was considered quite a breakthrough but was quickly replaced by 4K, 16K, and 64K memories. Today, 265K-bit memories are available and 1M (megabit) devices are being introduced. These large-capacity memories are fabricated by NMOS technology, with smaller capacity units being available in CMOS and bipolar processing.

33. Memory functions. Functionally, electronic memories are divided into two basic classifications: random-access memories (RAMs) and read-only memories (ROMs). RAMs are *volatile* memories whose content disappears when power to the memory is interrupted. ROMs are *nonvolatile*, in that they retain their content even when power is shut off. Hence, RAMs are used for the actual manipulation of a program or the storing of a program on a temporary basis, while ROMs are employed for storing permanent data such as microprograms, look-up tables, and display graphics.

The addresses of both RAM and ROM are accessible in a random fashion, but RAMs are read-write memories whose contents can be changed at will, whereas ROMs are read-only memories. In general, ROMs are preprogrammed during manufacture with the custom program specified by the customer. There are, however, a number of variations—PROMs, EPROMs, EEPROMs—which are custom-programmable by the user.

Random-Access Memories (RAMs). There are two types of RAMs: static and dynamic. In a static RAM, the individual cells are flip-flops which, once set to either 1 or 0, will retain their setting indefinitely, until either deliberately reset or until power is removed. The basic cell (Fig. 6.82) consists of six transistors. T_1 and T_2 represent the actual flip-flop, T_3 and T_4 function as load resistors for the flip-flop, and T_5 and T_6 are isolation transistors that isolate the cell from the access lines (bit lines) until the cell is ready to be addressed.

The basic cell of a dynamic MOS RAM (Fig. 6.83) utilizes only a single transistor and therefore requires considerably less chip space. Data storage is accomplished by charging the associated capacitor for a 1 level or discharging it for a 0 level. In the diagram, the capacitor

FIGURE 6.82 A typical six-transistor static MOS memory cell. T_1 and T_2 comprise a flip-flop, with T_3 and T_4 representing load resistors (note the fixed bias on these transistors). T_5 and T_6 are isolation transistors which, when turned on by a row-select signal, cause the state of the flip-flop to be reflected on the bit (data) lines.

FIGURE 6.83 A single-transistor dynamic RAM cell. Additional circuitry is needed to refresh all cells in the memory on a regular, periodic schedule.

is charged when both *X* and *Y* lines are made high and discharged when the *X* line is high and the *Y* line is low. Unfortunately, the small capacitor will not retain its charge very long. Therefore, dynamic RAMs must be refreshed (the charged cells must be recharged) periodically (say, every millisecond) in order to maintain their information. The refreshing circuitry adds substantial complexity to the circuit. On the other hand, dynamic RAMs dissipate a relatively small amount of power. For this reason and because of the smaller space requirements, they are preferred for memories with a large number of cells (large capacity).

Read-Only Memories (ROMs, PROMs, EPROMs, EEPROMs)

ROMs. Read-only memories are an integral part of all microcomputers. They store the operating routines of the system (microprograms) and provide conversion data, display codes, and other information that is periodically accessed by the computer but is not subject to change.

A ROM consists basically of a series of OR gates addressed by a decoder circuit (Fig. 6.84). The truth table associated with the diagram indicates the state of the four output

FIGURE 6.84 (a) Basic configuration of a typical read-only memory. (b) Truth table corresponding to the simple circuit.

lines, b_0 to b_3 , as a function of the input signals A and B . If, for example, the input signals are both HIGH, then output lines b_1 and b_3 are HIGH because the output of AND gate 11 in the decoder is HIGH. Similarly, if B is HIGH and A is LOW, output lines b_0 , b_1 , and b_3 will be HIGH because the output of decoder gate 10 is HIGH. Output b_2 will be HIGH only when the output of NAND gate 01 is HIGH, which occurs only if A is HIGH and B is LOW. Thus, for any combination of input signals, the output can be determined by the number and placement of the diodes that comprise the OR gates.

The simple circuit described is a 4×4 ROM consisting of 4 words, with 4 bits per word. If the number of output lines were extended to 8, the resultant ROM would be 4×8 . An increase in the capacity of the decoder will provide ROMs with thousands of different 8-bit output combinations.

ROMs are available as factory mask-programmable devices which are fabricated by the manufacturer to any set of custom patterns specified by the user. They can also be obtained as standard preprogrammed devices containing various popular functions such as character generators, code converters, look-up tables, etc.

PROMs. The ROM of Fig. 6.84 can be converted into a unit that is user-programmable (PROM) simply by placing diodes in all possible locations within the matrix and fabricating a fusible link in series with each diode (Fig. 6.85). The user can burn out any link, using a PROM programmer, in order to create any special set of codes desired. Of course, this can be done only once, so that this type of PROM is sometimes called a *one-time programmable ROM*.

Erasable Programmable ROMs (EPROMs). The ideal memory is a nonvolatile one which maintains its program even after power is removed from the system (as with a standard mask-programmed or one-time field-programmed PROM discussed above), yet one whose program can be altered at will (as with a standard RAM). Development efforts in that direction are bearing fruit, and several iterations of programmable ROMs have been introduced. These do not yet have the reprogramming speed and ease of the conventional RAM, but they are enjoying considerable popularity for a number of applications, and they are indicative of the rapidly expanding technology.

One of the earliest practical ROMs that was repeatedly erasable and reprogrammable in the field was labeled EPROM. The information stored in the memory cells could be erased by subjecting the device to ultraviolet light, which entered the package through a quartz window at the top (Fig. 6.86). While the EPROM can be erased and reprogrammed repeatedly, it must be removed from the system and bulk-erased by exposing the entire unit to a high-intensity ultraviolet-light source. There are a number of suitable ultraviolet programmers, but the erase time is on the order of half an hour, which falls far short of meeting the criteria for the ideal memory. Moreover, the EPROM can be unintentionally erased by sunlight and fluorescent light and requires special shielding after programming. Despite these limitations, the UV EPROM still enjoys considerable use, and its principles of operation are fundamental to even the more advanced devices currently emerging.

FIGURE 6.85 Fusible links in series with each diode can be “blown” in a PROM programmer to create any desired pattern arrangement.

FIGURE 6.86 Ultraviolet erasable read-only memory (UV-EPROM).

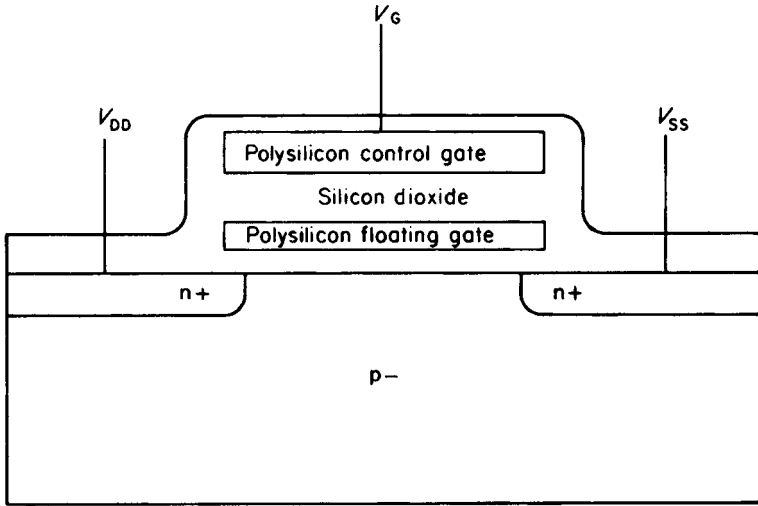

FIGURE 6.87 A typical EPROM-device structure.

The EPROM is basically a MOS device whose structure is illustrated in Fig. 6.87. It is characterized by two stacked polysilicon gates which are separated from each other and from the substrate of the cell by an insulating layer of silicon dioxide. The gate closest to the substrate is a floating gate which is not connected in the circuit. The upper gate is the control gate, which is used to energize the cell. Under the initial condition, the cell acts as a conventional MOS transistor so that when a positive voltage is applied to the control gate and the drain, a channel is created between source and drain, permitting a drain-current flow.

If the drain voltage and the control-gate voltage are raised to a high level (say, 30 V), some of the electrons in the channel gain enough energy to cross the silicon dioxide barrier and impinge upon the floating gate, where they become trapped. This raises the turn-on threshold level of the MOS transistor so that it will not be turned on when normal operating voltages are applied. The cell then is said to be charged, representing an open circuit and yielding a high output level (1) when connected in a conventional circuit.

The charge on the floating gate can be removed by the application of light to the structure. Sunlight or fluorescent light will erase the charge but would require an excessive amount of time. A strong dose of ultraviolet light will bulk-erase the entire memory in about 30 min.

Electrically Erasable Programmable ROMs (EEPROMs). The EEPROM is very similar in theory and structure to the EPROM. The principal difference is in the thickness of the oxide between the floating gate and the substrate. Whereas the thickness of this oxide layer for the EPROM is on the order of 1000 Å, that of the EEPROM is on the order of 100 Å or less. As a result of this thinner oxide, the floating gate can be charged *and discharged* by a voltage applied to the control gate. Write and erase times for typical EEPROMs with present technology are on the order of 10 ms. While the EEPROM is not competitive with RAM speeds, its in-circuit program-erase capability makes it suitable for a great many applications. Devices of this type are currently available with 64K-bit capacity. They are also included as on-chip peripheral circuits for a number of MCUs to expand MCU versatility.

34. Accessing the memory. The total number of cells in a single memory chip can range from several hundred on the low end to 1 million (1 megabit) with current state-of-the-art technology. The cells are arranged in rows and columns (Fig. 6.88), with the exact location of each cell specified by its row and column number. There are two basic organizational schemes for accessing the memory: bit organization and word organization.

Bit Organization. In a bit-organized memory chip (e.g., $1K \times 1$, $64K \times 1$, etc.), each cell is addressed in conjunction with similarly located cells on other chips of the same capacity and organization. In Fig. 6.89, for example, eight identical chips are used to store information in byte-sized (8-bit) words. Each chip stores one of the 8 bits, and all chips are addressed simultaneously for programming or reading.

Word Organization. A word-organized memory chip is one in which a number of columns corresponding to the number of bits in the word are addressed simultaneously. In this manner, a complete word can be stored in a single chip (Fig. 6.90).

FIGURE 6.88 A semiconductor memory is a rectilinear pattern of digital circuits, called cells, each of which can hold a high-level (logic-1) or low-level (logic-0) voltage charge. Each cell is accessed for programming or reading simply by energizing the proper column and row.

FIGURE 6.89 Bit-organized memory requires multiple memory chips, with each chip storing one bit of a complete word.

FIGURE 6.90 A 1K (128 × 8) byte-organized chip addresses all bits associated with a complete word on a single chip.

35. Memory circuitry. A memory array receives a number of signals from the micro-processor. The primary ones are as follows:

1. The address signal which activates the rows and columns on each chip that represent the cells associated with a given address
2. The binary word representing the data to be entered into the addressed cells in the case of a programming step
3. A read-write signal generated by the processor which determines whether information is to be entered into the memory or extracted from it

The circuitry required to respond to these signals and generate the desired results resides directly on the memory chip along with the array of memory cells. Typical operation can be described with the aid of diagrams utilized in a representative MOS static memory chip.

The Memory Cell. Figure 6.91 is a conventional MOS flip-flop in which T_1 and T_2 are cross-coupled inverters and T_3 and T_4 represent their respective load resistors. A positive pulse applied to point A appears at the gate of T_2 , turning this transistor on. As a result, the voltage at point B goes to 0 (ground), and since this voltage is applied to the gate of T_1 , the latter is turned off. Voltage at A therefore

FIGURE 6.91 A typical MOS static memory cell.

goes high and remains high even when the external signal is removed. In this condition, the cell is considered to store a 1.

To reprogram the cell to contain a 0, a positive pulse is applied to point B , turning T_1 on and T_2 off. Again, this condition remains stable until it is deliberately changed by another positive signal to point A . Clearly, the cell is programmable.

Row Address. In practice, a cell is programmed by means of a two-rail bit-line system (Fig. 6.92), in which a signal and its complement are simultaneously applied to points A and B . To be applied to the cell, however, isolation transistors T_5 and T_6 must be turned on. Programming is accomplished by applying the desired programming signals on the bit lines and then momentarily turning on T_5 and T_6 with a pulse applied simultaneously to their gates. Once programmed, a cell is read by briefly turning T_5 and T_6 on without having an external signal on the bit lines.

FIGURE 6.92 A cell is programmed or read by a signal on the row-select line which causes the cell to be connected to its bit lines through T_5 and T_6 .

Column Address. In Fig. 6.93, the column-select circuitry and a write buffer have been added to Fig. 6.90. Note that the write buffer generates the programming signal and its complement, to be applied to the bit lines. To access the bit lines, however, transistors T_7 and T_8 must be turned on. The address code defines which of the columns is to be activated. In Fig. 6.93, each of the columns can be separately addressed, as required for a single-bit organization. In Fig. 6.90, all eight of the column-select circuits are activated simultaneously, as required for a byte-organized orientation.

Read-Write Circuit. In Fig. 6.94, a read buffer circuit has been added to the previous diagram, permitting the data on the bit lines to be applied to the data bus for transmittal back to the MPU. Note, however, that the data line that carries the data from the memory to the MPU is the same as the line that carries the programming data from the MPU to the memory. To avoid undesirable feedback, the read buffer must be disabled during a write operation. This is accomplished with a three-state read buffer circuit as in Fig. 6.94b.

Three-State Buffer. A three-state buffer is a circuit whose output can be high, low, or open-circuited. A high output at bit line 1 turns T_4 on and T_1 off. If T_2 and T_3 are turned on by a separate high-level signal on their gates, then the output line is connected to the positive-voltage source through T_3 and T_4 , and the output is high. A high output at bit line 2 turns on T_1 , turns off T_4 , and presents a low signal to the output. But if T_2 and T_3 are turned off, then regardless of the state of T_1 and T_4 the output is isolated from the inputs because of the very high resistance of T_2 and T_3 .

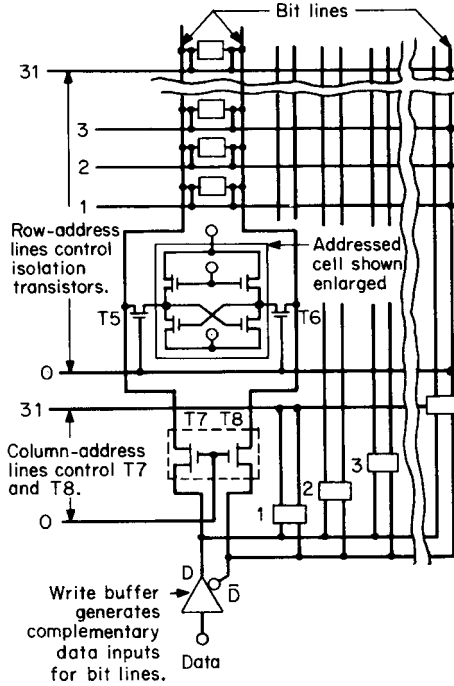

FIGURE 6.93 Column-address circuitry. Data can be entered into the memory only when transistors T_7 and T_8 are turned on.

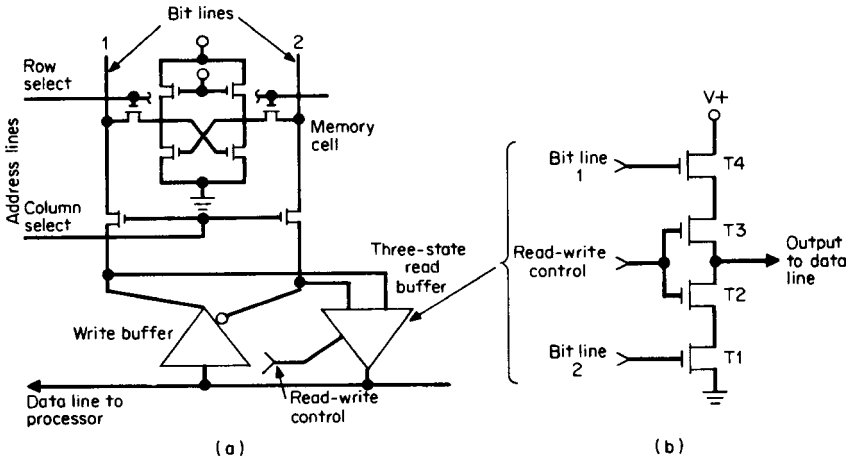

FIGURE 6.94 (a) Connection of read buffer to memory column. (b) Three-state read-buffer schematic diagram.

T_2 and T_3 are turned off during writing operations and turned on at all other times. Thus, the cell is always connected to the data line through the read buffer except during a write cycle, during which the read buffer is in the open-circuit state.

36. Address decoding. The number of unique bit patterns required to address all rows in a single-column, word-organized memory equals 2^n , where n is the number of rows. Thus, a small 128×8 -bit memory, for example, requires 128, or 2^7 , unique address patterns, which can be generated with a 7-bit binary code. These 128 unique address patterns can be applied to a single-address decoder that has 128 output lines. For each address, the decoder provides a high-level signal on a different output line. There are many different decoder circuit configurations. The circuit shown in Fig. 6.95 is for illustration and does not necessarily represent any specific design.

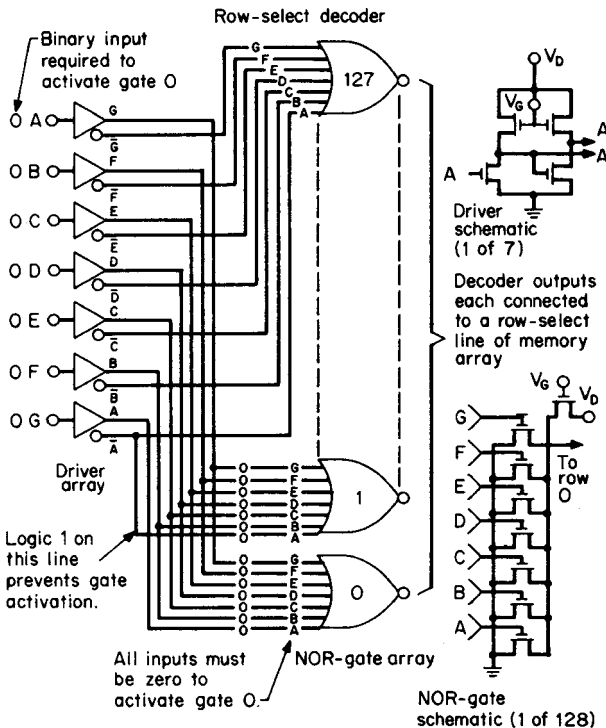

FIGURE 6.95 Example of an address decoder for a single-column 128×8 bit memory. The output from each NOR gate enables one of the 128 different rows in the memory matrix.

Decoder Circuit. The decoder circuit consists of 128 seven-input NOR gates having a common driver circuit. Each NOR gate is activated (puts out a high-level signal) only when all seven inputs are low. The driver circuit, in turn, is configured so that each of the 128 possible input patterns activates a different NOR gate.

Each NOR gate consists of seven parallel-connected transistors (switches) in series with a single fixed-bias transistor (resistor). When all seven parallel-connected transistors are turned off by a low-level input to each, the output is high and the row of cells associated with that gate is activated.

To provide the required all-zero signals to the gate to be activated, the 7-bit energizing signal is first sent through double-inverter driver stages, one for each bit. The output of each driver then makes available both the signal (A, B, C, \dots) and its complement ($\bar{A}, \bar{B}, \bar{C}, \dots$).

For example, if gate 0 (row 0) is to be activated by the first address pattern (0000000), then gate-0 input terminals are connected to outputs (A, B, C, D, E, F, G) of the driver. To activate gate 1 by address No. 2 (0000001), gate-1 terminals are connected to driver outputs A, B, C, D, E, F, G . The last gate in the system (No. 127) has all its inputs connected to the inverted outputs of the driver. It is possible, therefore, to connect the driver outputs to each gate in such a manner that each gate receives an all-zero input for a different combination of 1s and 0s at the decoder input.

Most memories, instead of being arranged in one continuous sequence of rows, are arranged physically and electrically in different blocks. A 128×8 -bit memory, for example, could contain four blocks, each with 32 rows and 8 columns. Here, the 8-bit data signal could be applied via a data bus to all eight columns of each block simultaneously. However, this arrangement needs separate decoding circuits to activate not only the desired row but the desired eight-column block as well. Accordingly, a 2-bit block-select decoder (Fig. 6.96) is needed for four-pattern (2^2) selectivity. However, since the row-select decoder need now decode only 32 lines (2^5) rather than 128, a 5-bit decoder is sufficient for row selection. Thus, again, a 7-bit decoder handles the entire job.

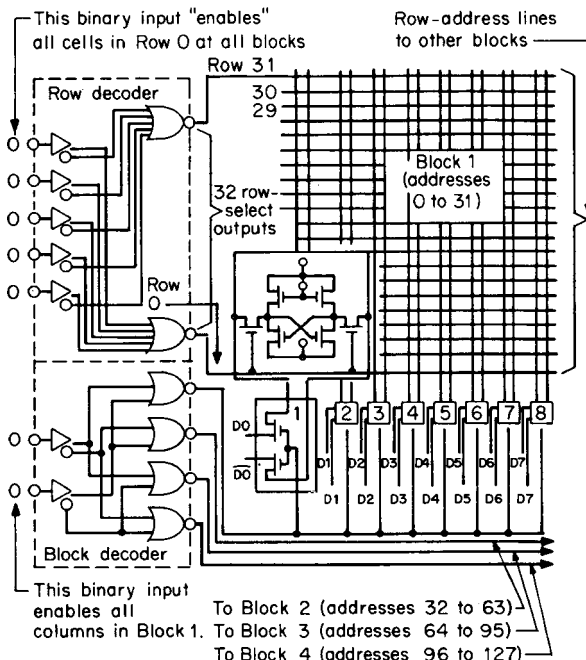

FIGURE 6.96 A row-and-block-select decoder.

The only difference between this circuit and the previous one is that four gates of the decoder are used to select the blocks while the row-select function is handled by 32 five-input NOR gates. The same binary address pattern that accesses a memory address in a one-block system can access the same address in a four-block organization and other organizations as well.

NOTE Much of the information provided in this division is based on the work of technical and marketing specialists of the Motorola Semiconductor Sector. The author gratefully acknowledges the kind permission of Motorola for the use of material from its various data sheets, application notes, and other documents.

PRODUCT RELIABILITY

37. Semiconductor reliability. In today's marketplace, quality and reliability are paramount to the success of a product. Quality is defined here as the ability of a device to operate within its specifications when received by the user; reliability refers to its capability to operate within specifications over long periods of time and under the most adverse environmental conditions to be encountered in practice.

Semiconductors are inherently extremely reliable. Properly designed and used, they can be expected to outlive the equipment in which they are employed. Yet they are subject to a wide range of failure mechanisms that must be anticipated and circumvented during manufacture in order to achieve this inherent feature.

To ensure high reliability, the government has developed a stringent series of tests and screens involving all phases of manufacturing for military applications. The manufacturing techniques required to meet these qualifications have been adopted in some measure by manufacturers of products intended for commercial applications so that, except for very special requirements, there are no longer significant variations in inherent reliability between commercial and military products.

Basic Military Qualifications Tests. The Basic MIL-qualification tests, called *JAN* (*Joint Army-Navy*), are divided into groups to satisfy three objectives:

1. Group A—verifies that form, fit, and function conform to design specifications.
2. Group B—assures manufacturing integrity and verifies reliability in ground support applications.
3. Group C—provides evidence of long-term reliability under harsh environmental conditions where severe mechanical and environmental stresses exist.

Examples of the types of tests included in each group are given below.

Group A Tests

Visual/mechanical. Consists of a sampling of devices that is examined to determine whether they meet the applicable materials, design, construction, marking, and workmanship standards.

DC tests. Verify the major voltage, current, and other dc parameters of the device first under normal (25°C) temperature conditions, then at an appropriate high and/or low temperature limit to confirm satisfactory performance over the entire temperature range.

AC tests. Check parameters associated with dynamic operating conditions, such as capacitances, noise figure, switching time, etc.

Safe operating area (SOA) tests. Limited to power transistors, these tests corroborate the power limits over which the devices are designed to operate.

Current surge. Applies principally to diodes, e.g., rectifiers.

Selected tests. Assigned to specific devices for unique specifications that do not fit a general specification.

Thus, the complete spectrum of electrical device characteristics is accounted for, and successful completion of this test sequence provides assurance that the devices are capable of operating, at least initially, in accordance with their design.

Group B Tests. This sequence of tests includes screens that are intended to verify that the devices are mechanically sound and that they can be expected to operate satisfactorily over time and under adverse operating conditions. Since a number of these screens involve stress factors that could result in ultimate performance degradation, the electrical parameters expected to be affected are tested before and after the applied screen to ascertain that the performance change remains within prescribed limits.

Solderability. Determines the solderability of wires, lugs, tabs, and all types of terminals that are normally joined by a soldering operation. The procedure includes an accelerated aging test that simulates a minimum of 2 to 10 years natural aging under a combination of various storage conditions that have different deleterious effects.

Resistance to solvents. Verifies that the markings will not become illegible when the component is subjected to various solvents employed by equipment manufacturers.

Thermal shock. Simulates transferring equipment from a heated shelter to the outside environment in an arctic area. While temperature limits may vary with specified conditions, the test usually involves exposure of the components to temperatures of -55°C and $+125^{\circ}\text{C}$, or the maximum rated specification of the component.

Surge current test. Subjects devices under test to high forward current stress conditions to determine the ability of the chip and the contacts to withstand current surges.

Hermetic seal. Determines the effectiveness of the seal of semiconductors with internal cavities. There are two types of required tests—fine leak and gross leak.

Steady-state operation life. Designed to weed out components that might be subject to “infant mortality” on the proven premise that if a semiconductor device is likely to fail, it will do so during the early hours of normal operation.

Intermittent operation life. Similar to the steady-state operation life test, above, except that the devices are subject to sudden sequential on-off periods to provide added stress.

Blocking life. Performed on rectifier diodes only, this test is normally run at an elevated temperature of 150°C for 340 h, with the primary blocking junction reverse-biased. The reverse-bias voltage is 80 to 85 percent of the rated voltage of the device.

Decap internal visual. Verifies conformance to the original specifications by “opening” samples of a completed lot and comparing the internal structure with the qualified design report.

Scanning electron microscope (SEM) inspection. Verifies the quality of the metalization on the semiconductor die by checking for defects such as voids, separations, notches, cracks, depressions, or tunnels and other processing-related faults.

Bond strength. Verifies the integrity of wire (or clip) bonds within the package by applying stresses that will cause the maximum potential for wire breaks and associated die failures.

Thermal resistance tests. Determine the efficiency of the chip-to-header interface in transferring heat from the chip to the header.

High-temperature (nonoperating) life. Verifies that the devices will not degrade after storage at maximum temperature for 340 h.

Group C Tests. Whereas previous test groups deal with the design and manufacturing integrity of semiconductors, this group of tests adds additional assurances that the products will withstand severe environmental stresses over prolonged time periods.

Thermal shock (glass strain). Exposes the devices to sudden extreme changes in temperature by alternately immersing them in hot and cold liquids ranging from 0 to 100°C and, subsequently, testing them for hermeticity and electrical parameters to determine if any failures occurred.

Terminal strength. Checks the capabilities of the device leads, welds, and seals for their ability to withstand pulls and bends and other physical stresses.

Moisture resistance. An accelerated test method of evaluating the resistance of the device to the deteriorative effects of high humidity and heat typical of tropical conditions.

Mechanical shock. Consists of mounting the devices in a fixture that is subsequently dropped repeatedly from a predetermined height to produce a high-impact force on the various mechanical parts and bonds.

Vibration. Simulates the use of devices in the field, when mounted on a jeep, truck, or airplane, in order to confirm the integrity of the package and the wire bonds within the package.

Constant acceleration. Designed to detect structural and mechanical weaknesses not detected in other shock and vibration tests.

Salt atmosphere. An accelerated laboratory corrosion test simulating the effect of shipboard or seacoast atmospheres on devices by subjecting them to a controlled salt atmosphere fog stream to detect subsequent flaking, pitting, or corrosion that will interfere with device application.

The above tests are required for all standard military (MIL-Qualified) semiconductors and are described in detail in documents MIL-S-19500 and MIL-STD-750 maintained by the Department of the Navy. In addition, many of them are employed routinely during the manufacturing process of commercial products as a safeguard against processing faults and to provide a continual check of end-product quality and reliability.

38. Semiconductor packages. Semiconductor devices are available in a seemingly endless variety of packages. Some of these variations are cost-related, others are function-related, and still others are preference-related.

Cost-related selections normally include metal and ceramic packages on the high end of the scale, and plastic packages on the low end. Plastic packages are dominant in commercial equipment, while metal and ceramic packages are usually mandated for military and high-reliability applications, or where power requirements are beyond the capabilities of plastic packages.

For this discussion, function-related packages relate to sizes and shapes dictated by the functions contained on the chip. Thus, discrete components may utilize from two to four pins, while integrated circuit packages may require hundreds of pins to accommodate the I/O requirements of the enclosed function.

Preference-related packages are those that offer the same or similar functions in different package configurations to accommodate design preferences. Typical choices include such variations as leaded or surface-mount packages, in-line or dual in-line pin configurations or special structures such as press-fit and stud packages.

Integrated circuits, typically, are housed in dual in-line packages (Fig. 6.97*a*) to accommodate a large number of leads in an acceptable amount of space. Large-scale integrated circuits, whose I/O requirements cannot easily be satisfied even with dual in-line structures are accommodated by special VLSI packages such as pin grid arrays (PGAs) and leaded chip carriers (LCCs) (Fig. 6.97*b*). And for equipment where available space is at a premium, equivalent space-saving small outline integrated circuit (SOIC) packages for surface-mount applications (Fig. 6.97*c*) are gaining in popularity and availability. While integrated circuits for military and hi-rel applications are usually made of ceramic, a few metal packages with relatively high pin counts are also available (Fig. 6.97*d*).

FIGURE 6.97 Typical integrated circuit package configurations.

The selection of discrete component packages is equally prolific. Higher-power devices come in standard JEDEC-registered (TO-numbered) metal and plastic housings (Fig. 6.98a) and a wide variety of package variations carrying a manufacturer's proprietary case numbers. Often, these offer similar specifications in a number of different package choices. Small-signal components are equally endowed. Typical examples of JEDEC-registered three-leaded transistors and two-terminal diodes are shown in Fig. 6.98b. Packages housing multiple transistors and diodes take the form of conventional dual in-line integrated circuits, with the number of leads depending on the number of devices contained.

Mounting Considerations for Power Packages*. Heat is a principal enemy of semiconductor devices. Except for lead-mounted parts used at low currents, a heat exchange is required to prevent junction temperatures from exceeding their rated limits, thereby risking device failure. Proper mounting of power devices, during manufacture and eventual substitution or replacement, is a prerequisite for reliable operation. This necessitates attention to the following areas:

1. Mounting surface preparation
2. Application of thermal compounds
3. Electrical insulation
4. Assembly fastening
5. Lead bending and soldering

Intimate thermal contact between the package and the heat sink is essential for proper heat dissipation. Rough or scratched heat sink surfaces, excessively large mounting holes, and oxidized or unclean surfaces all can have deleterious effects on heat transfer, thereby contributing to potential device degradation in high-power circuits. Significantly improved contact can be achieved through the use of thermal joint compounds ("grease"), which fill air voids between all mating surfaces. Satisfactory joint compounds can reduce the thermal resistivity of such voids from $1200^{\circ}\text{C}\cdot\text{in}/\text{W}$ to approximately $60^{\circ}\text{C}\cdot\text{in}/\text{W}$. This compares much more favorably to the $0.10^{\circ}\text{C}\cdot\text{in}/\text{W}$ for copper film.

Since power semiconductors normally have their collectors or anodes connected to the case, many applications require that the case be electrically insulated from circuit ground. This can be accomplished most effectively by insulating the entire heat sink–semiconductor assembly from ground rather than using an insulator between the semiconductor package and the heat sink. Where this is not possible, in cases where the chassis serves as the heat

*Abstracted from Motorola Application Note AN1040.

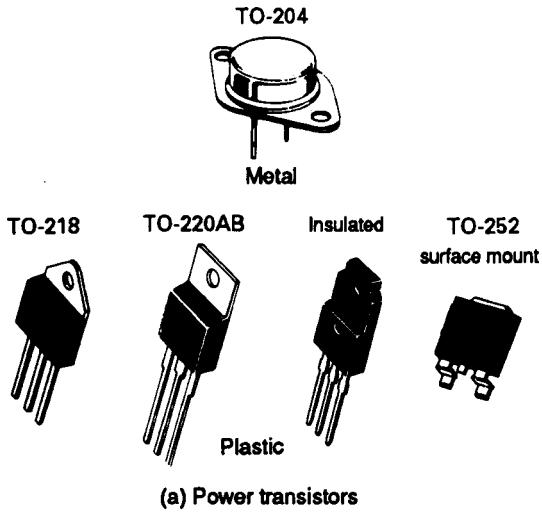

FIGURE 6.98 Representative sampling of packages used for discrete devices.

sink, or where the heat sink is common to several devices, insulating (mica or silicone rubber) washers can be used between the package and the heat sink.

When electrical insulation is required prior to heat sinking, the need for a thermal grease becomes more pronounced since there are now two isolating surfaces between the package and the heat sink. Data obtained by Thermalloy, Inc. (Fig. 6.99) show relative thermal resistance values between different types of insulating materials and also for various mounting screw torque values. It is quite evident that the use of grease is much more effective in reducing thermal resistance than an increase in the amount of force used to mate the two surfaces. Indeed, excessive tightening of the mounting screw can cause potential problems, particularly if the mounting hole is too large, by pulling the package into the hole (Fig. 6.100). The resulting buckling not only reduces surface contact, but can also cause cracking of the die in the package. Die rupture can also occur when the leads of a device must be bent in order to fit into a fixture or socket.

Typical examples of mounting several types of semiconductor packages are illustrated in Fig. 6.101.

FIGURE 6.99 Interface thermal resistance for various types of insulating materials as a function of mounting screw torque—with and without the use of grease.

FIGURE 6.100 Exaggerated example of improperly mounted semiconductor package.

FIGURE 6.101 Typical methods for mounting various types of power device packages.

To reduce insulation problems, some of the more recent power devices are being produced in insulated packages. These newer packages, housing multiple-chip and monolithic integrated power circuits as well as discrete components, come in two basic forms. The first (Fig. 6.102*a*) uses a mounting plate that is insulated from the chip and can be fastened directly to a grounded chassis or heat sink. The second (Fig. 6.102*b*) utilizes a thermal conductive plastic overmold to cover the metal mounting base of the basic package.

FIGURE 6.102 Two commercial types of power packages requiring no external insulation.

39. Transient suppression*. A not-infrequent cause for semiconductor problems is the incidence of transients, which can stress the devices beyond their electrical design limits.

Some transients are internally generated as a result of inductive switching, commutation voltage spikes, etc. These are easily suppressed because their energy content is known and predictable. Others, however, may be created outside the circuit and coupled into it. These are more difficult to anticipate, and their suppression is often beyond the control of the circuit designer. Such transients include lightning-generated spikes and substation problems, but can also be caused by switching of parallel loads within the same branch of a power distribution system. Effective transient suppression requires that the impulse energy within the transient be dissipated in an added transient suppressor at a low enough voltage so that the capabilities of the circuit or associated components will not be exceeded.

Several types of transient suppressors have been in widespread use. Among these are the carbon block spark gaps, gas tubes, selenium rectifiers, metal oxide varactors, and zener diodes. Of these, zener diodes, especially those designed specifically for surge suppression, e.g., the 1N6267–1N6303 series, have the most favorable set of characteristics.

There are two characteristics of primary importance for surge suppressors. The first, the zener breakdown voltage rating, must be equal to or lower than the maximum voltage of the equipment or circuits it is to protect. The second is the maximum power rating of the suppressor, beyond which it may itself be damaged. The latter must take into account both the maximum peak voltage and current ratings of the device, as well as the voltage excursions and pulse width of the transients.

*Abstracted from Motorola Application Note AN843.

FIGURE 6.103 Typical indoor (a) and outdoor (b) transient waveshapes.

Typical waveshapes for indoor and outdoor locations (Fig. 6.103) are defined in IEEE standard 28, ANSI standard C62.1, and can be considered as realistic representations. Peak ac power line voltage transients in indoor locations are usually limited to approximately 6.0 kV due to the spark-over spacing between conductors used in standard wiring practices. In outdoor locations, such as electrical service entrances, power line connections to additional buildings, etc., no such limitations exist.

The amplitude of randomly induced voltage transients and their energy content are difficult to define, but data from surge counters and other sources (Fig. 6.104) have provided some insight. In this plot, data for low exposure were taken from locations with little load switching or lightning activity; medium exposure is considered as areas with severe switching transients and frequent lightning activity; high-exposure systems are those supplied by long unprotected overhead lines with high spark-over clearances. Surge characteristics deemed representative of various locations within a building are given in Table 8.

FIGURE 6.104 Peak surge voltages versus surges per year. [EIA Paper, 587.1/F. May 1979, p. 10]

TABLE 8 Surge Voltages and Currents Anticipated at Various Locations

Location	Surge voltage	Surge current	Energy (joules*) dissipated in suppressor with clamp voltage of		
			250 V	500 V	1000 V
1	6.0 kV	200 A	0.4	0.8	1.6
2	6.0 kV	500 A	1.0	2.0	4.0
3	10 kV or more	10 kV or more	20	40	80

*Joules = power × time.

1. Outlets and circuits a long distance from electrical service entrance
2. Major bus lines and circuits a short distance from service entrance
3. Electrical service entrance and outdoor locations

A safe approximation of the peak power contained in a transient can be obtained by considering its shape to be that of a rectangular pulse with the same peak power. For example, an exponential discharge with a time constant of 1.0 ms can be approximated with a rectangular 1.0-ms pulse with the same peak power as the transient.

Because pulse width determines the heating effect of the transient, the peak power dissipation ratings of typical zener diodes are also a function of pulse width, as shown in Fig. 6.105*a*. And when the transient is expected to be repetitive, peak power must be further derated as in Fig. 6.105*b*.

FIGURE 6.105 (a) Peak power ratings of typical zener diodes as a function of pulse width. (b) Power derating as a function of duty cycle.

PRINCIPLES, CHARACTERISTICS, AND MANAGEMENT OF DC GENERATORS (DYNAMOS)

1. Direct-current generators impress on the line a direct or continuous emf, one that is always in the same direction. Commercial dc generators have commutators, which distinguish them from ac generators. The function of a commutator and the elementary ideas of generation of emf and commutation are discussed in Div. 1. Additional information about commutation as applied to dc motors, which in general is true for dc generators, is given below.

2. Excitation of generator fields. To generate an emf, conductors must cut a magnetic field which in commercial machines must be relatively strong. A permanent magnet can be used for producing such a field in a generator of small output, such as a telephone magneto or the magneto of an insulation tester, but in generators for light and power the field is produced by electromagnets, which may be excited by the machine itself or be separately excited from another source.

Self-excited machines may be of the series, shunt, or compound type, depending upon the manner of connecting the field winding to the armature. In the series type of machine, the field winding (the winding which produces the magnetic field) is connected in series with the armature winding. In the shunt type, the field winding is connected in parallel,

shunt, with the armature winding. Compound machines have two field windings on each pole. One of these windings is connected in series with the armature winding, and the other is connected in parallel or shunt with the armature winding.

3. Armature winding of dc machines may be of the *lap* or the *wave* type. The difference in the two types is in the manner of connecting the armature coils to the commutator. A coil is the portion of the armature winding between successive connections to the commutator. In the lap type of winding (see Fig. 7.1) the two ends of a coil are connected to adjacent commutator segments. In the wave type of winding (see Fig. 7.2) the two ends of a coil are connected to commutator segments that are displaced from each other by approximately 360 electrical degrees.

FIGURE 7.1 Two coils of a four-pole lap-wound armature.

FIGURE 7.2 Coil on a four-pole wave-wound armature.

The type of armature winding employed affects the voltage and current capacity of the machine but has no effect upon the power capacity. This is due to the fact that the number of parallel paths between armature terminals is affected by the type of winding. For a wave-wound machine there are always two paths in parallel in the armature winding between armature terminals. For a lap-wound machine there are as many parallel paths in the armature winding as there are pairs of poles on the machine. For the same number and size of armature conductors, a machine when wave-connected would generate a voltage that would equal the voltage generated when lap-connected times the number of pairs of poles. But the current capacity would be decreased in the same proportion that the voltage was increased. The current capacity of a machine when wave-connected is therefore equal to the capacity when lap-connected divided by the number of pairs of poles.

4. The value of the voltage generated by a dc machine depends upon the armature winding, the speed, and the field current. For a given machine, therefore, the voltage generated can be controlled by adjusting either the speed or the field current. Since generators are usually operated at a constant speed, the voltage must be controlled by adjusting the field current.

5. Separately excited dc generators are used for electroplating and for other electrolytic work for which the polarity of a machine must not be reversed. Self-excited machines may change their polarities. The essential diagrams are shown in Fig. 7.3. The fields can be excited from any dc constant-potential source, such as a storage battery, or from a rectifier connected to an ac supply.

FIGURE 7.3 Separately excited generator.

The field magnets can be wound for any voltage because they have no electric connection with the armature. With a constant field excitation, the voltage will drop slightly from no load to full load because of armature drop and armature reaction.

Separate excitation is advantageous when the voltage generated by the machine is not suitable for field excitation. This is true for especially low- or high-voltage machines.

6. Series-wound generators have their armature winding, field coils, and external circuit connected in series with each other so that the same current flows through all parts of the circuit (see Fig. 7.4). If a series generator is operated at no load (external circuit open), there will be no current through the field coils, and the only magnetic flux present in the machine will be that due to the residual magnetism which has been retained by the poles from previous operation. Therefore, the no-load voltage of a series generator will be only a few volts produced by cutting the residual flux. If the external circuit is closed and the current increased, the voltage will increase with the increase in current until the magnetic circuit becomes saturated. With any further increases of load the voltage will decrease.

Series generators have been used sometimes in street-railway service. They have been connected in series with long trolley feeders supplying sections of the system distant from the supply point in order to boost the voltage. However, power rectifiers have replaced dc generators for most installations of this type.

FIGURE 7.4 Series generator.

7. The shunt-wound generator is shown diagrammatically in Fig. 7.5, I and II. A small part of the total current, the exciting current, is shunted through the fields. The exciting current varies from possibly 5 percent of the total current in small machines to 1 percent in large ones. The exciting current is determined by the voltage at the brushes and the

FIGURE 7.5 Shunt generator.

resistance of the field winding. Residual magnetism in the field cores permits a shunt generator to “build-up.” This small amount of magnetism that is retained in the field cores induces a voltage in the armature (William H. Timbie, *Elements of Electricity*). This voltage sends a slight current through the field coils, which increases the magnetization. Thus, the induced voltage in the armature is increased. This in turn increases the current in the fields, which still further increases the magnetization, and so on, until the normal voltage of the machine is reached and conditions are stable. This “building-up” action is the same for any self-excited generator and often requires 20 to 30 s.

If a shunt generator (Timbie) runs at a constant speed, as more and more current is drawn from the generator, the voltage across the brushes falls slightly. This fall is due to the act that more and more of the generated voltage is required to force the increasing current through the windings of the armature; i.e., the armature IR drop increases. This leaves a smaller part of the total emf for brush emf, and when the brush voltage falls, there is a slight decrease in the field current, which is determined by the brush voltage. This and armature reactions cause the total emf to drop a little, which still further lowers the brush potential. These causes combine to lower the voltage gradually, especially at heavy overloads. The curve in Fig. 7.5, III, shows these characteristics. For small loads the curves is nearly horizontal, but at heavy overloads it shows a decided drop. The point at which the voltage of a commercial machine drops off rapidly is beyond the operating range and is of importance only for short-circuit conditions.

The voltage of a shunt machine can be kept fairly constant by providing extra resistance in the field circuit (see Fig. 7.6), which may be cut out as the brush potential falls. This will allow more current to flow through the field coils and increase the number of magnetic lines set up in the magnetic circuit. If the speed is kept constant, the armature conductors cut through the stronger magnetic field at the same speed and thus induce a greater emf and

FIGURE 7.6 Shunt-wound generator with a rheostat.

FIGURE 7.7 Changing the rotation direction of a shunt machine.

restore the brush potential to its former value. This resistance can be cut out either automatically or by hand (see Sec. 42 of Div. 1).

Shunt-wound generators give a fairly constant voltage, even with varying loads, and can be used for any system which incorporates constant-potential loads. This will operate well in parallel because the voltage of the machines decreases as the load increases. Shunt generators running in parallel will divide the load well between themselves if the machines have similar characteristics.

The necessary change in connections when reversing the direction of rotation of a shunt-wound machine is indicated in Fig. 7.7. Rotation is *clockwise* when, facing the commutator end of a machine, the rotation is in the direction of the hands of a clock. *Counterclockwise* rotation is the reverse. When changing the direction of rotation, do not reverse the direction of current through the field windings. If the direction is reversed, the magnetism developed by the windings on starting will oppose the residual magnetism and the machine will not “build up.”

8. Parallel operation of shunt generators. As suggested in Sec. 7, shunt-wound generators will in general operate very well in parallel and will divide the load well if the machines have similar characteristics. If the machines do not have similar characteristics, one machine will take more than its share of the load and may tend to drive the other as a motor. When this machine is running as a motor, its direction of rotation will be the same as when it was generating; hence the operator must watch the ammeters closely for an indication of this trouble. Shunt generators are now seldom installed. Figure 7.8 shows the connections for shunt generators that are to be operated in parallel.

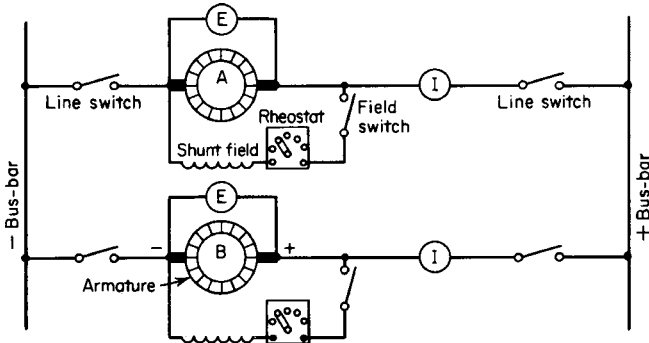

FIGURE 7.8 Connections for shunt generators for parallel operation.

9. The compound-wound generator is shown diagrammatically in Fig. 7.9, I. If a series winding is added in a proper manner to a shunt generator (Fig. 7.5), the two windings will tend to maintain a constant voltage as the load increases. The magnetization due to the series windings increases as the line current increases, thus tending to increase the generated voltage. The drop of voltage at the brushes that occurs in a shunt generator can thus be compensated for.

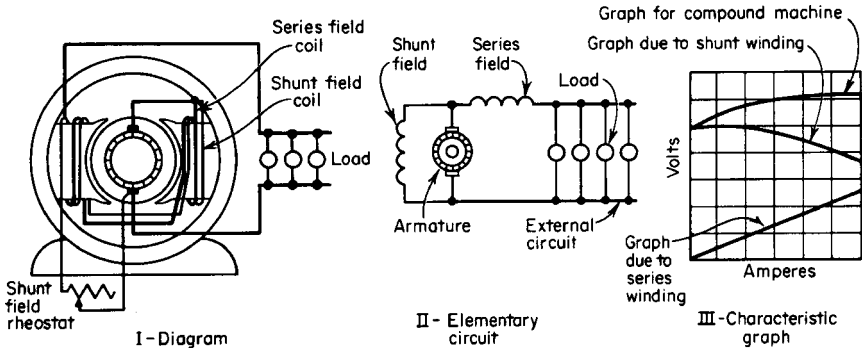

FIGURE 7.9 Compound generator.

The series winding must be connected in such a manner that its current will aid that of the shunt-field winding in producing magnetic flux. With this proper connection, the machine is said to be cumulatively connected. If the series field is connected in the reverse manner, so that the series field tends to produce flux in the opposite direction to that produced by the shunt field, the machine is said to be differentially connected. Differential connection of compound machines is used in very special cases.

10. A flat-compounded generator is one having its series coils so proportioned that the voltage remains practically constant at all loads from 0 to $1\frac{1}{4}$ full load.

11. An overcompounded generator has its series windings so proportioned that its full-load voltage is greater than its no-load voltage. Overcompounding is necessary when it is desirable to maintain a practically constant voltage at some point out on the line distant from the generator. It compensates for line drop. The characteristic curve (Fig. 7.9, III) indicates how the terminal voltage of a compound-wound machine is due to the action of both shunt and series windings. Generators are usually overcompounded, so that the full-load voltage is from 5 to 10 percent greater than the no-load voltage.

Although compound-wound generators are usually provided with a field rheostat, it is not intended for regulating voltage, as the rheostat of a shunt-wound machine is. It is provided to permit initial adjustment of voltage and to compensate for changes of the resistance of the shunt winding caused by heating. With a compound-wound generator, the voltage having been once adjusted, the series coils automatically strengthen the magnetic field as the load increases. For dc power work, compound-wound generators are used almost universally when rectifiers are not employed.

12. An undercompounded generator is one with a relatively weak series-field winding, so that the voltage decreases with increased load.

13. If a compound-wound generator is short-circuited, the field strength due to the series windings will be greatly increased but the field due to the shunt winding will lose its strength. For the instant or so that the shunt magnetization is diminishing, a heavy current will flow. If the shunt magnetization constitutes a considerable proportion of the total magnetization, the current will decrease after the heavy rush and little harm will be done if the armature has successfully withstood the heavy rush. However, if the series magnetization is quite strong in proportion to the shunt, their combined effect may so magnetize the fields that the armature will be burned out.

14. A short-shunt compound-wound generator has its shunt field connected directly across the brushes (see Fig. 7.9, II). Generators are usually connected in this way because this arrangement tends to maintain the shunt-field current more nearly constant on variable loads, as the drop in the series winding does not directly affect the voltage on the shunt field.

15. A long-shunt generator has its shunt-field winding connected across the terminals of the generator (see Fig. 7.10).

16. Nearly all commercial dc generators have more than two poles. A two-pole machine is a bipolar machine; one having more than two poles is a multipolar machine. Figure 7.11 shows the connections for a four-pole compound-wound machine. Diagrams for machines having more poles would be similar. In multipolar machines there is usually one set of brushes for each pair of poles, but with wave-wound armatures, such as those used for railway motors, one set of brushes may suffice for a multipolar machine. The connections of different makes of machines vary in detail; since manufacturers will always furnish complete diagrams, no attempt will be made to give them here. The directions of the field windings on

FIGURE 7.10 Long-shunt compound-wound generator.

FIGURE 7.11 Four-pole compound-wound generator.

III Multipolar machine

FIGURE 7.12 Directions of field windings on generator frames.

generator frames are given in Fig. 7.12. The directions of the windings on machines having more than four poles are similar in general to those of the four-pole machines.

17. A series shunt for a compound generator consists of a low-resistance connection across the terminals of the series field (see Figs. 7.13 and 7.14) through which the compounding effect of the series winding can be regulated by shunting more or less of the armature current around the series coils. The shunting resistance may be in the form of grids, on large machines, or of ribbon resistors. In the latter case it is usually insulated and folded into small compass.

FIGURE 7.13 Elementary connections for parallel operation of compound-wound generators.

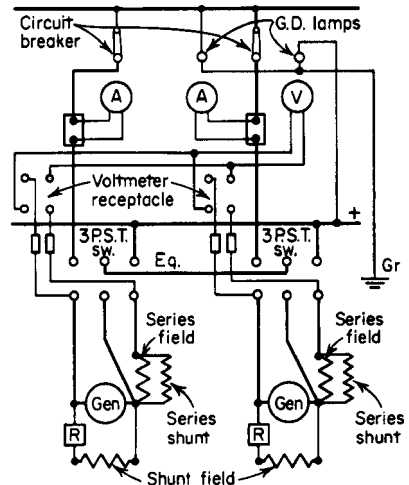

FIGURE 7.14 Connections of two compound-wound generators to a switchboard.

18. Parallel operation of compound-wound generators is readily effected if the machines are of the same make and voltage or are designed with similar electrical characteristics (Westinghouse Electric Corp.) The only change that is usually required is the addition of an equalizer connection between machines. If the generators have different compounding ratios, it may be necessary to adjust the series-field shunts to obtain uniform conditions.

19. An equalizer, or equalizer connection, connects two or more generators operating in parallel at a point where the armature and series-field leads join (see Fig. 7.13), thus

connecting the armatures in multiple and the series coils in multiple so that the load will divide between the generators in proportion to their capacities. The arrangement of connections to a switchboard (Westinghouse Electric Corp.) is illustrated in Fig. 7.14. Consider, for example, two overcompound-wound machines operating in parallel without an equalizer. If for some reason there is a light increase in the speed of one machine, it will take more than its share of load. The increased current flowing through its series field will strengthen the magnetism, raise the voltage, and cause the machine to carry a still greater amount until it carries the entire load. When equalizers are used, the current flowing through each series coil is inversely proportional to the resistance of the series-coil circuit and is independent of the load on any machine; consequently, an increase of voltage on one machine builds up the voltage of the other at the same time, so that the first machine cannot take all the load but will continue to share it in proper proportion with the other generators.

20. Operation of a shunt and a compound dynamo in parallel is not successful because the compound machine will take more than its share of the load unless the shunt-machine field rheostat is adjusted at each change in load.

21. Connecting leads for compound generators. See that all the cables for machines of equal capacity that lead from the series fields of the various machines to the busbars are of equal resistance. This means that if the machines are at different distances from the switchboard, different sizes of wire should be used or resistance inserted in the low-resistance leads.

With generators of small capacity the equalizer is usually carried to the switchboard, as suggested in Figs. 7.14 and 7.15, but with larger ones it is carried under the floor directly between the machines (Fig. 7.16). The positive and the equalizer switches of each machine may be mounted side by side on a pedestal near the generator (Fig. 7.16). The

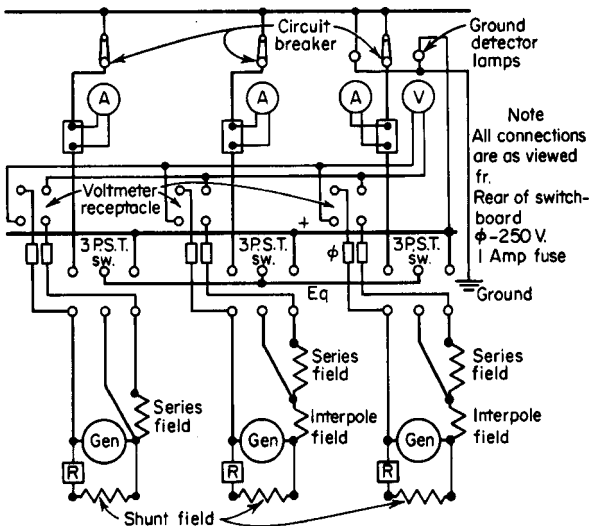

FIGURE 7.15 Connections of two dc commutating-pole generators in parallel with one generator without commutating poles.

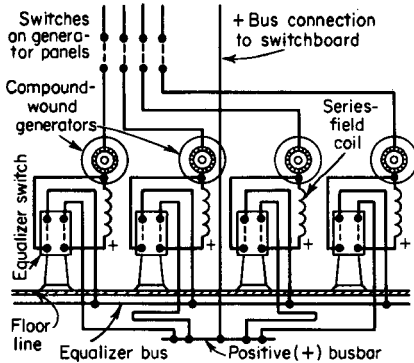

FIGURE 7.16 Equalizer carried directly between machines.

difference in potential between the two switches is only due to the small drop in the series coil. The positive busbar is carried under the floor near the machines, permitting leads of minimum length. Leads of equal length should be used for generation of equal capacities. If the capacities are unequal (see Sec. 25), it may be necessary to loop the leads (see Fig. 7.16).

22. Ammeters and circuit breakers for compound generators

should, as in Fig. 7.14, always be inserted in the lead not containing the compound winding. If the ammeters are put in the compound-winding lead, the current indications will be inaccurate

because current from this side of the machine can flow through either the equalizer or the compound-winding lead.

23. Starting a shunt- or compound-wound generator. (1) See that there is enough oil in the bearings, that the oil rings are working, and that all field resistance is cut in. (2) Start the prime mover slowly and permit it to come up to speed. See that the oil rings are working. (3) When machine is up to normal speed, cut out field resistance until the voltage of the machine is normal or equal to or a trifle above that on the busbars. (4) Throw on the load. If three separate switches are used, as in Fig. 7.13, close the equalizer switch first, the series-coil line switch second, and the other line switch third. If a three-pole switch is used, as in Fig. 7.14, all three poles are, of course, closed at the same time. (5) Watch the voltmeter and ammeter and adjust the field rheostat until the machine takes its share of the load. A machine generating the higher voltage will take more than its share of the load and if its voltage is too high, it will run the other machine as a motor.

24. Shutting down a shunt- or compound-wound generator operating in parallel with others.

(1) Reduce the load on the machine as much as possible by cutting resistance into the shunt-field circuit with the field rheostat. (2) Throw off the load by opening the circuit breaker if one is used; otherwise open the main generator switches. (3) Shut down the driving machine. (4) Wipe off all oil and dirt, clean the machine, and put it in good order for the next run. Turn on all resistance in the field rheostat. Open the main switch.

25. Adjusting the division of load between two compound-wound generators.

First adjust the series shunts of both machines so that, as nearly as possible, the voltages of both will be the same at one-fourth, one-half, three-fourths, and full load. Then connect the machines in parallel, as suggested in Fig. 7.13, for trial. If, upon loading, one machine takes more than its share of the load (amperes), increase the resistance of the path through its series-field coil path until the load divides between the machines proportionally to their capacities. Only a small increase in resistance is usually needed. The increase can be provided by inserting a longer conductor between the generator and the busbar, or iron or

nickel silver washers can be inserted under a connection lug. Inasmuch as adjustment of the series-coil shunt affects both machines when the machines are connected in parallel, nothing can be accomplished through making such an adjustment.

26. Commutating-pole dc generators. Generators which do not have commutating poles (Westinghouse Electric Corp.) and which operate under severe overloads and over a wide speed range are apt to spark under the brushes at the extreme overloads and at the higher speeds. This happens because the field due to the armature current distorts the main field to such an extent that the coils being commutated under the brush are no longer in a magnetic field of the proper direction and strength. To overcome this, *commutating poles* are placed between the main poles (see Fig. 7.17). These poles introduce a magnetic field of such direction and strength as to maintain the magnetic field, at the point where the coils are commutated, at the proper strength for good communication. Commutating poles are sometimes called *interpoles*. Commutating poles is the preferable term.

FIGURE 7.17 Compound-wound commutating-pole (interpole) machine.

The winding on the commutating poles is connected in series with the armature so that the strength of the corrective field increases and decreases with the load. The adjustment and operation of commutating-pole generators are not materially different from those of non-commutating-pole machines.

When the brush position of a commutating-pole machine has once been properly fixed, no shifting is required afterward or should be made, and most commutating-pole generators are shipped without any shifting device. An arrangement for clamping the brush holder rings securely to the field frame is provided.

In commutating-pole apparatus, accurate adjustment of the brush position is necessary. The correct brush position is on the no-load neutral point, which is located by the manufacturer. A template is furnished with each machine, or some other provision is made so that the brush location can be determined in the field. If the brushes are given a backward lead on a commutating-pole generator, the machine will overcompound and will not commute properly. With a forward lead of the brushes, a generator will undercompound and will not commute properly.

27. The object in using a commutating pole is to produce within the armature coil under commutation an emf of the proper value and direction to reverse the current in the coil which it is yet under the brush—a result that is essential to perfect commutation. The variation in the flux distribution in the air gap of a commercial dc machine of the ordinary shunt-wound type, at no load and under full load, is shown in Fig. 7.18. Consider now the value and position of the flux in the coil under the brush when the machine is operating at full load. The motion of the armature through this flux causes the generation within the coil of an emf, and the sign of this emf is such as to tend to cause the current in the coil to continue in the direction which it had before the coil reached the brush; hence it opposes the desired reversal of the current before the coil leaves the brush.

There is an additional detrimental influence which tends to retard the rapid reversal of the current even when all other influences are absent. This influence is due to the local magnetizing effect of the current in the coil under the brush. This effect causes the lines of force which surround the conductor to change in value with the fluctuations of the current as it tends to be reversed. As a result, an emf which opposes the change in the value of the current is generated in the coil. This reactive emf is in the same direction as that due to the cutting of the flux by the coil under the brush and is likewise proportional to the speed.

It will be apparent that even if the field distortion were completely neutralized, the detrimental reactive emf would remain. The improved and practically perfect commutation of the commutating-pole machine is due to the fact that the flux, which is superposed locally upon the main field, not only counterbalances the undesirable main flux cut by the coil under the brush but causes an emf sufficient to equal and opposite the reactive emf to be generated within the coil. This effect will be appreciated from a study of Fig. 7.19, which represents the distorted flux of the motor of the usual design, as shown in Fig. 7.18, and indicates the results to be expected when the flux due to the auxiliary or commutating pole is given the relatively proper value.

FIGURE 7.18 Distribution of magnetic flux at no load and at full load, without commutating poles.

FIGURE 7.19 Distribution of magnetic flux at full load, with and without commutating poles.

This desirable effect is more pronounced the weaker the main field. The commutation voltage, if correct for a low speed, is correct for a high speed; and with the increase of load-current and main-field distortion there is a proportional increase of the counter-magnetizing field produced in the coil under the brush, up to the point of magnetic saturation of the auxiliary pole. Sparkless operation is ensured for all operating ranges of both speed and load.

28. The action of the magnetic flux in a commutating-pole generator

is illustrated in Fig. 7.20. The direction of the main-field flux is shown by the dashed line. The direction of the armature magnetization is shown by the dotted lines. The direction of the flux in the commutating pole is shown by the full line. It is evident that the commutating-pole flux is in a direction opposite to that of the armature flux, and as the commutating-pole coil is more powerful at the commutating point in its magnetizing action than the armature coils, the flux of the armature coils is neutralized. With a less powerful magnetizing force from the commutating pole than from the armature at the commutating point, the armature would overpower the commutating pole and reverse the direction of the flux, which would result in a bad commutating condition.

FIGURE 7.20 Distribution of flux in a commutating-pole generator.

29. Determining the neutral point of a motor or generator

(Fig. 7.21). Two copper-wire contact points, or contactors, *C* are inserted in an insulating block and are allowed to extend through it about $\frac{1}{16}$ in (1.6 mm). The distance between the centers of the points should be equal to the width of one commutator bar. The contactors are connected to a millivoltmeter *V*, which preferably should be of the differential type. Place both points on the commutator while the machine is being rotated with the brushes lifted from the commutator and the shunt field is being excited. While shifting the points around the periphery of the commutator, hold the block so that an imaginary line connecting the two contact points will be perpendicular to the axis of the commutator.

FIGURE 7.21 Connections for determination of the neutral point.

If a differential voltmeter is used, its needle will indicate either to the right or to the left of the zero point until the contacts are exactly over the neutral position; then the voltmeter will read zero. The brushes can now be shifted so that an imaginary line, parallel to the axis of the commutator and bisecting the bearing surface of the brush, will coincide with a point equidistant between the two contact points.

FIGURE 7.22A Polarity of commutating poles (clockwise rotation).

30. Determining the proper polarity of the commutating poles. For a motor, proceeding from pole to pole around the frame in the direction of armature rotation, each commutating pole should have the same polarity as the main pole which just precedes it (Fig. 7.22A, I). For a generator, proceeding from pole to pole around the frame in the direction of armature rotation, each commutating pole should have a polarity opposite to that of the main pole which just precedes it (Fig. 7.22A, II).

31. Commutating-pole machines will run in parallel with each other and with non-commutating-pole machines, provided correct connections are made (see illustrations). The series-field windings on commutating-pole machines are usually less powerful than on non-commutating-pole machines, and particular attention should therefore be paid to getting the proper drop in accordance with instructions of Sec. 25. A connection diagram is shown in Fig. 7.15.

FIGURE 7.22B Section of a dc machine showing the location of a compensating field winding.

additional winding called a *compensating field winding*. A compensating field winding consists of coils embedded in slots in the pole faces of the machine, as shown in Figs. 7.22B and 7.22C. The compensating winding is connected in series with the armature in such a manner that the current through the individual conductors of the compensating field winding will be opposite to the direction of the corresponding armature conductors, as shown in Fig. 7.22B.

32. Compensating field windings.

The commutating poles of a dc motor or generator do not neutralize the effect of the armature current upon the flux of the machine. They simply produce a local flux at the commutating location of the armature conductors. For machines that must operate under very severe conditions of overload and speed range, means must be provided for satisfactory operation to neutralize the tendency of the armature current to distort and change the flux of the machine. This neutralization is produced by means of an

33. Three-wire dc generators are ordinary dc generators with the modifications and additions described below. They are usually wound for 125/250-V, three-wire circuits. In the case of commercial three-wire generators (Westinghouse Electric Corp.), four equidistant taps are made in the armature winding, and each pair of taps diametrically opposite each other is connected through a balance coil. The balance coil may be external (Fig. 7.23) or wound within the armature. The middle points of the two balance coils are connected, and this junction constitutes the neutral point to which the third, or neutral,

FIGURE 7.22C Frame and field structure of a dc motor showing compensating windings in the faces of the main poles. [Westinghouse Electric Corp.]

wire of the system is connected. A constant voltage is maintained between the neutral and outside wires which, within narrow limits, is one-half the generator voltage. The generator shaft is extended at the commutator end for the collector rings. Four collector brushes and brush holders are used in addition to the regular dc brushes and brush holders.

34. The series coils of compound-wound three-wire generators are divided into halves (see Fig. 7.23), one of which is connected to the positive and

one to the negative side. This is done to obtain compounding on either side of the system when operating on an unbalanced load. To understand this procedure, consider a generator with the series field on the negative side only and with most of the load on the positive side of the system. The current flows from the positive brush through the load and back along the neutral wire without passing through the series field. The generator is then operating as an ordinary shunt machine. If most of the load is on the negative side, the current flows out the neutral wire and back through the series fields, boosting the voltage by the maximum amount. Such operation is evidently not satisfactory, and so divided series fields are provided.

FIGURE 7.23 Connections for a three-wire generator.

35. Switchboard connections for three-wire generators. Figure 7.24 is a diagrammatical representation of switchboard connections for two three-wire generators operated in multiple (Westinghouse publication). Two ammeters indicate the unbalanced load. The positive lead and equalizer are controlled by a double-pole circuit breaker, as are the negative lead and equalizer. Note that both the positive and the negative equalizer connections as well as both the positive and the negative leads are run to the circuit breakers as well as to the main switches on the switchboard. This must be done in all cases. Otherwise, when two or more machines are running in multiple and the breaker comes out, opening the main circuit to one of them but not breaking its equalizer leads, its ammeter is left connected to the equalizer busbars and current is fed into it from the other machines through the equalizer leads, either driving it as a motor or destroying the armature winding (see also Figs. 7.25 and 7.26).

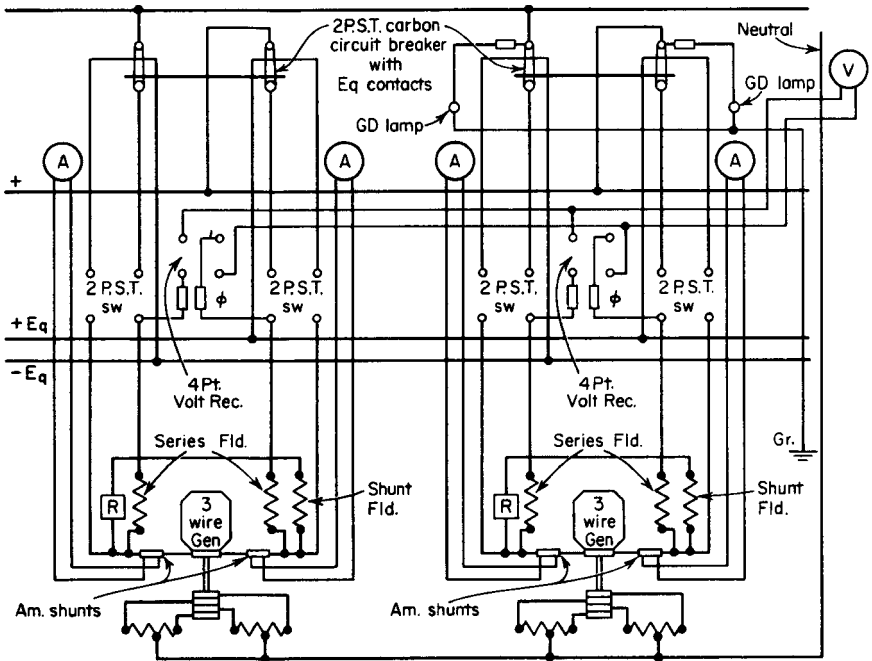

FIGURE 7.24 Connections of two three-wire dc generators operating in parallel, $125/250$ V.

36. As there are two series fields, two equalizer buses are required when several three-wire machines are installed (see Fig. 7.24) and are to be operated in parallel. The two equalizers serve to distribute the load equally between the machines and to prevent crosscurrents due to differences in voltage on the different generators. Because of the equalizer connections, two small terminal boards, one for each side of the generator, are supplied. Arrangement is also made for ammeter shunts on the terminal boards.

An ammeter shunt is mounted directly on each of the contact boards of the machine. The total current output of the machine can thereby be read at the switchboard. Because the shunts are at the machine, there is no chance for current to leak across between generator

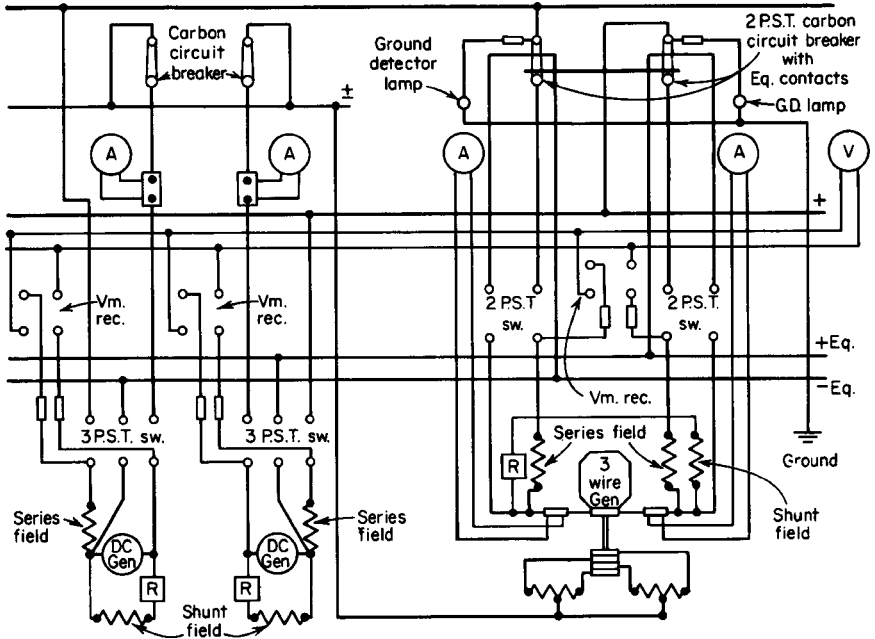

FIGURE 7.25 Connections of a three-wire dc generator, $125/250$ V, in parallel with two two-wire generators, 125 V.

FIGURE 7.26 Connections of a three-wire dc generator, $125/250$ V, in parallel with a two-wire generator, 250 V.

switchboard leads without causing a reading on the ammeters. Two ammeters must be provided for reading the current in the outside wires. It is important that the current be measured on both sides of the system, because with an ammeter on one side of the system only it is possible for a large unmeasured current to flow in the other side with disastrous results.

37. Wires connecting the balance coils to a three-wire generator must be short and of low resistance. Any considerable resistance in these wires will affect the voltage regulation. The unbalanced current flows along these connections; consequently, if they have much resistance, the resulting drop in voltage reduces the voltage on the heavily loaded side.

Switches are not ordinarily placed in the circuits connecting the four collector rings to the balance coils. When necessary, the coils can be disconnected from the generator by raising the brushes from the collector rings. Switching arrangements often make it necessary to run the balance-coil connections to the switchboard and back, requiring heavy leads to keep the drop low, or if heavy leads are not used, poor regulation may result. The balance coils are so constructed that there is very little likelihood of anything happening to them that will not be taken care of by the main circuit breakers. Complete switchboard connection diagrams are given in Figs. 7.24, 7.25, and 7.26.

38. Commutating-pole three-wire generators. In three-wire generators, connections are so made that one-half of the commutating-pole winding is in the positive side and the other half is in the negative side. This ensures proper action of the commutating pole at an unbalanced load (see Figs. 7.24, 7.25, and 7.26 and the text accompanying them).

39. Three-wire dc generators can be operated in parallel with each other (Westinghouse publication) and in parallel with other machines on the three-wire system (see Figs. 7.24, 7.25, and 7.26). When a three-wire, 250-V generator is operated in multiple with two-wire, 125-V generators, the series fields of the two two-wire generators must be connected, one on the positive side and one on the negative side of the system, and an equalizer must be run to each machine. Similarly, when a three-wire, 250-V generator is operated in multiple with a 250-V two-wire generator, the series field of the 250-V two-wire generator must be divided and one-half connected to each outside wire. The method of doing this is to disconnect the connectors between the series-field coils and to reconnect these coils so that all the N pole fields will be in series on one side of the three-wire system and all the S pole fields in series on the other side of the system.

40. Testing for polarity. When a machine that is to operate in parallel with others is connected to the busbars for the first time, it should be tested for polarity. The + lead of the machine should connect to the + busbar and the - lead to the - busbar (Fig. 7.27, I). The machine to be tested should be brought up to normal voltage but not connected to the bars. The test can be made with two lamps (Fig. 7.27, II), each lamp of the voltage of the circuit. Each is temporarily connected between a machine terminal and the bus terminal of the main switch. If the lamps do not burn, the polarity of the new machine is correct, but if they burn brightly, its polarity is incorrect and should be reversed. A voltmeter can be used (Fig. 7.27, III). A temporary connection is made across one pair of outside terminals, and the voltmeter is connected across the other pair. No deflection or a small deflection indicates correct polarity. (Test with voltmeter leads one way and then reverse them, as

FIGURE 7.27 Tests for polarity.

indicated by the dotted lines.) A full-scale deflection indicates incorrect polarity. Use a voltmeter having a voltage range equal to twice the voltage on the busbars.

41. Third-brush generators were often used on automobiles to provide the necessary electric power for the changing of the storage battery and the operation of lights. If an ordinary generator were employed for this purpose, the voltage would vary over a wide range as the speed of the car changed. The voltage would vary nearly proportionally to the speed. This, of course, would not be satisfactory either for the proper charging of the battery or for operation of the car lights. The third-brush generator is a special shunt generator with the field winding connected between one of the main brushes and the auxiliary, or third, brush (see Fig. 7.28). As the speed of the automobile increased, thereby increasing the speed of the generator, the voltage tended to increase. This increase in voltage increased the current delivered by the generator. But the increase in current so changed the magnetic-flux distribution in the machine that the voltage between the third brush and main brush A was reduced. This reduced the field current and therefore the flux of the machine and tended to bring the main voltage between brushes A and C back to its former value. This action did not maintain an absolutely constant voltage for different speeds, but the voltage

FIGURE 7.28 Third-brush generator. [Charles L. Dawes, "Direct Currents," *A Course in Electrical Engineering*]

was held within certain limits so that an excessive voltage which would overcharge the battery and shorten the life of the lamps was not developed at high speeds. It should be noted that present-day automobiles use an ac generator (alternator) with rectifier diodes to provide a 12-V dc supply.

42. Diverter-pole generators are a special type of dc generators (developed by the Electric Products Co.) that have particular advantages for the charging of batteries by the floating method. The machine is constructed with additional pole pieces (the diverter poles) located midway between the main poles in the same manner as commutating poles. Each main pole is connected by a magnetic bridge to one diverter pole. The windings of the main poles are connected in shunt with the armature winding, and the windings of the diverter poles in series with the armature winding. The construction, connections, and load-voltage characteristics for such a generator are shown in Fig. 7.29. These generators will produce an almost constant terminal voltage from no load to 110 percent of rated load. Above 110 percent of rated load, the voltage drops very rapidly.

At no load, a part of the magnetic flux resulting from the shunt coil on the main pole piece is diverted and does not pass through the armature. As the load increases, the series winding on the diverter pole rediverts this flux to the armature and provides a commutating field.

If the shunt and series windings are properly proportioned, the flux in the armature varies with the load to compensate for the IR drop in the generator and for speed changes of the driving motor.

A flat voltage curve is obtained, since the necessary magnetic changes produced by the series winding take place only in the diverter pole, the flux from the main pole remaining constant. The flux densities in the diverter pole are kept low, so that the magnetic changes which occur in this part of the magnetic circuit take place on the straight portion of the magnetization curve, thus eliminating most of the curvature from the voltage characteristic. By correct adjustment of the diverter-pole winding by means of an adjustable shunt, a very straight, flat curve is obtained with only a very slight rise on approaching zero load.

At some value of the load current the ampere-turns on the diverter pole will equal those on the main pole, and at this time the magnetic flux leaking across the ridge to the diverter pole is all rediverted across the air gap; hence there is no further leakage flux for an increased current to be rediverted to the armature. When the load is increased beyond this point, the increased ampere-turns on the diverter pole combine with the armature cross-magnetizing force to send magnetic flux in the reverse direction across the leakage bridge, which tends to demagnetize the main pole and reduce the generator voltage. Good commutation is assured, as the diverter pole provides a commutating field of the correct direction for improving commutation, and this field varies with the current output just as in a commutating-pole generator.

43. Control generators are specifically designed dc generators which are employed for the precise automatic control of dc motors. They are used to perform a wide variety of functions, such as:

1. Controlling and regulating speed, voltage, current, or power accurately over a wide range
2. Controlling tension and torque to maintain product uniformity in winding, drawing, and similar operations
3. Speeding up acceleration or deceleration to increase the production of high-inertia machines, etc.

I. Frame and field-winding construction.

II. Connections.

III. Load-voltage characteristics.

FIGURE 7.29 Diverter-pole generator. [Electric Products Co.]

Small motors can be supplied directly with power from the control generator. In the majority of applications, however, the capacity of the control generator is not sufficient to supply the motor directly, and the control generator energizes the field of a main generator which supplies the motor with power. A control generator must possess the characteristics of moderately fast response and low power consumption from the activating control circuit. The application of control generators for motor control is discussed in greater detail in Sec. 143.

44. The amplidyne is a control generator manufactured by the General Electric Co. Its construction, as shown in Fig. 7.30A, differs from that of the conventional dc generator in the following ways:

1. Separately excited field windings (up to four individual windings) with only a small number of ampere-turns in each winding. The field windings are called *control fields* or *control windings*.
2. Brushes (*A* and *B* in Fig. 7.30A) located in the conventional neutral position which are short-circuited on each other.
3. Pole structure split in two.
4. The addition of a second set of brushes (*C* and *D* in Fig. 7.30A) 90 electrical degrees from the conventional neutral position. These brushes are the load brushes of the machine and are connected to the output terminals of the machine.
5. A compensating field winding wound around the pole structure of the machine instead of being located in slots on the face of the poles. The compensating field winding is connected in series with the load-brush circuit.

FIGURE 7.30A Cross section of an amplidyne generator.

The amplidyne functions in the following manner. When a control-field winding or windings are energized, a magnetic flux will be produced in paths G and H of Fig. 7.30A. The rotation of the armature through this flux will generate voltage in the armature conductors. However, because of the small number of ampere-turns in the control-field windings, the voltage generated from brush B to brush A will produce only a reasonable value of current in the short-circuited armature. The direction of this short-circuited armature current will be as shown by the designations inside the conductors in Fig. 7.30A. The short-circuited armature current will produce magnetic flux in the paths E and F . Voltages will be induced in the armature conductors by this flux E and F . These conductor voltages will produce no net voltage from brush B to brush A , since the voltages in the conductors from B to C and B to D will just neutralize the voltages produced in the conductors from C to A and D to A , respectively. A voltage will be produced, however, from brush C to brush D . Since brushes C and D are connected to the terminals of the machine, an output voltage will be produced whenever a control-field winding is energized. When brushes C and D are connected to an external load circuit, current will flow through the armature conductors because of the load current in the directions designated in Fig. 7.30A by the markings alongside each conductor. The actual current through each individual armature conductor will be the combination of the armature short-circuit current in paths B to A and the armature load current in paths C to D . The load current in the armature should not materially affect the flux of the machine. Therefore, a compensating field winding is connected in series with the load. This winding is so located and designed that its ampere-turns will practically neutralize the ampere-turns produced by the armature load current. The functioning of the machine is summarized as follows:

1. Excitation of a control-field winding produces flux G and H .
2. Flux G and H produces no net voltage between brushes C and D but does produce net voltage in armature paths BCA and BDA .
3. Voltage in paths BCA and BDA produces current in the armature because of the short circuit AB .
4. Short-circuit current in the armature produces flux E and F .
5. Flux E and F produces no net voltage between brushes A and B but does produce net voltage between brushes C and D . This is the load or output voltage of the machine.
6. Voltage CD produces load current in the armature and external circuit.
7. Ampere-turns (flux-producing tendency) of the load armature current are neutralized by ampere-turns of compensating field winding.

Thus the control-field current controls the short-circuit armature current, which in turn controls the output voltage. Since the control-field winding is designed with a very small watt capacity, a very small change of input power to a control-field winding will produce a large change in output power.

The symbolic representation of an amplidyne generator as used in wiring diagrams is shown in Fig. 7.30B.

FIGURE 7.30B Basic symbol for an amplidyne.

45. Rototrol is the trade name of the control generator made by the Westinghouse Electric Corp. The Rototrol is essentially a small dc generator that is similar in electrical and mechanical construction to a standard dc generator of equal size, except that the Rototrol is provided with a number of field windings. The voltage output of the machine

FIGURE 7.30C Basic symbol for the Rototrol.

depends entirely upon the control and interaction of these field windings. The Rototrol is provided with a self-energizing field winding and two or more control-field windings (see Fig. 7.30C.) The self-energizing field winding is generally connected in series with the Rototrol armature and furnishes the necessary excitation for the normal operation of the machine. All the other field windings are called *control-field windings*. The control-field windings are used to measure and compare standard and actual values representative of the quantity to be regulated. One of the control-field windings is called a *pattern-field winding*, and the others are called *pilot-field windings*. The pattern field is the control field, which is separately excited from an independent source and is used as a calibration, or standard of comparison. The pilot fields, the rest of the control-field windings, measure directly or indirectly the quantity to be regulated.

46. The efficiency of a dc generator increases with the load up to a certain point. Figure 7.31 indicates typical efficiency performances. Large-capacity machines have higher full-load efficiencies than small ones. Generators should be of such capacity that insofar as possible they will operate at loads in the neighborhood of their normal ratings.

FIGURE 7.31 Efficiency graph of a 12 kW compound-wound dc generator.

47. Approximate data on standard compound-wound dc commutating-pole generators. The efficiency of a generator depends on its design and, to a certain extent, on its speed and voltage. Average values that are fairly representative of modern practice are given in the following table.

Capacity, kW	Output current, A			Efficiency, percent		
	125 V	250 V	500 V	½ load	¾ load	Full load
5	40	20	10	77.0	81.0	82.5
10	80	40	20	82.0	85.0	86.0
15	120	60	30	82.5	86.5	86.5
20	160	80	40	84.0	86.6	87.5
25	200	100	50	85.0	88.0	89.0
35	280	140	70	87.0	89.0	89.5
50	400	200	100	88.0	89.6	90.5
60	480	240	120	88.5	90.5	91.0
75	600	300	150	88.5	90.5	91.0
90	720	360	180	88.5	90.5	91.0
100	800	400	200	89.0	90.5	91.0
125	1,000	500	250	90.5	91.0	91.0
150	1,200	600	300	90.5	91.3	91.5
200	1,600	800	400	91.0	91.5	92.0
300	2,400	1,200	600	91.3	91.8	92.0
400	3,200	1,600	800	91.8	92.3	92.5
500	4,000	2,000	1,000	91.8	92.2	92.5
750	6,000	3,000	1,500	92.0	92.3	92.5
1,000	8,000	4,000	2,000	92.5	93.0	93.5

48. Rating of dc generators. The standard methods of rating generators are as follows.

Continuous Rating. A generator given a continuous power output rating will carry its rated load continuously in an ambient temperature of 40°C without exceeding a specified rise in temperature. Some large generators (larger than 1 kW/rpm) designed for metal-rolling-mill service (other than reversing hot-mill service) will carry 115 percent of their rated load continuously without injury to themselves, provided service conditions are normal. The factor of 1.15 is known as a *service factor*.

Overload. A general-use industrial generator will carry 150 percent of its rated current for 1 min without injury to itself. Some large generators (larger than 1 kW/rpm) have additional overload-time capabilities.

49. Brushes: their adjustment and care (*Westinghouse Instruction Book*). Brushes on a dc generator should be on or near the no-load neutral point of the commutator. The neutral point on most standard non-commutating-pole generators is in line with the center of the pole, and the brushes should be set a little in advance of this neutral point. The brushes of non-commutating-pole generators should be given a slight forward lead in the direction of rotation of the armature. Motor brushes should be set somewhat back of the neutral point, the backward lead in this case being approximately equal to the forward lead on generators. The exact position in either case is that which gives the best commutation at normal voltage for all loads. In no case should the brushes be set far enough from the neutral point to cause dangerous sparking at no load. For commutating-pole machines it is essential that the brushes be located at the neutral point.

FIGURE 7.32 Sandpapering brushes.

Treat each set of brushes similarly in turn. Start with coarse and finish with fine sandpaper. With copper-plated brushes, bevel their edges slightly so that the copper will not touch the commutator.

The ends of all brushes should be fitted to the commutator so that they make good contact over their entire bearing faces. This can be most easily accomplished after the brush holders have been adjusted and the brushes inserted as follows. Lift a set of brushes sufficiently to permit a sheet of sandpaper to be inserted. Draw the sandpaper in one direction only, preferably in the direction of rotation, under the brushes (Fig. 7.32), being careful to keep the ends of the paper as close to the commutator surface as possible and thus avoid rounding the edges of the brushes.

50. Operating instructions. Do not lubricate the commutator with oil; a piece of muslin moistened with Vaseline can be used to clean and lubricate the commutator.

Emery is a conductor and should not be used in fitting brushes or cleaning the commutator; use sandpaper or sandstone (Sec. 80), and do not use it on the commutator too frequently.

Do not use greater brush tension than necessary; tension greater than 2 lb/in^2 ($13,790 \text{ Pa}$) is seldom required. When replacing brushes, use the quality and size originally supplied with the machine and fit them to the commutator with sandpaper before use (Sec. 49). Do not open generator-field circuits quickly; open the switch slowly, permitting the arc to extinguish gradually, which should take about 5 s.

51. When starting, a generator may fall to excite itself (*Westinghouse Instruction Book*). This may occur even when the generator operated perfectly during the preceding run. It will generally be found that this trouble is caused by a loose connection or a break in the field circuit, by poor contact at the brushes due to a dirty commutator or perhaps to a loss of residual magnetism, or by the incorrect position of the brushes. Examine all connections, try a temporarily increased pressure on the brushes, and look for a broken or burned-out resistance coil in the rheostat. An open circuit in the field winding can sometimes be traced with the aid of a magneto bell, but this is not an infallible test, as some magnetos will not ring through a circuit of such high resistance and reactance even though it is intact. If no open circuit is found in the rheostat or in the field winding, the trouble is probably in the armature. But if nothing is wrong with the connections or the winding, it may be necessary to excite the field from another generator or some other outside source.

Calling the generator we desire to excite 1 and the other machine from which current is to be taken 2, we should follow this procedure. Open all switches and remove all brushes from generator 1, connect the positive brush holder of generator 1 with the positive brush holder of generator 2; also connect the negative holders of the machines together (it is desirable to complete the circuit through a switch having a fuse of about 5 A capacity in series). Close the switch. If the generator in trouble connects to busbars fed by other generators, the same result can be effected by insulating the brushes of the machine in trouble from their commutator and closing the main switch (see Fig. 7.33A.) If the shunt winding of generator 1 is all right, its field will show considerable magnetism. If possible, reduce the voltage of generator 2 before opening the exciting circuit;

FIGURE 7.33A Exciting a generator.

FIGURE 7.33B Another method of exciting a generator.

then break the connections. If this cannot be done, throw in all the rheostat resistance of generator 1; then open the switch very slowly, lengthening the arc which will be formed until it breaks.

A simple means of getting a compound-wound machine to pick up is to short-circuit it through a fuse having approximately the current capacity of the generator (see Fig. 7.33B). If sufficient current to melt this fuse is not generated, there is something wrong with the armature, either a short circuit or an open circuit. If, however, the fuse has blown, make one more attempt to get the machine to excite itself. If it does not pick up, something is wrong with the shunt winding or connections.

If a new machine refuses to excite and the connections seem to be all right, reverse the connections of the shunt field; i.e., connect the wire which leads from the positive brush to the negative brush and the wire which leads from the negative brush to the positive brush. If this change of connections does no good, change back and locate the fault as previously suggested.

52. The proper connections for a shunt motor are shown in Fig. 7.34. The field *B* is connected as shown, so that when switch *D* is closed, it becomes excited before the armature circuit through switch *E* is closed. Thus when the motor armature has current admitted to it through switch *E* and starting resistance box *A*, the field is already on and the full torque of the motor is obtained. The torque of a motor is equal to the product of a constant, the flux per pole, and ampere-turns on the armature, and the number of poles. Hence, if the full field is not on the motor at starting, full torque will not be obtained.

FIGURE 7.34 Control-apparatus connections for a shunt motor.

53. If a motor will not start when the starting box is operated and when current is flowing in the armature, investigate to see if field flux is present. This can be done by holding a piece of iron, such as a key, against the pole piece. If the flux exists, the key will be drawn strongly against the pole piece; if there is no flux, there will be practically no attraction.

54. Reversed field-spool connection. In some cases a manufacturer may have shipped a motor with one or more field spools reversed. Then no torque or, perhaps, very weak torque will be noticed. Under such conditions a trial with an iron key will indicate the presence of field magnetism, yet the weakness or total absence of torque will be present, and a trial of polarity should be made.

55. Running in the wrong direction. Sometimes a motor when set up and started will run in the wrong direction. The only change necessary is to reverse the field connection. Thus Fig. 7.35, I, shows the connection for one direction of rotation, and Fig. 7.35, II, that for the other. Note that in Fig. 7.35, I, the brushes are shifted backward against the direction of rotation. For the opposite rotation, a backward lead, as shown in Fig. 7.35, II, must be chosen.

FIGURE 7.35 Connections for shunt-wound motors.

56. Testing polarity of field. This can be done in two ways. The first way is to use a compass, bringing it near the various poles and noting the direction of the deflection of the needle. Since in all motors the poles alternate in magnetic polarity, in one pole the magnetism coming out and in the next going in, a certain end of a compass needle will point toward one pole and away from the next when conditions are normal. If, however, two adjacent poles show similar magnetism, the trouble is located and the offending spool should be reversed. This should be done end for end, not by turning the axis. The latter operation does not change the direction of magnetism, while the former does.

FIGURE 7.36 Direction of magnetism and current about a pole.

Direction of magnetism is determined by the following rule. When looking at the face of an electromagnet (such as the field spool of a motor), a pole will be north if the current is flowing around it in a direction opposite to the motion of the hands of a watch (Fig. 7.36) and south if in the same direction as the motion of the hands of a watch (see also the rules outlined in Div. 1).

Another method of determining whether the magnetism of the poles is correct is to use two ordinary nails, their lengths depending upon the distance between pole tips. The point of one nail should touch one pole tip, the point of the other nail should touch the other pole tip, and the heads of nails should touch each other.

When the current flows around the field spools, the polarity between any poles is properly related if the nails placed as suggested stick together by the magnetism. If there is no tendency to stick, the polarity of the two poles is alike and therefore wrong.

57. Open field circuit. If, on closing the field switch, no magnetism is obtained by trial with an iron key as suggested above, there is an open circuit within one of the spools or in the wires leading to these spools. The open circuit can be located by shunting out one spool at a time and allowing current to flow through the rest until the defective spool is discovered. On a two-pole motor try first one spool and then the other. For a very short time, say, 10 min, double voltage can be carried on a spool. On a motor having four or more poles, three spools can always be left in circuit during the open-circuit investigations.

58. A method of locating an open-circuit field coil is illustrated in Fig. 7.37A. Connect one terminal of the voltmeter to one side of the field-coil circuit, and with the bared end of a wire or a contactor successively touch the junctions of the field-coil leads around the frame. When the open coil is bridged, the voltmeter will show a full deflection. Another way is to connect the field-coil circuit terminals to a source of voltage. Connect the voltmeter successively across each coil as indicated by the dotted lines in Fig. 7.37A. There will be no deflection on the voltmeter until the open coil is bridged, when the full voltage of the circuit will be indicated.

59. A grounded field coil can be located (Fig. 7.37B) by connecting a source of voltage to the machine terminals, having first raised the brushes from the commutator, if it is a dc machine. Connect one terminal of the voltmeter to the frame and the other to a lead with a bared end. Tap exposed parts of the field circuit with the bared end of the lead. The voltmeter deflection will be least near the grounded coil.

FIGURE 7.37A Locating field-coil troubles.

FIGURE 7.37B Locating a grounded coil.

60. Heating of field circuits (*Westinghouse Instruction Book*). Field coils may heat from any of the following causes: (1) too low speed, (2) too high voltage, (3) too great forward or backward lead of brushes, (4) partial short circuit of one coil, and (5) overload.

FIGURE 7.38 Method of testing an armature.

an insulating block *j*. In use, the current is adjusted to produce a convenient deflection of the voltmeter when each of the points rests on an adjacent bar. The points are moved around the commutator and bridged across the insulation between every two bars. If the voltmeter deflection is the same for every pair of bars, there is no trouble in the armature.

62. Sparking due to an open armature circuit. A cause of a sparking commutator is an open circuit in the winding, either in the armature body or, more often, at the point where the lead from the armature winding is soldered to the commutator. In the latter case resoldering is a ready remedy. If, however, the point of open circuit cannot be located, the bars can be bridged over on the commutator itself by fastening with solder or otherwise a strip of copper around the segments which indicate the break.

The indication of this trouble is very apparent, for if an open circuit exists, the long, heavy spark which accompanies it soon eats away the mica between the two segments on each side of the break. This shows positively where to bridge over. An open circuit also shows itself, when the machine is running, by the viciousness of the spark. It is unlike any other kind of commutator sparking, being heavy, long, and destructive in its action.

63. A poor connection between a bar and coil leads will cause a considerable deflection of the voltmeter (Fig. 7.38) when one of the points rests on the bar in trouble and the other on either of the adjacent bars.

64. An open-circuited coil such as *h*, Fig. 7.38, will prevent the flow of current through its half of the armature. There will be no deflection on that half of the armature until the "open" is bridged. Then the voltage of the testing circuit will be indicated.

65. Tests for open armature circuits. Another method (Fig. 7.39A) is to apply to the commutator, at two opposite points, a low voltage, say from a battery or a dynamo with

61. Direct-current armatures can be tested for common troubles with the arrangement of Fig. 7.38. Terminals *b* and *c* are clamped to the commutator at points displaced 180 electrical degrees from each other and connected with a source of steady current through an adjustable resistance and an ammeter. For a two-pole machine the terminals *b* and *c* will be located at opposite sides of the commutator. The terminals of a low-reading voltmeter (a galvanometer can often be used) are connected to two bare metal points, which are separated, by a distance equal to the width of one commutator segment plus the width of one mica strip, by

FIGURE 7.39A Testing for an armature open circuit with an ammeter.

FIGURE 7.39B Testing for an armature open circuit with a voltmeter.

its voltage kept low. Place an ammeter in circuit and clean the surface of the commutator so that it is bright and smooth.

The terminal ends leading the current into and out of the commutator should be small, so that each rests only on a single segment (Fig. 7.39A). Note the ammeter reading and rotate the armature slowly. At the point where the open circuit exists, the ammeter needle will go to zero if the leads to the commutator bar have become entirely open-circuited. This occurs because the segment is attached to the winding through the commutator leads.

If the armature does not show the above symptoms, try connecting a low-reading voltmeter or a galvanometer to two adjacent segments while the current is passing through the armature as described from some external low-voltage source (Fig. 7.39B). Note the deflection. Pass from segment to segment in this manner, recording the drop between the successive pairs of bars. This drop, if the current is held constant from the external source, should be the same between each pair of adjacent segments. If any pair shows a higher drop than the others near it, a higher-resistance connection exists there, perhaps causing sparking and biting of commutator insulation, to a less degree, to be sure, than with an actual open circuit but perhaps enough to cause the trouble requiring the investigation.

66. The test for armature short circuits can be made as indicated in Fig. 7.39B. Called a *bar-to-bar test*, it is most valuable in locating faults in armatures. This is the method to use if a short circuit from one segment to another is suspected. When the section in which the short circuit or partial short circuit exists comes under the contacts, a low or perhaps no deflection is shown on the galvanometer or voltmeter, thus locating the defective place. Such short circuits, if they occur when running, owing to defective insulation, burn out the coil short-circuited. When the coil passes through the active field in front of the pole piece, an immense current is induced in it, causing destruction of the insulation. When this occurs, the coil should be open-circuited and bridged over, as suggested above, until a new coil can be inserted.

67. If two bars or a coil is short-circuited as at *f* or *g*, Fig. 7.38, respectively, there will be little or no voltmeter deflection when the two bars connecting to the “short circuit” are bridged by the points.

68. A grounded armature coil can be detected in the same manner as indicated in Fig. 7.39A for a field coil. Impress a low voltage on the terminals clamped to the commutator. Ground one side of the voltmeter on the shaft or spider, and touch a lead connected to the other side to all the bars in succession. The minimum deflection will obtain when the bars connecting to the grounded coil are touched.

69. Crossed coil leads as at *a*, Fig. 7.38, are indicated by a twice-normal deflection when the points bridge the bars 6 and 7 to which the crossed coils should rightly connect. The crossing of the coil leads connects two coils in series between the adjacent commutator segments and hence causes a twice-normal drop.

70. Reversed armature coil. Instead of the armature winding progressing uniformly around from bar to bar of the commutator, at some point a coil may be connected backward. Such a reversed coil often causes bad sparking. One way to locate such a trouble is to pass a current through the armature at opposite points on the commutator. Then with a compass explore around the armature the direction of magnetism from slot to slot. If a coil is reversed when the compass comes before it, the needle will reverse, giving a very definite indication of the improperly connected coil.

71. Heating of armature (*Westinghouse Instruction Book*). Excessive heating of the armature may develop from any of the following causes: (1) too great a load, (2) a partial short circuit of two coils heating the two particular coils affected, and (3) short circuits or grounds on armature or commutator.

72. Hot armature coils. Sometimes when a new machine is started, local heating occurs in the armature, following the exact shape of the armature coil. This may occur because, in receiving the final turning off, the commutator bars were bridged with copper from one segment to another by the action of the turning tool. An examination of the commutator surface will reveal this bridging. When it is removed, satisfactory operation will ensue if the trouble has not gone too far and seriously injured the insulation of the coil.

73. Care of commutators. Commutators should be kept smooth by the occasional use of No. 00 sandpaper. A small quantity of Vaseline should be used as a lubricant. The lubricant should be applied to high-voltage generators with a piece of cloth attached to the end of a dry stick. If the commutator gets out of true, it should be turned down (refer to Sec. 80). Inspect the commutator surface carefully to see that the copper has not been burned over from segment to segment in the mica, and remove with a scraper any particles of copper which may be embedded in the mica. Keep oil away from the mica end rings of the commutator, as oily mica will soon burn out and ground the machine.

FIGURE 7.40 Armature coil short-circuited when commutating.

74. Process of commutation and correction of glowing and pitting. The path of the current is as shown in Fig. 7.40. *A* is the carbon brush; *C*, *C'*, *C''* are the commutator segments; *B*, *B'*, *B''* are the windings of the armature. At the position shown, coil *B* is short-circuited by the carbon, the current passing into the face of the brush and out again as shown by the dotted line. This local current may be many times larger than the normal flow of current and is the one that causes pitting.

With perfect commutation and no sparking or glowing, an emf should be created in the short-circuited coil under the brush by means of the flux from the pole tip away from which the armature is revolving. This emf should be just large enough to reverse the current within the short-circuited coil and to render it equal to the current in the winding proper. Since on one side of the brush the current is in one direction and on the other side in the other direction, the act of commutation beneath the brush is to reverse this current and bring it up to the correct amount in the opposite direction.

With copper brushes this reversal of current must be very accurately effected. With carbon brushes there is a much smaller tendency to spark; hence they will stand a certain inexactness in commutation adjustment. Experiments indicate that the carbon can resist as much as 3 V creating current in the wrong direction and still not spark or glow. This is the property that has caused the use of carbon brushes instead of copper on most apparatus. When, however, this potential, induced in the wrong direction, rises above 3 V during the passage of the armature coil underneath the brush, trouble from sparking and glowing occurs.

This is the reason that the brushes in a motor are pulled backward as far as possible at no load, so that the coil short-circuited by the brush can enter the fringe of flux from the pole tip, thus creating the proper reversal of current while the coil is passing under the brush. Since adjacent poles are opposite in polarity, only one pole can provide the proper flux direction for this reversal. In a motor it is always the pole behind the brush, and thus the brush requires a backward lead. In a generator it is the pole ahead of the brush in the direction of rotation. Hence generators require a forward lead.

If a motor gives trouble from glowing and pitting, the cause is probably this induced current, and the remedy is, first, to see that the lead of the brushes brings them in the most satisfactory position. If no change of lead or brush position which will eliminate the trouble can be found, the width of the brush must be changed. The wider the brush, the longer the coil suffers a short circuit, as described. Conversely, the narrower the brush, the sooner the current must be reversed. There is, therefore, a width of brush which best satisfies both conditions.

Usually, however, when glowing occurs, the cause is too wide a brush, and often serious trouble from this cause can be entirely eliminated by varying the width of the brush, perhaps only by $\frac{1}{8}$ in (3.175 mm).

75. Sparking due to a rough commutator. First, the commutator surface may not be perfectly smooth after receiving its last turnoff. The work may have been poorly done by the manufacturer, with the result that the commutator surface, instead of being left smooth, is somewhat rough. The result, especially with high-speed commutators, is that the brush does not make first-class contact with the commutator surface. It may chatter with attending noise, and thus the operation of many motors (especially those of high voltage) will be attended by sparking. As a result, the commutator surface, instead of becoming bright and smooth with time, becomes rough and dull or raw. Under these conditions the brushes do not make good contact, and the heat generated even under proper commutator conditions, owing to the resistance of brush contact, is multiplied several times, with a consequent increase of the commutator's temperature. In addition, the friction of brush contact (which should give a coefficient of 0.2) is, with a rough commutator, much higher than it should be. This high friction tends to increase the temperature.

76. Heating of a commutator (*Westinghouse Instruction Book*) may develop from any of the following causes: (1) overload, (2) sparking at the brushes, (3) too high brush pressure, and (4) lack of lubrication on the commutator.

77. Hot commutator. All this trouble (Sec. 75) is cumulative. The result is that the temperature will finally rise to a point at which the solder in the commutator will melt, perhaps short-circuiting or open-circuiting the winding. A commutator will stand very slight sparking, but if sparking is noticeable and if it continues for long periods of time, trouble is apt to result. If the load is usually very light on a motor and full load or overload is infrequent, a smoothing of the commutator occurs during the light-load period, averting trouble. This is the reason that certain railway motors, which sometimes show sparking under their normal hour-rating load, give satisfaction in commutation. The coasting of the car smooths the imperceptible damage done by the sparking during the heavy load.

FIGURE 7.41 Section of a dc motor armature.

insulated from them and should hold each segment individually from any movement relative to another.

Since the clamp must touch and hold down all segments, a failure to do so in any case results in a loose bar, which moves relatively to the next bar and causes roughness and thus sparking, with all its commutators due to poor turning or to poor design is shown uniformly over the surface of the commutator on which brushes rest. A roughness due to a high or loose bar is shown by local trouble near the bad bar and its corresponding bars around the commutator. The jump of the brush occurs at the high bar and causes the sparking (see also Secs. 79 and 81).

79. Blackening of a commutator. Sparking due to a loose or high bar causes a local blackening instead of a uniform blackening, which occurs in the case of poor design or a poor commutator surface resulting from poor turning. Also, if the speed of the commutator is low enough, a spark will occur when the bad segment passes the brush. At ordinary speeds or in cases of several loose bars, the appearance of the sparking will not differ from that due to poor design or poor turning. In such a case the commutator surface must be examined to identify the cause.

It must be remembered that the slightest movement of a bar, especially with higher-voltage and high-commutator-speed machines, may cause the trouble. A splendidly designed motor may operate very poorly because of a commutator fault.

80. Grinding commutator (Westinghouse Electric Corp.). When a commutator must be resurfaced, the resurfacing should always be done with a grinding rig, whether the surface is to be ground concentric or to remove high bars or flat spots. A sandstone should never be used on a commutator to obtain a true surface because it simply follows the irregularities in the surface and in some cases may even exaggerate them. The grinding rig consists of an abrasive stone set up similarly to a lathe tool in a rigging or carriage which may be moved back and forth in an axial direction and may be equipped with a radial feed. It should be supported very rigidly so that the stone is subjected to a very minimum of vibration.

78. Loose commutator segments.

A further and more serious cause of sparking and commutator trouble is the fact that the commutator may not be "settled" when shipped by the manufacturer. A commutator is made of many parts (Fig. 7.41) insulated one from another and bound together by mechanical clamping arrangements. The segments themselves are held on each end by a clamp ring, which must be insulated from them and should hold each segment individually from any movement relative to another.

In large dc equipment, such a rigging can be mounted on a brush arm by removing the brush holders on that arm. In some cases, to obtain maximum rigidity it may even be desirable to brace the brush-holder bracket arm while grinding. It is also possible by removing the brush rigging to hold the grinder on parallels supported from the bedplate.

Grinding should be done when the machine is running in its own bearings and at rated speed in the case of a constant-speed machine. If grinding is done at a low speed, any slight unbalance will cause the commutator to run eccentric at rated speed.

Great care must be exercised to prevent copper and stone dust from entering the windings. The grinding rig should be equipped with a vacuum-cleaner arrangement, fitted over the stone to catch all dust. If a suction system is not available, the necks of the commutator and the front end windings should be protected by pasting heavy paper over them or by covering them with a cloth hood properly applied.

A simple, effective, and inexpensive device for collecting dust during the grinding of commutators and collectors is illustrated in Fig. 7.42. It can be made from three small pieces of equipment: (1) a 4-ft (1.2-m) length of 1/2-in rubber hose, (2) a vacuum bag from a household vacuum cleaner, and (3) a small ejector which can either be purchased or be improvised from a 1/2-in Y pipe fitting.

At one end of the rubber hose cut away, in the form of a long arc, the bottom and about half of the sidewalls to fit the radius of the commutator or ring to be ground. Cut a hole in the hose in the middle of the remaining arc portion to fit the grinding stone. Fit the hose to the stone and commutator or ring so as to form an enclosure, or shoe, around the grinding surface to collect the dust. Attach the other end of the hose to the intake of the ejector. Attach the vacuum bag to the exhaust of the ejector. Use compressed air from a shop air line to produce the suction.

The stones used in grinding commutators may be classed as rough, medium, and fine. The rough stone has a grit of about 80 mesh and is used only when a very large amount of copper is to be removed. It should be employed very seldom, because if sufficient copper is to be removed to warrant its use, it would be better to take a cut off the surface in a lathe. The medium stone has a grit of about 120 mesh and is used for the bulk of the grinding work, the fine stone being used only to obtain a fine finish. The fine stone should have a grit of about 200 mesh.

After grinding, all commutator slots should be cleaned out thoroughly and the edges of the bars beveled. Beveling accomplishes two things. It removes the burrs caused by the stone's dragging copper over the slots and eliminates the sharp edge at the entering side of the bar under a brush. The bevel on the bars is achieved with a special beveling tool; it should be about 1/32 in (0.8 mm) chamfer at 45° for medium thickness of bars. For thinner or wider bars, the beveling can be changed accordingly.

Practically all up-to-date machines have undercut mica. This undercutting should be kept 1/16 in (1.6 mm) deep \pm 1/64 in (0.4 mm). If it is apparent that enough copper is going to be removed by grinding so that the undercutting will be shallow, the commutator should be reundercut before grinding. This is done by means of a small circular high-speed saw about 0.003 in (0.76 mm) thicker than the nominal thickness of the mica. In undercutting, great care must be taken to see that a thin sliver of mica is not left against one side of the slot. Sometimes such a sliver must be removed by scraping by hand.

FIGURE 7.42 Method of commutator grinding, showing dust collector. [Westinghouse Electric Corp.]

After grinding, undercutting the mica, and beveling the edges of the bars, the commutator surface should be polished while operating at rated speed. Aloxite or sandpaper (never emery cloth or paper) should first be used, as it will remove the burrs due to beveling. After a very fine grade of sandpaper is used, a high polish can be obtained by burnishing the commutator with dense felt or canvas. The surface can be even further improved if a small amount of light oil is applied to the canvas during the polishing.

81. Loose commutator clamp rings. First, draw the clamps of the commutator down firmly so that when the commutator is at normal temperature, the clamping rings cannot be screwed down farther without excessive effort. This is necessary so that all the bars may have direct pressure from the clamp, rendering impossible any movement up or down. Second, smooth the surface of the commutator.

To get the clamps down firmly, run the motor. If roughness appears, shut the motor down at a convenient time, and while it is hot, tighten the clamping rings. If the tightening bolts can be screwed up somewhat, the machine should again be put in service for at least 4 h. At the end of this time, shut it down again and make another trial on the tightening bolts. If the tightening bolts cannot be screwed farther, the commutator should be surfaced, either by turning with a tool or by grinding. If the clamps are down tight and the surface of the commutator has been properly smoothed, there will be no further trouble.

82. Slotting commutators. There seems to be a prevalent idea that slotting should cure all commutator troubles irrespective of their causes. This is not true, but slotting is a cure for certain specific troubles. If the peripheral speed of the commutator is so slow that the dirt which may collect in the slots between commutator bars will not be thrown out by centrifugal force, slotting may aggravate rather than correct commutation difficulties (see Sec. 86).

83. The principal reason for slotting commutator is to relieve them of high mica, i.e., mica that projects above the surface. High mica is generally due to one of two causes: either the mica is too hard and does not wear down at an equal rate with the copper, or the commutator does not hold the mica securely between the segments, allowing it to work out by the combined action of centrifugal force and the heating and cooling of the commutator.

It is even that a commutator with a surface made irregular by projecting mica rotating at high speed under a brush must impart to the brush a vibratory action and thus impair the close contact that should exist between brush and commutator. The result is that sparking takes place more or less violently, depending on the condition of the commutator surface and the rate of speed.

This condition generally manifests itself after the machine has been running for some time and often will account for the development of sparking which did not occur at the time of installation. Often a case of this kind is aggravated by increasing the brush tension, causing a still faster rate of wear of copper over mica, with attendant increased heating of the commutator.

84. What is accomplished by slotting. A harder brush can at times be used, with the idea of grinding off the mica and bringing it down to the commutator surface. Instead of the trouble being cured, the commutator will, in most cases, assume the raw appearance of being freshly sandpapered instead of the glossy surface it should have, and both brush and commutator will wear rapidly.

This condition can be restored to normal and the commutator kept to a true surface by slotting, after which, with proper care and the use of proper brushes, commutator troubles will generally cease, provided the electrical design of the machine is not at fault. Even then there are cases that may be benefited to a certain extent by slotting, by reason of the good brush contact obtained. Most cases that show improvement are ones in which the trouble is not inherent in the design of the machine but is due to mechanical causes.

With a slotted commutator it is possible to use a brush of fine grain and soft texture because there is not the same tendency to wear away the brush as with an unslotted commutator. The commutator will then take on the much-desired polish that is generally not possible with the harder brush. The lift of both brush and commutator will be increased, and friction and consequent heating will be reduced. These advantages will effect a saving that will more than offset the cost of slotting.

85. Various methods of slotting. A variety of slotting devices are on the market (Figs. 7.43 to 7.47). Some operate with the armature swung between the centers of a lathe; others use a special tool in a shaper, with the armature secured to its bed. Still others are operated by hand, with the armature resting on blocks. In all cases the full width of the mica should be removed and the resulting slot carefully cleaned of burrs and rough edges. The slotting need not be carried deeply in the commutator: $1/16$ (1.6 mm) is generally considered sufficient (see also Sec. 80).

FIGURE 7.43 Hand-type mica miller. [The Martindale Electric Co.]

FIGURE 7.45 Flexible-shaft undercutter in use on a large generator. [The Martindale Electric Co.]

FIGURE 7.46 Bench-type undercutter for a horizontal commutator. [The Martindale Electric Co.]

86. A slotted commutator should have proper and frequent care, as there is a chance of small particles of copper being dragged across from bar to bar and for dirt, oil, and carbon dust to accumulate in the slots and short-circuit the commutator.

87. High mica in commutator. Some motors, under certain conditions, roughen their commutators after a short term of service, although there seem to be no excessive sparking under or at the edges of the brushes. Roughening may occur even though the commutator has been well settled. The commutator acts as if the mica used between bars to insulate the various segments from each other had protruded upward, causing roughness and excessive sparking.

FIGURE 7.47 Shop-type undercutter. [The Martindale Electric Co.]

Actual raising of the mica is a very rare occurrence, and if it occurs, it does so at certain spot and is easily and positively identified. An actual uniform protruding of mica all over a commutator, as described, is practically an unknown phenomenon. What does occur is an eating away of the copper surface of the commutator, leaving the high mica between the bars. A good machine will not spark enough to cause this condition. A poor machine will.

The phenomenon is easily identified, as the commutator surface looks raw all over instead of smooth and bright with a good brown gloss. If the condition is allowed to continue, a general roughness appears, accompanied by sparking, until finally the sparking and heating will so increase that the machine may flash over from brush to brush, blowing the fuses or opening the circuit breakers. The trouble is aggravated if the motor operates continuously under heavy load. If there are periods of light load, the commutator has an opportunity to be smoothed down by the brushes. This condition is appreciated by railway-motor designers. A railway motor coasts a considerable portion of the time. Thus the commutator is smoothed, neutralizing the roughening that occurs under load.

88. Remedying a roughened high-mica commutator. (1) Use the commutator on work for which the load is somewhat intermittent, (2) replace it altogether, or (3) slot the commutator. Then, as there no longer are two different materials to wear down or to be worn away by sparking, an unequal surface will not result. The mica need to be cut down only $\frac{1}{16}$ in (1.6 mm), and a narrow, sharp chisel will do the work satisfactorily. No trouble will result from short-circuiting in this case, since centrifugal force keeps the slots clean. Some manufacturers ship machines with slotted commutators.

89. Brush troubles. When there is an excessive drop in speed from no load to full load, the position of the brushes on the commutator (Sec. 49) should first be investigated. No brush position that causes sparking should be chosen. The following sections outline brush troubles and their remedies.

90. Sparking of the brushes may be due to one of the following causes (*Westinghouse Instruction Book*): (1) The machine may be overloaded. (2) The brushes may not be set exactly at the point of commutation—a position where there is no perceptible sparking can always be found, and at this point the brushes should be set and secured. (3) The brushes may be wedged in the holders. (4) The brushes may not be fitted to the circumference of the commutator. (5) The brushes may not bear on the commutator with sufficient pressure. (6) The brushes may be burned on the ends. (7) The commutator may be rough; if so, it should be smoothed off. (8) A commutator bar may be loose or may project above the others. (9) The commutator may be dirty, oily, or worn out. (10) The carbon in the brushes may be unsuitable. (11) The brushes may not be spaced equally around the periphery of the commutator. (12) Some brushes may have extra pressure and may be taking more than their share of the current. (13) Mica may be high. (14) The brushes may be vibrating. (15) Brush toes may not be in line.

These are the more common causes, but sparking may be due to an open circuit or a loose connection in the armature. This trouble is indicated by a bright spark which appears to pass completely around the commutator and can be recognized by the scarring of the commutator at the point of open circuit. If a lead from the armature winding to the commutator becomes loose or is broken, it will draw a bright spark as the break passes the brush position. This trouble can be readily located, as the insulation on each side of the disconnected bar will be more or less pitted. The commutator should run smoothly and true, with a dark, glossy surface.

91. Glowing and pitting of the carbon brushes. This condition may be due to either of two causes; poor design or a wrong position of the brushes on the commutator. The error of design may be only in the choice of width of carbon brush used. The pitting is due to glowing. If the glowing is at the edge of the carbon, it is plainly visible and easily located. It may, however, occur underneath the carbon, so that only with difficulty can it be seen. Such glowing pits the carbon face by heat disintegration. With some machines three-fourths of the brush face may be eaten away, and the pits may be $\frac{1}{4}$ to $\frac{1}{2}$ in (6.35 to 12.7 mm) deep when discovered. A usual (incorrect) decision is that the current per square inch of contact is too great, the calculation being made by dividing the *line amperes* by the *square-inch cross section of either the positive or the negative brushes*. If this calculation gives a value under 45 or 50, it is certain that the cause of the trouble has not been judged correctly.

The real cause of the glowing is, to be sure, excessive current through the carbon, but this is not the line current if the calculation, as stated, shows a brush-face density below 50 A/in² (7.75 A/cm²). It is a local current caused by the short circuiting of two or more segments of the commutator when the brush rests upon them. The usual overlap of a carbon brush is about two segments, and while these two segments are under the brush, the armature coils connected to them are short-circuited. If the design of the machine is such that the coil so short-circuited encloses stray flux from the pole tip, this flux will create in the short-circuited coil a current perhaps many times larger than the brush is capable of carrying, with the result that glowing and pitting occur.

92. Chattering of brushes is sometimes experienced on dc machines. Under certain conditions it may become so prominent as not only to be of annoyance but also actually to break the carbons. An examination of the commutator will reveal no roughness, the surface being, perhaps, perfectly smooth and bright. This trouble occurs principally with the type of brush holder which has a box guide for the carbon. The spring which forces the brush into contact rests on the carbon, which has fairly free play in the box guide. Chattering usually occurs with high-speed commutators, running at 4000 to 5000 ft/min (20.3 to 25.4 m/s) peripheral speed.

Such brush holders are necessary on commutators which, like those on engine-driven machines, may run out of true owing to the shaft play in the bearings caused by the reciprocating motion of the engine. The clamped type of holder is usually free from bad chattering but rocks on a commutator that runs out, causing poor contact and perhaps sparking.

Lubricating the commutator causes the chattering to disappear immediately, but there is no commutator compound which gives a lubricating effect lasting over possibly $\frac{1}{2}$ h. Thus, it is not practical to lubricate often enough to prevent the chattering. There will be no chattering if the angle of the brush with the radial line, passing through the center of the carbon and the center of the commutator, is less than 10° and if the carbon trails instead of leads on the commutator. Figure 7.48 shows the correct setting which will stop all serious chattering, together with two incorrect settings which may give trouble.

FIGURE 7.48 Methods of setting brushes.

93. Low speed. The fault may be in the winding of the armature or field, in which case a remedy is difficult. Considerable range of speed can be obtained by the choice of brush position on the commutator. For many motors a speed variation of 15 percent can be obtained, without sparking by brush shift. Therefore, if the discrepancy of speed is within this amount, the brushes should be moved to counteract it. A backward shift of the brush gives increased speed, and a forward shift decreased speed. At any brush position, however, there must be practically no sparking. A first-class motor should run at full load within 4 percent (up or down) of the nameplate speed if the voltage is as specified on the nameplate. The speed at no load should not be more than 5 percent higher than this; and the speed at full load, hot, should not be over 5 percent greater than the speed at full load, cold.

94. Bearing troubles of dc motors and generators. See Sec. 236.

95. Sporadic motor sparking has been known to be due to irregular short circuits on the line which were caused by wind blowing the line wires together.

PRINCIPLES, CHARACTERISTICS, AND MANAGEMENT OF AC GENERATORS (ALTERNATORS)

96. Types of ac generators. The different types of ac generators (alternators), classified according to the method of producing the voltage, are listed below:

1. Synchronous alternators
 - a. Revolving field
 - b. Revolving armature
2. Induction alternators
 - a. Stator winding
 - b. Rotor winding
3. Inductor alternators

97. Synchronous ac generators are discussed in an elementary way in Secs. 73, 115, 144, 145, 148, and 152 of Div. 1. These generators may be constructed with either the armature or the field structure as the revolving member. Small generators up to 50 kW are commonly made with the revolving-armature construction. The required magnetic field is produced by dc electromagnets, which are excited as a small dc generator or exciter. The fundamental construction and connections for a revolving-field alternator are shown in Fig. 7.49.

98. The emf in a synchronous alternator is generated as suggested in Fig. 7.50. As each field coil, *D* for instance, sweeps past the armature coils, the lines of flux from the field coil cut the armature coils. As coil *D* passes from *A* to *C*, an alternating emf represented by the curve *ABC* will be generated in the armature. It should be understood that in commercial alternators the armature coils are set in slots and arranged differently from those shown in Fig. 7.50, which only illustrate a principle.

FIGURE 7.49 Elementary diagram of an ac generator and exciter.

FIGURE 7.50 Armature and field structure developed.

The value of the voltage generated by a given synchronous alternator depends upon the speed and direct field current. Since the speed must be held constant to maintain the proper frequency, the voltage must be controlled by adjustment of the field current.

99. The speed and number of poles of an alternator determine the frequency which it generates.

$$f = \frac{p \times \text{rpm}}{120} \quad \text{or} \quad p = \frac{120f}{\text{rpm}} \quad \text{or} \quad \text{rpm} = \frac{120f}{p} \quad (1)$$

where af = frequency in hertz (cycles per second)
 rpm = revolutions per minute of rotor and
 p = the number of field poles

EXAMPLE What is the frequency of a two-pole alternator running at 3600 rpm?

SOLUTION Substitute in the formula

$$f = \frac{p \times \text{rpm}}{120} = \frac{2 \times 3600}{120} = \frac{7200}{120} = 60 \text{ Hz}$$

EXAMPLE How many poles has a 25-Hz alternator running at 500 rpm?

SOLUTION Substitute in the formula

$$p = \frac{120f}{\text{rpm}} = \frac{120 \times 25}{500} = \frac{3000}{500} = 6 \text{ poles}$$

100. Synchronous Speeds: AC Generators and Motors

Application to Generators. The table shows the speeds at which the rotor of an alternator having a given number of field poles must turn to generate voltage at given frequencies.

Application to Motors. The table indicates the synchronous speed of the rotary magnetic field of an induction motor having a given number of poles and taking current at a given frequency.

The table also shows the speeds of synchronous motors having a given number of field poles and taking currents at given frequencies.

Number of poles	RPM when frequency is											
	25	30	33½	40	50	60	66⅔	80	100	120	125	133½

FIGURE 7.51 Single-phase armature windings.

single-phase windings. Single-phase alternators are seldom made now, except for emergency or standby power.

102. Two-phase alternator. In a generator of the type indicated in Fig. 7.52, the centers of the two component coils I and II are situated 90 electrical degrees apart, and the single-phase emf's generated in coils I and II by the passage of the field system past them differ in phase by 90 degrees. This property has given rise to the term *quarter-phase* for this type of machine, but it is more frequently called a *two-phase machine*. The emf in coil I is zero when that in coil II is a maximum, and vice versa. The curves of emf in coils I and II can be plotted as indicated in Fig. 7.53. Figure 7.54 shows two methods of connecting the armature windings of two-phase alternators. The armature coils can be arranged in one or

101. Single-phase alternator. The circumferential distance from the centerline of one pole to the centerline of the next pole of the same polarity constitutes 360 electrical degrees. See Fig. 7.50, which shows how a single-phase emf is generated. Figure 7.49 is a diagrammatic illustration of a single-phase alternator, and Fig. 7.51 shows diagrammatically two different kinds of

FIGURE 7.52 Two-phase alternator.

FIGURE 7.53 Graph of two-phase current.

FIGURE 7.54 Methods of connecting two-phase generator armature windings.

FIGURE 7.55 Two-phase armature windings.

more slots per pole per phase, as suggested diagrammatically in Fig. 7.55. In commercial machines the windings are almost always arranged in more than one slot per pole. (See Div. 1 for further information about two-phase currents.)

103. Three-phase alternator coils are arranged as illustrated in Fig. 7.58, and the curves of instantaneous emf are displaced from one another by 120 electrical degrees as indicated in Fig. 7.57. These curves also represent the emf's for the winding shown diagrammatically by coils I, II, and III in Fig. 7.56. Here three coils are distributed (60 electrical degrees apart) over a pole pitch, and the phase displacement between the emf's is 60 degrees. However, if in connecting the coils the middle coil is connected in the reverse sense from the other two, the result will be three voltages 120 electrical degrees apart, as shown in Fig. 7.57.

FIGURE 7.56 Six-phase grouping.

FIGURE 7.57 Graph of three-phase currents.

FIGURE 7.58 Three-phase Y-connected alternator.

The two methods of connecting three-phase armature windings are shown in Fig. 7.59. These methods are discussed in greater detail in Div. 1. Armature windings can be arranged in one or more slots per pole per phase (Fig. 7.60). The Y method is almost always used to connect three-phase generators.

104. Approximate Performance Values of AC Generators

(208Y/120, 240, 480Y/277, 480, 600, and 2400 V, three-phase)

It should be understood that values will vary somewhat with speed and other conditions. Those given are general and approximate only and do not apply to any particular manufacturer's line. A slow-speed machine is assumed to be one turning at from 100 to 200 rpm; a medium-speed machine, one turning at from 200 to 300 rpm; and a high-speed machine, one turning at from 300 to 1200 rpm. In the table, S indicates slow speed, M medium speed, and H high speed.

Output kVA	Current				Efficiency			Exciter capacity required
	208Y/120, 240 V	Three-phase			1/2 load	3/4 load	Full load	
		480Y/277, 480 V	600 V	2,400 V

105. Exciters for ac generators are compound-wound dc generators, flat-compounded and rated at 125 V for the smaller sizes of generators and at 250 V for the larger sizes. Systems of excitation in general use are:

1. Individual exciter for each generator unit
 - a. Direct-connected to the alternator shaft
 - b. Belt-connected to the alternator shaft
 - c. Brushless with integral rectifiers
2. Exciter-bus system supplied by one of the following combinations:
 - a. Induction-motor-driven exciters and steam-driven exciters
 - b. Induction-motor-driven exciters and hydraulic-turbine-driven exciters
 - c. Built-in rectifiers, solid-state

The individual exciter unit (Fig. 7.61) has the advantage of rapid response at the time of system short circuits or rapid fluctuations in load. It also has a high efficiency due to being driven by the highly efficient prime mover of the generator and to eliminating the loss in a generator field rheostat, since the generator voltage is controlled through variation of the field current of the exciter. The direct connection to the generator shaft is used for 1200-, 1800-, and 3600-rpm alternators. The belt connection is ordinarily used for slower-speed alternators so that a cheaper, higher-speed exciter (usually 1800 rpm) can be used.

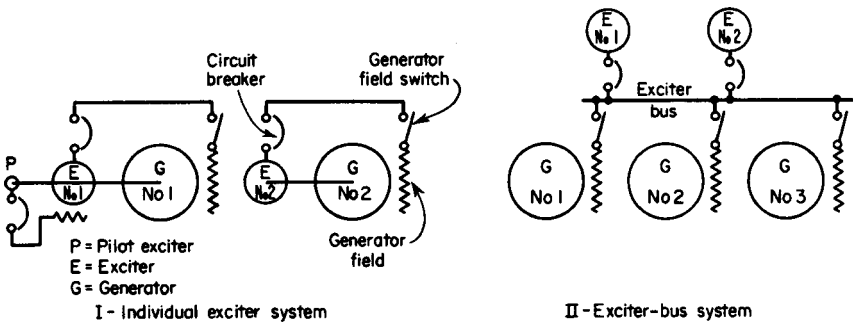

FIGURE 7.61 Systems of excitation for ac generators.

The exciter-bus system (Fig. 7.61) has the advantage of not crippling the alternator because of trouble with the exciter and of keeping closer voltage regulation when the primer mover driving the alternator is subject to speed variations. With this system at least two of the exciters should be steam- or hydraulic-driven to ensure ability to start the plant up after a shutdown.

Since failure of the excitation power will produce a failure of the ac generation and a possible shutdown of the station, the exciter system should be as reliable as possible. With the exciter-bus system there should be at least one or two spare exciter units. In some plants, for extreme reliability a storage battery is floated on the exciter bus to ensure continuity of the dc excitation. Induction motors should be used for driving the exciters, because they can be started rapidly and will not fall out of step during voltage fluctuations caused by short circuits on the system.

With the individual-exciter system, pilot exciters are frequently used to supply the field of the main exciter. This procedure adds to the rapidity of response to voltage fluctuations.

106. Synchronizing. Two or more ac generators will not operate satisfactorily in parallel unless (1) their voltages, as registered by a voltmeter, are the same, (2) their frequencies are the same, and (3) their voltages are in phase. If the machines are not in phase, even if their individual voltages and their frequencies are the same, the voltage of one will, at given instants, be different from that of the other and there will be an interchange of current between the machines. When two or more generators all satisfy the three listed requirements, they are in synchronism. *Synchronizing* is the operation of getting machines into synchronism. Incandescent lamps or instruments are, as described below, used to indicate when machines are in synchronism.

107. Synchronizing a single-phase circuit with lamps. The elementary principle involved in determining synchronism is indicated in Fig. 7.62. If the voltage and frequency of generators *A* and *B* are the same and the machines are in phase, point *a* will be at the same potential as point *a'* at every instant. Hence the lamps between *a* and *a'* will not light as long as the three conditions are satisfied. As long as the conditions are not satisfied, there will be a fluctuating crosscurrent from *a* to *a'* and a constant fluctuation of the brilliancy of the incandescent lamps. When the lamps become dark and remain so, the generators are in synchronism and may be thrown together. Had the connection at *a'* been made to the *b'* generator lead, the lamps would be bright when the generators were in synchronism, but for reasons outlined in Sec. 110 the connection shown, which provides the dark-lamp method of synchronizing, is preferred. The same condition occur in the *b—b'* set of lamps as in the *a—a'* set. A voltmeter of proper rating can be substituted for the lamps.

If the voltage generated is so high that it is not desirable to connect a sufficient number of lamps in series for it, a single lamp fed through voltage transformers can be used for synchronizing, as suggested in Fig. 7.63.

FIGURE 7.62 Circuits for synchronizing with lamps.

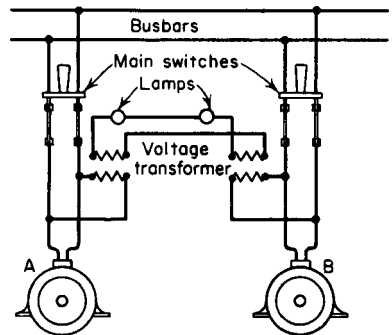

FIGURE 7.63 Circuits for synchronizing high-voltage circuits with lamps.

108. Phasing out three-phase circuits. Before connecting the leads from a polyphase generator that is to operate in parallel with others to the generator switch, the circuits must be *phased out*; i.e., the leads must be so arranged that when the generator switch is thrown, each lead from the generator will connect to the corresponding lead of the other generator. If this is not arranged, there may be considerable damage owing to an interchange of current when the two machines are in parallel. After once phasing out it is necessary to synchronize only one phase of the machine with the corresponding phase of the other machine.

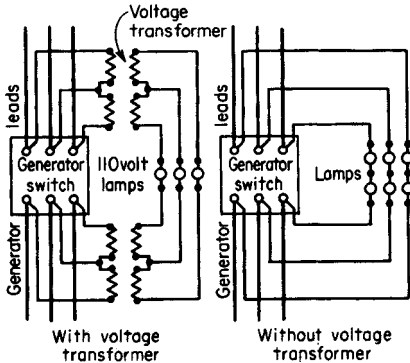

FIGURE 7.64 Connections for phasing out three-phase circuits.

Connections for phasing out three-phase circuits are shown in Fig. 7.64. If voltage transformers are not used, the sum of the voltages of the lamp in each line should be approximately the same as the voltage of the circuits. On 460-V circuits two 230-V or four 115-V lamps should be used in each phasing-out lead.

To phase out, run the two machines at about synchronous speed. If all the lamps do not become bright and dark together, interchange any two of the main leads on one side of the switch, leaving the lamps connected to the same switch terminals, after which all the lamps should fluctuate together, indicating that the connections are correct. The machines are in phase when all the lamps are dark.

109. The synchronizing connections for three-phase generators are shown in Fig. 7.65. A synchronizing plug can be used instead of the single-pole synchronizing switch shown. The illustration indicates the connection used when machines are to be synchronized to a bus. If only two machines are to be synchronized, the connections are the same as shown in Fig. 7.65, except that the bus transformer and the corresponding lamp are omitted and one plug is required instead of two.

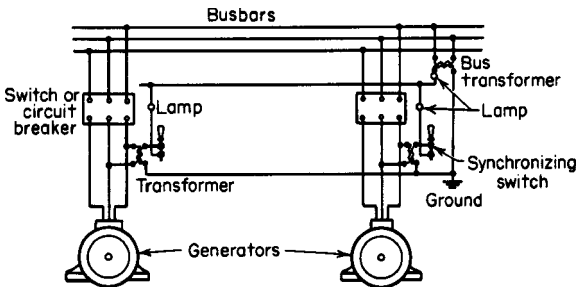

FIGURE 7.65 Connections for synchronizing three-phase circuits when transformers are required.

110. Synchronizing dark or light. *Synchronizing dark* appears to be the preferable method. All the connections shown are for synchronizing dark. When the lamps are dark, the machines are in phase, and it is necessary to close the switch when the pulsation is the slowest obtainable or ceases altogether, i.e., at or just before the middle of the longest dark period.

Should a filament break, the synchronizing lamps would remain dark and thus apparently indicate synchronism and possibly cause an accident. Therefore it is considered desirable by some authorities to reverse the synchronizing circuit connections and thereby to *synchronize light*. Synchronizing light eliminates the danger due to the breaking of a filament but has the disadvantage that the time of greater brilliancy is difficult to determine. The light period is relatively long compared with the dark period, so that synchronizing

light is usually considered more difficult, and if the synchronizing-light method did not eliminate the danger due to filament breakage, it would never be used.

The probability of a filament's breaking when synchronism approaches and the machines are not in phase is remote. If breakage occurs at any other time in the operation, it will be noticed. As a protection against accidents due to breakage, two synchronizing lamps should always be placed in multiple.

111. The number of lamps to use in a group to indicate synchronism is determined by the voltage of the generators. With high-voltage circuits it is not feasible to use a sufficient number of lamps, so a transformer that has a secondary voltage of 115 V is employed (see the diagrams). The greatest voltage impressed on the lamps is double that of one generator or the secondary voltage of one transformer. Thus the maximum voltage on the lamps when two 230-V generators are being synchronized is 460 V. The dark period can be shortened by impressing on the lamps a voltage higher than their normal. For two 230-V machines, for example, three 115-V lamps might be used, but the life of the lamps would be greatly reduced.

112. A synchroscope (see Fig. 7.66) is an instrument that indicates the difference in phase and frequency between two alternators. It shows whether the machine to be synchronized is running fast or slow. The pointer rotates clockwise if the machine is running fast and counterclockwise if it is running slow. When the pointer remains stationary pointing upward, the machines are

FIGURE 7.66 Synchroscope and wiring diagram.

in synchronism. It is quite common to use two synchronizing lamps in addition to a synchroscope, so that one system is a check against the failure of the other. Should the lamps remain dark any longer than a few seconds, the operator should look for trouble in either the lamps or the connections. After the main switches have been thrown, thus connecting the machines in parallel, the machines will hold themselves in synchronism.

113. Although for successful parallel operation ac generators need not be of the same type, output, and speed, it is universally conceded that the question of wavelength is important, since if the waves are of different shapes, crosscurrents will always be present. Similar waveshapes are more readily obtained with machines of similar type. Satisfactory parallel operation, the previously mentioned conditions being fulfilled, consists in obtaining

1. Correct division of the load among the machines
2. Freedom from hunting

114. Division of load. Machines with similar characteristics tend to divide the common load proportionally to the ratings of the machines. Such a proportional load division may be disturbed if the steam supply to the engines is defective or variable from any cause. The steam supply is regulated by the engine governors, and defects in one or more of these governors will cause poor load division. It is essential that the governors of all the engines have similar speed-regulation characteristics so that a sudden change in the load will cause

the same amount of regulation on each engine. Correct load division is therefore essentially a problem for the engine governors.

Varying the voltage of an alternator running in parallel with others by adjusting its field rheostat will not vary the load on it as with a dc generator. To increase the energy delivered by an alternator the prime mover must be caused to do more work. An engine should be given more steam or a waterwheel more water.

115. Adjustment of field current. When the rheostats of two alternators running in parallel at normal speed are not adjusted to give a proper excitation, a crosscurrent will flow between the armatures. The intensity of this current depends only upon the difference in the field currents and the impedances of the armature windings. It may vary over a wide range, from a minimum of zero when both field currents are normal to more than full-load current when they differ greatly. The effect of this crosscurrent is to increase the temperature of the armatures and, consequently, to decrease the allowable useful output of the generators. It is important that the rheostats be adjusted to reduce it to a minimum. This crosscurrent registers on the ammeters of both generators and usually increases both readings. The sum of the ammeter readings will be minimized when the idle current or crosscurrent is zero.

In general, the proper field current for a machine running in parallel with others is that which it would have if running alone and delivering its load at the same voltage. To determine the proper position of the rheostats, trial adjustments must be made after the alternators have been paralleled until the position at which the sum of the ammeter readings is minimized is found.

To illustrate this method let us consider two similar alternators *A* and *B* (Fig. 7.67) operating in parallel. When the generator field rheostats of both are properly adjusted, no crosscurrents will flow through the armatures, and the main ammeters will show equal readings if each machine is receiving the same amount of power from its prime mover. If the rheostat of *A* is partly cut in to reduce its field current, a crosscurrent lagging in *B* and leading in *A* will flow between the armatures. The effect of this crosscurrent will be to strengthen *A*'s magnetization and weaken *B*'s until they are approximately equal. The resultant emf of the system will thereby be lowered.

On the other hand, if the rheostat of *B* is partly cut out to increase its field current, a crosscurrent leading in *A* and lagging in *B* will flow between the armatures, strengthening *A*'s magnetization and weakening *B*'s magnetization until they are again equal. The resultant emf of the system will thereby be raised. A crosscurrent of the same character is therefore produced by decreasing one field current or increasing the other; i.e., in both cases it will lead in the first machine and lag in the second. The emf of the system will, however, be decreased in one case and increased in the other. It is obvious that by simultaneously adjusting the two rheostats the strength of the crosscurrent can be varied considerably and the emf of the system maintained constant.

For the first trial adjustment, cut in *A*'s rheostat several notches and cut out *B*'s by the same amount so as not to vary the emf of the system. If this reduces the sum of the main ammeter readings, continue the adjustment in the same direction until the result is minimized. After this point has been reached, a further adjustment of the rheostat in either direction will increase the ammeter readings. If the first adjustment increases the sum of the ammeter readings, it is being made in the wrong direction; in this case move the rheostats back to the original positions, and then cut out *A*'s rheostat and cut in *B*'s. If both adjustments increase the sum of the ammeter readings, the original positions of the rheostats are the proper ones.

In making these adjustments it may be difficult to locate the exact points at which the crosscurrent is minimized, as it may be possible to move the rheostats over a considerable range when near the correct positions without materially changing the ammeter readings.

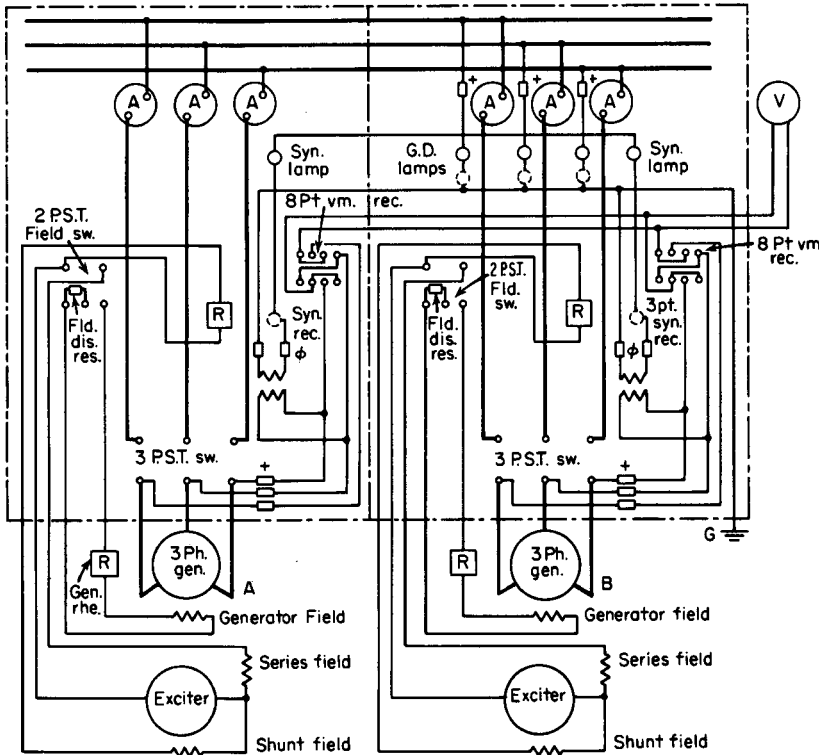

FIGURE 7.67 Two three-phase alternators of similar characteristics operating in parallel.

When the adjustment is carried this far, it is close enough for practical operation. If the generators are provided with power-factor meters, the same result can be obtained by adjusting the field currents until all the power-factor meters read the same while maintaining the voltage constant.

116. Starting a single alternator. (1) See that there is plenty of oil in the bearings, that the oil rings are free to turn, and that all switches are open. (2) Start the exciter and adjust for normal voltage. Start the generator slowly. See that the oil rings are turning. (3) Permit the machine to reach normal speed. Turn the generator field rheostat so that all its resistance is in the field circuit. Close the field switch. (4) Adjust the rheostat of the exciter for the normal exciting voltage. Slowly increase the alternator voltage to normal by cutting out the resistance of the field rheostat. (5) Close the main switch.

117. Starting an alternator to run in parallel with others. (1) Bring the exciter and generator to speed as described in Sec. 116. Adjust the exciter voltage and close the field switch, the generator field resistance being all in. (2) Adjust the generator field resistance so that the generator voltage will be the same as the busbar voltage. (3) Synchronize, as outlined above. Close the main switch. (4) Adjust the field rheostat until crosscurrents

are at a minimum (see Sec. 115), and adjust the governors of the prime movers so that the load will be properly distributed between the operating units in proportion to their capacities. (5) Adjust the governor of the machine which is to take the greatest load so that it will admit more steam.

118. Cutting out a generator which is running in parallel with others (*Westinghouse Instruction Book*). (1) Preferably cut down the driving power until it is just sufficient to run the generator at no load. This will reduce the load on the generator. (2) Adjust the resistance in the field circuit until the armature current is at a minimum. (3) Open the main switch.

Caution. The field circuit of a generator which is to be disconnected from the busbars must not be opened before the main switch has been opened, for if the field circuit is opened first, a heavy current will flow between the armatures.

119. Induction generators have the same construction as induction motors (see Sec. 117). A revolving magnetic field is produced by the stator currents in exactly the same manner as in an induction motor (see Sec. 147). Induction generators are made in two types as listed in Sec. 96. The type in which the stator winding is the source of voltage is used to produce voltages of ordinary power frequencies, such as 25, 50, or 60 Hz. The type in which the rotor winding is the source of voltage is used to produce voltages of higher frequencies than ordinary power frequencies, such as 90, 100, 175, 180, or 400 Hz. These higher frequencies are often required for the operation of high-speed portable tools and machines, 400-Hz lighting, and large electronic computers.

Induction generators, in which the stator windings are the source of voltage, have their stator windings connected to the electric system which is to receive the power and their rotor windings short-circuited as shown in Fig. 7.68. The machine cannot function as a generator until a revolving magnetic field has been produced in the machine. The current which produces the rotating magnetic field must therefore be supplied in the stator winding from a source external to the machine. Therefore, an induction generator of this type must be operated in parallel with a synchronous generator. Such an induction generator is, in effect, an induction motor which is driven at a speed above the speed of its rotating magnetic field.

FIGURE 7.68 Induction-generator connections.

Suppose that an induction motor which has a slip of 5 percent at full load when operating as a motor is driven at a speed 5 percent greater than the speed of the rotating magnetic field. The flux cut by the rotor conductors will be practically the same as when it was operating as a motor. But the direction of motion of the conductors relative to the flux will be reversed. Hence the machine will become a generator and deliver power to the line approximately equal to its full-load motor rating. The frequency of the current supplied by an induction generator will always be the same as that of the synchronous generator with which it is in parallel. The induction generator tends to supply a leading current, just as does a condenser. The power factor at which it operates is determined by the slip and the design and does not depend upon the load.

Induction generators in which the rotor is the source of voltage are used for the generators, in motor-generator frequency-changer sets. The stator windings are connected to a

25-, 50-, or 60-Hz main power supply, and the rotor supplies the power to the higher-frequency circuits as shown in Fig. 7.69. If a 60-Hz current is passed into the primary winding of a standard wound-rotor motor and the motor is operated at synchronous or no-load speed, practically no voltage is generated in the secondary. If, however, the rotor is held stationary, a 60-Hz voltage can be obtained from the secondary. If the rotor is revolved in the opposite direction to that in which it would revolve as a motor, a voltage of a frequency higher than 60 Hz is generated. The high frequency depends upon the speed and number of poles in the generator and can be calculated from the following formula:

$$\text{High frequency} = \frac{\text{poles} \times \text{rpm}}{120} + \text{line frequency} \tag{2}$$

The voltage delivered by the induction frequency changer depends upon the design of the primary and secondary windings, the speed of the set, and the applied primary voltage.

FIGURE 7.69 Schematic diagram of induction frequency-changer set.

120. Inductor alternators are employed to produce voltages of frequencies between 500 and 10,000 Hz for supplying the power to induction furnaces for the melting and heating of steel and alloys. The rotating element carries no electrical windings but consists simply of a toothed steel member (Fig. 7.70). The stationary member supports two sets of windings, the field windings and the armature coils. As the toothed member revolves, it varies the reluctance of the magnetic paths and thereby varies the flux produced by the current in the field windings. The flux also links with the armature coils, and its variation induces a voltage in these cells.

FIGURE 7.70 An inductor alternator. This type of construction has been used for relatively small alternators employed in radio transmission and gives as high as 200,000 Hz. [Charles H. Sanderson, ed., *Electric System Handbook*]

PRINCIPLES, CHARACTERISTICS, AND MANAGEMENT OF ELECTRIC MOTORS

121. Types of electric motors. Electric motors are manufactured in a number of different types. They may be divided into three main groups, depending upon the type of electric system from which they are designed to operate: dc, single-phase ac, and polyphase ac. There are several types of motors in each one of these groups, constructed so that they

produce different starting and running characteristics. The principal types of electric motors follow:

- Direct-current
 - Shunt-wound
 - Straight shunt-wound
 - Stabilized shunt-wound
 - Series-wound
 - Compound-wound
 - Permanent magnet
- Polyphase alternating-current
 - Induction
 - Squirrel-cage
 - Normal-torque, normal-starting-current
 - Normal-torque, low-starting-current
 - High-torque, low-starting-current
 - Low-torque, low-starting current
 - High-resistance-rotor
 - Automatic-start
 - Multispeed
 - Wound-rotor
 - Commutator, brush-shifting
 - Synchronous
 - Direct-current excited
 - Permanent-magnet
 - Reluctance
 - Single-phase alternating-current
 - Repulsion
 - Induction
 - Shading-pole-starting
 - Inductively split-phase-starting
 - Capacitor-type
 - Capacitor start
 - Permanent-split capacitor
 - Two-value capacitor
 - Repulsion-start, induction-run
 - Repulsion-induction
 - Series
 - Universal
 - Series-wound
 - Compensated series-wound

122. Speed classification of motor. Each electric motor possesses an inherent speed characteristic by which it can be classified in one of several groups. The following classification of speed characteristics is that adopted by the National Electrical Manufacturers Association (NEMA).

1. A *constant-speed motor* is one in which the speed of normal operation is constant or practically constant; for example, a synchronous motor, an induction motor with small slip, or a direct-current shunt-wound motor.
2. An *adjustable-speed motor* is one in which the speed can be controlled over a defined range, but when once adjusted remains practically unaffected by the load. Examples of

adjustable-speed motors are: a direct-current shunt-wound motor with field resistance control designed for a considerable range of speed adjustments, or an alternating current motor controlled by an adjustable frequency power supply.

3. A *multispeed motor* is one which can be operated at any one of two or more definite speeds, each being practically independent of the load; for example, a direct-current motor with two armature windings or an induction motor with windings capable of various pole groupings. In the case of multispeed permanent-split capacitor and shaded-pole motors, the speeds are dependent upon the load.
4. A *varying-speed motor* is one in which the speed varies with the load, ordinarily decreasing when the load increases, such as a series-wound or repulsion motor.
5. An *adjustable varying-speed motor* is one in which the speed can be adjusted gradually, but when once adjusted for a given load, will vary in considerable degree with change in load, such as a direct-current compound-wound motor adjusted by field control or a wound-rotor induction motor with rheostatic speed control.
6. The *base speed of an adjustable-speed motor* is the lowest-rated speed obtained at rated load and rated voltage at the temperature rise specified in the rating.

123. Service classification of motors. Electric motors are classified into two groups, depending upon the type of service for which they are designed. *General-purpose motors* are those motors designed for general use without restriction to a particular application. They meet certain specifications as standardized by NEMA. A *definite-purpose motor* is one which is designed in standard ratings and with standard operating characteristics for use under service conditions other than usual or for use on a particular type of application. A *special-purpose motor* is one with special operating characteristics or special mechanical construction, or both, which is designed for a particular application and which does not meet the definition of a general-purpose or a definite-purpose motor.

124. Brake motors are motors equipped with electrically controlled brakes as an integral part of the motor assembly. The brake motor manufactured by one company consists of one or more rotating steel disks splined on a pinion on the motor shaft, with stationary friction linings on each side of each disk. A helical spring in the center applies pressure to provide the required braking, and two, three, or four magnets, depending on the rating of the brake, supply force to compress the spring and release the brake while the motor is running.

When power is applied to the motor, the brake is immediately energized, since the brake leads are connected directly to the motor leads in the conduit box. The current energizes the magnets, which pull the armature plate toward the end plate. This action removes the pressure on the revolving disks and allows them to move freely between the friction linings, releasing the brake. Since the rotating disks are separated from the friction surfaces at all times except during actual braking, the motor delivers full rated horsepower at the output shaft.

When the motor is disconnected from the power supply, the magnets are immediately deenergized, and the spring pushes the armature plate away from the adjustable plate toward the motor. This applies braking pressure on the surfaces between the revolving disks and the friction linings, bringing the motor to a quick, smooth stop. This inherent smooth action, free from hammer blow, keeps stresses at the minimum in the brake and in belts, cables, gears, or chains through which the motor drives.

125. Gear motors are motors equipped with a built-in reduction gear as an integral part of the motor assembly. The motor itself is generally a 60-Hz, nominal 1750-rpm machine. Output-shaft speeds between 4 and 1430 rpm are available. These motors can be

obtained equipped with almost any type of general-purpose polyphase induction, single-phase, or dc motor.

Loads of the same horsepower and speed rating will require different gear sizes, depending upon the type of load. Therefore, time of operation and frequency and severity of shock must be determined to select the proper gear motor for a specific application. To assist engineers in their selection, the American Gear Manufacturers Association (AGMA) has defined three classes of service, according to the degree to which all these variables are present:

Class I. Steady loads not exceeding the normal rating of the motor on 8-h-per-day service or moderate shock loads if service is intermittent.

Class II. Steady loads not exceeding the normal rating of the motor on 24-h-per-day service or moderate shock loads running 8 h per day.

Class III. Moderate shock loads on 24-h-per-day service or heavy shock loads running 8 h per day.

126. Direction of mounting of motors. The standard type of motor is designed to be mounted with its shaft horizontal. Motors can be obtained, however, for mounting with their shafts vertical, but such motors are more expensive and require more careful attention.

127. Bearings for motors may be of the sleeve or the ball-bearing type. Ball-bearing construction is of two kinds: (1) ball bearings with provision for in-service lubrication and (2) prelubricated ball bearings which require no service lubrication. Ball bearings generally are used for small motors up to 30 hp. The type to use is largely one of individual preference, since both types when properly designed and maintained will give satisfactory service. Most manufacturers are prepared to furnish from regular stock with either sleeve or ball bearings any type of motor up to 200 hp, except some totally enclosed motors.

For especially quiet operation, sleeve bearings are preferable.

The application of grease-packed ball bearings is particularly advantageous under the following conditions:

1. When the motor frame does not remain in a stationary position after installation
2. If the motor is located in an inaccessible place
3. For many totally enclosed motor applications
4. For motors with vertically mounted shafts
5. For high speeds
6. For heavy-thrust loads

The cost of ball-bearing-equipped motors is slightly higher than that of sleeve-bearing motors.

128. Types of motor enclosure. The various types of electric motors can be obtained with constructions which offer different degrees of enclosure and protection to the operating parts and windings. The different standard types as explained and defined by NEMA are as follows:

Open

General-Purpose. Ventilating openings permit the passage of external cooling air over and around the windings of the machine.

Dripproof. Ventilating openings are so constructed that successful operation is not interfered with when drops of liquid or solid particles strike or enter the enclosure at any angle from 0 to 15° downward from the vertical.

Splashproof. Ventilating openings are so constructed that successful operation is not interfered with when drops of liquid or solid particles strike or enter the enclosure at any angle not greater than 100° downward from the vertical.

Guarded. Openings giving direct access to live metal or rotating parts (except smooth rotating surfaces) are limited in size by the structural parts or by screens, baffles, grills, expanded metal, or other means, to prevent accidental contact with hazardous parts. Openings giving access to such live or rotating parts shall not permit the passage of a cylindrical rod 0.75 in (19.05 mm) in diameter.

Semiguarded. Some of the ventilating openings, usually in the top half, are guarded as in the case of a *guarded* machine, but the others are left open.

Dripproof Guarded. This type of dripproof machine has ventilating openings as in a *guarded* machine.

Externally Ventilated. Designating a machine that is ventilated by a separate motor-driven blower mounted on the machine enclosure. Mechanical protection may be as defined above. This machine is sometimes known as a *blower-ventilated* or *force-ventilated* machine.

Pipe-Ventilated. Openings for the admission of ventilating air are so arranged that inlet ducts or pipes can be connected to them. Open pipe-ventilated machines may be self-ventilated (air circulated by means integral with the machine) or force-ventilated (air circulated by means external to, and not part of, the machine).

Weather-Protected. Type I: Ventilation passages are so constructed as to minimize the entrance of rain, snow, and airborne particles to the electric parts, and having its ventilated openings constructed as to prevent the passage of a cylindrical rod 0.75 in (19.05 mm) in diameter. Type II: In addition to the enclosure described for a Type I machine, ventilating passages at both intake and discharge are so arranged that high-velocity air and airborne particles blown into the machine by storms or high winds can be discharged without entering the internal ventilating passages leading directly to the electric parts.

The normal path of the ventilating air that enters the electric parts of the machine is so arranged by baffling or separate housings as to provide at least three abrupt changes in direction, none of which is less than 90°. In addition, an area of low velocity not exceeding 600 ft/min (183 m/min) is provided in the intake air path to minimize the possibility of moisture or dirt being carried into the electric parts.

Encapsulated Windings. A machine with moisture-resistant windings is one in which the windings have been treated such that exposure to a moist atmosphere will not readily cause malfunction. This type of machine is intended for exposure to moisture conditions that are more excessive than the usual insulation system can withstand.

Sealed Windings. A machine with sealed windings is one which has an insulation system which, through the use of materials, processes, or a combination of materials and processes, results in windings and connections that are sealed against contaminants. This type of machine is intended for environmental conditions that are more severe than the usual insulation system can withstand.

Totally Enclosed

Nonventilated. Not equipped for cooling by means external to the enclosing parts.

Fan-Cooled. Equipped for exterior cooling by means of a fan or fans, integral with the machine but external to the enclosing parts.

Fan-Cooled Guarded. All openings giving direct access to the fan are limited in size by design of the structural parts or by screens, grills, expanded metal, etc., to prevent accidental contact with the fan. Such openings do not permit the passage of a rod 0.75 in (19.05 mm) in diameter.

Explosion-Proof. Designed and constructed to withstand an explosion of a specified gas or vapor which may occur within it and to prevent the ignition of the specified gas or vapor surrounding the machine by sparks, flashes, or explosions of the specified gas or vapor which may occur within the machine casing.

Dust-Ignition-Proof. Designed and constructed in a manner which will exclude ignitable amounts of dust or amounts which might affect performance or rating, and which will not permit arcs, sparks, or heat otherwise generated or liberated inside of the enclosure to cause ignition of exterior accumulations or atmospheric suspensions of a specific dust on or in the vicinity of the enclosure.

Pipe-Ventilated. Openings are so arranged that when inlet and outlet ducts or pipes are connected to them, there is no free exchange of the internal air and the air outside the case. Totally enclosed pipe-ventilated machines may be ventilated as described for other pipe-ventilated machines.

Water-Cooled. Cooled by circulating water; the water or water conductors coming in direct contact with the machine parts.

Air-Over. Intended for exterior cooling by a ventilating means external to the machine.

Air-to-Air-Cooled. Cooled by circulating the internal air through a heat exchanger which, in turn, is cooled by circulating external air. It is provided with an air-to-air heat exchanger for cooling the internal air and a fan or fans, integral with the rotor shaft or separate, but external to the enclosing part or parts, for circulating the external air.

129. Torques of motors. The *locked-rotor or static torque* of a motor is the minimum torque which it will develop at rest for all angular positions of the rotor, with rated voltage applied at rated frequency.

The *pull-up torque* of a motor is the minimum torque developed by the motor during the period of acceleration from rest to the speed at which breakdown torque occurs. For motors which do not have a definite breakdown torque, the pull-up torque is the minimum torque developed up to rated speed.

The *breakdown torque* of a motor is the maximum torque that the motor will develop with rated voltage applied at rated frequency without an abrupt drop in speed.

The *pull-in torque* of a synchronous motor is the maximum constant torque under which the motor will pull its connected inertia load into synchronism at rated voltage and frequency.

The *pullout torque* of a synchronous motor is the maximum sustained torque which the motor will develop at synchronous speed with rated voltage applied at rated frequency with normal excitation.

The *full-load torque* of a motor is the torque necessary to produce its rated horsepower at full-load speed.

130. The rating of an electric motor includes the service classification (Sec. 120), voltage, full-load current, speed, number of phases and frequency if alternating-current, and full-load horsepower. The horsepower rating that is stamped on the motor nameplate by the manufacturer is the horsepower load which the motor will carry without injury to any part of the motor.

In any motor a certain amount of the input energy is lost in the machine. This energy is dissipated in the form of heat, which raises the temperature of the motor. As the load on a motor is increased, the losses increase, and therefore the temperatures of the different parts of the machine increase with the load. If too great a load is put on the motor, the motor will become excessively hot, causing probable injury to the insulation of the windings.

Motor and generator insulation systems are divided into classes according to the thermal endurance of the system for temperature-rating purposes. Four classes of insulating

systems are used in motors and generators, namely, Classes A, B, F, and H. These classes have been established in accordance with IEEE standards. The insulation class is one which by experience or accepted test can be shown to have suitable thermal endurance when operated at the limiting temperature specified in the NEMA temperature-rise standard for the machine under consideration. *Experience* means successful operation for a long time under actual operating conditions of machines designed with temperature rise at or near the temperature-rating limit. *Accepted test* means a test on a system or model system which stimulates the electrical, thermal, and mechanical stresses occurring in service.

Depending on the type of motor, winding type, motor service factor, etc., the insulation classes are generally based on maximum internal winding temperatures measured by the change-of-resistance method using maximum actual anticipated normal winding temperatures of 105 to 115°C for Class A systems, 130 to 140°C for Class B systems, 155 to 160°C for Class F systems, and 180°C for Class H systems.

In general, maximum ambient temperature is 40°C for any motor unless that motor is specifically designed for a different figure, in which case the correct ambient should be stamped elsewhere on the nameplate.

General-purpose open-type motors are usually rated for continuous operation in a 40°C ambient temperature under normal service conditions. These conditions include, in addition to the 40°C ambient temperature, operation at an altitude no greater than 3300 ft (1006 m) above sea level, applied voltage within 10 percent of rated value, system frequency within 5 percent of rated value, combined variation of both voltage and frequency within 10 percent of rated values, unobstructed or unhampered ventilation, and proper mounting and mechanical connection to the driven load. Motors may be provided with various classes of insulation as shown in the motor insulation list above.

131. Starting currents of motors. In stating the current taken by a motor, specify just what current is meant, as starting currents are given in several different ways. In some cases the starting current pulled from the line is not the same as the current flowing into the motor itself at the instant of starting. If the rotating member of a motor is held stationary (locked rotor) and voltage is applied to the machine, a certain current would be indicated. This current is the first inrush current that will occur at starting. If the starting current is measured with a well-damped ammeter under actual starting conditions (the rotor is free to revolve), the current indicated on the ammeter will be less than the first inrush current. This is true because the ammeter does not have a chance to indicate the peak current before the motor has started to revolve and the current has decreased somewhat. It is a standard practice to take the free-rotor values of starting currents as 75 percent of the locked-rotor values.

The *locked-rotor current of a motor* is the current taken directly by the motor with the revolving part held stationary.

The *locked-rotor current of a motor and its starter* is the current taken from the line with the revolving part held stationary.

The *free-rotor current of a motor* is the maximum current taken directly by the motor during the starting period as indicated by a well-damped ammeter.

The *free-rotor current of a motor and its starter* is the maximum current drawn from the line during the starting period as indicated by a well-damped ammeter.

The *average starting current* of a motor is the average value of the starting current that must be considered in selecting fuses or circuit breakers. Fuses with a rating equal to the average starting current of a motor will allow the motor to start without rupturing the fuses. Owing to the time-lag characteristic of fuses, the peak value of the starting current will not rupture fuses of a rating considerably less than the peak value of the starting current.

132. Permissible motor-starting currents. The operating conditions of an electric power system are affected by the currents taken by motors under starting conditions. Excessive power fluctuations will cause large changes in the voltage of the system and excessive voltage drops under the peak-current conditions. These power and voltage fluctuations may produce unsatisfactory operating conditions for one or more of the following reasons:

1. Actuation of undervoltage protective or release devices on motor controllers, causing the shutdown of motors
2. Stalling of induction motors that are operating close to full load or slightly over full load
3. Objectionable dips in the light output of lamps and flickering of lamps
4. In the case of small private generating plants, danger of overloading of generators

Each electric power company has definite rules for permissible starting currents for motors supplied from its system. At present there is no standardization of these rules, each company having its own set of rules. Some of these rules limit the starting current on the basis of an allowable percentage of full-load current of the motor. With one of the newer rules, called the *increment method*, the maximum starting current of any motor must not be greater than a certain number of amperes per kilowatt of the customer's maximum-demand load.

133. The speed regulation of a motor is the percentage drop in speed between no load and full load based on the full-load speed.

$$\text{Percent speed regulation} = \frac{\text{no-load speed} - \text{full-load speed}}{\text{full-load speed}} \times 100 \quad (3)$$

DIRECT-CURRENT MOTORS

134. Direct-current motors. All dc motors must receive their excitation from some outside source of supply. Therefore they are always separately excited. The interconnection of the field and armature windings can be made, however, in one of the three different ways employed for self-excited dc generators. A dc motor may be designed, therefore, to operate with its field connected in parallel or in series with its armature, producing, respectively, a shunt or a series motor. If the machine is provided with two field windings, one connected shunt and the other series, it is a compound motor. The speed of a shunt motor connected directly to the line is nearly constant from no load to full load, while the speed of a series motor drops off rapidly as the load is increased. If a series motor were operated at no load with normal voltage, it would attain a dangerous speed, so high in most cases that it would throw itself apart by centrifugal force. A series motor should never be operated at no load unless there is sufficient external resistance connected in series with the motor to limit its speed to be a safe value. For this reason a belt drive should never be used with a series motor.

Standard compound motors are designed to operate with the shunt and series fields connected so as to aid each other (cumulative). Their operating characteristics therefore are a

compromise between those of shunt and series motors. Their speed drops off considerably as the load is increased, but not nearly so much as with series motors. A compound motor will not run away under no load. The amount of change of speed from no load to full load depends upon the strength of the series field. The stronger the series field, the greater the change in speed from no load to full load. Special compound motors with their field windings connected to buck each other (differential motors) are used sometimes for special applications. If the series field is of just the proper strength, a differential compound motor will operate at a more constant speed than a shunt motor, but it tends to be unstable under overload conditions.

Many shunt motors have a weak series-field winding in addition to the shunt-field winding. The series-field winding is connected cumulatively and consists of only a very few turns. The purpose of the series-field winding is to counteract partially the effect of the armature current upon the speed of the motor. The armature current tends to reduce the strength of the magnetic field of the motor. Therefore, as the load on the motor is increased, the decrease in the strength of the field may cause a rise in the speed. A motor with a rising-speed characteristic is unstable. A few series-field turns will sufficiently counteract the demagnetizing effect of the armature current and stabilize the speed characteristic of the motor. These motors, although actually cumulative compound motors with a very weak series field, are called stabilized shunt motors.

Typical characteristics for shunt, series, and compound motors are shown in Figs. 7.71, 7.72, and 7.73.

FIGURE 7.71 Typical characteristics for a shunt motor.

FIGURE 7.72 Typical characteristics for a series motor.

135. Torque characteristics of dc motors.

The torque developed by any one of the three types of dc motors, either at starting or while running, depends upon the product of the magnetic flux and the armature current. Since in a shunt motor the flux is nearly constant at all times, the torque varies nearly directly with the value of the armature current. In a series motor the armature current flows directly through the field winding, so that the flux is not constant but varies almost directly with the value of the armature current. The torque

of a series motor, therefore, varies approximately as the square of the armature current. Doubling the armature current will make the torque 4 times as great. The cumulative compound motor has a torque characteristic that is a compromise between that of the series motor and that of the shunt motor. The torque will increase faster than the increase in armature current but not so fast as the square of the armature current. The way in which the torque varies with the armature current for a cumulative compound motor depends upon the relative strength of the series and shunt fields. The curves of Fig. 7.74 indicate the relation between torque and armature current for the different types of dc motors.

FIGURE 7.74 Torque characteristics for dc motors.

The maximum value of starting torque that it is satisfactorily possible for any dc motor to produce is limited only by the commutating conditions. These usually limit the current to approximately 200 percent of full-load current for a shunt motor and 250 percent of full-load current for a series or compound motor. The corresponding torques are approximately 200 percent of full-load torque for a shunt motor, 300 percent for a compound motor, and 400 percent for a series motor.

There is no value of pullout torque for a dc motor. If the load on a dc motor were continually increased, the motor would gradually slow down as the load increased until finally

the load would become so great that the motor would gradually stop. Of course, it would never be feasible in practice to overload the machine to such an extent that it would stop, and long before such a load was reached the fuses in the circuit would blow.

136. Method of starting dc motors A dc motor of any capacity, when its armature is at rest, will offer a very low resistance to the flow of current, and an excessive and perhaps destructive current would flow through it if it were connected directly across the supply mains while at rest. Consider a motor adapted to a normal full-load current of 100 A and having a resistance of 0.25Ω ; if this motor were connected across a 250-V circuit, a current of 1000 A would flow through its armature; in other words, it would be overloaded 900 percent, with consequent danger to its windings and also to the driven machine. For the same motor, with a rheostat having a resistance of 2.25Ω inserted in the motor circuit, at the time of starting the total resistance to the flow of current would be the resistance of the motor (0.25Ω) plus the resistance of the rheostat (2.25Ω), or a total of 2.5Ω . Under these conditions exactly full-load current, or 100 A, would flow through the motor, and neither the motor nor the driven machine would be overstrained in starting. This indicates the necessity of a rheostat for limiting the flow of current in starting the motor from rest.

An electric motor is simply an inverted generator or dynamo. Consequently when its armature begins to revolve, a voltage is generated within its windings just as a voltage is generated in the windings of a generator when driven by a prime mover. This voltage generated within the moving armature of a motor opposes the voltage of the circuit from which the motor is supplied and hence is known as a *counter-emf*. The net voltage tending to force current through the armature of a motor when the motor is running is, therefore, the line voltage minus the counter-emf.

For the motor cited above, when the armature reaches such a speed that a voltage of 125 is generated within its windings, the effective voltage will be 250 minus 125, or 125 V, and therefore the resistance of the rheostat may be reduced in 1Ω without the full-load current of the motor being exceeded. As the armature further increases its speed, the resistance of the rheostat may be further reduced until when the motor has almost reached full speed, all the rheostat may be cut out and the counter-emf generated by the motor will almost equal the voltage supplied by the line, so that an excessive current cannot flow through the armature.

It is a general practice to provide a rheostat for starting a dc electric motor except for small fractional-horsepower motors of $1/4$ hp or smaller. In special cases, when the motor is started very infrequently and the starting load is light, larger motors can be started by throwing them directly across the line. Motors as large as 5 hp have been successfully started in this way, but the manufacturer should be consulted whenever one contemplates starting a motor larger than 1 hp by this method. The resistor providing the starting resistance is divided into sections and is so arranged that the entire length or maximum resistance of the rheostat is in circuit with the motor at the instant of starting and that the effective length of the resistance conductor, and hence its resistance, can be reduced as the motor comes up to speed.

In cutting out the resistance of a starting rheostat care must be used not to cut it too rapidly. If the resistance is cut out more rapidly than the armature can speed up, a sufficient counter-emf will not be generated to oppose the flow of current properly and the current will be excessive.

The standard starting rheostat, when thrown into the first position, limits the armature current to about 150 percent of the full-load current. This current will produce a starting torque of about 150 percent of full-load torque for a shunt motor, of about 175 percent for a standard cumulative compound motor, and of about 225 percent for a series machine. If greater starting torque is required, it can be obtained by advancing the starter to the second or third point. The allowable starting torque that can be obtained in this way is limited by commutating conditions to about 200 percent of full-load torque for a shunt motor, to

300 percent for a compound motor, and to 400 percent for a series motor. The currents corresponding to these maximum allowable torques are approximately 200 percent of full-load current for a shunt motor, 250 percent of full-load current for a cumulative compound motor, and 250 percent of full-load current for a series motor.

137. Speed control of dc motors. The speed of dc motors for a given load can be controlled by the following methods:

1. Armature control
 - a. Variable resistance in series with armature
 - b. Variable-voltage generator supplying armature (Ward-Leonard system)
 - c. Variable voltage supplied to armature by controlled electronic rectifier
 - d. Resistance shunted across armature
2. Field control
 - a. Shunt-field rheostat
 - b. Variable-voltage generator supplying shunt field
 - c. Variable voltage supplied to shunt field by controlled electronic rectifier
 - d. Resistance shunted across series field
3. Combination of armature and field control

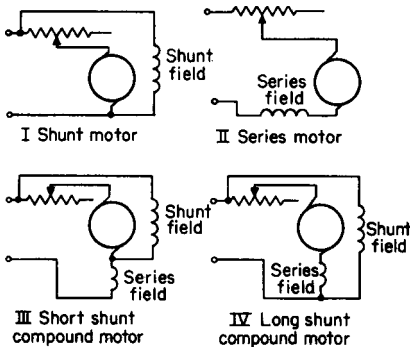

FIGURE 7.75 Speed control with armature resistance.

is easy to apply and requires only simple and relatively inexpensive equipment, and gradual control of the speed down to practically zero speed can be obtained. Armature series resistance control, however, has the following objections:

1. *Bulk of rheostat.* This may not be very objectionable if only a few motors are so controlled, but for larger numbers the extra space becomes a factor, and in many cases it is difficult to find sufficient room near the motor.
2. *Inefficiency of the system.* The same amount of power is supplied at all speeds, but at low speeds only a small part is converted into useful work, the balance being wasted in the rheostat as heat.
3. *Poor speed regulation with varying loads.* Since the impressed voltage at the armature terminals is equal to the line voltage minus the resistance drop in the rheostat ($V_t = V - I_a R_x$), any change in the current drawn by the motor produces a change in the terminal voltage, the counter-emf, and therefore the speed.

138. Armature speed control. Any dc motor may have its speed reduced below normal by armature control. With this method, the speed is controlled by varying the voltage impressed upon the armature, while the voltage of the field is held constant. For a constant-torque load, the speed will vary in approximate proportion to the voltage impressed on the armature. The allowable horsepower output will decrease proportionally to the decrease in speed.

Armature speed control can be obtained by inserting an external variable resistance in series with the armature circuit. The location of such a resistance for the different types of dc motors is shown in Fig. 7.75. This method

Armature series resistance control is the type of speed control most commonly employed for series motors. Series motors requiring speed control are used chiefly for intermittent duty, and the total loss of energy in the control resistance therefore is not so great as it would be for continuous duty. Generally, armature series resistance control is not employed for shunt and compound motors unless a wider speed range than can be obtained satisfactorily by field control is desired or unless very low speeds are required.

Armature speed control obtained by a variable-voltage generator (Ward-Leonard system) requires an individual motor-generator set for each motor whose speed is to be controlled. Although this method is applicable to any type of dc motor, it is most commonly used with shunt or compound motors. A schematic diagram is given in Fig. 7.76. The Ward-Leonard system gives very close control of the speed over a wide range but has the disadvantage of requiring three full-size machines for each motor drive. For automatic drive control with dc motors, a variation of the Ward-Leonard system can be used, employing control generators (see Secs. 43, 44, 45, and 143).

The variable voltage for armature control can be obtained from a controlled electronic rectifier. Electronic armature speed control gives close control of the speed over a wide range. Electronic control of dc motor speed can be adapted for automatic drive control (see Sec. 142).

Resistance shunted across the armature is useful for controlling the speed of dc motors to very low values at light loads. It is used only in conjunction with armature series resistance control. Connections for this method are shown in Fig. 7.77.

FIGURE 7.76 Ward-Leonard system of speed control.

FIGURE 7.77 Speed control using a shunt across the armature.

139. Field speed control. The speed of dc motors can be controlled by varying the field current of the motor while the armature voltage is held constant. Reducing the field-current will reduce the flux and consequently increase the speed of the motor. Field control gives close control of the speed over a limited range. The speed of any shunt motor can be increased by approximately 25 percent above normal by field control. If a greater speed range than this is required, a shunt motor designed for adjustable-speed service should be used. A speed range of 4:1 is the practical limit for field control with an adjustable-speed shunt motor. The simplest method of obtaining field speed control for shunt or compound motors is by means of a field rheostat connected in series with the shunt field. The proper location of a field rheostat in motor circuits is shown in Fig. 7.78. This method is the one most commonly used for speed control of shunt and compound motors. It is very easy to apply, requires simple and inexpensive equipment that occupies only a very small space,

FIGURE 7.78 Control of speed with a field rheostat.

does not consume any appreciable amount of power in the control equipment, and gives good speed regulation with varying loads.

Field control of shunt or compound motors can be obtained by energizing the shunt field from a variable-voltage generator. This method requires an individual motor-generator set for each motor to be controlled and has no advantage over the simple field rheostat method except for automatic drive control of small motors requiring only a limited speed range. When this method is employed in automatic drive control, the shunt field of the

motor is excited by a control generator (see Secs. 43, 44, and 45).

Field control of shunt and compound motors is sometimes obtained by supplying the shunt field from a controlled electronic rectifier. The fundamental principles and connections of controlled rectifiers are the same as those discussed for rectifiers employed for electronic armature control. Electronic field control generally is employed only in combination with electronic armature control when a very wide speed range is required.

Field control of series motors is obtained by shunting a resistance across the series field. If a resistance or rheostat is placed in parallel with the field of a series-wound motor, the speed will be increased instead of decreased at a given load. This procedure is known as *shunting the field of the motor*. This shunt would not be applied until the motor had been brought up to normal full speed by cutting out the starting resistance. With a shunted field a motor drives a load at a speed higher than normal and therefore requires a correspondingly increased current. More current is required to produce a given torque. The allowable torque at speeds above normal is therefore less than the rated full-load torque. With this type of speed control the motor is practically a constant-horsepower machine, the allowable rating being almost the same for all speeds.

140. A combination of armature and field control is employed when a wide speed range is required. The following combinations are frequently employed:

1. Armature resistance combined with a shunt-field rheostat
2. Ward-Leonard system combined with a shunt-field rheostat
3. Electronic armature control combined with electronic field control

A common combination used for controlling the speed of standard constant-speed motors is to employ armature control for reducing the speed to 50 percent below normal and field control for increasing the speed 25 percent above normal.

141. Automatic drive control (servo system) is the automatic control of a motor to meet specified requirements of the driven equipment or material. A few of the more common requirements that are automatically fulfilled by automatic drive control are:

1. Production of uniform acceleration and deceleration
2. Maintenance of constant speed regardless of load and control of speed over a wide speed range
3. Production of constant torque over a wide speed range

The essential elements of an electric drive-control system are shown in the block diagram of Fig. 7.79. An electric drive-control system must have the ability (1) to pick up a signal whenever there is a deviation from the required performance of a driven machine or process, (2) to convert this variation signal into a proportional electrical signal, (3) to compare this electrical signal with the desired standard, (4) to have the deviation from the standard activate a correction in the electrical input to the drive motor, and (5) to provide antihunting characteristics.

Requirements 1 and 2 are fulfilled by the conversion element (pickup) of Fig. 7.79. The conversion element may take a variety of forms. It may be a pilot generator coupled to

the drive motor or driven machine, which will pick up any variation in speed and translate this speed variation into a proportional voltage variation. It may be a resistor in series with the armature of the drive motor. The voltage across such a resistor will act as a pickup for any variation in the current delivered to the motor. Such a pickup can be used for constant-torque control of a motor. Phototubes are used as the pickup device in many cases. A phototube circuit will pick up and convert into a voltage any deviation from the proper position of a machine tool or of a driven object. The pickup device may be a set of synchros, which will pick up and convert into a signal voltage any deviation from a desired angular position (see Sec. 178).

Requirement 3 of the control system is fulfilled by the comparison circuit of Fig. 7.79. For example, consider the conditions for automatic speed control of a motor. The voltage of the conversion element (a pilot generator) is connected in series with a standard voltage, and any variation in the voltage of the pilot generator results in a variation of current in the comparison circuit. This variation in current will be controlled in magnitude and direction by the variation in the voltage of the pilot generator. The output of the comparison circuit may not be great enough to produce proper functioning of the activation circuit. In such cases, a modification circuit, which will consist of an electronic amplifying circuit, must be employed. Often it is desired that the controlled machine be influenced by some factor or factors in addition to the main controlling function. Such requirements are fulfilled by modification circuits.

Requirement 4 of the control system is fulfilled by the activation circuit of Fig. 7.79. The output of the comparison and modification circuit must be connected to an activation circuit, which will control the input circuit to the drive motor so as to correct the deviation of the driven device. For example, the output of the comparison circuit may act upon the control circuit of a thyristor and in this manner control the input to the drive motor.

Requirement 5 of the control system is fulfilled through coupling or feedback circuits between comparison and activation circuits. The purpose of these antihunt circuits is to prevent overshooting of the correction and to prevent serious oscillations about the desired controlled condition. Although these antihunt circuits are in many cases essential, a discussion of them is beyond the scope of this book.

In the majority of dc drive-control applications, the requirements are met through the use of dc motors controlled by electronic or electrodynamic control systems. In both these control systems, dc motor performance is controlled through (1) control of input to the motor armature, (2) control of input to the motor field, or (3) combination control of input to the motor armature and field. In the electronic control systems, the motor input is adjusted by means of thyristor rectifiers. In electrodynamic control systems, the motor input is adjusted by means of control generators (see Sec. 43).

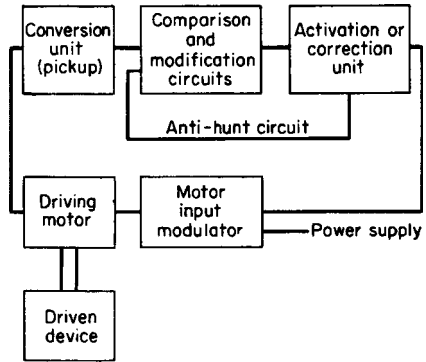

FIGURE 7.79 Elements for automatic drive control.

142. In the electronic control of dc motors, either the armature or the field, or both, are supplied through electronic rectifiers. The output of the rectifiers is automatically controlled in accordance with the requirements of the driven machine or process.

143. Automatic electrodynamic drive control is frequently called a *servo system*. In electrodynamic control of dc motors, the input to the motor is automatically controlled in accordance with the requirements of the load by means of a control generator. Small motors may be supplied with power directly from the control generator. When the capacity of the control generator is not sufficient to supply the motor director, the control generator energizes the field of a main generator and thus controls the input to the motor. Electrodynamic control circuits for constant-speed control of a dc motor are shown in Figs. 7.80 and 7.81. The circuit of Fig. 7.80 employs an amplidyne control generator, and that of Fig. 7.81 a Rototrol control generator. When a sufficient speed range can be obtained by field control, the control generator may control the input to the field of the motor instead of the input to the armature, as is shown in the figures. In the circuits of both Figs. 7.80 and 7.81, the conversion element, or pickup, is the pilot generator, which is coupled to the main dc drive motor. In the circuit of Fig. 7.80, the voltage of the pilot generator is impressed upon the comparison circuit so as to oppose the reference voltage. In the circuit of Fig. 7.81, the voltage of the pilot generator energizes the pilot field of the Rototrol. The comparison circuit of Fig. 7.81 consists of the combination of the pilot- and pattern-field circuits. In the circuits of both figures, the activation circuit is the armature circuit of the control generator. When the signal voltage from the pilot generator is not sufficient to actuate the field circuit of the control generator directly, an electronic amplifier is inserted between the pickup circuit and the field of the control generator. In both the circuits shown in the figures, the circuit is adjusted for the desired speed by means of the adjusting rheostat.

In the amplidyne control circuit of Fig. 7.80, if the speed of the motor rises above the value corresponding to the setting of the adjusting rheostat, the greater opposing voltage of the pilot generator weakens the field of the amplidyne. This will lower the voltage output of the amplidyne and thereby weaken the field of the main generator. The voltage output of the main generator is thus reduced. Therefore, the input and consequently the speed of the motor are reduced until the speed has been brought back to the value determined by the setting of the adjusting rheostat.

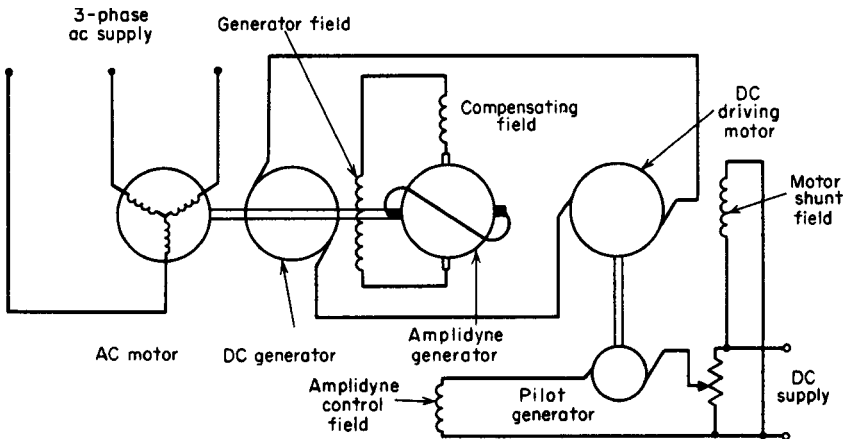

FIGURE 7.80 Speed control using an amplidyne generator.

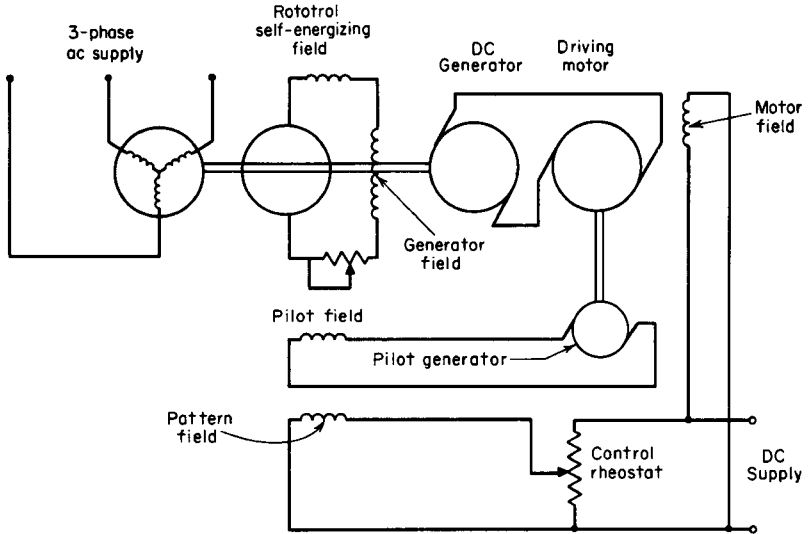

FIGURE 7.81 Speed control using a Rototrol.

In the Rototrol circuit of Fig. 7.81, if the speed of the motor rises above the value corresponding to the setting of the adjusting rheostat, the strength of the pilot field of the Rototrol is increased. Since the pilot field opposes the constant pattern field, the field flux of the Rototrol will be reduced. This will lower the voltage of the Rototrol and thereby weaken the field of the main generator. The voltage output of the main generator is thus reduced. Therefore, the input and consequently the speed of the motor are reduced until the speed has been brought back to the value determined by the setting of the adjusting rheostat.

Circuits for constant-current control of a dc motor by means of electrodynamic control systems are shown in Figs. 7.82 and 7.83. The pickup element consists of a resistor in series with the motor armature circuit. Any deviation in the armature current will result in a

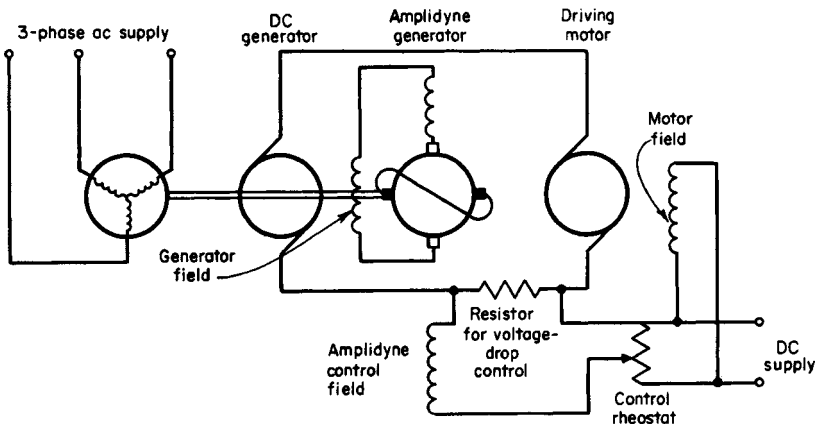

FIGURE 7.82 Constant-current control using an amplidyne generator.

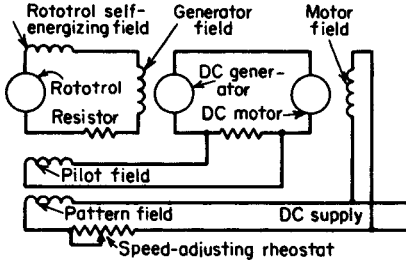

FIGURE 7.83 Constant-current control using a Rotrotol control generator.

error voltage of a synchro circuit (see Sec. 178). The phototube or synchro pickup and conversion element can actuate either an electronic or an electrodynamic control system so as to control the process or driven machine in accordance with the position desired.

proportionate change in voltage across the resistor. The voltage across the resistor activates the comparison circuit in the manner discussed for constant-speed controls.

144. Position control. It is often desirable to have a control system that functions to control the position of a driven object or rotating machine. The position of a driven object may be indicated by a phototube scanning the driven object. The angular position of a rotating machine may be indicated by the

ALTERNATING-CURRENT MOTORS

146. General construction of polyphase induction motors. Polyphase induction motors have two windings, one on the stationary part of the machine, or stator, and one mounted on the revolving part, or rotor. The stator winding is embedded in slots in the inner surface of the frame of the machine and is similar to the armature winding of a revolving-field type of ac generator. The rotor winding may be one of two types, squirrel-cage or wound-rotor. In a *squirrel-cage machine* the rotor winding consists simply of copper or aluminum bars embedded in slots in the iron core of the rotor and connected together at each end by a copper or aluminum ring. The rotor winding thus forms a complete closed circuit in itself. The rotor winding of the *wound-rotor machine* is similar to the armature winding of a revolving-armature type of ac generator. The free ends of the winding are brought out to slip rings. The rotor circuit is not closed until the slip rings are connected either directly together or through some resistances external to the machine.

147. Principle of operation of the induction motor. The induction motor differs from other types of motors in that there is no electrical connection from the rotor winding to any source of electrical energy. The necessary voltage and current in the rotor circuits are produced by induction from the stator winding. The operation of the induction motor depends upon the production of a revolving magnetic field. The stator winding of a simple two-phase induction motor connected to a simple two-phase alternator is shown in Fig. 7.84.

FIGURE 7.84 Principle of the induction motor.

Windings of the types shown in the illustration are not used in commercial machines, but the general theory involved is the same as with commercial windings. The revolving field of the generator, in turning the direction shown by the arrow, generates a two-phase current, which is transmitted to the motor. The current in conductors of one phase magnetizes poles *A* and *B*, and that in the other phase poles *C* and *D*. The winding is so arranged that a current entering at *A* will produce a south pole at *A* and a north pole at *B*. At the instant shown at I, motor poles *A* and *B* are magnetized while poles *C* and *D* are not, because it is a property of a two-phase circuit that when the current in one of the phases is at a maximum value, the current in the other phase is at a zero value. Hence, at this instant a magnetic field will be set up in the machine in a vertical direction, with a north pole at *B* and a south pole at *A*.

At another later instant, represented at II, the currents in both of the phases are equal and in the same direction. The motor poles will be magnetized as shown. The currents in changing from their values in I to their values in II have moved the magnetic field through an angle of 45° toward the right. At the instant illustrated at III, because of the properties of two-phase currents there is no current in the phase of the conductors which are wound on poles *A* and *B*, but the current in the phase of the conductors which magnetize poles *C* and *D* is at maximum. Hence, the magnetic field produced in the machine at instant III is in a horizontal direction with a south pole at *C* and a north pole at *D*. The magnetic field has been moved around another 45° . Similar action occurs during successive instants, and the magnetic field is caused to rotate continually in the same direction within the motor frame as long as the two-phase current is applied to the stator terminals. Thus, when the stator winding of a polyphase motor is connected to a source of polyphase power, a revolving field is produced inside the machine.

If a closed electric circuit such as the rotor winding of an induction motor is inserted in the machine, the revolving magnetic field will cut across the conductors of this winding and in that way produce a voltage in them. This voltage acting upon the closed rotor circuit will send a current through the different conductors of the rotor winding. The rotor conductors then will be carrying a current and lying in a magnetic field. Such a condition will produce a force upon the conductors of the rotor winding, tending to turn them in the same direction as that in which the magnetic field is revolving.

If the rotor winding were revolved at the same rate of speed as that at which the magnetic field revolves, there would be no relative motion between the field and the conductors of the rotor winding. Since there would be no relative motion, there would be no cutting of the magnetic field across the conductors and therefore no voltage or current produced in the rotor winding. If there is no current in the rotor winding, no torque can be produced, which tends to keep the machine revolving. As the machine slows down, however, the magnetic field will revolve at a higher speed than the rotor, producing a relative motion between the magnetic field and the conductors of the rotor winding. This relative motion produces a cutting of the conductors by the flux, with the resultant voltage and current necessary to develop a turning effort upon the rotor. The operation of an induction motor depends upon the difference in speed between the revolving magnetic field and the actual speed of the machine or rotor. This difference in speed is called the *slip of the motor*. The rotor is said to slip a certain number of revolutions behind the revolving magnetic field. The greater the load on an induction motor, the more the rotor must slip behind the revolving magnetic field to produce a greater cutting of the flux by the rotor conductors, with the resulting greater current in the rotor and greater turning effort to carry the greater load. Even at no load an induction motor cannot revolve as fast as the magnetic field revolves, since enough torque must be developed to overcome the friction and other losses in the motor.

148. The synchronous speed of an induction motor is the speed at which its magnetic field revolves. It depends upon the number of poles for which the stator is wound and the frequency of the supply voltage.

$$\text{Synchronous speed} = \frac{120f}{P} \quad (4)$$

where f = frequency of supply

P = the number of poles per phase for which the stator is wound

Synchronous speed is in revolutions per minute.

148A. The slip of an induction motor is the ratio of the difference between the rotating magnetic-field speed (rpm or angular velocity) and the actual rotor speed to the rotating magnetic-field speed. The speed of the rotating magnetic field is equivalent to the synchronous speed of the machine (see Table 100), which is determined by the frequency of the current and the number of poles of the machine (Sec. 147). Then

$$\text{Slip in rpm} = \text{synchronous speed} - \text{actual speed} \quad (5a)$$

$$\text{Percent slip} = \frac{\text{synchronous speed} - \text{actual speed}}{\text{synchronous speed}} \times 100 \quad (5b)$$

When there is no load on a motor, the slip is very small; i.e., the rotor speed is practically equal to the synchronous speed. Slip varies with the design of a motor and may vary from 4.0 to 8.5 percent at full load in motors of from 1 to 75 hp of ordinary design.

EXAMPLE What is the slip at full load of a four-pole 60-Hz induction motor which has a full-load speed of 1700 rpm?

SOLUTION From Table 100 or Sec. 147 the speed of the rotating field or the synchronous speed of a four-pole 60-Hz motor is 1800 rpm. Then, substituting in the above formula,

$$\begin{aligned}\text{Percent slip} &= \frac{\text{synchronous speed} - \text{actual speed}}{\text{synchronous speed}} \times 100 = \frac{1800 - 1700}{1800} \times 100 \\ &= \frac{100}{1800} \times 100 = 5.5 \text{ percent}\end{aligned}$$

Therefore the slip is 5.5 percent. The voltage of the motor and whether it is single-phase, two-phase, or three-phase are not factors in the problem.

148B. Breakdown torque of an induction motor. Most induction motors will “break down” at a certain torque if they are overloaded. The breakdown limit, the maximum running torque that can be developed, is the point at which a further increase in load will cause the motor speed to decrease rapidly and then to stop. This point is usually between 2 and 4 times the full-load rated torque, depending on the design and the capacity of the motor. In a few cases there is no breakdown torque, the maximum torque occurring at standstill. Under these conditions there will be no sudden decrease in the speed as the load is increased. Instead, the speed will gradually decrease as the load is increased until standstill is reached.

149. General operating characteristics of induction rotors. The following rules, though approximate, are accurate enough for practical use under the normal range of operation of an induction motor from no load to 150 percent of rated load:

1. The slip of an induction motor varies directly with the load. Doubling the load will double the slip.
2. For any given load the slip varies directly with the resistance of the rotor circuit. If the resistance of the rotor circuit is doubled, the slip for the same load will be twice its original value.
3. For any load the slip varies inversely as the square of the voltage impressed on the stator winding. If the voltage is reduced to one-half of its normal value, the slip is increased to 4 times its normal value for any load.
4. The torque developed by an induction motor varies directly with the slip.
5. The torque developed at any particular slip varies inversely with the resistance of the rotor circuit.
6. The torque for any particular slip varies directly as the square of the voltage impressed on the stator.
7. The maximum torque is not affected by the resistance of the rotor circuit. A large value of resistance for the rotor circuit simply makes the maximum torque occur at a high slip.
8. The maximum torque varies directly with the square of the voltage impressed on the stator circuit.

150. Starting characteristics of induction motors. The starting torque varies directly with the square of the voltage impressed on the stator. If three-fourths of normal voltage is impressed at starting, the starting torque will equal only nine-sixteenths of the torque developed with normal voltage impressed at starting.

The value of the starting torque of an induction motor also depends on the value of the resistance of the rotor circuit. As the resistance of the rotor circuit is increased, the starting torque is increased until the resistance of the rotor circuit is of just the right value to make the maximum torque occur at starting. If the resistance of the rotor circuit is still further increased, the starting torque will be decreased. Thus, a certain value of rotor resistance will produce maximum starting torque, and either a greater or a smaller value of motor resistance than this amount of resistance produces less starting torque (see Fig. 7.87).

The current taken at starting by an induction motor depends upon the voltage impressed on the stator and the resistance of the rotor circuit. For a fixed rotor resistance the starting current varies directly with the impressed voltage. For a particular impressed voltage, increasing the resistance of the rotor circuit decreases the value of the starting current.

151. Characteristic curves of the induction motor. The curves of Fig. 7.85 are fairly typical of the average normal-torque, normal-starting-current, commercial induction motor. Note that the normal rating of the motor is taken at such a point that both the power factor and the efficiency are the highest possible. The motor could be designed so that either the power factor or the efficiency, but not both, could be higher than shown at normal load, but the design of an induction motor is a compromise between the leading factors that results in the best efficiency and power factor obtainable with suitable overload and starting characteristics.

The characteristics of a polyphase induction motor running single-phase are shown in Fig. 7.86. In Fig. 7.88 is shown the speed-torque characteristic of a polyphase induction motor running single-phase. Note that the starting torque when operated single-phase is zero. A polyphase induction motor will not start when connected to a single-phase supply. Once started, however, it will operate from a single-phase supply and carry approximately half the rated load without over-heating.

FIGURE 7.85 Typical performance graph of a 20-hp (14.9-kW) three-phase induction motor.

FIGURE 7.86 Performance graph of the motor shown in Fig. 7.85 when running single-phase.

152. High-efficiency induction motors. Efficiency is a measure of the effectiveness with which a motor converts electrical energy into mechanical energy; in other words, watts in versus watts out. In the conversion process, watts are lost, transformed into heat which is dissipated by the motor-cooling system, such as through the motor frame, or lost through friction and windage. High-efficiency motors available from many manufacturers reduce the watts loss in one or all of several areas over standard industrial motor designs, in some cases by as much as 50 percent. General techniques for watts-loss reduction include the following:

Watts-Loss area	Efficiency improvements
1. Iron	Iron losses are essentially independent of load. Use of thinner-gage, lower-loss core steel reduces eddy-current losses, and adding iron by making the motor core longer reduces losses due to lower operating flux densities.
2. Stator I^2R	Use of more copper and larger conductors increases the cross-sectional area of stator windings, lowering resistance R and reducing losses due to current flow I . I^2R losses are load dependent.
3. Rotor I^2R	Use of larger rotor conductor bars increases the size of the cross section, lowering resistance R and reducing losses due to current flow I .
4. Friction and windage	Friction and windage losses are independent of load. Use of low-loss fan designs (on fan-cooled motors) reduces losses due to air movement. Bearing design can reduce friction losses.
5. Stray load loss	Use of optimized design and improved quality-control procedures minimize stray load losses, such as those due to nonuniform current distribution in stator and rotor conductors, air gap, and so forth. These losses combined may be 10 to 15 percent of total motor losses and tend to increase with load.

Generally, high-efficiency motors are more expensive than standard industrial motors; however, the additional initial investment may be more than justified by the reduction in the cost of electricity used. There are a number of ways to evaluate the economic impact of motor efficiency. An example of a simple payback analysis is given here. Other methods include a present-worth life-cycle analysis and a cash-flow and payback analysis. Details of the various methods of analysis can be found in financial-management texts.

The simple payback method gives the number of years required to recover the differential investment for a higher-efficiency motor to determine the payback period. The premium for the higher-efficiency motor is divided by the annual savings. First, the annual savings must be determined by using the following formula:

$$S = 0.746 \times \text{hp} \times L \times C \times N \left(\frac{100}{E_B} - \frac{100}{E_A} \right) \quad (5c)$$

where S = annual dollar savings
 hp = horsepower
 L = percentage load \div 100
 C = energy cost, dollars/kWh
 N = annual hours of operation
 E_B = lower-motor percent efficiency
 E_A = higher-motor percent efficiency

The efficiencies for the percent load at which the motor will be operated must be used, since motor efficiency varies with load, as shown in Fig. 7.85. Then, the motor-cost premium is divided by the annual savings to compute the payback period for the higher-efficiency motor. If motor A costs \$300 more than motor B and yields annual savings of \$100, the simple payback period is \$300/\$100, or 3 years. The payback method is easy to apply but ignores savings occurring after the end of the payback period and does not consider the time value of money or changes in energy costs.

See Sec. 6 of Div. 1 for coverage of financial tools that account for the time value of money and future changes in operating expenses. See Sec. 173 for motor-efficiency marking and minimum efficiencies of "energy-efficient" motors.

153. The torque curves of an induction motor with a wound rotor, from rest to synchronism, running both three-phase and single-phase with external resistance and without external resistance, are shown in Fig. 7.87. The curves are plotted with torque in foot pounds at 1-ft (0.3-m) radius. Curve *A* shows the torque from rest to synchronism without resistance in the rotor circuit. If the proper value of resistance is inserted, curve *B* is obtained, and the starting torque is 440 ft·lb (596.6 J) against 170 ft·lb (230.5 J) without resistance. Curve *C* indicates the torque when too much resistance is used in the motor. Curve *E* illustrates the torque for single-phase, which is zero at starting. A wound-rotor induction motor starts as shown on curve *B* until it reaches point *F*, when the resistance is cut out and the motor adjusts itself to its operating position at *G*. Thus, if the torque required of the motor for which the curve is shown is greater than 440 ft·lb, shown at *H*, the motor will break down and come to rest. With the resistance in the rotor, a starting torque of 440 ft·lb is available, but this load cannot be brought up to normal speed. The motor can bring only the torque represented by point *F*, or 290 ft·lb (393.2 J), to normal speed.

In Fig. 7.87, note that the torque of a three-phase motor rises to a maximum and then drops, reaching zero at synchronism. This means that an induction motor never runs at synchronous speed.

FIGURE 7.87 Torque graph of a 30-hp (22.4-kW) induction motor.

FIGURE 7.88 Torque graph of a 1-hp (745.7-W) three-phase induction motor running single-phase.

154. Speed control of induction motors. It is possible to control the speed of an induction motor by any one of the following methods:

1. Changing the impressed voltage
2. Changing the number of poles for which the machine is wound
3. Changing the frequency of the supply
4. Changing the resistance of the rotor circuit
5. Introducing a foreign voltage into the secondary circuit
6. Operating two or more motors connected in cascade

155. Reducing the impressed voltage will increase the slip of an induction motor proportionally to the square of the voltage. At the same time, however, the breakdown torque of the motor is also reduced as the square of the voltage, so that the motor is in danger

of stalling under load. For this reason, changing the impressed voltage alone is employed for the speed control of induction motors only in emergencies or other special cases.

156. Speed control of induction motors by changing the number of poles.

The actual speed of an induction motor depends upon the speed of the revolving magnetic field produced by the stator winding (synchronous speed). The synchronous speed of an induction motor is inversely proportional to the number of poles for which the stator winding is wound. Thus, on a 60-Hz circuit a two-pole induction motor has a synchronous speed of 3600 rpm; a four-pole motor, 1800 rpm; an eight-pole motor, 900 rpm, etc. It is therefore possible to alter the speed of an induction motor by changing the number of its poles.

This can be accomplished by using two or more separate primary windings, each having a different number of poles, or by using a single winding which can be connected to form different number of poles. This method is, of course, not applicable to the ordinary type of induction motor but requires a motor with a number of leads brought out from the primary winding (see Sec. 172). Gradual speed control cannot be obtained by this method. Only a certain number of definite speeds, four at the most, can be obtained.

157. Speed control of a polyphase motor by adjusting the frequency of the primary current.

Since the synchronous speed of an induction motor is equal to the alternations per minute of the supply circuit divided by the number of poles in each phase circuit, a change in speed can be effected by changing the frequency of the supply circuit.

Figure 7.89 shows the speed-torque and other curves of a 60-Hz motor when operated at 60, 30, 15, and 6 Hz, or at 100, 50, 25, and 10 percent of the normal frequency. The speed-torque curves corresponding to the above frequencies are *a*, *b*, *c*, and *d*. The current curves are *A*, *B*, *C*, and *D*. This figure shows that for the rated torque *T* the current is practically constant for all speeds, but the emf varies with the frequency. Consequently, the apparent power supplied, represented by the product of the current by emf, varies with the speed of the motor and is practically proportionate to the power developed.

When only one motor is operated, the generator speed can be varied. If the generator is driven by a waterwheel, its speed can be varied over a wide range and the motor speed will also vary. If the generator field is held at practically constant strength, the motor speed can be varied from zero to a maximum at constant torque with a practically constant current.

Controlling the speed of an induction motor by changing the frequency of the supply requires a separate generator for each motor or an electronic adjustable-speed drive for each motor.

158. Speed control of induction motors by adjusting the resistance of the secondary circuit.

Inserting resistance in series with the rotor of an induction motor will decrease the speed of the motor. The amount of decrease in speed produced will depend on the load on the motor. It is not possible to produce much change in speed by this method at light loads. This method of speed control is, of course, applicable only to wound-rotor

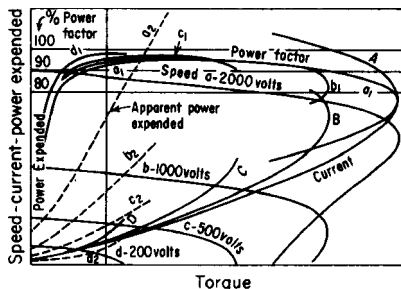

FIGURE 7.89 Performance graph of a polyphase induction motor with different applied frequencies and different applied voltages.

motors. Speed control by adjusting the resistance of the rotor circuit has two drawbacks. After the speed has been adjusted for any load, it does not remain constant with a change in load. With external resistance in series with the rotor, the motor has a varying-speed characteristic. Considerable power is wasted in the external resistance required for changing the speed. The amount of power wasted depends upon the value of the external resistance. The efficiency of the motor is thus decreased approximately proportionally to the reduction in speed.

Speed control by means of adjustable secondary resistance is, however, very useful when constant speeds are not essential, for example, in operating cranes, hoists, elevators, and dredges and also for service in which the torque remains constant at each speed, as in driving fans, blowers, and centrifugal pumps. In service for which reduced speeds are required only occasionally and speed variation is not objectionable, this method of control can also be used to good advantage. On account of energy loss in the resistors, efficiency is reduced when the motor is operated at reduced speeds, the reduction being greatest at the slowest speeds. The circuits are essentially the same as for starting by varying resistance in the rotor circuit. The rotor usually has a Y-connected winding in which is connected, in series in each phase, an external resistance. If the adjustable arm is moved, the amount of resistance in series in each phase can be varied from a maximum to zero and the speed varied gradually from the highest speed to the lowest.

159. Speed control of induction motors by introduction of a foreign voltage into the secondary circuit. If a foreign voltage is introduced into the secondary circuit of an induction motor, it will alter the speed of the motor. If this foreign voltage acts in a direction opposite to that of the voltage induced in the secondary circuit, the speed of the motor will be reduced. If the foreign voltage acts in the same direction as the voltage induced in the secondary circuit, the speed of the motor will be increased. With this method of speed control it is possible to obtain speeds both above and below the synchronous speed of the motor. Speed control by the introduction of a foreign voltage into the secondary circuit has two advantages. No power is wasted in resistance, and the speed is practically constant for all loads with the same value of foreign voltage introduced.

The brush-shifting type of polyphase induction motors, as explained in Sec. 177, employs the foreign-voltage method of speed control. When the operating characteristics of these motors are applicable, the motors provide a very efficient means of obtaining adjustable speed for ac installations.

An electronic method of foreign-voltage speed control is feasible for medium-size and small motors. The diagram of the circuit for such a method is shown in Fig. 7.90. The arma-

FIGURE 7.90 Control of a wound-motor induction motor using electronic means.

ture of a dc motor is connected through a three-phase full-wave ignitron or thyatron rectifier to the rotor slip rings of the induction motor. This connection introduces the counter-emf of the dc motor into the rotor circuit of the induction motor. The value of the counter-emf of the dc motor is adjusted by adjustment of the field rheostat of the dc motor. The speed of the induction motor is therefore controlled through adjustment of the field rheostat of the dc motor. The dc motor may be coupled mechanically to the induction motor so that it helps to drive the load, or the dc motor may drive an ac generator so that the greater portion of the power taken by the dc motor is returned to the ac supply system.

There are other methods of obtaining speed control by the foreign-voltage method, but all require additional revolving machines besides the motor itself. Their use is not feasible for ordinary applications, and they are employed in special cases for the speed control of large motors.

160. Speed control of polyphase motors by operating two or more motors connected in cascade offers, under some conditions of service, the most convenient and economical method of speed variation. In this arrangement all the rotors are mounted on one shaft, or the several shafts are rigidly connected. The primary of the first motor is connected to the line; its secondary, which must be of the phase-wound slipping type, is connected to the primary of the second motor, and so on. The secondary of the last motor can be of either the squirrel-cage or the phase-wound type. In practice more than two motors are rarely used. The arrangement is shown in Fig. 7.91.

FIGURE 7.91 Two polyphase motors connected in cascade.

Speed changes are obtained by varying the connections of the motors. The following combinations are possible with two motors: each motor can be operated separately at its normal speed with its primary connected to the line, the other motor running idle; the motors can be connected in cascade so that the rotors tend to start in the same direction (direct concatenation); or the motors can be connected so that the rotors tend to start in opposite directions (differential concatenation). If the first motor has 12 poles and the second 4, the following synchronous speeds can be obtained on a 25-Hz circuit:

1. Motor 2 (4 poles) running single, 750 rpm
2. Motors in differential concatenation (equivalent of 8 poles), 375 rpm
3. Motor 1 (12 poles) running single, 250 rpm
4. Motors in direct concatenation (equivalent of 16 poles), 187.5 rpm

By the use of adjustable resistance in the secondary circuits, changes from one speed to the next can be made with uniform gradations.

A great number of speed combinations are possible with this method; the control is simple and safe, as few leads are required and main circuits are not opened for most of the speeds. The rotors can be made with smaller diameters than is possible with other multi-speed motors; hence the flywheel effect is reduced to a minimum. In general, a cascade set is applicable when speed changes must be made frequently with high horsepower output and primary voltage and when speed ratios are other than 1:2.

161. Application of the methods of speed control of induction motors.

From the preceding sections, it is apparent that changing the speed of an induction motor by simple reduction of the impressed voltage (Sec. 155), changing the number of poles
