*Mechanical Engineering Handbook*

Ed. Frank Kreith

Boca Raton: CRC Press LLC, 1999

### **SECTION 1 Mechanics of Solids** *Bela I. Sandor*

- 1.1 Introduction *Bela I Sandor*
- 1.2 Statics *Bela I. Sandor*
- 1.3 Dynamics *Stephen M. Birn and Bela I. Sandor*
- 1.4 Vibrations *Bela I. Sandor*
- 1.5 Mechanics of Materials *Bela I. Sandor*
- 1.6 Structural Integrity and Durability *Bela I. Sandor*
- 1.7 Comprehensive Example of Using Mechanics of Solids Methods  
*Richard C. Duveneck, David A. Jahnke, Christopher J. Watson, and Bela I. Sandor*

### **SECTION 2 Engineering Thermodynamics** *Michael J. Moran*

- 2.1 Fundamentals *Michael J. Moran*
- 2.2 Control Volume Applications *Michael J. Moran*
- 2.3 Property Relations and Data *Michael J. Moran*
- 2.4 Combustion *Michael J. Moran*
- 2.5 Exergy Analysis *Michael J. Moran*
- 2.6 Vapor and Gas Power Cycles *Michael J. Moran*
- 2.7 Guidelines for Improving Thermodynamic Effectiveness  
*Michael J. Moran*

### **SECTION 3 Fluid Mechanics** *Frank Kreith*

- 3.1 Fluid Statics *Stanley A. Berger*
- 3.2 Equations of Motion and Potential Flow *Stanley A. Berger*
- 3.3 Similitude: Dimensional Analysis and Data Correlation *Suar W. Churchill*
- 3.4 Hydraulics of Pipe Systems *J. Paul Tullis*
- 3.5 Open Channel Flow *Frank M. White*
- 3.6 External Incompressible Flow *Alan T. McDonald*
- 3.7 Compressible Flow *Ajay Kumar*
- 3.8 Multiphase Flow *John C. Chen*
- 3.9 Non-Newtonian Flow *Thomas F. Irvine Jr. and Massimo Capobianchi*
- 3.10 Tribology, Lubrication, and Bearing Design *Francis E. Kennedy,  
E. Richard Booser, and Donald F. Wilcock*
- 3.11 Pumps and Fans *Rober F. Boehm*
- 3.12 Liquid Atomization and Spraying *Rolf D. Reitz*
- 3.13 Flow Measurement *Alan T. McDonald and Sherif A. Sherif*
- 3.14 Micro/Nanotribology *Bharat Bhushan*

### **SECTION 4 Heat and Mass Transfer** *Frank Kreith*

- 4.1 Conduction Heat Transfer *Rober F. Boehm*
- 4.2 Convection Heat Transfer *George D. Raithby, K.G. Terry Hollands,  
and N.V. Suryanarayana*
- 4.3 Radiation *Michael F. Modest*
- 4.4 Phase-Change *Van P. Carey, John C. Chen and Noam Lior*

- 4.5 Heat Exchangers *Ramesh K.Shah and Kenneth J.Bell*
- 4.6 Temperature and Heat Transfer Measurements *Robert J.Moffat*
- 4.7 Mass Transfer *Anthony F.Mills*
- 4.8 Applications *Arthur E.Bergles, Anthony F.Mills, Larry W.Swanson, and Vincent W.Antonetti*
- 4.9 Non-Newtonian Fluids —Heat Transfer *Thomas F.Irvine,Jr. and Massimo Capobianchi*

## **SECTION 5 Electrical Engineering *Giorgio Rizzoni***

- 5.1 Introduction *Giorgio Rizzoni*
- 5.2 Fundamentals of Electric Circuits *Giorgio Rizzoni*
- 5.3 Resistive Network Analysis *Giorgio Rizzoni*
- 5.4 AC Network Analysis *Giorgio Rizzoni*
- 5.5 AC Power *Giorgio Rizzoni*
- 5.6 Frequency Response,Filters,and Transient Analysis *Giorgio Rizzoni*
- 5.7 Electronics *Giorgio Rizzoni*
- 5.8 Power Electronics *Giorgio Rizzoni*
- 5.9 Operational Amplifiers *Giorgio Rizzoni*
- 5.10 Digital Circuits *Giorgio Rizzoni*
- 5.11 Measurements and Instrumentation *Giorgio Rizzoni*
- 5.12 Electromechanical Systems *Giorgio Rizzoni*

## **SECTION 6 Mechanical System Controls *Jan F. Kreider***

- 6.1 Human – Machine Interaction *Thomas B. Sheridan*
- 6.2 The Need for Control of Mechanical Systems *Peter S. Curtiss*
- 6.3 Control System Analysis *Peter S. Curtiss*
- 6.4 Control System Design and Application *Peter S. Curtiss*
- 6.5 Advanced Control Topics *Peter S. Curtiss, Jan Kreider, Ronald M.Nelson, and Shou-Heng Huang*

## **SECTION 7 Energy Resources *D. Yogi Goswami***

- 7.1 Introduction *D.Yogi Goswami*
- 7.2 Types of Derived Energy *D.Yogi Goswami*
- 7.3 Fossil Fuels *Robert Reuther, Richard Bajura, Larry Grayson, and Philip C. Crouse*
- 7.4 Biomass Energy *Michael C.Reed, Lynn L.Wright, Ralph P.Overend, and Carlton Wiles*
- 7.5 Nuclear Resources *James S. Tulenko*
- 7.6 Solar Energy Resources *D.Yogi Goswami*
- 7.7 Wind Energy Resources *Dale E.Berg*
- 7.8 Geothermal Energy *Joel L. Renner and Marshall J. Reed*

## **SECTION 8 Energy Conversion *D. Yogi Goswami***

- 8.1 Steam Power Plant *Lawrence Conway*
- 8.2 Gas Turbines *Steven I. Freedman*
- 8.3 Internal Combustion Engines *David E. Klett and Elsayed A.Adfify*
- 8.4 Hydraulic Turbines *Roger E.A. Arndt*
- 8.5 Stirling Engines *William B. Stine*
- 8.6 Advanced Fossil Fuel Power Systems *Anthony F. Armor*
- 8.7 Energy Storage *Chand K. Jotshi and D.Yogi Goswami*
- 8.8 Nuclear Power *Robert Pagano and James S. Tulenko*

- 8.9 Nuclear Fusion *Thomas E. Shannon*
- 8.10 Solar Thermal Energy Conversion *D.Yogi Goswami*
- 8.11 Wind Energy Conversion *Dale E. Berg*
- 8.12 Energy Conversion of the Geothermal Resource *Carl J. Bliem and Gregory L. Mines*
- 8.13 Direct Energy Conversion *Kitt C. Reinhardt, D.Yogi Goswami, Mysore L. Ramalingam, Jean-Pierre Fleurial, and William D. Jackson*
- 8.14 Ocean Energy Technology *Desikan Bharathan and Federica Zangrando*
- 8.15 Combined Cycle Power Plants *William W. Bathie*
- 8.16 EMERGY Evaluation and Transformity *Howard T. Odum*

## **SECTION 9 Air Conditioning and Refrigeration** *Shan K. Wang*

- 9.1 Introduction *Shan K. Wang*
- 9.2 Psychrometrics *Shan K. Wang*
- 9.3 Air Conditioning Processes and Cycles *Shan K. Wang*
- 9.4 Refrigerants and Refrigeration Cycles *Shan K. Wang*
- 9.5 Outdoor Design Conditions and Indoor Design Criteria *Shan K. Wang*
- 9.6 Load Calculations *Shan K. Wang*
- 9.7 Air Handling Units and Packaged Units *Shan K. Wang*
- 9.8 Refrigeration Components and Evaporative Coolers *Shan K. Wang*
- 9.9 Water Systems *Shan K. Wang*
- 9.10 Heating Systems *Shan K. Wang*
- 9.11 Refrigeration Systems *Shan K. Wang*
- 9.12 Thermal Storage Systems *Shan K. Wang*
- 9.13 Air Systems *Shan K. Wang*
- 9.14 Absorption Systems *Shan K. Wang*
- 9.15 Air Conditioning Systems and Selection *Shan K. Wang*
- 9.16 Desiccant Dehumidification and Air Conditioning *Zalman Lavan*

## **SECTION 10A Electronic Packaging**

- 10A.1 Electronic Packaging Technologies *Kevin D. Cluff and Michael G. Pecht*
- 10A.2 Thermal Management in Electronic Packaging and Systems *B.G. Sammakia and K. Ramakrishna*
- 10A.3 Mechanical Design and Reliability of Electronic Systems *Fred Barez*
- 10A.4 Electronic Manufacturing: Processes, Optimization, and Control *Roop L. Mahajan*

## **SECTION 10 Transportation** *Frank Kreith*

- 10.1 Transportation Planning *Michael D. Meyer*
- 10.2 Design of Transportation Facilities *John Leonard II and Michael D. Meyer*
- 10.3 Operations and Environmental Impact *Paul W. Shuldiner and Kenneth B. Black*
- 10.4 Transportation Systems *Paul Schonfeld*
- 10.5 Alternative Fuels for Motor Vehicles *Paul Norton*
- 10.6 Electric Vehicles *Frank Kreith*
- 10.7 Intelligent Transportation Systems *James B. Reed*

## **SECTION 11 Engineering Design** *Leonard D. Albano and Nam P. Suh*

- 11.1 Introduction *Nam P. Suh*
- 11.2 Elements of the Design Process *Nam P. Suh*
- 11.3 Concept of Domains *Nam P. Suh*
- 11.4 The Axiomatic Approach to Design *Nam P. Suh*

- 11.5 Algorithmic Approaches to Design *Leonard D. Albano*
- 11.6 Strategies for Product Design *Michael Pecht*
- 11.7 Design of Manufacturing Systems and Processes *Leonard D. Albano*
- 11.8 Precision Machine Design *Alexander Slocum*
- 11.9 Robotics *Leonard D. Albano*
- 11.10 Computer-Based Tools for Design Optimization *Mark Jakiela,  
Kemper Lewis, Farrokh Mistree, and J.R. Jagannatha Rao*

## **SECTION 12 Material** *Richard L. Lehman and Malcolm G. McLaren*

- 12.1 Metals *Victor A. Greenhut*
- 12.2 Polymers *James D. Idol and Richard L. Lehman*
- 12.3 Adhesives *Richard L. Lehman*
- 12.4 Wood *Daniel J. Strange*
- 12.5 Portland Cement Concrete *Steven H. Kosmatka*
- 12.6 Composites *Victor A. Greenhut*
- 12.7 Ceramics and Glass *Richard L. Lehman, Daniel J. Strange, and  
William F. Fischer III*

## **SECTION 13 Modern Manufacturing** *Jay Lee and Robert E. Schafrik*

- 13.1 Introduction *Jay Lee and Robert E. Schafrik*
- 13.2 Unit Manufacturing and Assembly Processes *Robert E. Schafrik*
- 13.3 Essential Elements in Manufacturing Processes and Equipment  
*John Fildes, Yoram Koren, M. Tomizuka, Kam Lau, and Tai-Ran Hsu*
- 13.4 Modern Design and Analysis Tools for Manufacturing  
*David C. Anderson, Tien-Chien Chang, Hank Grant, Tien-I. Liu,  
J.M.A. Tanchoco, Andrew C. Lee, and Su-Hsia Yang*
- 13.5 Rapid Prototyping *Takeo Nakagawa*
- 13.6 Underlying Paradigms in Manufacturing Systems and Enterprise  
for the 21st Century *H.E. Cook, James J. Solberg, and Chris Wang*

## **SECTION 14 Robotics** *Frank L. Lewis*

- 14.1 Introduction *Frank L. Lewis*
- 14.2 Commercial Robot Manipulators *John M. Fitzgerald*
- 14.3 Robot Configurations *Ian D. Walker*
- 14.4 End Effectors and Tooling *Mark R. Cutkosky and Peter McCormick*
- 14.5 Sensors and Actuators *Kok-Meng Lee*
- 14.6 Robot Programming Languages *Ron Bailey*
- 14.7 Robot Dynamics and Control *Frank L. Lewis*
- 14.8 Planning and Intelligent Control *Chen Zhou*
- 14.9 Design of Robotic Systems *Kok-Meng Lee*
- 14.10 Robot Manufacturing Applications *John W. Priest and G.T. Stevens, Jr.*
- 14.11 Industrial Material Handling and Process Applications of Robots  
*John M. Fitzgerald*
- 14.12 Mobile, Flexible-Link, and Parallel-Link Robots *Kai Liu*

## **SECTION 15 Computer-Aided Engineering** *Kyran D. Mish*

- 15.1 Introduction *Kyran D. Mish*
- 15.2 Computer Programming and Computer Architecture  
*Kyran D. Mish*
- 15.3 Computational Mechanics *Kyran D. Mish*

- 15.4 Computer Intelligence *Kyran D. Mish*  
15.5 Computer-Aided Design (CAD) *Joseph Mello*

## **SECTION 16 Environmental Engineering** *Jan F. Kreider*

- 16.1 Introduction *Ari Rabl and Jan F. Kreider*  
16.2 Benchmarks and Reference Conditions *Ari Rabl, Nevis Cook, Ronald H. Hewitt Cohen, and Tissa Illangasekare*  
16.3 Sources of Pollution and Regulations *Jan F. Kreider, Nevis Cook, Tissa Illangasekare, and Ronald H. Hewitt Cohen*  
16.4 Regulations and Emission Standards *Nevis Cook and Ronald H. Hewitt Cohen*  
16.5 Mitigation of Water and Air Pollution *Jan F. Kreider, Nevis Cook, and Ronald H. Hewitt Cohen*  
16.6 Environmental Modeling *Paolo Zannetti, Ronald H. Hewitt Cohen, Nevis Cook, Ari Rabl, and Peter S. Curtiss*  
16.7 Global Climate Change *Frank Kreith*

## **SECTION 17 Engineering Economics and Project Management**

***Chan S. Park and Donald D. Tippett***

- 17.1 Engineering Economic Decisions *Chan S. Park*  
17.2 Establishing Economic Equivalence *Chan S. Park*  
17.3 Measures of Project Worth *Chan S. Park*  
17.4 Cash Flow Projections *Chan S. Park*  
17.5 Sensitivity and Risk Analysis *Chan S. Park*  
17.6 Design Economics *Chan S. Park*  
17.7 Project Management *Donald D. Tippett*

## **SECTION 18 Communications and Information Systems**

***Lloyd W. Taylor***

- 18.1 Introduction *Lloyd W. Taylor*  
18.2 Network Components and Systems *Lloyd W. Taylor and Daniel F. DiFonzo*  
18.3 Communications and Information Theory *A. Britton Cooper III*  
18.4 Applications *Lloyd W. Taylor, Dhammika Kurumbalapitiya, and S. Ratnajeewan H. Hoole*

## **SECTION 19 Mathematics** *William F. Ames and George Cain*

- 19.1 Tables *William F. Ames*  
19.2 Linear Algebra and Matrices *George Cain*  
19.3 Vector Algebra and Calculus *George Cain*  
19.4 Difference Equations *William F. Ames*  
19.5 Differential Equations *William F. Ames*  
19.6 Integral Equations *William F. Ames*  
19.7 Approximation Methods *William F. Ames*  
19.8 Integral Transforms *William F. Ames*  
19.9 Calculus of Variations Approximation *William F. Ames*  
19.10 Optimization Methods *George Cain*  
19.11 Engineering and Statistics *Y.L. Tong*  
19.12 Numerical Methods *William F. Ames*  
19.13 Experimental Uncertainty Analysis *W.G. Steele and H.W. Coleman*  
19.14 Chaos *R.L. Kautz*  
19.15 Fuzzy Sets and Fuzzy Logic *Dan M. Frangopol*

## **SECTION 20 Patent Law and Miscellaneous Topics** *Frank Kreith*

20.1 Patents and Other Intellectual Property *Thomas H. Young*

20.2 Product Liability and Safety *George A. Peters*

20.3 Bioengineering *Jeff R. Crandall, Gregory W. Hall, and  
Walter D. Pilkey*

20.4 Mechanical Engineering Codes and Standard *Michael Merker*

20.5 Optics *Roland Winston and Walter T. Welford*

20.6 Water Desalination *Noam Lior*

20.7 Noise Control *Malcolm J. Crocker*

20.8 Lighting Technology *Barbara Atkinson, Andrea Denver, James E. McMahon,  
Leslie Shown, Robert Clear, and Craig B Smith*

20.9 New Product Development *Philip R. Teakle and Duncan B. Gilmore*

## 1.1 Introduction

---

*Bela I. Sandor*

Engineers use the concepts and methods of mechanics of solids in designing and evaluating tools, machines, and structures, ranging from wrenches to cars to spacecraft. The required educational background for these includes courses in statics, dynamics, mechanics of materials, and related subjects. For example, dynamics of rigid bodies is needed in generalizing the spectrum of service loads on a car, which is essential in defining the vehicle's deformations and long-term durability. In regard to structural

**FIGURE 1.1.1** Artist's concept of a moving stainless steel roadway to drive the suspension system through a spinning, articulated wheel, simulating three-dimensional motions and forces. (MTS Systems Corp., Minneapolis, MN. With permission.) Notes: Flat-Trac® Roadway Simulator, R&D100 Award-winning system in 1993. See also Color Plate 1.\*

integrity and durability, the designer should think not only about preventing the catastrophic failures of products, but also of customer satisfaction. For example, a car with gradually loosening bolts (which is difficult to prevent in a corrosive and thermal and mechanical cyclic loading environment) is a poor product because of safety, vibration, and noise problems. There are sophisticated methods to assure a product's performance and reliability, as exemplified in [Figure 1.1.1](#). A similar but even more realistic test setup is shown in [Color Plate 1](#).

It is common experience among engineers that they have to review some old knowledge or learn something new, but what is needed at the moment is not at their fingertips. This chapter may help the reader in such a situation. Within the constraints of a single book on mechanical engineering, it provides overviews of topics with modern perspectives, illustrations of typical applications, modeling to solve problems quantitatively with realistic simplifications, equations and procedures, useful hints and reminders of common errors, trends of relevant material and mechanical system behaviors, and references to additional information.

The chapter is like an emergency toolbox. It includes a coherent assortment of basic tools, such as vector expressions useful for calculating bending stresses caused by a three-dimensional force system on a shaft, and sophisticated methods, such as life prediction of components using fracture mechanics and modern measurement techniques. In many cases much more information should be considered than is covered in this chapter.

## 1.2 Statics

Bela I. Sandor

### Vectors. Equilibrium of Particles. Free-Body Diagrams

Two kinds of quantities are used in engineering mechanics. A scalar quantity has only magnitude (mass, time, temperature, ...). A vector quantity has magnitude and direction (force, velocity, ...). Vectors are represented here by arrows and bold-face symbols, and are used in analysis according to universally applicable rules that facilitate calculations in a variety of problems. The vector methods are indispensable in three-dimensional mechanics analyses, but in simple cases equivalent scalar calculations are sufficient.

#### Vector Components and Resultants. Parallelogram Law

A given vector  $\mathbf{F}$  may be replaced by two or three other vectors that have the same net effect and representation. This is illustrated for the chosen directions  $m$  and  $n$  for the components of  $\mathbf{F}$  in two dimensions (Figure 1.2.1). Conversely, two concurrent vectors  $\mathbf{F}$  and  $\mathbf{P}$  of the same units may be combined to get a resultant  $\mathbf{R}$  (Figure 1.2.2).

FIGURE 1.2.1 Addition of concurrent vectors  $\mathbf{F}$  and  $\mathbf{P}$ .

FIGURE 1.2.2 Addition of concurrent, coplanar vectors  $\mathbf{A}$ ,  $\mathbf{B}$ , and  $\mathbf{C}$ .

Any set of components of a vector  $\mathbf{F}$  must satisfy the *parallelogram law*. According to Figure 1.2.1, the law of sines and law of cosines may be useful.

$$\frac{F_n}{\sin \alpha} = \frac{F_m}{\sin \beta} = \frac{F}{\sin[180^\circ - (\alpha + \beta)]} \tag{1.2.1}$$

$$F^2 = F_n^2 + F_m^2 - 2F_n F_m \cos[180^\circ - (\alpha + \beta)]$$

Any number of concurrent vectors may be summed, mathematically or graphically, and in any order, using the above concepts as illustrated in Figure 1.2.3.

FIGURE 1.2.3 Addition of concurrent, coplanar vectors  $\mathbf{A}$ ,  $\mathbf{B}$ , and  $\mathbf{C}$ .

**Unit Vectors**

Mathematical manipulations of vectors are greatly facilitated by the use of unit vectors. A unit vector  $\mathbf{n}$  has a magnitude of unity and a defined direction. The most useful of these are the unit coordinate vectors  $\mathbf{i}$ ,  $\mathbf{j}$ , and  $\mathbf{k}$  as shown in Figure 1.2.4.

**FIGURE 1.2.4** Unit vectors in Cartesian coordinates (the same  $\mathbf{i}$ ,  $\mathbf{j}$ , and  $\mathbf{k}$  set applies in a parallel  $x'y'z'$  system of axes).

The three-dimensional components and associated quantities of a vector  $\mathbf{F}$  are shown in Figure 1.2.5. The unit vector  $\mathbf{n}$  is collinear with  $\mathbf{F}$ .

**FIGURE 1.2.5** Three-dimensional components of a vector  $\mathbf{F}$ .

The vector  $\mathbf{F}$  is written in terms of its scalar components and the unit coordinate vectors,

$$\mathbf{F} = F_x \mathbf{i} + F_y \mathbf{j} + F_z \mathbf{k} = F \mathbf{n} \tag{1.2.2}$$

where

$$F_x = F \cos \theta_x \quad F_y = F \cos \theta_y \quad F_z = F \cos \theta_z$$

$$F = \sqrt{F_x^2 + F_y^2 + F_z^2}$$

$$n_x = \cos \theta_x \quad n_y = \cos \theta_y \quad n_z = \cos \theta_z$$

$$n_x^2 + n_y^2 + n_z^2 = 1$$

$$\frac{n_x}{F_x} = \frac{n_y}{F_y} = \frac{n_z}{F_z} = \frac{1}{F}$$

The unit vector notation is convenient for the summation of concurrent vectors in terms of scalar or vector components:

Scalar components of the resultant  $\mathbf{R}$ :

$$R_x = \sum F_x \quad R_y = \sum F_y \quad R_z = \sum F_z \tag{1.2.3}$$

Vector components:

$$\mathbf{R}_x = \sum \mathbf{F}_x = \sum F_x \mathbf{i} \quad \mathbf{R}_y = \sum \mathbf{F}_y = \sum F_y \mathbf{j} \quad \mathbf{R}_z = \sum \mathbf{F}_z = \sum F_z \mathbf{k} \quad (1.2.4)$$

### Vector Determination from Scalar Information

A force, for example, may be given in terms of its magnitude  $F$ , its sense of direction, and its line of action. Such a force can be expressed in vector form using the coordinates of any two points on its line of action. The vector sought is

$$\mathbf{F} = F_x \mathbf{i} + F_y \mathbf{j} + F_z \mathbf{k} = F \mathbf{n}$$

The method is to find  $\mathbf{n}$  on the line of points  $A(x_1, y_1, z_1)$  and  $B(x_2, y_2, z_2)$ :

$$\mathbf{n} = \frac{\text{vector A to B}}{\text{distance A to B}} = \frac{d_x \mathbf{i} + d_y \mathbf{j} + d_z \mathbf{k}}{\sqrt{d_x^2 + d_y^2 + d_z^2}}$$

where  $d_x = x_2 - x_1$ ,  $d_y = y_2 - y_1$ ,  $d_z = z_2 - z_1$ .

### Scalar Product of Two Vectors. Angles and Projections of Vectors

The scalar product, or dot product, of two concurrent vectors  $\mathbf{A}$  and  $\mathbf{B}$  is defined by

$$\mathbf{A} \cdot \mathbf{B} = AB \cos \phi \quad (1.2.5)$$

where  $A$  and  $B$  are the magnitudes of the vectors and  $\phi$  is the angle between them. Some useful expressions are

$$\mathbf{A} \cdot \mathbf{B} = \mathbf{B} \cdot \mathbf{A} = A_x B_x + A_y B_y + A_z B_z$$

$$\phi = \arccos \frac{A_x B_x + A_y B_y + A_z B_z}{AB}$$

The projection  $F'$  of a vector  $\mathbf{F}$  on an arbitrary line of interest is determined by placing a unit vector  $\mathbf{n}$  on that line of interest, so that

$$F' = \mathbf{F} \cdot \mathbf{n} = F_x n_x + F_y n_y + F_z n_z$$

### Equilibrium of a Particle

A particle is in **equilibrium** when the resultant of all forces acting on it is zero. In such cases the algebraic summation of rectangular scalar components of forces is valid and convenient:

$$\sum F_x = 0 \quad \sum F_y = 0 \quad \sum F_z = 0 \quad (1.2.6)$$

### Free-Body Diagrams

Unknown forces may be determined readily if a body is in equilibrium and can be modeled as a particle. The method involves **free-body diagrams**, which are simple representations of the actual bodies. The appropriate model is imagined to be isolated from all other bodies, with the significant effects of other bodies shown as force vectors on the free-body diagram.

**Example 1**

A mast has three guy wires. The initial tension in each wire is planned to be 200 lb. Determine whether this is feasible to hold the mast vertical (Figure 1.2.6).

**FIGURE 1.2.6** A mast with guy wires.

*Solution.*

$$\mathbf{R} = \mathbf{T}_{AB} + \mathbf{T}_{AC} + \mathbf{T}_{AD}$$

The three tensions of known magnitude (200 lb) must be written as vectors.

$$\begin{aligned} \mathbf{T}_{AB} &= (\text{tension } AB)(\text{unit vector } A \text{ to } B) = 200 \text{ lb } \mathbf{n}_{AB} = 200 \text{ lb } \frac{(d_x \mathbf{i} + d_y \mathbf{j} + d_z \mathbf{k})}{d} \\ &= \frac{200 \text{ lb}}{\sqrt{5^2 + 10^2 + 4^2}} (-5\mathbf{i} - 10\mathbf{j} + 4\mathbf{k}) \frac{\text{ft}}{\text{ft}} = -84.2 \text{ lb } \mathbf{i} - 168.4 \text{ lb } \mathbf{j} + 67.4 \text{ lb } \mathbf{k} \end{aligned}$$

$$\mathbf{T}_{AC} = \frac{200 \text{ lb}}{11.87 \text{ ft}} (5\mathbf{i} - 10\mathbf{j} + 4\mathbf{k}) \text{ ft} = 84.2 \text{ lb } \mathbf{i} + 168.4 \text{ lb } \mathbf{j} + 67.4 \text{ lb } \mathbf{k}$$

$$\mathbf{T}_{AD} = \frac{200 \text{ lb}}{11.66 \text{ ft}} (0\mathbf{i} - 10\mathbf{j} + 6\mathbf{k}) \text{ ft} = -171.5 \text{ lb } \mathbf{j} - 102.9 \text{ lb } \mathbf{k}$$

The resultant of the three tensions is

$$\begin{aligned} \mathbf{R} &= \sum F_x \mathbf{i} + \sum F_y \mathbf{j} + \sum F_z \mathbf{k} = (-84.2 + 84.2 + 0) \text{ lb } \mathbf{i} + (-168.4 - 168.4 - 171.5) \text{ lb } \mathbf{j} \\ &\quad + (67.4 + 67.4 - 102.9) \text{ lb } \mathbf{k} = 0 \text{ lb } \mathbf{i} - 508 \text{ lb } \mathbf{j} + 31.9 \text{ lb } \mathbf{k} \end{aligned}$$

There is a horizontal resultant of 31.9 lb at A, so the mast would not remain vertical.

**Forces on Rigid Bodies**

All solid materials deform when forces are applied to them, but often it is reasonable to model components and structures as rigid bodies, at least in the early part of the analysis. The forces on a rigid body are generally not concurrent at the center of mass of the body, which cannot be modeled as a particle if the force system tends to cause a rotation of the body.

### Moment of a Force

The turning effect of a force on a body is called the moment of the force, or torque. The moment  $M_A$  of a force  $\mathbf{F}$  about a point  $A$  is defined as a scalar quantity

$$M_A = Fd \tag{1.2.7}$$

where  $d$  (the moment arm or lever arm) is the nearest distance from  $A$  to the line of action of  $\mathbf{F}$ . This nearest distance may be difficult to determine in a three-dimensional scalar analysis; a vector method is needed in that case.

### Equivalent Forces

Sometimes the equivalence of two forces must be established for simplifying the solution of a problem. The necessary and sufficient conditions for the equivalence of forces  $\mathbf{F}$  and  $\mathbf{F}'$  are that they have the same magnitude, direction, line of action, and moment on a given rigid body in static equilibrium. Thus,

$$\mathbf{F} = \mathbf{F}' \quad \text{and} \quad M_A = M'_A$$

For example, the ball joint  $A$  in [Figure 1.2.7](#) experiences the same moment whether the vertical force is pushing or pulling downward on the yoke pin.

FIGURE 1.2.7 Schematic of testing a ball joint of a car.

### Vector Product of Two Vectors

A powerful method of vector mechanics is available for solving complex problems, such as the moment of a force in three dimensions. The *vector product* (or cross product) of two concurrent vectors  $\mathbf{A}$  and  $\mathbf{B}$  is defined as the vector  $\mathbf{V} = \mathbf{A} \times \mathbf{B}$  with the following properties:

1.  $\mathbf{V}$  is perpendicular to the plane of vectors  $\mathbf{A}$  and  $\mathbf{B}$ .
2. The sense of  $\mathbf{V}$  is given by the right-hand rule ([Figure 1.2.8](#)).
3. The magnitude of  $\mathbf{V}$  is  $V = AB \sin\theta$ , where  $\theta$  is the angle between  $\mathbf{A}$  and  $\mathbf{B}$ .
4.  $\mathbf{A} \times \mathbf{B} \neq \mathbf{B} \times \mathbf{A}$ , but  $\mathbf{A} \times \mathbf{B} = -(\mathbf{B} \times \mathbf{A})$ .
5. For three vectors,  $\mathbf{A} \times (\mathbf{B} + \mathbf{C}) = \mathbf{A} \times \mathbf{B} + \mathbf{A} \times \mathbf{C}$ .

FIGURE 1.2.8 Right-hand rule for vector products.

The vector product is calculated using a determinant,

$$\mathbf{V} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ A_x & A_y & A_z \\ B_x & B_y & B_z \end{vmatrix} = A_y B_z \mathbf{i} + A_z B_x \mathbf{j} + A_x B_y \mathbf{k} - A_y B_x \mathbf{k} - A_x B_z \mathbf{j} - A_z B_y \mathbf{i} \quad (1.2.8)$$

### Moment of a Force about a Point

The vector product is very useful in determining the moment of a force  $\mathbf{F}$  about an arbitrary point  $O$ . The vector definition of moment is

$$\mathbf{M}_O = \mathbf{r} \times \mathbf{F} \quad (1.2.9)$$

where  $\mathbf{r}$  is the position vector from point  $O$  to any point on the line of action of  $\mathbf{F}$ . A double arrow is often used to denote a moment vector in graphics.

The moment  $\mathbf{M}_O$  may have three scalar components,  $M_x$ ,  $M_y$ ,  $M_z$ , which represent the turning effect of the force  $\mathbf{F}$  about the corresponding coordinate axes. In other words, a single force has only one moment about a given point, but this moment may have up to three components with respect to a coordinate system,

$$\mathbf{M}_O = M_x \mathbf{i} + M_y \mathbf{j} + M_z \mathbf{k}$$

### Triple Products of Three Vectors

Two kinds of products of three vectors are used in engineering mechanics. The *mixed triple product* (or scalar product) is used in calculating moments. It is the dot product of vector  $\mathbf{A}$  with the vector product of vectors  $\mathbf{B}$  and  $\mathbf{C}$ ,

$$\mathbf{A} \cdot (\mathbf{B} \times \mathbf{C}) = \begin{vmatrix} A_x & A_y & A_z \\ B_x & B_y & B_z \\ C_x & C_y & C_z \end{vmatrix} = A_x(B_y C_z - B_z C_y) + A_y(B_z C_x - B_x C_z) + A_z(B_x C_y - B_y C_x) \quad (1.2.10)$$

The *vector triple product*  $(\mathbf{A} \times \mathbf{B}) \times \mathbf{C} = \mathbf{V} \times \mathbf{C}$  is easily calculated (for use in dynamics), but note that

$$(\mathbf{A} \times \mathbf{B}) \times \mathbf{C} \neq \mathbf{A} \times (\mathbf{B} \times \mathbf{C})$$

### Moment of a Force about a Line

It is common that a body rotates about an axis. In that case the moment  $M_\ell$  of a force  $\mathbf{F}$  about the axis, say line  $\ell$ , is usefully expressed as

$$\mathbf{M}_\ell = \mathbf{n} \cdot \mathbf{M}_O = \mathbf{n} \cdot (\mathbf{r} \times \mathbf{F}) = \begin{vmatrix} n_x & n_y & n_z \\ r_x & r_y & r_z \\ F_x & F_y & F_z \end{vmatrix} \quad (1.2.11)$$

where  $\mathbf{n}$  is a unit vector along the line  $\ell$ , and  $\mathbf{r}$  is a position vector from point  $O$  on  $\ell$  to a point on the line of action of  $\mathbf{F}$ . Note that  $M_\ell$  is the projection of  $\mathbf{M}_O$  on line  $\ell$ .

**Special Cases**

1. The moment about a line  $\ell$  is zero when the line of action of  $\mathbf{F}$  intersects  $\ell$  (the moment arm is zero).
2. The moment about a line  $\ell$  is zero when the line of action of  $\mathbf{F}$  is parallel to  $\ell$  (the projection of  $\mathbf{M}_O$  on  $\ell$  is zero).

**Moment of a Couple**

A pair of forces equal in magnitude, parallel in lines of action, and opposite in direction is called a *couple*. The magnitude of the moment of a couple is

$$M = Fd$$

where  $d$  is the distance between the lines of action of the forces of magnitude  $F$ . The moment of a couple is a free vector  $\mathbf{M}$  that can be applied anywhere to a rigid body with the same turning effect, as long as the direction and magnitude of  $\mathbf{M}$  are the same. In other words, a couple vector can be moved to any other location on a given rigid body if it remains parallel to its original position (equivalent couples). Sometimes a curled arrow in the plane of the two forces is used to denote a couple, instead of the couple vector  $\mathbf{M}$ , which is perpendicular to the plane of the two forces.

**Force-Couple Transformations**

Sometimes it is advantageous to transform a force to a force system acting at another point, or vice versa. The method is illustrated in [Figure 1.2.9](#).

**FIGURE 1.2.9** Force-couple transformations.

1. A force  $\mathbf{F}$  acting at  $B$  on a rigid body can be replaced by the same force  $\mathbf{F}$  acting at  $A$  and a moment  $\mathbf{M}_A = \mathbf{r} \times \mathbf{F}$  about  $A$ .
2. A force  $\mathbf{F}$  and moment  $\mathbf{M}_A$  acting at  $A$  can be replaced by a force  $\mathbf{F}$  acting at  $B$  for the same total effect on the rigid body.

**Simplification of Force Systems**

Any force system on a rigid body can be reduced to an equivalent system of a resultant force  $\mathbf{R}$  and a resultant moment  $\mathbf{M}_R$ . The **equivalent force-couple system** is formally stated as

$$\mathbf{R} = \sum_{i=1}^n \mathbf{F}_i \quad \text{and} \quad \mathbf{M}_R = \sum_{i=1}^n \mathbf{M}_i = \sum_{i=1}^n (\mathbf{r}_i \times \mathbf{F}_i) \tag{1.2.12}$$

where  $\mathbf{M}_R$  depends on the chosen reference point.

**Common Cases**

1. The resultant force is zero, but there is a resultant moment:  $\mathbf{R} = 0, \mathbf{M}_R \neq 0$ .
2. Concurrent forces (all forces act at one point):  $\mathbf{R} \neq 0, \mathbf{M}_R = 0$ .
3. Coplanar forces:  $\mathbf{R} \neq 0, \mathbf{M}_R \neq 0$ .  $\mathbf{M}_R$  is perpendicular to the plane of the forces.
4. Parallel forces:  $\mathbf{R} \neq 0, \mathbf{M}_R \neq 0$ .  $\mathbf{M}_R$  is perpendicular to  $\mathbf{R}$ .

**Example 2**

The torque wrench in Figure 1.2.10 has an arm of constant length  $L$  but a variable socket length  $d = OA$  because of interchangeable tool sizes. Determine how the moment applied at point  $O$  depends on the length  $d$  for a constant force  $\mathbf{F}$  from the hand.

**FIGURE 1.2.10** Model of a torque wrench.

*Solution.* Using  $\mathbf{M}_O = \mathbf{r} \times \mathbf{F}$  with  $\mathbf{r} = L\mathbf{i} + d\mathbf{j}$  and  $\mathbf{F} = F\mathbf{k}$  in Figure 1.2.10,

$$\mathbf{M}_O = (L\mathbf{i} + d\mathbf{j}) \times F\mathbf{k} = Fd\mathbf{i} - FL\mathbf{j}$$

**Judgment of the Result**

According to a visual analysis the wrench should turn clockwise, so the  $-\mathbf{j}$  component of the moment is justified. Looking at the wrench from the positive  $x$  direction, point  $A$  has a tendency to rotate counterclockwise. Thus, the  $\mathbf{i}$  component is correct using the right-hand rule.

**Equilibrium of Rigid Bodies**

The concept of equilibrium is used for determining unknown forces and moments of forces that act on or within a rigid body or system of rigid bodies. The equations of equilibrium are the most useful equations in the area of statics, and they are also important in dynamics and mechanics of materials. The drawing of appropriate free-body diagrams is essential for the application of these equations.

**Conditions of Equilibrium**

*A rigid body is in static equilibrium when the equivalent force-couple system of the external forces acting on it is zero.* In vector notation, this condition is expressed as

$$\begin{aligned} \sum \mathbf{F} &= 0 \\ \sum \mathbf{M}_O &= \sum (\mathbf{r} \times \mathbf{F}) = 0 \end{aligned} \tag{1.2.13}$$

where  $O$  is an arbitrary point of reference.

In practice it is often most convenient to write Equation 1.2.13 in terms of rectangular scalar components,

$$\begin{aligned} \sum F_x &= 0 & \sum M_x &= 0 \\ \sum F_y &= 0 & \sum M_y &= 0 \\ \sum F_z &= 0 & \sum M_z &= 0 \end{aligned}$$

**Maximum Number of Independent Equations for One Body**

1. One-dimensional problem:  $\sum F = 0$
2. Two-dimensional problem:

$$\sum F_x = 0 \quad \sum F_y = 0 \quad \sum M_A = 0$$

or  $\sum F_x = 0 \quad \sum M_A = 0 \quad \sum M_B = 0 \quad (x \text{ axis not } \perp AB)$

or  $\sum M_A = 0 \quad \sum M_B = 0 \quad \sum M_C = 0 \quad (AB \text{ not } \parallel BC)$

3. Three-dimensional problem:

$$\sum F_x = 0 \quad \sum F_y = 0 \quad \sum F_z = 0$$

$$\sum M_x = 0 \quad \sum M_y = 0 \quad \sum M_z = 0$$

where  $xyz$  are orthogonal coordinate axes, and  $A, B, C$  are particular points of reference.

**Calculation of Unknown Forces and Moments**

In solving for unknown forces and moments, always draw the free-body diagram first. Unknown external forces and moments must be shown at the appropriate places of action on the diagram. The directions of unknowns may be assumed arbitrarily, but should be done consistently for systems of rigid bodies. A negative answer indicates that the initial assumption of the direction was opposite to the actual direction. Modeling for problem solving is illustrated in Figures 1.2.11 and 1.2.12.

**FIGURE 1.2.11** Example of two-dimensional modeling.

**FIGURE 1.2.12** Example of three-dimensional modeling.

**Notes on Three-Dimensional Forces and Supports**

Each case should be analyzed carefully. Sometimes a particular force or moment is possible in a device, but it must be neglected for most practical purposes. For example, a very short sleeve bearing cannot

support significant moments. A roller bearing may be designed to carry much larger loads perpendicular to the shaft than along the shaft.

**Related Free-Body Diagrams**

When two or more bodies are in contact, separate free-body diagrams may be drawn for each body. The mutual forces and moments between the bodies are related according to Newton’s third law (action and reaction). The directions of unknown forces and moments may be arbitrarily assumed in one diagram, but these initial choices affect the directions of unknowns in all other related diagrams. The number of unknowns and of usable equilibrium equations both increase with the number of related free-body diagrams.

**Schematic Example in Two Dimensions (Figure 1.2.13)**

FIGURE 1.2.13 Free-body diagram.

Given:  $F_1, F_2, F_3, M$

Unknowns:  $P_1, P_2, P_3$ , and forces and moments at joint A (rigid connection)

**Equilibrium Equations**

$$\sum F_x = -F_1 + P_3 = 0$$

$$\sum F_y = P_1 + P_2 - F_2 - F_3 = 0$$

$$\sum M_O = P_1c + P_2(c + d + e) + M - F_2a - F_3(a + b) = 0$$

Three unknowns ( $P_1, P_2, P_3$ ) are in three equations.

**Related Free-Body Diagrams (Figure 1.2.14)**

FIGURE 1.2.14 Related free-body diagrams.

Dimensions  $a, b, c, d$ , and  $e$  of Figure 1.2.13 are also valid here.

**New Set of Equilibrium Equations**

Left part:  
 (OA)  $\sum F_x = -F_1 + A_x = 0$   
 $\sum F_y = P_1 + A_y - F_2 = 0$   
 $\sum M_O = P_1c + A_y(c + d) + M_A - F_2a = 0$

Right side:  
 (AB)  $\sum F_x = -A_x + P_3 = 0$   
 $\sum F_y = P_2 - A_y - F_3 = 0$   
 $\sum M_A = -M_A + P_2e + M - F_3f = 0$

Six unknowns ( $P_1, P_2, P_3, A_x, A_y, M_A$ ) are in six equations.

*Note:* In the first diagram (Figure 1.2.13) the couple  $M$  may be moved anywhere from  $O$  to  $B$ .  $M$  is not shown in the second diagram ( $O$  to  $A$ ) because it is shown in the third diagram (in which it may be moved anywhere from  $A$  to  $B$ ).

**Example 3**

The arm of a factory robot is modeled as three bars (Figure 1.2.15) with coordinates  $A: (0.6, -0.3, 0.4)$  m;  $B: (1, -0.2, 0)$  m; and  $C: (0.9, 0.1, -0.25)$  m. The weight of the arm is represented by  $\mathbf{W}_A = -60 \text{ Nj}$  at  $A$ , and  $\mathbf{W}_B = -40 \text{ Nj}$  at  $B$ . A moment  $\mathbf{M}_C = (100\mathbf{i} - 20\mathbf{j} + 50\mathbf{k}) \text{ N} \cdot \text{m}$  is applied to the arm at  $C$ . Determine the force and moment reactions at  $O$ , assuming that all joints are temporarily fixed.

**FIGURE 1.2.15** Model of a factory robot.

*Solution.* The free-body diagram is drawn in Figure 1.2.15b, showing the unknown force and moment reactions at  $O$ . From Equation 1.2.13,

$$\sum \mathbf{F} = 0$$

$$\mathbf{F}_O + \mathbf{W}_A + \mathbf{W}_B = 0$$

$$\mathbf{F}_O - 60 \text{ N j} - 40 \text{ N j} = 0$$

$$\mathbf{F}_O = 100 \text{ N } \mathbf{j}$$

$$\sum M_O = 0$$

$$\mathbf{M}_O + \mathbf{M}_C + (\mathbf{r}_{OA} \times \mathbf{W}_A) + (\mathbf{r}_{OB} \times \mathbf{W}_B) = 0$$

$$\mathbf{M}_O + (100\mathbf{i} - 20\mathbf{j} + 50\mathbf{k}) \text{ N} \cdot \text{m} + (0.6\mathbf{i} - 0.3\mathbf{j} + 0.4\mathbf{k}) \text{ m} \times (-60 \text{ N } \mathbf{j}) + (\mathbf{i} - 0.2\mathbf{j}) \text{ m} \times (-40 \text{ N } \mathbf{j}) = 0$$

$$\mathbf{M}_O + 100 \text{ N} \cdot \text{m } \mathbf{i} - 20 \text{ N} \cdot \text{m } \mathbf{j} + 50 \text{ N} \cdot \text{m } \mathbf{k} - 36 \text{ N} \cdot \text{m } \mathbf{k} + 24 \text{ N} \cdot \text{m } \mathbf{i} - 40 \text{ N} \cdot \text{m } \mathbf{k} = 0$$

$$\mathbf{M}_O = (-124\mathbf{i} + 20\mathbf{j} + 26\mathbf{k}) \text{ N} \cdot \text{m}$$

**Example 4**

A load of 7 kN may be placed anywhere within *A* and *B* in the trailer of negligible weight. Determine the reactions at the wheels at *D*, *E*, and *F*, and the force on the hitch *H* that is mounted on the car, for the extreme positions *A* and *B* of the load. The mass of the car is 1500 kg, and its weight is acting at *C* (see Figure 1.2.16).

FIGURE 1.2.16 Analysis of a car with trailer.

*Solution.* The scalar method is best here.

Put the load at position *A* first  
 For the trailer alone, with *y* as the vertical axis  
 $\sum M_F = 7(1) - H_y(3) = 0, H_y = 2.33 \text{ kN}$   
 On the car  
 $H_y = 2.33 \text{ kN} \quad \downarrow \text{Ans.}$   
 $\sum F_y = 2.33 - 7 + F_y = 0, F_y = 4.67 \text{ kN} \quad \uparrow \text{Ans.}$   
 For the car alone  
 $\sum M_E = -2.33(1.2) - D_y(4) + 14.72(1.8) = 0$   
 $D_y = 5.93 \text{ kN} \quad \uparrow \text{Ans.}$   
 $\sum F_y = 5.93 + E_y - 14.72 - 2.33 = 0$   
 $E_y = 11.12 \text{ kN} \quad \uparrow \text{Ans.}$

Put the load at position *B* next  
 For the trailer alone  
 $\sum M_F = 0.8(7) - H_y(3) = 0, H_y = -1.87 \text{ kN}$   
 On the car  
 $H_y = 1.87 \text{ kN} \quad \downarrow \text{Ans.}$   
 $\sum F_y = -1.87 - 7 + E_y = 0$   
 $E_y = 8.87 \text{ kN} \quad \uparrow \text{Ans.}$   
 For the car alone  
 $\sum M_E = -(1.87)(1.2) - D_y(4) + 14.72(1.8) = 0$   
 $D_y = 7.19 \text{ kN} \quad \uparrow \text{Ans.}$   
 $\sum F_y = 7.19 + E_y - 14.72 - (-1.87) = 0$   
 $E_y = 5.66 \text{ kN} \quad \uparrow \text{Ans.}$

**Forces and Moments in Beams**

Beams are common structural members whose main function is to resist bending. The geometric changes and safety aspects of beams are analyzed by first assuming that they are rigid. The preceding sections enable one to determine (1) the external (supporting) reactions acting on a statically determinate beam, and (2) the internal forces and moments at any cross section in a beam.

### Classification of Supports

Common supports and external reactions for two-dimensional loading of beams are shown in Figure 1.2.17.

FIGURE 1.2.17 Common beam supports.

### Internal Forces and Moments

The internal force and moment reactions in a beam caused by external loading must be determined for evaluating the strength of the beam. If there is no torsion of the beam, three kinds of internal reactions are possible: a horizontal normal force  $H$  on a cross section, vertical (transverse) shear force  $V$ , and bending moment  $M$ . These reactions are calculated from the equilibrium equations applied to the left or right part of the beam from the cross section considered. The process involves free-body diagrams of the beam and a consistently applied system of signs. The modeling is illustrated for a cantilever beam in Figure 1.2.18.

FIGURE 1.2.18 Internal forces and moments in a cantilever beam.

*Sign Conventions.* Consistent sign conventions should be used in any given problem. These could be arbitrarily set up, but the following is slightly advantageous. It makes the signs of the answers to the equilibrium equations correct for the directions of the shear force and bending moment.

A moment that makes a beam concave upward is taken as positive. Thus, a clockwise moment is positive on the left side of a section, and a counterclockwise moment is positive on the right side. A

shear force that acts upward on the left side of a section, or downward on the right side, is positive (Figure 1.2.19).

FIGURE 1.2.19 Preferred sign conventions.

### Shear Force and Bending Moment Diagrams

The critical locations in a beam are determined from shear force and bending moment diagrams for the whole length of the beam. The construction of these diagrams is facilitated by following the steps illustrated for a cantilever beam in Figure 1.2.20.

FIGURE 1.2.20 Construction of shear force and bending moment diagrams.

1. Draw the free-body diagram of the whole beam and determine all reactions at the supports.
2. Draw the coordinate axes for the shear force ( $V$ ) and bending moment ( $M$ ) diagrams directly below the free-body diagram.
3. Immediately plot those values of  $V$  and  $M$  that can be determined by inspection (especially where they are zero), observing the sign conventions.
4. Calculate and plot as many additional values of  $V$  and  $M$  as are necessary for drawing reasonably accurate curves through the plotted points, or do it all by computer.

### Example 5

A construction crane is modeled as a rigid bar AC which supports the boom by a pin at B and wire CD. The dimensions are  $AB = 10\ell$ ,  $BC = 2\ell$ ,  $BD = DE = 4\ell$ . Draw the shear force and bending moment diagrams for bar AC (Figure 1.2.21).

*Solution.* From the free-body diagram of the entire crane,

$$\begin{aligned} \sum F_x = 0 & & \sum F_y = 0 & & \sum M_A = 0 \\ A_x = 0 & & -P + A_y = 0 & & -P(8\ell) + M_A = 0 \\ & & A_y = P & & M_A = 8P\ell \end{aligned}$$

FIGURE 1.2.21 Shear force and bending moment diagrams of a component in a structure.

Now separate bar AC and determine the forces at B and C.

$$\begin{aligned}
 \sum F_x = 0 & & \sum F_y = 0 & & \sum M_A = 0 \\
 -B_x + T_{CD_x} = 0 & & P - B_y - T_{CD_y} = 0 & & -\frac{2}{\sqrt{5}} T_{CD}(12\ell) + B_x(10\ell) + M_A = 0 \\
 \text{(a) } B_x = \frac{2}{\sqrt{5}} T_{CD} & & \text{(b) } B_y = P - \frac{1}{\sqrt{5}} T_{CD} & & -\frac{24\ell}{\sqrt{5}} T_{CD} + \frac{20\ell}{\sqrt{5}} T_{CD} = -8Pl \\
 & & & & \text{(c) } T_{CD} = \frac{8\sqrt{5}}{4} P = 2\sqrt{5}P
 \end{aligned}$$

From (a) and (c),  $B_x = 4P$  and  $T_{CD_x} = 4P$ . From (b) and (c),  $B_y = P - 2P = -P$  and  $T_{CD_y} = 2P$ .

Draw the free-body diagram of bar AC horizontally, with the shear force and bending moment diagram axes below it. Measure  $x$  from end C for convenience and analyze sections  $0 \leq x \leq 2\ell$  and  $2\ell \leq x \leq 12\ell$  (Figures 1.2.21b to 1.2.21f).

1.  $0 \leq x \leq 2\ell$

$$\begin{aligned}
 \sum F_y = 0 & & \sum M_K = 0 \\
 -4P + V_{K_1} = 0 & & M_{K_1} + 4P(x) = 0 \\
 V_{K_1} = 4P & & M_{K_1} = -4Px
 \end{aligned}$$

2.  $2\ell \leq x \leq 12\ell$

$$\begin{aligned} \sum F_y = 0 & & \sum M_K = 0 \\ 4P - 4P + V_{K_2} = 0 & & M_{K_2} - 4P(x - 2\ell) + 4P(x) = 0 \\ V_{K_2} = 0 & & M_{K_2} = -8P\ell \end{aligned}$$

At point  $B$ ,  $x = 2\ell$ ,  $M_{K_1} = -4P(2\ell) = -8P\ell = M_{K_2} = M_A$ . The results for section  $AB$ ,  $2\ell \leq x \leq 12\ell$ , show that the combined effect of the forces at  $B$  and  $C$  is to produce a couple of magnitude  $8P\ell$  on the beam. Hence, the shear force is zero and the moment is constant in this section. These results are plotted on the axes below the free-body diagram of bar  $A$ - $B$ - $C$ .

## Simple Structures and Machines

*Ryan Roloff and Bela I. Sandor*

Equilibrium equations are used to determine forces and moments acting on statically determinate simple structures and machines. A simple structure is composed solely of two-force members. A machine is composed of multiforce members. The method of joints and the method of sections are commonly used in such analysis.

### Trusses

Trusses consist of straight, slender members whose ends are connected at joints. Two-dimensional *plane trusses* carry loads acting in their planes and are often connected to form three-dimensional *space trusses*. Two typical trusses are shown in [Figure 1.2.22](#).

**FIGURE 1.2.22** Schematic examples of trusses.

To simplify the analysis of trusses, assume frictionless pin connections at the joints. Thus, all members are two-force members with forces (and no moments) acting at the joints. Members may be assumed weightless or may have their weights evenly divided to the joints.

### Method of Joints

Equilibrium equations based on the entire truss and its joints allow for determination of all internal forces and external reactions at the joints using the following procedure.

1. Determine the support reactions of the truss. This is done using force and moment equilibrium equations and a free-body diagram of the entire truss.
2. Select any arbitrary joint where only one or two unknown forces act. Draw the free-body diagram of the joint assuming unknown forces are tensions (arrows directed away from the joint).
3. Draw free-body diagrams for the other joints to be analyzed, using Newton's third law consistently with respect to the first diagram.
4. Write the equations of equilibrium,  $\sum F_x = 0$  and  $\sum F_y = 0$ , for the forces acting at the joints and solve them. To simplify calculations, attempt to progress from joint to joint in such a way that each equation contains only one unknown. Positive answers indicate that the assumed directions of unknown forces were correct, and vice versa.

### Example 6

Use the method of joints to determine the forces acting at  $A$ ,  $B$ ,  $C$ ,  $H$ , and  $I$  of the truss in [Figure 1.2.23a](#). The angles are  $\alpha = 56.3^\circ$ ,  $\beta = 38.7^\circ$ ,  $\phi = 39.8^\circ$ , and  $\theta = 36.9^\circ$ .

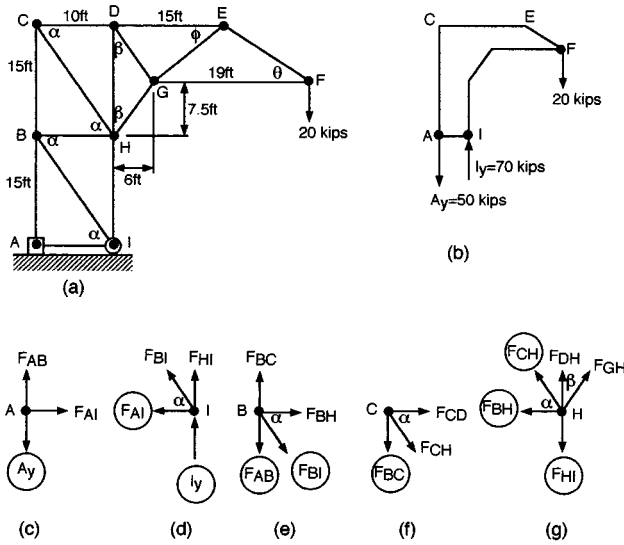

FIGURE 1.2.23 Method of joints in analyzing a truss.

*Solution.* First the reactions at the supports are determined and are shown in Figure 1.2.23b. A joint at which only two unknown forces act is the best starting point for the solution. Choosing joint A, the solution is progressively developed, always seeking the next joint with only two unknowns. In each diagram circles indicate the quantities that are known from the preceding analysis. Sample calculations show the approach and some of the results.

**Joint A:**

$$\sum F_x = 0 \qquad \sum F_y = 0$$

$$F_{AI} = 0 \qquad F_{AB} - A_y = 0$$

$$F_{AB} - 50 \text{ kips} = 0$$

$$F_{AB} = 50 \text{ kips (tension)}$$

**Joint H:**

$$\sum F_x = 0 \qquad \sum F_y = 0$$

$$F_{GH} \sin \beta - F_{CH} \cos \alpha - F_{BH} = 0 \qquad F_{CH} \sin \alpha + F_{DH} + F_{GH} \cos \beta - F_{HI} = 0$$

$$F_{GH}(0.625) + (60.1 \text{ kips})(0.555) - 0 = 0 \qquad -(60.1 \text{ kips})(0.832) + F_{DH} - (53.4 \text{ kips})(0.780) + 70 \text{ kips} = 0$$

$$F_{GH} = -53.4 \text{ kips (compression)} \qquad F_{DH} = 21.7 \text{ kips (tension)}$$

**Method of Sections**

The method of sections is useful when only a few forces in truss members need to be determined regardless of the size and complexity of the entire truss structure. This method employs any section of the truss as a free body in equilibrium. The chosen section may have any number of joints and members in it, but the number of unknown forces should not exceed three in most cases. Only three equations of equilibrium can be written for each section of a plane truss. The following procedure is recommended.

1. Determine the support reactions if the section used in the analysis includes the joints supported.

- Section the truss by making an imaginary cut through the members of interest, preferably through only three members in which the forces are unknowns (assume tensions). The cut need not be a straight line. The sectioning is illustrated by lines *l-l*, *m-m*, and *n-n* in Figure 1.2.24.
- Write equations of equilibrium. Choose a convenient point of reference for moments to simplify calculations such as the point of intersection of the lines of action for two or more of the unknown forces. If two unknown forces are parallel, sum the forces perpendicular to their lines of action.
- Solve the equations. If necessary, use more than one cut in the vicinity of interest to allow writing more equilibrium equations. Positive answers indicate assumed directions of unknown forces were correct, and vice versa.

FIGURE 1.2.24 Method of sections in analyzing a truss.

### Space Trusses

A space truss can be analyzed with the method of joints or with the method of sections. For each joint, there are three scalar equilibrium equations,  $\sum F_x = 0$ ,  $\sum F_y = 0$ , and  $\sum F_z = 0$ . The analysis must begin at a joint where there are at least one known force and no more than three unknown forces. The solution must progress to other joints in a similar fashion.

There are six scalar equilibrium equations available when the method of sections is used:  $\sum F_x = 0$ ,  $\sum F_y = 0$ ,  $\sum F_z = 0$ ,  $\sum M_x = 0$ ,  $\sum M_y = 0$ , and  $\sum M_z = 0$ .

### Frames and Machines

Multiforce members (with three or more forces acting on each member) are common in structures. In these cases the forces are not directed along the members, so they are a little more complex to analyze than the two-force members in simple trusses. Multiforce members are used in two kinds of structure. *Frames* are usually stationary and fully constrained. *Machines* have moving parts, so the forces acting on a member depend on the location and orientation of the member.

The analysis of multiforce members is based on the consistent use of related free-body diagrams. The solution is often facilitated by representing forces by their rectangular components. Scalar equilibrium equations are the most convenient for two-dimensional problems, and vector notation is advantageous in three-dimensional situations.

Often, an applied force acts at a pin joining two or more members, or a support or connection may exist at a joint between two or more members. In these cases, a choice should be made of a single member at the joint on which to assume the external force to be acting. This decision should be stated in the analysis. The following comprehensive procedure is recommended.

Three independent equations of equilibrium are available for each member or combination of members in two-dimensional loading; for example,  $\sum F_x = 0$ ,  $\sum F_y = 0$ ,  $\sum M_A = 0$ , where A is an arbitrary point of reference.

- Determine the support reactions if necessary.
- Determine all two-force members.

3. Draw the free-body diagram of the first member on which the unknown forces act assuming that the unknown forces are tensions.
4. Draw the free-body diagrams of the other members or groups of members using Newton's third law (action and reaction) consistently with respect to the first diagram. Proceed until the number of equilibrium equations available is no longer exceeded by the total number of unknowns.
5. Write the equilibrium equations for the members or combinations of members and solve them. Positive answers indicate that the assumed directions for unknown forces were correct, and vice versa.

## Distributed Forces

The most common distributed forces acting on a body are parallel force systems, such as the force of gravity. These can be represented by one or more concentrated forces to facilitate the required analysis. Several basic cases of distributed forces are presented here. The important topic of stress analysis is covered in mechanics of materials.

### Center of Gravity

The center of gravity of a body is the point where the equivalent resultant force caused by gravity is acting. Its coordinates are defined for an arbitrary set of axes as

$$\bar{x} = \frac{\int x dW}{W} \quad \bar{y} = \frac{\int y dW}{W} \quad \bar{z} = \frac{\int z dW}{W} \quad (1.2.14)$$

where  $x, y, z$  are the coordinates of an element of weight  $dW$ , and  $W$  is the total weight of the body. In the general case  $dW = \gamma dV$ , and  $W = \int \gamma dV$ , where  $\gamma$  = specific weight of the material and  $dV$  = elemental volume.

### Centroids

If  $\gamma$  is a constant, the center of gravity coincides with the centroid, which is a geometrical property of a body. Centroids of lines  $L$ , areas  $A$ , and volumes  $V$  are defined analogously to the coordinates of the center of gravity,

$$\text{Lines:} \quad \bar{x} = \frac{\int x dL}{L} \quad \bar{y} = \frac{\int y dL}{L} \quad \bar{z} = \frac{\int z dL}{L} \quad (1.2.15)$$

$$\text{Areas:} \quad \bar{x} = \frac{\int x dA}{A} \quad \bar{y} = \frac{\int y dA}{A} \quad \bar{z} = \frac{\int z dA}{A} \quad (1.2.16)$$

$$\text{Volumes:} \quad \bar{x} = \frac{\int x dV}{V} \quad \bar{y} = \frac{\int y dV}{V} \quad \bar{z} = \frac{\int z dV}{V} \quad (1.2.17)$$

For example, an area  $A$  consists of discrete parts  $A_1, A_2, A_3$ , where the centroids  $x_1, x_2, x_3$  of the three parts are located by inspection. The  $x$  coordinate of the centroid of the whole area  $A$  is  $\bar{x}$  obtained from  $A\bar{x} = A_1x_1 + A_2x_2 + A_3x_3$ .

*Surfaces of Revolution.* The surface areas and volumes of bodies of revolution can be calculated using the concepts of centroids by the theorems of Pappus (see texts on Statics).

**Distributed Loads on Beams**

The distributed load on a member may be its own weight and/or some other loading such as from ice or wind. The external and internal reactions to the loading may be determined using the condition of equilibrium.

*External Reactions.* Replace the whole distributed load with a concentrated force equal in magnitude to the area under the load distribution curve and applied at the centroid of that area parallel to the original force system.

*Internal Reactions.* For a beam under a distributed load  $w(x)$ , where  $x$  is distance along the beam, the shear force  $V$  and bending moment  $M$  are related according to Figure 1.2.25 as

**FIGURE 1.2.25** Internal reactions in a beam under distributed loading.

$$w(x) = -\frac{dV}{dx} \quad V = \frac{dM}{dx} \tag{1.2.18}$$

Other useful expressions for any two cross sections  $A$  and  $B$  of a beam are

$$V_A - V_B = \int_{x_A}^{x_B} w(x) dx = \text{area under } w(x) \tag{1.2.19}$$

$$M_B - M_A = \int_{x_A}^{x_B} V dx = \text{area under shear force diagram}$$

**Example 7 (Figure 1.2.26)**

**FIGURE 1.2.26** Shear force and bending moment diagrams for a cantilever beam.

**Distributed Loads on Flexible Cables**

The basic assumptions of simple analyses of cables are that there is no resistance to bending and that the internal force at any point is tangent to the cable at that point. The loading is denoted by  $w(x)$ , a

continuous but possibly variable load, in terms of force per unit length. The differential equation of a cable is

$$\frac{d^2y}{dx^2} = \frac{w(x)}{T_o} \tag{1.2.20}$$

where  $T_o = \text{constant} = \text{horizontal component of the tension } T \text{ in the cable.}$

Two special cases are common.

*Parabolic Cables.* The cable supports a load  $w$  which is uniformly distributed horizontally. The shape of the cable is a parabola given by

$$y = \frac{wx^2}{2T_o} \quad (x = 0 \text{ at lowest point}) \tag{1.2.21}$$

In a symmetric cable the tension is  $T = \sqrt{T_o^2 + w^2x^2}$ .

*Catenary Cables.* When the load  $w$  is uniformly distributed along the cable, the cable's shape is given by

$$y = \frac{T_o}{w} \left( \cosh \frac{wx}{T_o} - 1 \right) \tag{1.2.22}$$

The tension in the cable is  $T = T_o + wy$ .

### Friction

A friction force  $F$  (or  $\mathcal{F}$ , in typical other notation) acts between contacting bodies when they slide relative to one another, or when sliding tends to occur. This force is tangential to each body at the point of contact, and its magnitude depends on the normal force  $N$  pressing the bodies together and on the material and condition of the contacting surfaces. The material and surface properties are lumped together and represented by the coefficient of friction  $\mu$ . The friction force opposes the force that tends to cause motion, as illustrated for two simple cases in [Figure 1.2.27](#).

**FIGURE 1.2.27** Models showing friction forces.

The friction forces  $F$  may vary from zero to a maximum value,

$$F_{\max} = \mu N \quad (0 \leq F \leq F_{\max}) \tag{1.2.23}$$

depending on the applied force that tends to cause relative motion of the bodies. The coefficient of kinetic friction  $\mu_k$  (during sliding) is lower than the coefficient of static friction  $\mu$  or  $\mu_s$ ;  $\mu_k$  depends on the speed of sliding and is not easily quantified.

aspect of a wedge may be of interest. The analysis is straightforward using interrelated free-body diagrams and equilibrium equations.

Screw threads are special applications of the concept of wedges. Square threads are the easiest to model and analyze. The magnitude  $M$  of the moment of a couple required to move a square-threaded screw against an axial load  $P$  is

$$M = Pr \tan(\alpha + \phi) \quad (1.2.25)$$

where  $r$  = radius of the screw  
 $\alpha = \tan^{-1}(L/2\pi r) = \tan^{-1}(np/2\pi r)$   
 $L$  = lead = advancement per revolution  
 $n$  = multiplicity of threads  
 $p$  = pitch = distance between similar points on adjacent threads  
 $\phi = \tan^{-1}\mu$

The relative values of  $\alpha$  and  $\phi$  control whether a screw is self-locking;  $\phi > \alpha$  is required for a screw to support an axial load without unwinding.

### Disk Friction

Flat surfaces in relative rotary motion generate a friction moment  $M$  opposing the motion. For a hollow member with radii  $R_o$  and  $R_i$ , under an axial force  $P$ ,

$$M = \frac{2}{3} \mu P \frac{R_o^3 - R_i^3}{R_o^2 - R_i^2} \quad (1.2.26)$$

The friction moment tends to decrease (down to about 75% of its original value) as the surfaces wear. Use the appropriate  $\mu_s$  or  $\mu_k$  value.

### Axle Friction

The friction moment  $M$  of a rotating axle in a journal bearing (sliding bearing) is approximated (if  $\mu$  is low) as

$$M = Pr\mu \quad (1.2.27)$$

where  $P$  = transverse load on the axle  
 $r$  = radius of the axle

Use the appropriate  $\mu_s$  or  $\mu_k$  value.

### Rolling Resistance

Rolling wheels and balls have relatively low resistance to motion compared to sliding. This resistance is caused by internal friction of the materials in contact, and it may be difficult to predict or measure.

A coefficient of rolling resistance  $a$  is defined with units of length,

$$a \cong \frac{Fr}{P} \quad (1.2.28)$$

where  $r$  = radius of a wheel rolling on a flat surface  
 $F$  = minimum horizontal force to maintain constant speed of rolling  
 $P$  = load on wheel

Values of  $a$  range upward from a low of about 0.005 mm for hardened steel elements.

### Belt Friction

The tensions  $T_1$  and  $T_2$  of a belt, rope, or wire on a pulley or drum are related as

$$T_2 = T_1 e^{\mu\beta} \quad (T_2 > T_1) \quad (1.2.29)$$

where  $\beta$  = total angle of belt contact, radians ( $\beta = 2\pi n$  for a member wrapped around a drum  $n$  times). Use  $\mu_s$  for impending slipping and  $\mu_k$  for slipping.

For a V belt of belt angle  $2\phi$ ,

$$T_2 = T_1 e^{\mu\beta/\sin\phi}$$

### Work and Potential Energy

Work is a scalar quantity. It is the product of a force and the corresponding displacement. Potential energy is the capacity of a system to do work on another system. These concepts are advantageous in the analysis of equilibrium of complex systems, in dynamics, and in mechanics of materials.

#### Work of a Force

The work  $U$  of a constant force  $\mathbf{F}$  is

$$U = Fs \quad (1.2.30)$$

where  $s$  = displacement of a body in the direction of the vector  $\mathbf{F}$ .

For a displacement along an arbitrary path from point 1 to 2, with  $d\mathbf{r}$  tangent to the path,

$$U = \int_1^2 \mathbf{F} \cdot d\mathbf{r} = \int_1^2 (F_x dx + F_y dy + F_z dz)$$

In theory, there is no work when:

1. A force is acting on a fixed, rigid body ( $dr = 0$ ,  $dU = 0$ ).
2. A force acts perpendicular to the displacement ( $\mathbf{F} \cdot d\mathbf{r} = 0$ ).

#### Work of a Couple

A couple of magnitude  $M$  does work

$$U = M\theta \quad (1.2.31)$$

where  $\theta$  = angular displacement (radians) in the same plane in which the couple is acting.

In a rotation from angular position  $\alpha$  to  $\beta$ ,

$$U = \int_{\alpha}^{\beta} \mathbf{M} \cdot d\theta = \int_{\alpha}^{\beta} (M_x d\theta_x + M_y d\theta_y + M_z d\theta_z)$$

#### Virtual Work

The concept of virtual work (through imaginary, infinitesimal displacements within the constraints of a system) is useful to analyze the equilibrium of complex systems. The virtual work of a force  $\mathbf{F}$  or moment  $\mathbf{M}$  is expressed as

$$\delta U = \mathbf{F} \cdot \delta \mathbf{r}$$

$$\delta U = \mathbf{M} \cdot \delta \theta$$

There is equilibrium if

$$\delta U = \sum_{i=1}^m \mathbf{F}_i \cdot \delta \mathbf{r}_i + \sum_{j=1}^n \mathbf{M}_j \cdot \delta \theta_j = 0 \quad (1.2.32)$$

where the subscripts refer to individual forces or couples and the corresponding displacements, ignoring frictional effects.

### Mechanical Efficiency of Real Systems

Real mechanical systems operate with frictional losses, so

$$\text{input work} = \text{useful work} + \text{work of friction}$$

(output work)

The mechanical efficiency  $\eta$  of a machine is

$$\eta = \frac{\text{output work}}{\text{input work}} = \frac{\text{useful work}}{\text{total work required}}$$

$$0 < \eta < 1$$

### Gravitational Work and Potential Energy

The potential of a body of weight  $W$  to do work because of its relative height  $h$  with respect to an arbitrary level is defined as its potential energy. If  $h$  is the vertical ( $y$ ) distance between level 1 and a lower level 2, the work of weight  $W$  in descending is

$$U_{12} = \int_1^2 W \, dy = Wh = \text{potential energy of the body at level 1 with respect to level 2}$$

The work of weight  $W$  in rising from level 2 to level 1 is

$$U_{21} = \int_2^1 -W \, dy = -Wh = \text{potential energy of the body at level 2 with respect to level 1}$$

### Elastic Potential Energy

The potential energy of elastic members is another common form of potential energy in engineering mechanics. For a linearly deforming helical spring, the axial force  $F$  and displacement  $x$  are related by the spring constant  $k$ ,

$$F = kx \quad (\text{similarly, } M = k\theta \text{ for a torsion spring})$$

The work  $U$  of a force  $F$  on an initially undeformed spring is

$$U = \frac{1}{2} kx^2 \quad (1.2.33)$$

In the general case, deforming the spring from position  $x_1$  to  $x_2$ ,

$$U = \frac{1}{2}k(x_2^2 - x_1^2)$$

### Notation for Potential Energy

The change in the potential energy  $V$  of a system is

$$U = -\Delta V$$

Note that negative work is done by a system while its own potential energy is increased by the action of an external force or moment. The external agent does positive work at the same time since it acts in the same direction as the resulting displacement.

### Potential Energy at Equilibrium

For equilibrium of a system,

$$\frac{dV}{dq} = 0$$

where  $q$  = an independent coordinate along which there is possibility of displacement.

For a system with  $n$  degrees of freedom,

$$\frac{\partial V}{\partial q_i} = 0, \quad i = 1, 2, \dots, n$$

Equilibrium is stable if  $(d^2V/dq^2) > 0$ .

Equilibrium is unstable if  $(d^2V/dq^2) < 0$ .

Equilibrium is neutral only if all derivatives of  $V$  are zero. In cases of complex configurations, evaluate derivatives of higher order as well.

### Moments of Inertia

The topics of inertia are related to the methods of first moments. They are traditionally presented in statics in preparation for application in dynamics or mechanics of materials.

#### Moments of Inertia of a Mass

The moment of inertia  $dI_x$  of an elemental mass  $dM$  about the  $x$  axis ([Figure 1.2.28](#)) is defined as

$$dI_x = r^2 dM = (y^2 + z^2) dM$$

where  $r$  is the nearest distance from  $dM$  to the  $x$  axis. The moments of inertia of a body about the three coordinate axes are

$$\begin{aligned}
 I_x &= \int r^2 dM = \int (y^2 + z^2) dM \\
 I_y &= \int (x^2 + z^2) dM \\
 I_z &= \int (x^2 + y^2) dM
 \end{aligned}
 \tag{1.2.34}$$

FIGURE 1.2.28 Mass element  $dM$  in  $xyz$  coordinates.

**Radius of Gyration.** The radius of gyration  $r_g$  is defined by  $r_g = \sqrt{I_x/M}$ , and similarly for any other axis. It is based on the concept of the body of mass  $M$  being replaced by a point mass  $M$  (same mass) at a distance  $r_g$  from a given axis. A thin strip or shell with all mass essentially at a constant distance  $r_g$  from the axis of reference is equivalent to a point mass for some analyses.

**Moment of Inertia of an Area**

The moment of inertia of an elemental area  $dA$  about the  $x$  axis (Figure 1.2.29) is defined as

$$dI_x = y^2 dA$$

where  $y$  is the nearest distance from  $dA$  to the  $x$  axis. The moments of inertia (second moments) of the area  $A$  about the  $x$  and  $y$  axes (because  $A$  is in the  $xy$  plane) are

$$I_x = \int y^2 dA \quad I_y = \int x^2 dA \tag{1.2.35}$$

FIGURE 1.2.29 Area  $A$  in the  $xy$  plane.

The radius of gyration of an area is defined the same way as it is for a mass:  $r_g = \sqrt{I_x/A}$ , etc.

**Polar Moment of Inertia of an Area**

The polar moment of inertia is defined with respect to an axis perpendicular to the area considered. In Figure 1.2.29 this may be the  $z$  axis. The polar moment of inertia in this case is

$$J_o = \int r^2 dA = \int (x^2 + y^2) dA = I_x + I_y \tag{1.2.36}$$

**Parallel-Axis Transformations of Moments of Inertia**

It is often convenient to first calculate the moment of inertia about a centroidal axis and then transform this with respect to a parallel axis. The formulas for the transformations are

$$\begin{aligned}
 I &= I_C + Md^2 && \text{for a mass } M \\
 I &= I_C + Ad^2 && \text{for an area } A \\
 J_O &= J_C + Ad^2 && \text{for an area } A
 \end{aligned}
 \tag{1.2.37}$$

where  $I$  or  $J_O$  = moment of inertia of  $M$  or  $A$  about any line  $\ell$

$I_C$  or  $J_C$  = moment of inertia of  $M$  or  $A$  about a line through the mass center or centroid and parallel to  $\ell$

$d$  = nearest distance between the parallel lines

Note that one of the two axes in each equation must be a centroidal axis.

### Products of Inertia

The products of inertia for areas and masses and the corresponding parallel-axis formulas are defined in similar patterns. Using notations in accordance with the preceding formulas, products of inertia are

$$\begin{aligned}
 I_{xy} &= \int xy \, dA && \text{for area,} && \text{or} && \int xy \, dM && \text{for mass} \\
 I_{yz} &= \int yz \, dA && && \text{or} && \int yz \, dM && \\
 I_{xz} &= \int xz \, dA && && \text{or} && \int xz \, dM &&
 \end{aligned}
 \tag{1.2.38}$$

Parallel-axis formulas are

$$\begin{aligned}
 I_{xy} &= I_{x'y'} + A d_x d_y && \text{for area,} && \text{or} && I_{x'y'} + M d_x d_y && \text{for mass} \\
 I_{yz} &= I_{y'z'} + A d_y d_z && && \text{or} && I_{y'z'} + M d_y d_z && \\
 I_{xz} &= I_{x'z'} + A d_x d_z && && \text{or} && I_{x'z'} + M d_x d_z &&
 \end{aligned}
 \tag{1.2.39}$$

*Notes:* The moment of inertia is always positive. The product of inertia may be positive, negative, or zero; it is zero if  $x$  or  $y$  (or both) is an axis of symmetry of the area. Transformations of known moments and product of inertia to axes that are inclined to the original set of axes are possible but not covered here. These transformations are useful for determining the principal (maximum and minimum) moments of inertia and the principal axes when the area or body has no symmetry. The principal moments of inertia for objects of simple shape are available in many texts.

## 1.3 Dynamics

*Stephen M. Birn and Bela I. Sandor*

There are two major categories in dynamics, kinematics and kinetics. **Kinematics** involves the time- and geometry-dependent motion of a particle, rigid body, deformable body, or a fluid without considering the forces that cause the motion. It relates position, velocity, acceleration, and time. **Kinetics** combines the concepts of kinematics and the forces that cause the motion.

### Kinematics of Particles

#### Scalar Method

The scalar method of particle kinematics is adequate for one-dimensional analysis. A particle is a body whose dimensions can be neglected (in some analyses, very large bodies are considered particles). The equations described here are easily adapted and applied to two and three dimensions.

#### Average and Instantaneous Velocity

The average velocity of a particle is the change in distance divided by the change in time. The instantaneous velocity is the particle's velocity at a particular instant.

$$v_{ave} = \frac{\Delta x}{\Delta t} \quad v_{inst} = \lim_{\Delta t \rightarrow 0} \frac{\Delta x}{\Delta t} = \frac{dx}{dt} = \dot{x} \quad (1.3.1)$$

#### Average and Instantaneous Acceleration

The average acceleration is the change in velocity divided by the change in time. The instantaneous acceleration is the particle's acceleration at a particular instant.

$$a_{ave} = \frac{\Delta v}{\Delta t} \quad a_{inst} = \lim_{\Delta t \rightarrow 0} \frac{\Delta v}{\Delta t} = \frac{dv}{dt} = \dot{v} = \ddot{x} \quad (1.3.2)$$

Displacement, velocity, acceleration, and time are related to one another. For example, if velocity is given as a function of time, the displacement and acceleration can be determined through integration and differentiation, respectively. The following example illustrates this concept.

#### Example 8

A particle moves with a velocity  $v(t) = 3t^2 - 8t$ . Determine  $x(t)$  and  $a(t)$ , if  $x(0) = 5$ .

*Solution.*

1. Determine  $x(t)$  by integration

$$v = \frac{dx}{dt}$$

$$v dt = dx$$

$$\int 3t^2 - 8t dt = \int dx$$

$$t^3 - 4t^2 + C = x$$

$$\text{from } x(0) = 5 \quad C = 5$$

$$x(t) = t^3 - 4t^2 + 5$$

2. Determine  $a(t)$  by differentiation

$$a = \frac{dv}{dt} = \frac{d}{dt}(3t^2 - 8t)$$

$$a(t) = 6t - 8$$

There are four key points to be seen from these graphs (Figure 1.3.1).

**FIGURE 1.3.1** Plots of a particle's kinematics.

1.  $v = 0$  at the local maximum or minimum of the  $x-t$  curve.
2.  $a = 0$  at the local maximum or minimum of the  $v-t$  curve.
3. The area under the  $v-t$  curve in a specific time interval is equal to the net displacement change in that interval.
4. The area under the  $a-t$  curve in a specific time interval is equal to the net velocity change in that interval.

### Useful Expressions Based on Acceleration

Equations for nonconstant acceleration:

$$a = \frac{dv}{dt} \Rightarrow \int_{v_0}^v dv = \int_0^t a dt \tag{1.3.3}$$

$$v dv = a dx \Rightarrow \int_{v_0}^v v dv = \int_{x_0}^x a dx \tag{1.3.4}$$

Equations for constant acceleration (projectile motion; free fall):

$$v = at + v_0$$

$$v^2 = 2a(x - x_0) + v_0^2 \tag{1.3.5}$$

$$x = \frac{1}{2}at^2 + v_0t + x_0$$

These equations are only to be used when the acceleration is known to be a constant. There are other expressions available depending on how a variable acceleration is given as a function of time, velocity, or displacement.

### Scalar Relative Motion Equations

The concept of relative motion can be used to determine the displacement, velocity, and acceleration between two particles that travel along the same line. Equation 1.3.6 provides the mathematical basis for this method. These equations can also be used when analyzing two points on the same body that are not attached rigidly to each other (Figure 1.3.2).

**FIGURE 1.3.2** Relative motion of two particles along a straight line.

$$x_{B/A} = x_B - x_A$$

$$v_{B/A} = v_B - v_A \tag{1.3.6}$$

$$a_{B/A} = a_B - a_A$$

The notation *B/A* represents the displacement, velocity, or acceleration of particle *B* as seen from particle *A*. Relative motion can be used to analyze many different degrees-of-freedom systems. A degree of freedom of a mechanical system is the number of independent coordinate systems needed to define the position of a particle.

### Vector Method

The vector method facilitates the analysis of two- and three-dimensional problems. In general, curvilinear motion occurs and is analyzed using a convenient coordinate system.

### Vector Notation in Rectangular (Cartesian) Coordinates

Figure 1.3.3 illustrates the vector method.

**FIGURE 1.3.3** Vector method for a particle.

The mathematical method is based on determining  $\mathbf{v}$  and  $\mathbf{a}$  as functions of the position vector  $\mathbf{r}$ . Note that the time derivatives of unit vectors are zero when the xyz coordinate system is fixed. The scalar components  $(\dot{x}, \dot{y}, \ddot{x}, \dots)$  can be determined from the appropriate scalar equations previously presented that only include the quantities relevant to the coordinate direction considered.

$$\mathbf{r} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$$

$$\mathbf{v} = \frac{d\mathbf{r}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k} = \dot{x}\mathbf{i} + \dot{y}\mathbf{j} + \dot{z}\mathbf{k} \tag{1.3.7}$$

$$\mathbf{a} = \frac{d\mathbf{v}}{dt} = \frac{d^2x}{dt^2}\mathbf{i} + \frac{d^2y}{dt^2}\mathbf{j} + \frac{d^2z}{dt^2}\mathbf{k} = \ddot{x}\mathbf{i} + \ddot{y}\mathbf{j} + \ddot{z}\mathbf{k}$$

There are a few key points to remember when considering curvilinear motion. First, the instantaneous velocity vector is *always* tangent to the path of the particle. Second, the speed of the particle is the magnitude of the velocity vector. Third, the acceleration vector is *not* tangent to the path of the particle and not collinear with  $\mathbf{v}$  in curvilinear motion.

**Tangential and Normal Components**

Tangential and normal components are useful in analyzing velocity and acceleration. Figure 1.3.4 illustrates the method and Equation 1.3.8 is the governing equations for it.

$$\mathbf{v} = v\mathbf{n}_t$$

$$\mathbf{a} = a_t\mathbf{n}_t + a_n\mathbf{n}_n$$

$$a_t = \frac{dv}{dt} \quad a_n = \frac{v^2}{\rho} \tag{1.3.8}$$

$$\rho = \frac{[1 + (dy/dx)^2]^{3/2}}{d^2y/dx^2}$$

$\rho = r = \text{constant}$  for a circular path

**FIGURE 1.3.4** Tangential and normal components. C is the center of curvature.

The *osculating plane* contains the unit vectors  $\mathbf{n}_t$  and  $\mathbf{n}_n$ , thus defining a plane. When using normal and tangential components, it is common to forget to include the component of normal acceleration, especially if the particle travels at a constant speed along a curved path.

For a particle that moves in circular motion,

$$\begin{aligned}
 v &= r\dot{\theta} = r\omega \\
 a_t &= \frac{dv}{dt} = r\ddot{\theta} = r\alpha \\
 a_n &= \frac{v^2}{r} = r\dot{\theta}^2 = r\omega^2
 \end{aligned}
 \tag{1.3.9}$$

**Motion of a Particle in Polar Coordinates**

Sometimes it may be best to analyze particle motion by using polar coordinates as follows (Figure 1.3.5):

$$\begin{aligned}
 \mathbf{v} &= \dot{r}\mathbf{n}_r + r\dot{\theta}\mathbf{n}_\theta \quad (\text{always tangent to the path}) \\
 \frac{d\theta}{dt} &= \dot{\theta} = \omega, \text{ rad/s} \\
 \mathbf{a} &= (\ddot{r} - r\dot{\theta}^2)\mathbf{n}_r + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\mathbf{n}_\theta
 \end{aligned}
 \tag{1.3.10}$$

FIGURE 1.3.5 Motion of a particle in polar coordinates.

For a particle that moves in circular motion the equations simplify to

$$\begin{aligned}
 \frac{d\dot{\theta}}{dt} &= \ddot{\theta} = \dot{\omega} = \alpha, \text{ rad/s}^2 \\
 \mathbf{v} &= r\dot{\theta}\mathbf{n}_\theta \\
 \mathbf{a} &= -r\dot{\theta}^2\mathbf{n}_r + r\ddot{\theta}\mathbf{n}_\theta
 \end{aligned}
 \tag{1.3.11}$$

**Motion of a Particle in Cylindrical Coordinates**

Cylindrical coordinates provide a means of describing three-dimensional motion as illustrated in Figure 1.3.6.

$$\begin{aligned}
 \mathbf{v} &= \dot{r}\mathbf{n}_r + r\dot{\theta}\mathbf{n}_\theta + \dot{z}\mathbf{k} \\
 \mathbf{a} &= (\ddot{r} - r\dot{\theta}^2)\mathbf{n}_r + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\mathbf{n}_\theta + \ddot{z}\mathbf{k}
 \end{aligned}
 \tag{1.3.12}$$

FIGURE 1.3.6 Motion of a particle in cylindrical coordinates.

**Motion of a Particle in Spherical Coordinates**

Spherical coordinates are useful in a few special cases but are difficult to apply to practical problems. The governing equations for them are available in many texts.

**Relative Motion of Particles in Two and Three Dimensions**

Figure 1.3.7 shows relative motion in two and three dimensions. This can be used in analyzing the translation of coordinate axes. Note that the unit vectors of the coordinate systems are the same. Subscripts are arbitrary but must be used consistently since  $r_{B/A} = -r_{A/B}$  etc.

$$\begin{aligned}
 \mathbf{r}_B &= \mathbf{r}_A + \mathbf{r}_{B/A} \\
 \mathbf{v}_B &= \mathbf{v}_A + \mathbf{v}_{B/A} \\
 \mathbf{a}_B &= \mathbf{a}_A + \mathbf{a}_{B/A}
 \end{aligned}
 \tag{1.3.13}$$

FIGURE 1.3.7 Relative motion using translating coordinates.

**Kinetics of Particles**

Kinetics combines the methods of kinematics and the forces that cause the motion. There are several useful methods of analysis based on Newton’s second law.

**Newton’s Second Law**

*The magnitude of the acceleration of a particle is directly proportional to the magnitude of the resultant force acting on it, and inversely proportional to its mass. The direction of the acceleration is the same as the direction of the resultant force.*

$$\mathbf{F} = m\mathbf{a}
 \tag{1.3.14}$$

where  $m$  is the particle’s mass. There are three key points to remember when applying this equation.

1.  $\mathbf{F}$  is the resultant force.
2.  $\mathbf{a}$  is the acceleration of a single particle (use  $\mathbf{a}_C$  for the center of mass for a system of particles).
3. The motion is in a nonaccelerating reference frame.

## Equations of Motion

The **equations of motion** for vector and scalar notations in rectangular coordinates are

$$\begin{aligned} \sum \mathbf{F} &= m\mathbf{a} \\ \sum F_x &= ma_x \quad \sum F_y = ma_y \quad \sum F_z = ma_z \end{aligned} \quad (1.3.15)$$

The equations of motion for tangential and normal components are

$$\begin{aligned} \sum F_n &= ma_n = m \frac{v^2}{\rho} \\ \sum F_t &= ma_t = m\dot{v} = mv \frac{dv}{ds} \end{aligned} \quad (1.3.16)$$

The equations of motion in a polar coordinate system (radial and transverse components) are

$$\begin{aligned} \sum F_r &= ma_r = m(\ddot{r} - r\dot{\theta}^2) \\ \sum F_\theta &= ma_\theta = m(r\ddot{\theta} - 2\dot{r}\dot{\theta}) \end{aligned} \quad (1.3.17)$$

## Procedure for Solving Problems

1. Draw a free-body diagram of the particle showing all forces. (The free-body diagram will look unbalanced since the particle is not in static equilibrium.)
2. Choose a convenient nonaccelerating reference frame.
3. Apply the appropriate equations of motion for the reference frame chosen to calculate the forces or accelerations applied to the particle.
4. Use kinematics equations to determine velocities and/or displacements if needed.

## Work and Energy Methods

Newton's second law is not always the most convenient method for solving a problem. Work and energy methods are useful in problems involving changes in displacement and velocity, if there is no need to calculate accelerations.

### Work of a Force

The total work of a force  $\mathbf{F}$  in displacing a particle  $P$  from position 1 to position 2 along any path is

$$U_{12} = \int_1^2 \mathbf{F} \cdot d\mathbf{r} = \int_1^2 (F_x dx + F_y dy + F_z dz) \quad (1.3.18)$$

### Potential and Kinetic Energies

Gravitational potential energy:  $U_{12} = \int_1^2 W dy = Wh = V_g$ , where  $W$  = weight and  $h$  = vertical elevation difference.

Elastic potential energy:  $U = \int_{x_1}^{x_2} kx dx = \frac{1}{2}k(x_2^2 - x_1^2) = V_e$ , where  $k$  = spring constant.

Kinetic energy of a particle:  $T = 1/2mv^2$ , where  $m$  = mass and  $v$  = magnitude of velocity.

Kinetic energy can be related to work by the *principle of work and energy*,

$$U_{12} = T_2 - T_1 \quad (1.3.19)$$

where  $U_{12}$  is the work of a force on the particle moving it from position 1 to position 2,  $T_1$  is the kinetic energy of the particle at position 1 (initial kinetic energy), and  $T_2$  is the kinetic energy of the particle at position 2 (final kinetic energy).

### Power

Power is defined as work done in a given time.

$$\text{power} = \frac{dU}{dt} = \frac{\mathbf{F} \cdot d\mathbf{r}}{dt} = \mathbf{F} \cdot \mathbf{v} \quad (1.3.20)$$

where  $\mathbf{v}$  is velocity.

Important units and conversions of power are

$$1 \text{ W} = 1 \text{ J/s} = 1 \text{ N} \cdot \text{m/s}$$

$$1 \text{ hp} = 550 \text{ ft} \cdot \text{lb/s} = 33,000 \text{ ft} \cdot \text{lb/min} = 746 \text{ W}$$

$$1 \text{ ft} \cdot \text{lb/s} = 1.356 \text{ J/s} = 1.356 \text{ W}$$

### Advantages and Disadvantages of the Energy Method

There are four advantages to using the energy method in engineering problems:

1. Accelerations do not need to be determined.
2. Modifications of problems are easy to make in the analysis.
3. Scalar quantities are summed, even if the path of motion is complex.
4. Forces that do not do work are ignored.

The main disadvantage of the energy method is that quantities of work or energy cannot be used to determine accelerations or forces that do no work. In these instances, Newton's second law has to be used.

### Conservative Systems and Potential Functions

Sometimes it is useful to assume a conservative system where friction does not oppose the motion of the particle. The work in a conservative system is independent of the path of the particle, and potential energy is defined as

$$\underbrace{U_{12}}_{\substack{\text{work of } \mathbf{F} \\ \text{from 1 to 2}}} = \underbrace{-\Delta V}_{\substack{\text{difference of potential} \\ \text{energies at 1 and 2}}}$$

A special case is where the particle moves in a closed path. One trip around the path is called a *cycle*.

$$U = \oint dU = \oint \mathbf{F} \cdot d\mathbf{r} = \oint (F_x dx + F_y dy + F_z dz) = 0 \quad (1.3.21)$$

In advanced analysis differential changes in the potential energy function ( $V$ ) are calculated by the use of partial derivatives,

$$\mathbf{F} = F_x \mathbf{i} + F_y \mathbf{j} + F_z \mathbf{k} = -\left( \frac{\partial V}{\partial x} \mathbf{i} + \frac{\partial V}{\partial y} \mathbf{j} + \frac{\partial V}{\partial z} \mathbf{k} \right)$$

**Conservation of Mechanical Energy**

Conservation of mechanical energy is assumed if kinetic energy ( $T$ ) and potential energy ( $V$ ) change back and forth in a conservative system (the dissipation of energy is considered negligible). Equation 1.3.22 formalizes such a situation, where position 1 is the initial state and position 2 is the final state. The reference (datum) should be chosen to reduce the number of terms in the equation.

$$T_1 + V_1 = T_2 + V_2 \tag{1.3.22}$$

**Linear and Angular Momentum Methods**

The concept of linear momentum is useful in engineering when the accelerations of particles are not known but the velocities are. The linear momentum is derived from Newton’s second law,

$$\mathbf{G} = m\mathbf{v} \tag{1.3.23}$$

The time rate of change of linear momentum is equal to force. When  $m\mathbf{v}$  is constant, the conservation of momentum equation results,

$$\sum \mathbf{F} = \dot{\mathbf{G}} = \frac{d}{dt}(m\mathbf{v}) \tag{1.3.24}$$

$$\sum \mathbf{F} = 0 \quad m\mathbf{v} = \text{constant} \quad (\text{conservation of momentum})$$

The method of angular momentum is based on the momentum of a particle about a fixed point, using the vector product in the general case (Figure 1.3.8).

$$\mathbf{H}_O = \mathbf{r} \times m\mathbf{v} \tag{1.3.25}$$

**FIGURE 1.3.8** Definition of angular momentum for a particle.

The angular momentum equation can be solved using a scalar method if the motion of the particle remains in a plane,

$$\mathbf{H}_O = mrv\sin\phi = mrv_\theta = mr^2\dot{\theta}$$

If the particle does not remain in a plane, then the general space motion equations apply. They are derived from the cross-product  $\mathbf{r} \times m\mathbf{v}$ ,

$$\begin{aligned}\mathbf{H}_O &= H_x \mathbf{i} + H_y \mathbf{j} + H_z \mathbf{k} \\ H_x &= m(yv_z - zv_y) \\ H_y &= m(zv_x - xv_z) \\ H_z &= m(xv_y - yv_x)\end{aligned}\tag{1.3.25a}$$

### Time Rate of Change of Angular Momentum

In general, a force acting on a particle changes its angular momentum: *the time rate of change of angular momentum of a particle is equal to the sum of the moments of the forces acting on the particle.*

$$\text{Vectors:} \quad \dot{\mathbf{H}}_O = \frac{d}{dt}(\mathbf{r} \times m\mathbf{v}) = \mathbf{r} \times \sum \mathbf{F} = \sum \mathbf{H}_O \tag{1.3.26}$$

$$\begin{aligned}\text{Scalars:} \quad \sum M_x &= \dot{H}_x & \sum M_y &= \dot{H}_y & \sum M_z &= \dot{H}_z \\ \sum \mathbf{M}_O &= 0 & \mathbf{H}_O &= \mathbf{r} \times m\mathbf{v} = \text{constant} \\ & & & \text{(conservation of angular momentum)} & & \end{aligned}\tag{1.3.27}$$

A special case is when the sum of the moments about point  $O$  is zero. This is the conservation of angular momentum. In this case (motion under a central force), if the distance  $r$  increases, the velocity must decrease, and vice versa.

### Impulse and Momentum

Impulse and momentum are important in considering the motion of particles in impact. The linear impulse and momentum equation is

$$\underbrace{\int_{t_1}^{t_2} \mathbf{F} dt}_{\text{impulse}} = \underbrace{m\mathbf{v}_2}_{\text{final momentum}} - \underbrace{m\mathbf{v}_1}_{\text{initial momentum}} \tag{1.3.28}$$

### Conservation of Total Momentum of Particles

Conservation of total momentum occurs when *the initial momentum of  $n$  particles is equal to the final momentum of those same  $n$  particles,*

$$\underbrace{\sum_i^n (m_i \mathbf{v}_i)_1}_{\text{total initial momentum at time } t_1} = \underbrace{\sum_i^n (m_i \mathbf{v}_i)_2}_{\text{total final momentum at time } t_2} \tag{1.3.29}$$

When considering the response of two deformable bodies to direct central impact, the coefficient of restitution is used. This coefficient  $e$  relates the initial velocities of the particles to the final velocities,

$$e = \frac{v_{Bf} - v_{Af}}{v_A - v_B} = \frac{|\text{relative velocity of separation}|}{|\text{relative velocity of approach}|} \tag{1.3.30}$$

For real materials,  $0 < e < 1$ . If both bodies are *perfectly elastic*,  $e = 1$ , and if either body is *perfectly plastic*,  $e = 0$ .

### Kinetics of Systems of Particles

There are three distinct types of systems of particles: discrete particles, continuous particles in fluids, and continuous particles in rigid or deformable bodies. This section considers methods for discrete particles that have relevance to the mechanics of solids. Methods involving particles in rigid bodies will be discussed in later sections.

#### Newton's Second Law Applied to a System of Particles

Newton's second law can be extended to systems of particles,

$$\sum_{i=1}^n \mathbf{F}_i = \sum_{i=1}^n m_i \mathbf{a}_i \tag{1.3.31}$$

#### Motion of the Center of Mass

The center of mass of a system of particles moves under the action of internal and external forces as if the total mass of the system and all the external forces were at the center of mass. Equation 1.3.32 defines the position, velocity, and acceleration of the center of mass of a system of particles.

$$m\mathbf{r}_C = \sum_{i=1}^n m_i \mathbf{r}_i \quad m\mathbf{v}_C = \sum_{i=1}^n m_i \mathbf{v}_i \quad m\mathbf{a}_C = \sum_{i=1}^n m_i \mathbf{a}_i \quad \sum \mathbf{F} = m\mathbf{a}_C \tag{1.3.32}$$

#### Work and Energy Methods for a System of Particles

*Gravitational Potential Energy.* The gravitational potential energy of a system of particles is the sum of the potential energies of the individual particles of the system.

$$V_g = g \sum_{i=1}^n m_i y_i = \sum_{i=1}^n W_i y_i = mgy_C = Wy_C \tag{1.3.33}$$

where  $g$  = acceleration of gravity

$y_C$  = vertical position of center of mass with respect to a reference level

*Kinetic Energy.* The kinetic energy of a system of particles is the sum of the kinetic energies of the individual particles of the system with respect to a fixed reference frame,

$$T = \frac{1}{2} \sum_{i=1}^n m_i v_i^2 \tag{1.3.34}$$

A translating reference frame located at the mass center  $C$  of a system of particles can be used advantageously, with

$$T = \underbrace{\frac{1}{2} m v_C^2}_{\text{motion of total mass imagined to be concentrated at } C} + \underbrace{\frac{1}{2} \sum_{i=1}^n m_i v_i'^2}_{\text{motion of all particles relative to } C} \quad (v' \text{ are with respect to a translating frame}) \tag{1.3.35}$$

### Work and Energy

The work and energy equation for a system of particles is similar to the equation stated for a single particle.

$$\sum_{i=1}^n U'_i = \sum_{i=1}^n V_i + \sum_{i=1}^n T_i \quad (1.3.36)$$

$$U' = \Delta V + \Delta T$$

### Momentum Methods for a System of Particles

*Moments of Forces on a System of Particles.* The moments of external forces on a system of particles about a point  $O$  are given by

$$\sum_{i=1}^n (\mathbf{r}_i \times \mathbf{F}_i) = \sum_{i=1}^n \mathbf{M}_{i_o} + \sum_{i=1}^n (\mathbf{r}_i \times m_i \mathbf{a}_i) \quad (1.3.37)$$

*Linear and Angular Momenta of a System of Particles.* The resultant of the external forces on a system of particles equals the time rate of change of linear momentum of that system.

$$\mathbf{G} = \sum_{i=1}^n m_i \mathbf{v}_i \quad \sum \mathbf{F} = \dot{\mathbf{G}} \quad (1.3.38)$$

The angular momentum equation for a system of particles about a fixed point  $O$  is

$$\mathbf{H}_O = \sum_{i=1}^n (\mathbf{r}_i \times m_i \mathbf{a}_i) \quad (1.3.39)$$

$$\sum \mathbf{M}_O = \dot{\mathbf{H}}_O = \sum_{i=1}^n (\mathbf{r}_i \times m_i \mathbf{a}_i)$$

The last equation means that *the resultant of the moments of the external forces on a system of particles equals the time rate of change of angular momentum of that system.*

### Angular Momentum about the Center of Mass

The above equations work well for reference frames that are stationary, but sometimes a special approach may be useful, noting that *the angular momentum of a system of particles about its center of mass  $C$  is the same whether it is observed from a fixed frame at point  $O$  or from the centroidal frame which may be translating but not rotating.* In this case

$$\mathbf{H}_O = \mathbf{H}_C + \mathbf{r}_C \times m \mathbf{v}_C \quad (1.3.40)$$

$$\sum \mathbf{M}_O = \dot{\mathbf{H}}_C + \mathbf{r}_C \times m \mathbf{a}_C$$

### Conservation of Momentum

The conservation of momentum equations for a system of particles is analogous to that for a single particle.

$$\left. \begin{aligned} \mathbf{G} &= \text{constant} \\ \mathbf{H}_O &= \text{constant} \\ \mathbf{H}_C &= \text{constant} \end{aligned} \right\} \text{ not the same constants in general}$$

**Impulse and Momentum of a System of Particles**

The linear impulse momentum for a system of particles is

$$\sum_{i=1}^n \int_{t_1}^{t_2} \mathbf{F}_i dt = \mathbf{G}_2 - \mathbf{G}_1 = m\mathbf{v}_{C_2} - m\mathbf{v}_{C_1} \tag{1.3.41}$$

The angular impulse momentum for a system of particles is

$$\sum_{i=1}^n \int_{t_1}^{t_2} \mathbf{M}_{iO} dt = \mathbf{H}_{O_2} - \mathbf{H}_{O_1} \tag{1.3.42}$$

**Kinematics of Rigid Bodies**

Rigid body kinematics is used when the methods of particle kinematics are inadequate to solve a problem. A rigid body is defined as one in which the particles are rigidly connected. This assumption allows for some similarities to particle kinematics. There are two kinds of rigid body motion, translation and rotation. These motions may occur separately or in combination.

**Translation**

Figure 1.3.9 models the translational motion of a rigid body.

$$\begin{aligned} \mathbf{r}_B &= \mathbf{r}_A + \mathbf{r}_{B/A} \quad (\mathbf{r}_{B/A} = \text{constant}) \\ \mathbf{v}_B &= \dot{\mathbf{r}}_B = \dot{\mathbf{r}}_A = \mathbf{v}_A \\ \mathbf{a}_B &= \dot{\mathbf{v}}_B = \dot{\mathbf{v}}_A = \mathbf{a}_A \end{aligned} \tag{1.3.43}$$

**FIGURE 1.3.9** Translational motion of a rigid body.

These equations represent an important fact: *when a rigid body is in translation, the motion of a single point completely specifies the motion of the whole body.*

**Rotation about a Fixed Axis**

Figure 1.3.10 models a point *P* in a rigid body rotating about a fixed axis with an angular velocity  $\omega$ .

The velocity  $\mathbf{v}$  of point *P* is determined assuming that the magnitude of  $\mathbf{r}$  is constant,

$$\mathbf{v} = \omega \times \mathbf{r} \tag{1.3.44}$$

FIGURE 1.3.10 Rigid body rotating about a fixed axis.

The acceleration  $\mathbf{a}$  of point  $P$  is determined conveniently by using normal and tangential components,

$$\mathbf{a}_P = \underbrace{\alpha \times \mathbf{r}}_{\mathbf{a}_t} + \underbrace{\omega \times (\omega \times \mathbf{r})}_{\mathbf{a}_n} \tag{1.3.45}$$

$$a_t = \rho\alpha \quad a_n = \rho\omega^2$$

Note that the angular acceleration  $\alpha$  and angular velocity  $\omega$  are valid for any line perpendicular to the axis of rotation of the rigid body at a given instant.

**Kinematics Equations for Rigid Bodies Rotating in a Plane**

For rotational motion with or without a fixed axis, if displacement is measured by an angle  $\theta$ ,

Angular speed:  $\omega = \frac{d\theta}{dt}$

Angular acceleration:  $\alpha = \frac{d\omega}{dt} = \omega \frac{d\omega}{d\theta}$

For a constant angular speed  $\omega$ ,

Angular displacement:  $\theta = \theta_o + \omega t \quad (\theta = \theta_o \text{ at } t = 0)$

For a constant angular acceleration  $\alpha$ ,

$$\omega = \omega_o + \alpha t \quad (\omega = \omega_o \text{ at } t = 0)$$

$$\theta = \theta_o + \omega_o t + \frac{1}{2} \alpha t^2$$

$$\omega^2 = \omega_o^2 + 2\alpha(\theta - \theta_o)$$

**Velocities in General Plane Motion**

General plane motion of a rigid body is defined by simultaneous translation and rotation in a plane. Figure 1.3.11 illustrates how the velocity of a point A can be determined using Equation 1.3.46, which is based on relative motion of particles.

$$\mathbf{v}_A = \underbrace{\mathbf{v}_B}_{\text{translation}} + \underbrace{\omega \times \mathbf{r}_{A/B}}_{\text{rotation}} \tag{1.3.46}$$

FIGURE 1.3.11 Analysis of velocities in general plane motion.

There are five important points to remember when solving general plane motion problems, including those of interconnected rigid bodies.

1. The angular velocity of a rigid body in plane motion is independent of the reference point.
2. The common point of two or more pin-jointed members must have the same absolute velocity even though the individual members may have different angular velocities.
3. The points of contact in members that are in temporary contact may or may not have the same absolute velocity. If there is sliding between the members, the points in contact have different absolute velocities. The absolute velocities of the contacting particles are always the same if there is no sliding.
4. If the angular velocity of a member is not known, but some points of the member move along defined paths (i.e., the end points of a piston rod), these paths define the directions of the velocity vectors and are useful in the solution.
5. The geometric center of a wheel rolling on a flat surface moves in rectilinear motion. If there is no slipping at the point of contact, the linear distance the center point travels is equal to that portion of the rim circumference that has rolled along the flat surface.

**Instantaneous Center of Rotation**

The method of *instantaneous center of rotation* is a geometric method of determining the angular velocity when two velocity vectors are known for a given rigid body. Figure 1.3.12 illustrates the method. This procedure can also be used to determine velocities that are parallel to one of the given velocities, by similar triangles.

FIGURE 1.3.12 Schematic for instantaneous center of rotation.

Velocities  $v_A$  and  $v_B$  are given; thus the body is rotating about point  $I$  at that instant. Point  $I$  has zero velocity at that instant, but generally has an acceleration. This method does *not* work for the determination of angular accelerations.

**Acceleration in General Plane Motion**

Figure 1.3.13 illustrates a method of determining accelerations of points of a rigid body. This is similar to (but more difficult than) the procedure of determining velocities.

FIGURE 1.3.13 Accelerations in general plane motion.

$$\begin{aligned}
 \mathbf{a}_B &= \mathbf{a}_A + \alpha \times \mathbf{r}_{B/A} + \omega \times (\omega \times \mathbf{r}_{B/A}) \\
 \mathbf{a}_B &= \underbrace{\mathbf{a}_A}_{\text{translation}} + \underbrace{(\mathbf{a}_{B/A})_t + (\mathbf{a}_{B/A})_n}_{\text{rotation}}
 \end{aligned}
 \tag{1.3.47}$$

There are six key points to consider when solving this kind of a problem.

1. The angular velocity and acceleration of a rigid body in plane motion are independent of the reference point.
2. The common points of pin-jointed members must have the same absolute acceleration even though the individual members may have different angular velocities and angular accelerations.
3. The points of contact in members that are in temporary contact may or may not have the same absolute acceleration. Even when there is no sliding between the members, only the tangential accelerations of the points in contact are the same, while the normal accelerations are frequently different in magnitude and direction.
4. The instantaneous center of zero velocity in general has an acceleration and should *not* be used as a reference point for accelerations unless its acceleration is known and included in the analysis.
5. If the angular acceleration of a member is not known, but some points of the member move along defined paths, the geometric constraints of motion define the directions of normal and tangential acceleration vectors and are useful in the solution.
6. The geometric center of a wheel rolling on a flat surface moves in rectilinear motion. If there is no slipping at the point of contact, the linear acceleration of the center point is parallel to the flat surface and equal to  $r\alpha$  for a wheel of radius  $r$  and angular acceleration  $\alpha$ .

**General Motion of a Rigid Body**

Figure 1.3.14 illustrates the complex general motion (three-dimensional) of a rigid body. It is important to note that here the angular velocity and angular acceleration vectors are not necessarily in the same direction as they are in general plane motion.

Equations 1.3.48 give the velocity and acceleration of a point on the rigid body. These equations are the same as those presented for plane motion.

FIGURE 1.3.14 General motion of a rigid body.

$$\mathbf{v}_B = \mathbf{v}_A + \boldsymbol{\omega} \times \mathbf{r}_{B/A}$$

$$\mathbf{a}_B = \mathbf{a}_A + \boldsymbol{\alpha} \times \mathbf{r}_{B/A} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}_{B/A}) \tag{1.3.48}$$

$$\mathbf{a}_B = \mathbf{a}_A + (\mathbf{a}_{B/A})_t + (\mathbf{a}_{B/A})_n$$

The most difficult part of solving a general motion problem is determining the angular acceleration vector. There are three cases for the determination of the angular acceleration.

1. The direction of  $\boldsymbol{\omega}$  is constant. This is plane motion and  $\boldsymbol{\alpha} = \dot{\boldsymbol{\omega}}$  can be used in scalar solutions of problems.
2. The magnitude of  $\boldsymbol{\omega}$  is constant but its direction changes. An example of this is a wheel which travels at a constant speed on a curved path.
3. Both the magnitude and direction of  $\boldsymbol{\omega}$  change. This is *space motion* since all or some points of the rigid body have three-dimensional paths. An example of this is a wheel which accelerates on a curved path.

A useful expression can be obtained from item 2 and Figure 1.3.15. The rigid body is fixed at point  $O$  and  $\boldsymbol{\omega}$  has a constant magnitude. Let  $\boldsymbol{\omega}$  rotate about the  $Y$  axis with angular velocity  $\boldsymbol{\Omega}$ . The angular acceleration is determined from Equation 1.3.49.

FIGURE 1.3.15 Rigid body fixed at point  $O$ .

$$\boldsymbol{\alpha} = \frac{d\boldsymbol{\omega}}{dt} = \boldsymbol{\Omega} \times \boldsymbol{\omega} \tag{1.3.49}$$

For *space motion* it is essential to combine the results of items 1 and 2, which provide components of  $\boldsymbol{\alpha}$  for the change in magnitude and the change in direction. The following example illustrates the procedure.

**Example 9**

The rotor shaft of an alternator in a car is in the horizontal plane. It rotates at a constant angular speed of 1500 rpm while the car travels at  $v = 60$  ft/sec on a horizontal road of 400 ft radius (Figure 1.3.16). Determine the angular acceleration of the rotor shaft if  $v$  increases at the rate of 8 ft/sec<sup>2</sup>.

FIGURE 1.3.16 Schematic of shaft's motion.

*Solution.* There are two components of  $\alpha$ . One is the change in the direction of the rotor shaft's  $\omega_x$ , and the other is the change in magnitude from the acceleration of the car.

1. Component from the change in direction. Determine  $\omega_c$  of the car.

$$v = r\omega_c$$

$$\omega_c = 0.15 \text{ rad/sec } \mathbf{k}$$

Use Equation 1.3.49:

$$\alpha = \omega_c \times \omega = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ 0 & 0 & 0.15 \\ 157.1 & 0 & 0 \end{vmatrix} = 23.6\mathbf{j} \text{ rad/sec}^2$$

2. Component from the acceleration of the car. Use Equation 1.3.9:

$$\alpha_c r = a_t$$

$$\alpha_c = 0.02\mathbf{k} \text{ rad/sec}^2$$

The angular acceleration of the rotor shaft is

$$\alpha = (23.6\mathbf{j} + 0.02\mathbf{k}) \text{ rad/sec}^2$$

This problem could also be solved using the method in the next section.

### Time Derivative of a Vector Using a Rotating Frame

The basis of determining time derivatives of a vector using a rotating frame is illustrated in Figure 1.3.17.

$$(\mathbf{Q})_{XYZ} = (\dot{\mathbf{Q}})_{xyz} + \boldsymbol{\Omega} \times \mathbf{Q}$$

FIGURE 1.3.17 Time derivative of a vector using a rotating reference frame.

### Analysis of Velocities and Accelerations Using Rotating and Translating Frames

With the concept of general motion understood, an advantageous method of determining velocities and accelerations is available by the method of rotating reference frames. There are two cases in which this method can be used.

For a common origin of  $XYZ$  and  $xyz$ , with  $\mathbf{r}$  being a position vector to a point  $P$ ,

$$\begin{aligned}\mathbf{v}_P &= \mathbf{v}_{xyz} + \boldsymbol{\Omega} \times \mathbf{r} \\ \mathbf{a}_P &= \mathbf{a}_{xyz} + \dot{\boldsymbol{\Omega}} \times \mathbf{r} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{r}) + 2\boldsymbol{\Omega} \times \mathbf{v}_{xyz}\end{aligned}\tag{1.3.50}$$

For the origin  $A$  of  $xyz$  translating with respect  $XYZ$ :

$$\begin{aligned}\mathbf{v}_P &= \mathbf{v}_A + \left(\dot{\mathbf{r}}_{P/A}\right)_{xyz} + \boldsymbol{\Omega} \times \mathbf{r}_{P/A} \\ \mathbf{a}_P &= \mathbf{a}_A + \mathbf{a}_{xyz} + \dot{\boldsymbol{\Omega}} \times \mathbf{r}_{P/A} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{r}_{P/A}) + 2\boldsymbol{\Omega} \times \mathbf{v}_{xyz}\end{aligned}\tag{1.3.51}$$

where  $\boldsymbol{\Omega}$  is the angular velocity of the  $xyz$  frame with respect to  $XYZ$ .  $2\boldsymbol{\Omega} \times \mathbf{v}_{xyz}$  is the Coriolis acceleration.

## Kinetics of Rigid Bodies in Plane Motion

### Equation of Translational Motion

The fundamental equation for rigid body translation is based on Newton’s second law. In Equation 1.3.52,  $\mathbf{a}$  is the acceleration of the center of mass of the rigid body, no matter where the resultant force acts on the body. *The sum of the external forces is equal to the mass of the rigid body times the acceleration of the mass center of the rigid body*, independent of any rotation of the body.

$$\sum \mathbf{F} = m\mathbf{a}_c\tag{1.3.52}$$

### Equation of Rotational Motion

Equation 1.3.53 states that *the sum of the external moments on the rigid body is equal to the moment of inertia about an axis times the angular acceleration of the body about that axis*. The angular acceleration  $\alpha$  is for the rigid body rotating about an axis. This equation is independent of rigid body translation.

$$\sum \mathbf{M}_c = I_c\alpha\tag{1.3.53}$$

where  $\sum \mathbf{M}_c = \dot{\mathbf{H}}_c$ ,  $\mathbf{H}_c = I_c\omega$ . An application is illustrated in [Color Plate 2](#).

### Applications of Equations of Motion

It is important to use the equations of motion properly. For plane motion, three scalar equations are used to define the motion in a plane.

$$\sum F_x = ma_{c_x} \quad \sum F_y = ma_{c_y} \quad \sum M_c = I_c\alpha\tag{1.3.54}$$

If a rigid body undergoes only translation,

$$\sum F_x = ma_{C_x} \quad \sum F_y = ma_{C_y} \quad \sum M_C = 0 \quad (1.3.55)$$

If the rigid body undergoes pure rotation about the center of mass,

$$\sum F_x = 0 \quad \sum F_y = 0 \quad \sum M_C = I_C \alpha \quad (1.3.56)$$

Rigid body motions are categorized according to the constraints of the motion:

1. *Unconstrained Motion*: Equations 1.3.54 are directly applied with all three equations independent of one another.
2. *Constrained Motion*: Equations 1.3.54 are not independent of one another. Generally, a kinematics analysis has to be made to determine how the motion is constrained in the plane. There are two special cases:
  - a. Point constraint: the body has a fixed axis.
  - b. Line constraint: the body moves along a fixed line or plane.

When considering systems of rigid bodies, it is important to remember that at most only three equations of motion are available from each free-body diagram for plane motion to solve for three unknowns. The motion of interconnected bodies must be analyzed using related free-body diagrams.

### Rotation about a Fixed Axis Not Through the Center of Mass

The methods presented above are essential in analyzing rigid bodies that rotate about a fixed axis, which is common in machines (shafts, wheels, gears, linkages). The mass of the rotating body may be nonuniformly distributed as modeled in [Figure 1.3.18](#).

**FIGURE 1.3.18** Rotation of a rigid body about a fixed axis.

Note that  $r_C$  is the nearest distance between the fixed axis  $O$  and the mass center  $C$ . The figure also defines the normal and tangential coordinate system used in Equations 1.3.57, which are the scalar equations of motion using normal and tangential components. The sum of the forces must include all reaction forces on the rigid body at the axis of rotation.

$$\sum F_n = mr_C \omega^2 \quad \sum F_t = mr_C \alpha \quad \sum M_O = I_O \alpha \quad (1.3.57)$$

### General Plane Motion

A body that is translating and rotating is in general plane motion. The scalar equations of motion are given by Equation 1.3.54. If an arbitrary axis  $A$  is used to find the resultant moment,

$$\sum \mathbf{M}_A = I_A \alpha + \mathbf{r} \times m \mathbf{a}_C \quad (1.3.58)$$

where  $C$  is the center of mass. It is a common error to forget to include the cross-product term in the analysis.

There are two special cases in general plane motion, *rolling* and *sliding*.

Figure 1.3.19 shows pure rolling of a wheel without slipping with the center of mass  $C$  at the geometric center of the wheel. This is called pure rolling of a balanced wheel.

FIGURE 1.3.19 Pure rolling of a wheel.

From this figure the scalar equation of motion results,

$$a_{C_x} = r\alpha \quad \sum M_A = I_A \alpha \quad (1.3.59)$$

For balanced wheels either sliding or not sliding, the following schematic is helpful.

$\sum F_x = ma_{C_x}$	$P - f = ma_{C_x}$		
$\sum F_y = ma_{C_y}$	$N - mg = 0$	for no	for
$\sum M_C = I_C \alpha$	$f r = I_C \alpha$	slipping	slipping
$a_{C_x} = \alpha r$			
$f = \mu_k N$			

If slipping is not certain, assume there is no slipping and check whether  $\mathcal{F} \leq \mu_s N$ . If  $\mathcal{F} > \mu_s N$  (not possible; there is sliding), start the solution over using  $\mathcal{F} = \mu_k N$  but not using  $a_{C_x} = r\alpha$ , which is not valid here.

For the problem involving unbalanced wheels (the mass center and geometric center do not coincide), Equations 1.3.60 result.

$$a_{C_x} \neq r\alpha \quad a_G = r\alpha \quad (1.3.60)$$

$$\mathbf{a}_C = \mathbf{a}_G + \mathbf{a}_{C/G} = \mathbf{a}_G + (\mathbf{a}_{C/G})_n + (\mathbf{a}_{C/G})_t$$

### Energy and Momentum Methods for Rigid Bodies in Plane Motion

Newton's second law in determining kinetics relationships is not always the most efficient, although it always works. As for particles, energy and momentum methods are often useful to analyze rigid bodies in plane motion.

#### Work of a Force on a Rigid Body

The work of a force acting on a rigid body moving from position 1 to 2 is

$$U_{12} = \int_1^2 \mathbf{F} \cdot d\mathbf{r} = \int_1^2 \mathbf{F} \cdot \mathbf{v} dt \quad (1.3.61)$$

### Work of a Moment

The work of a moment has a similar form, for angular positions  $\theta$ ,

$$U_{12} = \int_{\theta_1}^{\theta_2} \mathbf{M} \cdot d\theta \quad (1.3.62)$$

In the common case where the moment vector  $\mathbf{M}$  is perpendicular to the plane of motion,  $\mathbf{M} \cdot d\theta = M d\theta$ .

It is important to note those forces that do no work:

1. Forces that act at fixed points on the body do not do work. For example, the reaction at a fixed, frictionless pin does no work on the body that rotates about that pin.
2. A force which is always perpendicular to the direction of the motion does no work.
3. The weight of a body does no work when the body's center of gravity moves in a horizontal plane.
4. The friction force  $\mathcal{F}$  at a point of contact on a body that rolls without slipping does no work. This is because the point of contact is the instantaneous center of zero velocity.

### Kinetic Energy of a Rigid Body

The kinetic energy of a particle only consists of the energy associated with its translational motion. The kinetic energy of a rigid body also includes a term for the rotational energy of the body,

$$T = T_{trans} + T_{rot} = \frac{1}{2}mv_C^2 + \frac{1}{2}I_C\omega^2 \quad (1.3.63)$$

where  $C$  is the center of mass of the rigid body.

The kinetic energy of a rigid body rotating about an arbitrary axis at point  $O$  is

$$T = \frac{1}{2}I_O\omega^2$$

### Principle of Work and Energy

The principle of work and energy for a rigid body is the same as used for particles with the addition of the rotational energy terms.

$$T_2 = T_1 + U_{12} \quad (1.3.64)$$

where  $T_1$  = initial kinetic energy of the body

$T_2$  = final kinetic energy of the body

$U_{12}$  = work of all external forces and moments acting on the body moving from position 1 to 2

This method is advantageous when displacements and velocities are the desired quantities.

### Conservation of Energy

The conservation of energy in a conservative rigid body system is

$$T_1 + V_1 = T_2 + V_2 \quad (1.3.65)$$

where  $T$  = kinetic energy

$V$  = total potential energy (gravitational and elastic)

### Power

The net power supplied to or required of the system is

$$\text{power} = \dot{T}_{trans} + \dot{T}_{rot} + \dot{V}_g + \dot{V}_e \tag{1.3.66}$$

This can be calculated by taking time derivatives of the kinetic and potential energy terms. Each term is considered positive when it represents the power supplied to the system and negative when power is taken from the system.

**Impulse and Momentum of a Rigid Body**

Impulse and momentum methods are particularly useful when time and velocities are of interest. Figure 1.3.20 shows how rigid bodies are to be considered for this kind of analysis. Notice that rotational motion of the rigid body must be included in the modeling.

FIGURE 1.3.20 Impulse and momentum for rigid bodies.

The impulse of the external forces in the given interval is

$$\int_{t_1}^{t_2} \sum \mathbf{F} dt = m_{C_2} (\mathbf{v}_{C_2} - \mathbf{v}_{C_1}) \tag{1.3.67}$$

where  $t$  is time,  $C$  is the center of mass, and  $\sum \mathbf{F}$  includes all external forces.

The impulse of the external moments in the given interval is

$$\int_{t_1}^{t_2} \sum \mathbf{M}_C dt = \mathbf{H}_{C_2} - \mathbf{H}_{C_1} \tag{1.3.68}$$

For plane motion, if  $\sum \mathbf{M}$  is parallel to  $\omega$ , the scalar expressions are

$$\int_{t_1}^{t_2} \sum M_C dt = I_C (\omega_2 - \omega_1) \tag{1.3.69}$$

$$\int_{t_1}^{t_2} \sum M_O dt = I_O (\omega_2 - \omega_1) \quad \text{for rotation about a fixed point } O$$

**Impulse and Momentum of a System of Rigid Bodies**

A system of rigid bodies can be analyzed using one of the two following procedures, illustrated in Figure 1.3.21.

1. Apply the principle of impulse and momentum to each rigid member separately. The mutual forces acting between members must be included in the formulation of the solution.
2. Apply the principle of impulse and momentum to the entire system of bodies, ignoring the mutual forces between members.

FIGURE 1.3.21 System of rigid bodies.

### Conservation of Momentum

The principle of conservation of linear and angular momentum of particles can be extended to rigid bodies that have no external forces or moments acting on them. The conservation of linear momentum means that the center of mass  $C$  moves at a constant speed in a constant direction,

$$\sum \mathbf{F} = 0 \Rightarrow \Delta \mathbf{G} = 0 \tag{1.3.70}$$

$$\mathbf{v}_{C_1} = \mathbf{v}_{C_2}$$

Likewise, for conservation of angular momentum of rigid bodies,

$$\sum \mathbf{M} = 0 \Rightarrow \Delta \mathbf{H}_C = 0 \tag{1.3.71}$$

$$I_C \omega_1 = I_C \omega_2$$

For a system of rigid bodies, use the same fixed reference point  $O$  for all parts of the system. Thus, for plane motion,

$$\Delta \mathbf{H}_O = 0 \quad I_O \omega_1 = I_O \omega_2 \tag{1.3.72}$$

There are two important points to remember when using these equations. First,  $\Delta \mathbf{H}_C = 0$  does not imply that  $\Delta \mathbf{H}_O = 0$ , or vice versa. Second, conservation of momentum does not require the simultaneous conservation of both angular and linear momenta (for example, there may be an angular impulse while linear momentum is conserved).

### Kinetics of Rigid Bodies in Three Dimensions

The concepts of plane rigid body motion can be extended to the more complicated problems in three dimensions, such as of gyroscopes and jet engines. This section briefly covers some fundamental topics. There are many additional topics and useful methods that are included in the technical literature.

#### Angular Momentum in Three Dimensions

For analyzing three-dimensional angular momentum, three special definitions are used. These can be visualized by considering a spinning top (Figure 1.3.22).

*Precession* — rotation of the angular velocity vector about the  $y$  axis.

*Space Cone* — locus of the absolute positions of the instantaneous axis of rotation.

*Body Cone* — locus of the positions of the instantaneous axis relative to the body. The body cone appears to roll on the space cone (not shown here).

FIGURE 1.3.22 Motion of an inclined, spinning top.

Equations 1.3.73 provide the scalar components of the total angular momentum.

$$\begin{aligned}
 H_x &= I_x \omega_x - I_{xy} \omega_y - I_{xz} \omega_z \\
 H_y &= -I_{xy} \omega_x + I_y \omega_y - I_{yz} \omega_z \\
 H_z &= -I_{zx} \omega_x - I_{zy} \omega_y + I_z \omega_z
 \end{aligned}
 \tag{1.3.73}$$

**Impulse and Momentum of a Rigid Body in Three-Dimensional Motion**

The extension of the planar motion equations of impulse and momentum to three dimensions is straightforward.

$$\text{System momenta} = \begin{cases} \text{linear momentum of mass center (G)} \\ \text{angular momentum about mass center (H}_C) \end{cases}
 \tag{1.3.74}$$

where **G** and **H** have different units. The principle of impulse and momentum is applied for the period of time  $t_1$  to  $t_2$ ,

$$\begin{aligned}
 \mathbf{G}_2 &= \mathbf{G}_1 + (\text{external linear impulses})_1^2 \\
 \mathbf{H}_{C_2} &= \mathbf{H}_{C_1} + (\text{external angular impulses})_1^2
 \end{aligned}
 \tag{1.3.75}$$

**Kinetic Energy of a Rigid Body in Three-Dimensional Motion**

The total kinetic energy of a rigid body in three dimensions is

$$T = \underbrace{\frac{1}{2} m v_C^2}_{\text{translation of mass center}} + \underbrace{\frac{1}{2} \boldsymbol{\omega} \cdot \mathbf{H}_C}_{\text{rotation about mass center}}
 \tag{1.3.76}$$

For a rigid body that has a fixed point  $O$ ,

$$T = \frac{1}{2} \boldsymbol{\omega} \cdot \mathbf{H}_O
 \tag{1.3.77}$$

### Equations of Motion in Three Dimensions

The equations of motion for a rigid body in three dimensions are extensions of the equations previously stated.

$$\begin{aligned}\sum \mathbf{F} &= m\mathbf{a}_c \\ \sum \mathbf{M}_C &= \dot{\mathbf{H}}_C = \left(\dot{\mathbf{H}}_C\right)_{xyz} + \boldsymbol{\Omega} \times \mathbf{H}_C\end{aligned}\quad (1.3.78)$$

where  $\mathbf{a}_c$  = acceleration of mass center

$\mathbf{H}_C$  = angular momentum of the body about its mass center

$xyz$  = frame fixed in the body with origin at the mass center

$\boldsymbol{\Omega}$  = angular velocity of the  $xyz$  frame with respect to a fixed  $XYZ$  frame

Note that an arbitrary fixed point  $O$  may be used for reference if done consistently.

### Euler's Equations of Motion

Euler's equations of motion result from the simplification of allowing the  $xyz$  axes to coincide with the principal axes of inertia of the body.

$$\begin{aligned}\sum M_x &= I_x \dot{\omega}_x - (I_y - I_z) \omega_y \omega_z \\ \sum M_y &= I_y \dot{\omega}_y - (I_z - I_x) \omega_z \omega_x \\ \sum M_z &= I_z \dot{\omega}_z - (I_x - I_y) \omega_x \omega_y\end{aligned}\quad (1.3.79)$$

where all quantities must be evaluated with respect to the appropriate principal axes.

### Solution of Problems in Three-Dimensional Motion

In order to solve a three-dimensional problem it is necessary to apply the six independent scalar equations.

$$\begin{aligned}\sum F_x &= ma_{c_x} & \sum F_y &= ma_{c_y} & \sum F_z &= ma_{c_z} \\ \sum M_x &= \dot{H}_x + \omega_y H_z - \omega_z H_y \\ \sum M_y &= \dot{H}_y + \omega_z H_x - \omega_x H_z \\ \sum M_z &= \dot{H}_z + \omega_x H_y - \omega_y H_x\end{aligned}\quad (1.3.80)$$

These equations are valid in general. Some common cases are briefly stated.

*Unconstrained motion.* The six governing equations should be used with  $xyz$  axes attached at the center of mass of the body.

*Motion of a body about a fixed point.* The governing equations are valid for a body rotating about a noncentroidal fixed point  $O$ . The reference axes  $xyz$  must pass through the fixed point to allow using a set of moment equations that do not involve the unknown reactions at  $O$ .

*Motion of a body about a fixed axis.* This is the generalized form of plane motion of an arbitrary rigid body. The analysis of unbalanced wheels and shafts and corresponding bearing reactions falls in this category.

## 1.4 Vibrations

*Bela I. Sandor with assistance by Stephen M. Birn*

Vibrations in machines and structures should be analyzed and controlled if they have undesirable effects such as noise, unpleasant motions, or fatigue damage with potentially catastrophic consequences. Conversely, vibrations are sometimes employed to useful purposes, such as for compacting materials.

### Undamped Free and Forced Vibrations

The simplest vibrating system has motion of one degree of freedom (DOF) described by the coordinate  $x$  in Figure 1.4.1. (An analogous approach is used for torsional vibrations, with similar results.)

FIGURE 1.4.1 Model of a simple vibrating system.

Assuming that the spring has no mass and that there is no damping in the system, the equation of motion for **free vibration** (motion under internal forces only;  $F = 0$ ) is

$$m\ddot{x} + kx = 0 \quad \text{or} \quad \ddot{x} + \omega^2 x = 0 \tag{1.4.1}$$

where  $\omega = \sqrt{k/m}$  = natural circular frequency in rad/sec.

The displacement  $x$  as a function of time  $t$  is

$$x = C_1 \sin \omega t + C_2 \cos \omega t \tag{1.4.2}$$

where  $C_1$  and  $C_2$  are constants depending on the initial conditions of the motion. Alternatively,

$$x = A \sin(\omega t + \phi)$$

where  $C_1 = A \cos \phi$ ,  $C_2 = A \sin \phi$ , and  $\phi$  is the phase angle, another constant. A complete cycle of the motion occurs in time  $\tau$ , the *period of simple harmonic motion*,

$$\tau = \frac{2\pi}{\omega} = 2\pi \sqrt{\frac{m}{k}} \text{ (seconds per cycle)}$$

The *frequency* in units of cycles per second (cps) or hertz (Hz) is  $f = 1/\tau$ .

The simplest case of **forced vibration** is modeled in Figure 1.4.1, with the force  $F$  included. Using typical simplifying assumptions as above, the equation of motion for a harmonic force of forcing frequency  $\Omega$ ,

$$m\ddot{x} + kx = F_0 \sin \Omega t \tag{1.4.3}$$

The vibrations of a mass  $m$  may also be induced by the displacement  $d = d_o \sin \Omega t$  of a foundation or another mass  $M$  to which  $m$  is attached by a spring  $k$ . Using the same reference point and axis for both  $x$  and  $d$ , the equation of motion for  $m$  is

$$\begin{aligned} m\ddot{x} + k(x - d_o \sin \Omega t) &= 0 \\ m\ddot{x} + kx &= kd_o \sin \Omega t \end{aligned} \quad (1.4.4)$$

where  $d_o$  is the amplitude of vibration of the moving support  $M$ , and  $\Omega$  is its frequency of motion.

The general solution of the forced vibration in the *steady state* (after the initial, transient behavior) is

$$\begin{aligned} x &= A \sin \Omega t \\ A &= \frac{F_o}{k - m\Omega^2} = \frac{F_o/k}{1 - (\Omega/\omega)^2} \end{aligned} \quad (1.4.5)$$

where  $\Omega$  is the forcing frequency and  $\omega$  is the natural circular frequency of the system of  $m$  and  $k$ .

**Resonance.** The amplitude of the oscillations in forced vibrations depends on the frequency ratio  $\Omega/\omega$ . Without damping or physical constraints, the amplitude would become infinite at  $\Omega = \omega$ , the condition of **resonance**. Dangerously large amplitudes may occur at resonance and at other frequency ratios near the resonant frequency. A *magnification factor* is defined as

$$MF = \frac{F}{F_o/k} = \frac{A}{d_o} = \frac{1}{1 - (\Omega/\omega)^2} \quad (1.4.6)$$

Several special cases of this are noted:

1. Static loading:  $\Omega = 0$ , or  $\Omega \ll \omega$ ;  $MF \approx 1$ .
2. Resonance:  $\Omega = \omega$ ;  $MF = \infty$ .
3. High-frequency excitation:  $\Omega \gg \omega$ ;  $MF \approx 0$ .
4. Phase relationships: The vibration is *in phase* for  $\Omega < \omega$ , and it is  $180^\circ$  *out of phase* for  $\Omega > \omega$ .

## Damped Free and Forced Vibrations

A vibrating system of one degree of freedom and damping is modeled in [Figure 1.4.2](#). The equation of motion for *damped free vibrations* ( $F = 0$ ) is

$$m\ddot{x} + c\dot{x} + kx = 0 \quad (1.4.7)$$

**FIGURE 1.4.2** Model of a damped vibrating system.

The displacement  $x$  as a function of time  $t$  is

$$x = e^{\lambda t} \tag{1.4.8}$$

$$\lambda_{1,2} = \frac{-c}{2m} \pm \sqrt{\left(\frac{c}{2m}\right)^2 - \frac{k}{m}}$$

The value of the coefficient of viscous damping  $c$  that makes the radical zero is the *critical damping coefficient*  $c_c = 2m \sqrt{k/m} = 2m\omega$ . Three special cases of damped free vibrations are noted:

1. Overdamped system:  $c > c_c$ ; the motion is *nonvibratory* or *aperiodic*.
2. Critically damped system:  $c = c_c$ ; this motion is also nonvibratory;  $x$  decreases at the fastest rate possible without oscillation of the mass.
3. Underdamped system:  $c < c_c$ ; the roots  $\lambda_{1,2}$  are complex numbers; the displacement is

$$x = Ae^{-(c/2m)t} \sin(\omega_d t + \phi)$$

where  $A$  and  $\phi$  are constants depending on the initial conditions, and the *damped natural frequency* is

$$\omega_d = \omega \sqrt{1 - \left(\frac{c}{c_c}\right)^2}$$

The ratio  $c/c_c$  is the *damping factor*  $\zeta$ . The damping in a system is determined by measuring the rate of decay of free oscillations. This is expressed by the *logarithmic decrement*  $\delta$ , involving any two successive amplitudes  $x_i$  and  $x_{i+1}$ ,

$$\delta = \ln \frac{x_i}{x_{i+1}} = \frac{2\pi\zeta}{\sqrt{1-\zeta^2}} \approx 2\pi\zeta$$

The simplifying approximation for  $\delta$  is valid for up to about 20% damping ( $\zeta \approx 0.2$ ).

The *period of the damped vibration* is  $\tau_d = 2\pi/\omega_d$ . It is a constant, but always larger than the period of the same system without damping. In many real systems the damping is relatively small ( $\zeta < 0.2$ ), where  $\tau_d \approx \tau$  and  $\omega_d \approx \omega$  can be used.

The equation of motion for *damped forced vibrations* (Figure 1.4.2;  $F \neq 0$ ) is

$$m\ddot{x} + c\dot{x} + kx = F_o \sin\Omega t \tag{1.4.9}$$

The solution for steady-state vibration of the system is

$$x = A \sin(\Omega t - \phi) \tag{1.4.10}$$

where the amplitude and phase angle are from

$$A = \frac{F_o}{\sqrt{(c\Omega)^2 + (k - m\Omega^2)^2}}$$

$$\tan \phi = \frac{c\Omega}{k - m\Omega^2}$$

The *magnification factor* for the amplitude of the oscillations is

$$MF = \frac{A}{F_o/k} = \frac{A}{d_o} = \frac{1}{\sqrt{[2\zeta(\Omega/\omega)]^2 + [1 - (\Omega/\omega)^2]^2}} \tag{1.4.11}$$

This quantity is sketched as a function of the frequency ratio  $\Omega/\omega$  for several damping factors in [Figure 1.4.3](#). Note that the amplitude of vibration is reduced at all values of  $\Omega/\omega$  if the coefficient of damping  $c$  is increased in a particular system.

**FIGURE 1.4.3** Magnification factor in damped forced vibration.

## Vibration Control

### Vibration Isolation

It is often desirable to reduce the forces transmitted, or the noise and motions inside or in the neighborhood of vibrating machines and structures. This can be done to some extent within the constraints of space and additional weight and cost by the use of isolators, such as rubber engine mounts and wheel suspension systems in cars. Many kinds of isolating materials and systems are available commercially.

The effectiveness of vibration isolation is expressed by the *transmissibility*  $TR$ , the ratio of the force transmitted  $F_T$  to the disturbing force  $F_o$ . A simple isolation system is modeled as a spring and a dashpot in parallel, for which the transmissibility is given by Equation 1.4.12 and sketched in [Figure 1.4.4](#).

$$TR = \frac{F_T}{F_o} = \frac{\sqrt{1 + 4\zeta^2(\Omega/\omega)^2}}{\sqrt{[1 - (\Omega/\omega)^2]^2 + 4\zeta^2(\Omega/\omega)^2}} \tag{1.4.12}$$

**FIGURE 1.4.4** Transmissibility patterns of a vibration isolator.

When damping is negligible,

$$TR \approx \frac{1}{(\Omega/\omega)^2 - 1}$$

Note from the figure that

1. Vibration isolation occurs at  $\Omega/\omega > \sqrt{2}$ .
2. Isolation efficiency increases with decreasing stiffness of the isolation mounts.
3. Damping reduces isolation efficiency. However, some damping is normally required if resonance may occur in a system even for short periods.
4. The response curves are essentially independent of damping when  $\Omega/\omega$  is large ( $\geq 3$ ) and damping is low ( $\zeta \leq 0.2$ ). Here  $TR \approx 1/[(\Omega/\omega)^2 - 1]$ .
5. For a system with more than one excitation frequency, the lowest excitation frequency is of primary importance.

The efficiency of an isolating system is defined by the reduction  $R$  in transmissibility,

$$R = 1 - TR$$

If a certain reduction  $R$  in transmissibility is desired, the appropriate stiffness  $k$  of an isolation system is obtained from  $\omega = \sqrt{k/m}$  and

$$\frac{\Omega}{\omega} = \sqrt{\frac{2 - R}{1 - R}}$$

A small magnitude of stiffness  $k$  makes the reduction  $R$  in transmissibility large. It is difficult to achieve isolation for very low excitation frequencies because of the required large static deflections. To obtain highly efficient isolation at low excitation frequencies, a large supporting mass  $M$  may be utilized, with the value of  $\omega = \sqrt{k/(m + M)}$ .

### Vibration Absorption

In some cases a vibratory force is purposely generated in a system by a secondary spring-mass system to oppose a primary disturbing force and thereby reduce or eliminate the undesirable net effect. An interesting example of this is the “tuned-mass damper” in a few skyscrapers, designed to counter the oscillatory motions caused by wind. The secondary spring-mass system has disadvantages of its own, such as extra weight, complexity, and effectiveness limited to a single frequency.

### Balancing of Rotating Components

The conditions of static or dynamic unbalance of rotating bodies have long been recognized. These can be analyzed by the methods of elementary mechanics, simple tests can be performed in many cases, and adequate corrections can be made routinely to achieve balance, such as for the wheels of automotive vehicles. Three categories of increasing complexity are distinguished.

1. *Static unbalance.* The distributed or lumped masses causing unbalance are in a single axial plane and all on the same side of the axis of rotation (Figure 1.4.5). Thin disks are also in this category. Static unbalance is detected in a static test since the center of gravity of the body is not on the axis, and correction is made by adding or removing mass at a convenient radial distance from the axis.
2. *Static balance with dynamic unbalance.* This may be the case when the masses causing unbalance are in a single axial plane but on opposite sides of the axis of rotation (Figure 1.4.6a). Static balance is achieved if the center of gravity of the body is on the axis, but dynamic unbalance

results from the couple of the unbalance forces ( $m\omega^2r$ ) during rotation, causing a shaking of the axle.

3. *Static and dynamic unbalance.* This is the general case of unbalance, which can be visualized by letting  $m_1$  and  $m_2$  and the axis of rotation not all lie in the same plane (Figure 1.4.6b).

FIGURE 1.4.5 Schematic of static unbalance.

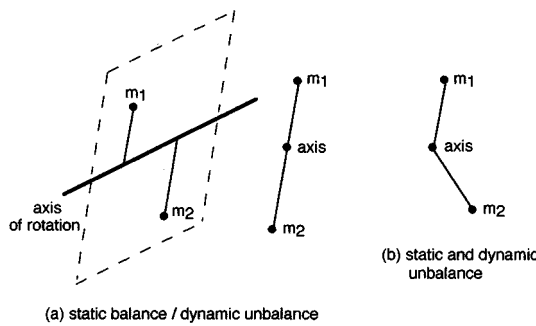

FIGURE 1.4.6 Schematic of two cases of dynamic unbalance.

The magnitude and angular position of a body’s unbalance can be determined using a dynamic balancing machine. Here the shaking forces are measured by electronically sensing the small oscillations of the bearings that can be correlated with the position of the body.

### Critical Speed of Rotating Shafts

A rotating shaft may become dangerously unstable and whirl with large lateral amplitudes of displacement at a critical speed of rotation. The critical speed, in revolutions per second, corresponds with the natural frequency of lateral vibration of the system. Thus, it can be analytically predicted fairly well and can be safely measured in a real but nonrotating machine with high precision.

If unavoidable, as at startup, the critical speed should be passed over rapidly. Other ways of minimizing the problems of whirling shafts include the proper balancing of rotors and the replacing of bent shafts and worn bearings.

### Random Vibrations. Shock Excitation

Many structures are subjected to nonharmonic excitations and respond with transient vibrations rather than steady-state motions. Random vibration is often caused by *shock* excitation, which implies that the loading occurs suddenly, in a short time with respect to the natural period of vibration of the system. Such a loading, typically caused by impact conditions, may be highly irregular in terms of amplitude, waveform, and repetition (Figure 1.4.7), but normally it is possible to extract practically uniform critical events from the loading history for purposes of future design and life prediction.

For most practical purposes, this plot represents aperiodic motion, where the important quantities are the maximum and average large amplitudes and the projected total repetitions (in this case, at the rate of about 1000 per day) over the design life of the structure. The small-amplitude transient vibrations

**FIGURE 1.4.7** Strain-time history at one strain-gage location on a steel bridge caused by two trucks moving in opposite directions. (A) Garbage truck in the near lane; (B) tractor trailer in the far lane. Weights unknown. (Data courtesy Mark J. Fleming, University of Wisconsin-Madison.)

associated with the large events are likely to be negligible here in terms of both dynamic behavior and fatigue damage, although the relatively large number of small oscillations may cause one to be concerned in some cases.

Random vibrations are difficult to deal with analytically. Numerical methods involving computers are advantageous to obtain response (or shock) spectrums of a system, assuming key parameters and simple models of nonharmonic excitations such as impulsive forces and force step functions. Since the maximum transient response is relatively insensitive to damping, an undamped system is useful in modeling response spectrums. Experimental techniques are needed to verify the analytical predictions, especially when the behavior of a multiple-degree-of-freedom system is determined from the response spectrum of a single-degree-of-freedom system.

**Multiple-Degree-of-Freedom Systems. Modal Analysis**

The analysis of a system with more than one degree of freedom requires an independent coordinate for each degree of freedom to describe the configurations. Thus, an  $n$ -degree-of-freedom system has  $n$  natural frequencies and  $n$  normal *modes* of vibration. Complex systems can be classified as (1) discrete and lumped-parameter systems with finite numbers of degrees of freedom or (2) continuous elastic bodies of distributed mass with infinite number of degrees of freedom (in theory). A common example of the latter is a vibrating beam, with the first two modes of vibration shown in Figure 1.4.8. Each *nodal point* is a point of zero deflection. Usually the *fundamental natural frequency* (the lowest) is the most important, and only the lowest few frequencies are considered in practice.

**FIGURE 1.4.8** Simply supported beam in two modes of vibration.

A system's harmonic vibrations are its *principal modes*. There are also many ways in which the system can vibrate nonharmonically. Periodic motion of complex wave form can be analyzed as a combination of principal-mode vibrations.

The classical method of mathematical solution and the experimental techniques become increasingly cumbersome and sometimes inaccurate for a system of more than a few degrees of freedom. The recent emergence of sophisticated numerical (finite element; Figure 1.4.9) and experimental (electro-optics) techniques has resulted in significant progress in this area. The synergistic aspects of several new methods are especially remarkable. For example, damage caused by vibrations can significantly affect a system's own modal behavior and, consequently, the rate of damage evolution. Such nonlinear changes of a system can now be investigated and eventually predicted by the hybrid applications of computerized numerical methods, fatigue and fracture mechanics (Section 1.6), and high-speed, noncontacting, full-field vibration and stress imaging (Sections 1.4, "Vibration-Measuring Instruments," and 1.5, "Experimental Stress Analysis and Mechanical Testing"). These enhance the already powerful modern methods of *modal analysis* for accurately describing the response of multiple-degree-of-freedom systems.

## Vibration-Measuring Instruments

There are many kinds of instruments for the experimental investigation of vibrating systems. They range from simple, inexpensive devices to sophisticated electro-optics with lasers or infrared detectors, with the list still expanding in many areas.

The basic quantities of interest regarding a vibrating system are the displacement, velocity, acceleration, and frequency. A typical sensor (or pickup or transducer) for determining these is the piezoelectric accelerometer, which is attached to the vibrating machine or structure to be analyzed. The complete setup normally includes amplifiers, frequency analyzer, oscilloscope, and recorders. An instrumented

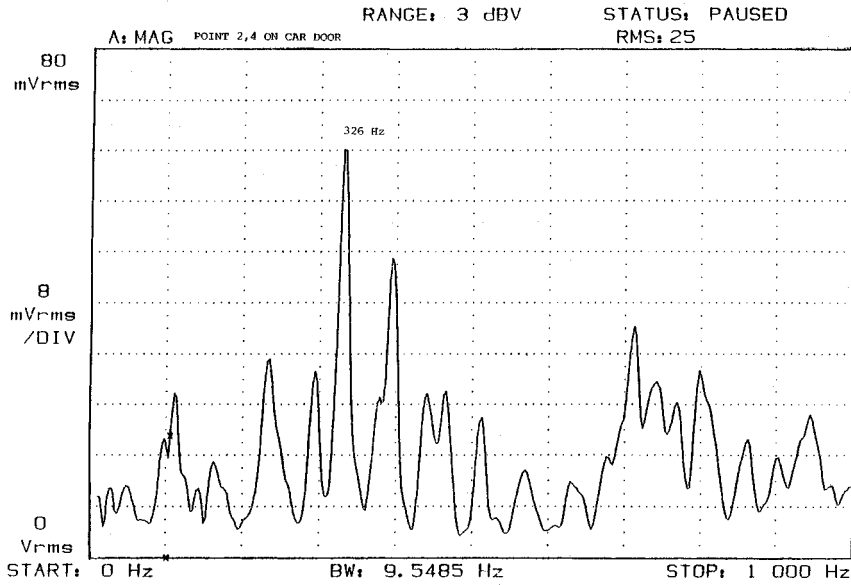

impact hammer may be used to provide well-defined impulse excitation to determine the natural frequencies of structures. The frequency analyzer can display the accelerometer output in either the time or the frequency domain.

Other kinds of devices used for vibration sensing include seismic spring-mass systems, electrical-resistance strain gages, and electromagnetic transducers.

Care must be exercised in matching a transducer to the task at hand, since reliable data can be obtained only if the transducer has a “flat-response” frequency region for the measurements of interest. For example, electromagnetic vibrometers (or seismometers) are low-frequency transducers that have low natural frequency compared to the frequency of the motion to be measured. At the other extreme, piezoelectric accelerometers are designed to have higher natural frequency than the frequency to be measured.

It is also important to use transducers of negligible mass compared to the mass of the vibrating system being measured. Very small, light-weight accelerometers are available to satisfy this condition in many cases. There are situations, however, where only noncontacting means of motion measurement provide satisfactory results. Optical techniques are prominent in this area, offering several advantages besides the noncontacting measurement capability. They can be full-field techniques, which means that data may be obtained rapidly from many points on a body using one instrument. They have excellent resolution and precision, and some of them are easy to use. Three kinds of optical instruments are distinguished here for vibratory system analysis, depending on the primary quantity measured:

1. *Displacement measurement.* Holography and speckle pattern imaging have excellent resolution, but they are adversely affected by unstable measuring conditions. They are most useful in laboratory applications.
2. *Velocity measurement.* Laser Doppler systems provide time-resolved, accelerometer-like measurements. They are relatively unaffected by measuring conditions, and are simple and rugged enough to use either in the laboratory or in the field. Several important capabilities of such a vibration pattern imaging system are worth mentioning (Color Plates 3 to 7):
  - Noncontacting; the structure’s response is not affected by the instrumentation; applicable in some hazardous environments (hot structures etc.), and short or long range (over 200 m) on natural surfaces
  - Single-point or full-field data acquisition at high resolution from areas of  $0.5 \times 0.5$  mm to  $8 \times 8$  m; up to 500 individual points can be programmed
  - Wide frequency range; 0 to 100 kHz (for example, Figure 1.4.10)
  - Sensitivity to a wide range of vibration velocities; 0.005 to 1000 mm/sec
  - Large depth of focus;  $\pm 3$  m at 10-m working distance
  - Node spacing down to a few millimeters can be resolved
  - Resolution of small displacements, down to the wavelength of the laser source (typically,  $\approx 1$  Å)
  - Safe, class II laser system;  $< 1$  mW output
  - Conventional signal processing is used to give multipoint modal parameters in familiar format for analytical comparisons
3. *Dynamic stress measurement.* Differential thermography via dynamic thermoelasticity (Figure 1.4.11) has recently become a powerful technique for measuring the modal response of vibrating structures and, uniquely, for directly assessing the structural integrity and durability aspects of the situation. This approach uses high-speed infrared electro-optics and has predictive capability because it can be quantitatively combined with modern fatigue and fracture mechanics methods. For example, it can effectively relate vibration modes to complex fracture modes and damage evolution rates of a real component even under arbitrary and unknown loading with unknown boundary conditions. See Section 1.5, “Experimental Stress Analysis and Mechanical Testing,” for more on the dynamic thermoelasticity technique.

## 1.5 Mechanics of Materials

*Bela I. Sandor*

Mechanics of materials, also called strength of materials, provides quantitative methods to determine stresses (the intensity of forces) and strains (the severity of deformations), or overall deformations or load-carrying abilities of components and structures. The stress-strain behavior of materials under a wide range of service conditions must be considered in many designs. It is also crucial to base the analysis on correct modeling of component geometries and external loads. This can be difficult in the case of multiaxial loading, and even more so if time- or temperature-dependent material behaviors must be considered.

Proper modeling involves free-body diagrams and equations of equilibrium. However, it is important to remember that *the equilibrium equations of statics are valid only for forces or for moments of forces, and not for stresses.*

### Stress

The intensity of a force is called stress and is defined as the force acting on an infinitesimal area. A normal stress  $\sigma$  is defined as

$$\sigma = \lim_{dA \rightarrow 0} \frac{dF}{dA} \tag{1.5.1}$$

where  $dF$  is a differential normal force acting on a differential area  $dA$ . It is often useful to calculate the average normal stress  $\sigma = P/A$ , where  $P$  is the resultant force on an area  $A$ . A shear stress  $\tau$  caused by a shearing force  $V$  is defined likewise,

$$\tau = \lim_{dA \rightarrow 0} \frac{dV}{dA} \tag{1.5.2}$$

An average shear stress is obtained from  $V/A$ .

It is helpful to consider the general cases of stresses using rectangular elements in two and three dimensions, while ignoring the deformations caused by the stresses.

### Plane Stress

There are relatively simple cases where all stress vectors lie in the same plane. This is represented by a two-dimensional element in [Figure 1.5.1](#), where  $\sigma_x$  and/or  $\sigma_y$  may be either tensile (pulling on the element as shown) or compressive (pushing on the element; not shown). Normal stresses are easy to visualize and set up correctly.

**FIGURE 1.5.1** Generalized plane stress.

Shear stresses need to be discussed here in a little detail. The notation means that  $\tau_{yx}$ , for example, is a shear stress acting in the  $y$  direction, on a face that is perpendicular to the  $x$  axis. It follows that  $\tau_{xy}$  is acting in the  $x$  direction, on a face that is perpendicular to the  $y$  axis. The four shear stress vectors are

pointed as they are because of the requirement that the element be in equilibrium: the net forces and moments of forces on it must be zero. Thus, reversing the direction of all four  $\tau$ 's in Figure 1.5.1 is possible, but reversing less than four is not realistic.

**Three-Dimensional State of Stress**

The concept of plane stress can be generalized for a three-dimensional element as shown in Figure 1.5.2, working with the three primary faces of the cube and not showing stresses on the hidden faces, for clarity.

FIGURE 1.5.2 Three-dimensional general state of stress.

Again, the normal stresses are easy to set up, while the shear stresses may require considerable attention. The complex cases of stresses result from multiaxial loading, such as combined axial, bending, and torsional loading. Note that even in complex situations simplifications are possible. For example, if the right face in Figure 1.5.2 is a free surface,  $\sigma_x = \tau_{xz} = \tau_{xy} = 0$ . This leaves a plane stress state with  $\sigma_y$ ,  $\sigma_z$ , and  $\tau_{yz}$ , at most.

**Stress Transformation**

A free-body element with known stresses on it allows the calculation of stresses in directions other than the given  $xyz$  coordinates. This is useful when potentially critical welded or glued joints, or fibers of a composite, are along other axes. The stress transformations are simplest in the case of plane stress and can be done in several ways. In any case, at a given point in a material there is only one state of stress at a particular instant. At the same time, the components of the stresses depend on the orientation of the chosen coordinate system.

The stress transformation equations depend on the chosen coordinate system and the sign convention adopted. A common arrangement is shown in Figure 1.5.3, where (a) is the known set of stresses and (b) is the unknown set, denoted by primes.

FIGURE 1.5.3 Elements for stress transformation.

In the present sign convention an outward normal stress is positive, and an upward shear stress on the right-hand face of the element is positive. The transformation equations are

$$\begin{aligned}\sigma_{x'} &= \frac{\sigma_x + \sigma_y}{2} + \frac{\sigma_x - \sigma_y}{2} \cos 2\theta + \tau_{xy} \sin 2\theta \\ \sigma_{y'} &= \frac{\sigma_x + \sigma_y}{2} - \frac{\sigma_x - \sigma_y}{2} \cos 2\theta - \tau_{xy} \sin 2\theta \\ \tau_{x'y'} &= -\frac{\sigma_x - \sigma_y}{2} \sin 2\theta + \tau_{xy} \cos 2\theta\end{aligned}\quad (1.5.3)$$

If a result is negative, it means that the actual direction of the stress is opposite to the assumed direction.

### Principal Stresses

It is often important to determine the maximum and minimum values of the stress at a point and the orientations of the planes of these stresses. For plane stress, the maximum and minimum normal stresses, called **principal stresses**, are obtained from

$$\sigma_{1,2} = \frac{\sigma_x + \sigma_y}{2} \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \quad (1.5.4)$$

There is no shear stress acting on the principal planes on which the principal stresses are acting. However, there are shear stresses on other planes. The maximum shear stress is calculated from

$$\tau_{\max} = \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \quad (1.5.5)$$

This stress acts on planes oriented  $45^\circ$  from the planes of principal stress. There is a normal stress on these planes of  $\tau_{\max}$ , the average of  $\sigma_x$  and  $\sigma_y$ ,

$$\sigma_{ave} = \frac{\sigma_x + \sigma_y}{2} \quad (1.5.6)$$

### Mohr's Circle for Plane Stress

The equations for plane stress transformation have a graphical solution, called Mohr's circle, which is convenient to use in engineering practice, including "back-of-the-envelope" calculations. Mohr's circle is plotted on a  $\sigma - \tau$  coordinate system as in [Figure 1.5.4](#), with the center  $C$  of the circle always on the  $\sigma$  axis at  $\sigma_{ave} = (\sigma_x + \sigma_y)/2$  and its radius  $R = \sqrt{[(\sigma_x - \sigma_y)/2]^2 + \tau_{xy}^2}$ . The positive  $\tau$  axis is downward for convenience, to make  $\theta$  on the element and the corresponding  $2\theta$  on the circle agree in sense (both counterclockwise here).

The following aspects of Mohr's circle should be noted:

1. The center  $C$  of the circle is always on the  $\sigma$  axis, but it may move left and right in a dynamic loading situation. This should be considered in failure prevention.
2. The radius  $R$  of the circle is  $\tau_{\max}$ , and it may change, even pulsate, in dynamic loading. This is also relevant in failure prevention.
3. Working back and forth between the rectangular element and the circle should be done carefully and consistently. An angle  $\theta$  on the element should be represented by  $2\theta$  in the corresponding circle. If  $\tau$  is positive downward for the circle, the sense of rotation is identical in the element and the circle.

FIGURE 1.5.4 Mohr's circle.

4. The principal stresses  $\sigma_1$  and  $\sigma_2$  are on the  $\sigma$  axis ( $\tau = 0$ ).
5. The planes on which  $\sigma_1$  and  $\sigma_2$  act are oriented at  $2\theta_p$  from the planes of  $\sigma_x$  and  $\sigma_y$  (respectively) in the circle and at  $\theta_p$  in the element.
6. The stresses on an arbitrary plane can be determined by their  $\sigma$  and  $\tau$  coordinates from the circle. These coordinates give magnitudes and signs of the stresses. The physical meaning of  $+\tau$  vs.  $-\tau$  regarding material response is normally not as distinct as  $+\sigma$  vs.  $-\sigma$  (tension vs. compression).
7. To plot the circle, either use the calculated center  $C$  coordinate and the radius  $R$ , or directly plot the stress coordinates for two mutually perpendicular planes and draw the circle through the two points ( $A$  and  $B$  in Figure 1.5.4) which must be diametrically opposite on the circle.

**Special Cases of Mohr's Circles for Plane Stress**

See Figures 1.5.5 to 1.5.9

FIGURE 1.5.5 Uniaxial tension.

FIGURE 1.5.6 Uniaxial compression.

FIGURE 1.5.7 Biaxial tension:  $\sigma_x = \sigma_y$  (and similarly for biaxial compression:  $-\sigma_x = -\sigma_y$ ).

FIGURE 1.5.8 Pure shear.

FIGURE 1.5.9 Biaxial tension-compression:  $|\sigma_x| = |\sigma_y|$  (similar to the case of pure shear).

**Absolute Maximum Shear Stress**

In the case of a general three-dimensional state of stress, the transformations to arbitrary planes are complex and beyond the scope of this book. It is useful to note, however, that in general there are three principal stresses at any point in a material. (Plane stress is a special case with one of these stresses being zero.) If the three principal stresses are known, it is easy to determine the absolute maximum shear stress, which is valuable in assessing a material’s performance in service. The idea is to view the element as three separate two-dimensional elements, each time from a different principal direction, and plot the Mohr’s circles for them in the same diagram. This is illustrated schematically in Figure 1.5.10 for an element with three tensile principal stresses, of a maximum, a minimum, and an intermediate value.

FIGURE 1.5.10 Principal stresses of three-dimensional element.

The Mohr’s circles are interrelated since the three views of the element have common principal stresses associated with them. The absolute maximum shear stress is

$$\tau_{\text{abs max}} = \frac{\sigma_{\text{max}} - \sigma_{\text{min}}}{2} \tag{1.5.7}$$

Note that in calculating the absolute maximum shear stress for a state of plane stress, the actual third principal stress of  $\sigma_3 = 0$  may be significant if that is the minimum stress, and should be used in Equation 1.5.7 instead of a larger intermediate stress. For example, assume  $\sigma_x = 200$  ksi and  $\sigma_y = 100$  ksi in a case of plane stress. Using these as  $\sigma_{\text{max}}$  and  $\sigma_{\text{min}}$ ,  $\tau_{\text{max}} = (200 - 100)/2 = 50$  ksi. However, the fact that  $\sigma_z = 0$  is important here. Thus, correctly,  $\tau_{\text{abs max}} = (200 - 0)/2 = 100$  ksi. There is an important lesson here: apparently negligible quantities cannot always be ignored in mechanics of materials.

**Strain**

Solid materials deform when forces are acting on them. Large deformations are possible in some materials. Extremely small deformations are difficult to measure, but they still may be significant in critical geometry change or gradual damage evolution. Deformations are normally nonuniform even in apparently uniform components of machines and structures. The severity of deformation is called strain, which is separately defined for volumetric change and angular distortion of a body.

**Normal Strain**

The elongation or shortening of a line segment of unit length is called normal strain or axial strain. To define this quantitatively, consider a uniform bar of length  $L_o$ , and call this original length the gage length. Assume the bar elongates by an amount  $e$  to a new length  $L_1$  under the action of a force  $F$  (Figure 1.5.11) or by thermal expansion. The normal strain  $\epsilon$  is defined, with the gage length approaching zero in the limit, as

$$\epsilon = \frac{e}{L_o} \tag{1.5.8}$$

**FIGURE 1.5.11** Model for calculating axial or normal strain.

The strain calculated this way is called engineering strain, which is useful and fairly accurate for small deformations. Elongation is considered positive.

Normal strain is a dimensionless quantity, but it is customary to label it in a way that indicates strain, such as in./in., or m/m, or %, or  $\mu$  in./in., or  $\mu\epsilon$  (microstrain), depending on the system of units and the numerical representation.

**True Strain**

A difficulty of proper definition arises if the deformation  $e$  is not infinitesimal, because in a sense the gage length itself is increasing. The correct definition in such a case is based on the instantaneous length  $L$  and infinitesimal changes  $dL$  in that length. Thus, the total true strain in a member axially deforming from length  $L_o$  to a final length  $L_f$  by an amount  $e$  is

$$\epsilon = \int_{L_o}^{L_f} \frac{dL}{L} = \ln \frac{L_f}{L_o} = \ln(1 + e) \tag{1.5.9}$$

True strain is practically identical to engineering strain up to a few percent of engineering strain. The approximate final length  $L_f$  of an axially deformed, short line segment of original length  $L_o$  is sometimes expressed as

$$L_f \approx (1 + \epsilon)L_o \tag{1.5.10}$$

**Shear Strain**

Angular distortions are called shear strains. More precisely, shear strain  $\gamma$  is the change in angle of two originally perpendicular ( $\theta = \pi/2$ ) line segments. For consistency, assume that a decreasing angle represents positive shear strain, and an increasing angle is from negative shear strain. The angle  $\gamma$  is measured in radians. A useful way to show shear strain is given in Figure 1.5.12.

**FIGURE 1.5.12** Shear strain in two dimensions.

### Strain Transformation

The method of transforming strain at a point is similar to that for stress. In general, there are three components of normal strain,  $\epsilon_x$ ,  $\epsilon_y$ , and  $\epsilon_z$ , and three components of shear strain,  $\gamma_{xy}$ ,  $\gamma_{xz}$ , and  $\gamma_{yz}$ . Transformations of plane strain components are the simplest.

For a consistent approach, assume that strain transformation is desired from an  $xy$  coordinate system to an  $x'y'$  set of axes, where the latter is rotated counterclockwise ( $+\theta$ ) from the  $xy$  system. The transformation equations for plane strain are

$$\begin{aligned}\epsilon_{x'} &= \frac{\epsilon_x + \epsilon_y}{2} + \frac{\epsilon_x - \epsilon_y}{2} \cos 2\theta + \frac{\gamma_{xy}}{2} \sin 2\theta \\ \epsilon_{y'} &= \frac{\epsilon_x + \epsilon_y}{2} - \frac{\epsilon_x - \epsilon_y}{2} \cos 2\theta - \frac{\gamma_{xy}}{2} \sin 2\theta \\ \frac{\gamma_{x'y'}}{2} &= -\frac{\epsilon_x - \epsilon_y}{2} \sin 2\theta + \frac{\gamma_{xy}}{2} \cos 2\theta\end{aligned}\quad (1.5.11)$$

Note the similarity between the strain and stress transformation equations, as well as the differences.

### Principal Strains

For isotropic materials only, principal strains (with no shear strain) occur along the principal axes for stress. In plane strain the principal strains  $\epsilon_1$  and  $\epsilon_2$  are expressed as

$$\epsilon_{1,2} = \frac{\epsilon_x + \epsilon_y}{2} \pm \sqrt{\left(\frac{\epsilon_x - \epsilon_y}{2}\right)^2 + \left(\frac{\gamma_{xy}}{2}\right)^2} \quad (1.5.12)$$

The angular position  $\theta_p$  of the principal axes (measured positive counterclockwise) with respect to the given  $xy$  system is determined from

$$\tan 2\theta_p = \frac{\gamma_{xy}}{\epsilon_x - \epsilon_y} \quad (1.5.13)$$

Like in the case of stress, the maximum in-plane shear strain is

$$\frac{\gamma_{x'y'} \max}{2} = \sqrt{\left(\frac{\epsilon_x - \epsilon_y}{2}\right)^2 + \left(\frac{\gamma_{xy}}{2}\right)^2} \quad (1.5.14)$$

which occurs along axes at  $45^\circ$  from the principal axes, determined from

$$\tan 2\theta = -\frac{\epsilon_x - \epsilon_y}{\gamma_{xy}} \quad (1.5.15)$$

The corresponding average normal strain is

$$\epsilon_{ave} = \frac{\epsilon_x + \epsilon_y}{2} \quad (1.5.16)$$

**Mohr's Circle for Plane Strain**

As in the case of stress, there is a graphical overview by Mohr's circle of the directional dependence of the normal and shear strain components at a point in a material. This circle has a center  $C$  at  $\epsilon_{ave} = (\epsilon_x + \epsilon_y)/2$  which is always on the  $\epsilon$  axis, but is shifting left and right in a dynamic loading situation. The radius  $R$  of the circle is

$$R = \sqrt{\left(\frac{\epsilon_x - \epsilon_y}{2}\right)^2 + \left(\frac{\gamma_{xy}}{2}\right)^2} \tag{1.5.17}$$

Note the proper labeling ( $\epsilon$  vs.  $\gamma/2$ ) and preferred orientation of the strain axes as shown in Figure 1.5.13. This sets up a favorable uniformity of angular displacement between the element ( $+\theta$  counterclockwise) and the circle ( $+2\theta$  counterclockwise).

**FIGURE 1.5.13** Mohr's circle for plane strain.

**Mechanical Behaviors and Properties of Materials**

The stress-strain response of a material depends on its chemical composition, microstructure, geometry, the magnitude and rate of change of stress or strain applied, and environmental factors. Numerous quantitative mechanical properties are used in engineering. Some of the basic properties and common variations of them are described here because they are essential in mechanics of materials analyses.

**Stress-Strain Diagrams**

There are several distinctive shapes of uniaxial tension or compression stress-strain plots, depending on the material, test conditions, and the quantities plotted. The chosen representative schematic diagram here is a true stress vs. true strain curve for a ductile, nonferrous metal tested in tension (Figure 1.5.14). The important mechanical properties listed in Table 1.5.1 are obtained from such a test or a similar one in pure shear (not all are shown in Figure 1.5.14).

**FIGURE 1.5.14** True stress vs. true strain for a ductile, nonferrous metal.

**Table 1.5.1 Basic Mechanical Properties**

Symbol	Definition	Remarks
$E$	Modulus of elasticity; Young's modulus; $E = \sigma/\epsilon_e$	Hooke's law; $T$ and $\epsilon_p$ effects small
$G$	Shear modulus of elasticity; $G = \frac{\tau}{\gamma_e} = E/2(1 + \nu)$	$T$ and $\epsilon_p$ effects small
$\nu$	Poisson's ratio; $\nu = \frac{\epsilon_{lateral}}{\epsilon_{longit.}}$	$T$ and $\epsilon_p$ effects small
$\sigma_{PL}$	Proportional limit; at onset of noticeable yielding (or at onset of nonlinear elastic behavior)	Flow property; inaccurate; $T$ and $\epsilon_p$ effects large
$\sigma_y$	0.2% offset yield strength (but yielding can occur at $\sigma < \sigma_y$ if $\sigma_{PL} < \sigma_y$ )	Flow property; accurate; $T$ and $\epsilon_p$ effects large
$\sigma_f$	True fracture strength; $\sigma_f = \frac{P_f}{A_f}$	Fracture property; $T$ and $\epsilon_p$ effects medium
$\epsilon_f$	True fracture ductility; $\epsilon_f = \ln \frac{A_o}{A_f} = \ln \frac{100}{100 - \%RA}$	Max. $\epsilon_p$ ; fracture property; $T$ and $\epsilon_p$ effects medium
% RA	Percent reduction of area; $\%RA = \frac{A_o - A_f}{A_o} \times 100$	Fracture property; $T$ and $\epsilon_p$ effects medium
$n$	Strain hardening exponent; $\sigma = K \epsilon_p^n$	Flow property; $T$ and $\epsilon_p$ effects small to large
Toughness	Area under $\sigma$ vs. $\epsilon_p$ curve	True toughness or intrinsic toughness; $T$ and $\epsilon_p$ effects large
$\sigma_u$	Ultimate strength; $\frac{P_{max}}{A_o}$	Fracture property; $T$ and $\epsilon_p$ effects medium
$M_r$	Modulus of resilience; $M_r = \frac{\sigma_{PL}^2}{2E}$	Area under original elastic portion of $\sigma - \epsilon$ curve

Notes:  $T$  is temperature;  $\epsilon_p$  refers to prior plastic strain, especially cyclic plastic strain (fatigue) (these are qualitative indicators here; exceptions are possible)

$$\epsilon_{total} = \epsilon_e + \epsilon_p = \frac{\sigma}{E} + \left(\frac{\sigma}{K}\right)^{1/n} = \frac{\sigma}{E} + \epsilon_f \left(\frac{\sigma}{\sigma_f}\right)^{1/n}$$

Another useful mechanical property (not measured from the  $\sigma - \epsilon$  plot) is hardness. This is a flow property, with some qualitative correlations to the other properties.

It is important to appreciate that the mechanical properties of a material depend on its chemical composition and its history of thermal treatment and plastic deformations (cold work; cyclic plasticity). For example, consider the wide ranges of monotonic and cyclic stress-strain curves for 1045 steel (a given chemical composition) at room temperature, as functions of its hardness resulting from thermal treatment (Figure 1.5.15). See Section 1.6, "Fatigue," for more on cycle-dependent material behaviors.

**Generalized Stress-Strain Expressions. Hooke's Law**

An important special case of stress-strain responses is when the material acts entirely elastically ( $\epsilon_p = 0, \epsilon_t = \epsilon_e$ ). In this case, for uniaxial loading, the basic **Hooke's law**  $\sigma = E\epsilon$  can be used, and similarly for unidirectional shear,  $\tau = G\gamma$ . For multiaxial loading (Color Plate 9), the generalized Hooke's law is applicable,

**FIGURE 1.5.15** Influence of hardness and deformation history on the stress-strain response of SAE 1045 steel.

$$\begin{aligned} \epsilon_x &= \frac{1}{E} [\sigma_x - \nu(\sigma_y + \sigma_z)] \\ \epsilon_y &= \frac{1}{E} [\sigma_y - \nu(\sigma_x + \sigma_z)] \\ \epsilon_z &= \frac{1}{E} [\sigma_z - \nu(\sigma_x + \sigma_y)] \end{aligned} \tag{1.5.18}$$

Other useful expressions for ideally elastic behavior are as follows. Relating the axial and shear moduli,

$$G = \frac{E}{2(1 + \nu)} \tag{1.5.19}$$

The change in volume per unit volume is the volumetric strain or dilatation,

$$e = \frac{1 - 2\nu}{E} (\sigma_x + \sigma_y + \sigma_z) \tag{1.5.20}$$

The bulk modulus  $k$  is the ratio of a uniform stress (hydrostatic) to the dilatation,

$$k = \frac{\sigma}{e} = \frac{E}{3(1 - 2\nu)} \tag{1.5.21}$$

For most metals,  $\nu \approx 1/3$  and  $k \approx E$ .

### Uniaxial Elastic Deformations

The total elastic deformation  $\delta$  of axially loaded bars, columns, and wires is calculated with the aid of basic expressions. Using  $\sigma = E\epsilon$  and  $\sigma = P(x)/A(x)$ , where  $P(x)$  and  $A(x)$  are, respectively, the internal force and cross-sectional area of a bar at a distance  $x$  from one end,

$$\delta = \int_0^L \frac{P(x)}{A(x)E} dx \tag{1.5.22}$$

where  $L$  is the total length considered.

In most cases,  $A(x)$  is a constant;  $P(x)$  may also be a constant, except where several different axial forces are applied, and occasionally for vertical bars and columns, where the member's own weight may cause  $P(x)$  to vary significantly along the length. If  $A(x)$ ,  $P(x)$ , and  $E$  are constants,

$$\delta = \frac{PL}{AE} \tag{1.5.23}$$

**Thermally Induced Deformations**

Thermal expansion or contraction is a linearly dependent, recoverable deformation like purely elastic deformations are. For a homogeneous and isotropic material, the thermally induced deformation from the original length  $L$  is calculated from

$$\delta_T = \alpha\Delta TL \tag{1.5.24}$$

where  $\alpha$  is the linear coefficient of thermal expansion (strain per degree of temperature, a material property), and  $\Delta T$  is the change in temperature.

The thermal strain can be prevented or reduced by constraining a member. In that case the stresses and strains can be calculated using the methods pertaining to statically indeterminate members.

**Stresses in Beams**

To calculate stresses in beams, one must first model the beam correctly in terms of its supports and loading (such as simply supported, with distributed loading), determine the appropriate unknown external reactions, and establish the corresponding shear and moment diagrams using a consistent sign convention. Both normal and shear stresses may have to be calculated, but typically the normal stresses are the most significant.

**Flexure Formula**

The normal stresses at a particular cross section in a beam are caused by the bending moment that acts at that cross section, and are distributed by magnitude and sign (both tension and compression) so that the beam is in equilibrium. The basic concept for calculating the stresses is that there is a neutral axis  $n-n$  of  $\epsilon = \sigma = 0$  in the beam, and that the longitudinal normal strain varies linearly with distance  $y$  from the neutral axis.

If the beam is behaving entirely elastically, the stress distribution is also linear, as in [Figure 1.5.16](#). In this case, the stress at a distance  $y$  from the neutral axis is calculated from  $M = \int \sigma(y)y \, dA$  and results in

$$\sigma(y) = \frac{My}{I} \tag{1.5.25}$$

**FIGURE 1.5.16** Internal normal stresses in a beam caused by bending.

where  $I$  = moment of inertia of the cross-sectional area about the neutral axis.

The maximum stress, with the appropriate sign, is

$$\sigma = \frac{Mc}{I} \tag{1.5.26}$$

There are several special cases of bending that require additional considerations and analysis as outlined below.

### Inelastic Bending

A beam may plastically deform under an increasing moment, yielding first in its outer layers and ultimately throughout its depth. Such a beam is analyzed by assuming that the normal strains are still linearly varying from zero at the neutral axis to maximum values at the outer layers. Thus, the stress distributions depend on the stress-strain curve of the material. With the stress distribution established, the neutral axis can be determined from  $\int \sigma(y) dA = 0$ , and the resultant moment from  $M = \int y \sigma(y) dA$ .

A fully plastic beam of rectangular cross section and flat-top yielding supports 50% more bending moment than its maximum elastic moment.

### Neutral Axis of Semisymmetric Area

If the cross-sectional area is semisymmetric, such as a T-shape, and the loading is in a centroidal plane of symmetry, the neutral axis for elastic deformations is at the centroid  $C$  of the area as shown in Figure 1.5.17, and Equation 1.5.25 can be used. Note that the magnitudes of the maximum tensile and compressive stresses are not the same in this case.

FIGURE 1.5.17 Neutral axis of a semisymmetric area.

### Unsymmetric Bending

In the general case, the cross-sectional area has an arbitrary shape and the loading is arbitrarily applied. The problem of an arbitrary area is handled by choosing the centroidal  $xy$  coordinate system such that the axes are principal axes of inertia for the area. The principal axes can be determined by using inertia transformation equations or Mohr's circle of inertia. Having an axis of symmetry is a simple special case because the principal axes are the axis of symmetry and the axis perpendicular to it.

The flexure formula can be applied directly if the principal axes of inertia are known, and the bending moment is applied about one of these centroidal principal axes. A more complex case is if the moment is not about a principal axis as shown in Figure 1.5.18.

FIGURE 1.5.18 Schematic of arbitrary bending moment.

Different texts may present different formulas for calculating the bending stresses in such situations, depending on the choice of a coordinate system and the sign convention adopted. It is better not to rely on a cookbook formula, but to break down the problem into simple, easily visualized parts, and then reason out an algebraic superposition of the stress components. To illustrate this approach schematically, consider the stresses at points  $A$  and  $B$  in Figure 1.5.18. Instead of working directly with the applied moment  $M$ , resolve  $M$  into its components  $M_x$  and  $M_y$ .  $M_x$  causes a tensile stress  $\sigma_{zA_1}$  at  $A$  and a compressive stress  $-\sigma_{zB_1}$  at  $B$ .  $M_y$  causes tensile stresses at both  $A$  and  $B$ ,  $\sigma_{zA_2}$  and  $\sigma_{zB_2}$ . The magnitudes of these stress components are readily calculated from the flexure formula with the appropriate dimensions and inertias for each. The resultant stresses are

$$\sigma_A = \sigma_{z_{A_1}} + \sigma_{z_{A_2}}$$

$$\sigma_B = -\sigma_{z_{B_1}} + \sigma_{z_{B_2}}$$

The neutral axis at angle  $\alpha$  in the general case is not coincident with the direction of  $\mathbf{M}$  (Figure 1.5.18). In the present case  $\alpha$  is defined by

$$\tan \alpha = \frac{I_x}{I_y} \tan \theta \tag{1.5.27}$$

**Composite Beams**

Nonhomogeneous beams are often designed to take advantage of the properties of two different materials. The approach for analyzing these is to imagine a transformation of the beam’s cross section to an equivalent cross section of a different shape but of a single material, so that the flexure formula is usable. This is illustrated for a beam  $A$  with reinforcing plates  $B$ , as in Figure 1.5.19.

**FIGURE 1.5.19** Equivalent area method for a symmetric composite beam.

The transformation factor  $n$  is obtained from

$$n = \frac{E_B}{E_A} \tag{1.5.28}$$

Note that in a composite beam the strains vary linearly with distance from the neutral axis, but the stresses do not, because of the different elastic moduli of the components. The actual stress  $\sigma$  in the transformed area is determined by first calculating the “pretend” stress  $\sigma'$  for the uniform transformed area and then multiplying it by  $n$ ,

$$\sigma = n\sigma' \tag{1.5.29}$$

Nonsymmetric composite beams (such as having only one reinforcing plate  $B$  in Figure 1.5.19) are analyzed similarly, but first require the location of the neutral axis.

Reinforced concrete beams are important special cases of composite beams. The stress analysis of these is influenced by the fact that concrete is much weaker in tension than in compression. Empirical approaches are particularly useful in this area.

**Curved Beams**

The stress analysis of curved beams requires some additional considerations. For example, the flexure formula is about 7% in error (the calculated stresses are too low) when the beam’s radius of curvature is five times its depth (hooks, chain links). The curved-beam formula provides realistic values in such cases.

**Shear Stresses in Beams**

Transverse loads on beams are common, and they cause transverse and complementary longitudinal shear stresses in the beams. Schematically, the transverse shear stresses are distributed on a rectangular cross section as shown in Figure 1.5.20. The shear stress is zero at free surfaces by definition.

**FIGURE 1.5.20** Transverse shear stress distribution.

The internal shear stress is calculated according to Figure 1.5.20 from

$$\tau = \frac{VQ}{It} \tag{1.5.30}$$

- where  $\tau$  = shear stress value at any point on the line  $\ell - \ell$  at a distance  $y'$  from the neutral axis
- $V$  = total shear force on cross-sectional area  $A$
- $Q = \bar{y}'A'$ ;  $A'$  = area above line  $\ell - \ell$ ;  $\bar{y}'$  = distance from neutral axis to centroid of  $A'$
- $I$  = moment of inertia of entire area  $A$  about neutral axis
- $t$  = width of cross section where  $\tau$  is to be determined

This shear formula gives  $\tau_{max} = 1.5 V/A$  if  $t$  is constant for the whole section (rectangle).

Note that the magnitude of the shear stress distribution changes sharply where there is an abrupt change in width  $t$ , such as in an I-beam, Figure 1.5.21.

**FIGURE 1.5.21** Shear stress distribution for I-beam.

**Shear Flow**

In the analysis of built-up members, such as welded, bolted, nailed, or glued box beams and channels, a useful quantity is the shear flow  $q$  measured in force per unit length along the beam,

$$q = \frac{VQ}{I} \tag{1.5.31}$$

where all quantities are defined as for Equation 1.5.30. Care must be taken to use the appropriate value for  $Q$ . For example, consider a channel section of three flat pieces glued together as in Figure 1.5.22. There are two critical joint regions  $B$  here, and the area  $A'$  is between them. The shear flow is carried by the two joints together, so the actual force per unit length on one joint is  $q/2$  here.

FIGURE 1.5.22 Critical joint regions of a built-up beam.

**Shear Flow in Thin-Walled Beams**

The shear-flow distribution over the cross section of a thin-walled member is governed by equilibrium requirements. Schematic examples of this are given in Figure 1.5.23. Note the special case of unsymmetrical loading in part (c), which causes a bending and a twisting of the beam. The twisting is prevented if the vertical force  $V$  is applied at the shear center  $C$ , defined by the quantity  $e$ ,

$$e = \frac{dH}{V} \tag{1.5.32}$$

where  $d$  is the centroidal distance between the two horizontal flanges and  $H$  is the shear force in the flanges ( $q_{ave}$  times width of flange).

FIGURE 1.5.23 Shear flow distributions.

**Deflections of Beams**

Small deflections of beams can be determined relatively easily. The first step is to assess a beam’s loading and support conditions and sketch an exaggerated elastic deflection curve as in Figure 1.5.24.

FIGURE 1.5.24 Exaggerated elastic curve of a beam in bending.

The boundary conditions at the supports are useful in the solution for the whole beam. Here at the fixed end  $A$  there is no vertical displacement and no rotation, while at the roller support  $B$  there is no vertical displacement but rotation of the continuous beam occurs. The boundary and continuity conditions can be determined by inspection in simple cases.

### Moment vs. Curvature

For a homogeneous and elastic beam,

$$\frac{1}{\rho} = \frac{M}{EI} \quad (1.5.33)$$

where  $\rho$  = radius of curvature at a specific point on the elastic curve;  $1/\rho$  is the curvature. The product  $EI$  is called the flexural rigidity; it is often a constant along the whole beam.

### Integration Method for Slope and Displacement

For small displacements,  $1/\rho = d^2y/dx^2$ . In the general case, a distributed external loading  $w(x)$  should be included in the modeling of the problem. A set of expressions is available to solve for the deflections in rectangular coordinates:

$$\begin{aligned} -w(x) &= \frac{dV}{dx} = EI \frac{d^4y}{dx^4} \\ V(x) &= \frac{dM}{dx} = EI \frac{d^3y}{dx^3} \\ M(x) &= EI \frac{d^2y}{dx^2} \end{aligned} \quad (1.5.34)$$

The deflection  $y$  of the elastic curve is obtained by successive integrations, using appropriate constants of integration to satisfy the boundary and continuity conditions. In general, several functions must be written for the moment  $M(x)$ , one for each distinct region of the beam, between loading discontinuities. For example, these regions in Figure 1.5.24 are  $AC$ ,  $CB$ , and  $BD$ . Considerable care is required to set up a solution with a consistent sign convention and selection of coordinates for simple and efficient forms of  $M(x)$ .

In practice, even relatively complex problems of beam deflections are solved using the principle of superposition and handbook values of slopes and deflections for subsets of basic loadings and supports. The literature contains a large variety of such subsets. A sampling of these is given in [Table 1.5.2](#).

### Deflection Caused by Shear

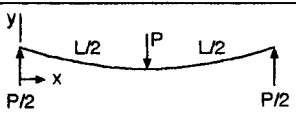

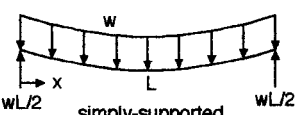

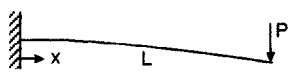

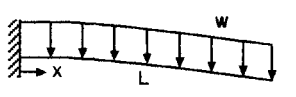

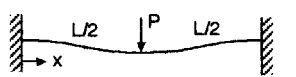

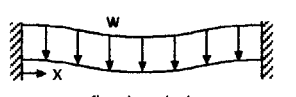

The transverse shear acting on a beam causes a displacement that tends to be significant compared to bending deflections only in very short beams. The shear deflection over a length  $L$  is approximated by

$$y = \frac{\tau_{ave} L}{G} \quad (1.5.35)$$

### Torsion

The simplest torsion members have circular cross sections. The main assumptions in their analysis are that cross-sectional circles remain plane circles during twisting of a shaft and that radial lines on any cross section remain straight and rotate through the same angle. The length and diameter of the shaft are unchanged in small angular displacements. It is useful in the analysis that shear strain  $\gamma$  varies linearly

TABLE 1.5.2

Beam	Slope: $ dy/dx $	Max. deflection
 <p>simply-supported</p>	$\frac{PL^2}{16EI}$ at $x=0, L$	$\frac{PL^3}{48EI}$ at $x=L/2$
 <p>simply-supported</p>	$\frac{wL^3}{24EI}$ at $x=0, L$	$\frac{5wL^4}{384EI}$ at $x=L/2$
 <p>cantilever</p>	$\frac{PL^2}{2EI}$ at $x=L$	$\frac{PL^3}{3EI}$ at $x=L$
 <p>cantilever</p>	$\frac{wL^3}{6EI}$ at $x=L$	$\frac{wL^4}{8EI}$ at $x=L$
 <p>fixed-ended</p>	$0$ at $x=0, L/2, L$	$\frac{PL^3}{192EI}$ at $x=L/2$
 <p>fixed-ended</p>	$0$ at $x=0, L/2, L$	$\frac{wL^4}{384EI}$ at $x=L/2$

along any radial line, from zero at the centerline of a solid or tubular shaft to a maximum at the outer surface,

$$\gamma = \frac{\rho}{r} \gamma_{\max} \tag{1.5.36}$$

where  $\rho$  = radial distance to any element in the shaft  
 $r$  = radius of the shaft

Using  $\tau = G\gamma$  for an elastically deforming material (Figure 1.5.25),

$$\tau = \frac{\rho}{r} \tau_{\max} \tag{1.5.37}$$

The torsion formula relating shear stress to the applied torque  $T$  is from  $T = 2\pi \int \tau \rho^2 d\rho$ ,

$$\tau_{\max} = \frac{Tr}{J} \text{ or } \tau = \frac{T\rho}{J} \tag{1.5.38}$$

**FIGURE 1.5.25** Shear stress distributions in a shaft.

where  $J$  = the polar moment of inertia of the cross-sectional area; for a solid circle,  $J = \pi r^4/2$ ; for a tube,  $J = (\pi/2)(r_0^4 - r_i^4)$ .

**Power Transmission**

The power  $P$  transmitted by a shaft under torque  $T$  and rotating at angular velocity  $\omega$  is

$$P = T\omega \tag{1.5.39}$$

where  $\omega = 2\pi f$ ;  $f$  = frequency of rotation or number of revolutions per second.

**Angle of Twist**

For a homogeneous shaft of constant area and  $G$  over a length  $L$ , under a torque  $T$ , the angular displacement of one end relative to the other is

$$\phi = \frac{TL}{JG} \tag{1.5.40}$$

For a shaft consisting of segments with various material and/or geometric properties, under several different torques in each, the net angular displacement is calculated from the vector sum of the individual twists,

$$\phi = \sum \frac{T_i L_i}{J_i G_i} \tag{1.5.41}$$

The right-hand rule is used for a sign convention for torques and angles: both  $T$  and  $\phi$  are positive, with the thumb pointing outward from a shaft and the fingers curling in the direction of torque and/or rotation, as in [Figure 1.5.26](#). Note that regardless of the number of torques applied to a shaft at various places along its length, there is only one torque at a given cross section, and this torque is a constant in that segment of the shaft (until another external torque is encountered, requiring a different free-body diagram).

**FIGURE 1.5.26** Right-hand rule for positive torque and angle.

**Inelastic Torsion**

A shaft may plastically deform under an increasing torque, yielding first in its outer layers and ultimately throughout the cross section. Such a shaft is analyzed by assuming that the shear strains are still linearly

varying from zero at the centerline to a maximum at the outer layers. Thus, the shear stress distribution depends on the shear stress-strain curve of the material. For example, an elastic, elastic-plastic, and fully plastic solid circular shaft is modeled in Figure 1.5.25, assuming flat-top yielding at  $\tau_y$ . The torque  $T$  in any case is obtained by integrating the shear stresses over the whole area,

$$T = 2\pi \int_A \tau \rho^2 d\rho \tag{1.5.42}$$

The fully plastic torque in this case is 33% greater than the maximum elastic torque.

**Noncircular Shafts**

The analysis of solid noncircular members, such as rectangles and triangles, is beyond the scope of this book. The reason for the difficulty is that plane sections do not remain plane, but warp. It can be noted here, however, that a circular shaft utilizes material the most efficiently since it has a smaller maximum shear stress and a smaller angle of twist than a noncircular shaft of the same weight per unit length under the same torque.

Noncircular tubes with thin walls can be analyzed using the concept of shear flow that must be continuous and constant on the closed path of the cross-sectional area. The shear stress under a torque  $T$  is essentially constant over a uniformly thin wall (from inside to outside), and is given by

$$\tau = \frac{T}{2tA_m} \tag{1.5.43}$$

where  $t$  = thickness of the tube  
 $A_m$  = mean area within the centerline of the wall thickness

The angle of twist for an elastically deforming thin-walled tube of length  $L$  and constant thickness  $t$  is

$$\phi = \frac{TL}{4A_m^2 G t} \oint ds \tag{1.5.44}$$

where the line integral represents the total length of the wall's centerline boundary in the cross section (for a circular tube, this becomes  $\approx 2\pi r$ ). For a tube with variable thickness  $t$ , the integrand becomes  $\oint ds/t$ .

**Statically Indeterminate Members**

Members that have more supports or constraints than the minimum required for static equilibrium are called statically indeterminate. They can be analyzed if a sufficient number of additional relationships are available. These are fundamentally similar to one another in terms of compatibility for displacements, and are described separately for special cases.

**Statically Indeterminate Axially Loaded Members**

Several subsets of these are common; three are shown schematically in Figure 1.5.27.

1. From a free-body diagram of part (a), assuming upward forces  $F_A$  and  $F_B$  at ends  $A$  and  $B$ , respectively, the force equilibrium equation is

$$F_A + F_B - P = 0$$

**FIGURE 1.5.27** Statically indeterminate axially loaded members.

The displacement compatibility condition is that both ends are fixed, so

$$\delta_{A/B} = 0$$

Then

$$\frac{F_A L_{AC}}{AE} - \frac{F_B L_{BC}}{AE} = 0, \quad F_A = P \frac{L_{BC}}{L_{AB}}, \quad F_B = P \frac{L_{AC}}{L_{AB}}$$

Alternatively, first assume that  $F_B = 0$ , and calculate the total downward displacement (tensile) of the free end  $B$ . Then calculate the required force  $F_B$  to compressively deform the rod upward so that after the superposition there is no net displacement of end  $B$ . The results are the same as above for elastically deforming members.

2. Constrained thermal expansion or contraction of part (b) is handled as above, using the expression for thermally induced deformation,

$$\delta_T = \alpha \Delta T L \tag{1.5.45}$$

where  $\alpha$  = linear coefficient of thermal expansion  
 $\Delta T$  = change in temperature

3. The force equilibrium equation of part (c) is

$$P - F_A - F_B = 0$$

Here the two different component materials are deforming together by the same amount, so

$$\delta_A = \delta_B$$

$$\frac{F_A L}{A_A E_A} = \frac{F_B L}{A_B E_B}$$

providing two equations with two unknowns,  $F_A$  and  $F_B$ . Note that rigid supports are not necessarily realistic to assume in all cases.

**Statically Indeterminate Beams**

As for axially loaded members, the redundant reactions of beams are determined from the given conditions of geometry (the displacement compatibility conditions). There are various approaches for solving problems of statically indeterminate beams, using the methods of integration, moment-areas, or

superposition. Handbook formulas for the slopes and deflections of beams are especially useful, noting that the boundary conditions must be well defined in any case. The method of superposition is illustrated in Figure 1.5.28.

FIGURE 1.5.28 A statically indeterminate beam.

Choosing the reaction at  $C$  as the redundant support reaction (otherwise, the moment at  $A$  could be taken as redundant), and first removing the unknown reaction  $C_y$ , the statically determinate and stable primary beam is obtained in Figure 1.5.28b. Here the slope and deflection at  $A$  are both zero. The slopes at  $B$  and  $C$  are the same because segment  $BC$  is straight. Next the external load  $P$  is removed, and a cantilever beam fixed at  $A$  and with load  $C_y$  is considered in Figure 1.5.28c. From the original boundary conditions at  $C$ ,  $-y_1 + y_2 = 0$ , and the problem can be solved easily using any appropriate method.

**Statically Indeterminate Torsion Members**

Torsion members with redundant supports are analyzed essentially the same way as other kinds of statically indeterminate members. The unknown torques, for example, are determined by setting up a solution to satisfy the requirements of equilibrium ( $\sum T = 0$ ), angular displacement compatibility, and torque-displacement (angle =  $TL/JG$ ) relationships. Again, the boundary conditions must be reasonably well defined.

**Buckling**

The elastic buckling of relatively long and slender members under axial compressive loading could result in sudden and catastrophic large displacements. The critical buckling load is the smallest for a given ideal column when it is pin-supported at both ends; the critical load is larger than this for other kinds of supports. An ideal column is made of homogeneous material, is perfectly straight prior to loading, and is loaded only axially through the centroid of its cross-sectional area.

**Critical Load. Euler's Equation**

The buckling equation (Euler's equation) for a pin-supported column gives the critical or maximum axial load  $P_{cr}$  as

$$P_{cr} = \frac{\pi^2 EI}{L^2} \tag{1.5.46}$$

- where  $E$  = modulus of elasticity
- $I$  = smallest moment of inertia of the cross-sectional area
- $L$  = unsupported length of the pinned column

A useful form of this equation gives the critical average stress prior to any yielding, for arbitrary end conditions,

$$\sigma_{cr} = \frac{\pi^2 E}{(kL/r)^2} \tag{1.5.47}$$

where  $r = \sqrt{I/A}$  = radius of gyration of cross-sectional area  $A$   
 $L/r$  = slenderness ratio  
 $k$  = effective-length factor; constant, dependent on the end constraints  
 $kL/r$  = effective-slenderness ratio

The slenderness ratio indicates, for a given material, the tendency for elastic buckling or failure by yielding (where the Euler formula is not applicable). For example, buckling is expected in mild steel if  $L/r$  is approximately 90 or larger, and in an aluminum alloy if  $L/r > 60$ . Yielding would occur first at smaller values of  $L/r$ . Ratios of 200 or higher indicate very slender members that cannot support large compressive loads.

Several common end conditions of slender columns are shown schematically in Figure 1.5.29.

FIGURE 1.5.29 Common end conditions of slender columns.

### Secant Formula

Real columns are not perfectly straight and homogeneous and are likely to be loaded eccentrically. Such columns first bend and deflect laterally, rather than buckle suddenly. The maximum elastic compressive stress in this case is caused by the axial and bending loads and is calculated for small deflections from the secant formula,

$$\sigma_{\max} = \frac{P}{A} \left[ 1 + \frac{ec}{r^2} \sec \left( \frac{L}{2r} \sqrt{\frac{P}{EA}} \right) \right] \quad (1.5.48)$$

where  $e$  is the eccentricity of the load  $P$  (distance from the neutral axis of area  $A$ ) and  $c$  is measured from the neutral axis to the outer layer of the column where  $\sigma_{\max}$  occurs.

The load and stress are nonlinearly related; if there are several loads on a column, the loads should be properly combined first before using the secant formula, rather than linearly superposing several individually determined stresses. Similarly, factors of safety should be applied to the resultant load.

### Inelastic Buckling

For columns that may yield before buckling elastically, the generalized Euler equation, also called the Engesser equation, is appropriate. This involves substituting the tangent modulus  $E_T$  (tangent to the stress-strain curve) for the elastic modulus  $E$  in the Euler equation,

$$\sigma_{cr} = \frac{\pi^2 E_T}{(kL/r)^2} \quad (1.5.49)$$

Note that  $E_T$  must be valid for the stress  $\sigma_{cr}$ , but  $E_T$  is dependent on stress when the deformations are not entirely elastic. Thermal or plastic-strain events may even alter the stress-strain curve of the material, thereby further changing  $E_T$ . Thus, Equation 1.5.49 should be used with caution in a trial-and-error procedure.

## Impact Loading

A mass impacting another object causes deformations that depend on the relative velocity between them. The simplest model for such an event is a mass falling on a spring. The maximum dynamic deformation  $d$  of a linearly responding spring is related to the static deformation  $d_{st}$  (the deformation caused by a weight  $W$  applied slowly) by a factor that depends on  $h$ , the height of free fall from a static position.

$$d = d_{st} \left( 1 + \sqrt{1 + \frac{2h}{d_{st}}} \right) \quad (1.5.50)$$

The dynamic and static stresses are related in a similar way,

$$\sigma = \sigma_{st} \left( 1 + \sqrt{1 + \frac{2h}{d_{st}}} \right) \quad (1.5.51)$$

The quantity in parentheses is called the impact factor, which shows the magnification of deflection or stress in impacts involving free fall. Note that the real impact factor is somewhat smaller than what is indicated here, because some energy is always dissipated by friction during the fall and deceleration of the body. This includes internal friction during plastic flow at the points of contact between the bodies. Other small errors may result from neglecting the mass and possible inelasticity of the spring.

A special value of the impact factor is worth remembering. When the load is applied suddenly without a prior free fall,  $h = 0$ , and

$$d = 2d_{st} \quad \text{and} \quad \sigma = 2\sigma_{st}$$

This means that the minimum impact factor is about two, and it is likely to be larger than two, causing perhaps a “bottoming out” of the spring, or permanent damage somewhere in the structure or the payload supported by the spring.

## Combined Stresses

Combinations of different kinds of loads on a member are common. The resultant states of stress at various points of interest can be determined by superposition if the material does not yield. The three-dimensional visualization and correct modeling of such a problem is typically the most difficult part of the solution, followed by routine calculations of the stress components and resultants. No new methods of analysis are needed here.

The approach is to sketch an infinitesimal cube at each critical point in the member and determine the individual stresses (magnitudes and signs) acting on that element, generally caused by axial, shear, bending, torsion, and internal pressure loading. This is illustrated in [Figure 1.5.30](#), for a case of medium complexity.

Consider a solid circular rod of radius  $R$ , fixed at  $z = 0$  (in the  $xy$  plane), and loaded by two forces at point  $B$  of a rigid arm. Set up the stress analysis at point  $A$  ( $-R, 0, 0$ ), assuming there is no stress concentration at the wall fixture of the rod ([Figure 1.5.30a](#)).

First the equivalent loading at the origin  $0$  is determined ([Figure 1.5.30b](#)). This can be done most accurately in vector form. The individual stresses at point  $A$  are set up in the subdiagram (c). Check that

**FIGURE 1.5.30** Illustration of stress analysis for combined axial, shear, bending, and torsion loading.

each stress even in symbolic form has the proper units of force per area. The net normal force in this case is  $\sigma_1 + \sigma_2$ , and the net shear stress is  $\tau_1 + \tau_2$ .

The state of stress is different at other points in the member. Note that some of the stresses at a point could have different signs, reducing the resultant stress at that location. Such is the case at a point *C* diametrically opposite to point *A* in the present example ( $R, 0, 0$ ), where the axial load *F* and *M<sub>y</sub>* generate normal stresses of opposite signs. This shows the importance of proper modeling and setting up a problem of combined loads before doing the numerical solution.

### Pressure Vessels

*Maan H. Jawad and Bela I. Sandor*

Pressure vessels are made in different shapes and sizes (Figure 1.5.31 and Color Plate 10) and are used in diverse applications. The applications range from air receivers in gasoline stations to nuclear reactors in submarines to heat exchangers in refineries. The required thicknesses for some commonly encountered pressure vessel components depend on the geometry as follows.

#### Cylindrical Shells

The force per unit length in the hoop (tangential) direction, *N<sub>t</sub>*, required to contain a given pressure *p* in a cylindrical shell is obtained by taking a free-body diagram (Figure 1.5.32a) of the cross section. Assuming the thickness *t* to be much smaller than the radius *R* and summing forces in the vertical direction gives

$$2N_t L = 2RLp$$

or

$$N_t = pR \tag{1.5.52}$$

(a)

(b)

**FIGURE 1.5.31** Various pressure vessels. (Photos courtesy Nooter Corp., St. Louis, MO.)

The corresponding hoop stress is  $\sigma_t = pR/t$ .

The longitudinal force per unit length,  $N_x$ , in the cylinder due to pressure is obtained by summing forces in the axial direction (Figure 1.5.32b),

FIGURE 1.5.32 Analysis of cylindrical pressure vessels.

$$2\pi RN_x = \pi R^2 p$$

or

$$N_x = pR/2 \tag{1.5.53}$$

The corresponding axial stress is  $\sigma_x = pR/2t$ . It is seen that the magnitude of  $N_t$  (and  $\sigma_t$ ) is twice that of  $N_x$  (and  $\sigma_x$ ). If  $S$  is the allowable stress and  $t$  is the required minimum thickness,

$$t = pR/S \tag{1.5.54}$$

**Spherical Shells**

A free-body diagram of the spherical cross section is shown in Figure 1.5.33. Summation of forces gives

$$t = pR/2S \tag{1.5.55}$$

FIGURE 1.5.33 Analysis of spherical pressure vessels.

**Example 10**

Determine the required thickness of the shell and heads of the air receiver shown in Figure 1.5.34 if  $p = 100$  psi and  $S = 15,000$  psi.

FIGURE 1.5.34 Sketch of a pressure vessel.

*Solution.* From Equation 1.5.54, the required thickness for the cylindrical shell is

$$t = 100 \times 18/15,000 = 0.12 \text{ in.}$$

The required head thickness from Equation 1.5.55 is

$$t = 100 \times 18/2 \times 15,000 = 0.06 \text{ in.}$$

**Conical Shells**

The governing equations for the longitudinal and circumferential forces in a conical shell (Figure 1.5.35a) due to internal pressure are similar to Equations 1.5.52 and 1.5.53 for cylindrical shells, with the radius taken normal to the surface. Thus,

$$N_t = pr/\cos\alpha \tag{1.5.56}$$

$$N_x = pr/2\cos\alpha \tag{1.5.57}$$

where  $\alpha$  is half the apex angle of the cone.

**FIGURE 1.5.35** Analysis of conical shells.

The junction between a conical and cylindrical shell, Figure 1.5.35b, is subjected to an additional force,  $H$ , in the horizontal direction due to internal pressure. The magnitude of this additional force per unit length can be obtained by taking a free-body diagram as shown in Figure 1.5.35b,

$$H = N_x \sin\alpha \tag{1.5.58}$$

A ring is usually provided at the cone-to-cylinder junction to carry the horizontal force  $H$ . The required area  $A$  of the ring is obtained from Figure 1.5.35c as

$$H2r = 2AS$$

or

$$A = Hr/S = (N_x \sin\alpha)r/S = (pr^2 \sin\alpha)/(2S\cos\alpha) \tag{1.5.59}$$

The stress in the ring is compressive at the large end of the cone and tensile at the small end of the cone due to internal pressure. This stress may reverse in direction due to other loading conditions such as weight of contents and end loads on the cone due to wind and earthquake loads.

**Example 11**

Determine the required thickness of the two cylindrical shells and cone shown in Figure 1.5.36a due to an internal pressure of 200 psi. Calculate the area of the rings required at the junctions. Assume the allowable stress to be 20 ksi in tension and 10 ksi in compression.

**FIGURE 1.5.36** Cylindrical shells with cone connection.

*Solution.* From Equation 1.5.54, the thickness of the large cylinder is

$$t = 200 \times 60 / 20,000 = 0.60 \text{ in.}$$

The thickness of the small cylinder is

$$t = 200 \times 30 / 20,000 = 0.30 \text{ in.}$$

The thickness of the cone is obtained from Equation 1.5.56 as

$$t = 200 \times 60 / (20,000 \times \cos 30^\circ) = 0.69 \text{ in.}$$

The required area of the ring at the large end of the cone is obtained from Equation 1.5.59 using the allowable compressive stress of 10 ksi.

$$A = 200 \times 60^2 \times \sin 30^\circ / (2 \times 10,000 \times \cos 30^\circ) = 20.78 \text{ in.}^2$$

The required area of the ring at the small end of the cone is obtained from Equation 1.5.59 using the allowable tensile stress of 20 ksi.

$$A = 200 \times 30^2 \times \sin 30^\circ / (2 \times 20,000 \times \cos 30^\circ) = 2.60 \text{ in.}^2$$

The rings at the junction are incorporated in a number of ways such as those shown in [Figure 1.5.36b](#).

### Nozzle Reinforcement

Reinforcements around openings in pressure vessels are needed to minimize the local stress in the area of the opening. The calculation for the needed reinforcement around an opening is based on the concept that pressure in a given area of a vessel is contained by the material in the vessel wall surrounding the pressure. Thus in [Figure 1.5.37](#), if we take an infinitesimal length  $dL$  along the cylinder, the force caused by the pressure within this length is given by the quantity  $pR dL$ . The force in the corresponding vessel wall is given by  $St dL$ . Equating these two quantities results in the expression  $t = pR/S$  which is given earlier as Equation 1.5.54. Similarly for the nozzle in [Figure 1.5.37](#),  $T = pr/S$ . The intersection of the nozzle with the cylinder results in an opening where the pressure in area  $ABCD$  is not contained by any material. Accordingly, an additional area must be supplied in the vicinity of the opening to prevent overstress of the vessel. The required area  $A$  is determined from [Figure 1.5.37](#) as

$$A = p Rr/S$$

Substituting Equation 1.5.54 into this expression gives

$$A = tr \tag{1.5.60}$$

This equation indicates that the needed additional area is equal to the removed area of the vessel wall.

FIGURE 1.5.37 Nozzle reinforcement.

### Creep-Fatigue of Boilers and Pressure Vessels

See Figure 1.6.27 in Section 1.6, “Fatigue.”

### Composite Materials for Pressure Vessels

*Ian K. Glasgow*

Some pressure vessels can be made of fibrous composite materials with high strength-to-weight ratios. The advantages of using such a material are remarkable in the case of a tubular vessel, where the hoop stress is twice the longitudinal stress, if the fiber quantities and orientations are optimally designed to resist the applied load caused by internal pressure. Simplistically (since a basic element of a composite is strong along the fibers and weak perpendicular to the fibers), this requires twice as many fibers oriented circumferentially as axially. In practice, fibers are commonly laid at  $\pm$  (a winding angle) at which the hoop and axial stress components are equal, to efficiently create an optimized configuration.

#### Example 12

Determine the minimum weight of the tube portion of a thin-walled cylindrical pressure vessel of  $r = 8$  in. (20 mm),  $\ell = 10$  ft (3.05 m),  $p = 8$  ksi (55 MPa);  $t = ?$  Assume using a typical graphite/epoxy composite of 60% fibers by volume with allowable tensile stress  $\sigma_y = 300$  ksi (207 MPa) at  $0.058$  lb/in.<sup>3</sup> (1600 kg/m<sup>3</sup>). For comparison, consider a steel of  $\sigma_y = 200$  ksi (138 MPa) at  $0.285$  lb/in.<sup>3</sup> (7890 kg/m<sup>3</sup>).

*Solution.*

Composite:  $\sigma_y = pr/t$ ,  $t = 0.213$  in. (5.41 mm) for circumferential plies

$\sigma_y = pr/2t$ ,  $t = 0.107$  in. (2.72 mm) for axial plies

Total minimum wall thickness: 0.32 in. (8.13 mm)

Total material in tube: 112 lb (50.8 kg)

Steel:  $\sigma_y = pr/t$ ,  $t = 0.32$  in. (8.13 mm)

Total material in tube: 550 lb (249 kg) = 4.9 (composite material)

Note that there are additional considerations in practice, such as cost and potential problems in making adequate connections to the tube.

## Experimental Stress Analysis and Mechanical Testing

*Michael L. Brown and Bela I. Sandor*

Experimental stress analysis is based mostly on the measurement of strains, which may be transformed into stresses. A variety of techniques are available to measure strains. A few of these are described here.

### Properties of Strain-Measuring Systems

Strain-measuring systems are based on a variety of sensors, including mechanical, optical, and electrical devices. Each has some special advantages but can usually be adapted for other needs as well. No one system is entirely satisfactory for all practical requirements, so it is necessary to optimize the gage system to each problem according to a set of desirable characteristics. Some of the common characteristics used to evaluate the system's adequacy for a typical application are

1. The calibration constant for the gage should be stable; it should not vary with either time, temperature, or other environmental factors.
2. The gage should be able to measure strains with an accuracy of  $\pm 1 \mu\epsilon$  over a strain range of  $\pm 10\%$ .
3. The gage size, i.e., the gage length  $l_0$  and width  $w_0$ , should be small so that strain at a point is approximated with small error.
4. The response of the gage, largely controlled by its inertia, should be sufficient to permit recording of dynamic strains with frequency components exceeding 100 kHz.
5. The gage system should permit on-location or remote readout.
6. Both the gage and the associated auxiliary equipment should be inexpensive.
7. The gage system should be easy to install and operate.
8. The gage should exhibit a linear response to strain over a wide range.

Three of these basic characteristics deserve further mention here: the gage length  $l_0$ , the gage sensitivity, and the range of the strain gage. The gage length is often the most important because in nonlinear strain fields the error will depend on the gage length.

Sensitivity is the smallest value of strain that can be read on the scale associated with the strain gage and should not be mistaken for accuracy or precision. The sensitivity chosen should not be higher than necessary because it needlessly increases the complexity of the measuring method and introduces new problems.

The range of the strain gage refers to the maximum value of strain that can be recorded. Since the range and sensitivity of the gage are interrelated, it is often necessary to compromise between the two for optimal performance of both. Various compromises have resulted in the two main kinds of strain gages, extensometers and electrical strain gages. There are numerous electrical strain gage systems, but only electrical-resistance strain gages will be considered here.

### Extensometers

Various extensometers involving mechanical, electrical, magnetic, or optical devices are used in material test systems. A typical extensometer (Figure 1.5.38) is used in the conventional tensile test where the stress-strain diagram is recorded. This kind of extensometer is attached to the specimen by knife edges and spring clips. Electrical-resistance strain gages are attached to the cross-flexural member and provide the strain output. The main advantage of extensometers is that they can be reused and recalibrated after each test. The disadvantages are that they are much larger and more expensive than electrical-resistance strain gages.

### Electrical-Resistance Strain Gages

The electrical-resistance strain gage fulfills most of the requirements of an optimum system and is widely used for experimental stress analysis. The electrical-resistance strain gage consists of a metal-foil grid bonded to a polymer backing (Figure 1.5.39). A Wheatstone bridge is often used in this system to enhance the ability to measure changes in resistance. As a specimen is deformed the strain is transmitted

**FIGURE 1.5.38** Extensometer attached to a tensile specimen.

to the grid, which has a current applied to it. The change in resistance of the grid is converted to a voltage signal output of the Wheatstone bridge. The basic equation used with this system is

$$\frac{\Delta R}{R} = S_A \epsilon \tag{1.5.61}$$

where  $R$  is the resistance of the gage,  $\epsilon$  is the applied strain, and  $S_A$  is the sensitivity, or gage factor, of the metallic alloy used in the conductor. The most commonly used alloy is a copper-nickel alloy called Advance, for which the sensitivity is 2.1.

**FIGURE 1.5.39** Model of metal-foil strain gages.

### Electrical-Resistance Strain Gage Mounting Methods

For precision strain measurements, both the correct adhesive and proper mounting procedures must be employed. The adhesive serves a vital function in the strain-measuring system; it must transmit the strain from the specimen to the sensing element without distortion. Bonding a strain gage to a specimen is one of the most critical steps in the entire process of measuring strain with an electric-resistance strain gage. When mounting a strain gage, it is important to carefully prepare the surface of the component where the gage is to be located. This includes sanding, degreasing, etching, cleaning, and finally neutralizing the surface where the gage is to be mounted. Next, the surface is marked to allow accurate orientation of the strain gage. The gage is then put in place and held with tape while the adhesive is allowed to dry. Several of the adhesive systems commonly used for this are epoxy cements, cyanoacrylate cement, polyester adhesives, and ceramic adhesives. Once the adhesive has been placed, the drying process becomes vitally important, as it can cause residual stresses in the grid work of the gage which could influence the output. After allowing the adhesive to dry, the cure must be tested to ensure complete drying. Failure to do so will affect the stability of the gage and the accuracy of the output. The cure state of the adhesive can be tested by various resistance tests. Also, the bonded surface is inspected to determine if any voids are present between the gage and the specimen due to bubbling of the adhesive.

After the bonding process is complete, the lead wires are attached from the soldering tabs of the gage to an anchor terminal, which is also bonded to the test specimen. This anchoring terminal is used to protect the fragile metal-foil gages. Finally, wires are soldered from this anchor terminal to the instrumentation being used to monitor the resistance changes.

**Gage Sensitivities and Gage Factor**

The electrical-resistance strain gage has a sensitivity to both axial and transverse strain. The magnitude of the transverse strain transmitted to the grid depends on a number of factors, including the thickness and elastic modulus of the adhesive, the carrier material, the grid material, and the width-to-thickness ratio of the axial segments of the grid. Sometimes it is necessary to calculate the true value of strain that includes all contributions, from

$$\epsilon_a = \frac{(\Delta R/R)}{S_g} \frac{1 - \nu_0 K_t}{1 + K_t (\epsilon_t/\epsilon_a)} \tag{1.5.62}$$

where  $\epsilon_a$  is the normal strain along the axial direction of the gage,  $\epsilon_t$  is the normal strain along the transverse direction of the gage,  $\nu_0 = 0.285$  is Poisson's ratio for the calibration beam, and  $K_t$  is the transverse-sensitivity factor of the gage. The strain gage sensitivity factor,  $S_g$ , is a calibration constant provided by the manufacturer. By using Equations 1.5.61 and 1.5.62 the percent error involved in neglecting the transverse sensitivity can be calculated. These errors can be significant for large values of both  $K_t$  and  $\epsilon_t/\epsilon_a$ , so it may be necessary to correct for the transverse sensitivity of the gage (Figure 1.5.40).

**FIGURE 1.5.40** Error as a function of transverse-sensitivity factor with the biaxial strain ratio as a parameter.

**Strain Analysis Methods**

Electrical-resistance strain gages are normally employed on the free surface of a specimen to establish the stress at a particular point on this surface. In general it is necessary to measure three strains at a point to completely define either the stress or the strain field. For this general case, where nothing is known about the stress field or its directions before experimental analysis, three-element rosettes are required to establish the stress field. This is accomplished by using the three-element gage with orientations at arbitrary angles, as shown in Figure 1.5.41. Using this setup, the strains  $\epsilon_x$ ,  $\epsilon_y$ , and  $\gamma_{xy}$  can be determined. These values can be used to determine the principal strains and principal directions,

$$\begin{aligned} \epsilon_1 &= \frac{1}{2}(\epsilon_{xx} + \epsilon_{yy}) + \frac{1}{2}\sqrt{(\epsilon_{xx} - \epsilon_{yy})^2 + \gamma_{xy}^2} \\ \epsilon_2 &= \frac{1}{2}(\epsilon_{xx} + \epsilon_{yy}) - \frac{1}{2}\sqrt{(\epsilon_{xx} - \epsilon_{yy})^2 + \gamma_{xy}^2} \\ \tan 2\phi &= \frac{\gamma_{xy}}{\epsilon_{xx} - \epsilon_{yy}} \end{aligned} \tag{1.5.63}$$

where  $\phi$  is the angle between the principal axis ( $\sigma_1$ ) and the  $x$  axis. The principal stresses can be computed using the principal strains,

$$\sigma_1 = \frac{E}{1-\nu^2}(\epsilon_1 + \nu\epsilon_2)$$

$$\sigma_2 = \frac{E}{1-\nu^2}(\epsilon_2 + \nu\epsilon_1)$$
(1.5.64)

These expressions give the complete state of stress since the principal directions are known from Equation 1.5.63.

**FIGURE 1.5.41** Three gage elements placed at arbitrary angles relative to the  $x$  and  $y$  axes.

**Optical Methods of Strain Analysis**

*Moiré Method of Strain Analysis.* The moiré technique depends on an optical phenomenon of fringes caused by relative displacement of two sets of arrays of lines. The arrays used to produce the fringes may be a series of straight parallel lines, a series of radial lines emanating from a point, a series of concentric circles, or a pattern of dots. The straight parallel line “grids” are used most often for strain analysis work and consist of equal width lines with opaque spacing of the same width between them. These straight parallel lines are spaced in a “grating” scheme of typically 50 to 1000 lines per inch for moiré work. In the cross-grid system of two perpendicular line arrays, the grid placed on the specimen is referred to as the model grid. The second grid is referred to as the reference grid and is overlaid on top of the model grid. Often a thin layer of oil or some other low-friction substance is placed between the model grid and the reference grid to keep them in contact while attempting to minimize the transmission of strains from the model to the reference grid.

To obtain a moiré fringe pattern the grids are first aligned on the unloaded model so that no pattern is present. The model is loaded and light is transmitted through the two grids. Strain displacement is observed in the model grid while the reference grid remains unchanged. A moiré fringe pattern is formed each time the model grating undergoes a deformation in the primary direction equal to the pitch  $p$  of the reference grating. For a unit gage length,  $\Delta L = np$ , where  $\Delta L$  is the change in length per unit length,  $p$  is the pitch of the reference grating and  $n$  is the number of fringes in the unit gage length. In order to calculate  $\epsilon_x$ ,  $\epsilon_y$ , and  $\gamma_{xy}$ , two sets of gratings must be applied in perpendicular directions. Then displacements  $u$  and  $v$  (displacements in the  $x$  and  $y$  directions, respectively) can be established and the Cartesian strain components can be calculated from slopes of the displacement surfaces:  $\epsilon_{xx} = \partial u/\partial x$ ,  $\epsilon_{yy} = \partial v/\partial y$ , and  $\gamma_{xy} = \partial v/\partial x + \partial u/\partial y$ . The displacement gradients in the  $z$  direction,  $\partial w/\partial x$  and  $\partial w/\partial y$ , have been neglected here because they are not considered in moiré analysis of in-plane deformation fields.

*Photoelasticity.* The method of photoelasticity is based on the physical behavior of transparent, noncrystalline, optically isotropic materials that exhibit optically anisotropic characteristics, referred to as temporary double refraction, while they are stressed. To observe and analyze these fringe patterns a device called a polariscope is used. Two kinds of polariscope are common, the plane polariscope and the circular polariscope.

The plane polariscope (Figure 1.5.42) consists of a light source, two polarizing elements, and the model. The axes of the two polarizing elements are oriented at a  $90^\circ$  angle from each other. If the specimen is not stressed, no light passes through the analyzer and a dark field is observed. If the model is stressed, two sets of fringes, isoclinics and isochromatics, will be obtained. Black isoclinic fringe patterns are the loci of points where the principal-stress directions coincide with the axis of the polarizer. These fringe patterns are used to determine the principal stress directions at all points of a photoelastic model. When the principal stress difference is zero ( $n = 0$ ) or sufficient to produce an integral number of wavelengths of retardation ( $n = 1, 2, 3, \dots$ ), the intensity of light emerging from the analyzer is zero. This condition for extinction gives a second fringe pattern, called isochromatics, where the fringes are the loci of points exhibiting the same order of extinction ( $n = 0, 1, 2, 3, \dots$ ).

$$n = N = \frac{h}{f_\sigma} (\sigma_1 - \sigma_2) \quad (1.5.65)$$

where  $N$  is the isochromatic fringe order. The order of extinction  $n$  depends on the principal stress difference ( $\sigma_1 - \sigma_2$ ), the thickness  $h$  of the model, and the material fringe value  $f_\sigma$ . When monochromatic light is used, the isochromatic fringes appear as dark bands. When white light is used, the isochromatic fringes appear as a series of colored bands. Black fringes appear in this case only where the principal stress difference is zero.

FIGURE 1.5.42 Schematic of a stressed photoelastic model in a plane polariscope.

A circular polariscope is a plane polariscope with two additional polarizing plates, called quarter-wave plates, added between the model and the original polarizing plates (Figure 1.5.43). The two quarter-wave plates are made of a permanently doubly refracting material. The circular polariscope is used to eliminate the isoclinic fringes while maintaining the isochromatic fringes. To accomplish this, monochromatic light must be used since the quarter-wave plates are designed for a specific wavelength of light. For the dark-field arrangement shown, no light is passed through the polariscope when the model is unstressed. A light-field arrangement is achieved by rotating the analyzer  $90^\circ$ . The advantage of using

FIGURE 1.5.43 Schematic of a stressed photoelastic model in a circular polariscope.

both light- and dark-field analysis is that twice as much data is obtained for the whole-field determination of  $\sigma_1 - \sigma_2$ . If a dark-field arrangement is used,  $n$  and  $N$  still coincide, as in Equation 1.5.65. If a light-field arrangement is used, they are not coincident. In this case Equation 1.5.65 becomes

$$N = \frac{1}{2} + n = \frac{h}{f_\sigma}(\sigma_1 - \sigma_2) \quad n = 0, 1, 2, 3, \dots \quad (1.5.66)$$

By determining both the isoclinic fringes and the isochromatic fringes, the principal-stress directions and the principal-stress difference can be obtained. In order to obtain the individual principal stresses, a stress separation technique would need to be employed.

The advantages of the photoelastic method are that it allows a full-field stress analysis and it makes it possible to determine both the magnitude and direction of the principal stresses. The disadvantages are that it requires a plastic model of the actual component and it takes a considerable effort to separate the principal stresses.

*Thermoelastic Stress Analysis.* Modern thermoelastic stress analysis (TSA) employs advanced differential thermography (or AC thermography) methods based on dynamic thermoelasticity and focal-plane-array infrared equipment capable of rapidly measuring small temperature changes (down to 0.001°C) caused by destructive or nondestructive alternating stresses. Stress resolutions comparable to those of strain gages can be achieved in a large variety of materials. The digitally stored data can be processed in near-real time to determine the gradient stress fields and related important quantities (such as combined-mode stress intensity factors) in complex components and structures, with no upper limit in temperature. The efficient, user-friendly methods can be applied in the laboratory and in the field, in vehicles, and structures such as bicycles, automobiles, aircraft, surgical implants, welded bridges, and microelectronics. Optimum

design, rapid prototyping, failure analysis, life prediction, and rationally accelerated testing can be facilitated with the new TSA methods (Color Plates 8 and 11 to 14).

**Brittle Coatings.** If a coating is applied to a specimen that is thin in comparison with the thickness of the specimen, then the strains developed at the surface of the specimen are transmitted without significant change to the coating. This is the basis of the brittle coating method of stress analysis. The two kinds of coatings available are resin-based and ceramic-based coatings. The ceramic-based coatings are seldom used due to the high application temperatures (950 to 1100°F) required. The coatings are sprayed on the component until a layer approximately 0.003 to 0.010 in. thick has accumulated. It is also necessary to spray calibration bars with the coating at the same time in order to obtain the threshold strain at which the coating will crack. These calibration bars are tested in a cantilever apparatus and the threshold strain is calculated using the flexure formula and Hooke's law. Once the threshold strain is known and the actual specimen has been tested, the principal stress perpendicular to the crack can be determined by using Hooke's law. The procedure is to load the component, apply the coating, and then quickly release the loading in steps to observe any cracks.

The main advantages of this method are that both the magnitude and direction of the principal strains can be quickly obtained and that the coating is applied directly to the component. This also allows a quick analysis of where the maximum stress regions are located so that a better method can be used to obtain more accurate results. The main disadvantage is that the coatings are very sensitive to ambient temperature and might not have sufficiently uniform thickness.

### **Mechanical Testing**

**Standards.** Many engineering societies have adopted mechanical testing standards; the most widely accepted are the standards published by the American Society for Testing and Materials. Standards for many engineering materials and mechanical tests (tension, compression, fatigue, plane strain fracture toughness, etc.) are available in the *Annual Book of ASTM Standards*.

**Open-Loop Testing Machines.** In an open-loop mechanical testing system there is no feedback to the control mechanism that would allow for continuous adjustment of the controlled parameter. Instead, the chosen parameter is "controlled" by the preset factory adjustments of the control mechanism. It is not possible for such a machine to continually adjust its operation to achieve a chosen (constant or not constant) displacement rate or loading rate.

A human operator can be added to the control loop in some systems in an attempt to maintain some parameter, such as a loading rate, at a constant level. This is a poor means of obtaining improved equipment response and is prone to error.

**Closed-Loop Testing Machines.** In a closed-loop, most commonly electrohydraulic, testing system, a servo controller is used to continuously control the chosen parameter. When there is a small difference between the desired value that has been programmed in and the actual value that is being measured, the servo controller adjusts the flow of hydraulic fluid to the actuator to reduce the difference (the error). This correction occurs at a rate much faster than any human operator could achieve. A standard system makes 10,000 adjustments per second automatically.

A typical closed-loop system (Color Plates 9, 11, 15) allows the operator to control load, strain, or displacement as a function of time and can be adjusted to control other parameters as well. This makes it possible to perform many different kinds of tests, such as tension, compression, torsion, creep, stress relaxation, fatigue, and fracture.

**Impact Testing.** The most common impact testing machines utilize either a pendulum hammer or a dropped weight. In the pendulum system a hammer is released from a known height and strikes a small notched specimen, causing it to fracture. The hammer proceeds to some final height. The difference between the initial and final heights of the hammer is directly proportional to the energy absorbed by the specimen. For the Charpy test the specimen is mounted horizontally with the ends supported so that

the pendulum will strike the specimen in midspan, opposite the notch. In the Izod test the specimen bottom is mounted in a vertical cantilever support so that the pendulum will strike the specimen at a specific distance above the notch, near the unsupported top end.

A large variety of the drop-weight tests are also available to investigate the behaviors of materials and packages during impact.

*Hardness Testing.* The major hardness tests are the Brinell, Rockwell, Vickers, and Shore scleroscope tests.

The Brinell hardness test uses a hardened steel ball indenter that is pushed into the material under a specified force. The diameter of the indentation left in the surface of the material is measured and a Brinell hardness number is calculated from this diameter.

The Rockwell hardness test differs from the Brinell test in that it uses a  $120^\circ$  diamond cone with a spherical tip for hard metals and a 1/16-in. steel ball for soft metals. The Rockwell tester gives a direct readout of the hardness number. The Rockwell scale consists of a number of different letter designators (B, C, etc.) based on the depth of penetration into the test material.

The Vickers hardness test uses a small pyramidal diamond indenter and a specified load. The diagonal length of the indentation is measured and used to obtain the Vickers hardness number.

The Shore scleroscope uses a weight that is dropped on the specimen to determine the hardness. This hardness number is determined from the rebound height of the weight.

## 1.6 Structural Integrity and Durability

*Bela I. Sandor*

The engineer is often concerned about the long-term behavior and durability of machines and structures. Designs based just on statics, dynamics, and basic mechanics of materials are typically able to satisfy only minimal performance and reliability requirements. For realistic service conditions, there may be numerous degradations to consider. A simple and common approach is to use safety factors based on experience and judgment. The degradations could become severe and require sophisticated analyses if unfavorable interactions occur. For example, fatigue with corrosion or high temperatures is difficult to predict accurately, and much more so when corrosion is occurring at a high temperature.

There are many kinds of degradations and interactions between them, and a large (and still growing) technical literature is available in most of these areas. The present coverage cannot possibly do justice to the magnitude of the most serious problems and the available resources to deal with them. Instead, the material here is to highlight some common problems and provide fundamental concepts to prepare for more serious efforts. The reader is encouraged to study the technical literature (including that by technical societies such as ASM, ASME, ASNT, ASTM, SAE), attend specialized short courses, and seek consulting advice (ASM, ASTM, Teltech) as necessary.

### Finite Element Analysis. Stress Concentrations

The most common problem in creating a machine or structure with good strength-to-weight ratio is to identify its critical locations and the corresponding maximum stresses or strains and to adjust the design optimally. This is difficult if a member's geometry, including the geometry and time-dependence of the loading, is complex. The modern analytical tool for addressing such problems is finite element analysis (FEA) or finite element modeling (FEM).

#### Finite Element Analysis

The finite element (FE) method was developed by engineers using physical insight. In all applications the analyst seeks to calculate a *field quantity*: in stress analysis it is the displacement field or the stress field; in thermal analysis it is the temperature field or the heat flux; and so on. Results of the greatest interest are usually peak values of either the field quantity or its gradients. The FE method is a way of getting a *numerical* solution to a *specific* problem. An FEA does not produce a formula as a solution, nor does it solve a class of problems. Also, the solution is approximate unless the problem is so simple that a convenient exact formula is already available. Furthermore, it is important to validate the numerical solution instead of trusting it blindly.

The power of the FE method is its versatility. The structure analyzed may have arbitrary shape, arbitrary supports, and arbitrary loads. Such generality does not exist in classical analytical methods. For example, temperature-induced stresses are usually difficult to analyze with classical methods, even when the structure geometry and the temperature field are both simple. The FE method treats thermal stresses as readily as stresses induced by mechanical load, and the temperature distribution itself can be calculated by FE. However, it is easy to make mistakes in describing a problem to the computer program. Therefore *it is essential that the user have a good understanding of the problem and the modeling* so that errors in computed results can be detected by judgment.

#### Stress Concentrations

Geometric discontinuities cause localized stress increases above the average or far-field stress. A stress raiser's effect can be determined quantitatively in several ways, but not always readily. The simplest method, if applicable, is to use a known theoretical **stress concentration factor**,  $K_t$ , to calculate the peak stress from the nominal, or average, value,

$$\sigma_{\max} = K_t \sigma_{ave} \quad (1.6.1)$$

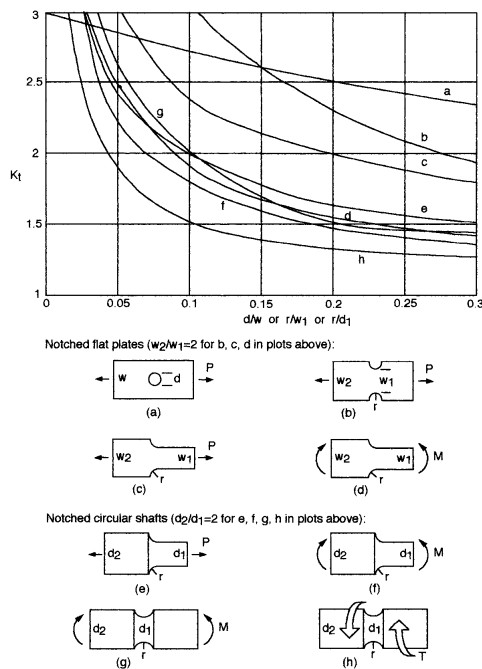

This is illustrated in [Figure 1.6.1](#). The area under the true stress distribution always equals the area under the nominal stress level,

$$\int_A \sigma_{true} dA = \int_A \sigma_{ave} dA = \sigma_{ave} A \tag{1.6.2}$$

**FIGURE 1.6.1** Stress distribution (simplistic) in a notched member under uniaxial load.

The factor  $K_t$  depends mainly on the geometry of the notch, not on the material, except when the material deforms severely under load.  $K_t$  values are normally obtained from plots such as in [Figure 1.6.2](#) and are strictly valid only for ideally elastic, stiff members.  $K_t$  values can also be determined by FEA or by several experimental techniques. There are no  $K_t$  values readily available for sharp notches and cracks, but one can always assume that such discontinuities produce the highest stress concentrations, sometimes factors of tens. This is the reason for brittle, high-strength materials being extremely sensitive even to minor scratches. In fatigue, for example, invisible toolmarks may lead to premature, unexpected failures in strong steels.

**FIGURE 1.6.2** Samples of elastic stress concentration factors. (Condensed from Figures 10.1 and 10.2, Dowling, N. E. 1993. *Mechanical Behavior of Materials*. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

There are many other factors that may seem similar to  $K_t$ , but they should be carefully distinguished. The first is the true stress concentration factor  $K_\sigma$ , defined as

$$K_\sigma = \frac{\sigma_{\max}}{\sigma_{\text{ave}}} \quad (1.6.3)$$

which means that  $K_\sigma = K_t$  (by Equation 1.6.1) for ideally elastic materials.  $K_\sigma$  is most useful in the case of ductile materials that yield at the notch tip and lower the stress level from that indicated by  $K_t$ .

Similarly, a true strain concentration factor,  $K_\epsilon$ , is defined as

$$K_\epsilon = \frac{\epsilon_{\max}}{\epsilon_{\text{ave}}} \quad (1.6.4)$$

where  $\epsilon_{\text{ave}} = \sigma_{\text{ave}}/E$ .

Furthermore, a large number of **stress intensity factors** are used in fracture mechanics, and these (such as  $K$ ,  $K_c$ ,  $K_I$ , etc.) are easily confused with  $K_t$  and  $K_\sigma$ , but their definitions and uses are different as seen in the next section.

## Fracture Mechanics

Notches and other geometric discontinuities are common in solid materials, and they tend to facilitate the formation of cracks, which are in turn more severe stress raisers. Sharp cracks and their further growth are seldom simple to analyze and predict, because the actual stresses and strains at a crack tip are not known with the required accuracy. In fact, this is the reason the classical failure theories (maximum normal stress, or Rankine, theory; maximum shear stress, or Tresca, theory; distortion energy, or von Mises or octahedral shear stress, theory), elegantly simple as they are, are not sufficiently useful in dealing with notched members. A powerful modern methodology in this area is fracture mechanics, which was originated by A. A. Griffith\*\* in 1920 and has grown in depth and breadth enormously in recent decades. The space here is not adequate to even list all of the significant references in this still expanding area. The purpose here is to raise the engineer's awareness to a quantitative, practically useful approach in dealing with stress concentrations as they affect structural integrity and durability.

### Brittle and Ductile Behaviors. Embrittlements

Brittleness and ductility are often the first aspects of fracture considerations, but they often require some qualifications. Simplistically, a material that fractures in a tension test with 0% reduction of area (RA) is perfectly brittle (and very susceptible to fracture at stress raisers), while one with 100% RA is perfectly ductile (and quite tolerant of discontinuities). Between these extremes fall most engineering materials, with the added complication that embrittlement is often made possible by several mechanisms or environmental conditions. For example, temperature, microstructure, chemical environment, internal gases, and certain geometries are common factors in embrittlement. A few of these will be discussed later.

---

\*\* The Griffith criterion of fracture states that a crack may propagate when the decrease in elastic strain energy is at least equal to the energy required to create the new crack surfaces. The available elastic strain energy must also be adequate to convert into other forms of energy associated with the fracture process (heat from plastic deformation, kinetic energy, etc.). The critical nominal stress for fracture according to the Griffith theory is proportional to  $1/\sqrt{\text{crack length}}$ . This is significant since crack length, even inside a member, is easier to measure nondestructively than stresses at a crack tip. Modern, practical methods of fracture analysis are sophisticated engineering tools on a common physical and mathematical basis with the Griffith theory.

**Linear-Elastic Fracture Mechanics (LEFM)**

A major special case of fracture mechanics is when little or no plastic deformations occur at the critical locations of notches and cracks. It is important that even intrinsically ductile materials may satisfy this condition in common circumstances.

*Modes of Deformation.* Three basic modes of deformation (or crack surface displacement) of cracked members are defined as illustrated schematically in Figure 1.6.3. Each of these modes is very common, but Mode I is the easiest to deal with both analytically and experimentally, so most data available are for Mode I.

**FIGURE 1.6.3** Modes of deformation.

*Stress Intensity Factors.* The stresses on an infinitesimal element near a crack tip under Mode I loading are obtained from the theory of linear elasticity. Referring to Figure 1.6.4,

$$\begin{aligned} \sigma_x &= \frac{K_I}{\sqrt{2\pi r}} f_1(\theta) + \dots \\ \sigma_y &= \frac{K_I}{\sqrt{2\pi r}} f_2(\theta) + \dots \\ \tau_{xy} &= \frac{K_I}{\sqrt{2\pi r}} f_3(\theta) + \dots \\ \tau_{xz} &= \tau_{zx} = 0 \end{aligned} \tag{1.6.5}$$

**FIGURE 1.6.4** Coordinates for fracture analysis.

There are two special cases of  $\sigma_z$ :

- $\sigma_z = 0$  for plane stress (thin members)
- $\sigma_z = \nu(\sigma_x + \sigma_y)$  for plane strain, with  $\epsilon_z = 0$  (thick members)

The factor  $K$  in these and similar expressions characterizes the intensity or magnitude of the stress field near the crack tip. It is thus called the stress intensity factor, which represents a very useful concept, but different from that of the well-known stress concentration factor.  $K_I$  is a measure of the severity of a crack, and most conveniently it is expressed as

$$K_I = \sigma \sqrt{\pi a} f(\text{geometry}) \quad (1.6.6)$$

where  $a$  is the crack length and  $f$  is a function of the geometry of the member and of the loading (typically,  $f \cong 1 \pm 0.25$ ). Sometimes  $f$  includes many terms, but all stress intensity factors have the same essential features and units of stress  $\sqrt{\text{length}}$ . In any case, expressions of  $K$  for many common situations are available in the literature, and numerical methods are presented for calculating special  $K$  values. Differential thermography via dynamic thermoelasticity is a powerful, efficient modern method for the measurement of actual stress intensity factors under a variety of complex conditions (Section 1.6, "Experimental Stress Analysis and Mechanical Testing"; Figure 1.6.12; Color Plates 8 and 11 to 14).

### Fracture Toughness of Notched Members

The stress intensity factor, simply  $K$  for now, is analogous to a stress-strain curve, as in Figure 1.6.5.  $K$  increases almost linearly from 0 at  $\sigma = 0$ , to a value  $K_c$  at a critical (fracture) event.  $K_c$  is called the *fracture toughness* of a particular member tested. It does depend on the material, but it is not a reliable material property because it depends on the size of the member too much. This is illustrated in Figure 1.6.6 for plates of the same material but different thicknesses.

FIGURE 1.6.5  $K_c$  = fracture toughness of a particular member.

FIGURE 1.6.6  $K_{Ic}$  = plane strain fracture toughness of material.

At very small thickness,  $K_c$  tends to drop. More significantly,  $K_c$  approaches a lower limiting value at large thickness ( $>A$ ). This worst-case value of  $K_c$  is called  $K_{Ic}$ , the *plane strain fracture toughness* in Mode I. It may be considered a pseudomaterial property since it is independent of geometry at least over a range of thicknesses. It is important to remember that the thickness effect can be rather severe. An intrinsically ductile metal may fracture in an apparently brittle fashion if it is thick enough and has a notch.

**Fracture Toughness Data.** Certain criteria about crack sharpness and specimen dimensions must be satisfied in order to obtain reliable basic  $K_{Ic}$  data (see *ASTM Standards*).  $K_{Ic}$  data for many engineering materials are available in the technical literature. A schematic overview of various materials'  $K_{Ic}$  values is given in Figure 1.6.7. Note that particular expected values are not necessarily attained in practice. Poor material production or manufacturing shortcomings and errors could result in severely lowered toughness. On the other hand, special treatments or combinations of different but favorably matched materials (as in composites) could substantially raise the toughness.

Besides the thickness effect, there are a number of major influences on a given material's toughness, and they may occur in favorable or unfavorable combinations. Several of these are described here schematically, showing general trends. Note that some of the actual behavior patterns are not necessarily as simple or well defined as indicated.

**FIGURE 1.6.7** Plane strain fracture toughness ranges (approximate).

**FIGURE 1.6.8** Yield strength effect on toughness.

*Yield Strength.* High yield strength results in a low fracture toughness (Figure 1.6.8), and therefore it should be chosen carefully, understanding the consequences.

*Temperature.* Two kinds of temperature effect on toughness should be mentioned here. They both may appear, at least for part of the data, as in Figure 1.6.9, with high temperature causing increased toughness. One temperature effect is by the increased ductility at higher temperature. This tends to lower the yield strength (except in low-carbon steels that strain-age at moderately elevated temperatures, about 100 to 500°C), increase the plastic zone at the notch tip, and effectively blunt the stress concentration. Another effect, the distinct temperature-transition behavior in low-carbon steels (BCC metals, in general; easily shown in Charpy tests), is caused by microstructural changes in the metal and is relatively complex in mechanism.

**FIGURE 1.6.9** Temperature effect on toughness.

*Loading Rate.* The higher the rate of loading, the lower the fracture toughness in most cases. Note that toughness results obtained in notch-impact or explosion tests are most relevant to applications where the rate of loading is high.

*Microstructural Aspects.* In some cases apparently negligible variations in chemical composition or manufacturing processes may have a large effect on a material’s fracture toughness. For example, carbon, sulfur, and hydrogen contents may be significant in several embrittling mechanisms. Also, the common mechanical processing of cold or hot working (rolling, extruding, forging) influences the grain structure (grain size and texture) and the corresponding toughness. Neutron radiation also tends to cause microscopic defects, increasing the yield strength and consequently lowering the ductility and toughness of the material.

*Overview of Toughness Degradations.* There is a multitude of mechanisms and situations that must be considered singly and in realistic combinations, as illustrated schematically in Figure 1.6.10 (review Figure 1.6.6 for relevant toughness definitions).

FIGURE 1.6.10 Trends of toughness degradations.

#### Degrading factors

---

Some chemical compositions  
 Sharper notch  
 Greater thickness  
 Faster loading  
 Lower temperature  
 Higher yield strength  
 Hostile chemical environment  
 Liquid metal embrittlement  
 Tensile residual stress  
 Neutron irradiation  
 Microstructural features  
 Moisture  
 Gases in solid solution  
 Surface hardening

---

*Note:* The toughness can drop essentially to zero in some cases.

### Crack Propagation

Crack growth may be classified as either stable (subcritical) or unstable (critical). Often stable cracks become unstable in time, although the opposite behavior, cracks decelerating and even stopping, is sometimes possible. Unstable cracks under load control are extremely dangerous because they propagate at speeds nearly 40% of the speed of sound in that particular solid. This means, for example in steels, a crack growth speed of about 1 mi/sec. Thus, warnings and even electronically activated, automated countermeasures during the unstable propagation are useless. The only reasonable course is to provide, by design and proper manufacture, preventive measures such as ductile regions in a structure where cracks become stable and slow to grow, allowing for inspection and repair.

There are three kinds of stable crack growth, each important in its own right, with interactions between them possible. Under steady loads, environmentally assisted crack growth (also called stress corrosion cracking) and creep crack growth are commonly found. Under cyclic loading fatigue crack growth is likely to occur. In each case the **rate of crack growth** tends to accelerate in time or with progressive cycles of load if the loads are maintained while the cracks reduce the load-bearing cross-sectional area. This common situation, caused by increasing true stresses, is illustrated schematically in Figure 1.6.11, where  $a_0$  is an initial flaw's size,  $da/dN$  and  $da/dt$  are the fatigue and creep crack growth rates, respectively, and  $a_c$  is the critical crack size. The rate of stable crack growth is controlled by the stress intensity factor. This will be discussed later.

### Design and Failure Analysis Using Stress Intensity Concepts

The concept of stress intensity of cracked members is highly useful and practical. Three major possibilities are outlined here with respect to the essential framework of

$$K \propto \text{stress} \sqrt{\text{crack length}} \quad (1.6.7)$$

FIGURE 1.6.11 Crack growth rates under constant load.

Here  $K$  may be either an operating stress intensity factor or a  $K_{Ic}$  value, a material property (the units are the same). In design, the idea is to fix one or two quantities by some initial constraints of the case, then work with the results according to Equation 1.6.7.

1. Operating stress and material ( $K_{Ic}$ ) are predetermined. This forces one to measure crack length and set the maximum allowable size of cracks.
2. Operating stress and detectable crack size are predetermined. This forces one to choose an appropriate material with the required  $K_{Ic}$  value.
3. The material ( $K_{Ic}$  value) and the detectable crack size are predetermined. This forces one to limit the operating stress accordingly.

Similar thinking can be used in failure analysis and corresponding design iteration. For example, the critical crack size at the end of the stable propagation (and start of the unstable, high-speed growth) can often be determined by looking at the broken parts. The material property,  $K_{Ic}$ , can also be estimated from the parts at hand, and thus the stress that caused the failure can be calculated. It can be determined if the stress was within normal bounds or was an overload from misuse of the equipment. These are powerful, quantitative methods that are useful in improving designs and manufacturing.

### Special Methods

There are many other important and useful methods in fracture mechanics that cannot even be listed here. For example, there are several methods in the area of elastic-plastic fracture mechanics. Within this area, mainly applicable to thin members of ductile materials, the J-integral approach alone has been covered in a large number of books and journal articles.

### Nondestructive Evaluation

Since all of fracture mechanics is based on knowing the crack size and its location and orientation, nondestructive evaluation (NDE) is a major part of quantitative, predictive work in this area. Many techniques of NDE are available, and some are still rapidly evolving. Two major categories of NDE methods are defined here:

1. *Geometry-based methods.* At best, the size, shape, location, and orientation of a flaw are measured. Considerable additional effort is needed to estimate the effect of the flaw on structural integrity and durability. Common methods involve acoustic, magnetic, microwave, optical (including thermal), or X-ray instruments.
2. *Stress-based methods.* A flaw's effect on the stress-strain field is directly measured, which is often much more important than just finding that flaw (a flaw of a given geometry may be benign or malignant, depending on the stress field of the neighborhood). Only a few optical methods are readily available for stress-based NDE; the most effective one for laboratory and field applications is thermoelastic stress analysis by infrared means (Figure 1.6.12; Color Plates 8, 11 to 14; Section 1.5, "Experimental Stress Analysis and Mechanical Testing").

**FIGURE 1.6.12** Practical fracture mechanics with NDE: nearly instantaneous measurement of crack size *and* the actual stress intensity factor via advanced thermoelastic stress analysis. The member’s loading (including boundary conditions) need not be known to obtain reliable data using this method.

### Creep and Stress Relaxation

Creep and stress relaxation are related time- and temperature-dependent phenomena, with creep occurring under load control and stress relaxation under deformation control. In both cases the material’s temperature is a governing factor regarding what happens. Specifically, for most metals, the creep and relaxation regimes are defined as high homologous (relative, dimensionless) temperatures, normally those above half the melting point in absolute temperature for each metal. Thus, solder at room temperature creeps significantly under load, while steel and aluminum do not. However, some creep and relaxation may occur even at low homologous temperatures, and they are not always negligible. For polymers, the creep regime is above the glass transition temperature. This is typically not far from room temperature. [Figures 1.6.13](#) and [1.6.14](#) show trends of creep and stress relaxation in the large-scale phenomenon region.

**FIGURE 1.6.13** Creep under constant load.  $d\epsilon/dt = A(\sigma)^n$ .  $A$  and  $n$  are material parameters.

**FIGURE 1.6.14** Stress relaxation under constant deformation.  $\sigma = \sigma_0 e^{-E/\eta}$ .  $E$  and  $\eta$  are material parameters.

Stress vs. rupture life curves for creep may be nearly linear when plotted on log-log coordinates ([Figure 1.6.15](#)).

**FIGURE 1.6.15** Approximate stress vs. rupture lives of S-590 alloy as functions of temperature. (After Figure 15.8, Dowling, N. E. 1993. *Mechanical Behavior of Materials*. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

**Mechanical Models of Viscoelastic Behaviors**

Creep and stress relaxation appear to be combinations of behaviors of viscous liquids and elastic solids. The so-called viscoelastic phenomena are commonly modeled by simple mechanical components, springs and dashpots, as in Figure 1.6.16. The Maxwell model and related others are based on such elements.

**FIGURE 1.6.16** Viscoelastic elements.

The Maxwell model for creep under constant stress  $\sigma_0$  is

$$\epsilon = \epsilon_1 + \epsilon_2 = \frac{\sigma}{E} + \int_0^t \frac{\sigma_0}{\eta} dt = \frac{\sigma_0}{E} + \frac{\sigma_0 t}{\eta} \tag{1.6.8}$$

For relaxation,  $\epsilon = \text{constant}$  and  $\sigma$  varies, so

$$\frac{d\epsilon}{dt} = 0 = \frac{1}{E} \frac{d\sigma}{dt} + \frac{\sigma}{\eta} \tag{1.6.9}$$

$$\int_{\sigma_0}^{\sigma} \frac{d\sigma}{\sigma} = -\frac{E}{\eta} \int_0^t dt, \quad \sigma = \sigma_0 e^{-Et/\eta}$$

**Time-Temperature Parameters. Life Estimation**

It is often necessary to extrapolate from laboratory creep test data, which are limited in time (from days to years), to real service lives, which tend to be from years to several decades. Time-temperature parameters are useful for this purpose. Three common parameters are outlined here. Note that no such parameter is entirely reliable in all cases. They are best if used consistently in direct comparisons of materials.

**Sherby-Dorn Parameter ( $P_{SD}$ )**

$$P_{SD} = \log \theta_r = \log t_r - 0.217Q \left( \frac{1}{T} \right) \quad (1.6.10)$$

where, for steady-state creep,

$\theta_r$  = temperature-compensated time to rupture

$t_r$  = rupture time, hours

$Q$  = activation energy = constant

$T$  = temperature, K

Stress-life data at high  $T$  and low  $t_r$  are needed to plot  $P_{SD}$  vs. stress, in order to predict a longer  $t_r$  at a lower  $T$ .

**Larson-Miller Parameter ( $P_{LM}$ )**

This approach is analogous to the Sherby-Dorn approach, but is based on different assumptions and equations.

$$P_{LM} = 0.217Q = T(\log t_r + C) \quad (1.6.11)$$

where  $C = -\log \theta_r \cong 20$  for steels. For using temperature in degrees Fahrenheit (as in most of the data),

$$P_{LM}|_{\circ F} = 1.8P_{LM}|_K \quad (1.6.12)$$

**Manson-Haferd Parameter ( $P_{MH}$ )**

$$P_{MH} = \frac{T - T_a}{\log t_r - \log t_a} \quad (1.6.13)$$

where  $T_a$  and  $t_a$  are temperature and time constants representing a point of convergence for a family of data points. As above, for different temperature scales,

$$P_{MH}|_{\circ F} = 1.8P_{MH}|_K \quad (1.6.14)$$

*Overview.* The greater the extrapolation using any parameter, the greater the likelihood of error. A factor of ten or less extrapolation in life is often reasonable. At very large extrapolations there may be different damage mechanisms from that of the tests, as well as unpredictable service loading and environmental conditions.

**Fatigue**

Fatigue is a process of damage evolving in a material due to repeated loads, also called cyclic loads. This is a common degradation that affects virtually all solid materials, and thus it is often the main (or a contributing) factor in the failure of vehicles, machinery, structures, appliances, toys, electronic devices, and surgical implants. Many apparently well-designed and -fabricated items that fail inexplicably have problems rooted in the fatigue area.

Nearly two centuries of fatigue studies and engineering efforts have resulted in a huge, and still expanding, technical literature. This brief review can cover only a few major topics, some old but valuable items of wisdom, and practical modern methods. Three important approaches are presented: the stress-based (useful for long lives), strain-based (useful for short lives), and fracture mechanics methods.

**Definitions**

Constant-amplitude, stress- or strain-controlled cycling is common in testing and some service situations. Figure 1.6.17 shows the stress ( $\sigma$ ) quantities in such cycling. Similar notations are used for strains. In completely reversed stress  $\sigma_m = 0$  and  $R = -1$ . Zero-to-tension (a special case of pulsating tension) has  $\sigma_{min} = 0$  and  $R = 0$ .

FIGURE 1.6.17 Notation for constant-amplitude stress cycling.

**Material Properties in Cyclic Loading**

The mechanical properties of some materials are gradually changed by cyclic plastic strains. The changes that occur are largest early in the fatigue life and become negligible beyond about 20 to 50% of the life. The most important material properties that could change significantly this way are the flow properties (yield strength, proportional limit, strain hardening exponent), while the modulus of elasticity is little affected. For metals, three initial conditions can be defined using the strain hardening exponent  $n$  as a key parameter. The concept of a cyclic stress-strain curve, as opposed to that in monotonic (static) loading, is also used to distinguish possible material behaviors in fatigue, as follows.

- **Stable:**  $0.15 < n < 0.2$  (approx.)

The monotonic and cyclic stress-strain curves are the same for most practical purposes (though seldom coincident).

Examples: 7075-T6 Al; 4142 steel (550 BHN)

- **Cycle-Dependent Softening:**  $n < 0.15$  (approx.) (means initially hard, cold-worked material)

The cyclic stress-strain curve falls significantly below the monotonic curve, which means a gradually decreasing deformation resistance as cyclic loading progresses. The cyclic yield strength may be less than half the tensile yield strength in some cases.

Examples: 4340 steel (350 BHN); 4142 steel (400 BHN)

- **Cycle-Dependent Hardening:**  $n > 0.2$  (approx.) (means initially soft, annealed material)

The cyclic stress-strain curve is significantly above the monotonic curve, which means a gradually increasing deformation resistance as cyclic loading progresses.

Examples: 2024-T4 Al; 4142 steel (670 BHN)

Note that the hardest steels tend to further harden in cyclic loading. Thus, a given steel (such as 4142) may be stable, softening, or hardening, depending on its initial hardness.

In the technical literature, primes are normally used to denote cyclic material properties. For example,  $\sigma'_y$  is the yield strength obtained from a cyclic stress-strain curve.

**Stress vs. Life (S-N) Curves**

The most common and historical fatigue life plots present data of stress amplitude (simplistically,  $S$  or  $S_a$ ) on a linear scale vs. cycles to failure ( $N$  or  $N_f$ ) on a logarithmic scale as in Figure 1.6.18.

FIGURE 1.6.18 Schematic of S-N curves.

Many steels (plain carbon or low alloy) appear to have a distinct fatigue limit. For other metals that do not have such a limit (aluminum, for example), an arbitrary fatigue limit is defined as a stress amplitude corresponding to a specified life, typically 10<sup>7</sup> or 10<sup>8</sup> cycles.

**Trends in S-N Curves**

There are many influences on the shape and position of a material’s fatigue life curve as briefly discussed below.

*Ultimate Strength.* It is widely believed that, at least for steels, the fatigue limit  $\sigma_e$  is about one half of the ultimate strength  $\sigma_u$ . In fact, this is a gross oversimplification, with actual values being lower or higher than that in many cases.

*Mean Stress, Residual Stress.* Several main points are worth remembering: residual stresses (also called self-stresses) are common, and they are to be treated as mean stresses (by sign and magnitude) in fatigue; a tensile mean stress lowers the life while a compressive one increases it. Simplistically, a tensile mean stress lowers the allowable cyclic stress amplitude according to Figure 1.6.19 where

$$\sigma_m + \sigma_a \leq \sigma_u \text{ or } \sigma_y \quad (\text{if yielding is to be prevented})$$

FIGURE 1.6.19 Schematic of tensile mean stress effect.

For example, if  $\sigma_m = 0.7\sigma_u$ , then the maximum alternating stress for one cycle is  $0.3\sigma_u$ . This kind of graphical relationship is called a Goodman diagram. There are several special expressions for dealing with the detrimental effects of tensile mean stresses. For example, the modified Goodman equation is

$$\frac{\sigma_a}{\sigma_e} + \frac{\sigma_m}{\sigma_u} = 1 \tag{1.6.15}$$

where  $\sigma_e$  is the fatigue limit for fully reversed loading.

Sometimes curved Gerber lines represent real behavior better than the linear theory shown in Figure 1.6.19. In that case the Gerber parabola may be appropriate, in the form of

$$\frac{\sigma_a}{\sigma_e} + \left(\frac{\sigma_m}{\sigma_u}\right)^2 = 1 \quad \text{for } \sigma_m \geq 0 \tag{1.6.16}$$

Another approach worth mentioning is the Morrow expression, a mechanistically elegant and sensible one, which will be presented later.

Note that tensile mean stresses are generally detrimental and that many approaches have been proposed to deal with them, yet no single method is capable of good predictions in all cases. In practice it is best to use a particular method that has a good track record for the material and situation at hand. Constant-life diagrams are useful, elaborate derivatives of the Goodman approach, if they include a broad data base (Figure 1.6.20).

FIGURE 1.6.20 Constant-life diagram.

**Notch Effects.** Stress raisers can be extremely detrimental in fatigue, except when they help create localized compressive residual stresses in ductile metals, delaying crack formation and growth. These are discussed in connection with the strain-based approach.

**Microstructure.** Large grain size (annealed metals) lowers the fatigue strength, and small grain size (by cold working) increases it, especially at long lives, under load control.

**Surface Effects.** The condition of a material’s surface may influence the fatigue behavior in many ways, typically in combinations.

**Toolmarks** are common detrimental features, especially since often they are aligned perpendicular to the principal tensile stress in axial or bending loading. An example is a shaft cut in a lathe. Note that in the case of high-strength, hard materials even invisible scratches from grinding and buffing may be stress raisers. Machining also tends to create tensile or compressive residual stresses in surface layers.

**Surface treatments** such as carburizing or nitriding of steels affect the fatigue life by changes in chemical composition, microstructure, hardness, or residual stress. Shot peening, surface rolling, or burnishing is done to introduce compressive residual stresses, which delay cracking in long-life service. Plating (chromium, nickel) tends to create layers of poor fatigue resistance and harmful tensile residual stresses. Shot peening after plating is a beneficial step.

**Environment.** Hostile chemical environments can severely reduce most materials’ fatigue resistance. Common causes of problems are salt water, salt in the air, salt on the road, moisture, and even pollutants in the air. For example, sulfur in the air results in aggressive sulfuric acid on machines and structures.

**Statistical Scatter.** There is always statistical scatter in a material’s fatigue life at any given stress level, especially at long lives. The scatter band may cover several orders of magnitude in life at a single stress

level. Because of the scatter, there is no unique fatigue life curve for any material — the curve depends not only on physical factors such as environment, but also on the number of tests done. It is not sufficient to do a handful of tests and draw a curve somewhere through the data points. As a simple rule, to have a high level of confidence (>99%) in a fatigue life curve, at least six identical tests are needed to obtain a mean value at each of several levels of stresses in the general life range of interest. A curve through these mean values is fairly representative of the average life curve (50% probability of failure), but still may not be adequate to deal with scatter. Note that the minimum number of test specimens according to the ASTM Standard E 739 is 6 to 12 for preliminary, exploratory work, or for research and development and component testing, and 12 to 24 for design allowables or reliability assessment.

Ideally, additional analysis is done, using Gaussian (normal) statistical distribution or some other model, such as the Weibull distribution. The latter is particularly informative in determining the probability of fatigue failure. The practical problem is that engineers may require very low probabilities of failure (less than 1%), but neither the necessary mathematical methods nor the data bases are available for that. A family of fatigue life curves for various probabilities of failure and other relevant considerations for one material are shown schematically in Figures 1.6.21 to 1.6.23.

FIGURE 1.6.21 Schematic S-N curves with various probabilities of failure.

FIGURE 1.6.22 Probability aspects of fatigue depending on stress level.

**Variable Amplitude Loading**

Many machines, vehicles, and structures experience random or blockwise changing loading. They can be simplistically modeled for life prediction using the Palmgren-Miner rule, illustrated in Figure 1.6.24.

There are two major assumptions for this rule for completely reversed loading:

1. Every cycle at a given level of stress amplitude causes the same amount of damage, whether the cycle is early or late in the life.
2. The percentage of damage caused by a cycle of load at any level of stress is equivalent to the same percentage of damage at any other level of stress.

**FIGURE 1.6.23** Probability aspects of fatigue depending on applied stress and product strength.

**FIGURE 1.6.24** Schematic for Palmgren-Miner rule.

Thus, since 100% of the life  $N_{fi}$  is exhausted at failure at any single stress amplitude  $\sigma_i$ , in multilevel loading the life fractions sum to unity, as mathematically formulated here and illustrated in [Figure 1.6.24](#),

$$\frac{N_1}{N_{f1}} + \frac{N_2}{N_{f2}} + \dots = \sum \frac{N_i}{N_{fi}} = 1 \tag{1.6.17}$$

where  $N_i$  is the actual number of cycles at  $\sigma_i$  and  $N_{fi}$  is the life at  $\sigma_i$ .

In practice, summations of about 0.8 to 1.2 can be accepted, saying that the Palmgren-Miner rule is valid in that case. Gross deviations from summations of 1 are common, especially when the mean stress is not zero. There are modified versions of the basic rule for such cases, but they should be used with caution.

*Cycle Counting.* Highly irregular loading requires the use of special cycle counting methods, such as level crossing, range counting, or rainflow cycle counting. The latter is the best modern method, lending itself to efficient field data acquisition and computer work (ASTM Standard E1049; *SAE Fatigue Design Handbook*).

### Multiaxial Fatigue

Complex states of stress are common in engineering components, and in fatigue analysis they may cause serious difficulties. There are many methods available, but none of them are adequate for all cases. The simplest situations that might be handled reasonably well involve fully reversed loading by in-phase or 180° out-of-phase proportional stresses at the same frequency. Multiaxial fatigue testing is difficult and expensive, so it is often desired to use uniaxial test data for predicting the multiaxial behavior. A typical approach for this is based on computing an effective stress amplitude  $\sigma_e$  from the amplitudes of the principal stresses  $\sigma_{1a}$ ,  $\sigma_{2a}$ ,  $\sigma_{3a}$ . With the concept of the octahedral shear yield criterion,

$$\sigma_e = \frac{1}{\sqrt{2}} \sqrt{(\sigma_{1a} - \sigma_{2a})^2 + (\sigma_{2a} - \sigma_{3a})^2 + (\sigma_{3a} - \sigma_{1a})^2} \quad (1.6.18)$$

where in-phase stresses are positive and 180° out-of-phase stresses are negative.

The life is estimated by entering  $\sigma_e$  on the appropriate S-N curve. Note that mean stresses, localized or general yielding, creep, and random frequencies of loading further complicate the problem and require more sophisticated methods than outlined here.

### Strain vs. Life ( $\epsilon$ -N) Curves

A strain-based approach is necessary in fatigue when measurable inelastic strains occur. In general, total strain consists of elastic, plastic, and creep strains, with the latter two being in the category of inelastic strains,

$$\epsilon_t = \epsilon_e + \epsilon_p + \epsilon_c \quad (1.6.19)$$

When  $\epsilon_p$  or/and  $\epsilon_c$  are dominant, the life is relatively short and the situation is called low-cycle fatigue (LCF), as opposed to high-cycle fatigue (HCF), where  $\epsilon_e$  is dominant. The mechanics of LCF can be understood by first considering hysteresis loops of elastic and plastic strains as defined in [Figure 1.6.25](#).

FIGURE 1.6.25 Hysteresis loop.

Simplistically, HCF means a thin loop (a straight line at very long life) and LCF means a fat loop. Strain-life plots are especially useful in the LCF regime where material properties ( $\epsilon_f$ ,  $\sigma_f$ ) obtained in monotonic tension tests are directly useful in fatigue life prediction as shown in [Figure 1.6.26](#). Most commonly the total strain amplitude  $\epsilon_a$  is plotted vs. the life  $2N_f$ , with a corresponding equation (called Coffin-Manson equation) for fully reversed loading,

$$\epsilon_a = \frac{\sigma_f}{E} (2N_f)^b + \epsilon_f (2N_f)^c \quad (1.6.20)$$

FIGURE 1.6.26 Schematic of strain vs. life curves.

It is remarkable that all metals are similar to one another in their values of the exponents  $b$  ( $\approx -0.1$ ) and  $c$  ( $\approx -0.6$ ), differing only in fracture strength  $\sigma_f$  and fracture ductility  $\epsilon_f$ . These allow a simplistic fatigue life prediction if at least  $\sigma_f$  and  $\epsilon_f$  are known.

If there is a mean stress, its effect is equivalent to an altered fracture strength. Using the Morrow approach in a simplified version,

$$\epsilon_a = \frac{\sigma_f}{E} \left( 1 - \frac{\sigma_m}{\sigma_f} \right) (2N_f)^b + \epsilon_f (2N_f)^c \tag{1.6.21}$$

where  $\sigma_m$  is positive for tensile and negative for compressive mean stress.

**Notch Effects**

The localized plastic strains of notched members complicate the fatigue analysis considerably. It should be noted, first of all, that the theoretical stress concentration factor  $K_t$  is not entirely relevant to such members, because yielding lowers the actual peak stresses from those predicted. This leads to the definitions of the true stress and strain concentration factors,

$$K_\sigma = \frac{\text{peak stress}}{\text{ave. stress}} \qquad K_\epsilon = \frac{\text{peak strain}}{\text{ave. strain}} \tag{1.6.22}$$

According to Neuber's rule,

$$K_t = \sqrt{K_\sigma K_\epsilon} \tag{1.6.23}$$

which is useful for notch analysis in fatigue. This expression is strictly true for ideally elastic behavior and is qualitatively evident for elastic-plastic deformations.

*Residual Stresses at Notches.* An extremely important, and somewhat surprising, phenomenon can occur in notched members if they yield locally under variable-amplitude loading. If a large load (called an overload) causes yielding at a notch and is followed only by smaller loads, a residual stress of the opposite sign to the overload's sign is generated at the root of the notch. Thus, a tensile overload (such as at one side of a shaft in a straightening operation) creates a compressive residual stress, and vice versa. These stresses may remain in the member for a long time or be relaxed by other plastic strain events or by annealing. Of course, such stresses are effective mean stresses and can alter the life greatly.

**Creep-Fatigue Interactions**

Inelastic strains (plastic and creep strains) are the basic causes of time- and cycle-dependent damage processes. When both kinds of strains occur during the life of a particular component, complex damage interactions may arise. The simplest and most elegant approach in such a case is to sum both of the different damages linearly (as in the Palmgren-Miner summation for pure fatigue), assuming that they are equivalent to one another. In other words, assume that X percentage of creep life exhausted is equivalent to the same X percentage of fatigue life exhausted. Thus, a linear expression involving time and cycle fractions can be stated,

$$\sum_{\text{pure creep}} \frac{t_i}{t_{ri}} + \sum_{\text{pure fatigue}} \frac{n_j}{N_{fj}} = 1 \quad \text{at failure} \tag{1.6.24}$$

where  $t_i$  = actual time spent at stress level  $i$  in creep,  $t_{ri}$  = total time to rupture at stress level  $i$ ,  $n_j$  = actual number of cycles at stress level  $j$ , and  $N_{fj}$  = cycles to failure at stress level  $j$ .

This idealized linear expression is plotted as a dashed line in Figure 1.6.27; in contrast, a more realistic ASME code and possible severe degradations are also plotted.

**FIGURE 1.6.27** Schematic of creep-fatigue interactions. The bilinear damage rule is recommended in the ASME Boiler and Pressure Vessel Code, Section III, Code Case N47.

There are many other methods (such as damage rate equations; strain-range partitioning) to deal with creep-fatigue problems, but none of them are adequate for all situations. The difficulty is mainly because of the need to account for important, complex details of the loading cycle (frequency, hold times, temperature, and deformation wave shape).

**Fracture Mechanics Method in Fatigue**

Cyclic loading can cause crack growth with or without the presence of a hostile chemical environment. The rate of crack growth depends on the stress intensity factor  $K \propto \sigma\sqrt{a}$ . Investigations of this dependence have led to the development of powerful techniques in design and failure analysis. The fatigue crack growth behavior is quantified by the Paris equation,

$$\frac{da}{dN} = C(\Delta K)^m \tag{1.6.25}$$

where  $da/dN$  = crack growth rate

$C, m$  = material constants

$\Delta K = K_{\max} - K_{\min}$  = stress intensity factor range

$K_{\max} \propto \sigma_{\max}$

$K_{\min} \propto \sigma_{\min}$

Typical data for a wide range of crack growth rates have patterns as in Figure 1.6.28, where  $\Delta K_{th}$  is a threshold value akin to a fatigue limit. The linear part of the curve is useful for life prediction and failure analysis.

FIGURE 1.6.28 Schematic of fatigue crack propagation data.

**Abridged Example of a Modern Fatigue Analysis**

Many of the concepts mentioned above are applied in Sandia National Laboratories’ “User’s Manual for FAROW: Fatigue and Reliability of Wind Turbine Components,” SAND94-2460, November 1994. FAROW is a computer program for the probabilistic analysis of large wind turbines, using structural reliability techniques to calculate the mean time to failure, probability of failure before a target lifetime, relative importance of each of the random inputs, and the sensitivity of the reliability to all input parameters. The method is useful whether extensive data are available or not (showing how much can be gained by reducing the uncertainty in each input). It helps one understand the fatigue reliability of a component and indicates how to improve the reliability. The sample figures (Figures 1.6.29 to 1.6.32) illustrate some of the key data and results for the machines and materials considered.

FIGURE 1.6.29 Relative importance factors as fractions of the total influence on the probability of failure. (Courtesy Sandia National Laboratories, Albuquerque, NM.)

Note especially a large discrepancy between mean lifetime and probability of failure in a few years. A mean lifetime of 600 years was calculated for a critical component, using the median values for all the random variables considered and using the constant values for all the other input parameters. However, the probability of the component failing in less than 5 years is estimated at 7.6% (Figure 1.6.32). This shows the uncertainty even in sophisticated fatigue life calculations because of reasonable uncertainty in the inputs and the sensitivity of fatigue life to parameter variation.

## 1.7 Comprehensive Example of Using Mechanics of Solids Methods

---

*Richard C. Duveneck, David A. Jahnke, Christopher J. Watson, and Bela I. Sandor*

A concise overview of an engineering project is presented to illustrate the relevance and coordinated application of several concepts and methods in this chapter. The sketchy outline is limited in breadth and depth, emphasizes modern methods, and is not aiming for completeness in any particular area.

### The Project

Analyze the currently used A-shaped arm of the suspension system of a small, special-purpose ground vehicle. The goal is to redesign the component to save weight and, more importantly, reduce the cost of manufacturing, while assuring the product's reliability over its expected service life.

### Concepts and Methods

#### Statics

- Vectors
- Free-body diagrams. Equilibrium
- Two-force member: shock absorber
- Frame components
- Beams. Bending moments
- Moments of inertia
- Center of mass

#### Dynamics

- Velocity, acceleration
- Rigid-body dynamics
- General plane motion
- Relative motion

#### Vibrations

- Natural frequency
- Damping. Logarithmic decrement

#### Mechanics of Materials

- Stress and strain. Transformation equations. Principal stresses. Maximum shear stress
- Material properties. Material selection
- Bending stresses. Beam optimization
- Strain gages. Mechanical testing with closed-loop equipment

#### Durability

- Stress concentrations. Finite element analysis
- Cumulative fatigue damage. Cycle counting in random loading. Mean stresses. Goodman diagrams.
  - Life prediction
- Thermoelastic stress analysis

#### Illustrations

A few aspects of the project are graphically illustrated in [Color Plate 16](#) and [Figures 1.7.1 to 1.7.3](#).

FIGURE 1.7.1 Accelerometer data from front suspension system of vehicle. Logarithmic decrement  $\delta = \ln(x_1/x_2)$ ; damping ratio  $\zeta = 0.16$ .

## Defining Terms

### STATICS

**Equilibrium:** A concept used to determine unknown forces and moments. A rigid body is in equilibrium when the equivalent force-couple system of the external forces acting on it is zero. The general conditions of equilibrium are expressed in vector form ( $\sum \mathbf{F} = 0$ ,  $\sum \mathbf{M}_O = \sum [\mathbf{r} \times \mathbf{F}] = 0$ ) or scalar form ( $\sum F_x = 0$ ,  $\sum F_y = 0$ ,  $\sum F_z = 0$ ,  $\sum M_x = 0$ ,  $\sum M_y = 0$ ,  $\sum M_z = 0$ ).

**Equivalent force-couple system:** Any system of forces and moments acting on a rigid body can be reduced to a resultant force and a resultant moment. Transformations of a force-couple system involving chosen points of reference are easy to make. These are useful for determining unknown forces and moments and the critical locations in structural members.

**Free-body diagram:** A method of modeling and simplifying a problem for the efficient use of the equilibrium equations to determine unknown forces and moments. A body or group of bodies is imagined to be isolated from all other bodies, and all significant external forces and moments (known or unknown) are shown to act on the free-body model.

FIGURE 1.7.2 Axial stress and force vs. time in shock absorber shaft.

## DYNAMICS

**Equations of motion:** Expressions of the acceleration of a body related to the forces acting on the body.

The basic equation of motion for a particle of mass  $m$  is  $\Sigma \mathbf{F} = m\mathbf{a}$ . Many other equations of motion may be stated, depending on the dimensions of the body and its motion (such as two- or three-dimensional motion) and the coordinate system chosen.

**Kinematics:** The analysis of motion based on geometry and time-dependent aspects. Forces may or may not be associated with the motion, but the analysis does not involve considerations of forces. The parameters of interest in kinematics are position, displacement, velocity, acceleration, and time.

**Kinetics:** The analysis of motion based on kinematics and the effects of forces on masses.

## VIBRATIONS

**Forced vibration:** Involves an exciting force applied periodically during the motion. A forced vibration may also be described in terms of the displacement of a foundation or primary mass that supports the vibrating system.

**Free vibration:** Occurs when only two kinds of forces are acting on a mass: (a) the elastic restoring force within the system and (b) the force of gravity or other constant forces that cause no displacement from the equilibrium configuration of the system.

**FIGURE 1.7.3** Stresses  $\sigma_x$ ,  $\sigma_y$ , and  $\tau_{xy}$  measured at one point of the A-arm by strain gages as the vehicle travels over bumps.

**Resonance:** A critical aspect of forced vibrations; it occurs when the forcing frequency equals the system's natural frequency. In this condition the amplitude of the displacements becomes infinite in theory, or dangerously large in practice when the damping is small. Near-resonance conditions may also be undesirable.

## MECHANICS OF MATERIALS

**Flexure formula:** Used to calculate the bending stresses in beams. Must be applied with modifications if there are inelastic deformations, unsymmetric bending, or for composite beams and curved beams.

**Hooke's law:** Applicable for calculating uniaxial or multiaxial stress-strain responses when the material acts entirely elastically. Involves the modulus of elasticity  $E$  and Poisson's ratio  $\nu$ .

**Principal stresses:** The maximum and minimum normal stresses at a point, on an infinitesimal element. An important related quantity is the absolute maximum shear stress. These quantities can be determined (given an arbitrary state of applied stress) from stress transformation equations or from their graphical solution, Mohr's circle. Principal strains are determined in a similar way.

**Stress-strain diagram:** Shows the stress-strain response and many important mechanical properties for a material. These properties depend greatly on the material's chemical composition and several other factors of fabrication and service conditions. Monotonic (tension or compression) and cyclic loading conditions may result in grossly different mechanical behaviors even for a given material.

## STRUCTURAL INTEGRITY AND DURABILITY

**Rate of crack growth:** A measure of damage evolution and remaining life of a member. In fatigue, the crack propagation rate  $da/dN$  depends on the stress intensity factor range  $\Delta K$  and material properties. This relationship is the basis of the powerful, well-established damage-tolerant design method.

**Stress concentration factor:** The localized stress-raising effect of a geometric discontinuity. There are many, potentially confusing, forms of quantifying this effect. The most prominent factors are distinguished concisely:

- a. Theoretical stress concentration factor,  $K_t = \sigma_{\max}/\sigma_{\text{ave}}$   
Depends on geometry of notch, not on material  
Has no engineering units
- b. True stress concentration factor,  $K_\sigma = \sigma_{\max}/\sigma_{\text{ave}}$   
Depends on geometry of notch and material;  $K_\sigma = K_t$  for perfectly elastic material,  $K_\sigma < K_t$  for ductile material  
Has no engineering units
- c. True strain concentration factor,  $K_\epsilon = \epsilon_{\max}/\epsilon_{\text{ave}}$ ,  $\epsilon_{\text{ave}} = \sigma_{\text{ave}}/E$   
Depends on geometry of notch and material;  $K_\epsilon = K_t$  for perfectly elastic material,  $K_\epsilon > K_t$  for ductile material  
Has no engineering units

**Stress intensity factor:** A measure of the severity of a crack, or the intensity of the stress field near the crack tip. There are many, potentially confusing, forms of this factor, having identical engineering units of stress  $\sqrt{\text{length}}$ , but a variety of definitions and applications. A few are listed concisely:

- a. Opening-mode stress intensity factor,  $K_I$   
Depends on geometry of a crack and applied stress, not on material  
Units of stress  $\sqrt{\text{length}}$
- b. Plane strain fracture toughness,  $K_{IC}$   
Depends on material but not on geometry above a certain thickness, and not on applied stress  
Units of stress  $\sqrt{\text{length}}$
- c. Stress intensity factor range,  $\Delta K = K_{\max} - K_{\min}$   
Depends on geometry of a crack and applied cyclic stress, not on material  
Units of stress  $\sqrt{\text{length}}$

### **Further Information**

Many technical societies are active in various areas of mechanics of solids, and they are excellent, steady sources of long-accepted and new information, some of which is available within hours. They also organize committee work, conferences, symposia, short courses, and workshops; establish codes and standards; and publish books, papers, journals, and proceedings, covering the latest developments in numerous specialties. A short list of societies is given here; note that they tend to have international breadth, regardless of the name. It is wise to belong to several relevant societies and at least scan their announcements.

- ASM International (formerly American Society for Metals) (800-336-5152)
- ASME — American Society for Mechanical Engineers (800-843-2763)
- ASNT — American Society for Nondestructive Testing (800-222-2768)
- ASTM — American Society for Testing and Materials (215-299-5585)
- SAE — Society of Automotive Engineers (412-776-4841)
- SEM — Society for Experimental Mechanics (203-790-6373)
- SES — Standards Engineering Society (513-223-2410)

As a hint of the scope and magnitude of what is available from the large technical societies, here are selected offerings of ASTM:

- ASTM Staff Access/Tel: 215-299-5585; Fax: 215-977-9679; E-mail: [infoctr@local.astm.org](mailto:infoctr@local.astm.org)
- *ASTM Standardization News*, a monthly magazine; regularly presents information on “the development of voluntary full consensus standards for materials, products, systems and services and the promotion of related knowledge... the research, testing and new activities of the ASTM standards-writing committees... the legal, governmental and international events impacting on the standards development process” (quotes from the masthead).
- Over 50 volumes of ASTM Standards
  - Samples of standards:
    - Friction, wear, and abrasion (B611 on wear resistance of carbides; G77 on ranking of materials in sliding wear)
    - Fracture mechanics (E399 on fracture toughness testing of metals)
    - Fatigue (E466 on axial fatigue tests of metals; D671 on flexural fatigue of plastics)
- Training courses for ASTM Standards (215-299-5480)

- ASTM International Directory of Testing Laboratories
- ASTM Directory of Scientific & Technical Consultants & Expert Witnesses
- ASTM Special Technical Publications (STP) are books of peer-reviewed papers on recent research and developments

Samples of STPs:

STP 1198 — *Nondestructive Testing of Pavements and Backcalculation of Moduli*, Second Volume; 1995

STP 1231 — *Automation in Fatigue and Fracture: Testing and Analysis*; 1995.

Although various aspects of what is now known as thermodynamics have been of interest since antiquity, formal study began only in the early 19th century through consideration of the motive power of *heat*: the capacity of hot bodies to produce *work*. Today the scope is larger, dealing generally with *energy and entropy*, and with relationships among the *properties* of matter. Moreover, in the past 25 years engineering thermodynamics has undergone a revolution, both in terms of the presentation of fundamentals and in the manner that it is applied. In particular, the second law of thermodynamics has emerged as an effective tool for engineering analysis and design.

## 2.1 Fundamentals

---

Classical thermodynamics is concerned primarily with the macrostructure of matter. It addresses the gross characteristics of large aggregations of molecules and not the behavior of individual molecules. The microstructure of matter is studied in kinetic theory and statistical mechanics (including quantum thermodynamics). In this chapter, the classical approach to thermodynamics is featured.

### Basic Concepts and Definitions

Thermodynamics is both a branch of physics and an engineering science. The scientist is normally interested in gaining a fundamental understanding of the physical and chemical behavior of fixed, quiescent quantities of matter and uses the principles of thermodynamics to relate the *properties* of matter. Engineers are generally interested in studying *systems* and how they interact with their *surroundings*. To facilitate this, engineers have extended the subject of thermodynamics to the study of systems through which matter flows.

#### System

In a thermodynamic analysis, the *system* is the subject of the investigation. Normally the system is a specified quantity of matter and/or a region that can be separated from everything else by a well-defined surface. The defining surface is known as the *control surface* or *system boundary*. The control surface may be movable or fixed. Everything external to the system is the *surroundings*. A system of fixed mass is referred to as a *control mass* or as a *closed system*. When there is flow of mass through the control surface, the system is called a *control volume*, or *open system*. An *isolated system* is a closed system that does not interact in any way with its surroundings.

#### State, Property

The condition of a system at any instant of time is called its *state*. The state at a given instant of time is described by the properties of the system. A *property* is any quantity whose numerical value depends on the state but not the history of the system. The value of a property is determined in principle by some type of physical operation or test.

*Extensive* properties depend on the size or extent of the system. Volume, mass, energy, and entropy are examples of extensive properties. An extensive property is additive in the sense that its value for the whole system equals the sum of the values for its parts. *Intensive* properties are independent of the size or extent of the system. Pressure and temperature are examples of intensive properties.

A *mole* is a quantity of substance having a mass numerically equal to its molecular weight. Designating the molecular weight by  $\mathcal{M}$  and the number of moles by  $n$ , the mass  $m$  of the substance is  $m = n\mathcal{M}$ . One kilogram mole, designated kmol, of oxygen is 32.0 kg and one pound mole (lbmol) is 32.0 lb. When an extensive property is reported on a unit mass or a unit mole basis, it is called a *specific* property. An overbar is used to distinguish an extensive property written on a per-mole basis from its value expressed per unit mass. For example, the volume per mole is  $\bar{v}$ , whereas the volume per unit mass is  $v$ , and the two specific volumes are related by  $\bar{v} = \mathcal{M}v$ .

#### Process, Cycle

Two states are identical if, and only if, the properties of the two states are identical. When any property of a system changes in value there is a change in state, and the system is said to undergo a *process*. When a system in a given initial state goes through a sequence of processes and finally returns to its initial state, it is said to have undergone a *cycle*.

#### Phase and Pure Substance

The term *phase* refers to a quantity of matter that is homogeneous throughout in both chemical composition and physical structure. Homogeneity in physical structure means that the matter is all *solid*, or all *liquid*, or all *vapor* (or equivalently all *gas*). A system can contain one or more phases. For example, a

system of liquid water and water vapor (steam) contains *two* phases. A *pure substance* is one that is uniform and invariable in chemical composition. A pure substance can exist in more than one phase, but its chemical composition must be the same in each phase. For example, if liquid water and water vapor form a system with two phases, the system can be regarded as a pure substance because each phase has the same composition. The nature of phases that coexist in equilibrium is addressed by the *phase rule* (Section 2.3, Multicomponent Systems).

### Equilibrium

Equilibrium means a condition of balance. In thermodynamics the concept includes not only a balance of forces, but also a balance of other influences. Each kind of influence refers to a particular aspect of thermodynamic (complete) equilibrium. *Thermal* equilibrium refers to an equality of temperature, *mechanical* equilibrium to an equality of pressure, and *phase* equilibrium to an equality of chemical potentials (Section 2.3, Multicomponent Systems). *Chemical* equilibrium is also established in terms of chemical potentials (Section 2.4, Reaction Equilibrium). For complete equilibrium the several types of equilibrium must exist individually.

To determine if a system is in thermodynamic equilibrium, one may think of testing it as follows: isolate the system from its surroundings and watch for changes in its observable properties. If there are no changes, it may be concluded that the system was in equilibrium at the moment it was isolated. The system can be said to be at an *equilibrium state*. When a system is *isolated*, it cannot interact with its surroundings; however, its state can change as a consequence of spontaneous events occurring internally as its intensive properties, such as temperature and pressure, tend toward uniform values. When all such changes cease, the system is in equilibrium. At equilibrium, temperature and pressure are uniform throughout. If gravity is significant, a pressure variation with height can exist, as in a vertical column of liquid.

### Temperature

A scale of temperature independent of the *thermometric substance* is called a *thermodynamic* temperature scale. The Kelvin scale, a thermodynamic scale, can be elicited from the second law of thermodynamics (Section 2.1, The Second Law of Thermodynamics, Entropy). The definition of temperature following from the second law is valid over all temperature ranges and provides an essential connection between the several *empirical* measures of temperature. In particular, temperatures evaluated using a *constant-volume gas thermometer* are identical to those of the Kelvin scale over the range of temperatures where gas thermometry can be used.

The empirical *gas scale* is based on the experimental observations that (1) at a given temperature level all gases exhibit the same value of the product  $p\bar{v}$  ( $p$  is pressure and  $\bar{v}$  the specific volume on a molar basis) if the pressure is low enough, and (2) the value of the product  $p\bar{v}$  increases with the temperature level. On this basis the gas temperature scale is defined by

$$T = \frac{1}{\bar{R}} \lim_{p \rightarrow 0} (p\bar{v})$$

where  $T$  is temperature and  $\bar{R}$  is the *universal gas constant*. The absolute temperature at the *triple point of water* (Section 2.3,  $P$ - $v$ - $T$  Relations) is fixed by international agreement to be 273.16 K on the *Kelvin* temperature scale.  $\bar{R}$  is then evaluated experimentally as  $\bar{R} = 8.314 \text{ kJ/kmol} \cdot \text{K}$  ( $1545 \text{ ft} \cdot \text{lbf/lbmol} \cdot ^\circ\text{R}$ ).

The *Celsius temperature scale* (also called the centigrade scale) uses the degree Celsius ( $^\circ\text{C}$ ), which has the same magnitude as the kelvin. Thus, temperature *differences* are identical on both scales. However, the zero point on the Celsius scale is shifted to 273.15 K, as shown by the following relationship between the Celsius temperature and the Kelvin temperature:

$$T(^{\circ}\text{C}) = T(\text{K}) - 273.15 \quad (2.1)$$

On the Celsius scale, the triple point of water is  $0.01^{\circ}\text{C}$  and 0 K corresponds to  $-273.15^{\circ}\text{C}$ .

Two other temperature scales are commonly used in engineering in the U.S. By definition, the *Rankine scale*, the unit of which is the degree rankine ( $^{\circ}\text{R}$ ), is proportional to the Kelvin temperature according to

$$T(^{\circ}\text{R}) = 1.8T(\text{K}) \quad (2.2)$$

The Rankine scale is also an absolute thermodynamic scale with an absolute zero that coincides with the absolute zero of the Kelvin scale. In thermodynamic relationships, temperature is always in terms of the Kelvin or Rankine scale unless specifically stated otherwise.

A degree of the same size as that on the Rankine scale is used in the *Fahrenheit scale*, but the zero point is shifted according to the relation

$$T(^{\circ}\text{F}) = T(^{\circ}\text{R}) - 459.67 \quad (2.3)$$

Substituting Equations 2.1 and 2.2 into Equation 2.3 gives

$$T(^{\circ}\text{F}) = 1.8T(^{\circ}\text{C}) + 32 \quad (2.4)$$

This equation shows that the Fahrenheit temperature of the *ice point* ( $0^{\circ}\text{C}$ ) is  $32^{\circ}\text{F}$  and of the *steam point* ( $100^{\circ}\text{C}$ ) is  $212^{\circ}\text{F}$ . The 100 Celsius or Kelvin degrees between the ice point and steam point corresponds to 180 Fahrenheit or Rankine degrees.

To provide a standard for temperature measurement taking into account both theoretical and practical considerations, the International Temperature Scale of 1990 (ITS-90) is defined in such a way that the temperature measured on it conforms with the thermodynamic temperature, the unit of which is the kelvin, to within the limits of accuracy of measurement obtainable in 1990. Further discussion of ITS-90 is provided by Preston-Thomas (1990).

## The First Law of Thermodynamics, Energy

Energy is a fundamental concept of thermodynamics and one of the most significant aspects of engineering analysis. Energy can be *stored* within systems in various macroscopic forms: kinetic energy, gravitational potential energy, and internal energy. Energy can also be *transformed* from one form to another and *transferred* between systems. For closed systems, energy can be transferred by *work* and *heat transfer*. The total amount of energy is *conserved* in all transformations and transfers.

### Work

In thermodynamics, the term *work* denotes a means for transferring energy. Work is an effect of one system on another that is identified and measured as follows: work is done by a system on its surroundings if the *sole effect* on everything external to the system *could have been* the raising of a weight. The test of whether a work interaction has taken place is not that the elevation of a weight is actually changed, nor that a force actually acted through a distance, but that the sole effect *could be* the change in elevation of a mass. The magnitude of the work is measured by the number of standard weights that could have been raised. Since the raising of a weight is in effect a force acting through a distance, the work concept of mechanics is preserved. This definition includes work effects such as is associated with rotating shafts, displacement of the boundary, and the flow of electricity.

Work done *by* a system is considered positive:  $W > 0$ . Work done *on* a system is considered negative:  $W < 0$ . The time rate of doing work, or *power*, is symbolized by  $\dot{W}$  and adheres to the same sign convention.

### Energy

A closed system undergoing a process that involves only work interactions with its surroundings experiences an *adiabatic* process. On the basis of experimental evidence, it can be postulated that *when*

a closed system is altered adiabatically, the amount of work is fixed by the end states of the system and is independent of the details of the process. This postulate, which is one way the first law of thermodynamics can be stated, can be made regardless of the type of work interaction involved, the type of process, or the nature of the system.

As the work in an adiabatic process of a closed system is fixed by the end states, an extensive property called *energy* can be defined for the system such that its change between two states is the work in an adiabatic process that has these as the end states. In engineering thermodynamics the change in the energy of a system is considered to be made up of three macroscopic contributions: the change in *kinetic energy*,  $KE$ , associated with the motion of the system *as a whole* relative to an external coordinate frame, the change in *gravitational potential energy*,  $PE$ , associated with the position of the system *as a whole* in the Earth's gravitational field, and the change in *internal energy*,  $U$ , which accounts for all other energy associated with the system. Like kinetic energy and gravitational potential energy, internal energy is an extensive property.

In summary, the change in energy between two states of a closed system in terms of the work  $W_{ad}$  of an adiabatic process between these states is

$$(KE_2 - KE_1) + (PE_2 - PE_1) + (U_2 - U_1) = -W_{ad} \quad (2.5)$$

where 1 and 2 denote the initial and final states, respectively, and the minus sign before the work term is in accordance with the previously stated sign convention for work. Since any arbitrary value can be assigned to the energy of a system at a given state 1, no particular significance can be attached to the value of the energy at state 1 or at *any* other state. Only *changes* in the energy of a system have significance.

The specific energy (energy per unit mass) is the sum of the specific internal energy,  $u$ , the specific kinetic energy,  $v^2/2$ , and the specific gravitational potential energy,  $gz$ , such that

$$\text{specific energy} = u + \frac{v^2}{2} + gz \quad (2.6)$$

where the velocity  $v$  and the elevation  $z$  are each relative to specified datums (often the Earth's surface) and  $g$  is the acceleration of gravity.

A property related to internal energy  $u$ , pressure  $p$ , and specific volume  $v$  is *enthalpy*, defined by

$$h = u + pv \quad (2.7a)$$

or on an extensive basis

$$H = U + pV \quad (2.7b)$$

## Heat

Closed systems can also interact with their surroundings in a way that cannot be categorized as work, as, for example, a gas (or liquid) contained in a closed vessel undergoing a process while in contact with a flame. This type of interaction is called a *heat interaction*, and the process is referred to as *nonadiabatic*.

A fundamental aspect of the energy concept is that energy is conserved. Thus, since a closed system experiences precisely the same energy change during a nonadiabatic process as during an adiabatic process between the same end states, it can be concluded that the *net* energy transfer to the system in each of these processes must be the same. It follows that heat interactions also involve energy transfer.

Denoting the amount of energy transferred *to* a closed system in heat interactions by  $Q$ , these considerations can be summarized by the *closed system energy balance*:

$$(U_2 - U_1) + (KE_2 - KE_1) + (PE_2 - PE_1) = Q - W \quad (2.8)$$

The closed system energy balance expresses the conservation of energy principle for closed systems of all kinds.

The quantity denoted by  $Q$  in Equation 2.8 accounts for the amount of energy transferred to a closed system during a process by means other than work. On the basis of experiments it is known that such an energy transfer is induced only as a result of a temperature difference between the system and its surroundings and occurs only in the direction of decreasing temperature. This means of energy transfer is called an *energy transfer by heat*. The following sign convention applies:

$Q > 0$ : heat transfer *to* the system

$Q < 0$ : heat transfer *from* the system

The time rate of heat transfer, denoted by  $\dot{Q}$ , adheres to the same sign convention.

Methods based on experiment are available for evaluating energy transfer by heat. These methods recognize two basic transfer mechanisms: *conduction* and *thermal radiation*. In addition, theoretical and empirical relationships are available for evaluating energy transfer involving *combined* modes such as *convection*. Further discussion of heat transfer fundamentals is provided in Chapter 4.

The quantities symbolized by  $W$  and  $Q$  account for *transfers* of energy. The terms *work* and *heat* denote different *means* whereby energy is transferred and not *what* is transferred. Work and heat are not properties, and it is improper to speak of work or heat “contained” in a system. However, to achieve economy of expression in subsequent discussions,  $W$  and  $Q$  are often referred to simply as work and heat transfer, respectively. This less formal approach is commonly used in engineering practice.

### Power Cycles

Since energy is a property, over each cycle there is no net change in energy. Thus, Equation 2.8 reads for *any* cycle

$$Q_{\text{cycle}} = W_{\text{cycle}}$$

That is, for *any* cycle the net amount of energy received through heat interactions is equal to the net energy transferred out in work interactions. A *power cycle*, or *heat engine*, is one for which a net amount of energy is transferred out by work:  $W_{\text{cycle}} > 0$ . This equals the net amount of energy transferred in by heat.

Power cycles are characterized both by addition of energy by heat transfer,  $Q_A$ , and inevitable rejections of energy by heat transfer,  $Q_R$ :

$$Q_{\text{cycle}} = Q_A - Q_R$$

Combining the last two equations,

$$W_{\text{cycle}} = Q_A - Q_R$$

The *thermal efficiency* of a heat engine is defined as the ratio of the net work developed to the total energy added by heat transfer:

$$\eta = \frac{W_{cycle}}{Q_A} = 1 - \frac{Q_R}{Q_A} \quad (2.9)$$

The thermal efficiency is strictly less than 100%. That is, some portion of the energy  $Q_A$  supplied is invariably rejected  $Q_R \neq 0$ .

## The Second Law of Thermodynamics, Entropy

Many statements of the second law of thermodynamics have been proposed. Each of these can be called a statement of the second law *or* a corollary of the second law since, if one is invalid, all are invalid. In every instance where a consequence of the second law has been tested directly or indirectly by experiment it has been verified. Accordingly, the basis of the second law, like every other physical law, is experimental evidence.

### Kelvin-Planck Statement

The Kelvin-Planck statement of the second law of thermodynamics refers to a *thermal reservoir*. A thermal reservoir is a system that remains at a constant temperature even though energy is added or removed by heat transfer. A reservoir is an idealization, of course, but such a system can be approximated in a number of ways — by the Earth's atmosphere, large bodies of water (lakes, oceans), and so on. Extensive properties of thermal reservoirs, such as internal energy, can change in interactions with other systems even though the reservoir temperature remains constant, however.

The Kelvin-Planck statement of the second law can be given as follows: *It is impossible for any system to operate in a thermodynamic cycle and deliver a net amount of energy by work to its surroundings while receiving energy by heat transfer from a single thermal reservoir.* In other words, a *perpetual-motion machine of the second kind* is impossible. Expressed analytically, the Kelvin-Planck statement is

$$W_{cycle} \leq 0 \quad (\text{single reservoir})$$

where the words *single reservoir* emphasize that the system communicates thermally only with a single reservoir as it executes the cycle. The “less than” sign applies when *internal irreversibilities* are present as the system of interest undergoes a cycle and the “equal to” sign applies only when no irreversibilities are present.

### Irreversibilities

A process is said to be *reversible* if it is possible for its effects to be eradicated in the sense that there is some way by which *both* the system and its surroundings can be *exactly restored* to their respective initial states. A process is *irreversible* if there is no way to undo it. That is, there is no means by which the system and its surroundings can be exactly restored to their respective initial states. A system that has undergone an irreversible process is not necessarily precluded from being restored to its initial state. However, were the system restored to its initial state, it would not also be possible to return the surroundings to their initial state.

There are many effects whose presence during a process renders it irreversible. These include, but are not limited to, the following: heat transfer through a finite temperature difference; unrestrained expansion of a gas or liquid to a lower pressure; spontaneous chemical reaction; mixing of matter at different compositions or states; friction (sliding friction as well as friction in the flow of fluids); electric current flow through a resistance; magnetization or polarization with hysteresis; and inelastic deformation. The term *irreversibility* is used to identify effects such as these.

Irreversibilities can be divided into two classes, *internal* and *external*. Internal irreversibilities are those that occur within the system, while external irreversibilities are those that occur within the surroundings, normally the immediate surroundings. As this division depends on the location of the boundary there is some arbitrariness in the classification (by locating the boundary to take in the

immediate surroundings, all irreversibilities are internal). Nonetheless, valuable insights can result when this distinction between irreversibilities is made. When internal irreversibilities are absent during a process, the process is said to be *internally reversible*. At every intermediate state of an internally reversible process of a closed system, all intensive properties are uniform throughout each phase present: the temperature, pressure, specific volume, and other intensive properties do not vary with position. The discussions to follow compare the actual and internally reversible process concepts for two cases of special interest.

For a gas as the system, the work of expansion arises from the force exerted by the system to move the boundary against the resistance offered by the surroundings:

$$W = \int_1^2 F dx = \int_1^2 p A dx$$

where the force is the product of the moving area and the pressure exerted by the system there. Noting that  $A dx$  is the change in total volume of the system,

$$W = \int_1^2 p dV$$

This expression for work applies to both actual and internally reversible expansion processes. However, for an internally reversible process  $p$  is not only the pressure at the moving boundary but also the pressure of the entire system. Furthermore, for an internally reversible process the volume equals  $m\nu$ , where the specific volume  $\nu$  has a single value throughout the system at a given instant. Accordingly, the work of an internally reversible expansion (or compression) process is

$$W = m \int_1^2 p d\nu \quad (2.10)$$

When such a process of a closed system is represented by a continuous curve on a plot of pressure vs. specific volume, the area *under* the curve is the magnitude of the work per unit of system mass (area a-b-c'-d' of [Figure 2.3](#), for example).

Although improved thermodynamic performance can accompany the reduction of irreversibilities, steps in this direction are normally constrained by a number of practical factors often related to costs. For example, consider two bodies able to communicate thermally. With a *finite* temperature difference between them, a spontaneous heat transfer would take place and, as noted previously, this would be a source of irreversibility. The importance of the heat transfer irreversibility diminishes as the temperature difference narrows; and as the temperature difference between the bodies vanishes, the heat transfer approaches *ideality*. From the study of heat transfer it is known, however, that the transfer of a finite amount of energy by heat between bodies whose temperatures differ only slightly requires a considerable amount of time, a large heat transfer surface area, or both. To approach *ideality*, therefore, a heat transfer would require an exceptionally long time and/or an exceptionally large area, each of which has cost implications constraining what can be achieved practically.

### Carnot Corollaries

The two corollaries of the second law known as *Carnot* corollaries state: (1) the thermal efficiency of an irreversible power cycle is always less than the thermal efficiency of a reversible power cycle when each operates between the same two thermal reservoirs; (2) all reversible power cycles operating between the same two thermal reservoirs have the same thermal efficiency. A cycle is considered *reversible* when there are no irreversibilities within the system as it undergoes the cycle, and heat transfers between the system and reservoirs occur ideally (that is, with a vanishingly small temperature difference).

### Kelvin Temperature Scale

Carnot corollary 2 suggests that the thermal efficiency of a reversible power cycle operating between two thermal reservoirs depends only on the temperatures of the reservoirs and not on the nature of the substance making up the system executing the cycle or the series of processes. With Equation 2.9 it can be concluded that the ratio of the heat transfers is also related only to the temperatures, and is independent of the substance and processes:

$$\left(\frac{Q_C}{Q_H}\right)_{rev\ cycle} = \psi(T_C, T_H)$$

where  $Q_H$  is the energy transferred to the system by heat transfer from a *hot* reservoir at temperature  $T_H$ , and  $Q_C$  is the energy rejected from the system to a *cold* reservoir at temperature  $T_C$ . The words *rev cycle* emphasize that this expression applies only to systems undergoing reversible cycles while operating between the two reservoirs. Alternative temperature scales correspond to alternative specifications for the function  $\psi$  in this relation.

The *Kelvin temperature scale* is based on  $\psi(T_C, T_H) = T_C/T_H$ . Then

$$\left(\frac{Q_C}{Q_H}\right)_{rev\ cycle} = \frac{T_C}{T_H} \quad (2.11)$$

This equation defines only a ratio of temperatures. The specification of the Kelvin scale is completed by assigning a numerical value to one standard reference state. The state selected is the same used to define the *gas scale*: at the triple point of water the temperature is specified to be 273.16 K. If a reversible cycle is operated between a reservoir at the reference-state temperature and another reservoir at an unknown temperature  $T$ , then the latter temperature is related to the value at the reference state by

$$T = 273.16 \left(\frac{Q}{Q'}\right)_{rev\ cycle}$$

where  $Q$  is the energy received by heat transfer from the reservoir at temperature  $T$ , and  $Q'$  is the energy rejected to the reservoir at the reference temperature. Accordingly, a temperature scale is defined that is valid over all ranges of temperature and that is independent of the thermometric substance.

### Carnot Efficiency

For the special case of a reversible power cycle operating between thermal reservoirs at temperatures  $T_H$  and  $T_C$  on the Kelvin scale, combination of Equations 2.9 and 2.11 results in

$$\eta_{\max} = 1 - \frac{T_C}{T_H} \quad (2.12)$$

called the *Carnot efficiency*. This is the efficiency of *all* reversible power cycles operating between thermal reservoirs at  $T_H$  and  $T_C$ . Moreover, it is the *maximum theoretical* efficiency that any power cycle, real or ideal, could have while operating between the same two reservoirs. As temperatures on the Rankine scale differ from Kelvin temperatures only by the factor 1.8, the above equation may be applied with either scale of temperature.

### The Clausius Inequality

The Clausius inequality provides the basis for introducing two ideas instrumental for quantitative evaluations of processes of systems from a second law perspective: *entropy* and *entropy generation*. The Clausius inequality states that

$$\oint \left( \frac{\delta Q}{T} \right)_b \leq 0 \quad (2.13a)$$

where  $\delta Q$  represents the heat transfer at a part of the system boundary during a portion of the cycle, and  $T$  is the absolute temperature at that part of the boundary. The symbol  $\delta$  is used to distinguish the differentials of *nonproperties*, such as heat and work, from the differentials of properties, written with the symbol  $d$ . The subscript  $b$  indicates that the integrand is evaluated at the boundary of the system executing the cycle. The symbol  $\oint$  indicates that the integral is to be performed over all parts of the boundary and over the entire cycle. The Clausius inequality can be demonstrated using the Kelvin-Planck statement of the second law, and the significance of the inequality is the same: the equality applies when there are no internal irreversibilities as the system executes the cycle, and the inequality applies when internal irreversibilities are present.

The Clausius inequality can be expressed alternatively as

$$\oint \left( \frac{\delta Q}{T} \right)_b = -S_{gen} \quad (2.13b)$$

where  $S_{gen}$  can be viewed as representing the *strength* of the inequality. The value of  $S_{gen}$  is positive when internal irreversibilities are present, zero when no internal irreversibilities are present, and can never be negative. Accordingly,  $S_{gen}$  is a measure of the irreversibilities present within the system executing the cycle. In the next section,  $S_{gen}$  is identified as the *entropy* generated (or *produced*) by internal irreversibilities during the cycle.

## Entropy and Entropy Generation

### Entropy

Consider two cycles executed by a closed system. One cycle consists of an internally reversible process A from state 1 to state 2, followed by an internally reversible process C from state 2 to state 1. The other cycle consists of an internally reversible process B from state 1 to state 2, followed by the same process C from state 2 to state 1 as in the first cycle. For these cycles, Equation 2.13b takes the form

$$\begin{aligned} \left( \int_1^2 \frac{\delta Q}{T} \right)_A + \left( \int_2^1 \frac{\delta Q}{T} \right)_C &= -S_{gen} = 0 \\ \left( \int_1^2 \frac{\delta Q}{T} \right)_B + \left( \int_2^1 \frac{\delta Q}{T} \right)_C &= -S_{gen} = 0 \end{aligned}$$

where  $S_{gen}$  has been set to zero since the cycles are composed of internally reversible processes. Subtracting these equations leaves

$$\left( \int_1^2 \frac{\delta Q}{T} \right)_A = \left( \int_1^2 \frac{\delta Q}{T} \right)_B$$

Since A and B are arbitrary, it follows that the integral of  $\delta Q/T$  has the same value for *any* internally reversible process between the two states: the value of the integral depends on the end states only. It can be concluded, therefore, that the integral defines the change in some property of the system. Selecting the symbol  $S$  to denote this property, its change is given by

$$S_2 - S_1 = \left( \int_1^2 \frac{\delta Q}{T} \right)_{int_{rev}} \quad (2.14a)$$

where the subscript *int rev* indicates that the integration is carried out for any internally reversible process linking the two states. This extensive property is called *entropy*.

Since entropy is a property, the change in entropy of a system in going from one state to another is the same for *all* processes, both internally reversible and irreversible, between these two states. In other words, once the change in entropy between two states has been evaluated, this is the magnitude of the entropy change for *any* process of the system between these end states.

The definition of entropy change expressed on a differential basis is

$$dS = \left( \frac{\delta Q}{T} \right)_{int_{rev}} \quad (2.14b)$$

Equation 2.14b indicates that when a closed system undergoing an internally reversible process *receives* energy by heat transfer, the system experiences an *increase* in entropy. Conversely, when energy is *removed* from the system by heat transfer, the entropy of the system *decreases*. This can be interpreted to mean that an entropy transfer is *associated* with (or accompanies) heat transfer. The direction of the entropy transfer is the same as that of the heat transfer. In an *adiabatic* internally reversible process of a closed system the entropy would remain constant. A constant entropy process is called an *isentropic* process.

On rearrangement, Equation 2.14b becomes

$$(\delta Q)_{int_{rev}} = TdS$$

Then, for an internally reversible process of a closed system between state 1 and state 2,

$$Q_{int_{rev}} = m \int_1^2 Tds \quad (2.15)$$

When such a process is represented by a continuous curve on a plot of temperature vs. specific entropy, the area *under* the curve is the magnitude of the heat transfer per unit of system mass.

### Entropy Balance

For a cycle consisting of an actual process from state 1 to state 2, during which internal irreversibilities are present, followed by an internally reversible process from state 2 to state 1, Equation 2.13b takes the form

$$\int_1^2 \left( \frac{\delta Q}{T} \right)_b + \int_2^1 \left( \frac{\delta Q}{T} \right)_{int_{rev}} = -S_{gen}$$

where the first integral is for the actual process and the second integral is for the internally reversible process. Since no irreversibilities are associated with the internally reversible process, the term  $S_{gen}$  accounting for the effect of irreversibilities during the cycle can be identified with the actual process only.

Applying the definition of entropy change, the second integral of the foregoing equation can be expressed as

$$S_1 - S_2 = \int_2^1 \left( \frac{\delta Q}{T} \right)_{int, rev}$$

Introducing this and rearranging the equation, the *closed system entropy balance* results:

$$S_2 - S_1 = \int_1^2 \left( \frac{\delta Q}{T} \right)_b + S_{gen} \quad (2.16)$$

_____	_____	_____	
entropy	entropy	entropy	
change	transfer	generation	

When the end states are fixed, the entropy change on the left side of Equation 2.16 can be evaluated independently of the details of the process from state 1 to state 2. However, the two terms on the right side depend explicitly on the nature of the process and cannot be determined solely from knowledge of the end states. The first term on the right side is associated with heat transfer to or from the system during the process. This term can be interpreted as the *entropy transfer associated with (or accompanying) heat transfer*. The direction of entropy transfer is the same as the direction of the heat transfer, and the same sign convention applies as for heat transfer: a positive value means that entropy is transferred into the system, and a negative value means that entropy is transferred out.

The entropy change of a system is not accounted for solely by entropy transfer, but is also due to the second term on the right side of Equation 2.16 denoted by  $S_{gen}$ . The term  $S_{gen}$  is positive when internal irreversibilities are present during the process and vanishes when internal irreversibilities are absent. This can be described by saying that entropy is *generated* (or produced) within the system by the action of irreversibilities. The second law of thermodynamics can be interpreted as specifying that entropy is generated by irreversibilities and conserved only in the limit as irreversibilities are reduced to zero. Since  $S_{gen}$  measures the effect of irreversibilities present within a system during a process, its value depends on the nature of the process and not solely on the end states. Entropy generation is *not* a property.

When applying the entropy balance, the objective is often to evaluate the entropy generation term. However, the value of the entropy generation for a given process of a system usually does not have much significance by itself. The significance is normally determined through comparison. For example, the entropy generation within a given component might be compared to the entropy generation values of the other components included in an overall system formed by these components. By comparing entropy generation values, the components where appreciable irreversibilities occur can be identified and rank ordered. This allows attention to be focused on the components that contribute most heavily to inefficient operation of the overall system.

To evaluate the entropy transfer term of the entropy balance requires information regarding both the heat transfer and the temperature on the boundary where the heat transfer occurs. The entropy transfer term is not always subject to direct evaluation, however, because the required information is either unknown or undefined, such as when the system passes through states sufficiently far from equilibrium. In practical applications, it is often convenient, therefore, to enlarge the system to include enough of the immediate surroundings that the temperature on the boundary of the *enlarged system* corresponds to the ambient temperature,  $T_{amb}$ . The entropy transfer term is then simply  $Q/T_{amb}$ . However, as the irreversibilities present would not be just those for the system of interest but those for the enlarged system, the entropy generation term would account for the effects of internal irreversibilities within the

system *and* external irreversibilities present within that portion of the surroundings included within the enlarged system.

A form of the entropy balance convenient for particular analyses is the *rate form*:

$$\frac{dS}{dt} = \sum_j \frac{\dot{Q}_j}{T_j} + \dot{S}_{gen} \quad (2.17)$$

where  $dS/dt$  is the time rate of change of entropy of the system. The term  $\dot{Q}_j/T_j$  represents the time rate of entropy transfer through the portion of the boundary whose instantaneous temperature is  $T_j$ . The term  $\dot{S}_{gen}$  accounts for the time rate of entropy generation due to irreversibilities within the system.

For a system *isolated* from its surroundings, the entropy balance is

$$(S_2 - S_1)_{isol} = S_{gen} \quad (2.18)$$

where  $S_{gen}$  is the total amount of entropy generated within the isolated system. Since entropy is generated in all actual processes, the only processes of an isolated system that actually can occur are those for which the entropy of the isolated system increases. This is known as the *increase of entropy principle*.

## 2.2 Control Volume Applications

Since most applications of engineering thermodynamics are conducted on a control volume basis, the control volume formulations of the mass, energy, and entropy balances presented in this section are especially important. These are given here in the form of *overall* balances. Equations of change for mass, energy, and entropy in the form of differential equations are also available in the literature (see, e.g., Bird et al., 1960).

### Conservation of Mass

When applied to a control volume, the principle of mass conservation states: *The time rate of accumulation of mass within the control volume equals the difference between the total rates of mass flow in and out across the boundary.* An important case for engineering practice is one for which inward and outward flows occur, each through one or more ports. For this case the conservation of mass principle takes the form

$$\frac{dm_{cv}}{dt} = \sum_i \dot{m}_i - \sum_e \dot{m}_e \quad (2.19)$$

The left side of this equation represents the time rate of change of mass contained within the control volume,  $\dot{m}_i$  denotes the mass flow rate at an inlet, and  $\dot{m}_e$  is the mass flow rate at an outlet.

The *volumetric flow rate* through a portion of the control surface with area  $dA$  is the product of the velocity component normal to the area,  $v_n$ , times the area:  $v_n dA$ . The *mass flow rate* through  $dA$  is  $\rho(v_n dA)$ . The mass rate of flow through a port of area  $A$  is then found by integration over the area

$$\dot{m} = \int_A \rho v_n dA$$

For *one-dimensional* flow the intensive properties are uniform with position over area  $A$ , and the last equation becomes

$$\dot{m} = \rho v A = \frac{v A}{v} \quad (2.20)$$

where  $v$  denotes the specific volume and the subscript  $n$  has been dropped from velocity for simplicity.

### Control Volume Energy Balance

When applied to a control volume, the principle of energy conservation states: *The time rate of accumulation of energy within the control volume equals the difference between the total incoming rate of energy transfer and the total outgoing rate of energy transfer.* Energy can enter and exit a control volume by work and heat transfer. Energy also enters and exits with flowing streams of matter. Accordingly, for a control volume with one-dimensional flow at a single inlet and a single outlet,

$$\frac{d(U + KE + PE)_{cv}}{dt} = \dot{Q}_{cv} - \dot{W} + \dot{m} \left( u_i + \frac{v_i^2}{2} + g z_i \right) - \dot{m} \left( u_e + \frac{v_e^2}{2} + g z_e \right) \quad (2.21)$$

where the underlined terms account for the specific energy of the incoming and outgoing streams. The terms  $\dot{Q}_{cv}$  and  $\dot{W}$  account, respectively, for the net rates of energy transfer by heat and work over the boundary (control surface) of the control volume.

Because work is always done on or by a control volume where matter flows across the boundary, the quantity  $\dot{W}$  of Equation 2.21 can be expressed in terms of two contributions: one is the work associated with the force of the fluid pressure as mass is introduced at the inlet and removed at the exit. The other, denoted as  $\dot{W}_{cv}$ , includes *all other* work effects, such as those associated with rotating shafts, displacement of the boundary, and electrical effects. The work rate concept of mechanics allows the first of these contributions to be evaluated in terms of the product of the pressure force,  $pA$ , and velocity at the point of application of the force. To summarize, the work term  $\dot{W}$  of Equation 2.21 can be expressed (with Equation 2.20) as

$$\begin{aligned} \dot{W} &= \dot{W}_{cv} + (p_e A_e) v_e - (p_i A_i) v_i \\ &= \dot{W}_{cv} + \dot{m}_e (p_e v_e) - \dot{m}_i (p_i v_i) \end{aligned} \tag{2.22}$$

The terms  $\dot{m}_i (p_i v_i)$  and  $\dot{m}_e (p_e v_e)$  account for the work associated with the pressure at the inlet and outlet, respectively, and are commonly referred to as *flow work*.

Substituting Equation 2.22 into Equation 2.21, and introducing the specific enthalpy  $h$ , the following form of the control volume energy rate balance results:

$$\frac{d(U + KE + PE)_{cv}}{dt} = \dot{Q}_{cv} - \dot{W}_{cv} + \dot{m}_i \left( h_i + \frac{v_i^2}{2} + gz_i \right) - \dot{m}_e \left( h_e + \frac{v_e^2}{2} + gz_e \right) \tag{2.23}$$

To allow for applications where there may be several locations on the boundary through which mass enters or exits, the following expression is appropriate:

$$\frac{d(U + KE + PE)_{cv}}{dt} = \dot{Q}_{cv} - \dot{W}_{cv} + \sum_i \dot{m}_i \left( h_i + \frac{v_i^2}{2} + gz_i \right) - \sum_e \dot{m}_e \left( h_e + \frac{v_e^2}{2} + gz_e \right) \tag{2.24}$$

Equation 2.24 is an *accounting* rate balance for the energy of the control volume. It states that the time rate of accumulation of energy within the control volume equals the difference between the total rates of energy transfer in and out across the boundary. The mechanisms of energy transfer are heat and work, as for closed systems, and the energy accompanying the entering and exiting mass.

### Control Volume Entropy Balance

Like mass and energy, entropy is an extensive property. And like mass and energy, entropy can be transferred into or out of a control volume by streams of matter. As this is the principal difference between the closed system and control volume forms, the control volume entropy rate balance is obtained by modifying Equation 2.17 to account for these entropy transfers. The result is

$$\frac{dS_{cv}}{dt} = \sum_j \frac{\dot{Q}_j}{T_j} + \sum_i \dot{m}_i s_i - \sum_e \dot{m}_e s_e + \dot{S}_{gen} \tag{2.25}$$

rate of	rate of	rate of
entropy	entropy	entropy
change	transfer	generation

where  $dS_{cv}/dt$  represents the time rate of change of entropy within the control volume. The terms  $\dot{m}_i s_i$  and  $\dot{m}_e s_e$  account, respectively, for rates of entropy *transfer* into and out of the control volume associated with mass flow. One-dimensional flow is assumed at locations where mass enters and exits.  $\dot{Q}_j$  represents the time rate of heat transfer at the location on the boundary where the instantaneous temperature is  $T_j$ ; and  $\dot{Q}_j/T_j$  accounts for the associated rate of entropy *transfer*.  $\dot{S}_{gen}$  denotes the time rate of entropy *generation* due to irreversibilities *within* the control volume. When a control volume comprises a number of components,  $\dot{S}_{gen}$  is the sum of the rates of entropy generation of the components.

## Control Volumes at Steady State

Engineering systems are often idealized as being at *steady state*, meaning that all properties are unchanging in time. For a control volume at steady state, the identity of the matter within the control volume change continuously, but the total amount of mass remains constant. At steady state, Equation 2.19 reduces to

$$\sum_i \dot{m}_i = \sum_e \dot{m}_e \quad (2.26a)$$

The energy rate balance of Equation 2.24 becomes, at steady state,

$$0 = \dot{Q}_{cv} - \dot{W}_{cv} + \sum_i \dot{m}_i \left( h_i + \frac{v_i^2}{2} + gz_i \right) - \sum_e \dot{m}_e \left( h_e + \frac{v_e^2}{2} + gz_e \right) \quad (2.26b)$$

At steady state, the entropy rate balance of Equation 2.25 reads

$$0 = \sum_j \frac{\dot{Q}_j}{T_j} + \sum_i \dot{m}_i s_i - \sum_e \dot{m}_e s_e + \dot{S}_{gen} \quad (2.26c)$$

Mass and energy are conserved quantities, but entropy is not generally conserved. Equation 2.26a indicates that the total rate of mass flow into the control volume equals the total rate of mass flow out of the control volume. Similarly, Equation 2.26b states that the total rate of energy transfer into the control volume equals the total rate of energy transfer out of the control volume. However, Equation 2.26c shows that the rate at which entropy is transferred out *exceeds* the rate at which entropy enters, the difference being the rate of entropy generation within the control volume owing to irreversibilities.

Applications frequently involve control volumes having a single inlet and a single outlet, as, for example, the control volume of [Figure 2.1](#) where heat transfer (if any) occurs at  $T_b$ : the temperature, or a suitable average temperature, on the boundary where heat transfer occurs. For this case the mass rate balance, Equation 2.26a, reduces to  $\dot{m}_i = \dot{m}_e$ . Denoting the common mass flow rate by  $\dot{m}$ , Equations 2.26b and 2.26c read, respectively,

$$0 = \dot{Q}_{cv} - \dot{W}_{cv} + \dot{m} \left[ (h_i - h_e) + \left( \frac{v_i^2 - v_e^2}{2} \right) + g(z_i - z_e) \right] \quad (2.27a)$$

$$0 = \frac{\dot{Q}_{cv}}{T_b} + \dot{m}(s_i - s_e) + \dot{S}_{gen} \quad (2.28a)$$

When Equations 2.27a and 2.28a are applied to particular cases of interest, additional simplifications are usually made. The heat transfer term  $\dot{Q}_{cv}$  is dropped when it is insignificant relative to other energy

**FIGURE 2.1** One-inlet, one-outlet control volume at steady state.

transfers across the boundary. This may be the result of one or more of the following: (1) the outer surface of the control volume is insulated; (2) the outer surface area is too small for there to be effective heat transfer; (3) the temperature difference between the control volume and its surroundings is small enough that the heat transfer can be ignored; (4) the gas or liquid passes through the control volume so quickly that there is not enough time for significant heat transfer to occur. The work term  $\dot{W}_{cv}$  drops out of the energy rate balance when there are no rotating shafts, displacements of the boundary, electrical effects, or other work mechanisms associated with the control volume being considered. The changes in kinetic and potential energy of Equation 2.27a are frequently negligible relative to other terms in the equation.

The special forms of Equations 2.27a and 2.28a listed in Table 2.1 are obtained as follows: when there is no heat transfer, Equation 2.28a gives

$$s_e - s_i = \frac{\dot{S}_{gen}}{\dot{m}} \geq 0 \quad (2.28b)$$

(no heat transfer)

Accordingly, when irreversibilities are present within the control volume, the specific entropy increases as mass flows from inlet to outlet. In the ideal case in which no internal irreversibilities are present, mass passes through the control volume with no change in its entropy — that is, *isentropically*.

For no heat transfer, Equation 2.27a gives

$$\dot{W}_{cv} = \dot{m} \left[ (h_i - h_e) + \left( \frac{v_i^2 - v_e^2}{2} \right) + g(z_i - z_e) \right] \quad (2.27b)$$

A special form that is applicable, at least approximately, to *compressors*, *pumps*, and *turbines* results from dropping the kinetic and potential energy terms of Equation 2.27b, leaving

$$\dot{W}_{cv} = \dot{m}(h_i - h_e) \quad (2.27c)$$

(*compressors, pumps, and turbines*)

**TABLE 2.1 Energy and Entropy Balances for One-Inlet, One-Outlet Control Volumes at Steady State and No Heat Transfer**

Energy balance

$$\dot{W}_{cv} = \dot{m} \left[ (h_i - h_e) + \left( \frac{v_i^2 - v_e^2}{2} \right) + g(z_i - z_e) \right] \quad (2.27b)$$

Compressors, pumps, and turbines<sup>a</sup>

$$\dot{W}_{cv} = \dot{m}(h_i - h_e) \quad (2.27c)$$

Throttling

$$h_e \cong h_i \quad (2.27d)$$

Nozzles, diffusers<sup>b</sup>

$$v_e = \sqrt{v_i^2 + 2(h_i - h_e)} \quad (2.27f)$$

Entropy balance

$$s_e - s_i = \frac{\dot{S}_{gen}}{\dot{m}} \geq 0 \quad (2.28b)$$

<sup>a</sup> For an ideal gas with constant  $c_p$ , Equation 1' of Table 2.7 allows Equation 2.27c to be written as

$$\dot{W}_{cv} = \dot{m}c_p(T_i - T_e) \quad (2.27c')$$

The power developed in an *isentropic process* is obtained with Equation 5' of Table 2.7 as

$$\dot{W}_{cv} = \dot{m}c_pT_i \left[ 1 - (p_e/p_i)^{(k-1)/k} \right] \quad (s=c) \quad (2.27c'')$$

where  $c_p = kR/(k-1)$ .

<sup>b</sup> For an ideal gas with constant  $c_p$ , Equation 1' of Table 2.7 allows Equation 2.27f to be written as

$$v_e = \sqrt{v_i^2 + 2c_p(T_i - T_e)} \quad (2.27f')$$

The exit velocity for an *isentropic process* is obtained with Equation 5' of Table 2.7 as

$$v_e = \sqrt{v_i^2 + 2c_pT_i \left[ 1 - (p_e/p_i)^{(k-1)/k} \right]} \quad (s=c) \quad (2.27f'')$$

where  $c_p = kR/(k-1)$ .

In *throttling devices* a significant reduction in pressure is achieved simply by introducing a restriction into a line through which a gas or liquid flows. For such devices  $\dot{W}_{cv} = 0$  and Equation 2.27c reduces further to read

$$h_e \cong h_i \quad (2.27d)$$

(*throttling process*)

That is, upstream and downstream of the throttling device, the specific enthalpies are equal.

A *nozzle* is a flow passage of varying cross-sectional area in which the velocity of a gas or liquid increases in the direction of flow. In a *diffuser*, the gas or liquid decelerates in the direction of flow. For such devices,  $\dot{W}_{cv} = 0$ . The heat transfer and potential energy change are also generally negligible. Then Equation 2.27b reduces to

$$0 = h_i - h_e + \frac{v_i^2 - v_e^2}{2} \quad (2.27e)$$

Solving for the outlet velocity

$$v_e = \sqrt{v_i^2 + 2(h_i - h_e)} \quad (2.27f)$$

(nozzle, diffuser)

Further discussion of the flow-through nozzles and diffusers is provided in Chapter 3.

The mass, energy, and entropy rate balances, Equations 2.26, can be applied to control volumes with multiple inlets and/or outlets, as, for example, cases involving heat-recovery steam generators, feedwater heaters, and counterflow and crossflow heat exchangers. Transient (or unsteady) analyses can be conducted with Equations 2.19, 2.24, and 2.25. Illustrations of all such applications are provided by Moran and Shapiro (1995).

### Example 1

A turbine receives steam at 7 MPa, 440°C and exhausts at 0.2 MPa for subsequent process heating duty. If heat transfer and kinetic/potential energy effects are negligible, determine the steam mass flow rate, in kg/hr, for a turbine power output of 30 MW when (a) the steam quality at the turbine outlet is 95%, (b) the turbine expansion is internally reversible.

*Solution.* With the indicated idealizations, Equation 2.27c is appropriate. Solving,  $\dot{m} = \dot{W}_{cv} / (h_i - h_e)$ . Steam table data (Table A.5) at the inlet condition are  $h_i = 3261.7$  kJ/kg,  $s_i = 6.6022$  kJ/kg · K.

(a) At 0.2 MPa and  $x = 0.95$ ,  $h_e = 2596.5$  kJ/kg. Then

$$\begin{aligned} \dot{m} &= \frac{30 \text{ MW}}{(3261.7 - 2596.5) \text{ kJ/kg}} \left( \frac{10^3 \text{ kJ/sec}}{1 \text{ MW}} \right) \left( \frac{3600 \text{ sec}}{1 \text{ hr}} \right) \\ &= 162,357 \text{ kg/hr} \end{aligned}$$

(b) For an internally reversible expansion, Equation 2.28b reduces to give  $s_e = s_i$ . For this case,  $h_e = 2499.6$  kJ/kg ( $x = 0.906$ ), and  $\dot{m} = 141,714$  kg/hr.

### Example 2

Air at 500°F, 150 lbf/in.<sup>2</sup>, and 10 ft/sec expands adiabatically through a nozzle and exits at 60°F, 15 lbf/in.<sup>2</sup>. For a mass flow rate of 5 lb/sec determine the exit area, in in.<sup>2</sup>. Repeat for an isentropic expansion to 15 lbf/in.<sup>2</sup>. Model the air as an ideal gas (Section 2.3, Ideal Gas Model) with specific heat  $c_p = 0.24$  Btu/lb · °R ( $k = 1.4$ ).

*Solution.* The nozzle exit area can be evaluated using Equation 2.20, together with the ideal gas equation,  $v = RT/p$ :

$$A_e = \frac{\dot{m}v_e}{v_e} = \frac{\dot{m}(RT_e/p_e)}{v_e}$$

The exit velocity required by this expression is obtained using Equation 2.27f' of Table 2.1,

$$\begin{aligned} v_e &= \sqrt{v_i^2 + 2c_p(T_i - T_e)} \\ &= \sqrt{\left( \frac{10 \text{ ft}}{s} \right)^2 + 2 \left( 0.24 \frac{\text{Btu}}{\text{lb} \cdot \text{R}} \right) \left( \frac{778.17 \text{ ft} \cdot \text{lbf}}{1 \text{ Btu}} \right) (440^\circ\text{R}) \left( \frac{32.174 \text{ lb} \cdot \text{ft}/\text{sec}^2}{1 \text{ lbf}} \right)} \\ &= 2299.5 \text{ ft/sec} \end{aligned}$$

**FIGURE 2.2** Open feedwater heater.

Finally, with  $R = \bar{R}/\mathcal{M} = 53.33 \text{ ft} \cdot \text{lbf}/\text{lb} \cdot ^\circ\text{R}$ ,

$$A_e = \frac{\left(5 \frac{\text{lb}}{\text{sec}}\right) \left(53.3 \frac{\text{ft} \cdot \text{lbf}}{\text{lb} \cdot ^\circ\text{R}}\right) (520^\circ\text{R})}{\left(2299.5 \frac{\text{ft}}{\text{sec}}\right) \left(15 \frac{\text{lbf}}{\text{in}^2}\right)} = 4.02 \text{ in}^2$$

Using Equation 2.27f'' in Table 2.1 for the isentropic expansion,

$$v_e = \sqrt{(10)^2 + 2(0.24)(778.17)(960)(32.174) \left[1 - \left(\frac{15}{150}\right)^{0.4/1.4}\right]}$$

$$= 2358.3 \text{ ft/sec}$$

Then  $A_e = 3.92 \text{ in}^2$ .

### Example 3

Figure 2.2 provides steady-state operating data for an open feedwater heater. Ignoring heat transfer and kinetic/potential energy effects, determine the ratio of mass flow rates,  $\dot{m}_1/\dot{m}_2$ .

*Solution.* For this case Equations 2.26a and 2.26b reduce to read, respectively,

$$\dot{m}_1 + \dot{m}_2 = \dot{m}_3$$

$$0 = \dot{m}_1 h_1 + \dot{m}_2 h_2 - \dot{m}_3 h_3$$

Combining and solving for the ratio  $\dot{m}_1/\dot{m}_2$ ,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{h_2 - h_3}{h_3 - h_1}$$

Inserting steam table data, in kJ/kg, from Table A.5,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{2844.8 - 697.2}{697.2 - 167.6} = 4.06$$

### Internally Reversible Heat Transfer and Work

For one-inlet, one-outlet control volumes at steady state, the following expressions give the heat transfer rate and power in the absence of internal irreversibilities:

$$\left(\frac{\dot{Q}_{cv}}{\dot{m}}\right)_{int, rev} = \int_1^2 T ds \tag{2.29}$$

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{int, rev} = -\int_1^2 v dp + \frac{v_1^2 - v_2^2}{2} + g(z_1 - z_2) \tag{2.30a}$$

(see, e.g., Moran and Shapiro, 1995).

If there is no significant change in kinetic or potential energy from inlet to outlet, Equation 2.30a reads

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{int, rev} = -\int_1^2 v dp \quad (\Delta ke = \Delta pe = 0) \tag{2.30b}$$

The specific volume remains approximately constant in many applications with liquids. Then Equation 30b becomes

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{int, rev} = -v(p_2 - p_1) \quad (v = \text{constant}) \tag{2.30c}$$

When the states visited by a unit of mass flowing without irreversibilities from inlet to outlet are described by a continuous curve on a plot of temperature vs. specific entropy, Equation 2.29 implies that the area under the curve is the magnitude of the heat transfer per unit of mass flowing. When such an ideal process is described by a curve on a plot of pressure vs. specific volume, as shown in [Figure 2.3](#), the magnitude of the integral  $\int v dp$  of Equations 2.30a and 2.30b is represented by the area a-b-c-d behind the curve. The area a-b-c'-d' under the curve is identified with the magnitude of the integral  $\int p dv$  of Equation 2.10.

**FIGURE 2.3** Internally reversible process on  $p$ - $v$  coordinates.

## 2.3 Property Relations and Data

Pressure, temperature, volume, and mass can be found experimentally. The relationships between the specific heats  $c_v$  and  $c_p$  and temperature at relatively low pressure are also accessible experimentally, as are certain other property data. Specific internal energy, enthalpy, and entropy are among those properties that are not so readily obtained in the laboratory. Values for such properties are calculated using experimental data of properties that are more amenable to measurement, together with appropriate property relations derived using the principles of thermodynamics. In this section property relations and data sources are considered for *simple compressible systems*, which include a wide range of industrially important substances.

Property data are provided in the publications of the *National Institute of Standards and Technology* (formerly the U.S. Bureau of Standards), of professional groups such as the *American Society of Mechanical Engineering (ASME)*, the *American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE)*, and the *American Chemical Society*, and of corporate entities such as *Dupont* and *Dow Chemical*. Handbooks and property reference volumes such as included in the list of references for this chapter are readily accessed sources of data. Property data are also retrievable from various commercial online data bases. Computer software is increasingly available for this purpose as well.

### Basic Relations for Pure Substances

An energy balance in differential form for a closed system undergoing an internally reversible process in the absence of overall system motion and the effect of gravity reads

$$dU = (\delta Q)_{int, rev} - (\delta W)_{int, rev}$$

From Equation 2.14b,  $(\delta Q)_{int, rev} = TdS$ . When consideration is limited to *simple compressible systems*: systems for which the only significant work in an internally reversible process is associated with volume change,  $(\delta W)_{int, rev} = pdV$ , the following equation is obtained:

$$dU = TdS - pdV \quad (2.31a)$$

Introducing enthalpy,  $H = U + pV$ , the Helmholtz function,  $\Psi = U - TS$ , and the Gibbs function,  $G = H - TS$ , three additional expressions are obtained:

$$dH = TdS + Vdp \quad (2.31b)$$

$$d\Psi = -pdV - SdT \quad (2.31c)$$

$$dG = Vdp - SdT \quad (2.31d)$$

Equations 2.31 can be expressed on a per-unit-mass basis as

$$du = Tds - pdv \quad (2.32a)$$

$$dh = Tds + vdp \quad (2.32b)$$

$$d\psi = -pdv - sdt \quad (2.32c)$$

$$dg = vdp - sdt \quad (2.32d)$$

Similar expressions can be written on a per-mole basis.

**Maxwell Relations**

Since only properties are involved, each of the four differential expressions given by Equations 2.32 is an *exact* differential exhibiting the general form  $dz = M(x, y)dx + N(x, y)dy$ , where the second mixed partial derivatives are equal:  $(\partial M/\partial y) = (\partial N/\partial x)$ . Underlying these exact differentials are, respectively, functions of the form  $u(s, v)$ ,  $h(s, p)$ ,  $\psi(v, T)$ , and  $g(T, p)$ . From such considerations the *Maxwell relations* given in Table 2.2 can be established.

**Example 4**

Derive the Maxwell relation following from Equation 2.32a.

**TABLE 2.2 Relations from Exact Differentials**

Function	Differential	Coefficients	Maxwell
General:			
$z = z(x, y)$	$dz = M(x, y)dx + N(x, y)dy$	$\left(\frac{\partial z}{\partial x}\right)_y = M$ $\left(\frac{\partial z}{\partial y}\right)_x = N$	$\left(\frac{\partial M}{\partial y}\right)_x = \left(\frac{\partial N}{\partial x}\right)_y$
Internal energy:			
$u(s, v)$	$du = Tds - pdv$	$\left(\frac{\partial u}{\partial s}\right)_v = T$ $\left(\frac{\partial u}{\partial v}\right)_s = -p$	$\left(\frac{\partial T}{\partial v}\right)_s = -\left(\frac{\partial p}{\partial s}\right)_v$
Enthalpy:			
$h(s, p)$	$dh = Tds + vdp$	$\left(\frac{\partial h}{\partial s}\right)_p = T$ $\left(\frac{\partial h}{\partial p}\right)_s = v$	$\left(\frac{\partial T}{\partial p}\right)_s = \left(\frac{\partial v}{\partial s}\right)_p$
Helmholtz function:			
$\psi(v, T)$	$d\psi = -pdv - sdT$	$\left(\frac{\partial \psi}{\partial v}\right)_T = -p$ $\left(\frac{\partial \psi}{\partial T}\right)_v = -s$	$\left(\frac{\partial p}{\partial T}\right)_v = \left(\frac{\partial s}{\partial v}\right)_T$
Gibbs function:			
$g(T, p)$	$dg = vdp - sdT$	$\left(\frac{\partial g}{\partial p}\right)_T = v$ $\left(\frac{\partial g}{\partial T}\right)_p = -s$	$\left(\frac{\partial v}{\partial T}\right)_p = -\left(\frac{\partial s}{\partial p}\right)_T$

*Solution.* The differential of the function  $u = u(s, v)$  is

$$du = \left( \frac{\partial u}{\partial s} \right)_v ds + \left( \frac{\partial u}{\partial v} \right)_s dv$$

By comparison with Equation 2.32a,

$$T = \left( \frac{\partial u}{\partial s} \right)_v, \quad -p = \left( \frac{\partial u}{\partial v} \right)_s$$

In Equation 2.32a,  $T$  plays the role of  $M$  and  $-p$  plays the role of  $N$ , so the equality of second mixed partial derivatives gives the Maxwell relation,

$$\left( \frac{\partial T}{\partial v} \right)_s = - \left( \frac{\partial p}{\partial s} \right)_v$$

Since each of the properties  $T$ ,  $p$ ,  $v$ , and  $s$  appears on the right side of two of the eight coefficients of Table 2.2, four additional property relations can be obtained by equating such expressions:

$$\left( \frac{\partial u}{\partial s} \right)_v = \left( \frac{\partial h}{\partial s} \right)_p, \quad \left( \frac{\partial u}{\partial v} \right)_s = \left( \frac{\partial \psi}{\partial v} \right)_T$$

$$\left( \frac{\partial h}{\partial p} \right)_s = \left( \frac{\partial g}{\partial p} \right)_T, \quad \left( \frac{\partial \psi}{\partial T} \right)_v = \left( \frac{\partial g}{\partial T} \right)_p$$

These four relations are identified in Table 2.2 by brackets. As any three of Equations 2.32 can be obtained from the fourth simply by manipulation, the 16 property relations of Table 2.2 also can be regarded as following from this single differential expression. Several additional first-derivative property relations can be derived; see, e.g., Zemansky, 1972.

### Specific Heats and Other Properties

Engineering thermodynamics uses a wide assortment of thermodynamic properties and relations among these properties. Table 2.3 lists several commonly encountered properties.

Among the entries of Table 2.3 are the specific heats  $c_v$  and  $c_p$ . These intensive properties are often required for thermodynamic analysis, and are defined as partial derivations of the functions  $u(T, v)$  and  $h(T, p)$ , respectively,

$$c_v = \left( \frac{\partial u}{\partial T} \right)_v \quad (2.33)$$

$$c_p = \left( \frac{\partial h}{\partial T} \right)_p \quad (2.34)$$

Since  $u$  and  $h$  can be expressed either on a unit mass basis or a per-mole basis, values of the specific heats can be similarly expressed. Table 2.4 summarizes relations involving  $c_v$  and  $c_p$ . The property  $k$ , the specific heat ratio, is

$$k = \frac{c_p}{c_v} \quad (2.35)$$

**TABLE 2.3 Symbols and Definitions for Selected Properties**

Property	Symbol	Definition	Property	Symbol	Definition
Pressure	$p$		Specific heat, constant volume	$c_v$	$(\partial u/\partial T)_v$
Temperature	$T$		Specific heat, constant pressure	$c_p$	$(\partial h/\partial T)_p$
Specific volume	$v$		Volume expansivity	$\beta$	$\frac{1}{v}(\partial v/\partial T)_p$
Specific internal energy	$u$		Isothermal compressivity	$\kappa$	$-\frac{1}{v}(\partial v/\partial p)_T$
Specific entropy	$s$		Isentropic compressibility	$\alpha$	$-\frac{1}{v}(\partial v/\partial p)_s$
Specific enthalpy	$h$	$u + pv$	Isothermal bulk modulus	$B$	$-v(\partial p/\partial v)_T$
Specific Helmholtz function	$\psi$	$u - Ts$	Isentropic bulk modulus	$B_s$	$-v(\partial p/\partial v)_s$
Specific Gibbs function	$g$	$h - Ts$	Joule-Thomson coefficient	$\mu_J$	$(\partial T/\partial p)_h$
Compressibility factor	$Z$	$pv/RT$	Joule coefficient	$\eta$	$(\partial T/\partial v)_u$
Specific heat ratio	$k$	$c_p/c_v$	Velocity of sound	$c$	$\sqrt{-v^2(\partial p/\partial v)_s}$

Values for  $c_v$  and  $c_p$  can be obtained via statistical mechanics using *spectroscopic* measurements. They can also be determined macroscopically through exacting property measurements. Specific heat data for common gases, liquids, and solids are provided by the handbooks and property reference volumes listed among the Chapter 2 references. Specific heats are also considered in Section 2.3 as a part of the discussions of the *incompressible model* and the *ideal gas model*. Figure 2.4 shows how  $c_p$  for water vapor varies as a function of temperature and pressure. Other gases exhibit similar behavior. The figure also gives the variation of  $c_p$  with temperature in the limit as pressure tends to zero (the ideal gas limit). In this limit  $c_p$  increases with increasing temperature, which is a characteristic exhibited by other gases as well

The following two equations are often convenient for establishing relations among properties:

$$\left(\frac{\partial x}{\partial y}\right)_z \left(\frac{\partial y}{\partial x}\right)_z = 1 \tag{2.36a}$$

$$\left(\frac{\partial y}{\partial z}\right)_x \left(\frac{\partial z}{\partial x}\right)_y \left(\frac{\partial x}{\partial y}\right)_z = -1 \tag{2.36b}$$

Their use is illustrated in Example 5.

**Example 5**

Obtain Equations 2 and 11 of Table 2.4 from Equation 1.

*Solution.* Identifying  $x, y, z$  with  $s, T,$  and  $v,$  respectively, Equation 2.36b reads

$$\left(\frac{\partial T}{\partial v}\right)_s \left(\frac{\partial v}{\partial s}\right)_T \left(\frac{\partial s}{\partial T}\right)_v = -1$$

Applying Equation 2.36a to each of  $(\partial T/\partial v)_s$  and  $(\partial v/\partial s)_T,$

**FIGURE 2.4**  $c_p$  of water vapor as a function of temperature and pressure. (Adapted from Keenan, J.H., Keyes, F.G., Hill, P.G., and Moore, J.G. 1969 and 1978. *Steam Tables — S.I. Units (English Units)*. John Wiley & Sons, New York.)

**TABLE 2.4 Specific Heat Relations<sup>a</sup>**

$$c_v = \left( \frac{\partial u}{\partial T} \right)_v = T \left( \frac{\partial s}{\partial T} \right)_v \quad (1)$$

$$= -T \left( \frac{\partial p}{\partial T} \right)_v \left( \frac{\partial v}{\partial T} \right)_s \quad (2)$$

$$c_p = \left( \frac{\partial h}{\partial T} \right)_p = T \left( \frac{\partial s}{\partial T} \right)_p \quad (3)$$

$$= T \left( \frac{\partial v}{\partial T} \right)_p \left( \frac{\partial p}{\partial T} \right)_s \quad (4)$$

$$c_p - c_v = T \left( \frac{\partial p}{\partial T} \right)_v \left( \frac{\partial v}{\partial T} \right)_p \quad (5)$$

$$= -T \left( \frac{\partial v}{\partial T} \right)_p^2 \left( \frac{\partial p}{\partial v} \right)_T \quad (6)$$

$$= \frac{Tv\beta^2}{\kappa} \quad (7)$$

$$c_p = \frac{1}{\mu_J} \left[ T \left( \frac{\partial v}{\partial T} \right)_p - v \right] \quad (8)$$

$$c_v = -\frac{1}{\eta} \left[ T \left( \frac{\partial p}{\partial T} \right)_v - p \right] \quad (9)$$

$$k = \frac{c_p}{c_v} = \left( \frac{\partial v}{\partial p} \right)_T \left( \frac{\partial p}{\partial v} \right)_s \quad (10)$$

$$\left( \frac{\partial c_v}{\partial v} \right)_T = T \left( \frac{\partial^2 p}{\partial T^2} \right)_v \quad (11)$$

$$\left( \frac{\partial c_p}{\partial p} \right)_T = -T \left( \frac{\partial^2 v}{\partial T^2} \right)_p \quad (12)$$

<sup>a</sup> See, for example, Moran, M.J. and Shapiro, H.N. 1995. *Fundamentals of Engineering Thermodynamics*, 3rd ed. Wiley, New York, chap. 11.

$$\left( \frac{\partial s}{\partial T} \right)_v = -\frac{1}{(\partial T/\partial v)_s (\partial v/\partial s)_T} = -\left( \frac{\partial v}{\partial T} \right)_s \left( \frac{\partial s}{\partial v} \right)_T$$

Introducing the Maxwell relation from [Table 2.2](#) corresponding to  $\psi(T, v)$ ,

$$\left( \frac{\partial s}{\partial T} \right)_v = -\left( \frac{\partial v}{\partial T} \right)_s \left( \frac{\partial p}{\partial T} \right)_v$$

With this, Equation 2 of [Table 2.4](#) is obtained from Equation 1, which in turn is obtained in Example 6. Equation 11 of [Table 2.4](#) can be obtained by differentiating Equation 1 with respect to specific volume at fixed temperature, and again using the Maxwell relation corresponding to  $\psi$ .

### P-v-T Relations

Considerable pressure, specific volume, and temperature data have been accumulated for industrially important gases and liquids. These data can be represented in the form  $p = f(v, T)$ , called an *equation of state*. Equations of state can be expressed in tabular, graphical, and analytical forms.

#### P-v-T Surface

The graph of a function  $p = f(v, T)$  is a surface in three-dimensional space. Figure 2.5 shows the  $p$ - $v$ - $T$  relationship for water. Figure 2.5b shows the projection of the surface onto the pressure-temperature plane, called the *phase diagram*. The projection onto the  $p$ - $v$  plane is shown in Figure 2.5c.

FIGURE 2.5 Pressure-specific volume-temperature surface and projections for water (not to scale).

Figure 2.5 has three regions labeled solid, liquid, and vapor where the substance exists only in a single phase. Between the single phase regions lie *two-phase* regions, where two phases coexist in equilibrium. The lines separating the single-phase regions from the two-phase regions are *saturation lines*. Any state represented by a point on a saturation line is a *saturation state*. The line separating the liquid phase and

the two-phase liquid-vapor region is the saturated liquid line. The state denoted by *f* is a saturated liquid state. The saturated vapor line separates the vapor region and the two-phase liquid-vapor region. The state denoted by *g* is a saturated vapor state. The saturated liquid line and the saturated vapor line meet at the *critical point*. At the critical point, the pressure is the *critical pressure*  $p_c$ , and the temperature is the *critical temperature*  $T_c$ . Three phases can coexist in equilibrium along the line labeled *triple line*. The triple line projects onto a point on the phase diagram. The triple point of water is used in defining the Kelvin temperature scale (Section 2.1, Basic Concepts and Definitions; The Second Law of Thermodynamics, Entropy).

When a phase change occurs during constant pressure heating or cooling, the temperature remains constant as long as both phases are present. Accordingly, in the two-phase liquid-vapor region, a line of constant pressure is also a line of constant temperature. For a specified pressure, the corresponding temperature is called the *saturation temperature*. For a specified temperature, the corresponding pressure is called the *saturation pressure*. The region to the right of the saturated vapor line is known as the *superheated vapor region* because the vapor exists at a temperature greater than the saturation temperature for its pressure. The region to the left of the saturated liquid line is known as the *compressed liquid region* because the liquid is at a pressure higher than the saturation pressure for its temperature.

When a mixture of liquid and vapor coexists in equilibrium, the liquid phase is a saturated liquid and the vapor phase is a saturated vapor. The total volume of any such mixture is  $V = V_f + V_g$ ; or, alternatively,  $mv = m_f v_f + m_g v_g$ , where  $m$  and  $v$  denote mass and specific volume, respectively. Dividing by the total mass of the mixture  $m$  and letting the *mass fraction* of the vapor in the mixture,  $m_g/m$ , be symbolized by  $x$ , called the *quality*, the apparent specific volume  $v$  of the mixture is

$$\begin{aligned} v &= (1-x)v_f + xv_g \\ &= v_f + xv_{fg} \end{aligned} \quad (2.37a)$$

where  $v_{fg} = v_g - v_f$ . Expressions similar in form can be written for internal energy, enthalpy, and entropy:

$$\begin{aligned} u &= (1-x)u_f + xu_g \\ &= u_f + xu_{fg} \end{aligned} \quad (2.37b)$$

$$\begin{aligned} h &= (1-x)h_f + xh_g \\ &= h_f + xh_{fg} \end{aligned} \quad (2.37c)$$

$$\begin{aligned} s &= (1-x)s_f + xs_g \\ &= s_f + xs_{fg} \end{aligned} \quad (2.37d)$$

For the case of water, [Figure 2.6](#) illustrates the phase change from solid to liquid (melting):  $a$ - $b$ - $c$ ; from solid to vapor (sublimation):  $a'$ - $b'$ - $c'$ ; and from liquid to vapor (vaporization):  $a''$ - $b''$ - $c''$ . During any such phase change the temperature and pressure remain constant and thus are not independent properties. The *Clapeyron equation* allows the change in enthalpy during a phase change at fixed temperature to be evaluated from  $p$ - $v$ - $T$  data pertaining to the phase change. For vaporization, the Clapeyron equation reads

$$\left(\frac{dp}{dT}\right)_{sat} = \frac{h_g - h_f}{T(v_g - v_f)} \quad (2.38)$$

**FIGURE 2.6** Phase diagram for water (not to scale).

where  $(dp/dT)_{sat}$  is the slope of the saturation pressure-temperature curve at the point determined by the temperature held constant during the phase change. Expressions similar in form to Equation 2.38 can be written for sublimation and melting.

The Clapeyron equation shows that the slope of a saturation line on a phase diagram depends on the signs of the specific volume and enthalpy changes accompanying the phase change. In most cases, when a phase change takes place with an increase in specific enthalpy, the specific volume also increases, and  $(dp/dT)_{sat}$  is positive. However, in the case of the melting of ice and a few other substances, the specific volume decreases on melting. The slope of the saturated solid-liquid curve for these few substances is negative, as illustrated for water in Figure 2.6.

### Graphical Representations

The intensive states of a pure, simple compressible system can be represented graphically with any two independent intensive properties as the coordinates, excluding properties associated with motion and gravity. While any such pair may be used, there are several selections that are conventionally employed. These include the  $p$ - $T$  and  $p$ - $v$  diagrams of Figure 2.5, the  $T$ - $s$  diagram of Figure 2.7, the  $h$ - $s$  (Mollier) diagram of Figure 2.8, and the  $p$ - $h$  diagram of Figure 2.9. The compressibility charts considered next use the compressibility factor as one of the coordinates.

### Compressibility Charts

The  $p$ - $v$ - $T$  relation for a wide range of common gases is illustrated by the generalized compressibility chart of Figure 2.10. In this chart, the compressibility factor,  $Z$ , is plotted vs. the *reduced* pressure,  $p_R$ , *reduced* temperature,  $T_R$ , and *pseudoreduced* specific volume,  $v'_R$ , where

$$Z = \frac{p\bar{v}}{RT} \quad (2.39)$$

and

**FIGURE 2.7** Temperature-entropy diagram for water. (Source: Jones, J.B. and Dugan, R.E. 1996. *Engineering Thermodynamics*, Prentice-Hall, Englewood Cliffs, NJ, based on data and formulations from Haar, L., Gallagher, J.S., and Kell, G.S. 1984. *NBS/NRC Steam Tables*. Hemisphere, Washington, D.C.)

**FIGURE 2.8** Enthalpy-entropy (Mollier) diagram for water. (Source: Jones, J.B. and Dugan, R.E. 1996. *Engineering Thermodynamics*. Prentice-Hall, Englewood Cliffs, NJ, based on data and formulations from Haar, L., Gallagher, J.S., and Kell, G.S. 1984. *NBS/NRC Steam Tables*. Hemisphere, Washington, D.C.)

$$p_R = \frac{p}{p_c}, \quad T_R = \frac{T}{T_c}, \quad v'_R = \frac{\bar{v}}{(\bar{R}T_c/p_c)} \tag{2.40}$$

In these expressions,  $\bar{R}$  is the universal gas constant and  $p_c$  and  $T_c$  denote the critical pressure and temperature, respectively. Values of  $p_c$  and  $T_c$  are given for several substances in Table A.9. The reduced isotherms of Figure 2.10 represent the best curves fitted to the data of several gases. For the 30 gases used in developing the chart, the deviation of observed values from those of the chart is at most on the order of 5% and for most ranges is much less.\*

Figure 2.10 gives a common value of about 0.27 for the compressibility factor at the critical point. As the critical compressibility factor for different substances actually varies from 0.23 to 0.33, the chart is inaccurate in the vicinity of the critical point. This source of inaccuracy can be removed by restricting the correlation to substances having essentially the same  $Z_c$  values, which is equivalent to including the critical compressibility factor as an independent variable:  $Z = f(T_R, p_R, Z_c)$ . To achieve greater accuracy

\* To determine  $Z$  for hydrogen, helium, and neon above a  $T_R$  of 5, the reduced temperature and pressure should be calculated using  $T_R = T/(T_c + 8)$  and  $p_R = p/(p_c + 8)$ , where temperatures are in K and pressures are in atm.

**FIGURE 2.9** Pressure-enthalpy diagram for water. (Source: Jones, J.B. and Dugan, R.E. 1996. *Engineering Thermodynamics*. Prentice-Hall, Englewood Cliffs, NJ, based on data and formulations from Haar, L., Gallagher, J.S., and Kell, G.S. 1984. *NBS/NRC Steam Tables*. Hemisphere, Washington, D.C.)

**FIGURE 2.10** Generalized compressibility chart ( $T_R = T/T_C$ ,  $p_R = p/p_C$ ,  $v'_R = \bar{v}p_C/RT_C$ ) for  $p_R \leq 10$ . (Source: Obert, E.F. 1960 *Concepts of Thermodynamics*. McGraw-Hill, New York.)

variables other than  $Z_c$  have been proposed as a third parameter — for example, the *acentric factor* (see, e.g., Reid and Sherwood, 1966).

Generalized compressibility data are also available in tabular form (see, e.g., Reid and Sherwood, 1966) and in equation form (see, e.g., Reynolds, 1979). The use of generalized data in any form (graphical, tabular, or equation) allows  $p$ ,  $v$ , and  $T$  for gases to be evaluated simply and with reasonable accuracy. When accuracy is an essential consideration, generalized compressibility data should not be used as a substitute for  $p$ - $v$ - $T$  data for a given substance as provided by computer software, a table, or an equation of state.

### Equations of State

Considering the isotherms of Figure 2.10, it is plausible that the variation of the compressibility factor might be expressed as an equation, at least for certain intervals of  $p$  and  $T$ . Two expressions can be written that enjoy a theoretical basis. One gives the compressibility factor as an infinite series expansion in pressure,

$$Z = 1 + \hat{B}(T)p + \hat{C}(T)p^2 + \hat{D}(T)p^3 + \dots$$

and the other is a series in  $1/\bar{v}$ ,

$$Z = 1 + \frac{B(T)}{\bar{v}} + \frac{C(T)}{\bar{v}^2} + \frac{D(T)}{\bar{v}^3} + \dots$$

These expressions are known as *virial expansions*, and the coefficients  $\hat{B}$ ,  $\hat{C}$ ,  $\hat{D}$ , ... and  $B$ ,  $C$ ,  $D$  ... are called *virial coefficients*. In principle, the virial coefficients can be calculated using expressions from statistical mechanics derived from consideration of the force fields around the molecules. Thus far only the first few coefficients have been calculated and only for gases consisting of relatively simple molecules. The coefficients also can be found, in principle, by fitting  $p$ - $v$ - $T$  data in particular realms of interest. Only the first few coefficients can be found accurately this way, however, and the result is a *truncated* equation valid only at certain states.

Over 100 equations of state have been developed in an attempt to portray accurately the  $p$ - $v$ - $T$  behavior of substances and yet avoid the complexities inherent in a full virial series. In general, these equations exhibit little in the way of fundamental physical significance and are mainly empirical in character. Most are developed for gases, but some describe the  $p$ - $v$ - $T$  behavior of the liquid phase, at least qualitatively. Every equation of state is restricted to particular states. The realm of applicability is often indicated by giving an interval of pressure, or density, where the equation can be expected to represent the  $p$ - $v$ - $T$  behavior faithfully. When it is not stated, the realm of applicability often may be approximated by expressing the equation in terms of the compressibility factor  $Z$  and the reduced properties, and superimposing the result on a generalized compressibility chart or comparing with compressibility data from the literature.

Equations of state can be classified by the number of adjustable constants they involve. The Redlich-Kwong equation is considered by many to be the best of the two-constant equations of state. It gives pressure as a function of temperature and specific volume and thus is *explicit* in pressure:

$$p = \frac{\bar{R}T}{\bar{v} - b} - \frac{a}{\bar{v}(\bar{v} + b)T^{1/2}} \quad (2.41)$$

This equation is primarily empirical in nature, with no rigorous justification in terms of molecular arguments. Values for the Redlich-Kwong constants for several substances are provided in Table A.9. Modified forms of the equation have been proposed with the aim of achieving better accuracy.

Although the two-constant Redlich-Kwong equation performs better than some equations of state having several adjustable constants, two-constant equations tend to be limited in accuracy as pressure (or density) increases. Increased accuracy normally requires a greater number of adjustable constants. For example, the Benedict-Webb-Rubin equation, which involves eight adjustable constants, has been successful in predicting the  $p$ - $v$ - $T$  behavior of *light hydrocarbons*. The Benedict-Webb-Rubin equation is also explicit in pressure,

$$p = \frac{\bar{R}T}{\bar{v}} + \left( B\bar{R}T - A - \frac{C}{T^2} \right) \frac{1}{\bar{v}^2} + \frac{(b\bar{R}T - a)}{\bar{v}^3} + \frac{a\alpha}{\bar{v}^6} + \frac{c}{\bar{v}^3 T^2} \left( 1 + \frac{\gamma}{\bar{v}^2} \right) \exp\left( -\frac{\gamma}{\bar{v}^2} \right) \quad (2.42)$$

Values of the Benedict-Webb-Rubin constants for various gases are provided in the literature (see, e.g., Cooper and Goldfrank, 1967). A modification of the Benedict-Webb-Rubin equation involving 12 constants is discussed by Lee and Kessler, 1975. Many multiconstant equations can be found in the engineering literature, and with the advent of high speed computers, equations having 50 or more constants have been developed for representing the  $p$ - $v$ - $T$  behavior of different substances.

### Gas Mixtures

Since an unlimited variety of mixtures can be formed from a given set of pure components by varying the relative amounts present, the properties of mixtures are reported only in special cases such as air. Means are available for predicting the properties of mixtures, however. Most techniques for predicting mixture properties are empirical in character and are not derived from fundamental physical principles. The realm of validity of any particular technique can be established by comparing predicted property values with empirical data. In this section, methods for evaluating the  $p$ - $v$ - $T$  relations for pure components are adapted to obtain plausible estimates for gas mixtures. The case of ideal gas mixtures is discussed in Section 2.3, Ideal Gas Model. In Section 2.3, Multicomponent Systems, some general aspects of property evaluation for multicomponent systems are presented.

The total number of moles of mixture,  $n$ , is the sum of the number of moles of the components,  $n_i$ :

$$n = n_1 + n_2 + \dots + n_j = \sum_{i=1}^j n_i \quad (2.43)$$

The *relative* amounts of the components present can be described in terms of *mole fractions*. The mole fraction  $y_i$  of component  $i$  is  $y_i = n_i/n$ . The sum of the mole fractions of all components present is equal to unity. The apparent molecular weight  $\mathcal{M}$  is the mole fraction average of the component molecular weights, such that

$$\mathcal{M} = \sum_{i=1}^j y_i \mathcal{M}_i \quad (2.44)$$

The *relative* amounts of the components present also can be described in terms of *mass fractions*:  $m_i/m$ , where  $m_i$  is the mass of component  $i$  and  $m$  is the total mass of mixture.

The  $p$ - $v$ - $T$  relation for a gas mixture can be estimated by applying an equation of state to the overall mixture. The constants appearing in the equation of state are *mixture values* determined with empirical combining rules developed for the equation. For example, mixture values of the constants  $a$  and  $b$  for use in the Redlich-Kwong equation are obtained using relations of the form

$$a = \left( \sum_{i=1}^j y_i a_i^{1/2} \right)^2, \quad b = \sum_{i=1}^j y_i b_i \quad (2.45)$$

where  $a_i$  and  $b_i$  are the values of the constants for component  $i$ . Combination rules for obtaining mixture values for the constants in other equations of state are also found in the literature.

Another approach is to regard the mixture as if it were a single pure component having critical properties calculated by one of several mixture rules. *Kay's rule* is perhaps the simplest of these, requiring only the determination of a mole fraction averaged critical temperature  $T_c$  and critical pressure  $p_c$ :

$$T_c = \sum_{i=1}^j y_i T_{c,i}, \quad p_c = \sum_{i=1}^j y_i p_{c,i} \quad (2.46)$$

where  $T_{c,i}$  and  $p_{c,i}$  are the critical temperature and critical pressure of component  $i$ , respectively. Using  $T_c$  and  $p_c$ , the mixture compressibility factor  $Z$  is obtained as for a single pure component. The unknown quantity from among the pressure  $p$ , volume  $V$ , temperature  $T$ , and total number of moles  $n$  of the gas mixture can then be obtained by solving  $Z = pV/nRT$ .

Additional means for predicting the  $p$ - $v$ - $T$  relation of a mixture are provided by empirical mixture rules. Several are found in the engineering literature. According to the *additive pressure rule*, the pressure of a gas mixture is expressible as a sum of pressures exerted by the individual components:

$$p = p_1 + p_2 + p_3 \dots \Big]_{T,V} \quad (2.47a)$$

where the pressures  $p_1$ ,  $p_2$ , etc. are evaluated by considering the respective components to be at the volume  $V$  and temperature  $T$  of the mixture. The additive pressure rule can be expressed alternatively as

$$Z = \sum_{i=1}^j y_i Z_i \Big]_{T,V} \quad (2.47b)$$

where  $Z$  is the compressibility factor of the mixture and the compressibility factors  $Z_i$  are determined assuming that component  $i$  occupies the entire volume of the mixture at the temperature  $T$ .

The *additive volume rule* postulates that the volume  $V$  of a gas mixture is expressible as the sum of volumes occupied by the individual components:

$$V = V_1 + V_2 + V_3 \dots \Big]_{p,T} \quad (2.48a)$$

where the volumes  $V_1$ ,  $V_2$ , etc. are evaluated by considering the respective components to be at the pressure  $p$  and temperature  $T$  of the mixture. The additive volume rule can be expressed alternatively as

$$Z = \sum_{i=1}^j y_i Z_i \Big]_{p,T} \quad (2.48b)$$

where the compressibility factors  $Z_i$  are determined assuming that component  $i$  exists at the pressure  $p$  and temperature  $T$  of the mixture.

## Evaluating $\Delta h$ , $\Delta u$ , and $\Delta s$

Using appropriate specific heat and  $p$ - $v$ - $T$  data, the changes in specific enthalpy, internal energy, and entropy can be determined between states of single-phase regions. [Table 2.5](#) provides expressions for such property changes in terms of particular choices of the independent variables: temperature and pressure, and temperature and specific volume.

Taking Equation 1 of Table 2.5 as a representative case, the change in specific enthalpy between states 1 and 2 can be determined using the three steps shown in the accompanying property diagram. This requires knowledge of the variation of  $c_p$  with temperature at a fixed pressure  $p'$ , and the variation of  $[v - T(\partial v/\partial T)_p]$  with pressure at temperatures  $T_1$  and  $T_2$ :

1-a: Since temperature is constant at  $T_1$ , the first integral of Equation 1 in Table 2.5 vanishes, and

$$h_a - h_1 = \int_{p_1}^{p'} [v - T(\partial v/\partial T)_p] dp$$

a-b: Since pressure is constant at  $p'$ , the second integral of Equation 1 vanishes, and

$$h_b - h_a = \int_{T_1}^{T_2} c_p(T, p') dT$$

b-2: Since temperature is constant at  $T_2$ , the first integral of Equation 1 vanishes, and

$$h_2 - h_b = \int_{p'}^{p_2} [v - T(\partial v/\partial T)_p] dp$$

Adding these expressions, the result is  $h_2 - h_1$ . The required integrals may be performed numerically or analytically. The analytical approach is expedited when an equation of state explicit in specific volume is known.

Similar considerations apply to Equations 2 to 4 of Table 2.5. To evaluate  $u_2 - u_1$  with Equation 3, for example, requires the variation of  $c_v$  with temperature at a fixed specific volume  $v'$ , and the variation of  $[T(\partial p/\partial T)_v - p]$  with specific volume at temperatures  $T_1$  and  $T_2$ . An analytical approach to performing the integrals is expedited when an equation of state explicit in pressure is known.

As changes in specific enthalpy and internal energy are related through  $h = u + pv$  by

$$h_2 - h_1 = (u_2 - u_1) + (p_2 v_2 - p_1 v_1) \quad (2.49)$$

only one of  $h_2 - h_1$  and  $u_2 - u_1$  need be found by integration. The other can be evaluated from Equation 2.49. The one found by integration depends on the information available:  $h_2 - h_1$  would be found when an equation of state explicit in  $v$  and  $c_p$  as a function of temperature at some fixed pressure is known,  $u_2 - u_1$  would be found when an equation of state explicit in  $p$  and  $c_v$  as a function of temperature at some specific volume is known.

### Example 6

Obtain Equation 1 of Table 2.4 and Equations 3 and 4 of Table 2.5.

*Solution.* With Equation 2.33 and the Maxwell relation corresponding to  $\psi(T, v)$  from Table 2.2, Equations 3' and 4' of Table 2.5 become, respectively,

$$du = c_v dT + \left( \frac{\partial u}{\partial v} \right)_T dv$$

$$ds = \left( \frac{\partial s}{\partial T} \right)_v dT + \left( \frac{\partial p}{\partial T} \right)_v dv$$

Introducing these expressions for  $du$  and  $ds$  in Equation 2.32a, and collecting terms,

**TABLE 2.5  $\Delta h$ ,  $\Delta u$ ,  $\Delta s$  Expressions**

Independent properties:

temperature and pressure

Preferred data:

$v(T, p)$ ,  $c_p(T, p)$

Property diagram:

Property expressions:

$h(T, p)$ :

$$dh = \left(\frac{\partial h}{\partial T}\right)_p dT + \left(\frac{\partial h}{\partial p}\right)_T dp \quad (1')$$

$$\underbrace{\hspace{1.5cm}}_{c_p} \quad \underbrace{\hspace{1.5cm}}_{\left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right]}$$

$$\Delta h = \int c_p dT + \int \left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right] dp \quad (1)$$

$s(T, p)$ :

$$ds = \left(\frac{\partial s}{\partial T}\right)_p dT + \left(\frac{\partial s}{\partial p}\right)_T dp \quad (2')$$

$$\underbrace{\hspace{1.5cm}}_{\frac{c_p}{T}} \quad \underbrace{\hspace{1.5cm}}_{-\left(\frac{\partial v}{\partial T}\right)_p}$$

$$\Delta s = \int \frac{c_p}{T} dT - \int \left(\frac{\partial v}{\partial T}\right)_p dp \quad (2)$$

temperature and specific volume

$p(T, v)$ ,  $c_v(T, v)$

$u(T, v)$ :

$$du = \left(\frac{\partial u}{\partial T}\right)_v dT + \left(\frac{\partial u}{\partial v}\right)_T dv \quad (3')$$

$$\underbrace{\hspace{1.5cm}}_{c_v} \quad \underbrace{\hspace{1.5cm}}_{\left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]}$$

$$\Delta u = \int c_v dT + \int \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right] dv \quad (3)$$

$s(T, v)$ :

$$ds = \left(\frac{\partial s}{\partial T}\right)_v dT + \left(\frac{\partial s}{\partial v}\right)_T dv \quad (4')$$

$$\underbrace{\hspace{1.5cm}}_{\frac{c_v}{T}} \quad \underbrace{\hspace{1.5cm}}_{\left(\frac{\partial p}{\partial T}\right)_v}$$

$$\Delta s = \int \frac{c_v}{T} dT + \int \left(\frac{\partial p}{\partial T}\right)_v dv \quad (4)$$

$$\left[ T \left( \frac{\partial s}{\partial T} \right)_v - c_v \right] dT = \left[ \left( \frac{\partial u}{\partial v} \right)_T + p - T \left( \frac{\partial p}{\partial T} \right)_v \right] dv$$

Since  $T$  and  $v$  are independent, the coefficients of  $dT$  and  $dv$  must vanish, giving, respectively,

$$\left( \frac{\partial s}{\partial T} \right)_v = \frac{c_v}{T}$$

$$\left( \frac{\partial u}{\partial v} \right)_T = T \left( \frac{\partial p}{\partial T} \right)_v - p$$

The first of these corresponds to Equation 1 of Table 2.4 and Equation 4 of Table 2.5. The second of the above expressions establishes Equation 3 of Table 2.5. With similar considerations, Equation 3 of Table 2.4 and Equations 1 and 2 of Table 2.5 may be obtained.

## Fundamental Thermodynamic Functions

A fundamental thermodynamic function is one that provides a complete description of the thermodynamic state. The functions  $u(s, v)$ ,  $h(s, p)$ ,  $\psi(T, v)$ , and  $g(T, p)$  listed in Table 2.2 are fundamental thermodynamic functions.

In principle, all properties of interest can be determined from a fundamental thermodynamic function by differentiation and combination. Taking the function  $\psi(T, v)$  as a representative case, the properties  $v$  and  $T$ , being the independent variables, are specified to fix the state. The pressure  $p$  and specific entropy  $s$  at this state can be determined by differentiation of  $\psi(T, v)$ , as shown in Table 2.2. By definition,  $\psi = u - Ts$ , so specific internal energy is obtained as

$$u = \psi + Ts$$

with  $u$ ,  $p$ , and  $v$  known, the specific enthalpy can be found from the definition  $h = u + pv$ . Similarly, the specific Gibbs function is found from the definition  $g = h - Ts$ . The specific heat  $c_v$  can be determined by further differentiation  $c_v = (\partial u / \partial T)_v$ .

The development of a fundamental function requires the selection of a functional form in terms of the appropriate pair of independent properties and a set of adjustable coefficients that may number 50 or more. The functional form is specified on the basis of both theoretical and practical considerations. The coefficients of the fundamental function are determined by requiring that a set of selected property values and/or observed conditions be satisfied in a least-squares sense. This generally involves property data requiring the assumed functional form to be differentiated one or more times, for example  $p$ - $v$ - $T$  and specific heat data. When all coefficients have been evaluated, the function is tested for accuracy by using it to evaluate properties for which accepted values are known such as *velocity of sound* and *Joule-Thomson* data. Once a suitable fundamental function is established, extreme accuracy in and consistency among the thermodynamic properties are possible. The properties of water tabulated by Keenan et al. (1969) and by Haar et al. (1984) have been calculated from representations of the Helmholtz function.

## Thermodynamic Data Retrieval

Tabular presentations of pressure, specific volume, and temperature are available for practically important gases and liquids. The tables normally include other properties useful for thermodynamic analyses, such as internal energy, enthalpy, and entropy. The various *steam tables* included in the references of this chapter provide examples. Computer software for retrieving the properties of a wide range of substances is also available, as, for example, the ASME Steam Tables (1993) and Bornakke and Sonntag (1996).

Increasingly, textbooks come with computer disks providing thermodynamic property data for water, certain refrigerants, and several gases modeled as ideal gases — see, e.g., Moran and Shapiro (1996).

The sample *steam table* data presented in Table 2.6 are representative of data available for substances commonly encountered in mechanical engineering practice. Table A.5 and Figures 2.7 to 2.9 provide *steam table* data for a greater range of states. The form of the tables and figures, and how they are used are assumed to be familiar. In particular, the use of *linear interpolation* with such tables is assumed known.

Specific internal energy, enthalpy, and entropy data are determined relative to arbitrary datums and such datums vary from substance to substance. Referring to Table 2.6a, the datum state for the specific internal energy and specific entropy of water is seen to correspond to saturated liquid water at 0.01°C (32.02°F), the triple point temperature. The value of each of these properties is set to zero at this state. If calculations are performed involving only differences in a particular specific property, the datum cancels. When there are changes in chemical composition during the process, special care should be exercised. The approach followed when composition changes due to chemical reaction is considered in Section 2.4.

Liquid water data (see Table 2.6d) suggests that at fixed temperature the variation of specific volume, internal energy, and entropy with pressure is slight. The variation of specific enthalpy with pressure at fixed temperature is somewhat greater because pressure is explicit in the definition of enthalpy. This behavior for  $v$ ,  $u$ ,  $s$ , and  $h$  is exhibited generally by liquid data and provides the basis for the following set of equations for estimating property data at liquid states from saturated liquid data:

$$v(T, p) \approx v_f(T) \quad (2.50a)$$

$$u(T, p) \approx u_f(T) \quad (2.50b)$$

$$h(T, p) \approx h_f(T) + v_f [p - p_{sat}(T)] \quad (2.50c)$$

-----

$$s(T, p) \approx s_f(T) \quad (2.50d)$$

As before, the subscript  $f$  denotes the saturated liquid state at the temperature  $T$ , and  $p_{sat}$  is the corresponding saturation pressure. The underlined term of Equation 2.50c is often negligible, giving  $h(T, p) \approx h_f(T)$ , which is used in Example 3 to evaluate  $h_1$ .

In the absence of saturated liquid data, or as an alternative to such data, the *incompressible model* can be employed:

$$\text{Incompressible model: } \begin{cases} v = \text{constant} \\ u = u(T) \end{cases} \quad (2.51)$$

This model is also applicable to solids. Since internal energy varies only with temperature, the specific heat  $c_v$  is also a function of only temperature:  $c_v(T) = du/dT$ . Although specific volume is constant, enthalpy varies with both temperature and pressure, such that

$$h(T, p) = u(T) + pv \quad (2.52)$$

Differentiation of Equation 2.52 with respect to temperature at fixed pressure gives  $c_p = c_v$ . The common specific heat is often shown simply as  $c$ . Specific heat and density data for several liquids and solids are

Source: Moran, M.J. and Shapiro, H.N. 1995. *Fundamentals of Engineering Thermodynamics*, 3rd ed. Wiley, New York, as extracted from Keenan, J. H., Keyes, F.G., Hill, P.G., and Moore, J.G. 1969. *Steam Tables*. Wiley, New York.

provided in Tables B.2, C.1, and C.2. As the variation of  $c$  with temperature is slight,  $c$  is frequently taken as constant.

When the incompressible model is applied. Equation 2.49 takes the form

$$\begin{aligned} h_2 - h_1 &= \int_{T_1}^{T_2} c(T) dT + v(p_2 - p_1) \\ &= c_{ave}(T_2 - T_1) + v(p_2 - p_1) \end{aligned} \quad (2.53)$$

Also, as Equation 2.32a reduces to  $du = Tds$ , and  $du = c(T)dT$ , the change in specific entropy is

$$\begin{aligned} \Delta s &= \int_{T_1}^{T_2} \frac{c(T)}{T} dT \\ &= c_{ave} \ln \frac{T_2}{T_1} \end{aligned} \quad (2.54)$$

## Ideal Gas Model

Inspection of the generalized compressibility chart, [Figure 2.10](#), shows that when  $p_R$  is small, and for many states when  $T_R$  is large, the value of the compressibility factor  $Z$  is close to 1. In other words, for pressures that are low relative to  $p_c$ , and for many states with temperatures high relative to  $T_c$ , the compressibility factor approaches a value of 1. Within the indicated limits, it may be assumed with reasonable accuracy that  $Z = 1$  — that is,

$$p\bar{v} = \bar{R}T \quad \text{or} \quad pv = RT \quad (2.55a)$$

where  $R = \bar{R}/M$  is the *specific* gas constant. Other forms of this expression in common use are

$$pV = n\bar{R}T, \quad pV = mRT \quad (2.55b)$$

Referring to Equation 3' of [Table 2.5](#), it can be concluded that  $(\partial u/\partial v)_T$  vanishes identically for a gas whose equation of state is *exactly* given by Equation 2.55, and thus the specific internal energy depends only on temperature. This conclusion is supported by experimental observations beginning with the work of Joule, who showed that the internal energy of air at low density depends primarily on temperature.

These considerations allow for an *ideal gas model* of each real gas: (1) the equation of state is given by Equation 2.55 and (2) the internal energy and enthalpy are functions of temperature alone. The real gas approaches the model in the limit of low reduced pressure. At other states the actual behavior may depart substantially from the predictions of the model. Accordingly, caution should be exercised when invoking the ideal gas model lest significant error is introduced.

Specific heat data for gases can be obtained by direct measurement. When extrapolated to zero pressure, ideal gas-specific heats result. Ideal gas-specific heats also can be calculated using molecular models of matter together with data from spectroscopic measurements. Table A.9 provides ideal gas-specific heat data for a number of substances. The following ideal gas-specific heat relations are frequently useful:

$$c_p(T) = c_v(T) + R \quad (2.56a)$$

$$c_p = \frac{kR}{k-1}, \quad c_v = \frac{R}{k-1} \quad (2.56b)$$

where  $k = c_p/c_v$ .

With the ideal gas model, Equations 1 to 4 of Table 2.5 give Equations 1 to 4 of Table 2.7, respectively. Equation 2 of Table 2.7 can be expressed alternatively using  $s^\circ(T)$  defined by

$$s^\circ(T) \equiv \int_0^T \frac{c_p(T)}{T} dT \tag{2.57}$$

as

$$s(T_2, p_2) - s(T_1, p_1) = s^\circ(T_2) - s^\circ(T_1) - R \ln \frac{p_2}{p_1} \tag{2.58}$$

Expressions similar in form to Equations 2.56 to 2.68 can be written on a molar basis.

**TABLE 2.7 Ideal Gas Expressions for  $\Delta h$ ,  $\Delta u$ , and  $\Delta s$**

Variable Specific Heats	Constant Specific Heats
$h(T_2) - h(T_1) = \int_{T_1}^{T_2} c_p(T) dT$ (1)	$h(T_2) - h(T_1) = c_p(T_2 - T_1)$ (1')
$s(T_2, p_2) - s(T_1, p_1) = \int_{T_1}^{T_2} \frac{c_p(T)}{T} dT - R \ln \frac{p_2}{p_1}$ (2)	$s(T_2, p_2) - s(T_1, p_1) = c_p \ln \frac{T_2}{T_1} - R \ln \frac{p_2}{p_1}$ (2')
$u(T_2) - u(T_1) = \int_{T_1}^{T_2} c_v(T) dT$ (3)	$u(T_2) - u(T_1) = c_v(T_2 - T_1)$ (3')
$s(T_2, v_2) - s(T_1, v_1) = \int_{T_1}^{T_2} \frac{c_v(T)}{T} dT + R \ln \frac{v_2}{v_1}$ (4)	$s(T_2, v_2) - s(T_1, v_1) = c_v \ln \frac{T_2}{T_1} + R \ln \frac{v_2}{v_1}$ (4')
$s_2 = s_1$	$s_2 = s_1$
$\frac{p_r(T_2)}{p_r(T_1)} = \frac{p_2}{p_1}$ (5)	$\frac{T_2}{T_1} = \left(\frac{p_2}{p_1}\right)^{(k-1)/k}$ (5')
$\frac{v_r(T_2)}{v_r(T_1)} = \frac{v_2}{v_1}$ (6)	$\frac{T_2}{T_1} = \left(\frac{v_1}{v_2}\right)^{k-1}$ (6')

For processes of an ideal gas between states having the same specific entropy,  $s_2 = s_1$ , Equation 2.58 gives

$$\frac{p_2}{p_1} = \frac{\exp[s^\circ(T_2)/R]}{\exp[s^\circ(T_1)/R]}$$

or with  $p_r = \exp[s^\circ(T)/R]$

$$\frac{p_2}{p_1} = \frac{p_r(T_2)}{p_r(T_1)} \quad (s_2 = s_1) \tag{2.59a}$$

A relation between the specific volume and temperatures for two states of an ideal gas having the same specific entropy can also be developed:

$$\frac{v_2}{v_1} = \frac{v_r(T_2)}{v_r(T_1)} \quad (s_2 = s_1) \tag{2.59b}$$

Equations 2.59 are listed in Table 2.7 as Equations 5 and 6, respectively.

Table A.8 provides a tabular display of  $h$ ,  $u$ ,  $s^\circ$ ,  $p_r$ , and  $v_r$  vs. temperature for air as an ideal gas. Tabulations of  $\bar{h}$ ,  $\bar{u}$ , and  $\bar{s}^\circ$  for several other common gases are provided in Table A.2. Property retrieval software also provides such data; see, e.g., Moran and Shapiro (1996). The use of data from Table A.8 for the nozzle of Example 2 is illustrated in Example 7.

When the ideal gas-specific heats are assumed constant, Equations 1 to 6 of Table 2.7 become Equations 1' to 6', respectively. The specific heat  $c_p$  is taken as constant in Example 2.

### Example 7

Using data from Table A.8, evaluate the exit velocity for the nozzle of Example 2 and compare with the exit velocity for an isentropic expansion to 15 lbf/in.<sup>2</sup>.

*Solution.* The exit velocity is given by Equation 2.27f

$$v_e = \sqrt{v_i^2 + 2(h_i - h_e)}$$

At 960 and 520°R, Table A.8 gives, respectively,  $h_i = 231.06$  Btu/lb and  $h_e = 124.27$  Btu/lb. Then

$$\begin{aligned} v_e &= \sqrt{\left(\frac{10 \text{ ft}}{\text{s}}\right)^2 + 2(231.06 - 124.27) \left(\frac{\text{Btu}}{\text{lb}}\right) \left(\frac{778.17 \text{ ft} \cdot \text{lbf}}{1 \text{ Btu}}\right) \left(\frac{32.174 \text{ lb} \cdot \text{ft}/\text{sec}^2}{1 \text{ lbf}}\right)} \\ &= 2312.5 \text{ ft/sec} \end{aligned}$$

Using Equation 2.59a and  $p_r$  data from Table A.8, the specific enthalpy at the exit for an isentropic expansion is found as follows:

$$p_r(T_e) = p_r(T_i) \frac{p_e}{p_i} = 10.61 \left(\frac{15}{150}\right) = 1.061$$

Interpolating with  $p_r$  data,  $h_e = 119.54$  Btu/lb. With this, the exit velocity is 2363.1 ft/sec. The actual exit velocity is about 2% less than the velocity for an isentropic expansion, the maximum theoretical value. In this particular application, there is good agreement in each case between velocities calculated using Table A.8 data and, as in Example 2, assuming  $c_p$  constant. Such agreement cannot be expected generally, however. See, for example, the Brayton cycle data of Table 2.15.

### Polytropic Processes

An internally reversible process described by the expression  $pv^n = \text{constant}$  is called a *polytropic process* and  $n$  is the *polytropic exponent*. Although this expression can be applied with real gas data, it most generally appears in practice together with the use of the ideal gas model. Table 2.8 provides several expressions applicable to polytropic processes and the special forms they take when the ideal gas model is assumed. The expressions for  $\int p dv$  and  $\int v dp$  have application to work evaluations with Equations 2.10 and 2.30, respectively. In some applications it may be appropriate to determine  $n$  by fitting pressure-specific volume data.

Example 8 illustrates both the polytropic process and the reduction in the compressor work achievable by cooling a gas as it is compressed.

### Example 8

A compressor operates at steady state with air entering at 1 bar, 20°C and exiting at 5 bar. (a) If the air undergoes a polytropic process with  $n = 1.3$ , determine the work and heat transfer, each in kJ/kg of air flowing. Repeat for (b) an isothermal compression and (c) an isentropic compression.

**TABLE 2.8 Polytropic Processes:  $pv^n = \text{Constant}^a$**

General	Ideal Gas <sup>b</sup>
$\frac{p_2}{p_1} = \left(\frac{v_1}{v_2}\right)^n \quad (1)$	$\frac{p_2}{p_1} = \left(\frac{v_1}{v_2}\right)^n = \left(\frac{T_2}{T_1}\right)^{n/(n-1)} \quad (1')$
$n = 0$ : constant pressure $n = \pm\infty$ : constant specific volume	$n = 0$ : constant pressure $n = \pm\infty$ : constant specific volume $n = 1$ : constant temperature $n = k$ : constant specific entropy when $k$ is constant
$n = 1$	$n = 1$
$\int_1^2 pdv = p_1 v_1 \ln \frac{v_2}{v_1} \quad (2)$	$\int_1^2 pdv = RT \ln \frac{v_2}{v_1} \quad (2')$
$-\int_1^2 vdp = -p_1 v_1 \ln \frac{p_2}{p_1} \quad (3)$	$-\int_1^2 vdp = -RT \ln \frac{p_2}{p_1} \quad (3')$
$n \neq 1$	$n \neq 1$
$\int_1^2 pdv = \frac{p_2 v_2 - p_1 v_1}{1-n} \quad (4)$ $= \frac{p_1 v_1}{n-1} \left[ 1 - \left(\frac{p_2}{p_1}\right)^{(n-1)/n} \right]$	$\int_1^2 pdv = \frac{R(T_2 - T_1)}{1-n} \quad (4')$ $= \frac{RT_1}{n-1} \left[ 1 - \left(\frac{p_2}{p_1}\right)^{(n-1)/n} \right]$
$-\int_1^2 vdp = \frac{n}{1-n} (p_2 v_2 - p_1 v_1) \quad (5)$ $= \frac{np_1 v_1}{n-1} \left[ 1 - \left(\frac{p_2}{p_1}\right)^{(n-1)/n} \right]$	$-\int_1^2 vdp = \frac{nR}{1-n} (T_2 - T_1) \quad (5')$ $= \frac{nRT_1}{n-1} \left[ 1 - \left(\frac{p_2}{p_1}\right)^{(n-1)/n} \right]$

<sup>a</sup> For polytropic processes of closed systems where volume change is the only work mode, Equations 2, 4, and 2', 4' are applicable with Equation 2.10 to evaluate the work. When each unit of mass passing through a one-inlet, one-exit control volume at steady state undergoes a polytropic process, Equations 3, 5, and 3', 5' are applicable with Equations 2.30a and 2.30b to evaluate the power. Also note that generally,  $-\int_1^2 vdp = n \int_1^2 pdv$ .

*Solution.* Using Equation 5' of Table 2.8 together with Equation 2.30b,

$$\begin{aligned} \frac{\dot{W}_{cv}}{\dot{m}} &= \frac{nRT_1}{n-1} \left[ 1 - \left( \frac{p_2}{p_1} \right)^{(n-1)/n} \right] \\ &= \left( \frac{1.3}{0.3} \right) \left( \frac{8.314 \text{ kJ}}{28.97 \text{ kg} \cdot \text{K}} \right) (293 \text{ K}) \left[ 1 - (5)^{0.3/1.3} \right] \\ &= -163.9 \frac{\text{kJ}}{\text{kg}} \end{aligned}$$

(The area behind process 1-2 of Figure 2.11, area 1-2-a-b, represents the magnitude of the work required, per unit mass of air flowing.) Also, Equation 1' of Table 2.8 gives  $T_2 = 425 \text{ K}$ .

**FIGURE 2.11** Internally reversible compression processes.

An energy rate balance at steady state and enthalpy data from Table A.8 gives

$$\begin{aligned} \frac{\dot{Q}_{cv}}{\dot{m}} &= \frac{\dot{W}_{cv}}{\dot{m}} + h_2 - h_1 \\ &= -163.9 + (426.3 - 293.2) = -30.8 \frac{\text{kJ}}{\text{kg}} \end{aligned}$$

(b) Using Equation 3' of Table 2.8 together with Equation 2.30b,

$$\begin{aligned}\frac{\dot{W}_{cv}}{\dot{m}} &= -RT \ln \frac{p_2}{p_1} \\ &= -\left(\frac{8.314}{28.97}\right)(293) \ln 5 \\ &= -135.3 \frac{\text{kJ}}{\text{kg}}\end{aligned}$$

Area 1-2'-*a-b* on Figure 2.11 represents the magnitude of the work required, per unit of mass of air flowing. An energy balance reduces to give  $\dot{Q}_{cv}/\dot{m} = \dot{W}_{cv}/\dot{m} = -135.3$  kJ/kg. (c) For an isentropic compression,  $\dot{Q}_{cv} = 0$  and an energy rate balance reduces to give  $\dot{W}_{cv}/\dot{m} = -(h_{2s} - h_1)$ , where 2s denotes the exit state. With Equation 2.59a and  $p_r$  data,  $h_{2s} = 464.8$  kJ/kg ( $T_{2s} = 463$ K). Then  $\dot{W}_{cv}/\dot{m} = -(464.8 - 293.2) = -171.6$  kJ/kg. Area 1-2s-*a-b* on Figure 2.11 represents the magnitude of the work required, per unit of mass of air flowing.

### Ideal Gas Mixtures

When applied to an ideal gas mixture, the additive pressure rule (Section 2.3, *p-v-T* Relations) is known as the *Dalton model*. According to this model, each gas in the mixture acts as if it exists separately at the volume and temperature of the mixture. Applying the ideal gas equation of state to the mixture as a whole and to each component *i*,  $pV = n\bar{R}T$ ,  $p_iV = n_i\bar{R}T$ , where  $p_i$ , the *partial pressure* of component *i*, is the pressure that component *i* would exert if  $n_i$  moles occupied the full volume *V* at the temperature *T*. Forming a ratio, the partial pressure of component *i* is

$$p_i = \frac{n_i}{n} p = y_i p \quad (2.60)$$

where  $y_i$  is the mole fraction of component *i*. The sum of the partial pressures equals the mixture pressure.

The internal energy, enthalpy, and entropy of the mixture can be determined as the sum of the respective properties of the component gases, provided that the contribution from each gas is evaluated at the condition at which the gas exists in the mixture. On a *molar* basis,

$$U = \sum_{i=1}^j n_i \bar{u}_i \quad \text{or} \quad \bar{u} = \sum_{i=1}^j y_i \bar{u}_i \quad (2.61a)$$

$$H = \sum_{i=1}^j n_i \bar{h}_i \quad \text{or} \quad \bar{h} = \sum_{i=1}^j y_i \bar{h}_i \quad (2.61b)$$

$$S = \sum_{i=1}^j n_i \bar{s}_i \quad \text{or} \quad \bar{s} = \sum_{i=1}^j y_i \bar{s}_i \quad (2.61c)$$

The specific heats  $\bar{c}_v$  and  $\bar{c}_p$  for an ideal gas mixture in terms of the corresponding specific heats of the components are expressed similarly:

$$\bar{c}_v = \sum_{i=1}^j y_i \bar{c}_{v_i} \quad (2.61d)$$

$$\bar{c}_p = \sum_{i=1}^j y_i \bar{c}_{pi} \quad (2.61e)$$

When working on a *mass* basis, expressions similar in form to Equations 2.61 can be written using *mass* and *mass fractions* in place of *moles* and *mole fractions*, respectively, and using  $u$ ,  $h$ ,  $s$ ,  $c_p$ , and  $c_v$  in place of  $\bar{u}$ ,  $\bar{h}$ ,  $\bar{s}$ ,  $\bar{c}_p$ , and  $\bar{c}_v$ , respectively.

The internal energy and enthalpy of an ideal gas depend only on temperature, and thus the  $\bar{u}_i$  and  $\bar{h}_i$  terms appearing in Equations 2.61 are evaluated at the temperature of the mixture. Since entropy depends on *two* independent properties, the  $\bar{s}_i$  terms are evaluated either at the temperature and the partial pressure  $p_i$  of component  $i$ , or at the temperature and volume of the mixture. In the former case

$$\begin{aligned} S &= \sum_{i=1}^j n_i \bar{s}_i(T, p_i) \\ &= \sum_{i=1}^j n_i \bar{s}_i(T, x_i p) \end{aligned} \quad (2.62)$$

Inserting the expressions for  $H$  and  $S$  given by Equations 2.61b and 2.61c into the Gibbs function,  $G = H - TS$ ,

$$\begin{aligned} G &= \sum_{i=1}^j n_i \bar{h}_i(T) - T \sum_{i=1}^j n_i \bar{s}_i(T, p_i) \\ &= \sum_{i=1}^j n_i \bar{g}_i(T, p_i) \end{aligned} \quad (2.63)$$

where the molar-specific Gibbs function of component  $i$  is  $g_i(T, p_i) = h_i(T) - Ts_i(T, p_i)$ . The Gibbs function of  $i$  can be expressed alternatively as

$$\begin{aligned} \bar{g}_i(T, p_i) &= \bar{g}_i(T, p') + \bar{R}T \ln(p_i/p') \\ &= \bar{g}_i(T, p') + \bar{R}T \ln(x_i p/p') \end{aligned} \quad (2.64)$$

where  $p'$  is some specified pressure. Equation 2.64 is obtained by integrating Equation 2.32d at fixed temperature  $T$  from pressure  $p'$  to  $p_i$ .

### Moist Air

An ideal gas mixture of particular interest for many practical applications is *moist air*. Moist air refers to a mixture of dry air and water vapor in which the dry air is treated as if it were a pure component. Ideal gas mixture principles usually apply to moist air. In particular, the *Dalton model* is applicable, and so the mixture pressure  $p$  is the sum of the partial pressures  $p_a$  and  $p_v$  of the dry air and water vapor, respectively.

*Saturated air* is a mixture of dry air and saturated water vapor. For saturated air, the partial pressure of the water vapor equals  $p_{sat}(T)$ , which is the saturation pressure of water corresponding to the dry-bulb (mixture) temperature  $T$ . The makeup of moist air can be described in terms of the *humidity ratio* (*specific humidity*) and the *relative humidity*. The bulb of a *wet-bulb thermometer* is covered with a wick saturated with liquid water, and the *wet-bulb* temperature of an air-water vapor mixture is the temperature indicated by such a thermometer exposed to the mixture.

When a sample of moist air is cooled at constant pressure, the temperature at which the sample becomes saturated is called the *dew point temperature*. Cooling below the dew point temperature results in the condensation of some of the water vapor initially present. When cooled to a final equilibrium state at a temperature below the dew point temperature, the original sample would consist of a gas phase of dry air and saturated water vapor in equilibrium with a liquid water phase.

*Psychrometric charts* are plotted with various moist air parameters, including the dry-bulb and wet-bulb temperatures, the humidity ratio, and the relative humidity, usually for a specified value of the mixture pressure such as 1 atm. Further discussion of moist air and related psychrometric principles and applications is provided in Chapter 9.

## Generalized Charts for Enthalpy, Entropy, and Fugacity

The changes in enthalpy and entropy between two states can be determined in principle by correcting the respective property change determined using the ideal gas model. The corrections can be obtained, at least approximately, by inspection of the generalized enthalpy correction and entropy correction charts, [Figures 2.12](#) and [2.13](#), respectively. Such data are also available in tabular form (see, e.g., Reid and Sherwood, 1966) and calculable using a generalized equation for the compressibility factor (Reynolds, 1979). Using the superscript \* to identify ideal gas property values, the changes in specific enthalpy and specific entropy between states 1 and 2 are

$$\bar{h}_2 - \bar{h}_1 = \underline{\bar{h}_2^* - \bar{h}_1^*} - \bar{R}T_c \left[ \left( \frac{\bar{h}^* - \bar{h}}{\bar{R}T_c} \right)_2 - \left( \frac{\bar{h}^* - \bar{h}}{\bar{R}T_c} \right)_1 \right] \quad (2.65a)$$

$$\bar{s}_2 - \bar{s}_1 = \underline{\bar{s}_2^* - \bar{s}_1^*} - \bar{R} \left[ \left( \frac{\bar{s}^* - \bar{s}}{\bar{R}} \right)_2 - \left( \frac{\bar{s}^* - \bar{s}}{\bar{R}} \right)_1 \right] \quad (2.65b)$$

The first underlined term on the right side of each expression represents the respective property change assuming ideal gas behavior. The second underlined term is the correction that must be applied to the ideal gas value to obtain the actual value. The quantities  $(\bar{h}^* - \bar{h})/\bar{R}T_c$  and  $(\bar{s}^* - \bar{s})/\bar{R}$  at state 1 would be read from the respective correction chart or table or calculated, using the reduced temperature  $T_{R1}$  and reduced pressure  $p_{R1}$  corresponding to the temperature  $T_1$  and pressure  $p_1$  at state 1, respectively. Similarly,  $(\bar{h}^* - \bar{h})/\bar{R}T_c$  and  $(\bar{s}^* - \bar{s})/\bar{R}$  at state 2 would be obtained using  $T_{R2}$  and  $p_{R2}$ . Mixture values for  $T_c$  and  $p_c$  determined by applying Kay's rule or some other mixture rule also can be used to enter the generalized enthalpy correction and entropy correction charts.

[Figure 2.14](#) gives the *fugacity coefficient*,  $f/p$ , as a function of reduced pressure and reduced temperature. The fugacity  $f$  plays a similar role in determining the specific Gibbs function for a real gas as pressure plays for the ideal gas. To develop this, consider the variation of the specific Gibbs function with pressure at fixed temperature (from [Table 2.2](#))

$$\left( \frac{\partial g}{\partial p} \right)_T = v$$

For an ideal gas, integration at fixed temperature gives

$$g^* = RT \ln p + C(T)$$

where  $C(T)$  is a function of integration. To evaluate  $g$  for a real gas, fugacity replaces pressure,

**FIGURE 2.12** Generalized enthalpy correction chart. (Source: Adapted from Van Wylen, G. J. and Sonntag, R. E. 1986. *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI. Wiley, New York.)

$$g = RT \ln f + C(T)$$

In terms of the fugacity coefficient the departure of the real gas value from the ideal gas value at fixed temperature is then

**FIGURE 2.13** Generalized entropy correction chart. (Source: Adapted from Van Wylen, G. J. and Sonntag, R. E. 1986. *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI. Wiley, New York.)

$$g - g^* = RT \ln \frac{f}{p} \tag{2.66}$$

As pressure is reduced at fixed temperature,  $f/p$  tends to unity, and the specific Gibbs function is given by the ideal gas value.

**FIGURE 2.14** Generalized fugacity coefficient chart. (Source: Van Wylen, G. J. and Sonntag, R. E. 1986. *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI. Wiley, New York.)

## Multicomponent Systems

In this section are presented some general aspects of the properties of multicomponent systems consisting of nonreacting mixtures. For a single phase *multicomponent* system consisting of  $j$  components, an extensive property  $X$  may be regarded as a function of temperature, pressure, and the number of moles of each component present in the mixture:  $X = X(T, p, n_1, n_2, \dots, n_j)$ . Since  $X$  is mathematically *homogeneous of degree one* in the  $n$ 's, the function is expressible as

$$X = \sum_{i=1}^j n_i \bar{X}_i \quad (2.67)$$

where the *partial molar property*  $\bar{X}_i$  is by definition

$$\bar{X}_i = \left. \frac{\partial X}{\partial n_i} \right)_{T,p,n_\ell} \quad (2.68)$$

and the subscript  $n_\ell$  denotes that all  $n$ 's except  $n_i$  are held fixed during differentiation. As  $\bar{X}_i$  depends in general on temperature, pressure, and mixture composition:  $\bar{X}_i(T, p, n_1, n_2, \dots, n_j)$ , the partial molar property  $\bar{X}_i$  is an intensive property of the mixture and not simply a property of the  $i$ th component.

Selecting the extensive property  $X$  to be volume, internal energy, enthalpy, entropy, and the Gibbs function, respectively, gives

$$\begin{aligned} V &= \sum_{i=1}^j n_i \bar{V}_i, & U &= \sum_{i=1}^j n_i \bar{U}_i \\ H &= \sum_{i=1}^j n_i \bar{H}_i, & S &= \sum_{i=1}^j n_i \bar{S}_i \\ G &= \sum_{i=1}^j n_i \bar{G}_i \end{aligned} \quad (2.69)$$

where  $\bar{V}_i, \bar{U}_i, \bar{H}_i, \bar{S}_i,$  and  $\bar{G}_i$  denote the respective partial molar properties.

When pure components, each initially at the same temperature and pressure, are mixed, the changes in volume, internal energy, enthalpy, and entropy on mixing are given by

$$\Delta V_{\text{mixing}} = \sum_{i=1}^j n_i (\bar{V}_i - \bar{v}_i) \quad (2.70a)$$

$$\Delta U_{\text{mixing}} = \sum_{i=1}^j n_i (\bar{U}_i - \bar{u}_i) \quad (2.70b)$$

$$\Delta H_{\text{mixing}} = \sum_{i=1}^j n_i (\bar{H}_i - \bar{h}_i) \quad (2.70c)$$

$$\Delta S_{\text{mixing}} = \sum_{i=1}^j n_i (\bar{S}_i - \bar{s}_i) \quad (2.70d)$$

where  $\bar{v}_i, \bar{u}_i, \bar{h}_i,$  and  $\bar{s}_i$  denote the molar-specific volume, internal energy, enthalpy, and entropy of pure component  $i$ .

### Chemical Potential

The partial molar Gibbs function of the  $i$ th component of a multicomponent system is the *chemical potential*,  $\mu_i$ ,

$$\mu_i = \bar{G}_i = \left. \frac{\partial G}{\partial n_i} \right)_{T,p,n_t} \quad (2.71)$$

Like temperature and pressure, the chemical potential,  $\mu_i$  is an *intensive* property.

When written in terms of chemical potentials, Equation 2.67 for the Gibbs function reads

$$G = \sum_{i=1}^j n_i \mu_i \quad (2.72)$$

For a *single component system*, Equation 2.72 reduces to  $G = n\mu$ ; that is, the chemical potential equals the molar Gibbs function. For an ideal gas mixture, comparison of Equations 2.63 and 2.72 suggests  $\mu_i = \bar{g}_i(T, p_i)$ ; that is, the chemical potential of component  $i$  in an ideal gas mixture equals its Gibbs function per mole of gas  $i$  evaluated at the mixture temperature and the partial pressure of the  $i$ th gas of the mixture.

The chemical potential is a measure of the *escaping tendency* of a substance in a multiphase system: a substance tends to move from the phase having the higher chemical potential for that substance to the phase having a lower chemical potential. A necessary condition for *phase equilibrium* is that the chemical potential of each component has the same value in every phase.

The *Gibbs phase rule* gives the number  $F$  of independent intensive properties that may be arbitrarily specified to fix the intensive state of a system at equilibrium consisting of  $N$  nonreacting components present in  $P$  phases:  $F = 2 + N - P$ .  $F$  is called the *degrees of freedom* (or the *variance*). For water as a single component, for example,  $N = 1$  and  $F = 3 - P$ .

- For a single phase,  $P = 1$  and  $F = 2$ : two intensive properties can be varied independently, say temperature *and* pressure, while maintaining a single phase.
- For two phases,  $P = 2$  and  $F = 1$ : only one intensive property can be varied independently if two phases are maintained — for example, temperature *or* pressure.
- For three phases,  $P = 3$  and  $F = 0$ : there are no degrees of freedom; each intensive property of each phase is fixed. For a system consisting of ice, liquid water, and water vapor at equilibrium, there is a unique temperature: 0.01°C (32.02°F) and a unique pressure: 0.6113 kPa (0.006 atm).

The phase rule does not address the relative amounts that may be present in the various phases.

With  $G = H - TS$  and  $H = U + pV$ , Equation 2.72 can be expressed as

$$U = TS - pV + \sum_{i=1}^j n_i \mu_i \quad (2.73)$$

from which can be derived

$$dU = TdS - pdV + \sum_{i=1}^j \mu_i dn_i \quad (2.74)$$

When the mixture composition is constant, Equation 2.74 reduces to Equation 2.31a.

### Ideal Solution

The *Lewis-Randall rule* states that the fugacity  $\bar{f}_i$  of each component  $i$  in an *ideal solution* is the product of its mole fraction and the fugacity of the pure component,  $f_i$ , at the same temperature, pressure, and state of aggregation (gas, liquid, or solid) as the mixture:

$$\bar{f}_i = y_i \bar{f}_i \quad (\text{Lewis-Randall rule}) \quad (2.75)$$

The following characteristics are exhibited by an ideal solution:  $\bar{V}_i = \bar{v}_i$ ,  $\bar{U}_i = \bar{u}_i$ ,  $\bar{H}_i = \bar{h}_i$ . With these, Equations 2.70a, b, and c show that there is no change in volume, internal energy, or enthalpy on mixing pure components to form an ideal solution. The *adiabatic* mixing of different pure components would result in an increase in entropy, however, because such a process is irreversible.

The volume of an ideal solution is

$$V = \sum_{i=1}^j n_i \bar{v}_i = \sum_{i=1}^j V_i \quad (\text{ideal solution}) \quad (2.76)$$

where  $V_i$  is the volume that pure component  $i$  would occupy when at the temperature and pressure of the mixture. Comparing Equations 2.48a and 2.76, the *additive volume rule* is seen to be exact for ideal solutions. The internal energy and enthalpy of an ideal solution are

$$U = \sum_{i=1}^j n_i \bar{u}_i, \quad H = \sum_{i=1}^j n_i \bar{h}_i \quad (\text{ideal solution}) \quad (2.77)$$

where  $\bar{u}_i$  and  $\bar{h}_i$  denote, respectively, the molar internal energy and enthalpy of pure component  $i$  at the temperature and pressure of the mixture. Many gaseous mixtures at low to moderate pressures are adequately modeled by the Lewis Randall rule. The ideal gas mixtures considered in Section 2.3, Ideal Gas Model, is an important special case. Some liquid solutions also can be modeled with the Lewis-Randall rule.

## 2.4 Combustion

---

The thermodynamic analysis of reactive systems is primarily an extension of principles presented in Sections 2.1 to 2.3. It is necessary, though, to modify the methods used to evaluate specific enthalpy and entropy.

### Reaction Equations

In combustion reactions, rapid oxidation of combustible elements of the fuel results in energy release as combustion products are formed. The three major combustible chemical elements in most common fuels are carbon, hydrogen, and sulfur. Although sulfur is usually a relatively unimportant contributor to the energy released, it can be a significant cause of pollution and corrosion.

The emphasis in this section is on hydrocarbon fuels, which contain hydrogen, carbon, sulfur, and possibly other chemical substances. Hydrocarbon fuels may be liquids, gases, or solids such as coal. Liquid hydrocarbon fuels are commonly derived from crude oil through distillation and cracking processes. Examples are gasoline, diesel fuel, kerosene, and other types of fuel oils. The compositions of liquid fuels are commonly given in terms of mass fractions. For simplicity in combustion calculations, gasoline is often considered to be octane,  $C_8H_{18}$ , and diesel fuel is considered to be dodecane,  $C_{12}H_{26}$ . Gaseous hydrocarbon fuels are obtained from natural gas wells or are produced in certain chemical processes. Natural gas normally consists of several different hydrocarbons, with the major constituent being methane,  $CH_4$ . The compositions of gaseous fuels are commonly given in terms of mole fractions. Both gaseous and liquid hydrocarbon fuels can be synthesized from coal, oil shale, and tar sands. The composition of coal varies considerably with the location from which it is mined. For combustion calculations, the makeup of coal is usually expressed as an *ultimate analysis* giving the composition on a mass basis in terms of the relative amounts of chemical elements (carbon, sulfur, hydrogen, nitrogen, oxygen) and ash. Coal combustion is considered further in Chapter 8, Energy Conversion.

A fuel is said to have burned *completely* if all of the carbon present in the fuel is burned to carbon dioxide, all of the hydrogen is burned to water, and all of the sulfur is burned to sulfur dioxide. In practice, these conditions are usually not fulfilled and combustion is *incomplete*. The presence of carbon monoxide (CO) in the products indicates incomplete combustion. The products of combustion of *actual* combustion reactions and the relative amounts of the products can be determined with certainty only by experimental means. Among several devices for the experimental determination of the composition of products of combustion are the *Orsat analyzer*, *gas chromatograph*, *infrared analyzer*, and *flame ionization detector*. Data from these devices can be used to determine the makeup of the gaseous products of combustion. Analyses are frequently reported on a “dry” basis: mole fractions are determined for all gaseous products as if no water vapor were present. Some experimental procedures give an analysis including the water vapor, however.

Since water is formed when hydrocarbon fuels are burned, the mole fraction of water vapor in the gaseous products of combustion can be significant. If the gaseous products of combustion are cooled at constant mixture pressure, the *dew point temperature* (Section 2.3, Ideal Gas Model) is reached when water vapor begins to condense. Corrosion of duct work, mufflers, and other metal parts can occur when water vapor in the combustion products condenses.

Oxygen is required in every combustion reaction. Pure oxygen is used only in special applications such as cutting and welding. In most combustion applications, air provides the needed oxygen. Idealizations are often used in combustion calculations involving air: (1) all components of air other than oxygen ( $O_2$ ) are lumped with nitrogen ( $N_2$ ). On a molar basis air is then considered to be 21% oxygen and 79% nitrogen. With this idealization the molar ratio of the nitrogen to the oxygen in combustion air is 3.76; (2) the water vapor present in air may be considered in writing the combustion equation or ignored. In the latter case the combustion air is regarded as *dry*; (3) additional simplicity results by regarding the nitrogen present in the combustion air as inert. However, if high-enough temperatures are attained, nitrogen can form compounds, often termed  $NO_x$ , such as nitric oxide and nitrogen dioxide.

Even trace amounts of oxides of nitrogen appearing in the exhaust of internal combustion engines can be a source of air pollution.

The minimum amount of air that supplies sufficient oxygen for the complete combustion of all the combustible chemical elements is the *theoretical*, or *stoichiometric*, amount of air. In practice, the amount of air actually supplied may be greater than or less than the theoretical amount, depending on the application. The amount of air is commonly expressed as the *percent of theoretical air* or the *percent excess* (or *percent deficiency*) of air. The *air-fuel ratio* and its reciprocal *the fuel-air ratio*, each of which can be expressed on a mass or molar basis, are other ways that fuel-air mixtures are described. Another is the *equivalence ratio*: the ratio of the actual fuel-air ratio to the fuel-air ratio for complete combustion with the theoretical amount of air. The reactants form a *lean* mixture when the equivalence ratio is less than unity and a *rich* mixture when the ratio is greater than unity.

### Example 9

Methane,  $\text{CH}_4$ , is burned with dry air. The molar analysis of the products on a dry basis is  $\text{CO}_2$ , 9.7%;  $\text{CO}$ , 0.5%;  $\text{O}_2$ , 2.95%; and  $\text{N}_2$ , 86.85%. Determine (a) the air-fuel ratio on both a molar and a mass basis, (b) the percent of theoretical air, (c) the equivalence ratio, and (d) the dew point temperature of the products, in  $^\circ\text{F}$ , if the pressure is 1 atm.

*Solution.*

- (a) The solution is conveniently conducted on the basis of 100 lbmol of dry products. The chemical equation then reads

where  $\text{N}_2$  is regarded as inert. Water is included in the products together with the assumed 100 lbmol of dry products. Balancing the carbon, hydrogen, and oxygen, the reaction equation is

The nitrogen also balances, as can be verified. This checks the accuracy of both the given product analysis and the calculations conducted to determine the unknown coefficients. Exact closure cannot be expected with measured data, however. On a molar basis, the air-fuel ratio is

$$\overline{\text{AF}} = \frac{23.1(4.76)}{10.2} = 10.78 \frac{\text{lbmol}(\text{air})}{\text{lbmol}(\text{fuel})}$$

On a mass basis

$$\text{AF} = (10.78) \left( \frac{28.97}{16.04} \right) = 19.47 \frac{\text{lb}(\text{air})}{\text{lb}(\text{fuel})}$$

- (b) The balanced chemical equation for the complete combustion of methane with the *theoretical* amount of air is

The theoretical air-fuel ratio on a molar basis is

$$(\overline{\text{AF}})_{\text{theo}} = \frac{2(4.76)}{1} = 9.52 \frac{\text{lbmol}(\text{air})}{\text{lbmol}(\text{fuel})}$$

The percent theoretical air is then

$$\begin{aligned}\% \text{ theoretical air} &= \frac{(\overline{\text{AF}})}{(\overline{\text{AF}})_{\text{theo}}} \\ &= \frac{10.78}{9.52} = 1.13(113\%)\end{aligned}$$

- (c) Equivalence ratio =  $(\overline{\text{FA}})/(\overline{\text{FA}})_{\text{theo}} = 9.52/10.78 = 0.88$ . The reactants form a lean mixture.  
 (d) To determine the dew point temperature requires the partial pressure  $p_v$  of the water vapor. The mole fraction of the water vapor is

$$y_v = \frac{20.4}{100 + 20.4} = 0.169$$

Since  $p = 1$  atm,  $p_v = 0.169$  atm = 2.48 lbf/in.<sup>2</sup>. With  $p_{\text{sat}} = 2.48$  lbf/in.<sup>2</sup>, the corresponding saturation temperature from the steam tables is 134°F. This is the dew point temperature.

## Property Data for Reactive Systems

Tables of thermodynamic properties such as the steam tables provide values for the specific enthalpy and entropy relative to some arbitrary datum state where the enthalpy (or alternatively the internal energy) and entropy are set to zero. When a chemical reaction occurs, however, reactants disappear and products are formed, and it is generally no longer possible to evaluate  $\Delta \bar{h}$  and  $\Delta \bar{s}$  so that these arbitrary datums cancel. Accordingly, special means are required to assign specific enthalpy and entropy for application to reacting systems.

Property data suited for the analysis of reactive systems are available from several sources. The encyclopedic *JANAF Thermochemical Tables* is commonly used. Data for a wide range of substances are retrievable from Knacke et al. (1991), which provides both tabular data and analytical expressions readily programmable for use with personal computers of the specific heat, enthalpy, entropy, and Gibbs function. Textbooks on engineering thermodynamics also provide selected data, as, for example, Moran and Shapiro (1995).

### Enthalpy of Formation

An enthalpy datum for reacting systems can be established by assigning arbitrarily a value of zero to the enthalpy of the *stable elements* at a *standard reference state* where the temperature is  $T_{\text{ref}} = 298.15$  K (25°C) and the pressure is  $p_{\text{ref}}$ , which may be 1 bar or 1 atm depending on the data source. The term *stable* simply means that the particular element is chemically stable. For example, at the standard state the stable forms of hydrogen, oxygen, and nitrogen are H<sub>2</sub>, O<sub>2</sub>, and N<sub>2</sub> and not the monatomic H, O, and N.

The molar enthalpy of a *compound* at the standard state equals its *enthalpy of formation*, symbolized here by  $\bar{h}_f^\circ$ . The enthalpy of formation is the energy released or absorbed when the compound is formed from its elements, the compound and elements all being at  $T_{\text{ref}}$  and  $p_{\text{ref}}$ . The enthalpy of formation may be determined by application of procedures from statistical thermodynamics using observed spectroscopic data. The enthalpy of formation also can be found in principle by measuring the heat transfer in a reaction in which the compound is formed from the elements. In this chapter, the superscript ° is used to denote  $p_{\text{ref}}$ . For the case of the enthalpy of formation, the reference temperature  $T_{\text{ref}}$  is also intended by this symbol. [Table 2.9](#) gives the values of the enthalpy of formation of various substances at 298 K and 1 atm.

The molar enthalpy of a substance at a state other than the standard state is found by adding the molar enthalpy change  $\Delta \bar{h}$  between the standard state and the state of interest to the molar enthalpy of formation:

**TABLE 2.9 Enthalpy of Formation, Gibbs Function of Formation, and Absolute Entropy of Various Substances at 298 K and 1 atm**

$\bar{h}_f^\circ$ and $\bar{g}_f^\circ$ (kJ/kmol), $\bar{s}^\circ$ (kJ/kmol·K)				
Substance	Formula	$\bar{h}_f^\circ$	$\bar{g}_f^\circ$	$\bar{s}^\circ$

Source: Adapted from Wark, K. 1983. *Thermodynamics*, 4th ed. McGraw-Hill, New York, as based on JANAF Thermochemical Tables, NSRDS-NBS-37, 1971; *Selected Values of Chemical Thermodynamic Properties*, NBS Tech. Note 270-3, 1968; and *API Research Project 44*, Carnegie Press, 1953.

$$\bar{h}(T, p) = \bar{h}_f^\circ + \left[ \bar{h}(T, p) - \bar{h}(T_{ref}, p_{ref}) \right] = \bar{h}_f^\circ + \Delta \bar{h} \quad (2.78)$$

That is, the enthalpy of a substance is composed of  $\bar{h}_f^\circ$ , associated with the formation of the substance from its elements, and  $\Delta \bar{h}$ , associated with a change of state at constant composition. An arbitrarily chosen datum can be used to determine  $\Delta \bar{h}$ , since it is a *difference* at constant composition. Accordingly,  $\Delta \bar{h}$  can be evaluated from sources such as the steam tables and the ideal gas tables.

The *enthalpy of combustion*,  $\bar{h}_{RP}$ , is the difference between the enthalpy of the products and the enthalpy of the reactants, each on a per-mole-of-fuel basis, when complete combustion occurs and both reactants and products are at the same temperature and pressure. For hydrocarbon fuels the enthalpy of combustion is negative in value since chemical internal energy is liberated in the reaction. The *heating value* of a fuel is a positive number equal to the magnitude of the enthalpy of combustion. Two heating values are recognized: the *higher* heating value and the *lower* heating value. The higher heating value

is obtained when all the water formed by combustion is a liquid; the lower heating value is obtained when all the water formed by combustion is a vapor. The higher heating value exceeds the lower heating value by the energy that would be required to vaporize the liquid water formed at the specified temperature. Heating values are typically reported at a temperature of 25°C (77°F) and a pressure of 1 bar (or 1 atm). These values also depend on whether the fuel is a liquid or a gas. A sampling is provided on a unit-mass-of-fuel basis in Table 2.10.

**TABLE 2.10 Heating Values in kJ/kg of Selected Hydrocarbons at 25°C**

Hydrocarbon	Formula	Higher Value <sup>a</sup>		Lower Value <sup>b</sup>

In the absence of work  $\dot{W}_{cv}$  and appreciable kinetic and potential energy effects, the energy liberated on combustion is transferred from a reactor at steady state in two ways: the energy accompanying the exiting combustion products and by heat transfer. The temperature that would be achieved by the products in the limit of adiabatic operation is the *adiabatic flame* or *adiabatic combustion* temperature.

For a specified fuel and specified temperature and pressure of the reactants, the *maximum* adiabatic flame temperature is realized for complete combustion with the theoretical amount of air. Example 10 provides an illustration. The measured value of the temperature of the combustion products may be several hundred degrees below the calculated maximum adiabatic flame temperature, however, for several reasons including the following: (1) heat loss can be reduced but not eliminated; (2) once adequate oxygen has been provided to permit complete combustion, bringing in more air dilutes the combustion products, lowering the temperature; (3) incomplete combustion tends to reduce the temperature of the products, and combustion is seldom complete; (4) as result of the high temperatures achieved, some of the combustion products may dissociate. Endothermic dissociation reactions also lower the product temperature.

### Absolute Entropy

A common datum for assigning entropy values to substances involved in chemical reactions is realized through the *third law* of thermodynamics, which is based on experimental observations obtained primarily from studies of chemical reactions at low temperatures and specific heat measurements at temperatures approaching absolute zero. The third law states that the entropy of a pure crystalline substance is zero at the absolute zero of temperature, 0 K or 0°R. Substances not having a pure crystalline structure have a nonzero value of entropy at absolute zero.

The third law provides a datum relative to which the entropy of each substance participating in a reaction can be evaluated. The entropy relative to this datum is called the *absolute* entropy. The change in entropy of a substance between absolute zero and any given state can be determined from measurements of energy transfers and specific heat data or from procedures based on statistical thermodynamics and observed molecular data. Table 2.9 and Tables A.2 and A.8 provide absolute entropy data for various substances. In these tables,  $p_{ref} = 1$  atm.

When the absolute entropy is known at pressure  $p_{ref}$  and temperature  $T$ , the absolute entropy at the same temperature and any pressure  $p$  can be found from

$$\bar{s}(T, p) = \bar{s}(T, p_{ref}) + \left[ \bar{s}(T, p) - \bar{s}(T, p_{ref}) \right] \quad (2.79)$$

For an ideal gas, the second term on the right side of Equation 2.79 can be evaluated by using Equation 2.58, giving

$$\bar{s}(T, p) = \bar{s}^\circ(T) - \bar{R} \ln \frac{p}{p_{ref}} \quad (\text{ideal gas}) \quad (2.80)$$

In this expression,  $\bar{s}^\circ(T)$  denotes the absolute entropy at temperature  $T$  and pressure  $p_{ref}$ .

The entropy of the  $i$ th component of an *ideal gas mixture* is evaluated at the mixture temperature  $T$  and the *partial* pressure  $p_i$ :  $\bar{s}_i(T, p_i)$ . For the  $i$ th component, Equation 2.80 takes the form

$$\begin{aligned} \bar{s}_i(T, p_i) &= \bar{s}_i^\circ(T) - \bar{R} \ln \frac{p_i}{p_{ref}} \\ &= \bar{s}_i^\circ(T) - \bar{R} \ln \frac{y_i p}{p_{ref}} \quad (\text{ideal gas}) \end{aligned} \quad (2.81)$$

where  $\bar{s}_i^\circ(T)$  is the absolute entropy of component  $i$  at temperature  $T$  and  $p_{ref}$ .

### Example 10

Liquid octane at 25°C, 1 atm enters a well insulated reactor and reacts with dry air entering at the same temperature and pressure. For steady-state operation and negligible effects of kinetic and potential energy, determine the temperature of the combustion products for complete combustion with the theoretical amount of air, and (b) the rates of entropy generation and exergy destruction, each per kmol of fuel.

*Solution.* For combustion of liquid octane with the theoretical amount of air, the chemical equation is

(a) At steady state, the control volume energy rate balance reduces to read

$$0 = \frac{\dot{Q}_{cv}}{\dot{n}_F} - \frac{\dot{W}_{cv}}{\dot{n}_F} + \sum_R n_i (\bar{h}_f^\circ + \Delta\bar{h})_i - \sum_P n_e (\bar{h}_f^\circ + \Delta\bar{h})_e$$

where  $R$  denotes reactants,  $P$  denotes products, and the symbols for enthalpy have the same significance as in Equation 2.78. Since the reactants enter at 25°C, the corresponding  $(\Delta\bar{h})_i$  terms vanish, and the energy rate equation becomes

$$\sum_P n_e (\Delta\bar{h})_e = \sum_R n_i \bar{h}_{fi}^\circ - \sum_P n_e \bar{h}_{fe}^\circ$$

Introducing coefficients from the reaction equation, this takes the form

$$\begin{aligned} 8(\Delta\bar{h})_{\text{CO}_2} + 9(\Delta\bar{h})_{\text{H}_2\text{O}(\text{g})} + 47(\Delta\bar{h})_{\text{N}_2} &= \left[ (\bar{h}_f^\circ)_{\text{C}_8\text{H}_{18}(\text{l})} + 12.5(\bar{h}_f^\circ)_{\text{O}_2} + 47(\bar{h}_f^\circ)_{\text{N}_2} \right] \\ &- \left[ 8(\bar{h}_f^\circ)_{\text{CO}_2} + 9(\bar{h}_f^\circ)_{\text{H}_2\text{O}(\text{g})} + 47(\bar{h}_f^\circ)_{\text{N}_2} \right] \end{aligned}$$

Using data from Table 2.9 to evaluate the right side,

$$8(\Delta\bar{h})_{\text{CO}_2} + 9(\Delta\bar{h})_{\text{H}_2\text{O}(\text{g})} + 47(\Delta\bar{h})_{\text{N}_2} = 5,074,630 \text{ kJ/kmol (fuel)}$$

Each  $\Delta\bar{h}$  term on the left side of this equation depends on the temperature of the products,  $T_p$ , which can be solved for iteratively as  $T_p = 2395 \text{ K}$ .

(b) The entropy rate balance on a per-mole-of-fuel basis takes the form

$$0 = \sum_j \frac{\dot{Q}_j/T_j}{\dot{n}_F} + \bar{s}_F + (12.5\bar{s}_{\text{O}_2} + 47\bar{s}_{\text{N}_2}) - (8\bar{s}_{\text{CO}_2} + 9\bar{s}_{\text{H}_2\text{O}(\text{g})} + 47\bar{s}_{\text{N}_2}) + \frac{\dot{S}^{gen}}{\dot{n}_F}$$

or on rearrangement,

$$\frac{\dot{S}^{gen}}{\dot{n}_F} = (8\bar{s}_{\text{CO}_2} + 9\bar{s}_{\text{H}_2\text{O}(\text{g})} + 47\bar{s}_{\text{N}_2}) - \bar{s}_F - (12.5\bar{s}_{\text{O}_2} + 47\bar{s}_{\text{N}_2})$$

The absolute entropy of liquid octane from Table 2.9 is  $360.79 \text{ kJ/mol} \cdot \text{K}$ . The oxygen and nitrogen in the combustion air enter the reactor as components of an ideal gas mixture at  $T_{ref}$ ,  $p_{ref}$ . With Equation 2.81, where  $p = p_{ref}$ , and absolute entropy data from Table 2.9,

$$\begin{aligned}\bar{s}_{\text{O}_2} &= \bar{s}_{\text{O}_2}^\circ(T_{ref}) - \bar{R} \ln y_{\text{O}_2} \\ &= 205.03 - 8.314 \ln 0.21 = 218.01 \text{ kJ/kmol} \cdot \text{K} \\ \bar{s}_{\text{N}_2} &= \bar{s}_{\text{N}_2}^\circ(T_{ref}) - \bar{R} \ln y_{\text{N}_2} \\ &= 191.5 - 8.314 \ln 0.79 = 193.46 \text{ kJ/kmol} \cdot \text{K}\end{aligned}$$

The product gas exits as a gas mixture at 1 atm, 2395 K with the following composition:  $y_{\text{CO}_2} = 8/64 = 0.125$ ,  $y_{\text{H}_2\text{O}(\text{g})} = 9/64 = 0.1406$ ,  $y_{\text{N}_2} = 47/64 = 0.7344$ . With Equation 2.81, where  $p = p_{ref}$ , and absolute entropy data at 2395 K from Table A.2,

$$\begin{aligned}\bar{s}_{\text{CO}_2} &= 320.173 - 8.314 \ln 0.125 = 337.46 \text{ kJ/kmol} \cdot \text{K} \\ \bar{s}_{\text{H}_2\text{O}} &= 273.986 - 8.314 \ln 0.1406 = 290.30 \text{ kJ/kmol} \cdot \text{K} \\ \bar{s}_{\text{N}_2} &= 258.503 - 8.314 \ln 0.7344 = 261.07 \text{ kJ/kmol} \cdot \text{K}\end{aligned}$$

Inserting values, the rate of entropy generation is

$$\begin{aligned}\frac{\dot{S}^{gen}}{\dot{n}_F} &= 8(337.46) + 9(290.30) + 47(261.07) - 360.79 - 12.5(218.01) - 47(193.46) \\ &= 5404 \text{ kJ/kmol} \cdot \text{K}\end{aligned}$$

Using Equation 2.87 and assuming  $T_0 = 298 \text{ K}$ , the rate of exergy destruction is  $\dot{E}_D/\dot{n}_F = 1.61 \times 10^6 \text{ kJ/kmol}$ .

**Gibbs Function of Formation**

Paralleling the approach used for enthalpy, a value of zero is assigned to the Gibbs function of each stable element at the standard state. The *Gibbs function of formation* of a compound equals the change in the Gibbs function for the reaction in which the compound is formed from its elements. Table 2.9 provides Gibbs function of formation data of various substances at 298 K and 1 atm.

The Gibbs function at a state other than the standard state is found by adding to the Gibbs function of formation the change in the specific Gibbs function  $\Delta\bar{g}$  between the standard state and the state of interest:

$$\bar{g}(T, p) = \bar{g}_f^\circ + \left[ \bar{g}(T, p) - \bar{g}(T_{ref}, p_{ref}) \right] = \bar{g}_f^\circ + \Delta\bar{g} \tag{2.82a}$$

where

$$\Delta\bar{g} = \left[ \bar{h}(T, p) - \bar{h}(T_{ref}, p_{ref}) \right] - \left[ T\bar{s}(T, p) - T_{ref}\bar{s}(T_{ref}, p_{ref}) \right] \tag{2.82b}$$

The Gibbs function of component *i* in an ideal gas mixture is evaluated at the partial pressure of component *i* and the mixture temperature.

As an application, the maximum theoretical work that can be developed, per mole of fuel consumed, is evaluated for the control volume of Figure 2.15, where the fuel and oxygen each enter in separate streams and carbon dioxide and water each exit separately. All entering and exiting streams are at the same temperature *T* and pressure *p*. The reaction is complete:

This control volume is similar to idealized devices such as a reversible fuel cell or a *van't Hoff equilibrium box*.

**FIGURE 2.15** Device for evaluating maximum work.

For steady-state operation, the energy rate balance reduces to give

$$\frac{\dot{W}_{cv}}{\dot{n}_F} = \frac{\dot{Q}_{cv}}{\dot{n}_F} + \bar{h}_F + \left( a + \frac{b}{4} \right) \bar{h}_{O_2} - a\bar{h}_{CO_2} - \frac{b}{2} \bar{h}_{H_2O}$$

where  $\dot{n}_F$  denotes the molar flow rate of the fuel. Kinetic and potential energy effects are regarded as negligible. If heat transfer occurs only at the temperature  $T$ , an entropy balance for the control volume takes the form

$$0 = \frac{\dot{Q}_{cv}/\dot{n}_F}{T} + \bar{s}_F + \left(a + \frac{b}{4}\right)\bar{s}_{\text{O}_2} - a\bar{s}_{\text{CO}_2} - \frac{b}{2}\bar{s}_{\text{H}_2\text{O}} + \frac{\dot{S}_{gen}}{\dot{n}_F}$$

Eliminating the heat transfer term from these expressions, an expression for the maximum theoretical value of the work developed per mole of fuel is obtained when the entropy generation term is set to zero:

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{int_{rev}} = \left[\bar{h}_F + \left(a + \frac{b}{4}\right)\bar{h}_{\text{O}_2} - a\bar{h}_{\text{CO}_2} - \frac{b}{2}\bar{h}_{\text{H}_2\text{O}}\right](T, p) - T\left[\bar{s}_F + \left(a + \frac{b}{4}\right)\bar{s}_{\text{O}_2} - a\bar{s}_{\text{CO}_2} - \frac{b}{2}\bar{s}_{\text{H}_2\text{O}}\right](T, p)$$

This can be written alternatively in terms of the enthalpy of combustion as

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{int_{rev}} = -\bar{h}_{RP}(T, p) - T\left[\bar{s}_F + \left(a + \frac{b}{4}\right)\bar{s}_{\text{O}_2} - a\bar{s}_{\text{CO}_2} - \frac{b}{2}\bar{s}_{\text{H}_2\text{O}}\right](T, p) \quad (2.83a)$$

or in terms of Gibbs functions as

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{int_{rev}} = \left[\bar{g}_F + \left(a + \frac{b}{4}\right)\bar{g}_{\text{O}_2} - a\bar{g}_{\text{CO}_2} - \frac{b}{2}\bar{g}_{\text{H}_2\text{O}}\right](T, p) \quad (2.83b)$$

Equation 2.83b is used in the solution to Example 11.

### Example 11

Hydrogen ( $\text{H}_2$ ) and oxygen ( $\text{O}_2$ ), each at  $25^\circ\text{C}$ , 1 atm, enter a fuel cell operating at steady state, and liquid water exits at the same temperature and pressure. The hydrogen flow rate is  $2 \times 10^{-4}$  kmol/sec and the fuel cell operates isothermally at  $25^\circ\text{C}$ . Determine the maximum theoretical power the cell can develop, in kW.

*Solution.* The overall cell reaction is  $\text{H}_2 + 1/2 \text{O}_2 \rightarrow \text{H}_2\text{O}(\ell)$ , and Equations 2.83 are applicable. Selecting Equation 2.83b, and using Gibbs function data from [Table 2.9](#),

$$\begin{aligned} \left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{int_{rev}} &= \left(\bar{g}_{\text{H}_2} + \frac{1}{2}\bar{g}_{\text{O}_2} - \bar{g}_{\text{H}_2\text{O}(\ell)}\right)(25^\circ\text{C}, 1 \text{ atm}) \\ &= 0 + \frac{1}{2}(0) - (-237,180) = 237,180 \text{ kJ/kmol} \end{aligned}$$

Then

$$\left(\dot{W}_{cv}\right)_{int_{rev}} = \left(237,180 \frac{\text{kJ}}{\text{kmol}}\right)\left(2 \times 10^{-4} \frac{\text{kmol}}{\text{s}}\right)\left(\frac{\text{kW}}{1 \text{ kJ/s}}\right) = 47.4 \text{ kW}$$

## Reaction Equilibrium

Let the objective be to determine the equilibrium composition of a system consisting of five gases A, B, C, D, and E, at a temperature  $T$  and pressure  $p$ , subject to a chemical reaction of the form

where the  $v$ 's are stoichiometric coefficients. Component E is assumed to be inert and thus does not appear in the reaction equation. The equation suggests that at equilibrium the tendency of A and B to form C and D is just balanced by the tendency of C and D to form A and B.

At equilibrium, the temperature and pressure would be uniform throughout the system. Additionally, the *equation of reaction equilibrium* must be satisfied:

$$v_A \mu_A + v_B \mu_B = v_C \mu_C + v_D \mu_D \quad (2.84a)$$

where the  $\mu$ 's are the chemical potentials (Section 2.3, Multicomponent Systems) of A, B, C, and D in the equilibrium mixture. In principle, the composition that would be present at equilibrium for a given temperature and pressure can be determined by solving this equation.

For ideal gas mixtures, the solution procedure is simplified by using the *equilibrium constant*  $K(T)$  and the following equation:

$$\begin{aligned} K(T) &= \frac{y_C^{v_C} y_D^{v_D}}{y_A^{v_A} y_B^{v_B}} \left( \frac{p}{p_{ref}} \right)^{v_C + v_D - v_A - v_B} \\ &= \frac{n_C^{v_C} n_D^{v_D}}{n_A^{v_A} n_B^{v_B}} \left( \frac{p/p_{ref}}{n} \right)^{v_C + v_D - v_A - v_B} \end{aligned} \quad (2.84b)$$

where  $y_A$ ,  $y_B$ ,  $y_C$ , and  $y_D$  denote the mole fractions of A, B, C, and D in the equilibrium mixture and  $n = n_A + n_B + n_C + n_D + n_E$ , where the  $n$ 's denote the molar amounts of the gases in the mixture. Tabulations of  $K(T)$  for each of several reactions of the form Equation 2.84a are provided in Table 2.11. An application of Equation 2.84b is provided in Example 12.

### Example 12

One kmol of CO reacts with the theoretical amount of dry air to form an equilibrium mixture of  $\text{CO}_2$ , CO,  $\text{O}_2$ , and  $\text{N}_2$  at 2500 K, 1 atm. Determine the amount of CO in the equilibrium mixture, in kmol.

*Solution.* The reaction of CO with the theoretical amount of dry air to form  $\text{CO}_2$ , CO,  $\text{O}_2$ , and  $\text{N}_2$  is

where  $z$  is the amount of CO, in kmol, present in the equilibrium mixture. The total number of moles  $n$  is

$$n = z + \frac{z}{2} + (1-z) + 1.88 = \frac{5.76 + z}{2}$$

At equilibrium  $\text{CO}_2 \leftrightarrow \text{CO} + 1/2 \text{O}_2$ ; and Equation 2.84b takes the form

$$K = \frac{z(z/2)^{1/2}}{1-z} \left[ \frac{p/p_{ref}}{(5.76+z)/2} \right]^{1/2}$$

where  $p/p_{ref} = 1$ . At 2500 K, Table 2.11 gives  $K = 0.0363$ . Solving iteratively,  $z = 0.175$ .

## 2.5 Exergy Analysis

The method of *exergy analysis (availability analysis)* presented in this section enables the location, cause, and true magnitude of energy resource waste and loss to be determined. Such information can be used in the design of new energy-efficient systems and for improving the performance of existing systems. Exergy analysis also provides insights that elude a purely first-law approach. For example, on the basis of first-law reasoning alone, the condenser of a power plant may be mistakenly identified as the component primarily responsible for the plant's seemingly low overall performance. An exergy analysis correctly reveals not only that the condenser loss is relatively unimportant (see the last two rows of the Rankine cycle values of Table 2.15), but also that the steam generator is the principal site of thermodynamic inefficiency owing to combustion and heat transfer irreversibilities within it.

When exergy concepts are combined with principles of engineering economy, the result is known as *thermoeconomics*. Thermoeconomics allows the real cost sources at the component level to be identified: capital investment costs, operating and maintenance costs, and the costs associated with the destruction and loss of exergy. Optimization of thermal systems can be achieved by a careful consideration of such cost sources. From this perspective thermoeconomics is *exergy-aided cost minimization*.

Discussions of exergy analysis and thermoeconomics are provided by Bejan et al. (1996), Moran (1989), and Moran and Shapiro (1995). In this section salient aspects are presented.

### Defining Exergy

An opportunity for doing work exists whenever two systems at different states are placed in communication because, in principle, work can be developed as the two are allowed to come into equilibrium. When one of the two systems is a suitably idealized system called an *environment* and the other is some system of interest, *exergy* is the maximum theoretical useful work (shaft work or electrical work) obtainable as the systems interact to equilibrium, heat transfer occurring with the environment only. (Alternatively, exergy is the minimum theoretical useful work required to form a quantity of matter from substances present in the environment and to bring the matter to a specified state.) Exergy is a measure of the *departure* of the state of the system from that of the environment, and is therefore an attribute of the system and environment together. Once the environment is specified, however, a value can be assigned to exergy in terms of property values for the system only, so exergy can be regarded as an extensive property of the system.

Exergy can be destroyed and generally is not conserved. A limiting case is when exergy would be completely destroyed, as would occur if a system were to come into equilibrium with the environment *spontaneously* with no provision to obtain work. The capability to develop work that existed initially would be completely wasted in the spontaneous process. Moreover, since no work needs to be done to effect such a spontaneous change, the value of exergy can never be negative.

### Environment

Models with various levels of specificity are employed for describing the environment used to evaluate exergy. Models of the environment typically refer to some portion of a system's surroundings, the intensive properties of each phase of which are uniform and do not change significantly as a result of any process under consideration. The environment is regarded as composed of common substances existing in abundance within the Earth's atmosphere, oceans, and crust. The substances are in their stable forms as they exist naturally, and there is no possibility of developing work from interactions — physical or chemical — between parts of the environment. Although the intensive properties of the environment are assumed to be unchanging, the extensive properties can change as a result of interactions with other systems. Kinetic and potential energies are evaluated relative to coordinates in the environment, all parts of which are considered to be at rest with respect to one another.

For computational ease, the temperature  $T_0$  and pressure  $p_0$  of the environment are often taken as standard-state values, such as 1 atm and 25°C (77°F). However, these properties may be specified

differently depending on the application.  $T_0$  and  $p_0$  might be taken as the average ambient temperature and pressure, respectively, for the location at which the system under consideration operates. Or, if the system uses atmospheric air,  $T_0$  might be specified as the average air temperature. If both air and water from the natural surroundings are used,  $T_0$  would be specified as the lower of the average temperatures for air and water.

### Dead States

When a system is in equilibrium with the environment, the state of the system is called the *dead state*. At the dead state, the conditions of mechanical, thermal, and chemical equilibrium between the system and the environment are satisfied: the pressure, temperature, and chemical potentials of the system equal those of the environment, respectively. In addition, the system has no motion or elevation relative to coordinates in the environment. Under these conditions, there is no possibility of a spontaneous change within the system or the environment, nor can there be an interaction between them. The value of exergy is zero.

Another type of equilibrium between the system and environment can be identified. This is a restricted form of equilibrium where only the conditions of mechanical and thermal equilibrium must be satisfied. This state of the system is called the *restricted dead state*. At the restricted dead state, the fixed quantity of matter under consideration is imagined to be sealed in an envelope impervious to mass flow, at zero velocity and elevation relative to coordinates in the environment, and at the temperature  $T_0$  and pressure  $p_0$ .

### Exergy Balances

Exergy can be transferred by three means: exergy transfer associated with work, exergy transfer associated with heat transfer, and exergy transfer associated with the matter entering and exiting a control volume. All such exergy transfers are evaluated relative to the environment used to define exergy. Exergy is also destroyed by irreversibilities within the system or control volume.

Exergy balances can be written in various forms, depending on whether a closed system or control volume is under consideration and whether steady-state or transient operation is of interest. Owing to its importance for a wide range of applications, an exergy rate balance for control volumes at steady state is presented next.

### Control Volume Exergy Rate Balance

At steady state, the control volume exergy rate balance takes the form

$$0 = \underbrace{\sum_j \dot{E}_{q,j}}_{\text{rates of exergy transfer}} - \dot{W}_{cv} + \underbrace{\sum_i \dot{E}_i}_{\text{rate of exergy}} - \underbrace{\sum_e \dot{E}_e - \dot{E}_D}_{\text{rate of exergy destruction}} \quad (2.85a)$$

or

$$0 = \sum_j \left( 1 - \frac{T_0}{T_j} \right) \dot{Q}_j - \dot{W}_{cv} + \sum_i \dot{m}_i e_i - \sum_e \dot{m}_e e_e - \dot{E}_D \quad (2.85b)$$

$\dot{W}_{cv}$  has the same significance as in Equation 2.22: the work rate excluding the flow work.  $\dot{Q}_j$  is the time rate of heat transfer at the location on the boundary of the control volume where the instantaneous temperature is  $T_j$ . The associated rate of exergy transfer is

$$\dot{E}_{q,j} = \left(1 - \frac{T_0}{T_j}\right) \dot{Q}_j \quad (2.86)$$

As for other control volume rate balances, the subscripts  $i$  and  $e$  denote inlets and outlets, respectively. The exergy transfer rates at control volume inlets and outlets are denoted, respectively, as  $\dot{E}_i = \dot{m}_i e_i$  and  $\dot{E}_e = \dot{m}_e e_e$ . Finally,  $\dot{E}_D$  accounts for the time rate of exergy destruction due to irreversibilities within the control volume. The exergy destruction rate is related to the entropy generation rate by

$$\dot{E}_D = T_0 \dot{S}_{gen} \quad (2.87)$$

The specific exergy transfer terms  $e_i$  and  $e_e$  are expressible in terms of four components: physical exergy  $e^{PH}$ , kinetic exergy  $e^{KN}$ , potential exergy  $e^{PT}$ , and chemical exergy  $e^{CH}$ :

$$e = e^{PH} + e^{KN} + e^{PT} + e^{CH} \quad (2.88)$$

The first three components are evaluated as follows:

$$e^{PH} = (h - h_0) - T_0 (s - s_0) \quad (2.89a)$$

$$e^{KN} = \frac{1}{2} v^2 \quad (2.89b)$$

$$e^{PT} = gz \quad (2.89c)$$

In Equation 2.89a,  $h_0$  and  $s_0$  denote, respectively, the specific enthalpy and specific entropy at the restricted dead state. In Equations 2.89b and 2.89c,  $v$  and  $z$  denote velocity and elevation relative to coordinates in the environment, respectively. The chemical exergy  $e^{CH}$  is considered next.

### Chemical Exergy

To evaluate the chemical exergy, the exergy component associated with the departure of the chemical composition of a system from that of the environment, the substances comprising the system are referred to the properties of a suitably selected set of environmental substances. For this purpose, alternative models of the environment have been developed. For discussion, see, for example, Moran (1989) and Kotas (1995).

Exergy analysis is facilitated, however, by employing a *standard environment* and a corresponding table of *standard chemical exergies*. Standard chemical exergies are based on standard values of the environmental temperature  $T_0$  and pressure  $p_0$  — for example, 298.15 K (25°C) and 1 atm, respectively. A standard environment is also regarded as consisting of a set of reference substances with standard concentrations reflecting as closely as possible the chemical makeup of the natural environment. The reference substances generally fall into three groups: gaseous components of the atmosphere, solid substances from the lithosphere, and ionic and nonionic substances from the oceans. The chemical exergy data of Table 2.12 correspond to two alternative standard exergy reference environments, called here model I and model II, that have gained acceptance for engineering evaluations.

Although the use of standard chemical exergies greatly facilitates the application of exergy principles, the term *standard* is somewhat misleading since there is no one specification of the environment that

suffices for all applications. Still, chemical exergies calculated relative to alternative specifications of the environment are generally in good agreement. For a broad range of engineering applications the simplicity and ease of use of standard chemical exergies generally outweigh any slight lack of accuracy that might result. In particular, the effect of slight variations in the values of  $T_0$  and  $p_0$  about the values used to determine the standard chemical exergies reported in Table 2.12 can be neglected.

The literature of exergy analysis provides several expressions allowing the chemical exergy to be evaluated in particular cases of interest. The molar chemical exergy of a gas mixture, for example, can be evaluated from

$$\bar{e}^{CH} = \sum_{i=1}^j y_i \bar{e}_i^{CH} + \bar{R}T_0 \sum_{i=1}^j y_i \ln y_i \quad (2.90)$$

where  $\bar{e}_i^{CH}$  is the molar chemical exergy of the  $i$ th component.

### Example 13

Ignoring the kinetic and potential exergies, determine the exergy rate, in kJ/kg, associated with each of the following streams of matter:

- (a) Saturated water vapor at 20 bar.
- (b) Methane at 5 bar, 25°C.

Let  $T_0 = 298$  K,  $p_0 = 1.013$  bar (1 atm).

*Solution.* Equation 2.88 reduces to read

$$e = (h - h_0) - T_0(s - s_0) + e^{CH}$$

- (a) From Table A.5,  $h = 2799.5$  kJ/kg,  $s = 6.3409$  kJ/kg · K. At  $T_0 = 298$  K (25°C), water would be a liquid; thus with Equations 2.50c and 2.50d,  $h_0 \approx 104.9$  kJ/kg,  $s_0 \approx 0.3674$  kJ/kg · K. Table 2.12 (model I) gives  $e^{CH} = 45/18.02 = 2.5$  kJ/kg. Then

$$\begin{aligned} e &= (2799.5 - 104.9) - 298(6.3409 - 0.3674) + 2.5 \\ &= 914.5 + 2.5 = 917.0 \text{ kJ/kg} \end{aligned}$$

Here the specific exergy is determined predominately by the physical component.

- (b) Assuming the ideal gas model for methane,  $h - h_0 = 0$ . Also, Equation 2.58 reduces to give  $s - s_0 = -R \ln p/p_0$ . Then, Equation 2.88 reads

$$e = RT_0 \ln p/p_0 + e^{CH}$$

With  $e^{CH} = 824,350/16.04 = 51,393.4$  kJ/kg from Table 2.12 (model I),

$$\begin{aligned} e &= \left( \frac{8.314 \text{ kJ}}{16.04 \text{ kg} \cdot \text{K}} \right) (298 \text{ K}) \ln \frac{5}{1.013} + 51,393.4 \frac{\text{kJ}}{\text{kg}} \\ &= 246.6 + 51,393.4 \\ &= 51,640 \text{ kJ/kg} \end{aligned}$$

Here the specific exergy is determined predominately by the chemical component.

**TABLE 2.12 Standard Molar Chemical Exergy,  $e^{CH}$  (kJ/kmol), of Various Substances at 298 K and  $p_0$** 

Substance	Formula	Model I <sup>a</sup>	Model II <sup>b</sup>

<sup>a</sup> Ahrendts, J. 1977. Die Exergie Chemisch Reaktionsfähiger Systeme, *VDI-Forschungsheft*. VDI-Verlag, Dusseldorf, 579. Also see Reference States, *Energy — The International Journal*, 5: 667–677, 1980. In Model I,  $p_0 = 1.019$  atm. This model attempts to impose a criterion that the reference environment be in equilibrium. The reference substances are determined assuming restricted chemical equilibrium for nitric acid and nitrates and unrestricted thermodynamic equilibrium for all other chemical components of the atmosphere, the oceans, and a portion of the Earth's crust. The chemical composition of the gas phase of this model approximates the composition of the natural atmosphere.

<sup>b</sup> Szargut, J., Morris, D. R., and Steward, F. R. 1988. *Energy Analysis of Thermal, Chemical, and Metallurgical Processes*. Hemisphere, New York. In Model II,  $p_0 = 1.0$  atm. In developing this model a reference substance is selected for each chemical element from among substances that contain the element being considered and that are abundantly present in the natural environment, even though the substances are not in completely mutual stable equilibrium. An underlying rationale for this approach is that substances found abundantly in nature have little economic value. On an overall basis, the chemical composition of the exergy reference environment of Model II is closer than Model I to the composition of the natural environment, but the equilibrium criterion is not always satisfied.

The small difference between  $p_0 = 1.013$  bar and the value of  $p_0$  for model I has been ignored.

## Exergetic Efficiency

The exergetic efficiency (second law efficiency, effectiveness, or rational efficiency) provides a true measure of the performance of a system from the thermodynamic viewpoint. To define the exergetic efficiency both a *product* and a *fuel* for the system being analyzed are identified. The product represents the desired result of the system (power, steam, some combination of power and steam, etc.). Accordingly, the definition of the product must be consistent with the purpose of purchasing and using the system.

The fuel represents the resources expended to generate the product and is not necessarily restricted to being an actual fuel such as a natural gas, oil, or coal. Both the product and the fuel are expressed in terms of exergy.

For a control volume at steady state whose exergy rate balance reads

$$\dot{E}_F = \dot{E}_P + \dot{E}_D + \dot{E}_L$$

the exergetic efficiency is

$$\varepsilon = \frac{\dot{E}_P}{\dot{E}_F} = 1 - \frac{\dot{E}_D + \dot{E}_L}{\dot{E}_F} \quad (2.91)$$

where the rates at which the fuel is supplied and the product is generated are  $\dot{E}_F$  and  $\dot{E}_P$ , respectively.  $\dot{E}_D$  and  $\dot{E}_L$  denote the rates of exergy destruction and exergy loss, respectively. Exergy is destroyed by irreversibilities within the control volume, and exergy is lost from the control volume via stray heat transfer, material streams vented to the surroundings, and so on. The exergetic efficiency shows the percentage of the fuel exergy provided to a control volume that is found in the product exergy. Moreover, the difference between 100% and the value of the exergetic efficiency, expressed as a percent, is the percentage of the fuel exergy wasted in this control volume as exergy destruction and exergy loss.

To apply Equation 2.91, decisions are required concerning what are considered as the fuel and the product. Table 2.13 provides illustrations for several common components. Similar considerations are used to write exergetic efficiencies for systems consisting of several such components, as, for example, a power plant.

Exergetic efficiencies can be used to assess the thermodynamic performance of a component, plant, or industry relative to the performance of *similar* components, plants, or industries. By this means the performance of a gas turbine, for instance, can be gauged relative to the typical present-day performance level of gas turbines. A comparison of exergetic efficiencies for *dissimilar* devices — gas turbines and heat exchangers, for example — is generally not significant, however.

The exergetic efficiency is generally more meaningful, objective, and useful than other efficiencies based on the first or second law of thermodynamics, including the thermal efficiency of a power plant, the isentropic efficiency of a compressor or turbine, and the effectiveness of a heat exchanger. The thermal efficiency of a cogeneration system, for instance, is misleading because it treats both work and heat transfer as having equal thermodynamic value. The isentropic turbine efficiency (Equation 2.95a) does not consider that the working fluid at the outlet of the turbine has a higher temperature (and consequently a higher exergy that may be used in the next component) in the actual process than in the isentropic process. The heat exchanger effectiveness fails, for example, to identify the exergy destruction associated with the pressure drops of the heat exchanger working fluids.

#### Example 14

Evaluate the exergetic efficiency of the turbine in part (a) of Example 1 for  $T_0 = 298 \text{ K}$ .

*Solution.* The exergetic efficiency from Table 2.13 is

$$\varepsilon = \frac{\dot{W}}{\dot{E}_1 - \dot{E}_2} = \frac{\dot{W}}{\dot{m}(e_1 - e_2)}$$

Using Equations 2.88 and 2.89a, and noting that the chemical exergy at 1 and 2 cancels,

**TABLE 2.13 The Exergetic Efficiency for Selected Components at Steady State<sup>a</sup>**

Component	Turbine or Expander	Extraction Turbine	Compressor, Pump, or Fan	Heat Exchanger <sup>b</sup>	Mixing Unit	Gasifier or Combustion Chamber	Boiler
$E_P$	$W$	$W$	$E_2 - E_1$	$E_2 - E_1$	$E_3$	$E_3$	$(E_6 - E_5) + (E_8 - E_7)$
$E_F$	$E_1 - E_2$	$E_1 - E_2 - E_3$	$W$	$E_3 - E_4$	$E_1 + E_2$	$E_1 + E_2$	$(E_1 + E_2) + (E_3 + E_4)$
$\epsilon$	$\frac{W}{E_1 - E_2}$	$\frac{W}{E_1 - E_2 - E_3}$	$\frac{E_2 - E_1}{W}$	$\frac{E_2 - E_1}{E_3 - E_4}$	$\frac{E_3}{E_1 + E_2}$	$\frac{E_3}{E_1 + E_2}$	$\frac{(E_6 - E_5) + (E_8 - E_7)}{(E_1 + E_2) - (E_3 + E_4)}$

<sup>a</sup> For discussion, see Bejan et al. (1996).

<sup>b</sup> This definition assumes that the purpose of the heat exchanger is to heat the cold stream ( $T_1 \geq T_0$ ). If the purpose of the heat exchanger is to provide cooling ( $T_3 \geq T_0$ ), then the following relations should be used:  $E_P = E_4 - E_3$  and  $E_F = E_1 - E_2$ .

$$\varepsilon = \frac{\dot{W}}{\dot{m}[(h_1 - h_2) - T_0(s_1 - s_2)]}$$

Since  $\dot{W} = \dot{m}(h_1 - h_2)$ ,

$$\varepsilon = \frac{\dot{W}}{\dot{W} + \dot{m}T_0(s_2 - s_1)}$$

Finally, using data from Example 1 and  $s_2 = 6.8473 \text{ kJ/kg} \cdot \text{K}$ ,

$$\begin{aligned} \varepsilon &= \frac{30 \text{ MW}}{30 \text{ MW} + \left(\frac{162,357 \text{ kg}}{3600 \text{ s}}\right)(298 \text{ K})(6.8473 - 6.6022) \left(\frac{\text{kJ}}{\text{kg} \cdot \text{K}}\right) \left(\frac{1 \text{ MW}}{10^3 \text{ kJ/sec}}\right)} \\ &= \frac{30 \text{ MW}}{(30 + 3.29) \text{ MW}} = 0.9(90\%) \end{aligned}$$

## Exergy Costing

Since exergy measures the true thermodynamic values of the work, heat, and other interactions between the system and its surroundings as well as the effect of irreversibilities within the system, exergy is a rational basis for assigning costs. This aspect of thermoeconomics is called *exergy costing*.

Referring to [Figure 2.16](#) showing a steam turbine-electric generator at steady state, the total cost to produce the electricity and exiting steam equals the cost of the entering steam plus the cost of owning and operating the device. This is expressed by the *cost rate balance* for the turbine-generator:

$$\dot{C}_e + \dot{C}_2 = \dot{C}_1 + \dot{Z} \quad (2.92a)$$

where  $\dot{C}_e$  is the cost rate associated with the electricity,  $\dot{C}_1$  and  $\dot{C}_2$  are the cost rates associated with the entering steam and exiting steam, respectively, and  $\dot{Z}$  accounts for the cost rate associated with owning and operating the system, each *annualized* in \$ per year.

**FIGURE 2.16** Steam turbine/electric generator used to discuss exergy costing.

With exergy costing, the cost rates  $\dot{C}_1$ ,  $\dot{C}_2$ , and  $\dot{C}_e$  are evaluated in terms of the associated rate of exergy transfer and a *unit cost*. Equation 2.92a then appears as

$$c_e \dot{W}_e + c_2 \dot{E}_2 = c_1 \dot{E}_1 + \dot{Z} \quad (2.92b)$$

The coefficients  $c_1$ ,  $c_2$ , and  $c_e$  in Equation 2.92b denote the *average* cost per unit of exergy for the associated exergy rate. The unit cost  $c_1$  of the entering steam would be obtained from exergy costing applied to the components upstream of the turbine. Assigning the same unit cost to the exiting steam:  $c_2 = c_1$  on the basis that the purpose of the turbine-generator is to generate electricity and thus all costs associated with owning and operating the system should be charged to the power, Equation 2.92b becomes

$$c_e \dot{W}_e = c_1 (\dot{E}_1 - \dot{E}_2) + \dot{Z} \quad (2.92c)$$

The first term on the right side accounts for the cost of the net exergy used and the second term accounts for cost of the system itself. Introducing the exergetic efficiency from Table 2.13, the unit cost of the electricity is

$$c_e = \frac{c_1}{\varepsilon} + \frac{\dot{Z}}{\dot{W}_e} \quad (2.93)$$

This equation shows, for example, that the unit cost of electricity would increase if the exergetic efficiency were to decrease owing to a deterioration of the turbine with use.

### Example 15

A turbine-generator with an exergetic efficiency of 90% develops  $7 \times 10^7$  kW · hr of electricity annually. The annual cost of owning and operating the system is  $\$2.5 \times 10^5$ . If the average unit cost of the steam entering the system is \$0.0165 per kW · hr of exergy, evaluate the unit cost of the electricity.

*Solution.* Substituting values into Equation 2.93,

$$\begin{aligned} c_e &= \frac{\$0.0165/\text{kW} \cdot \text{h}}{0.9} + \frac{\$2.5 \times 10^5/\text{year}}{7 \times 10^7 \text{ kW} \cdot \text{h}/\text{year}} \\ &= 0.0183 + 0.0036 = \$0.0219/\text{kW} \cdot \text{h} \end{aligned}$$

## 2.6 Vapor and Gas Power Cycles

Vapor and gas power systems develop electrical or mechanical power from energy sources of chemical, solar, or nuclear origin. In *vapor* power systems the *working fluid*, normally water, undergoes a phase change from liquid to vapor, and conversely. In *gas* power systems, the working fluid remains a gas throughout, although the composition normally varies owing to the introduction of a fuel and subsequent combustion. The present section introduces vapor and gas power systems. Further discussion is provided in Chapter 8. Refrigeration systems are considered in Chapter 9.

The processes taking place in power systems are sufficiently complicated that idealizations are typically employed to develop tractable thermodynamic models. The *air standard analysis* of gas power systems considered later in the present section is a noteworthy example. Depending on the degree of idealization, such models may provide only qualitative information about the performance of the corresponding real-world systems. Yet such information is frequently useful in gauging how changes in major operating parameters might affect actual performance. Elementary thermodynamic models can also provide simple settings to assess, at least approximately, the advantages and disadvantages of features proposed to improve thermodynamic performance.

### Rankine and Brayton Cycles

In their simplest embodiments vapor power and gas turbine power plants are represented conventionally in terms of four components in series, forming, respectively, the Rankine cycle and the Brayton cycle shown schematically in Table 2.14. The thermodynamically ideal counterparts of these cycles are composed of four internally reversible processes in series: two isentropic processes alternated with two constant pressure processes. Table 2.14 provides property diagrams of the actual and corresponding ideal cycles. Each actual cycle is denoted 1-2-3-4-1; the ideal cycle is 1-2<sub>s</sub>-3-4<sub>s</sub>-1. For simplicity, pressure drops through the boiler, condenser, and heat exchangers are not shown. Invoking Equation 2.29 for the ideal cycles, the heat added per unit of mass flowing is represented by the area *under* the isobar from state 2<sub>s</sub> to state 3: area a-2<sub>s</sub>-3-b-a. The heat rejected is the area *under* the isobar from state 4<sub>s</sub> to state 1: area a-1-4<sub>s</sub>-b-a. Enclosed area 1-2<sub>s</sub>-3-4<sub>s</sub>-1 represents the net heat added per unit of mass flowing. For any power cycle, the net heat added equals the net work done.

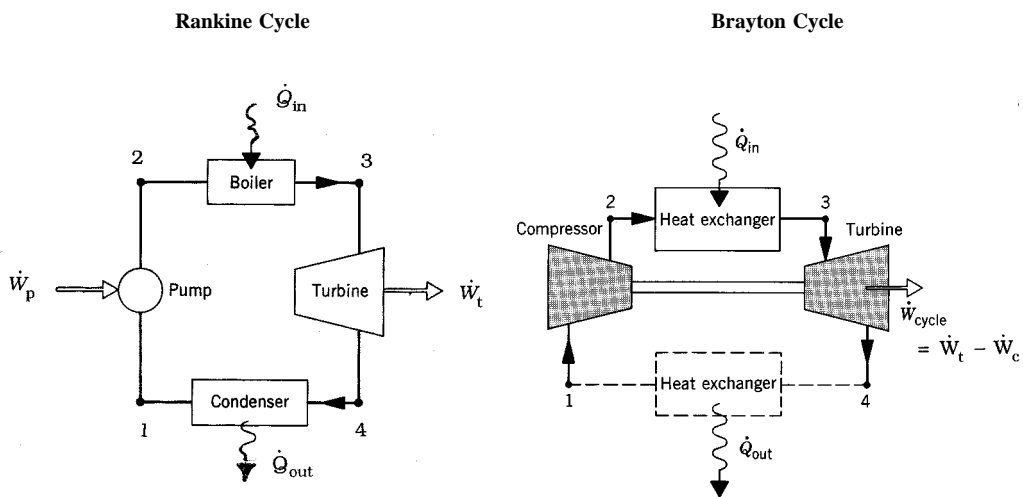

Expressions for the principal energy transfers shown on the schematics of Table 2.14 are provided by Equations 1 to 4 of the table. They are obtained by reducing Equation 2.27a with the assumptions of negligible heat loss and negligible changes in kinetic and potential energy from the inlet to the outlet of each component. All quantities are positive in the directions of the arrows on the figure. Using these expressions, the thermal efficiency is

$$\eta = \frac{(h_3 - h_4) - (h_2 - h_1)}{h_3 - h_2} \quad (2.94)$$

To obtain the thermal efficiency of the ideal cycle,  $h_{2s}$  replaces  $h_2$  and  $h_{4s}$  replaces  $h_4$  in Equation 2.94.

Decisions concerning cycle operating conditions normally recognize that the thermal efficiency tends to increase as the average temperature of heat addition increases and/or the temperature of heat rejection decreases. In the Rankine cycle, a high average temperature of heat addition can be achieved by superheating the vapor prior to entering the turbine, and/or by operating at an elevated steam-generator pressure. In the Brayton cycle an increase in the compressor pressure ratio  $p_2/p_1$  tends to increase the average temperature of heat addition. Owing to materials limitations at elevated temperatures and pressures, the state of the working fluid at the turbine inlet must observe practical limits, however. The turbine inlet temperature of the Brayton cycle, for example, is controlled by providing air far in excess of what is required for combustion. In a Rankine cycle using water as the working fluid, a low temperature of heat rejection is typically achieved by operating the condenser at a pressure below 1 atm. To reduce

TABLE 2.14 Rankine and Brayton Cycles

$$\left. \begin{matrix} \dot{W}_p \\ \dot{W}_c \end{matrix} \right\} = \dot{m}(h_2 - h_1) \quad (> 0) \tag{1}$$

$$\dot{Q}_{in} = \dot{m}(h_3 - h_2) \quad (> 0) \tag{2}$$

$$\dot{W}_t = \dot{m}(h_3 - h_4) \quad (> 0) \tag{3}$$

$$\dot{Q}_{out} = \dot{m}(h_1 - h_4) \quad (> 0) \tag{4}$$

erosion and wear by liquid droplets on the blades of the Rankine cycle steam turbine, at least 90% quality should be maintained at the turbine exit:  $x_4 > 0.9$ .

The *back work ratio*, bwr, is the ratio of the work required by the pump or compressor to the work developed by the turbine:

$$bwr = \frac{h_2 - h_1}{h_3 - h_4} \tag{2.95}$$

As a relatively high specific volume vapor expands through the turbine of the Rankine cycle and a much lower specific volume liquid is pumped, the back work ratio is characteristically quite low in vapor power plants — in many cases on the order of 1 to 2%. In the Brayton cycle, however, both the turbine and compressor handle a relatively high specific volume gas, and the back ratio is much larger, typically 40% or more.

The effect of friction and other irreversibilities for flow-through turbines, compressors, and pumps is commonly accounted for by an appropriate *isentropic efficiency*. The isentropic turbine efficiency is

$$\eta_t = \frac{h_3 - h_4}{h_3 - h_{4s}} \quad (2.95a)$$

The isentropic compressor efficiency is

$$\eta_c = \frac{h_{2s} - h_1}{h_2 - h_1} \quad (2.95b)$$

In the isentropic pump efficiency,  $\eta_p$ , which takes the same form as Equation 2.95b, the numerator is frequently approximated via Equation 2.30c as  $h_{2s} - h_1 \approx v_1 \Delta p$ , where  $\Delta p$  is the pressure rise across the pump.

Simple gas turbine power plants differ from the Brayton cycle model in significant respects. In actual operation, excess air is continuously drawn into the compressor, where it is compressed to a higher pressure; then fuel is introduced and combustion occurs; finally the mixture of combustion products and air expands through the turbine and is subsequently discharged to the surroundings. Accordingly, the low-temperature heat exchanger shown by a dashed line in the Brayton cycle schematic of Table 2.14 is not an actual component, but included only to account formally for the cooling in the surroundings of the hot gas discharged from the turbine.

Another frequently employed idealization used with gas turbine power plants is that of an *air-standard analysis*. An air-standard analysis involves two major assumptions: (1) as shown by the Brayton cycle schematic of Table 2.14, the temperature rise that would be brought about by combustion is effected instead by a heat transfer from an external source; (2) the working fluid throughout the cycle is air, which behaves as an ideal gas. In a *cold* air-standard analysis the specific heat ratio  $k$  for air is taken as constant. Equations 1 to 6 of Table 2.7 together with data from Table A.8 apply generally to air-standard analyses. Equations 1' to 6' of Table 2.7 apply to cold air-standard analyses, as does the following expression for the turbine power obtained from Table 2.1 (Equation 27c'')

$$\dot{W}_t = \dot{m} \frac{kRT_3}{k-1} \left[ 1 - (p_4/p_3)^{(k-1)/k} \right] \quad (2.96)$$

(Equation 2.96 also corresponds to Equation 5' of Table 2.8 when  $n = k$ .) An expression similar in form can be written for the power required by the compressor.

For the simple Rankine and Brayton cycles of Table 2.14 the results of sample calculations are provided in Table 2.15. The Brayton cycle calculations are on an air-standard analysis basis.

## Otto, Diesel, and Dual Cycles

Although most gas turbines are also internal combustion engines, the name is usually reserved to *reciprocating* internal combustion engines of the type commonly used in automobiles, trucks, and buses. Two principal types of reciprocating internal combustion engines are the *spark-ignition* engine and the *compression-ignition* engine. In a spark-ignition engine a mixture of fuel and air is ignited by a spark

plug. In a compression ignition engine air is compressed to a high-enough pressure and temperature that combustion occurs spontaneously when fuel is injected.

In a *four-stroke* internal combustion engine, a piston executes four distinct strokes within a cylinder for every two revolutions of the crankshaft. Figure 2.17 gives a pressure-displacement diagram as it might be displayed electronically. With the intake valve open, the piston makes an *intake stroke* to draw a fresh charge into the cylinder. Next, with both valves closed, the piston undergoes a *compression stroke* raising the temperature and pressure of the charge. A combustion process is then initiated, resulting in a high-pressure, high-temperature gas mixture. A *power stroke* follows the compression stroke, during which the gas mixture expands and work is done on the piston. The piston then executes an *exhaust stroke* in which the burned gases are purged from the cylinder through the open exhaust valve. Smaller engines operate on *two-stroke* cycles. In two-stroke engines, the intake, compression, expansion, and

**FIGURE 2.17** Pressure-displacement diagram for a reciprocating internal combustion engine.

exhaust operations are accomplished in one revolution of the crankshaft. Although internal combustion engines undergo *mechanical* cycles, the cylinder contents do not execute a *thermodynamic* cycle, since matter is introduced with one composition and is later discharged at a different composition.

A parameter used to describe the performance of reciprocating piston engines is the *mean effective pressure*, or *mep*. The mean effective pressure is the theoretical constant pressure that, if it acted on the piston during the power stroke, would produce the same *net* work as actually developed in one cycle. That is,

$$\text{mep} = \frac{\text{net work for one cycle}}{\text{displacement volume}} \quad (2.97)$$

where the displacement volume is the volume swept out by the piston as it moves from the top dead center to the bottom dead center. For two engines of equal displacement volume, the one with a higher mean effective pressure would produce the greater net work and, if the engines run at the same speed, greater power.

Detailed studies of the performance of reciprocating internal combustion engines may take into account many features, including the combustion process occurring within the cylinder and the effects of irreversibilities associated with friction and with pressure and temperature gradients. Heat transfer between the gases in the cylinder and the cylinder walls and the work required to charge the cylinder and exhaust the products of combustion also might be considered. Owing to these complexities, accurate modeling of reciprocating internal combustion engines normally involves computer simulation.

To conduct *elementary* thermodynamic analyses of internal combustion engines, considerable simplification is required. A procedure that allows engines to be studied *qualitatively* is to employ an *air-standard analysis* having the following elements: (1) a fixed amount of air modeled as an ideal gas is the system; (2) the combustion process is replaced by a heat transfer from an external source and generally represented in terms of elementary thermodynamic processes; (3) there are no exhaust and intake processes as in an actual engine: the cycle is completed by a constant-volume heat rejection process; (4) all processes are internally reversible.

The processes employed in air-standard analyses of internal combustion engines are selected to represent the events taking place within the engine simply and mimic the appearance of observed

pressure-displacement diagrams. In addition to the constant volume heat rejection noted previously, the compression stroke and at least a portion of the power stroke are conventionally taken as isentropic. The heat addition is normally considered to occur at constant volume, at constant pressure, or at constant volume followed by a constant pressure process, yielding, respectively, the Otto, Diesel, and Dual cycles shown in Table 2.16.

Reducing the closed system energy balance, Equation 2.8, gives the following expressions for heat and work applicable in each case shown in Table 2.16:

$$\frac{W_{12}}{m} = u_1 - u_2 \quad (< 0)$$

$$\frac{W_{34}}{m} = u_3 - u_4 \quad (> 0)$$

$$\frac{Q_{41}}{m} = u_1 - u_4 \quad (< 0)$$

Table 2.16 provides additional expressions for work, heat transfer, and thermal efficiency identified with each case individually. The thermal efficiency, evaluated from Equation 2.9, takes the form

$$\eta = 1 - \frac{|Q_{41}/m|}{Q_A/m}$$

Equations 1 to 6 of Table 2.7 together with data from Table A.8, apply generally to air-standard analyses. In a *cold* air-standard analysis the specific heat ratio  $k$  for air is taken as constant. Equations 1' to 6' of Table 2.7 apply to cold air-standard analyses, as does Equation 4' of Table 2.8, with  $n = k$  for the isentropic processes of these cycles.

Referring to Table 2.16, the ratio  $v_1/v_2$  is the *compression ratio*,  $r$ . For the Diesel cycle, the ratio  $v_3/v_2$  is the *cutoff ratio*,  $r_c$ . Figure 2.18 shows the variation of the thermal efficiency with compression ratio for an Otto cycle and Diesel cycles having cutoff ratios of 2 and 3. The curves are determined on a cold air-standard basis with  $k = 1.4$  using the following expression:

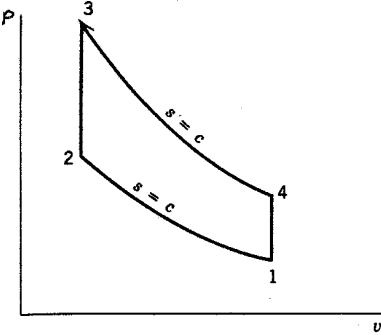

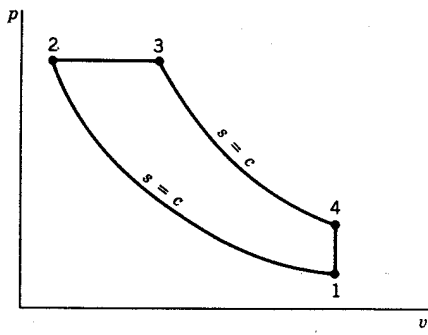

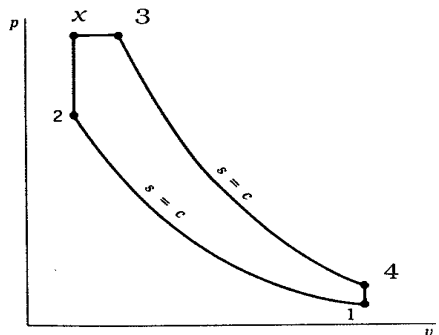

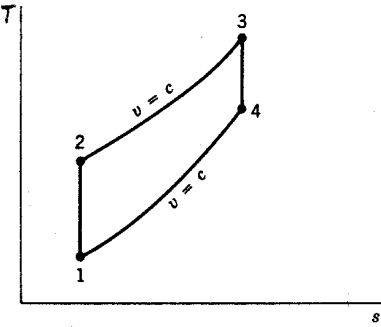

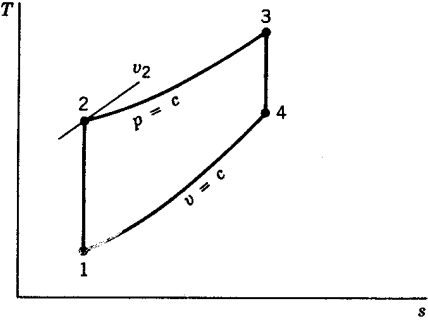

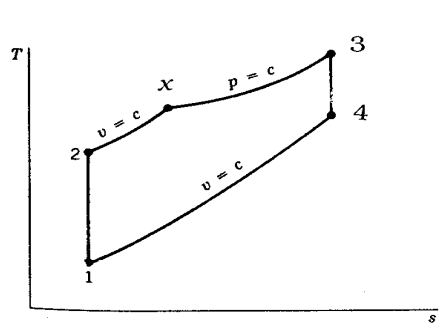

$$\eta = 1 - \frac{1}{r^{k-1}} \left[ \frac{r_c^k - 1}{k(r_c - 1)} \right] \quad (\text{constant } k) \quad (2.98)$$

where the Otto cycle corresponds to  $r_c = 1$ .

As all processes are internally reversible, areas on the  $p$ - $v$  and  $T$ - $s$  diagrams of Table 2.16 can be interpreted, respectively, as work and heat transfer. Invoking Equation 2.10 and referring to the  $p$ - $v$  diagrams, the areas under process 3-4 of the Otto cycle, process 2-3-4 of the Diesel cycle, and process  $x$ -3-4 of the Dual cycle represent the work done by the gas during the power stroke, per unit of mass. For each cycle, the area under the isentropic process 1-2 represents the work done on the gas during the compression stroke, per unit of mass. The enclosed area of each cycle represents the net work done per unit mass. With Equation 2.15 and referring to the  $T$ - $s$  diagrams, the areas under process 2-3 of the Otto and Diesel cycles and under process 2- $x$ -3 of the Dual cycle represent the heat added per unit of mass. For each cycle, the area under the process 4-1 represent the heat rejected per unit of mass. The enclosed area of each cycle represents the net heat added, which equals the net work done, each per unit of mass.

## Carnot, Ericsson, and Stirling Cycles

Three thermodynamic cycles that exhibit the Carnot efficiency (Equation 2.12) are the Carnot, Ericsson, and Stirling cycles shown in Figure 2.19. Each case represents a reversible power cycle in which heat is added from an external source at a constant temperature  $T_H$  (process 2-3) and rejected to the surroundings at a constant temperature  $T_C$  (process 4-1). Carnot cycles can be configured both as vapor power cycles and as cycles executed by a gas in a piston-cylinder assembly (see, e.g., Moran and Shapiro, 1995). Carnot cycles also can be executed in systems where a capacitor is charged and discharged, a paramagnetic substance is magnetized and demagnetized, and in other ways. Regardless of the type of device and the working substance used, the Carnot cycle always has the same four internally reversible processes in series: two isentropic processes alternated with two isothermal processes.

The Ericsson and Stirling cycles also consist of four internally reversible processes in series: heating from state 1 to state 2 (at constant pressure in the Ericsson cycle and at constant volume in the Stirling cycle), isothermal heating from state 2 to state 3 at temperature  $T_H$ , cooling from state 3 to state 4 (at constant pressure in the Ericsson cycle and at constant volume in the Stirling cycle), and isothermal cooling from state 4 to state 1 at temperature  $T_C$ . An ideal regenerator allows the heat input required for process 1-2 to be obtained from the heat rejected in process 3-4. Accordingly, as in the Carnot cycle all the heat added externally occurs at  $T_H$  and all of the heat rejected to the surroundings occurs at  $T_C$ .

The Ericsson and Stirling cycles are principally of theoretical interest as examples of cycles that exhibit the same thermal efficiency as the Carnot cycle: Equation 2.12. However, a practical engine of the piston-cylinder type that operates on a closed regenerative cycle having features in common with the Stirling cycle has been under study in recent years. This engine, known as the *Stirling engine*, offers the opportunity for high efficiency together with reduced emissions from combustion products because the combustion takes place externally and not within the cylinder as in internal combustion engines. In the Stirling engine, energy is transferred to the working fluid from products of combustion, which are kept separate. It is an *external* combustion engine.

**FIGURE 2.19** (A) Carnot, (B) Ericsson, and (C) Stirling cycles.

## 2.7 Guidelines for Improving Thermodynamic Effectiveness

Thermal design frequently aims at the most effective system from the cost viewpoint. Still, in the cost optimization process, particularly of complex energy systems, it is often expedient to begin by identifying a design that is nearly optimal thermodynamically; such a design can then be used as a point of departure for cost optimization. Presented in this section are guidelines for improving the use of fuels (natural gas, oil, and coal) by reducing sources of thermodynamic inefficiency in thermal systems. Further discussion is provided by Bejan et al. (1996).

To improve thermodynamic effectiveness it is necessary to deal directly with inefficiencies related to exergy destruction and exergy loss. The primary contributors to exergy destruction are chemical reaction, heat transfer, mixing, and friction, including unrestrained expansions of gases and liquids. To deal with them effectively, the principal sources of inefficiency not only should be understood qualitatively, but also determined quantitatively, at least approximately. Design changes to improve effectiveness must be done judiciously, however, for the cost associated with different sources of inefficiency can be different. For example, the unit cost of the electrical or mechanical power required to provide for the exergy destroyed owing to a pressure drop is generally higher than the unit cost of the fuel required for the exergy destruction caused by combustion or heat transfer.

Since chemical reaction is a significant source of thermodynamic inefficiency, it is generally good practice to minimize the use of combustion. In many applications the use of combustion equipment such as boilers is unavoidable, however. In these cases a significant reduction in the combustion irreversibility by conventional means simply cannot be expected, for the major part of the exergy destruction introduced by combustion is an inevitable consequence of incorporating such equipment. Still, the exergy destruction in practical combustion systems can be reduced by minimizing the use of excess air and by preheating the reactants. In most cases only a small part of the exergy destruction in a combustion chamber can be avoided by these means. Consequently, after considering such options for reducing the exergy destruction related to combustion, efforts to improve thermodynamic performance should focus on components of the overall system that are more amenable to betterment by cost-effective conventional measures. In other words, *some exergy destructions and energy losses can be avoided, others cannot. Efforts should be centered on those that can be avoided.*

Nonidealities associated with heat transfer also typically contribute heavily to inefficiency. Accordingly, unnecessary or cost-ineffective heat transfer must be avoided. Additional guidelines follow:

- The higher the temperature  $T$  at which a heat transfer occurs in cases where  $T > T_0$ , where  $T_0$  denotes the temperature of the environment (Section 2.5), the more valuable the heat transfer and, consequently, the greater the need to avoid heat transfer to the ambient, to cooling water, or to a refrigerated stream. Heat transfer across  $T_0$  should be avoided.
- The lower the temperature  $T$  at which a heat transfer occurs in cases where  $T < T_0$ , the more valuable the heat transfer and, consequently, the greater the need to avoid direct heat transfer with the ambient or a heated stream.
- Since exergy destruction associated with heat transfer between streams varies inversely with the temperature level, the lower the temperature level, the greater the need to minimize the stream-to-stream temperature difference.
- Avoid the use of intermediate heat transfer fluids when exchanging energy by heat transfer between two streams

Although irreversibilities related to friction, unrestrained expansion, and mixing are often secondary in importance to those of combustion and heat transfer, they should not be overlooked, and the following guidelines apply:

- Relatively more attention should be paid to the design of the lower temperature stages of turbines and compressors (the last stages of turbines and the first stages of compressors) than to the remaining stages of these devices.

- For turbines, compressors, and motors, consider the most thermodynamically efficient options.
- Minimize the use of throttling; check whether power recovery expanders are a cost-effective alternative for pressure reduction.
- Avoid processes using excessively large thermodynamic driving forces (differences in temperature, pressure, and chemical composition). In particular, minimize the mixing of streams differing significantly in temperature, pressure, or chemical composition.
- The greater the mass rate of flow, the greater the need to use the exergy of the stream effectively.
- The lower the temperature level, the greater the need to minimize friction.

*Flowsheeting* or *process simulation* software can assist efforts aimed at improving thermodynamic effectiveness by allowing engineers to readily model the behavior of an overall system, or system components, under specified conditions and do the required thermal analysis, sizing, costing, and optimization. Many of the more widely used flowsheeting programs: ASPEN PLUS, PROCESS, and CHEMCAD are of the *sequential-modular* type. SPEEDUP is a popular program of the *equation-solver* type. Since process simulation is a rapidly evolving field, vendors should be contacted for up-to-date information concerning the features of flowsheeting software, including optimization capabilities (if any). As background for further investigation of suitable software, see Biegler (1989) for a survey of the capabilities of 15 software products.

**FIGURE 3.8.6** Flow patterns for vertical upflow of solid particles and gas or liquid. (From Chen, J.C. 1994. *Proc. Xth Int. Heat Transfer Conf.*, Brighton, U.K., 1:369–386. With permission.)

**FIGURE 3.8.7** Transition at minimum fluidization. (From Chen, J.C. 1996. In *Annual Review of Heat Transfer*, Vol. VII, Begal House, Washington, D.C. With permission.)

where  $\phi$  = sphericity of particles (unity for spherical particles)

$\alpha_{mf}$  = volumetric fraction of fluid at minimum fluidization

Small, light particles have minimum fluidization voidage ( $\alpha_{mf}$ ) of the order 0.6, while larger particles such as sand have values closer to 0.4.

An alternative correlation for estimating the point of minimum fluidization is that of Wen and Yu (1966):

$$\frac{U_{mf} d_p \rho_f}{\mu_f} = (33.7 + 0.041 Ga)^{0.5} - 33.7 \quad (3.8.31)$$

where  $Ga = \rho_f d_p^3 (\rho_s - \rho_f) g / \mu_f^2$ .

When the fluid velocity exceeds  $U_{mf}$ , the two-phase mixture exists in the fluidized state in which the pressure gradient is essentially balanced by the gravitational force on the two-phase mixture:

$$\frac{dP}{dz} = g [\alpha_s \rho_s + \alpha_f \rho_f] \quad (3.8.32)$$

This fluidized state exists until the fluid velocity reaches a significant fraction of the terminal slip velocity, beyond which significant entrainment and transport of the solid particles occur.

### Terminal Slip Velocity

For an isolated single particle the maximum velocity relative to an upflowing fluid is the terminal slip velocity. At this condition, the interfacial drag of the fluid on the particle exactly balances the gravitational body force on the particle:

$$U_t = (U_f - U_s)_t = \left[ \frac{4d_p (\rho_s - \rho_f)}{3\rho_f} \cdot \frac{1}{C_D} \right]^{1/2} \quad (3.8.33)$$

where  $C_D$  = coefficient of drag on the particle.

The coefficient of drag on the particle ( $C_D$ ) depends on the particle Reynolds number:

$$\text{Re}_p = \frac{\rho_f d_p (U_f - U_s)}{\mu_f} \quad (3.8.34)$$

The following expressions may be used to estimate  $C_D$  as appropriate:

$$C_D = \frac{32}{\text{Re}_p}, \quad \text{Re}_p \leq 1$$

$$C_D = \frac{18.5}{\text{Re}_p^{0.67}}, \quad 1 \leq \text{Re}_p \leq 10^3 \quad (3.8.35)$$

### Pneumatic Conveying

A desirable mode of pneumatic conveying is two-phase flow with solid particles dispersed in the concurrent flowing fluid. Such dispersed flows can be obtained if the fluid velocity is sufficiently high. For both horizontal and vertical flows, there are minimum fluid velocities below which saltation of the solid particles due to gravitational force occurs, leading to settling of the solid particles in horizontal channels and choking of the particles in vertical channels. Figures 3.8.8 and 3.8.9 for Zenz and Othmer (1960) show these different regimes of pneumatic conveying for horizontal and vertical transport, respectively. Figure 3.8.8 shows that for a given rate of solids flow ( $W$ ) there is a minimum superficial fluid velocity below which solid particles tend to settle into a dense layer at the bottom of the horizontal channels. Above this saltation threshold, fully dispersed two-phase flow is obtained. In the case of

FIGURE 3.8.8 Flow characteristics in horizontal pneumatic conveying.

FIGURE 3.8.9 Flow characteristics in vertical pneumatic conveying.

vertical transport illustrated in [Figure 3.8.9](#), there is a minimum fluid velocity below which solid particles tend to detrain from the two-phase suspension. This choking limit varies not only with particle properties but also with the actual rate of particle flow. Well-designed transport systems must operate with superficial fluid velocities greater than these limiting saltation and choking velocities.

Zenz and Othmer (1960) recommend the empirical correlations represented in [Figure 3.8.10](#) estimating limiting superficial fluid velocities at incipient saltation or choking, for liquid or gas transport of uniformly sized particles. Note that these correlations are applicable for either horizontal or vertical concurrent flow. [Figure 3.8.10](#) is duplicated from the original source and is based on parameters in engineering units, as noted in the figure. To operate successfully in dispersed pneumatic conveying of solid particles, the superficial fluid velocity must exceed that determined from the empirical correlations of [Figure 3.8.10](#).

## Nomenclature

$A_c$	cross-sectional flow area of channel
$C_o$	Wallis' distribution coefficient
$d_p$	diameter of solid particles
$f_D$	Darcy friction factor
$G$	mass flow flux, $\text{kg/m}^2 \cdot \text{sec}$
$j$	volumetric flow flux, $\text{m/sec}$
$\dot{m}$	mass flow rate, $\text{kg/sec}$
$P$	pressure, $\text{N/m}^2$
$u$	velocity in axial flow direction, $\text{m/sec}$
$v$	superficial velocity in axial flow direction, $\text{m/sec}$
$x$	mass flow quality
$z$	axial coordinate

## 3.9 New-Newtonian Flows

*Thomas F. Irvine Jr. and Massimo Capobianchi*

### Introduction

An important class of fluids exists which differ from Newtonian fluids in that the relationship between the shear stress and the flow field is more complicated. Such fluids are called non-Newtonian or rheological fluids. Examples include various suspensions such as coal–water or coal–oil slurries, food products, inks, glues, soaps, polymer solutions, etc.

An interesting characteristic of rheological fluids is their large “apparent viscosities”. This results in laminar flow situations in many applications, and consequently the engineering literature is concentrated on laminar rather than turbulent flows. It should also be mentioned that knowledge of non-Newtonian fluid mechanics and heat transfer is still in an early stage and many aspects of the field remain to be clarified.

In the following sections, we will discuss the definition and classification of non-Newtonian fluids, the special problems of thermophysical properties, and the prediction of pressure drops in both laminar and turbulent flow in ducts of various cross-sectional shapes for different classes of non-Newtonian fluids.

### Classification of Non-Newtonian Fluids

It is useful to first define a Newtonian fluid since all other fluids are non-Newtonian. Newtonian fluids possess a property called viscosity and follow a law analogous to the Hookian relation between the stress applied to a solid and its strain. For a one-dimensional Newtonian fluid flow, the shear stress at a point is proportional to the rate of strain (called in the literature the *shear rate*) which is the velocity gradient at that point. The constant of proportionality is the dynamic viscosity, i.e.,

$$\tau_{y,x} = \mu \frac{du}{dy} = \mu \dot{\gamma} \quad (3.9.1)$$

where  $x$  refers to the direction of the shear stress  $y$  the direction of the velocity gradient, and  $\dot{\gamma}$  is the shear rate. The important characteristic of a Newtonian fluid is that the dynamic viscosity is independent of the shear rate.

Equation (3.9.1) is called a constitutive equation, and if  $\tau_{x,y}$  is plotted against  $\dot{\gamma}$ , the result is a linear relation whose slope is the dynamic viscosity. Such a graph is called a *flow curve* and is a convenient way to illustrate the viscous properties of various types of fluids.

Fluids which do not obey Equation (3.9.1) are called non-Newtonian. Their classifications are illustrated in [Figure 3.9.1](#) where they are separated into various categories of purely viscous time-independent or time-dependent fluids and viscoelastic fluids. Viscoelastic fluids, which from their name possess both viscous and elastic properties (as well as memory), have received considerable attention because of their ability to reduce both drag and heat transfer in channel flows. They will be discussed in a later subsection.

Purely viscous time-dependent fluids are those in which the shear stress is a function only of the shear rate but in a more complicated manner than that described in Equation (3.9.1). [Figure 3.9.2](#) illustrates the characteristics of purely viscous time-independent fluids. In the figure, (a) and (b) are fluids where the shear stress depends only on the shear rate but in a nonlinear way. Fluid (a) is called pseudoplastic (or shear thinning), and fluid (b) is called dilatant (or shear thickening). Curve (c) is one which has an initial yield stress after which it acts as a Newtonian fluid, called Buckingham plastic, and curve (d), called Hershel-Buckley, also has a yield stress after which it becomes pseudoplastic. Curve (e) depicts a Newtonian fluid.

[Figure 3.9.3](#) shows flow curves for two common classes of purely viscous time-dependent non-Newtonian fluids. It is seen that such fluids have a hysteresis loop or memory whose shape depends

FIGURE 3.9.1 Classification of fluids.

FIGURE 3.9.2 Flow curves of purely viscous, time-independent fluids: (a) pseudoplastic; (b) dilatant; (c) Bingham plastic; (d) Hershel–Buckley; (e) Newtonian.

FIGURE 3.9.3 Flow curves for purely viscous, time-dependent fluids: (a) thixotropic; (b) rheopectic.

upon the time-dependent rate at which the shear stress is applied. Curve (a) illustrates a pseudoplastic time-dependent fluid and curve (b) a dilatant time-dependent fluid. They are called, respectively, thixotropic and rheopectic fluids and are complicated by the fact that their flow curves are difficult to characterize for any particular application.

## Apparent Viscosity

Although non-Newtonian fluids do not have the property of viscosity, in the Newtonian fluid sense, it is convenient to define an apparent viscosity which is the ratio of the local shear stress to the shear rate at that point.

$$\mu_a = \frac{\tau}{\dot{\gamma}} \quad (3.9.2)$$

The apparent viscosity is not a true property for non-Newtonian fluids because its value depends upon the flow field, or shear rate. Nevertheless, it is a useful quantity and flow curves are often constructed with the apparent viscosity as the ordinate and shear rate as the abscissa. Such a flow curve will be illustrated in a later subsection.

## Constitutive Equations

A constitutive equation is one that expresses the relation between the shear stress or apparent viscosity and the shear rate through the rheological properties of the fluid. For example, Equation (3.9.1) is the constitutive equation for a Newtonian fluid.

Many constitutive equations have been developed for non-Newtonian fluids with some of them having as many as five rheological properties. For engineering purposes, simpler equations are normally satisfactory and two of the most popular will be considered here.

Since many of the non-Newtonian fluids in engineering applications are pseudoplastic, such fluids will be used in the following to illustrate typical flow curves and constitutive equations. Figure 3.9.4 is a qualitative flow curve for a typical pseudoplastic fluid plotted with logarithmic coordinates. It is seen in the figure that at low shear rates, region (a), the fluid is Newtonian with a constant apparent viscosity of  $\mu_0$  (called the *zero shear rate viscosity*). At higher shear rates, region (b), the apparent viscosity begins to decrease until it becomes a straight line, region (c). This region (c) is called the power law region and is an important region in fluid mechanics and heat transfer. At higher shear rates than the power law region, there is another transition region (d) until again the fluid becomes Newtonian in region (e). As discussed below, regions (a), (b), and (c) are where most of the engineering applications occur.

**FIGURE 3.9.4** Illustrative flow curve for a pseudoplastic fluid (a) Newtonian region; (b) transition region I; (c) power law region; (d) transition region II; (e) high-shear-rate Newtonian region.

### Power Law Constitutive Equation

Region (c) in [Figure 3.9.4](#), which was defined above as the power law region, has a simple constitutive equation:

$$\tau = K\dot{\gamma}^n \quad (3.9.3)$$

or, from Equation (3.9.2):

$$\mu_a = K\dot{\gamma}^{n-1} \quad (3.9.4)$$

Here,  $K$  is called the fluid consistency and  $n$  the flow index. Note that if  $n = 1$ , the fluid becomes Newtonian and  $K$  becomes the dynamic viscosity. Because of its simplicity, the power law constitutive equation has been most often used in rheological studies, but at times it is inappropriate because it has several inherent flaws and anomalies. For example, if one considers the flow of a pseudoplastic fluid ( $n < 1$ ) through a circular duct, because of symmetry at the center of the duct the shear rate (velocity gradient) becomes zero and thus the apparent viscosity from Equation (3.9.4) becomes infinite. This poses conceptual difficulties especially when performing numerical analyses on such systems. Another difficulty arises when the flow field under consideration is not operating in region (c) of [Figure 3.9.4](#) but may have shear rates in region (a) and (b). In this case, the power law equation is not applicable and a more general constitutive equation is needed.

### Modified Power Law Constitutive Equation

A generalization of the power law equation which extends the shear rate range to regions (a) and (b) is given by

$$\mu_a = \frac{\mu_o}{1 + \frac{\mu_o}{K}\dot{\gamma}^{1-n}} \quad (3.9.5)$$

Examination of Equation (3.9.5) reveals that at low shear rates, the second term in the denominator becomes small compared with unity and the apparent viscosity becomes a constant equal to  $\mu_o$ . This represents the Newtonian region in [Figure 3.9.4](#). On the other hand, as the second term in the denominator becomes large compared with unity, Equation (3.9.5) becomes Equation (3.9.4) and represents region (c), the power law region. When both denominator terms must be considered, Equation (3.9.5) represents region (b) in [Figure 3.9.4](#).

An important advantage of the modified power law equation is that it retains the rheological properties  $K$  and  $n$  of the power law model plus the additional property  $\mu_o$ . Thus, as will be shown later, in the flow and heat transfer equations, the same dimensionless groups as in the power law model will appear plus an additional dimensionless parameter which describes in which of the regions (a), (b), or (c) a particular system is operating. Also, solutions using the modified power law model will have Newtonian and power law solutions as asymptotes.

Equation (3.9.5) describes the flow curve for a pseudoplastic fluid ( $n < 1$ ). For a dilatant fluid, ( $n > 1$ ), an appropriate modified power law model is given by

$$\mu_a = \mu_o \left[ 1 + \frac{K}{\mu_o} \dot{\gamma}^{n-1} \right] \quad (3.9.6)$$

Many other constitutive equations have been proposed in the literature (Skelland, 1967; Cho and Hartnett, 1982; Irvine and Karni, 1987), but the ones discussed above are sufficient for a large number of engineering applications and agree well with the experimental determinations of rheological properties.

## Rheological Property Measurements

For non-Newtonian fluids, specifying the appropriate rheological properties for a particular fluid is formidable because such fluids are usually not pure substances but various kinds of mixtures. This means that the properties are not available in handbooks or other reference materials but must be measured for each particular application. A discussion of the various instruments for measuring rheological properties is outside the scope of the present section, but a number of sources are available which describe different rheological property measurement techniques and instruments: Skelland (1967), Whorlow (1980), Irvine and Karni (1987), and Darby (1988). Figure 3.9.5 is an illustration of experimental flow curves measured with a falling needle viscometer and a square duct viscometer for polymer solutions of different concentrations. Also known in the figure as solid lines is the modified power law equation used to represent the experimental data. It is seen that Equation (3.9.5) fits the experimental data within  $\pm 2\%$ . Table 3.9.1 lists the rheological properties used in the modified power law equations in Figure 3.9.5. It must be emphasized that a proper knowledge of these properties is vital to the prediction of fluid mechanics and heat transfer phenomena in rheological fluids.

**TABLE 3.9.1 Rheological Properties Used in the Modified Power Law Equations in Figure 3.9.5 for Three Polymer Solutions of CMC-7H4**

CMC	$K$ ( $\text{N} \cdot \text{sec}^n/\text{m}^2$ )	$n$	$\mu_o$ ( $\text{N} \cdot \text{sec}/\text{m}^2$ ) $n$

## Fully Developed Laminar Pressure Drops for Time-Independent Non-Newtonian Fluids

### Modified Power Law Fluids

This important subject will be considered by first discussing modified power law fluids. The reason is that such solutions include both friction factor–Reynolds number relations and a shear rate parameter. The latter allows the designer to determine the shear rate region in which his system is operating and thus the appropriate solution to be used, i.e., regions (a), (b), or (c) in Figure 3.9.4.

For laminar fully developed flow of a modified power law fluid in a circular duct, the product of the friction factor and a certain Reynolds number is a constant depending on the flow index,  $n$ , and the shear rate parameter,  $\beta$ .

$$f_D \cdot \text{Re}_m = \text{constant}(n, \beta) \quad (3.9.7)$$

where  $f_D$  is the Darcy friction factor and  $\text{Re}_m$  the modified power law Reynolds number, i.e.,

$$f_D = \frac{2 \Delta p D_H}{L \rho \bar{u}^2} \quad (\text{Darcy friction factor})^*$$

\* It should be noted that the Fanning friction factor is also used in the technical literature. The Fanning friction factor is  $1/4$  of the Darcy friction factor, and will be characterized by the symbol  $f_F$ .

**FIGURE 3.9.5** Experimental measurements of apparent viscosity vs. shear rate for polymer solutions (CMC-7H4) at different concentrations. (From Park, S. et al., in *Proc. Third World Conf. Heat Transfer, Fluid Mechanics, and Thermodynamics*, Vol. 1, Elsevier, New York, 1993, 900–908.).

$$Re_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

$$\mu^* = \frac{\mu_o}{1 + \beta}$$

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n}$$

where  $\beta$  is the shear rate parameter mentioned previously which can be calculated by the designer for a certain operating duct ( $\bar{u}$  and  $d$ ) and a certain pseudoplastic fluid ( $\mu_o$ ,  $K$ ,  $n$ ). The solution for a circular tube has been calculated by Brewster and Irvine (1987) and the results are shown in [Figure 3.9.6](#) and in [Table 3.9.2](#). Referring to 3.9.6, we can see that when the  $\log_{10} \beta$  is less than approximately  $-2$ , the duct is operating in region (a) of [Figure 3.9.4](#) which is the Newtonian region and therefore classical Newtonian solutions can be used. Note that in the Newtonian region,  $Re_m$  reverts to the Newtonian Reynolds number given by

**FIGURE 3.9.6** Product of friction factor and modified Reynolds number vs.  $\log_{10} \beta$  for a circular duct.

**TABLE 3.9.2** Summary of Computed Values of  $f_D \cdot Re_m$  for Various Values of  $n$  and  $\beta$  for a Circular Duct

Source: Brewster, R.A. and Irvine, T.F., Jr., *Wärme und Stoffübertragung*, 21, 83–86, 1987. With permission.

$$\text{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o} \quad (3.9.8)$$

When the value of  $\log_{10} \beta$  is approximately in the range  $-2 \leq \log_{10} \beta \leq 2$ , the duct is operating in the transition region (b) of Figure 3.9.4 and the values of  $f_D \cdot \text{Re}_m$  must be obtained from Figure 3.9.6 or from Table 3.9.2.

When  $\log_{10} \beta$  is greater than approximately 2, the duct is operating in the power law region (c) of Figure 3.9.4 and power law friction factor Reynolds number relations can be used. They are also indicated in Figure 3.9.6 and Table 3.9.2. In this region,  $\text{Re}_m$  becomes the power law Reynolds number given by

$$\text{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K} \quad (3.9.9)$$

For convenience, Brewster and Irvine (1987) have presented a correlation equation which agrees within 0.1% with the results tabulated in Table 3.9.2.

$$f_D \cdot \text{Re}_m = \frac{1 + \beta}{\frac{1}{64} + \frac{\beta}{2^{3n+3} \left( \frac{3n+1}{4n} \right)^n}} \quad (3.9.10)$$

Thus, Equation (3.9.10) contains all of the information required to calculate the circular tube laminar fully developed pressure drop for a pseudoplastic fluid depending upon the shear rate region(s) under consideration, i.e., regions (a), (b), or (c) of Figure 3.9.4. Note that in scaling such non-Newtonian systems, both  $\text{Re}_m$  and  $\beta$  must be held constant. Modified power law solutions have been reported for two other duct shapes. Park et al. (1993) have presented the friction factor–Reynolds number relations for rectangular ducts and Capobianchi and Irvine (1992) for concentric annular ducts.

### Power Law Fluids

Since the power law region of modified power law fluids ( $\log_{10} \beta \geq 2$ ) is often encountered, the friction factor–Reynolds number relations will be discussed in detail in this subsection.

An analysis of power law fluids which is most useful has been presented by Kozicki et al. (1967). Although the method is approximate, its overall accuracy ( $\pm 5\%$ ) is usually sufficient for many engineering calculations. His expression for the friction factor–Reynolds number product is given by

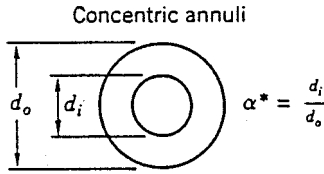

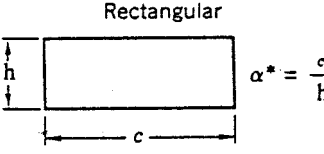

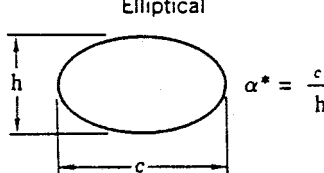

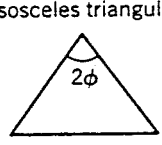

$$f_D \cdot \text{Re}^* = 2^{6n} \quad (3.9.11)$$

where

$$\text{Re}^* = \text{Kozicki Reynolds number}, \quad \text{Re}^* = \frac{\text{Re}_g}{\left[ \frac{a + bn}{n} \right]^n 8^{n-1}} \quad (3.9.12)$$

and  $a$  and  $b$  are geometric constants which depend on the cross-sectional shape of the duct. For example, for a circular duct,  $a = 0.25$  and  $b = 0.75$ . Values of  $a$  and  $b$  for other duct shapes are tabulated in Table 3.9.3. For additional duct shapes in both closed and open channel flows, Kozicki et al. (1967) may be consulted.

### Fully Developed Turbulent Flow Pressure Drops

In a number of engineering design calculations for turbulent flow, the shear rate range falls in region (c) of Figure 3.9.4. Thus, power law relations are appropriate for such pressure drop calculations.

Hartnett and Kostic (1990) have investigated the various correlations which have appeared in the literature for circular tubes and have concluded that for a circular tube the relation proposed by Dodge and Metzner (1959) is the most reliable for pseudoplastic fluids. It is given by

$$\frac{1}{f_F^{1/2}} = \frac{4.0}{n^{0.75}} \cdot \log_{10} \left[ \text{Re}'_g (f_F)^{1-(1/2n)} \right] - \frac{0.40}{n^{1.2}} \tag{3.9.13}$$

where  $f_F$  is the Fanning friction factor and

$$\text{Re}'_g = \text{Re}_g \left[ \frac{8^{1-n}}{\left[ \frac{3n+1}{4n} \right]^n} \right] \tag{3.9.14}$$

Figure 3.9.7 is a graphical representation of Equation (3.9.13) which indicates the Dodge and Metzner experimental regions by solid lines, and by dashed lines where the data are extrapolated outside of their experiments.

**FIGURE 3.9.7** Dodge and Metzner relation between Fanning friction factor and  $\text{Re}'_g$ . (From Dodge, D.W. and Metzner, A.B., *AIChE J.*, 5, 189–204, 1959.)

For noncircular ducts in turbulent fully developed flow, only a limited amount of experimental data are available. Kostic and Hartnett (1984) suggest the correlation:

$$\frac{1}{f_F^{1/2}} = \frac{4}{n^{0.75}} \cdot \log_{10} \left[ \text{Re}^* (f_F)^{1-(1/2n)} \right] - \frac{0.40}{n^{0.5}} \tag{3.9.15}$$

where  $f_F$  is again the Fanning friction factor and  $\text{Re}^*$  is the Kozicki Reynolds number:

$$\text{Re}^* = \frac{\text{Re}_g}{\left[ \frac{a+bn}{n} \right]^n 8^{n-1}} \tag{3.9.16}$$

and  $a$  and  $b$  are geometric constants given in Table 3.9.3.

## Viscoelastic Fluids

### Fully Developed Turbulent Flow Pressure Drops

Viscoelastic fluids are of interest in engineering applications because of reductions of pressure drop and heat transfer which occur in turbulent channel flows. Such fluids can be prepared by dissolving small amounts of high-molecular-weight polymers, e.g., polyacrylamide, polyethylene oxide (Polyox), etc., in water. Concentrations as low as 5 parts per million by weight (wppm) result in significant pressure drop reductions. Figure 3.9.8 from Cho and Hartnett (1982) illustrates the reduction in friction factors for Polyox solutions in a small-diameter capillary tube. It is seen that at zero polymer concentration the data agree with the Blasius equation for Newtonian turbulent flow. With the addition of only 7 wppm of Polyox, there is a significant pressure drop reduction and for concentrations of 70 wppm and greater all the data fall on the Virk line which is the maximum drag-reduction asymptote. The correlations for the Blasius and Virk lines as reported by Cho and Hartnett (1982) are

$$f_F = \frac{0.079}{\text{Re}_a^{1/4}} \quad (\text{Blasius}) \quad (3.9.17)$$

$$f_F = 0.20 \text{Re}_a^{-0.48} \quad (\text{Virk}) \quad (3.9.18)$$

**FIGURE 3.9.8** Reduction in friction factors for polyethylene oxide (Polyox) solutions in a small-diameter capillary tube. (From Cho, Y.I. and Hartnett, J.P., *Adv. Heat Transfer*, 15, 59–141, 1982. With permission.)

At the present time, no generally accepted method exists to predict the drag reduction between the Blasius and Virk lines. Kwack and Hartnett (1983) have proposed that the amount of drag reduction between those two correlations is a function of the Weissenberg number, defined as

$$w_s = \frac{\lambda \bar{u}}{D_H} \quad (3.9.19)$$

where  $\lambda$  = characteristic time of the viscoelastic fluid. They present correlations which allow the friction factor to be estimated at several Reynolds numbers between the Blasius and Virk lines.

### Fully Developed Laminar Flow Pressure Drops

The above discussion on viscoelastic fluids has only considered fully developed turbulent flows. Laminar fully developed flows can be considered as nonviscoelastic but purely viscous non-Newtonian. Therefore, the method of Kozicki et al. (1967) may be applied to such situations once the appropriate rheological properties have been determined.

### Nomenclature

- $a$  = duct shape geometric constant  
 $b$  = duct shape geometric constant  
 $c$  = duct width (see Table 3.9.3) (m)  
 $d_i$  = concentric annuli inner diameter (see Table 3.9.3) (m)  
 $d_o$  = concentric annuli outer diameter (see Table 3.9.3) (m)  
 $f_D$  = Darcy friction factor  
 $f_F$  = Fanning friction factor  
 $h$  = duct height (see Table 3.9.3) (m)  
 $K$  = fluid consistency ( $\text{Ns}^n/\text{m}^2$ )  
 $n$  = flow index  
 $N$  = number of sides in polygon (see Table 3.9.3)  
 $\text{Re}_g$  = generalized Reynolds number,

$$\text{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K}$$

$\text{Re}_m$  = modified power law Reynolds number,

$$\text{Re}_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

$\text{Re}_N$  = modified power law Reynolds number Newtonian asymptote,

$$\text{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o}$$

$\text{Re}_a$  = apparent Reynolds number

$$\text{Re}_a = \frac{\text{Re}_g}{\left(\frac{3n+1}{4n}\right)^{n-1} 8^{n-1}}$$

$\text{Re}^*$  = Kozicki Reynolds number

$$\text{Re}^* = \frac{\rho \bar{u}^{2-n} D_H^n}{K \left[\frac{a+bn}{n}\right]^n 8^{n-1}}$$

$Re'_g$  = Metzner Reynolds number

$$Re'_g = Re_g \left[ \frac{8^{1-n}}{\left[ \frac{3n+1}{4n} \right]^n} \right]$$

$\bar{u}$  = average streamwise velocity (m/sec)

$t$  = time (sec)

$w_s$  = Weissenberg number

$x$  = direction of shear stress (m)

$y$  = direction of velocity gradient (m)

## Greek

$\alpha^*$  = duct aspect ratio in [Table 3.9.3](#)

$\beta$  = shear rate parameter

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n}$$

$\dot{\gamma}$  = shear rate (L/sec)

$\Delta P$  = pressure drop (N/m<sup>2</sup>)

$\lambda$  = characteristic time of viscoelastic fluid (sec)

$\mu_a$  = apparent viscosity (N · sec/m<sup>2</sup>)

$\mu_o$  = zero shear rate viscosity (N · sec/m<sup>2</sup>)

$\mu_\infty$  = high shear rate viscosity (N · sec/m<sup>2</sup>)

$\mu^*$  = reference viscosity

$$\mu^* = \frac{\mu_o}{1 + \beta} \left( \text{N} \cdot \text{sec}/\text{m}^2 \right)$$

$\tau_o$  = yield stress (N/m<sup>2</sup>)

$\tau_{y,x}$  = shear stress (N/m<sup>2</sup>)

$\phi$  = half apex angle (see [Table 3.9.3](#)) (°)

### Further Information

It is not possible to include all of the interesting non-Newtonian topics in a section of this scope. Other items which may be of interest and importance are listed below along with appropriate references: hydrodynamic and thermal entrance lengths, Cho and Hartnett (1982); non-Newtonian flow over external surfaces, Irvine and Karni (1987); chemical, solute, and degradation effects in viscoelastic fluids, Cho and Harnett (1982); general references, Skelland (1967), Whorlow (1980), and Darby (1988).

## 3.10 Tribology, Lubrication, and Bearing Design

*Francis E. Kennedy, E. Richard Booser, and Donald F. Wilcock*

### Introduction

Tribology, the science and technology of contacting surfaces involving friction, wear, and lubrication, is extremely important in nearly all mechanical components. A major focus of the field is on friction, its consequences, especially wear and its reduction through lubrication and material surface engineering. The improper solution of tribological problems is responsible for huge economic losses in our society, including shortened component lives, excessive equipment downtime, and large expenditures of energy. It is particularly important that engineers use appropriate means to reduce friction and wear in mechanical systems through the proper selection of bearings, lubricants, and materials for all contacting surfaces. The aim of this section is to assist in that endeavor.

### Sliding Friction and its Consequences

#### Coefficient of Friction

If two stationary contacting bodies are held together by a normal force  $W$  and a tangential force is applied to one of them, the tangential force can be increased until it reaches a magnitude sufficient to initiate sliding. The ratio of the friction force at incipient sliding to the normal force is known as the static coefficient of friction,  $f_s$ . After sliding begins, the friction force always acts in the direction opposing motion and the ratio between that friction force and the applied normal force is the kinetic coefficient of friction,  $f_k$ .

Generally,  $f_k$  is slightly smaller than  $f_s$  and both coefficients are independent of the size or shape of the contacting surfaces. Both coefficients are very much dependent on the materials and cleanliness of the two contacting surfaces. For ordinary metallic surfaces, the friction coefficient is not very sensitive to surface roughness. For ultrasmooth or very rough surfaces, however, the friction coefficient can be larger. Typical friction coefficient values are given in Table 3.10.1. Generally, friction coefficients are greatest when the two surfaces are identical metals, slightly lower with dissimilar but mutually soluble metals, still lower for metal against nonmetal, and lowest for dissimilar nonmetals.

**TABLE 3.10.1 Some Typical Friction Coefficients<sup>a</sup>**

Material Pair	Static Friction Coefficient $f_s$		Kinetic Friction Coefficient $f_k$	
	In Air	In Vacuo	In Air, Dry	Oiled
Mild steel vs. mild steel	0.75	—	0.57	0.16
Mild steel vs. copper	0.53	0.5 (oxidized) 2.0 (clean)	0.36	0.18
Copper vs. copper	1.3	21.0	0.8	0.1
Tungsten carbide vs. copper	0.35	—	0.4	—
Tungsten carbide vs. tungsten carbide	0.2	0.4	0.15	—
Mild steel vs. polytetrafluoroethylene	0.04	—	0.05	0.04

<sup>a</sup> The friction coefficient values listed in this table were compiled from several of the references listed at the end of this section.

The kinetic coefficient of friction,  $f_k$ , for metallic or ceramic surfaces is relatively independent of sliding velocity at low and moderate velocities, although there is often a slight decrease in  $f_k$  at higher velocities. With polymers and soft metals there may be an increase in the friction coefficient with increasing velocity until a peak is reached, after which friction may decrease with further increases in velocity or temperature. The decrease in kinetic friction coefficient with increasing velocity, which may become especially pronounced at higher sliding velocities, can be responsible for friction-induced

vibrations (stick–slip oscillations) of the sliding systems. Such vibrations are an important design consideration for clutches and braking systems, and can also be important in the accurate control and positioning of robotic mechanisms and precision manufacturing systems.

### Wear

Wear is the unwanted removal of material from solid surfaces by mechanical means; it is one of the leading reasons for the failure and replacement of manufactured products. It has been estimated that the costs of wear, which include repair and replacement, along with equipment downtime, constitute up to 6% of the U.S. gross national product (Rabinowicz, 1995). Wear can be classified into four primary types: sliding wear, abrasion, erosion, and corrosive wear. Owing to its importance, wear and its control have been the subject of several handbooks (Peterson and Winer, 1980; Blau, 1992), which the interested reader may consult for further information.

*Types of Wear.* *Sliding wear* occurs to some degree whenever solid surfaces are in sliding contact. There are two predominant sliding wear mechanisms, adhesion and surface fatigue. *Adhesive wear* is caused by strong adhesive forces between the two surfaces within the real area of contact. It results in the removal of small particles from at least one of the surfaces, usually the softer one. These particles can then transfer to the other surface or mix with other material from both surfaces before being expelled as loose wear debris. Adhesive wear can be particularly severe for surfaces which have a strong affinity for each other, such as those made from identical metals. *Surface fatigue wear* occurs when repeated sliding or rolling/sliding over a wear track results in the initiation of surface or subsurface cracks, and the propagation of those cracks produces wear particles in ductile materials by a process that has been called delamination. With brittle materials, sliding wear often occurs by a *surface fracture* process.

After an initial transition or “running-in” period, sliding wear tends to reach a steady state rate which is approximated by the following Archard (or Holm/Archard) wear equation:

$$V = K * W * s / H \quad (3.10.1)$$

where  $V$  = volume of worn material,  $K$  = dimensionless wear coefficient,  $s$  = sliding distance,  $W$  = normal load between the surfaces, and  $H$  = hardness of the softer of the two contacting surfaces.

The dimensionless wear coefficient gives an indication of the tendency of a given material combination to wear; relative wear coefficient values are given in Figure 3.10.1. In general, wear coefficients are highest for identical metals sliding without lubrication, and wear is decreased by adding a lubricant and by having material pairs which are dissimilar.

*Abrasive wear* occurs when a hard, rough surface slides against a softer surface (*two-body abrasion*) or when hard particles slide between softer surfaces (*three-body abrasion*). This process usually results in material removal by plowing or chip formation, especially when the abraded surface is metallic; surface fracture can occur during abrasion of brittle surfaces. In fact, abrasion mechanisms are similar to those of grinding and lapping, which could be considered as intentional abrasion. Consideration of the cutting and plowing processes shows that abrasive wear obeys the same equation (3.10.1) as sliding wear (Archard, 1980; Rabinowicz, 1995). Typical wear coefficients for abrasive wear are given in Figure 3.10.1. Since the relative size, hardness, and sharpness of the abrading particles, or surface asperities, also affect abrasive wear rates, the wear coefficients for abrasion must include recognition of those factors (Rabinowicz, 1995).

*Erosion* occurs when solid particles or liquid droplets impinge on a solid surface. When impingement is on a ductile metallic surface, the wear process is similar to that caused by abrasion, and is dominated by plastic deformation. Brittle surfaces, on the other hand, tend to erode by surface fracture mechanisms. The material removal rate is dependent on the angle of attack of the particles, with erosion reaching a peak at low angles (about 20°) for ductile surfaces and at high angles (90°) for brittle materials. In either case, the wear rate is proportional to the mass rate of flow of the particles and to their kinetic energy; it is inversely proportional to the hardness of the surface and the energy-absorbing potential (or toughness)

**FIGURE 3.10.1** Typical values of wear coefficient for sliding and abrasive wear. (Modified from Rabinowicz, 1980, 1995.)

of the impinged surface (Schmitt, 1980). Although erosion is usually detrimental, it can be used beneficially in such material removal processes as sandblasting and abrasive water jet machining.

*Corrosive wear* results from a combination of chemical and mechanical action. It involves the synergistic effects of chemical attack (corrosion) of the surface, followed by removal of the corrosion products by a wear mechanism to expose the metallic surface, and then repetition of those processes. Since many corrosion products act to protect the surfaces from further attack, the removal of those films by wear acts to accelerate the rate of material removal. Corrosive wear can become particularly damaging when it acts in a low-amplitude oscillatory contact, which may be vibration induced, in which case it is called *fretting corrosion*.

#### Means for Wear Reduction.

The following actions can be taken to limit sliding wear:

- Insure that the sliding surfaces are well lubricated. This can best be accomplished by a liquid lubricant (see sub-section on effect of lubrication on friction and wear), but grease, or solid lubricants such as graphite or molybdenum disulfide, can sometimes be effective when liquid lubricants cannot be used.
- Choose dissimilar materials for sliding pairs.
- Use hardened surfaces.
- Add wear-resistant coatings to the contacting surfaces (see the following subsection).
- Reduce normal loads acting on the contact.
- Reduce surface temperatures. This is particularly important for polymer surfaces.

To reduce abrasive wear:

- Use hardened surfaces.
- Add a hard surface coating.
- Reduce the roughness of hard surfaces that are in contact with softer surfaces.
- Provide for the removal of abrasive particles from contacting surfaces. This can be done by flushing surfaces with liquid and/or filtering liquid coolants and lubricants.
- Reduce the size of abrasive particles.

To reduce erosion:

- Modify the angle of impingement of solid particles or liquid droplets.
- Provide for the removal of solid particles from the stream of fluid.
- Use hardened surfaces.
- Use tough materials for surfaces.
- Add protective coating to surfaces.

**Surface Engineering for Friction and Wear Reduction**

Surface treatments have long been an important remedy for wear problems, and that importance has grown in recent years with the introduction of new techniques to harden surfaces or apply hard surface coatings. Available processes and characteristics for treating a steel substrate are listed in Table 3.10.2.

*Thermal transformation hardening* processes are used to harden ferrous (primarily steel) surfaces by heating the surface rapidly, transforming it to austenite, and then quenching it to form martensite. The source of heat can be one of the following: an oxyacetylene or oxypropane flame (*flame hardening*), eddy currents induced by a high-frequency electric field (*induction hardening*), a beam from a high-power laser (*laser hardening*), or a focused electron beam (*electron beam hardening*). The depth and uniformity of the hard layer depend on the rate and method of heating. These processes are characterized by a short process time and all except electron beam hardening (which requires a moderate vacuum) can be done in air.

**TABLE 3.10.2 Characteristics of Surface Treatment Processes for Steel**

Process	Coating or Treated Layer		Substrate Temperature (°C)
	Hardness (HV)	Thickness (µm)	
Surface hardening			
Flame or induction hardening	500–700	250–6000	800–1000
Laser or electron beam hardening	500–700	200–1000	950–1050
Carburizing	650–900	50–1500	800–950
Carbonitriding	650–900	25–500	800–900
Nitriding	700–1200	10–200	500–600
Boronizing	1400–1600	50–100	900–1100
Coating			
Chrome plating	850–1250	1–500	25–100
Electroless nickel	500–700	0.1–500	25–100
Hardfacing	800–2000	500–50000	1300–1400
Thermal spraying	400–2000	50–1500	<250
Physical vapor deposition	100–3000	0.05–10	100–300
Chemical vapor deposition	1000–3000	0.5–100	150–2200
Plasma-assisted chemical vapor deposition	1000–5000	0.5–10	<300
Ion implantation	750–1250	0.01–0.25	<200

*Thermal diffusion processes* involve the diffusion of atoms into surfaces to create a hard layer. In the most widely used of these processes, *carburizing* (or case hardening), carbon diffuses into a low-carbon steel surface to produce a hard, carbon-rich case. The hardness and thickness of the case depend on the temperature, exposure time, and source of carbon (either a hydrocarbon gas, a salt bath, or a packed bed of carbon). *Carbonitriding* is a process similar to carburizing which involves the simultaneous diffusion of carbon and nitrogen atoms into carbon steel surfaces. In the *nitriding* process, nitrogen atoms diffuse into the surface of a steel which contains nitride-forming elements (such as Al, Cr, Mo, V, W, or Ti) and form fine precipitates of nitride compounds in a near-surface layer. The hardness of the surface layer depends on the types of nitrides formed. The source of nitrogen can be a hot gas (usually ammonia) or a plasma. *Nitrocarburizing* and *boronizing* are related processes in which nitrogen or boron atoms diffuse

into steel surfaces and react with the iron to form a hard layer of iron carbonitride or iron boride, respectively.

Thin, hard metallic coatings can be very effective in friction and wear reduction and can be applied most effectively by *electroplating processes* (Weil and Sheppard, 1992). The most common of such coatings are *chromium*, which is plated from a chromic acid bath, and *electroless nickel*, which is deposited without electric current from a solution containing nickel ions and a reducing agent. Chromium coatings generally consist of fine-grained chromium with oxide inclusions, while electroless nickel coatings contain up to 10% of either phosphorus or boron, depending on the reducing agent used.

*Thermal spray processes* (Kushner and Novinski, 1992) enable a large variety of coating materials, including metals, ceramics and polymers, to be deposited rapidly on a wide range of substrates. Four different thermal spray processes are commercially available: *oxyfuel* (or flame) spraying of metallic wire or metallic or ceramic powder, *electric arc* spraying of metallic wire, *plasma arc* spraying of powder (metallic or ceramic), and *high-velocity oxyfuel* (or detonation gun) powder spray. In each thermal spray process the coating material, in either wire or powder form, is heated to a molten or plastic state, and the heated particles are propelled toward the surface to be coated where they adhere and rapidly solidify to form a coating. The hardness of the coating depends on both the sprayed material and the process parameters.

*Weld hardfacing processes* (Crook and Farmer, 1992) involve the application of a wear-resistant material to the surface of a part by means of a weld overlay. Weld overlay materials include ferrous alloys (such as martensitic air-hardening steel or high-chromium cast iron), nonferrous alloys (primarily cobalt- or nickel-based alloys containing hard carbide, boride, or intermetallic particles), and cemented carbides (usually tungsten carbide/cobalt cermets). In each case the surface being coated is heated to the same temperature as the molten weld layer, thus posing a limitation to the process. Weld hardfacing is best used when abrasion or sliding wear cannot be avoided (as with earthmoving or mining equipment) and the goal is to limit the wear rate.

*Vapor deposition processes* for wear-resistant coatings include *physical vapor deposition* (PVD), *chemical vapor deposition* (CVD), and several variants of those basic processes (Bhushan and Gupta, 1991). Each of the processes consists of three steps: (1) creation of a vapor phase of the coating material, (2) transportation of the vapor from source to substrate, and (3) condensation of the vapor phase on the substrate and growth of a thin solid film. In PVD processes the vapor is produced by either evaporation (by heating of the coating source) or sputtering (in which coating material is dislodged and ejected from the source as a result of bombardment by energetic particles). In some PVD processes the vapor becomes ionized or reacts with a gas or plasma en route to the substrate, thus modifying the structure or composition of the deposited film. In CVD processes a gas composed of a volatile component of the coating material is activated either thermally or by other means in the vicinity of the substrate, and it reacts to form a solid deposit on the surface of the hot substrate.

Both PVD and CVD methods can be used to produce a wide variety of coatings, including metals, alloys, and refractory compounds. Among the most popular vapor-deposited hard coatings for wear resistance are titanium nitride and titanium carbide. Deposition rates are relatively low compared with some other coating processes, ranging from  $<0.1 \mu\text{m}/\text{min}$  for some ion beam-sputtering or ion-plating processes, up to  $25 \mu\text{m}/\text{min}$  or more for activated reactive evaporation or CVD processes. Most PVD processes are done in a vacuum, while CVD processes are done in a reaction chamber which may be at atmospheric pressure. *Plasma-assisted chemical vapor deposition* (PACVD) is a hybrid process in which the constituents of the vapor phase react to form a solid film when assisted by a glow discharge plasma. The advantages of PACVD over other CVD processes include lower substrate temperatures, higher deposition rates, and a wider variety of coating possibilities.

*Ion implantation* (Fenske, 1992) is a process in which charged particles are created in an ion source, accelerated toward the surface at high velocity, and then injected into the substrate surface. The most commonly implanted ions for surface engineering are nitrogen, carbon, boron, and titanium, although virtually any element could be implanted. The microstructure of the near-surface region is changed by

the presence of the implanted ions and the result can be high near-surface hardness and wear resistance. The affected layer is very thin ( $<1 \mu\text{m}$ ).

### Effect of Lubrication on Friction and Wear

Whenever lubricated surfaces slide together at low sliding speeds or with a high applied normal load, the lubricant may not separate the two solid surfaces completely. However, the lubricant can still significantly reduce the friction coefficient by reducing the shear strength of adhesive junctions between the two surfaces. In this so-called boundary lubrication regime, the effectiveness of the lubricant can be improved if the lubricant molecules adhere well to the solid surfaces. This is best accomplished by introducing a lubricant or additive that forms a surface film through adsorption, chemisorption, or chemical reaction with the surface. The ensuing reduced shear strength of the surface film can lower the friction coefficient by as much as an order of magnitude from the dry friction value.

When a good supply of a viscous lubricant is available, the separation between the surfaces will increase as the sliding speed increases or the normal load decreases. As the separation increases, the amount of solid/solid contact between the surfaces will decrease, as will the friction coefficient and wear rate. In this “mixed friction” regime, friction is determined by the amount of plowing deformation on the softer surface by the harder surface asperities and by adhesion within the solid/solid contacts. When the surfaces become completely separated by a self-acting or externally pressurized lubricant film, the lubricating regime is hydrodynamic, wear is reduced to nearly zero, and friction reaches a low value governed by viscous shear of the lubricant. Friction coefficients in such cases can be 0.001 or lower, depending on the surface velocities and the lubricant viscosity. This is the case for most journal or thrust bearings (see subsection on fluid film bearings).

### Bearings for Friction Reduction

Most mechanical systems contain moving components, such as shafts, which must be supported and held in position by stationary members. This is best done by appropriate design or selection of bearings to be used wherever the moving member is to be supported. Most bearings may be classified as either fluid film bearings, dry or semilubricated bearings, or rolling element bearings.

*Fluid film bearings* (see subsection below) have a conformal geometry, with a thin film of fluid separating the two surfaces. The fluid lubricant could be a liquid, such as oil, or a gas, such as air. Fluid film bearings are commonly used to support rotating cylindrical shafts, and the load on such a bearing could be either radial, in which case the bearing is called a journal bearing, or axial, for a thrust bearing. In most cases the fluid film is generated by the motion within the bearing itself, so the bearing is called self-acting or hydrodynamic. Whether or not a self-acting bearing can develop a fluid film sufficient to separate and support the two surfaces is determined by magnitude of the quantity  $\mu U/W$ , where  $\mu$  is the (absolute) fluid viscosity,  $U$  is the relative sliding velocity, and  $W$  is the normal load. If that quantity is too small, the fluid film will be too thin and high friction will occur. This can be a problem during start-up of equipment when sliding velocities are low. That problem can be overcome by pressurizing the fluid film from an external pressure source to create a hydrostatic bearing. Whether the fluid film is externally pressurized (hydrostatic) or self-acting (hydrodynamic), separation of the solid surfaces allows wear to be essentially eliminated and friction to be very low, even when very large loads are carried by the pressurized lubricant.

*Dry and semilubricated bearings* (see subsection below) have conformal surfaces which are in direct contact with each other. This category includes bearings which run dry (without liquid lubrication) or those which have been impregnated with a lubricant. Dry bearings are made of a material such as a polymer or carbon-graphite which has a low friction coefficient, and they are generally used in low-load and low-speed applications. Semilubricated bearings are made of a porous material, usually metal, and are impregnated with a lubricant which resides within the pores. The lubricant, which could be oil or grease, cannot provide a complete fluid film, but usually acts as a boundary lubricant. Semilubricated bearings can carry greater loads at greater speeds than dry bearings, but not as high as either fluid film or rolling element bearings. The failure mechanism for both dry and semilubricated bearings is wear.

*Rolling element bearings* (see subsection below) have the advantage that rolling friction is lower than sliding friction. These bearings include rolling elements, either balls or rollers, between hardened and ground rings or plates. Their main advantage over fluid film bearings is that they have low friction both during start-up and at operating velocities, although the friction can be higher than that of fluid film bearings during steady state operation. Ball and roller bearings are most commonly lubricated by either oil or grease. In either case the lubricating film at the concentrated contacts between rolling elements and rings is very thin and the pressures in the film are very high; this is the condition known as elastohydrodynamic lubrication. Rolling element bearings fail by a number of mechanisms, often stemming from improper installation or use or from poor lubrication, but the overriding failure mechanism is rolling contact fatigue.

Each type of bearing has advantages and disadvantages, and these are summarized in [Table 3.10.3](#). The Engineering Sciences Data Unit (ESDU) (1965; 1967) has developed some general guides to the selection of bearing type for different load and speed conditions, and those guides for journal and thrust bearing selection are given in [Figures 3.10.2 and 3.10.3](#).

**TABLE 3.10.3 Bearing Characteristics**

	Fluid Film Bearings	Dry Bearings	Semilubricated	Rolling Element Bearings
Start-up friction coefficient	0.25	0.15	0.10	0.002
Running friction coefficient	0.001	0.10	0.05	0.001
Velocity limit	High	Low	Low	Medium
Load limit	High	Low	Low	High
Life limit	Unlimited	Wear	Wear	Fatigue
Lubrication requirements	High	None	Low/None	Low
High temperature limit	Lubricant	Material	Lubricant	Lubricant
Low temperature limit	Lubricant	None	None	Lubricant
Vacuum	Not applicable	Good	Lubricant	Lubricant
Damping capacity	High	Low	Low	Low
Noise	Low	Medium	Medium	High
Dirt/dust	Need Seals	Good	Fair	Need seals
Radial space requirement	Small	Small	Small	Large
Cost	High	Low	Low	Medium

## Lubricant Properties

### Petroleum Oils

The vast majority of lubricants in use today are mineral oils which are obtained through the distillation of crude petroleum. Mineral oils are composed primarily of three types of hydrocarbon structures: paraffinic, aromatic, and alicyclic (naphthenic). The molecular weights of the hydrocarbons range from about 250 for low-viscosity grades, up to nearly 1000 for more-viscous lubricants.

Mineral oils by themselves do not have all of the properties required of modern lubricants. For that reason, almost all current lubricants are fortified with a chemical additive package which consists of some of the following:

*Oxidation inhibitors* limit oxidation of hydrocarbon molecules by interrupting the hydroperoxide chain reaction.

*Rust inhibitors* are surface-active additives that preferentially adsorb on iron or steel surfaces and prevent their corrosion by moisture.

*Antiwear and extreme pressure agents* form low shear strength films on metallic surfaces which limit friction and wear, particularly in concentrated contacts.

*Friction modifiers* form adsorbed or chemisorbed surface films which are effective in reducing friction of bearings during low-speed operation (boundary lubrication regime).

*Detergents and dispersants* reduce deposits of oil-insoluble compounds (e.g., sludge) in internal combustion engines.

**FIGURE 3.10.2** General guide to journal bearing-type selection. Except for rolling element bearings, curves are drawn for bearings with width/diameter = 1. A medium-viscosity mineral oil is assumed for hydrodynamic bearings. From ESDU, *General Guide to the Choice of Journal Bearing Type*, Item 67073, Institution of Mechanical Engineers, London, 1965. With permission.

*Pour-point depressants* lower the temperature at which petroleum oils become immobilized by crystallized wax.

*Foam inhibitors* are silicone polymers which enhance the separation of air bubbles from the oil.

*Viscosity-index improvers* are long-chain polymer molecules which reduce the effect of temperature on viscosity. They are used in multigrade lubricants.

**Properties of Petroleum Oils**

The lubricating oil property which is of most significance to bearing performance is viscosity. The absolute viscosity, designated as  $\mu$ , could be given in SI units as pascal second ( $\text{Pa} \cdot \text{sec} = \text{N} \cdot \text{sec}/\text{m}^2$ ) or centipoise ( $1 \text{ cP} = 0.001 \text{ Pa} \cdot \text{sec}$ ) or in English units as  $\text{lb} \cdot \text{sec}/\text{in}^2$  (or reyn). Kinematic viscosity, designated here as  $\nu$ , is defined as absolute viscosity divided by density. It is given in SI units as  $\text{m}^2/\text{sec}$  or centistokes ( $1 \text{ cSt} = 10^{-6} \text{ m}^2/\text{sec}$ ) and in English units as  $\text{in}^2/\text{sec}$ .

Viscosity data in [Table 3.10.4](#) are representative of typical petroleum “turbine” and “hydraulic” oils which are widely used in industry and closely correspond to properties of most other commercially available petroleum oils. [Table 3.10.5](#) gives equivalent viscosity grades for common automotive (SAE), gear (SAE and AGMA), and reciprocating aircraft engine (SAE) oils (Booser, 1995). Equivalent ISO viscosity grades are listed for the single-graded SAE automotive oils such as SAE 10W and SAE 30.

**FIGURE 3.10.3** General guide to thrust bearing type selection. Except for rolling element bearings, curves are drawn for a ratio of inside diameter to outside diameter equal to 2 and for a nominal life of 10,000 hr. A medium-viscosity mineral oil is assumed for hydrodynamic bearings. (Based on ESDU, *General Guide to the Choice of Journal Bearing Type*, Item 67073, Institution of Mechanical Engineers, London, 1965, and Neale, M.J., *Bearings*, Butterworth-Heinemann, Oxford, 1993.)

For multigrade oils such as SAE 10W–30, however, the added viscosity-index improvers provide unique viscosity–temperature characteristics. Typical properties of a number of these multigrade SAE oils are included in [Table 3.10.4](#).

ISO viscosity grade 32 and the equivalent SAE 10W are most widely used industrially. Lower-viscosity oils often introduce evaporation and leakage problems, along with diminished load capacity. Higher viscosity may lead to high temperature rise, unnecessary power loss, and start-up problems at low temperature. For low-speed machines, however, higher-viscosity oils ranging up to ISO 150, SAE 40 and sometimes higher are often used to obtain higher load capacity.

**TABLE 3.10.4 Representative Oil Properties**

	Viscosity				Density	
	Centistokes		10 <sup>-6</sup> reyns(lb·sec/in <sup>2</sup> )		gm/cc	lb/in <sup>3</sup>
	40°C	100°C	104°F	212°F	40°C	104°F
<b>ISO Grade (Equivalent SAE)</b>						
32 (10W)	32.0	5.36	3.98	0.64	0.857	0.0310
46 (20)	46.0	6.76	5.74	0.81	0.861	0.0311
68 (20W)	68.0	8.73	8.53	1.05	0.865	0.0313
100 (30)	100.0	11.4	12.60	1.38	0.869	0.0314
150 (40)	150.0	15.0	18.97	1.82	0.872	0.0315
220 (50)	220.0	19.4	27.91	2.36	0.875	0.0316
<b>SAE Multigrade</b>						
5W-30	64.2	11.0	8.15	0.99	0.860	0.0311

<sup>a</sup> Comparisons are nominal since SAE grades are not specified at 40°C viscosity; VI of lubes could change some of the comparisons.

Oil viscosity decreases significantly with increasing temperature as shown in Fig. 3.10.4. While Figure 3.10.4 provides viscosity data suitable for most bearing calculations, oil suppliers commonly provide only the 40°C and 100°C values of kinematic viscosity in centistokes (mm<sup>2</sup>/sec). The viscosity at other temperatures can be found by the following ASTM D341 equation relating kinematic viscosity  $\nu$  in centistokes (mm<sup>2</sup>/sec) to temperature  $T$  in degrees F:

$$\log \log(\nu + 0.7) = A - B \log(460 + T) \tag{3.10.2}$$

**FIGURE 3.10.4** Viscosity–temperature chart for industrial petroleum oils (Ramondi and Szeri, 1984).

where  $A$  and  $B$  are constants for any particular (petroleum or synthetic) oil. For ISO VG-32 oil in Table 3.10.4, for example,  $A = 10.54805$  and  $B = 3.76834$  based on the 104 and 212°F (40 and 100°C) viscosities. This gives a viscosity of 10.78 cSt at a bearing operating temperature of 160°F.

Conversion of kinematic to absolute viscosity requires use of density, which also varies with temperature. A coefficient of expansion of 0.0004/°F is typical for most petroleum oils, so the variation of density with temperature is in accordance with the following relation:

$$\rho_T = \rho_{104} [1 - 0.0004(T - 104)] \tag{3.10.3}$$

For the ISO-VG-32 oil with its density of 0.857 g/cc at 100°F (40°C), this equation gives 0.838 g/cc at 160°F. Multiplying 10.78 cSt by 0.838 then gives an absolute viscosity of 9.03 cP. Multiplying by the conversion factor of  $1.45 \times 10^{-7}$  gives  $1.31 \times 10^{-6}$  lb·sec/in.<sup>2</sup> (reyns).

Heat capacity  $C_p$  of petroleum oils used in bearing calculations is given by (Klaus and Tewksburg, 1984)

$$C_p = 3860 + 4.5(T) \text{ in.} \cdot \text{lb}/(\text{lb} \cdot ^\circ\text{F}) \tag{3.10.4}$$

The viscosity of petroleum oils is also affected significantly by pressure, and that increase can become important in concentrated contacts such as rolling element bearings where elastohydrodynamic lubrication occurs. The following relationship can be used for many oils to find the viscosity at elevated pressure:

$$\mu_p = \mu_o e^{\alpha p} \tag{3.10.5}$$

where  $\mu_o$  is the viscosity at atmospheric pressure,  $\mu_p$  is the viscosity at pressure  $p$ , and  $\alpha$  is the pressure–viscosity exponent. The pressure–viscosity exponent can be obtained from lubricant suppliers.

### Synthetic Oils

Synthetic oils of widely varying characteristics are finding increasing use for applications at extreme temperatures and for their unique physical and chemical characteristics. Table 3.10.6 gives a few representative examples of synthetic oils which are commercially available. Cost of the synthetics, ranging up to many times that of equivalent petroleum oils, is a common deterrent to their use where petroleum products give satisfactory performance

### Greases

Grease is essentially a suspension of oil in a thickening agent, along with appropriate additives. The oil generally makes up between 75 and 90% of the weight of a grease, and it is held in place by the gel structure of the thickener to carry out its lubricating function. The simplicity of the lubricant supply system, ease of sealing, and corrosion protection make grease the first choice for many ball-and-roller bearings, small gear drives, and slow-speed sliding applications (Booser, 1995). Consistencies of greases vary from soap-thickened oils that are fluid at room temperature to hard brick-types that may be cut with a knife. Greases of NLGI Grade 2 stiffness (ASTM D217) are most common. Softer greases down to grade 000 provide easier feeding to multiple-row roller bearings and gear mechanisms. Stiffer Grade 3 is used in some prepacked ball bearings to avoid mechanical churning as the seals hold the grease in close proximity with the rotating balls.

Petroleum oils are used in most greases; the oils generally are in the SAE 30 range, with a viscosity of about 100 to 130 cSt at 40°C. Lower-viscosity oil grades are used for some high-speed applications and for temperatures below about -20°C. Higher-viscosity oils are used in greases for high loads and low speeds. Synthetic oils are used only when their higher cost is justified by the need for special properties, such as capability for operation below -20°C or above 125 to 150°C.

The most common gelling agents are the fatty acid metallic soaps of lithium, calcium, sodium, or aluminum in concentrations of 8 to 25%. Of these, the most popular is lithium 12-hydroxystearate; greases based on this lithium thickener are suitable for use at temperatures up to 110°C, where some lithium soaps undergo a phase change. Greases based on calcium or aluminum soaps generally have an upper temperature limit of 65 to 80°C, but this limit can be significantly raised to the 120 to 125°C range through new complex soap formulations. Calcium-complex soaps with improved high-temperature stability, for instance, are prepared by reacting both a high-molecular-weight fatty acid (e.g., stearic acid) and a low-molecular-weight fatty acid (acetic acid) with calcium hydroxide dispersed in mineral oil.

Inorganic thickeners, such as fine particles of bentonite clay, are inexpensively applied by simple mixing with oil to provide nonmelting greases for use up to about 140°C. Polyurea nonmelting organic powders are used in premium petroleum greases for applications up to about 150 to 170°C.

Additives, such as those mentioned in the subsection on petroleum oils, are added to grease to improve oxidation resistance, rust protection, or extreme pressure properties. Because of the incompatibility of oils, thickeners, and additives, greases of different types should be mixed only with caution.

### Solid Lubricants

Solid lubricants provide thin solid films on sliding or rolling/sliding surfaces to reduce friction and wear. They are particularly useful for applications involving high operating temperatures, vacuum, nuclear radiation, or other environments which limit the use of oils or greases. Solid lubricant films do not prevent moving surfaces from contacting each other, so they cannot eliminate wear and their lives are limited by wear. The properties of some of the most common solid lubricants are given in Table 3.10.7.

**TABLE 3.10.7 Properties of Selected Solid Lubricants**

Material	Acceptable Usage Temperature, °C				Average Friction Coefficient, <i>f</i>		Remarks
	Minimum		Maximum		In Air	In N <sub>2</sub> or Vacuum	
	In Air	In N <sub>2</sub> or Vacuum	In Air	In N <sub>2</sub> or Vacuum			
Molybdenum disulfide, MoS <sub>2</sub>	-240	-240	370	820	0.10–0.25	0.05–0.10	Low <i>f</i> , carries high load, good overall lubricant, can promote metal corrosion
Graphite	-240	—	540	Unstable in vacuum	0.10–0.30	0.02–0.45	Low <i>f</i> and high load capacity in air, high <i>f</i> and wear in vacuum, conducts electricity
PTFE	-70	-70	290	290	0.02–0.15	0.02–0.15	Lowest <i>f</i> of solid lubricants, load capacity moderate and decreases at elevated temperature
Calcium fluoride–barium fluoride eutectic, CaF <sub>2</sub> –BaF <sub>2</sub>	430	430	820	820	0.10–0.25 above 540°C 0.25–0.40 below 540°C	Same as in air	Can be used at higher temperature than other solid lubricants, high <i>f</i> below 540°C

Modified from Booser, E.R., in *Encyclopedia of Chemical Technology*, 4th ed., Vol. 15, John Wiley & Sons, New York, 1995, 463–517.

The most important inorganic solid lubricants are layer–lattice solids such as molybdenum disulfide (MoS<sub>2</sub>) and graphite. These materials are characterized by strong covalent or ionic bonding between atoms in individual layers, but relatively weak van der Waals bonds between layers, enabling the layers

to slide easily relative to one another. Graphite is a very effective lubricant film when moisture or water vapor is present, since adsorbed water vapor lubricates the sliding layers, but it has poor friction properties in vacuum or other low-humidity applications. Molybdenum disulfide does not require the presence of adsorbed water vapor, so it is widely used in vacuum or space applications.

The most commonly used organic solid lubricant is polytetrafluoroethylene (PTFE) which can be used either as a fused surface coating or as a self-lubricating material (see subsection on plastics). Its low friction is attributed to the smooth profile of the PTFE molecule. The chemical inertness of PTFE makes it attractive for chemical and food-processing applications.

New ceramic-based solid lubricants have been developed for high-temperature applications, such as heat engines or space uses. One of the most promising of these is a calcium fluoride–barium fluoride eutectic, which can be used at temperatures exceeding 800°C.

## Fluid Film Bearings

### Journal Bearings

A journal bearing consists of an approximately cylindrical bearing body or sleeve around a rotating cylindrical shaft. In general, journal bearings are found in motors, pumps, generators, appliances, and internal combustion engines in which a fluid lubricant is used; and in smaller mechanisms such as switches, clocks, small motors, and circuit breakers in which a solid lubricant such as graphite, grease, or certain plastics serves to reduce friction. Air (gas) bearings are designed to utilize both fluid mechanics principles when operating and solid lubricant–surfaced materials for start, stop, and emergency operations.

A hydrodynamic journal bearing maintains separation of shaft from bearing because the lubricant viscosity and the speed of the shaft create pressure in the converging portion of the fluid film which carries load. The governing equations were first developed by Reynolds (1886). Their solution has led to numerous computer solutions, including those used for this section.

*Journal Bearing Design.* Figure 3.10.5 shows schematics of frequently used types of journal bearing in which one or more lobes of cylindrical shape are positioned around the shaft, their axis being assumed parallel to the shaft axis. The features of each design and applications where it is often found are listed in Table 3.10.8.

Noncontact journal bearings are designed to assure a continuous supply of lubricant to the load-carrying section, and the bearing grooves in Figure 3.10.5 are designed for that purpose. Oil must be resupplied to the bearing because of the continuous loss of lubricant as it is forced from the bearing by the load-carrying pressures generated within it. The subsection on lubricant supply methods describes some of the many systems designed to assure this supply and to cool the lubricant at the same time.

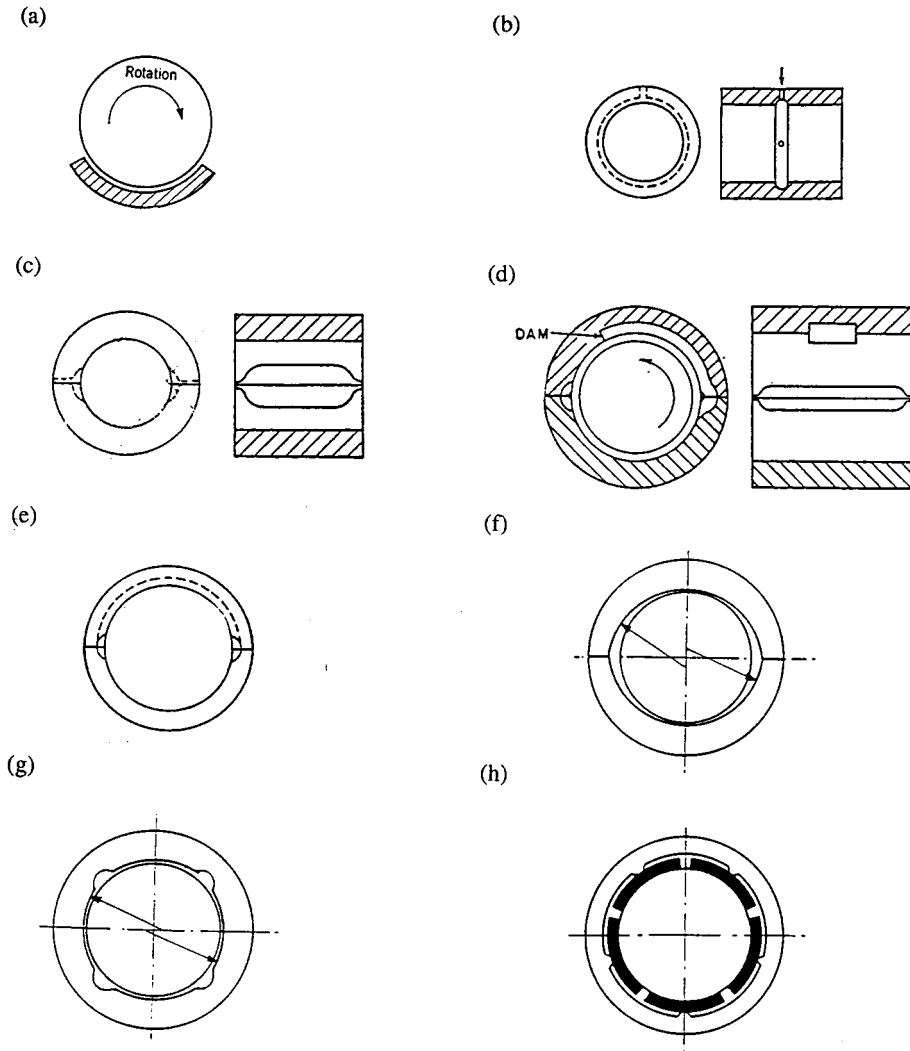

*Controlling Variables.* Definitions of the variables involved in journal bearing analysis are contained in Table 3.10.9. Because of the large range of many variables, nondimensional quantities are often used which are independent of the dimensional unit system involved. Examples are given in the English system unless otherwise stated.

*Calculating Bearing Performance.* Journal bearing performance can be calculated directly from dedicated computer codes which take account of load, speed, oil type, and delivery system, as well as bearing dimensions. This subsection presents two approximate solutions: a simple thermal approach and a set of interpolation tables based on computer solutions.

*Thermal Approach.* It is assumed that the bearing is operating at a constant but elevated temperature. A predicted operating temperature can then be found as a function of an assumed viscosity. A solution is found when the assumed viscosity equals the lubricant viscosity at that temperature. Three equations are used for this method. For radial loads, the power dissipation is

$$H_p = j\pi^3\mu(N/60)^2 D^3L/C \quad \text{in} \cdot \text{lb}/\text{sec} \quad (3.10.6)$$

**FIGURE 3.10.5** Types of pressure-fed journal bearings: (a) Partial arc. (b) Circumferential groove. (c) Cylindrical bearing–axial groove. (d) Pressure dam. (e) Cylindrical overshoot. (f) Elliptical. (g) Multilobe. (h) Tilting pad.

**TABLE 3.10.8 Journal Bearing Designs**

Type	Typical Loading	Applications
Partial arc	Unidirectional load	Shaft guides, dampers
Circumferential groove	Variable load direction	Internal combustion engines
Axial groove types		
Cylindrical	Medium to heavy unidirectional load	General machinery
Pressure dam	Light loads, unidirectional	High-speed turbines, compressors
Overshot	Light loads, unidirectional	Steam turbines
Multilobe	Light loads, variable direction	Gearing, compressors
Preloaded	Light loads, unidirectional	Minimize vibration
Tilting pad	Moderate variable loads	Minimize vibration

where  $j = 1$  for a shaft-centered design. The lubricant flow rate is

$\theta$	Angle in direction of rotation, from bottom dead center	—
$\Phi$	Energy dissipation	in.·lb/sec

$$Q = Q_o + qCR^2\omega/2 \text{ in.}^3/\text{sec} \tag{3.10.7}$$

where  $q$  is the proportion of side flow to circulating flow, and the zero speed flow,  $Q_o$  (in<sup>3</sup>/sec), represents other flows such as from the ends of the feed grooves which are not related to the load-carrying film itself.  $Q_o$  can usually be neglected for rough estimation, and this approximation is useful for eccentricities as high as 0.7. Note that both  $q$  and  $j$  are functions of specific design as well as load and speed. The average operating temperature for a given viscosity is

$$T_2 = T_f + \frac{(H_p - \Phi)}{(\rho C_p Q)} \text{ °F} \tag{3.10.8}$$

where  $T_f$  is the feed temperature and  $\Phi$  is the energy loss due to conduction and radiation. For diameters of 2" or more,  $\Phi$  can usually be assumed to be 0. Plotting  $T_2$  vs. viscosity for several values of  $\mu$  on a plot of the viscosity vs.  $T$  for the lubricant shows the operating temperature for the bearing as the intersection.

*Flow Dynamics Solution.* A more general solution for journal bearing performance is based on prediction of flow characteristics in the bearing, and of physical behavior of the bearing based on the Reynolds equation. A common two-pad journal bearing with pressurized oil feed will be used to provide specific design information. The Reynolds equation is the differential equation expressing the physical behavior of the fluid film between shaft and bearing, as written for cylindrical bearings:

$$1/R^2 \left[ \frac{\partial}{\partial \Theta} \left( h^3 / \mu \right) \frac{\partial p}{\partial \Theta} \right] + \frac{\partial}{\partial z} \left( h^3 / \mu \right) \frac{\partial p}{\partial z} = 6(U/R) \frac{\partial h}{\partial \Theta} \tag{3.10.9}$$

where  $z$  is the axial coordinate and  $\Theta$  is the angular coordinate.

*Bearing Configuration.* A cross section through a common type of two-pad cylindrical bearing is shown in Figure 3.10.6. Two pads having a radius of  $R + C$  and an angular extent of  $150^\circ$ , and with load applied vertically to the lower half through a shaft, make up the bearing. Lubricant is admitted under moderate feed pressure to the two  $30^\circ$  grooves formed at the split as shown in Figure 3.10.6. The shaft rotates counterclockwise, and lubricant pressures are balanced when the shaft center is displaced down and to the right.

FIGURE 3.10.6 Geometry of split cylindrical journal bearing.

*Lubricant Properties.* Pressures in the lubricant film are generated as a function of the local shear rates and the local viscosity as described by the Reynolds equation. The local temperature rise is given by the local energy dissipation divided by the local flow rate:

$$\Delta T = \left[ 2\mu\omega R^2 \Delta\theta \right] / \left[ h^2 \rho C_p \right] \tag{3.10.10}$$

As an alternative to Equation 3.10.2, an exponential relation between viscosity and temperature is used:

$$\mu = \mu_0 e^{-\beta(T-T_0)} \tag{3.10.11}$$

Assuming an ISO 32 oil, viscosity  $\mu_0$  at  $104^\circ\text{F}$  is 3.98 reyns, density is 0.0310, and  $\beta$  is 0.0170 for the range from  $104$  to  $212^\circ\text{F}$ . The value for  $\beta$  may be determined from Figure 3.10.4. A nondimensional

coefficient,  $C_\alpha$ , the *adiabatic coefficient*, is used as an indicator of the severity of thermal heating in a design. It contains the several factors responsible for temperature rise.

$$C_\alpha = 2\mu_f \beta \omega (R/C)^2 / \rho C_p \tag{3.10.12}$$

*Bearing Performance Tables.* Using computer-generated solutions of the Reynolds equation for the pressure field over the bearing surface, the relevant performance properties of the bearing/lubricant system can be determined. A number of programs are commercially available for this purpose. In order to illustrate how the behavior of a journal bearing can be determined, a two-pad split cylindrical bearing with an  $L/D$  of 0.5 has been selected, and a proprietary computer code has been used to develop a group of performance quantities for such a bearing. The code accounts for the internal lubricant circulation, including mixing in the inlet groove of feed lubricant with warm lubricant from the upper half, resulting in the viscosity  $\mu_f$ . The primary characteristics of the bearing are load, stiffness, and damping. Each of these factors is presented in nondimensional terms in [Table 3.10.10](#), and the corresponding dimensional and other quantities are given as follows:

Film thickness, in.  $h = C(1 + e \cos \Theta)$  (3.10.13a)

Shaft eccentricity, in.  $e = \epsilon C$  (3.10.13b)

Load, lb  $W = w [6\mu\omega (R/C)^2 DL]$  (3.10.13c)

Flow, in.<sup>3</sup>/sec  $Q = q (CR^2 \omega / 2)$  (3.10.13d)

Power loss, in. · lb/sec  $H_p = j (2\pi\mu\omega^2 R^3 L/C)$  (3.10.13e)

Stiffness, lb/in.  $S_{xx} = K_{xx} 6\mu\omega R (R/C)^2$  (3.10.13f)

Damping, lb · sec/in.  $D_{xx} = B_{xx} 12\mu R (R/C)^3$  (3.10.13g)

The axial length/diameter ratio also influences the performance of a journal bearing. To illustrate this, [Table 3.10.11](#) presents the performance of longer bearings ( $L/D = 0.75$  and  $1.00$ ) for comparison to the more common  $L/D = 0.5$  results in [Table 3.10.10](#).

Comparing [Tables 3.10.10](#) and [3.10.11](#), the use of longer bearings has several important effects on operation and performance. Comparing key variables, the effects at an eccentricity of ratio of 0.7 are as follows:

Variable	L/D = 0.5	L/D = 0.75	L/D = 1.00
Load, $w$	0.28	0.69	1.21
Flow, $q$	0.69	0.82	0.88
Attitude angle, $\phi$	36.4	36.1	35.8
Power ratio, $j$	1.00	1.15	1.17
Stiffness, $K_{xx}$	1.38	3.06	5.03
Damping, $B_{xx}$	0.99	2.52	4.31

*Effect of Turbulence.* Turbulence is a mixing phenomenon that occurs in larger high-speed bearings. When this behavior occurs, the simple viscous drag behavior that has been assumed in the preceding

subsections is broken up by numerous eddies which increase the drag. The Reynolds number is a nondimensional quantity that expresses this factor:

$$R_e = hU\rho/\mu \quad (3.10.14)$$

where  $h$  is the local film thickness,  $U$  is the relative velocity of one surface with respect to the other,  $\rho$  is the fluid density, and  $\mu$  is the local viscosity.

The influence of turbulence on an  $L/D = 0.5$  bearing is shown in Table 3.10.12. Examination of Table 3.10.12 shows that the principal effects of operation in the turbulent regime with a Reynolds number above about 1000 are in the greater power required ( $j$ ) and the maximum bearing temperature. Load capacity and flow are only moderately affected.

*Example Calculation.* The problem is to design a two-pad cylindrical bearing for support of a rotor having a bearing load of 8000 lb, a shaft diameter of 6 in., and a speed of 3600 rpm. Assume use of ISO VG-32 oil fed at a temperature of  $120^\circ\text{F}$ . Compute operating characteristics for a 3-in.-long bearing. Assume a radial clearance of 0.0044 in.

Feed viscosity,  $\mu_f = 3.98 \times 10^{-6} e^{-0.00170(120-104)} = 3.03 \times 10^{-6}$  reyn

Angular velocity,  $\omega = 3600 \times 2\pi/60 = 377$  rad/sec

Adiabatic coefficient:  $C_\alpha = 2 \times 3.03 \times 10^{-6} \times 0.0170 \times 377 \times (3/0.0044)^2/0.0310/4320 = 0.1345$

Load coefficient (from Equation 3.10.13c:  $w = 8000/[6 \times 3.03 \times 10^{-6} \times 377 \times 3 \times 6 \times (33/0.0044)^2] = 0.139$

The desired solution lies between Part 2 and Part 3 of Table 3.10.10. By using linear interpolation between the tabulated values for  $C_\alpha$  of 0.1 and 0.2, and values of  $\epsilon$  of 0.7 and 0.8, an approximate operating point of  $C_\alpha = 0.1345$  yields the following coefficients:  $\epsilon = 0.729$ ,  $w = 0.279$ ,  $q = 0.733$ ,  $j = 0.860$ , and  $\Delta T_b = 0.915$ .

By using Equations 3.10.13, the dimensional operating results are:

Shaft velocity:  $\omega = 3600 \times 2\pi/60 = 377$  rad/sec

Flow:  $Q = 0.733 \times 0.0044 \times 3^2 \times 377 = 5.47$  in<sup>3</sup>/sec

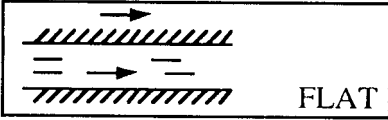

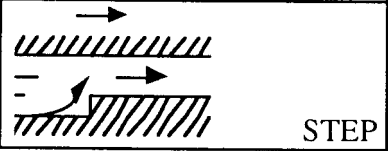

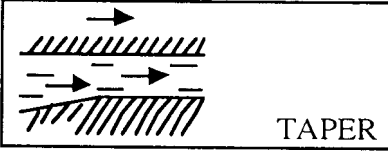

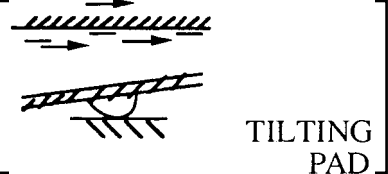

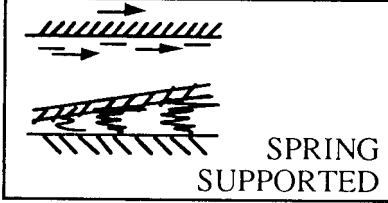

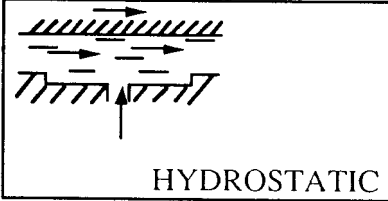

Power loss:  $H_p = 0.860 \times 2\pi \times 3.03 \times 10^{-6} \times 377^2 \times 3^3 \times 3/0.0044 = 42.8$  in. $\cdot$ lb/sec

Oil temperature:  $T_b = 120 + 0.915/0.0170 = 174^\circ\text{F}$

## Thrust Bearings

*Types of Thrust Bearings.* Oil film thrust bearings range from coin-size flat washers to sophisticated assemblies many feet in diameter. Of the six common types of thrust bearings shown in Table 3.10.13, the first five are hydrodynamic. As with journal bearings, each of these generates oil film pressure when

**TABLE 3.10.13 Common Thrust Bearings and Their Range of Application**

Type	O.D., in.	Unit Load, psi
 <p>FLAT</p>	0.5–20	20–100
 <p>STEP</p>	0.5–10	100–300
 <p>TAPER</p>	2–35	150–300
 <p>TILTING PAD</p>	4–120	250–700
 <p>SPRING SUPPORTED</p>	50–120	350–700
 <p>HYDROSTATIC</p>	3–50	500–3000

Source: Booser, E.R. and Wilcock, D.F., *Machine Design*, June 20, 1991, 69–72. With permission.

a rotating thrust face pumps oil by shear into a zone of reduced downstream clearance. When thrust load increases, film thickness drops until a new balance is reached between inflow and outflow, raising pressure until the higher bearing load is balanced. The hydrostatic bearing uses a separate oil pump to supply the pressurized flow.

*Flat-land bearings*, simplest to fabricate and least costly, are the first choice for simple positioning of a rotor and for light loads in electric motors, appliances, pumps, crankshafts, and other machinery. They carry less load than the other types because flat parallel planes do not directly provide the required pumping action. Instead, their action depends on thermal expansion of the oil and warping of the bearing

material induced by heating from the passing oil film. The resulting slight oil wedge then gives a load rating of about 10 to 20% of that for the other types.

*Step bearings* also offer relatively simple design. With a coined or etched step, they lend themselves to mass production as small-size bearings and thrust washers. Step height for optimum load capacity approximately equals the minimum film thickness, often 0.001 in. or less. Circumferential length beyond the step is ideally 45% of the total bearing segment (Wilcock and Booser, 1956). Step thrust bearings are well suited for low-viscosity fluids such as water, gasoline, fuels, and solvents. Minimum film thickness in these applications is so small that features such as pivots and tapers are usually impractical. Step height must be small enough for good load capacity, yet large enough to accommodate some wear without becoming worn away. Step erosion by contaminants is sometimes a problem.

*Tapered-land bearings* provide reliable, compact designs for mid- to large-size high-speed machines such as turbines, compressors, and pumps. Taper height normally should be about one to three times the minimum film thickness. For greater load capacity and to minimize wear during starting, stopping, and at low speeds, a flat land is commonly machined at the trailing edge to occupy from 10 to 30% of the circumferential length of each segment. Because operation of these bearings is sensitive to load, speed, and lubricant viscosity, they are typically designed for the rated range of operating conditions for specific machines.

*Tilting-pad thrust bearings* are used increasingly in turbines, compressors, pumps, and marine drives in much the same range of applications as tapered-land designs. They usually have a central supporting pivot for each of their three to ten bearing segments. Each of these thrust pad segments is free to adjust its position to form a nearly optimum oil wedge for widely varying loads, speeds, and lubricants, and with rotation in both directions. A secondary leveling linkage system is commonly introduced to support the individual pads; this provides a further advantage over tapered-land designs by accommodating some misalignment. Off-the-shelf units are available to match rotor shaft diameters from about 2 to 12 in., and custom designs range up to 120 to 170 in. in outside diameter. Recent trends to increase load capacity have led to offsetting pivots from the circumferential midpoint of a pad to about 60% beyond the leading edge, to substituting copper for steel as the backing for a tin babbitt bearing surface, and to nonflooded lubrication to minimize parasitic power loss from useless churning of oil passing through the bearing housing.

*Springs or other flexible supports* for thrust segments are employed for bearings ranging up to 10 ft or more in outside diameter and carrying millions of pounds of thrust. This flexible mounting avoids the high load concentration encountered by pivots in supporting large tilting-pads. Rubber backing can provide this flexible mounting for smaller thrust pads.

*Hydrostatic thrust bearings* are used where sufficient load support cannot be generated by oil film action within the bearing itself. This may be the case with low-viscosity fluids, or for load support on an oil film at standstill and very low speeds. The fluid is first pressurized by an external pump and then introduced into pockets in the bearing surface to float the load. A compact hydrostatic thrust bearing can sometimes be constructed with a single pocket at the end of a rotor. Larger bearings usually use three or more pressurized pockets to resist misalignment or to support off-center loads. Hydraulic flow resistance in the supply line to each pocket, or constant flow to each pocket (as with ganged gear pumps) then provides any asymmetric pressure distribution needed to support an off-center load. Bearing unit load is commonly limited to about 0.5 (0.75 with fixed flow systems) times the hydrostatic fluid supply pressure—up to 5000 psi with conventional lubricating oils.

*Design Factors for Thrust Bearings.* In preliminary sizing, the inside diameter  $d$  of a thrust bearing is made sufficiently larger than the shaft to allow for assembly, and to provide for any required oil flow to the thrust bearing inside diameter (see [Figure 3.10.7](#)). This clearance typically ranges from about  $1/8$  in. for a 2-in. shaft to  $1/2$  in. for a 10-in. shaft. Bearing outside diameter  $D$  is then set to provide bearing

FIGURE 3.10.7 Sector for tapered land thrust bearing.

area sufficient to support total thrust load  $W$  (lb or N) with an average loading  $P$  (psi or  $N/m^2$ ), using typical values from Table 3.10.13:

$$D = \left( \frac{4W}{\pi k_g P} + d^2 \right)^{0.5} \tag{3.10.15}$$

where  $k_g$  (typically 0.80 to 0.85) is the fraction of area between  $d$  and  $D$  not occupied by oil-distributing grooves. This bearing area is then divided by radial oil-feed groove passages, usually into “square” sectors with circumferential breadth  $B$  at their mean diameter equal to their radial length  $L$ .

While square pads usually produce optimum oil film performance, other proportions may be advantageous. With very large bearing diameters, for instance, square sectors may involve such a long circumferential dimension that the oil film overheats before reaching the next oil-feed groove. With a radially narrow thrust face, on the other hand, square sectors may become so numerous as to introduce excessive oil groove area, and their short circumferential length would interfere with hydrodynamic oil film action.

*Performance Analysis.* Performance analyses for sector thrust bearings using a fixed taper also hold approximately for most thrust bearing shapes (other than flat lands) with the same ratio of inlet to outlet oil film thickness (Wilcock and Booser, 1956; Neale, 1970; Fuller, 1984). Both for centrally pivoted pad thrust bearings and for spring-supported thrust bearings, use of an inlet-to-outlet film thickness ratio of two is usually appropriate in such an analysis.

While computer analyses in polar coordinates and with local oil film viscosity calculated over the whole oil film area gives more-exact solutions, the following constant viscosity approximations are made by relating a rectangular bearing sector (width  $B$ , length  $L$ ) to the circular configuration of Figure 3.10.7. This rectangular representation allows more ready evaluation of a range of variables and gives results which are quite similar to a more accurate polar coordinate analysis.

Employing the nomenclature of Figure 3.10.7, the following relations give minimum film thickness  $h_2$ , frictional power loss  $H$ , and oil flow into a sector  $Q$ . The dimensionless coefficients involved are given in Table 3.10.14 for a range of sector proportions  $L/B$  and ratios of inlet to outlet film thicknesses  $h_1/h_2$ .

$$h_2 = K_h (\mu UB/P)^{0.5} \quad \text{in. (m)} \tag{3.10.16a}$$

$$H = K_f \mu U^2 BL/h_2 \quad \text{lb} \cdot \text{in./sec (N} \cdot \text{m/sec)} \tag{3.10.16b}$$

$$Q = K_q ULh_2 \quad \text{in.}^3/\text{sec} \left( \text{m}^3/\text{sec} \right) \quad (3.10.16c)$$

$$\Delta T = H / (Q \rho C_p) = \frac{K_f}{K_q K_h^2 \rho C_p} P \quad ^\circ\text{F} \left( ^\circ\text{C} \right) \quad (3.10.16d)$$

where  $B$  = circumferential breadth of sector at mean radius, in. (m)

$K_h, K_f, K_q$  = dimensionless coefficients

$L$  = radial length of sector, in. (m)

$P$  = unit loading on projected area of sector,  $W/BL$ , lb/in.<sup>2</sup> (N/m<sup>2</sup>)

$U$  = surface velocity at mean diameter of sector, in./sec (m/sec)

$W$  = load on a sector, lb (N)

$C_p$  = oil specific heat, in.·lb/(lb·°F) (J/(kg·°C))

$h_1, h_2$  = leading edge and trailing edge film thicknesses, in. (m)

$\rho$  = oil density, lb/in.<sup>3</sup> (n/m<sup>3</sup>)

$\mu$  = oil viscosity at the operating temperature, lb·sec/in.<sup>2</sup> (N·sec/m<sup>2</sup>)

*Example.* The following example involves a bearing for 25,000 lb thrust load in a 1200 rpm compressor whose rotor has a 5-in.-diameter journal. ISO-32 viscosity grade oil is to be fed at 120°F. Allowing  $3/8$  in. radial clearance along the shaft sets thrust bearing bore  $d = 5.75$  in. Taking unit loading  $P = 300$  psi allows a margin for uncertainty in expected thrust load, and outside diameter  $D$  is given by Equation 3.10.14):

$$D = \left( \frac{4 \times 25000}{\pi(0.85)(300)} + 5.75^2 \right)^{0.5} = 12.6 \text{ in.}$$

With 15% of the area used for oil feed passages,  $k_g = 0.85$ . Thrust bearing segment radial length  $L = (12.6 - 5.75)/2 = 3.425$  in. With mean diameter  $(5.75 + 12.6)/2 = 9.175$  in., total circumferential breadth of all pads at the mean diameter =  $\pi D_m k_g = 24.5$  in. The number of sectors (and grooves) for  $B = L$  is then  $24.5/3.425 = 7.2$ . Using seven lands, adjusted circumferential breadth  $B$  for each sector =  $24.5/7 = 3.5$  in. (For simpler fabrication, six or eight sectors should also be considered.) Runner velocity at the mean diameter,  $U = \pi(9.175)(1200/60) = 576.5$  in./sec.

For square pads ( $L/B = 1$ ) in a pivoted-pad bearing with  $h_1/h_2 = 2$ , which represents experience with centrally pivoted pads, Table 3.10.14 gives the following performance coefficients:

$$K_h = 0.261, \quad K_f = 0.727, \quad K_q = 0.849$$

Temperature rise is given by Equation (3.10.16d) which assumes that the total frictional power loss  $H$  goes into heating the total oil flow  $Q$  passing over the pad.

$$\Delta T = \frac{K_f P}{K_q K_h^2 \rho C_p} = \frac{0.727(300)}{0.849(0.261)^2(0.0313)(4535)} = 27^\circ\text{F}$$

Adding this  $\Delta T$  to the 120°F feed temperature gives 147°F as the representative oil operating temperature with a viscosity from Figure 3.10.4 of  $1.6 \times 10^{-6}$  lb·sec/in.<sup>2</sup>. Temperature rise to the maximum oil film temperature would be expected to be about 53°F, twice the 27°F. If this bearing were in a housing fully flooded with oil, feed temperature to each pad would become the housing oil temperature, essentially the same as oil draining from the housing.

After Khonsari, M.M., in *Tribology Data Handbook*, CRC Press, Boca Raton, FL, 1997.

Minimum film thickness  $h_2$  becomes, from Equation (3.10.16a)

$$h_2 = 0.261 \left[ (1.6 \times 10^{-6})(576.5)(3.5)/300 \right]^{0.5} = 0.00086 \text{ in.}$$

With a fixed tapered land, rather than a centrally pivoted pad for which it could be assumed that  $h_1/h_2 = 2$ , several iterations might be required with different assumed values of the  $h_1/h_2$  ratio in order to determine the performance coefficients in Table 3.10.14. The proper value of  $h_1/h_2$  will be the one that gives the same final calculated value of  $h_2$  from the above equation as was assumed in the preliminary selection of  $K_h$ ,  $K_f$ , and  $K_q$ .

After finding the values for  $h_2$  and  $K_f$ , the power loss  $H$  can be determined using Equation (3.10.16b). For this example the power loss would be  $H = 5510 \text{ lb-in./sec.}$

The total oil feed to the bearing should satisfy two requirements: (1) provide a full oil film over the bearing segment and (2) maintain reasonably cool operation with no more than 30 to 40°F rise in the

oil temperature from feed to drain. Equation (3.10.16c) can be used to find the oil feed  $Q$  needed at the sector inlet to form a full film. The oil feed needed for a 40°F rise is given by the following heat balance using typical density and specific heat values for petroleum oil:

$$Q = H / (\rho C_p \Delta T) \quad (3.10.17)$$

The required oil feed will be the larger of the values determined by (3.10.16c) and (3.10.17).

The above calculations are for a single sector; power loss and oil feed would be multiplied by the number of sectors (seven) to obtain values for the total bearing. Consideration would normally follow for other pad geometries, and possibly other lubricants and oil flow patterns, in a search for the most-promising design. More-detailed calculations of film thickness, film temperatures, oil flow, and power loss could then be obtained by one of a number of computer codes available from bearing suppliers or other sources.

### Oil Film Bearing Materials

Selection of the material for use in a journal or thrust bearing depends on matching its properties to the load, temperature, contamination, lubricant, and required life.

**Babbitts.** Of the common bearing materials, listed in Table 3.10.15, first consideration for rotating machines is usually a babbitt alloy containing about 85% tin or lead together with suitable alloying elements. With their low hardness, they have excellent ability to embed dirt, conform to shaft misalignment, and rate highest for compatibility with steel journals. Tin babbitts, containing about 3 to 8% copper and 5 to 8% antimony, are usually the first choice for their excellent corrosion resistance. SAE 12 (ASTM Grade 2) tin babbitt is widely used in both automotive and industrial bearings. The much lower cost of lead babbitt, however, with 9 to 16% antimony and as much as 12% tin for improved corrosion resistance, brings SAE 13, 14, and 15 grades into wide use for both general automotive and industrial applications (Booser, 1992).

TABLE 3.10.15 Characteristics of Oil Film Bearing Materials

Material	Brinell Hardness	Load Capacity, psi	Max Operating Temp., °F	Compati-bility <sup>a</sup>	Conforma-bility and Embed-dability <sup>a</sup>	Corrosion Resistance <sup>a</sup>	Fatigue Strength <sup>a</sup>
Tin babbitt	20–30	800–1500	300	1	1	1	5
Lead babbitt	15–25	800–1200	300	1	1	3	5
Copper lead	20–30	1500–2500	350	2	2	5	4
Leaded bronze	60–65	3000–4500	450	3	4	4	3
Tin bronze	65–80	5000+	500	5	5	2	2
Aluminum alloy	45–65	4000+	300	4	3	1	2
Zinc alloy	90–125	3000	250	4	5	5	3
Silver overplated	—	5000+	300	2	4	2	1
Two-component, babbitt surfaced	—	3000+	300	2	4	2	3
Three-component, babbitt surfaced	—	4000+	300	1	2	2	1

<sup>a</sup> Arbitrary scale: 1 = best, 5 = worst.

To achieve the high fatigue strength needed in reciprocating engines, only a very thin layer (commonly 0.001") of babbitt is used so that much of the reciprocating load is taken on a stronger backing material (DeHart, 1984; Kingsbury, 1992). For bimetal bushings such as those used in automobile engines, oil

grooves and feed holes are formed in a continuous steel strip coated with babbitt. The strip is then cut to size and the individual segments are rolled into finished bearings.

For heavy-duty reciprocating engines, three-layer bearings are common. By using a steel strip backing, a thin overlay of SAE 19 or 190 lead babbitt is either electroplated or precision cast on an intermediate layer about 0.1 to 0.3" thick of copper–nickel, copper–lead, leaded bronze, aluminum, or electroplated silver.

**Copper Alloys.** Copper–lead alloys containing 20 to 50% lead, either cast or sintered on a steel back, provide good fatigue resistance for heavy-duty main and connecting rod bearings for automotive, truck, diesel, and aircraft engines. The 10% lead–10% tin leaded bronze has been a traditional selection for bearings in steel mills, appliances, pumps, automotive piston pins, and trunions. This has been replaced in many applications by CA932 (SAE 660) containing 3% zinc for easier casting. The harder tin bronzes require reliable lubrication, good alignment, and 300 to 400 Brinell minimum shaft hardness. Cast tin bronze bushings are used at high loads and low speeds in farm machinery, earthmoving equipment, rolling mills, and in automotive engines for connecting rod bearings.

Utility of copper alloy bearings is limited to relatively low surface speeds by the tendency to form a copper transfer film on a steel shaft. Above about 1500 to 3000 ft/min, selective plucking of softer copper material from hotter load zones in the bearing may result in welded lumps forming on the cooler, stronger transfer layer on the mating steel shaft.

**Zinc Alloys.** Zinc alloys containing about 10 to 30% aluminum find some use for lower cost and better wear life in replacing leaded bronzes. They are used for both oscillating and rotating applications involving speeds up to 1400 ft/min and temperatures up to 250°F.

**Aluminum Alloys** (DeHart, 1984; Shabel et al., 1992). Although finding only minor use in general industrial applications because of their limited compatibility with steel journals, aluminum alloys containing 6.5% tin, 1% copper, and up to 4% silicon are used as solid, bimetal, and trimetal bearings in automotive engines, reciprocating compressors, and aircraft equipment. Good journal finish and shaft hardness of Rockwell B 85 or higher are required. The good fatigue and corrosion resistance of aluminum alloys have led to use of a number of unique alloys containing major additions of silicon, lead, or tin to provide better compatibility characteristics.

## Dry and Semilubricated Bearings

Various plastics, porous bronze and porous iron, carbon–graphite, rubber, and wood are widely used for bearings operating dry or with sparse lubrication (Booser, 1992). Unique properties of these materials have led to their broad use in applications once employing oil film and ball and roller bearings. While these materials provide good performance under conditions of poor or nonexistent lubrication at low speeds, performance commonly improves the closer the approach to full film lubrication.

### Plastics

Most commercial plastics find some use both dry and lubricated in slow-speed bearings at light loads (Jamison, 1994). The most commonly used thermoplastics for bearings are PTFE, nylon, and acetal resins. Thermosetting plastics used for bearings include phenolics, polyesters, and polyimides. [Table 3.10.16](#) compares characteristics of typical plastic bearings with those of carbon–graphite, wood, and rubber which are used in similar applications.

In addition to the maximum temperature which can be tolerated, three operating limits shown in [Table 3.10.16](#) are normally defined for plastic bearings: (1) maximum load at low speed, which reflects the compressive yield strength, (2) maximum speed for running under very light load, and (3) a  $Pv$  load-speed limit at intermediate speeds, which serves as a measure of the maximum tolerable surface temperature. Since wear volume in dry sliding is approximately proportional to total load and the distance of sliding,  $Pv$  also gives a measure of wear depth  $d$  in the modified form of Archard's relation (3.10.1),  $d = k(Pv)t$ , where  $t$  is the operating time and wear factor  $k =$  wear coefficient  $K/\text{hardness } H$ .

**TABLE 3.10.16. Representative Limiting Conditions for Nonmetallic Bearing Materials**

Material	Maximum Temperature, °C	$P_v$ Limit, MN/(m <sup>2</sup> ·sec) <sup>a</sup>	Maximum Pressure, $P$ , MN/m <sup>2b</sup>	Maximum speed, $v$ , m/sec

<sup>b</sup> To convert MN/m<sup>2</sup> to psi, multiply by 145.

Typical values of this wear factor  $k$  are given in Table 3.10.17. Since  $k$  values involve substantial variability, prototype tests are highly desirable for any planned application. Added fillers can reduce the wear factor for the base polymer by a factor of 10 to 1000 and more (Blanchet and Kennedy, 1992). Common fillers include inorganic powders such as clay, glass fibers, graphite, molybdenum disulfide, and powdered metal, and also silicone fluid as an internally available lubricant.

**TABLE 3.10.17 Wear Factors for Plastic Bearings<sup>a</sup>**

<sup>c</sup> 15% glass fiber.

### Porous Metals

Bearings of compressed and sintered bronze, iron, and aluminum alloy powder are produced at the rate of millions per week for shaft sizes ranging from about 1.6 to 150 mm. These sleeve bearings and thrust washers are used in a wide variety of small electric motors, appliances, business machines, machine tools, automotive accessories, and farm and construction equipment (Morgan, 1984; Cusano, 1994). Traditional powder metal bearings consist of 90% copper and 10% tin (Table 3.10.18). The common pore volume of 20 to 30% is usually impregnated with a petroleum oil of SAE 30 viscosity. To promote

formation of an oil film, high porosity with its high oil content is employed for higher speeds, often with an oil wick or grease providing a supplementary lubricant supply. Lower porosity with up to 3.5% added graphite is used for lower speeds and oscillation where oil film formation is difficult.

Porous iron bearings are used for lower cost, often with some copper and graphite added for high load capacity at low speed. Iron with up to 40% of added 90–10 bronze powder provides many of the characteristics of porous bronze bearings while enjoying the lower cost of the iron. Porous aluminum containing 3 to 5% copper, tin, and lead finds limited use for providing cooler operation, better conformability, and lower weight.

Table 3.10.18 gives approximate operating limits for porous metal bearings. Generally, maximum  $P$  values for sleeve bearings range up to 50,000 psi-ft/min.  $Pv$  levels for thrust bearings should generally not exceed about 20% of this value.

**TABLE 3.10.18 Operating Limits for Porous Metal Bearings**

Porous Metal	Nominal Composition, wt%	Pressure limit, $P$ , MN/m <sup>2</sup>		Speed Limit $v$ , m/sec	$Pv$ Limit MN/(m·sec)
		Static	Dynamic		
Bronze	Cu 90, Sn 10	59	28	6.1	1.8 <sup>a</sup>
Iron		52	25	2.0	1.3
Iron–copper	Fe 90, Cu 10	140	28	1.1	1.4
Iron–copper–carbon	Fe 96, Cu 3, C 0.7	340	56	0.2	2.6

Aluminum		28	14	6.1	1.8

Note: To convert MN/m<sup>2</sup> to psi, multiply by 145.

<sup>a</sup> Approximately equivalent to 50,000 psi · ft/min limit often quoted by U.S. suppliers.

## Rolling Element Bearings

### Types of Rolling Element Bearings

Rolling element bearings may be classified according to the type of rolling element, i.e., ball or roller, and the loading direction. Ball and roller bearings can be designed to carry either radial or thrust loads, or a combination of the two. Standard rolling element bearing configurations are shown in Figure 3.10.8, and the capabilities of the different types are summarized in Figure 3.10.9.

*Ball bearings* usually consist of a number of hardened and precisely ground balls interposed between two grooved and hardened rings or races. A cage or separator is used to keep the balls equally spaced around the groove. The most common *radial ball bearing* is a deep groove, or Conrad, type which is designed to carry large radial loads, with a small thrust load capability. The radial capacity of a deep groove bearing can be increased by inserting more balls in the bearing, by means of either a face-located filling notch (which decreases the thrust capacity) or a split inner or outer ring (which requires a means to hold the ring halves axially together). The thrust capability of a radial ball bearing can be increased by inducing angular contact between ball and rings. A single-row angular contact bearing can carry thrust load in only one direction, with the thrust load capacity being dependent on the contact angle (angle between the line of action of the force and the plane perpendicular to the shaft axis). Duplex angular contact bearings consist of two angular contact bearings mounted together so they can carry thrust loads in either direction with little axial play, or they can be mounted in tandem to double the axial and radial load-carrying capacity. Self-aligning ball bearings are designed to accommodate more shaft misalignment than is possible with other radial ball bearings.

*Thrust ball bearings* are used primarily in machinery with a vertically oriented shaft which requires a stiff axial support. Many such bearings have a 90° contact angle and, as a result, can carry essentially no radial load; they also have limited high-speed capability. If thrust loads in both directions are to be carried, a second row of balls must be added.

**FIGURE 3.10.8** Major types of rolling element bearings.

*Roller bearings* can be made with cylindrical, tapered, or spherical rollers. As with ball bearings, the rollers are contained between two rings, with a cage or separator used to keep the rollers separated. The cage can be guided by either the rollers or one of the rings. Since roller bearings operate with line contacts, as opposed to the point (or elliptical) contacts that occur in ball bearings, roller bearings are stiffer (less radial displacement per unit load) and have a greater load-carrying capacity than a ball bearing of similar size. Roller bearings are more expensive than ball bearings of comparable size.

CHARACTERISTICS OF STANDARD ROLLING ELEMENT BEARING CONFIGURATIONS

	TYPE	SIZE RANGE IN INCHES		AVERAGE RELATIVE RATINGS				DIMENSIONS	
				Capacity		Limiting Speed	Permissible Misalignment	Metric	Inch
		Bore	O.D.	Radial	Thrust				
BALL BEARINGS	CONRAD TYPE 	.1181 to 41.7323	.3750 to 55.1181	Good	Fair $\longleftrightarrow$	Conrad is basis for comparison 1.00	$\pm 0^\circ 8'$	X	X

	SELF-ALIGNING SPHERICAL ROLLER 	3.3622 to 14.1732	4.3307 to 22.0472	Poor	Excellent $\longrightarrow$	0.50	$\pm 3^\circ$	X	

FIGURE 3.10.9 Characteristics of standard rolling element bearing configurations.

Radial cylindrical roller bearings are designed to carry primarily radial loads. Cylindrical roller bearings have a high radial load capacity and low friction, so they are suitable for high-speed operation. Their thrust load capacity is limited to that which can be carried by contact (sliding) between the ends of the rollers and the flange or shoulder on the ring which contains them. The rollers in many cylindrical

roller bearings are actually slightly crowned to relieve stress concentrations which would otherwise occur at the ends of the rollers and to compensate for misalignment of the bearing. In order to increase the load-carrying capacity of roller bearings, a second row of rollers is added instead of using longer rollers. This is because long rollers (i.e., length/diameter > 1.7) tend to skew in the roller path, thus limiting their high-speed capability and sometimes shortening their life. Needle bearings have long rollers, however, and they are useful when there are severe radial space limitations and when neither high load capacity nor high speeds are required.

*Spherical roller bearings* usually have an outer ring with a spherical inside diameter, within which are barrel-shaped rollers. This makes these bearings self-aligning, and also gives them a larger contact area between roller and ring than is the case for other rolling element bearings. Because of this, spherical roller bearings have a very high radial load-carrying capacity, along with some ability to carry thrust loads. They have higher friction between roller and ring, and this limits their high-speed capability.

*Tapered roller bearings* have tapered rollers, ideally shaped like truncated cones, contained between two mating cones of different angles, the inner cone and the outer cup. The contact angle of the bearing determines its thrust load capability; a steeper angle is chosen for more thrust capacity. If a single row of rollers is used, the bearing is separable and can carry thrust loads in only one direction. If the thrust is double acting, a second bearing can be mounted in a back-to-back configuration or a double row bearing can be selected. In tapered roller bearings there is sliding contact between the ends of the rollers and the guide flange on the inner cone, and this sliding contact requires lubrication to prevent wear and reduce friction.

*Thrust roller bearings* can be either cylindrical, needle, tapered, or spherical (Figure 3.10.9). In each case there is high load-carrying capacity, but the sliding that occurs between rollers and rings requires lubrication and cooling.

### Rolling Element Bearing Materials

Ball and roller bearings require materials with excellent resistance to rolling contact fatigue and wear, as well as good dimensional stability and impact resistance. The rolling elements are subjected to cyclic contact pressures which can range from 70 to 3500 MPa (100 to 500 ksi) or more, and the bearing materials must be hard enough to resist surface fatigue under those conditions. Of the through-hardening steels which meet these requirements, the most popular is AISI 52100, which contains about 1% carbon and 1.5% chromium. In general, balls and rollers made from 52100 are hardened to about Rockwell C60. Standard bearings made from 52100 may suffer from unacceptable dimensional changes resulting from metallurgical transformations at operating temperatures above 140°C (285°F). Special stabilization heat treatments enable operation at higher temperatures, with successful operation at temperatures as high as 200°C (390°F) having been achieved in cases involving low loads. The strength and fatigue resistance of the material diminish if the bearing temperature increases above about 175°C (350°F), however, so above that temperature materials with better hot-hardness, such as M50 tool steel, are required. Carburizing steels such as AISI 8620 have been developed for tapered roller bearings and other heavily loaded types that benefit from the tougher core and case compressive residual stress developed during carburizing. For applications in oxidative or corrosive environments, a hardened martensitic stainless steel such as SAE 440C may be chosen. For the highest operating temperatures, ceramic materials may be used in bearings. The most promising of the ceramics for rolling element bearing applications is silicon nitride. Its major use so far in bearings has been in hybrid bearings with ceramic balls or rollers and metallic rings, but all-ceramic bearings have also been developed.

The temperature limits of these bearing materials are given in Table 3.10.19. For all bearing materials, great care must be taken in the processing and production stages to ensure that no defects or inclusions are present that could serve as an initiation site for fatigue cracks. For most high-performance metallic bearings, this requires a very clean steel production process, such as vacuum arc remelting. Heat treatment of the material is also important to produce the required dimensional stability. The production process for ceramic bearings is even more critical, because a defect in a ceramic bearing element could result in catastrophic fracture of the brittle material.

**TABLE 3.10.19 Temperature Limits for Rolling Element Bearing Materials**

Material	Maximum Operating Temperature	
	°C	°F
AISI 52100	140–175	285–350
AISI 8620 (carburized)	150	300
440C stainless steel	170	340
M50 tool steel	315	600
Hybrid Si <sub>3</sub> N <sub>4</sub> -M50	425	800
All-ceramic (Si <sub>3</sub> N <sub>4</sub> )	650	1200

Bearing cages or retainers have as their primary purpose the separation of the rolling elements. In some cases, they also provide some solid lubrication to the bearing. Low-carbon steel is the most common cage material, but bronze (silicon iron bronze or aluminum bronze) and polymers (particularly nylon 6-6) are used in many applications.

**Selection of Rolling Element Bearings**

It has been stated that if a rolling element bearing in service is properly lubricated, properly aligned, kept free of abrasive particles, moisture, and corrosive agents, and properly loaded, then all causes of damage will be eliminated except one, contact fatigue (Harris, 1991). The fatigue process results in a spall which may originate on or just beneath the contact surface. Studies of rolling contact fatigue life by Lundberg and Palmgren (1947; 1952) and others showed that most rolling element bearings have fatigue lives which follow a Weibull statistical distribution, wherein the dependence of strength on volume is explained by the dispersion in material strength. Most bearings today are designed according to the Lundberg–Palmgren model, which has been standardized by international (ISO, 1990) and national standards (e.g., ANSI/AFBMA, 1990), although recent work (Ioannides and Harris, 1985) has found that modern bearings have longer lives than those predicted by the standard methods.

The basic rating life of rolling element bearings is the  $L_{10}$  life, which is the number of revolutions at constant speed for which there is a 10% probability of failure (or 90% reliability). The basic dynamic load-carrying capacity, or load rating, of a bearing is the constant load  $C$  which corresponds to an  $L_{10}$  life of one million revolutions. For any other bearing load  $F$ , the  $L_{10}$  life can be determined by the following relationship:

$$L_{10} = (C/F)^n \tag{3.10.18}$$

where the load-life exponent  $n = 3$  for ball bearings, and  $n = 10/3$  for roller bearings.

The equivalent bearing load includes contributions from both radial and thrust loads, and can be calculated by the following expression:

$$F = XF_r + YF_a \tag{3.10.19}$$

where  $X$  is a radial load factor,  $Y$  is a thrust load factor,  $F_r$  is the radial load applied to the bearing, and  $F_a$  is the applied thrust (or axial) load.

Values for the dynamic load rating  $C$ , as well as the load factors  $X$  and  $Y$  for any bearing configuration can be found in manufacturers’ catalogs, or they can be calculated according to formulas given in bearing texts by Harris (1991) or Eschmann et al. (1985). Those references also give life adjustment factors which can be used to adjust the desired  $L_{10}$  life to account for special operating conditions, special material selections, special lubrication conditions, or for a reliability different from 90%.

The bearing user will generally select a commercially available bearing by the following procedure:

1. Determine the axial and thrust loads acting at the bearing location.
2. Determine the required bearing life ( $L_{10}$ ).

3. Select the most appropriate bearing type from among those given in [Figure 3.10.9](#).
4. Use the  $X$  and  $Y$  values appropriate to the type of bearing and loading conditions in Equation (3.10.19) to find the equivalent dynamic bearing load  $F$ .
5. Determine the required dynamic load capacity  $C$  from Equation (3.10.18).
6. Select a bearing with a dynamic load capacity at least as large as the required value from a manufacturer's catalog.
7. Provide an appropriate mounting arrangement for the bearing. Manufacturers' catalogs can be consulted for guidance in designing the mounting and selecting appropriate fits for the bearing. The importance of the fit cannot be overemphasized, since improper fit can result in considerable reduction in bearing life.
8. Provide adequate lubrication for the bearing (see below). Seals and/or shields may be integrated into the bearing to retain or protect the lubricant in the bearing.

### Rolling Bearing Lubrication

The primary load-carrying contacts between rolling elements and rings exhibit nearly pure rolling. There are many sliding contacts in rolling element bearings, however, including those where roller ends contact the internal flanges of rings, where rolling elements contact separator/cage, and where the separator contacts the guiding (piloting) ring of the bearing. All of those contacts must be lubricated to limit friction and wear, and either a grease or an oil can be used for that purpose.

Under most normal operating conditions, rolling element bearings can be grease lubricated. *Greases* coat surfaces with a thin boundary lubricant film of oil, thickener, and additive molecules, thus providing protection against sliding wear, and provide oil to lubricate the concentrated rolling contacts (see below). The selection of a grease depends on its effective temperature range, oil viscosity, consistency, and rust-inhibiting properties. For normal applications, a bearing should be filled with grease up to 30 to 50% of its free volume. Overfilling will cause overheating, particularly at high speeds. Grease will deteriorate with time and will leak out. For that reason, there should be a relubrication schedule, with grease being added at intervals which can be estimated by the following expression (Neale, 1993):

$$\text{relubrication interval (hours)} = \left(k/d^{1/2}\right) \left[ \left(14 \times 10^6/n\right) - 4d^{1/2} \right] \quad (3.10.20)$$

where  $k = 10$  for radial ball bearings, 5 for cylindrical roller bearings, and 1 for spherical or tapered roller bearings;  $d =$  bearing bore diameter (mm); and  $n =$  speed (rpm)

*Oil lubrication* is required when high speed or high operating temperatures preclude the use of grease. It is necessary to choose an oil of proper viscosity and appropriate viscosity–temperature characteristics in order to insure sufficient thickness of oil film in the lubricated concentrated contacts. If viscosity is too low, the film thickness will not prevent metal/metal contact, but if the viscosity is too high, excessive friction will occur. Oil can be applied to a bearing by one of several methods (listed in order of increasing effectiveness at increasing bearing speed): *oil bath*, in which the rolling elements carry the oil through the bearing; *oil circulating system*, in which the oil is pumped from the bearing through an external filter and heat exchanger and back to the bearing; *oil mist*, in which an airstream carries oil droplets to the bearing; and *oil jets*, in which the oil is injected into the bearing through carefully positioned nozzles. The quantity and entry velocity of the oil must be carefully selected and controlled in order to dissipate the heat generated in the bearing.

The lubrication mechanism in the concentrated contacts of rolling element bearings is *elastohydrodynamic lubrication* (EHL). EHL typically occurs in lubricated, nonconforming elastic contacts, such as the elliptical contact that occurs between ball and raceway or the rectangular contact between roller and ring. These lubricated contacts have a very small area and the contact pressures are very high. Because of those high pressures, the contacting surfaces deform and the lubricant viscosity increases, thereby aiding its ability to sustain heavy loading without oil-film breakdown. A diagram of these phenomena is shown in [Figure 3.10.10](#). The most important parameter of the concentrated contact, from

the point of view of rolling element bearing performance, is minimum EHL film thickness,  $h_o$ . The following expression can be used to find minimum film thickness in most rolling element bearing contacts (Hamrock and Dowson, 1977):

$$h_o = 3.63R_x U^{0.68} G^{-0.49} W_p^{-0.73} (1 - e^{-0.68\kappa}) \tag{3.10.21}$$

where  $R_x = (R_{x1} R_{x2}) / (R_{x1} + R_{x2})$ ,  $R_y = (R_{y1} R_{y2}) / (R_{y1} + R_{y2})$ , ellipticity parameter  $\kappa = R_x / R_y$ ,  $U = \mu (u_1 + u_2) / 2E'R_x$ ,  $\mu$  = absolute viscosity,  $u_1$  and  $u_2$  are velocities of rolling element and ring,  $E' = E / (1 - \nu^2)$ ,  $E$  = modulus of elasticity,  $\nu$  = Poisson's ratio,  $G = \alpha E'$ ,  $\alpha$  = pressure-viscosity exponent,  $W_p = W / E' R_x^2$ , and  $W$  = radial load.

**FIGURE 3.10.10** Typical pressure and film thickness distributions in elastohydrodynamic contact.

The minimum film thickness must be large enough to prevent metal/metal contact within the lubricated conjunctions. The criterion for this is stated as

$$h_o \geq 1.5 (r_{q1}^2 + r_{q2}^2)^{0.5} \tag{3.10.22}$$

where  $r_{q1}$  and  $r_{q2}$  are the rms surface roughness of the rolling element and ring, respectively. If the minimum film thickness is less than this value, complete EHL will not occur, and this could result in wear, surface fatigue, and eventual early bearing failure (i.e., well before the predicted  $L_{10}$  life).

An alternative to oil or grease lubrication for rolling element bearings operating under severe conditions is *solid lubrication*. Solid lubricants can be used effectively in high temperatures or vacuum conditions where liquid lubricants are impractical or would provide marginal performance. Solid lubricants do not prevent solid/solid contact, so wear of the lubricant coating can be expected; bearing life is governed by the depletion of the solid lubricant film.

### Lubricant Supply Methods

Lubrication systems for oil film bearings can generally be grouped into three classifications: self contained devices for small machines; centralized systems, common in manufacturing plants; and circulating systems dedicated to a single piece of equipment such as a motor, turbine, or compressor. Upper speed limits for common journal bearing lubrication methods are indicated in [Figure 3.10.11](#) (Wilcock and Booser, 1987). Submerging the bearing directly in an oil bath is a common alternative for vertical machines.

**FIGURE 3.10.11** Upper limits for journal bearing lubrication methods. (From Wilcock, D.F. and Booser, E.R., *Mach. Des.*; April 23, 101–107, 1987. With permission.)

**Self-Contained Units**

Lifting of oil by *capillary action* from a small reservoir is used to feed small bearings in business machines, household appliances, electrical instruments, controls, and timer motors. In capillary tubes, the height *h* to which oil will rise is (Wilcock and Booser, 1987)

$$h = 2\sigma \cos\theta / (r\rho) \tag{3.10.23}$$

where  $\sigma$  = surface tension, lb/in.,  $r$  = capillary radius (or spacing between two parallel plates), in.;  $\rho$  = oil density, lb/in.<sup>3</sup>. Because oils wet most surfaces readily, the cosine of the contact angle can be taken as unity. As an example, with  $\sigma = 1.7 \times 10^{-4}$  lb/in. for a petroleum oil, the rise in an 0.005-in.-radius capillary will be  $h = 2(1.7 \times 10^{-4})(1)/(0.005)(0.0307) = 2.2$  in.

*Wick lubrication* is applied in millions of fractional horsepower motors annually. Although wicks generally are not efficient at raising oil more than about 2 in., lift may be up to 5 in. in railway journal bearings. By referring to [Figure 3.10.12](#), petroleum oil delivery by a typical wick can be estimated by the following equation (Elwell, 1994):

$$Q = kAF_o(h_u - h) / (\mu L) \text{ in.}^3/\text{min} \tag{3.10.24}$$

where the constant  $k$  reflects both the capillary spacing in the wick and the surface tension of the oil;  $A$  is the wick cross-section area, in.<sup>2</sup>;  $F_o$  is volume fraction of oil in the saturated wick (often about 0.75);  $h_u$  is the ultimate wicking height, about 7.5 in. for SAE Grade F-1 felt;  $h$  is oil delivery height above the reservoir surface, in.;  $L$  is wick length, in.; and  $\mu$  is viscosity at the wick temperature, lb-sec/in.<sup>2</sup>  $\times 10^6$ .  $k$  is approximately 0.26 for SAE Grade F-1 felt.

*Oil rings* hanging over a journal, as illustrated in [Figure 3.10.13](#) and [Table 3.10.20](#), are used to lift oil to journal bearings in electric motors, pumps, and medium-size industrial machines (Elwell, 1994).

**FIGURE 3.10.12** Wick-lubricated journal bearing. (From Elwell, R.C., in *Handbook of Lubrication and Tribology*, Vol. 3, CRC Press, Boca Raton, FL, 1994, 515–533. With permission.)

At very low journal surface speeds below about 2 to 3 ft/sec, the ring will run synchronously with its journal. At higher speeds, increasing viscous drag on the ring in its reservoir will slow the ring surface velocity; oil ring rpm at higher speeds is often in the range of  $1/10$  the journal rpm. Above about 45 ft/sec journal surface velocity, oil delivery drops to an unusably low level as centrifugal throw-off and windage interfere.

These self-contained systems usually supply much less oil to a bearing than needed to form a full hydrodynamic oil film (Elwell, 1994). With the starved oil supply generating an oil wedge of reduced circumferential extent, power loss will be lowered at the expense of reduced load capacity (smaller minimum film thickness).

### Centralized Distribution Systems

Limitations with individual localized lubricating devices have led to widespread use of centralized systems for factory production-line equipment, construction and mining machines, and small applications. Oil or soft grease is pumped from a central reservoir in pulses or as metered continuous feed. Oil mist is piped for distances up to 300 ft for machines in petrochemical plants and steel mills. Polymer additives in the 50,000 to 150,000 molecular-weight range greatly reduce the escape of stray oil mist into the atmosphere.

### Circulating Systems

Where bearing design, reliability requirements, or equipment considerations preclude use of a simpler oil feed, a circulating system is employed involving an oil reservoir, pump, cooler, and filter (Twidale and Williams, 1984). These systems become quite compact with the space limitations in aircraft, marine, or automobile engines where the reservoir may simply be the machine sump with capacity to hold only a 20- to 60-sec oil supply. Characteristics of typical oil-circulating systems for industrial use are given in [Table 3.10.21](#) (Wilcock and Booser, 1987).

### Dynamic Seals

Fluid seals commonly accompany bearings in a wide variety of machinery, both to control leakage of lubricating oil and process fluids and to minimize contamination. Static seals, such as O-rings and gaskets, provide sealing between surfaces which do not move relative to each other. Dynamic seals, which will be the focus of this discussion, restrain flow of fluid between surfaces in relative motion. Most dynamic seals could be classified as either contact or clearance seals. Contact seals are used when the surfaces are in sliding contact, while clearance seals imply that the surfaces are in close proximity to each other but do not contact. The major types of dynamic seals are listed in [Table 3.10.22](#). Further details about the design and analysis of dynamic sealing elements can be found in the handbook article by Stair (1984) and in the book by Lebeck (1991).

As an example of a contact seal, ball bearings are often sealed to retain their lubricant and to keep out contaminants over a long lifetime. For small grease-lubricated bearings, the sealing function is often accomplished by lightly loaded contact between a rubber lip seal component and the bearing ring. For shafts ranging up to about 2 in. (5 cm) in diameter, the lip seal may be replaced by a closely fitted, but noncontacting, shield which helps contain the grease and restricts intrusion of dirt and other contaminants.

**Oil-ring bearing elements.**

**Ring cross-sections.**

Centrifugal	x		L	M	L	H

H = High, M = Moderate, L = Low.

Modified from Stair, W.K., in *Handbook of Lubrication*, Vol. 2, CRC Press, Boca Raton, FL 1984, 581–622.

For more severe sealing requirements in rolling element bearings, labyrinth clearance seals may be used (Harris, 1991).

The most common seals for rotating shafts passing through fixed housings, such as pumps or gear-boxes, are radial lip seals and mechanical face seals. These contact seals can be designed to handle a wide range of sealed fluids, temperatures, velocities, and pressures (Stair, 1984; Lebeck, 1991). Material selection and surface finish considerations are similar to those discussed in the subsections on sliding friction and its consequences and on dry and semilubricated bearings.

When high surface speeds are encountered, wear and frictional heating may prohibit use of rubbing contact seals. For such applications, clearance seals such as close-fitting labyrinth seals or controlled-clearance fluid film seals can be used. Fluid film seals can be either hydrostatic or hydrodynamic; both types have a pressurized film of fluid which prevents contact between the sealed surfaces and use pressure balancing to restrain leakage. The principles governing their operation are similar to those discussed in the subsection on fluid film bearings. Details of fluid film seals can be found in Shapiro (1995).

## 3.11 Pumps and Fans

---

*Robert F. Boehm*

### Introduction

Pumps are devices that impart a pressure increase to a liquid. Fans are used to increase the velocity of a gas, but this is also accomplished through an increase in pressure. The pressure rise found in pumps can vary tremendously, and this is a very important design parameter along with the liquid flow rate. This pressure rise can range from simply increasing the elevation of the liquid to increasing the pressure hundreds of atmospheres. Fan applications, on the other hand, generally deal with small pressure increases. In spite of this seemingly significant distinction between pumps and fans, there are many similarities in the fundamentals of certain types of these machines as well as with their application and theory of operation.

The appropriate use of pumps and fans depends upon the proper choice of device and the proper design and installation for the application. A check of sources of commercial equipment shows that many varieties of pumps and fans exist. Each of these had special characteristics that must be appreciated for achieving proper function. Preliminary design criteria for choosing between different types is given by Boehm (1987).

As is to be expected, the wise applications of pumps and fans requires knowledge of fluid flow fundamentals. Unless the fluid mechanics of a particular application are understood, the design could be less than desirable.

In this section, pump and fan types are briefly defined. In addition, typical application information is given. Also, some ideas from fluid mechanics that are especially relevant to pump and fan operation are reviewed.

### Pumps

Raising of water from wells and cisterns is the earliest form of pumping (a very detailed history of early applications is given by Ewbank, 1842). Modern applications are much broader, and these find a wide variety of machines in use. Modern pumps function on one of two principles. By far the majority of pump installations are of the *velocity head* type. In these devices, the pressure rise is achieved by giving the fluid a movement. At the exit of the machine, this movement is translated into a pressure increase. The other major type of pump is called *positive displacement*. These devices are designed to increase the pressure of the liquid while essentially trying to compress the volume. A categorization of pump types has been given by Krutzsch (1986), and an adaptation of this is shown below.

- I. Velocity head
  - A. Centrifugal
    - 1. Axial flow (single or multistage)
    - 2. Radial flow (single or double suction)
    - 3. Mixed flow (single or double suction)
    - 4. Peripheral (single or multistage)
  - B. Special Effect
    - 1. Gas lift
    - 2. Jet
    - 3. Hydraulic ram
    - 4. Electromagnetic
- II. Positive displacement
  - A. Reciprocating
    - 1. Piston, plunger
      - a. Direct acting (simplex or duplex)

- b. Power (single or double acting, simplex, duplex, triplex, multiplex)
- 2. Diaphragm (mechanically or fluid driven, simplex or multiplex)
- B. Rotary
  - 1. Single rotor (vane, piston, screw, flexible member, peristaltic)
  - 2. Multiple rotor (gear, lobe, screw, circumferential piston)

In the next subsection, some of the more common pumps are described.

### Centrifugal and Other Velocity Head Pumps

Centrifugal pumps are used in more industrial applications than any other kind of pump. This is primarily because these pumps offer low initial and upkeep costs. Traditionally, pumps of this type have been limited to low-pressure-head applications, but modern pump designs have overcome this problem unless very high pressures are required. Some of the other good characteristics of these types of devices include smooth (nonpulsating) flow and the ability to tolerate nonflow conditions.

The most important parts of the centrifugal pump are the *impeller* and *volute*. An impeller can take on many forms, ranging from essentially a spinning disk to designs with elaborate vanes. The latter is usual. Impeller design tends to be somewhat unique to each manufacturer, as well as finding a variety of designs for a variety of applications. An example of an impeller is shown in Figure 3.11.1. This device imparts a radial velocity to the fluid that has entered the pump perpendicular to the impeller. The volute (there may be one or more) performs the function of slowing the fluid and increasing the pressure. A good discussion of centrifugal pumps is given by Lobanoff and Ross (1992).

**FIGURE 3.11.1.** A schematic of a centrifugal pump is shown. The liquid enters perpendicular to the figure, and a radial velocity is imparted by clockwise spin of the impeller.

A very important factor in the specification of a centrifugal pump is the *casing orientation* and *type*. For example, the pump can be oriented vertically or horizontally. Horizontal mounting is most common. Vertical pumps usually offer benefits related to ease of priming and reduction in required net positive suction head (see discussion below). This type also requires less floor space. Submersible and immersible pumps are always of the vertical type. Another factor in the design is the way the casing is split, and this has implications about ease of manufacture and repair. Casings that are split perpendicular to the shaft are called *radially split*, while those split parallel to the shaft axis are denoted as *axially split*. The latter can be *horizontally split* or *vertically split*. The number of *stages* in the pump greatly affects the pump-output characteristics. Several stages can be incorporated into the same casing, with an associated increase in pump output. Multistage pumps are often used for applications with total developed head over 50 atm.

Whether or not a pump is self-priming can be important. If a centrifugal pump is filled with air when it is turned on, the initiation of pumping action may not be sufficient to bring the fluid into the pump. Pumps can be specified with features that can minimize priming problems.

There are other types of velocity head pumps. *Jet pumps* increase pressure by imparting momentum from a high-velocity liquid stream to a low-velocity or stagnant body of liquid. The resulting flow then

goes through a diffuser to achieve an overall pressure increase. *Gas lifts* accomplish a pumping action by a drag on gas bubbles that rise through a liquid.

### Positive-Displacement Pumps

Positive-displacement pumps demonstrate high discharge pressures and low flow rates. Usually, this is accomplished by some type of pulsating device. A piston pump is a classic example of positive-displacement machines. Rotary pumps are one type of positive-displacement device that do not impart pulsations to the existing flow (a full description of these types of pumps is given by Turton, 1994). Several techniques are available for dealing with pulsating flows, including use of double-acting pumps (usually of the reciprocating type) and installation of pulsation dampeners.

Positive-displacement pumps usually require special seals to contain the fluid. Costs are higher both initially and for maintenance compared with most pumps that operate on the velocity head basis. Positive-displacement pumps demonstrate an efficiency that is nearly independent of flow rate, in contrast to the velocity head type (see [Figure 3.11.2](#) and the discussion related to it below).

Reciprocating pumps offer very high efficiencies, reaching 90% in larger sizes. These types of pumps are more appropriate for pumping abrasive liquids (e.g., slurries) than are centrifugal pumps.

A characteristic of positive displacement pumps which may be valuable is that the output flow is proportional to pump speed. This allows this type of pump to be used for metering applications. Also a positive aspect of these pumps is that they are self-priming, except at initial start-up.

Very high head pressures (often damaging to the pump) can be developed in positive-displacement pumps if the downstream flow is blocked. For this reason, a pressure-relief-valve bypass must always be used with positive-displacement pumps.

### Pump/Flow Considerations

Performance characteristics of the pump must be considered in system design. Simple diagrams of pump applications are shown in [Figure 3.11.2](#). First, consider the left-hand figure. This represents a flow circuit, and the pressure drops related to the piping, fittings, valves, and any other flow devices found in the circuit must be estimated using the laws of fluid mechanics. Usually, these resistances (pressure drops) are found to vary approximately with the square of the liquid flow rate. Typical characteristics are shown in [Figure 3.11.3](#). Most pumps demonstrate a flow vs. pressure rise variation that is a positive value at zero flow and decreases to zero at some larger flow. Positive-displacement pumps, as shown on the right-hand side of [Figure 3.11.3](#), are an exception to this in that these devices usually cannot tolerate a zero flow. An important aspect to note is that a closed system can presumably be pressurized. A contrasting situation and its implications are discussed below.

The piping diagram shown on the right-hand side of [Figure 3.11.2](#) is a once-through system, another frequently encountered installation. However, the leg of piping through “pressure drop 1” shown there can have some very important implications related to *net positive suction head*, often denoted as **NPSH**. In simple terms, NPSH indicates the difference between the local pressure and the thermodynamic saturation pressure at the fluid temperature. If  $NPSH = 0$ , the liquid can vaporize, and this can result in a variety of outcomes from noisy pump operation to outright failure of components. This condition is called **cavitation**. Cavitation, if it occurs, will first take place at the lowest pressure point within the piping arrangement. Often this point is located at, or inside, the inlet to the pump. Most manufacturers specify how much NPSH is required for satisfactory operation of their pumps. Hence, the actual NPSH (denoted as **NPSHA**) experienced by the pump must be larger than the manufacturer’s required NPSH (called **NPSHR**). If a design indicates insufficient NPSH, changes should be made in the system, possibly including alternative piping layout, including elevation and/or size, or use of a pump with smaller NPSH requirements.

The manufacturer should be consulted for a map of operational information for a given pump. A typical form is shown in [Figure 3.11.4](#). This information will allow the designer to select a pump that satisfied the circuit operational requirements while meeting the necessary NPSH and most-efficient-operation criteria.

**FIGURE 3.11.2.** Typical pump applications, either in circuits or once-through arrangements, can be represented as combined fluid resistances as shown. The resistances are determined from fluid mechanics analyses.

**FIGURE 3.11.3.** An overlay of the pump flow vs. head curve with the circuit piping characteristics gives the operating state of the circuit. A typical velocity head pump characteristic is shown on the left, while a positive-displacement pump curve is shown on the right.

**FIGURE 3.11.4.** A full range of performance information should be available from the pump manufacturer, and this may include the parameters shown.

Several options are available to the designer for combining pumps in systems. Consider a comparison of the net effect between operating pumps in series or operating the same two pumps in parallel. Examples of this for pumps with characteristics such as centrifugal units are shown in [Figure 3.11.5](#). It is clear that one way to achieve high pumping pressures with centrifugal pumps is to place a number of units in series. This is a related effect to what is found in *multistage* designs.

**FIGURE 3.11.5.** Series (a) and parallel (b) operation of centrifugal pumps are possible. The resultant characteristics for two identical pumps are shown.

## Fans

As noted earlier, fans are devices that cause air to move. This definition is broad and can include a flapping palm branch, but the discussion here deals only with devices that impart air movement due to *rotation of an impeller inside a fixed casing*. In spite of this limiting definition, a large variety of commercial designs are included.

Fans find application in many engineering systems. Along with the chillers and boilers, they are the heart of heating, ventilating, and air conditioning (HVAC) systems. When large physical dimensions of a unit are not a design concern (usually the case), centrifugal fans are favored over axial flow units for HVAC applications. Many types of fans are found in *power plants*. Very large fans are used to furnish air to the boiler, as well as to draw or force air through cooling towers and pollution-control equipment. *Electronic cooling* finds applications for small units. Even automobiles have several fans in them. Because of the great engineering importance of fans, several organizations publish rating and testing criteria (see, for example, ASME, 1990).

Generally fans are classified according to how the air flows through the impeller. These flows may be *axial* (essentially a propeller in a duct), *radial* (conceptually much like the centrifugal pumps discussed earlier), *mixed*, and *cross*. While there are many other fan designations, all industrial units fit one of these classifications. Mixed-flow fans are so named because both axial and radial flow occur on the vanes. Casings for these devices are essentially like those for axial-flow machines, but the inlet has a radial-flow component. On cross-flow impellers, the gas traverses the blading twice.

Characteristics of fans are shown in [Figure 3.11.6](#). Since velocities can be high in fans, often both the total and the static pressure increases are considered. While both are not shown on this figure, the curves have similar variations. Of course the total  $\Delta P$  will be greater than will the static value, the difference being the velocity head. This difference increases as the volume flow increases. At zero flow (the shutoff point), the static and total pressure difference values are the same. Efficiency variation shows a sharp optimum value at the design point. For this reason, it is critical that fan designs be carefully tuned to the required conditions.

A variety of vane type are found on fans, and the type of these is also used for fan classification. Axial fans usually have vanes of airfoil shape or vanes of uniform thickness. Some vane types that might be found on a centrifugal (radial-flow) fan are shown in [Figure 3.11.7](#).

One aspect that is an issue in choosing fans for a particular application is fan efficiency. Typical efficiency comparisons of the effect of blade type on a centrifugal fan are shown in [Figure 3.11.8](#). Since velocities can be high, the value of aerodynamic design is clear. Weighing against this are cost and other factors.

An additional aspect that may be important in the choice of fans is noise generation. This may be most critical in HVAC applications. It is difficult to describe noise characteristics in brief terms because of the frequency-dependent nature of these phenomena. However, a comparison of specific sound power

**FIGURE 3.11.6.** Shown are characteristics of a centrifugal fan. The drawbacks to operating away from optimal conditions are obvious from the efficiency variation.

**FIGURE 3.11.7.** A variety of vane types that might be used on a centrifugal fan are shown.

**FIGURE 3.11.8.** Efficiency variation with volume flow of centrifugal fans for a variety of vane types is shown.

level (usually denoted by  $K_w$ ) shows backward-curved centrifugal fans with aerodynamic blades perform best among the designs. Details of noise characteristics are given elsewhere (ASHRAE, 1991).

While each type of fan has some specific qualities for certain applications, most installations use centrifugal (radial-flow) fans. A primary exception is for very-high-flow, low-pressure-rise situations where axial (propeller) fans are used.

Similarities exist between fans and pumps because the fluid density essentially does not vary through either type of machine. Of course, in pumps this is because a liquid can be assumed to be incompressible. In fans, a gas (typically air) is moved with little pressure change. As a result, the gas density can be taken to be constant. Since most fans operate near atmospheric pressure, the ideal gas assumptions can be used in determining gas properties.

Flow control in fan applications, where needed, is a very important design concern. Methods for accomplishing this involve use of dampers (either on the inlet or on the outlet of the fan), variable pitch vanes, or variable speed control. Dampers are the least expensive to install, but also the most inefficient in terms of energy use. Modern solid state controls for providing a variable frequency power to the drive motor is becoming the preferred control method, when a combination of initial and operating costs is considered.

## Defining Terms

**Cavitation:** Local liquid conditions allow vapor voids to form (boiling).

**NPSH:** Net positive suction head is the difference between the local absolute pressure of a liquid and the thermodynamic saturation pressure of the liquid based upon the temperature of the liquid. Applies to the inlet of a pump.

**NPSHA:** Actual net positive suction head is the NPSH at the given state of operation of a pump.

**NPSHR:** Required net positive suction head is the amount of NPSH required by a specific pump for a given application.

### 3.12 Liquid Atomization and Spraying

Rolf D. Reitz

Sprays are involved in many practical applications, including in the process industries (e.g., spray drying, spray cooling, powdered metals); in treatment applications (e.g., humidification, gas scrubbing); in coating applications (e.g., surface treatment, spray painting, and crop spraying); in spray combustion (e.g., burners, furnaces, rockets, gas turbines, diesel and port fuel injected engines); and in medicinal and printing applications. To be able to describe sprays it is necessary to obtain a detailed understanding of spray processes.

In the simplest case, the liquid to be sprayed is injected at a high velocity through a small orifice. Atomization is the process whereby the injected liquid is broken up into droplets. Atomization has a strong influence on spray vaporization rates because it increases the total surface area of the injected liquid greatly. Fast vaporization may be desirable in certain applications, but undesirable in others, where the liquid is required to impinge on a target. The trajectories of the spray drops are governed by the injected momentum of the drop, drag forces, and interactions between the drops and the surrounding gas. Control of these and other spray processes can lead to significant improvements in performance and in quality of product, and to reduction of emission of pollutants.

#### Spray Characterization

Practical atomizers generate sprays with a distribution of drop sizes, with average sizes in the diameter range from a few microns ( $1 \mu\text{m} = 10^{-6} \text{m}$ ) to as large as 0.5 mm. It is important to quantify the details of the distribution depending on the application. For example, the smaller drops in a spray vaporize fast, and this is helpful to control ignition processes in some combustion systems. On the other hand, the large drops carry most of the mass and momentum of the injected liquid and these drops are able to penetrate into the high-pressure gases in engine combustion chambers. Typical average drop sizes for broad classes of sprays are shown schematically in Figure 3.12.1. It should be noted that the terminology used to describe sprays in Figure 3.12.1 is qualitative and is not universally agreed upon.

**FIGURE 3.12.1** Typical average spray drop sizes for various classes of sprays. A representative size distribution is depicted for the diesel spray.

Methods for characterizing the size distribution of spray drops are discussed in References 1 and 2. A probability distribution function,  $F(D)$ , is introduced that represents the fraction of drops per unit diameter range about the diameter,  $D$ , as shown in Figure 3.12.2. The spray drop sizes span a range from a minimum diameter,  $D_{\min}$ , to a maximum diameter,  $D_{\max}$ . It is also convenient to introduce a mean or average drop diameter instead of having to specify the complete drop size distribution. The number median drop diameter (NMD) represents that drop whose diameter is such that 50% of the drops in the spray have sizes less than this size. Spray drop size distribution data can also be represented as a volume

**FIGURE 3.12.2** Cumulative spray drop number and volume distributions.

(or mass) distribution function,  $F(D^3)$ ; this gives more weight to the large drops in the distribution. In this case, a volume median diameter (VMD) or a mass median diameter (MMD) can also be defined, as indicated in [Figure 3.12.2](#).

Various other mean diameters are also in common use. These are summarized using the standard notation of Mugele and Evans<sup>2</sup> as

$$(D_{jk})^{j-k} = \frac{\int_{D_{\min}}^{D_{\max}} D^j f(D) dD}{\int_{D_{\min}}^{D_{\max}} D^k f(D) dD} \quad (3.12.1)$$

where  $f(D) = dF(D)/dD$  is the drop size probability density function (usually normalized such that  $\int_{D_{\min}}^{D_{\max}} f(D)dD = 1$ ). Commonly used mean diameters are  $D_{10}$  (i.e.,  $j = 1, k = 0$ , sometimes called the length mean diameter<sup>3</sup> and  $D_{32}$  (i.e.,  $j = 3, k = 2$ , called the Sauter mean diameter or SMD). The Sauter mean diameter has a useful physical interpretation in combustion applications since drop vaporization rates are proportional to the surface area of the drop. It represents the size of that drop that has the same volume-to-surface area ratio as that of the entire spray.

Several distribution functions have been found to fit experimental data reasonably well. Among these are the Nukiyama–Tanasawa and the Rosin–Rammler distributions which have the general form<sup>3</sup>  $f(D) = aD^p \exp\{-bD\}^q$ , where the constants  $a, p, b$ , and  $q$  characterize the size distribution. The higher the parameter,  $q$ , the more uniform the distribution, and typically  $1.5 < q < 4$ . Other distributions have been proposed which consist of logarithmic transformations of the normal distribution, such as  $f(D) = a \exp(-y^2/2)$ , where  $y = \delta \ln(\eta D / (D_{\max} - D))$ , and  $a, \delta$ , and  $\eta$  are constants. In this case, the smaller  $\delta$ , the more uniform the size distribution. It should be noted that there is no theoretical justification for any of these size distributions. Spray drop size distributions can be measured nonintrusively by using optical laser diffraction and phase/Doppler instruments. A discussion of these techniques and their accuracy is reviewed by Chigier.<sup>4</sup>

## Atomizer Design Considerations

Atomization is generally achieved by forcing a liquid or a liquid–gas mixture through a small hole or slit under pressure to create thin liquid sheets or jets moving at a high relative velocity with respect to the surrounding ambient gas. Desirable characteristics of atomizers include the ability to atomize the

liquid over a wide range of flow rates, low power requirements, and low susceptibility to blockage or fouling. In addition, atomizers should produce consistent sprays with uniform flow patterns in operation.

Atomizers can be broadly characterized as those producing hollow cone or solid cone sprays, as depicted in Figure 3.12.3. In solid cone (or full cone) sprays the spray liquid is concentrated along the spray axis, Figure 3.12.3(a). These sprays are useful in applications requiring high spray penetration, such as in diesel engines. In hollow cone sprays the axis region is relatively free of drops, giving wide spray dispersal, Figure 3.12.3(b). These sprays are often used in furnaces, gas turbines, and spray-coating applications.

FIGURE 3.12.3 Schematic diagram of (a) solid cone and (b) hollow cone pressure atomizer sprays.

Many different atomizer designs are found in applications. Common atomizer types include pressure, rotary, twin-fluid (air-assist, air-blast, effervescent), flashing, electrostatic, vibratory, and ultrasonic atomizers, as discussed next.

### Atomizer Types

In *pressure atomizers* atomization is achieved by means of a pressure difference,  $\Delta P = P_{res} - P_{gas}$ , between the liquid in the supply reservoir pressure,  $P_{res}$ , and the ambient medium pressure,  $P_{gas}$ , across a nozzle. The simplest design is the plain orifice nozzle with exit hole diameter,  $d$ , depicted in Figure 3.12.3(a). The liquid emerges at the theoretical velocity  $U = \sqrt{2\Delta P/\rho_{liquid}}$ , the (Bernoulli) velocity along the streamline A–B in Figure 3.12.3(a), where  $\rho_{liquid}$  is the density of the liquid. The actual injection velocity is less than the ideal velocity by a factor called the discharge coefficient,  $C_D$ , which is between 0.6 and 0.9 for plain hole nozzles.  $C_D$  accounts for flow losses in the nozzle.

Four main jet breakup regimes have been identified, corresponding to different combinations of liquid inertia, surface tension, and aerodynamic forces acting on the jet, as shown in Figure 3.12.4. At low injection pressures the low-velocity liquid jet breaks up due to the unstable growth of long-wavelength waves driven by surface tension forces (Rayleigh regime). As the jet velocity is increased, the growth of disturbances on the liquid surface is enhanced because of the interaction between the liquid and the ambient gas (the first and second wind-induced breakup regimes). At high injection pressures the high-velocity jet disintegrates into drops immediately after leaving the nozzle exit (atomization regime). Criteria for the boundaries between the regimes are available.<sup>5</sup> Aerodynamic effects are found to become very important relative to inertial effects when the jet Weber number,  $We_j > 40$ , where  $We_j = \rho_{gas} U^2 d / \sigma$ ,  $\rho_{gas}$  is the gas density, and  $\sigma$  is the liquid surface tension.

Experiments show that the unstable growth of surface waves is aided by high relative velocities between the liquid and the gas, and also by high turbulence and other disturbances in the liquid and gas flows, and by the use of spray liquids with low viscosity and low surface tension.

**FIGURE 3.12.4** (a) Rayleigh breakup. Drop diameters are larger than the jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (b) First wind-induced regime. Drops with diameters of the order of jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (c) Second wind-induced regime. Drop sizes smaller than the jet diameter. Breakup starts some distance downstream of nozzle. (d) Atomization regime. Drop sizes much smaller than the jet diameter. Breakup starts at nozzle exit.

Liquid breakup characteristics such as the spray drop size, the jet breakup length, and the spray angle have been related to the unstable wave growth mechanism. The wavelengths and growth rates of the waves can be predicted using results from a linear stability analysis with<sup>6</sup>

$$\frac{\Lambda}{2} = 9.02 \frac{(1 + 0.45Z^{0.5})(1 + 0.4T^{0.7})}{(1 + 0.87We_2^{1.67})^{0.6}} \quad (3.12.2a)$$

$$\Omega \left( \frac{\rho_1 a^3}{\sigma} \right)^{0.5} = \frac{0.34 + 0.38We_2^{1.5}}{(1 + Z)(1 + 1.4T^{0.6})} \quad (3.12.2b)$$

where  $\Lambda$  is the wavelength,  $\Omega$  is the growth rate of the most unstable surface wave, and  $a$  is the liquid jet radius. The maximum wave growth rate increases, and the corresponding wavelength decreases with increasing Weber number,  $We_2 = \rho_{\text{gas}} U^2 a / \sigma$ , where  $U$  is the relative velocity between the liquid and the gas. The liquid viscosity appears in the Ohnesorge number,  $Z = We_1^{1/2} / Re_1$ . Here, the Weber number  $We_1$  is based on the liquid density, the Reynolds number is  $Re_1 = Ua/\nu_1$ ,  $\nu_1$  is the liquid viscosity, and the parameter  $T = ZWe_2^{1/2}$ . The wave growth rate is reduced and the wavelength is increased as the liquid viscosity increases.

The size of the drops formed from the breakup process is often assumed to be proportional to the wavelength of the unstable surface waves in modeling studies.<sup>6</sup> However, the drop sizes in the primary breakup region near the nozzle exist have also been found to be influenced by the length scale of the energy-containing eddies in the turbulent liquid flow.<sup>7</sup> There is uncertainty about atomization mechanisms since spray measurements are complicated by the high optical density of the spray in the breakup region

(e.g., see Figure 3.12.4(d)). As the drops penetrate into the ambient gas, they interact with each other through collisions and coalescence, and the spray drop size changes dynamically within the spray as a result of secondary breakup and vaporization effects. The drop trajectories are determined by complex drop drag, breakup, and vaporization phenomena, and by interactions with the turbulent gas flow.<sup>6</sup>

High-pressure diesel sprays are intermittent and are required to start and stop quickly without dribble between injections. This is accomplished by means of a plunger arrangement that is actuated by a cam and spring system in mechanical “jerk” pump systems (see Figure 3.12.5). Modern electronic injectors include electromagnetic solenoids that permit the duration and injection pressure to be varied independently of each other and of engine speed. Experiments on diesel-type injector nozzles show that the penetration distance,  $S$ , of the tip of the spray at time,  $t$ , after the beginning of the injection is given by<sup>8</sup>

$$S = 0.39Ut \left( \rho_{\text{liquid}} / \rho_{\text{gas}} \right)^{1/2} \quad \text{for } t < t_b$$

$$S = 2.46 \sqrt{U} dt \left( \rho_{\text{liquid}} / \rho_{\text{gas}} \right)^{1/4} \quad \text{for } t > t_b$$
(3.12.3)

where the “breakup time” is  $t_b = 40.5d(\rho_{\text{liquid}}/\rho_{\text{gas}})^{1/2}/U$ . The jet breakup length (see Figure 3.12.3(a)),  $L = Ut_b$  is independent of the injection velocity. On the other hand, for low-speed jets, or for jets injected into a low-gas-density environment,  $t_b = 1.04C (\rho_{\text{liquid}} d^3/\sigma)^{1/2}$ , where  $C$  is a constant typically between 12 and 16 and  $\sigma$  is the surface tension. In this case  $L$  increases with the injection velocity.<sup>9</sup> The functional form of the above jet breakup time and length correlations can be derived for an inviscid liquid in the limits of large and small Weber number,  $We_2$  from the unstable wave growth rate in Equation (3.12.2) with  $t_b \sim \Omega^{-1}$ .

**FIGURE 3.12.5** (a) Diesel injector multihole spray nozzle, (b) showerhead, and (c) doublet impingement nozzles.

For high-speed diesel-type jets in the atomization regime the resulting spray diverges in the form of a cone with cone angle,  $\theta$ , that is usually in the range from 5 to 20°.  $\theta$  increases with gas density following  $\tan \theta = A(\rho_{\text{gas}}/\rho_{\text{liquid}})^{1/2}$ , where  $A$  is a constant that depends on the nozzle passage length and (weakly) on the injection velocity.<sup>9</sup> Very high injection pressures are required to produce small drops. In diesel engines  $\Delta P$  is typically as high as 200 Mpa, and drops are produced with mean diameters of the order of 10  $\mu\text{m}$  (see Figure 3.12.1). Drop size correlations have been proposed for plain-orifice sprays, such as that presented in Table 3.12.1.<sup>3</sup> Note, however, that these correlations do not account for the fact that the spray drop size varies with time, and from place to place in the spray. Moreover, experimental correlations often do not include some parameters that are known to influence spray drop sizes, such as the nozzle passage length and its entrance geometry. Therefore, overall drop size correlations should only be used with caution.

**TABLE 3.12.1 Representative Drop Size Correlations for Various Spray Devices**  
(Dimensional quantities are in SI units, kg, m, s)

Device	Correlation	Notes
Plain orifice	$\text{SMD} = 3.08 v_i^{0.385} (\rho_{\text{liquid}} \sigma)^{0.737} \rho_{\text{gas}}^{0.06} \Delta P^{-0.54}$	Use SI units
Fan spray	$\text{SMD} = 2.83 d_h \left( \sigma \mu_{\text{liquid}}^2 / \rho_{\text{gas}} d_h^3 \Delta P^2 \right)^{0.25}$ $+ 0.26 d_h \left( \sigma \rho_{\text{liquid}} / \rho_{\text{gas}} d_h \Delta P \right)^{0.25}$	$d_h$ = nozzle hydraulic diameter
Rotary atomizer	$\text{SMD} = 0.119 Q^{0.1} \sigma^{0.5} / N d^{0.5} \rho_{\text{liquid}}^{0.4} \mu_{\text{liquid}}^{0.1}$	$N$ = rotational speed (rev/sec), $Q$ = volumetric flow rate, $A_{\text{inj}} U$
Pressure swirl	$\text{SMD} = 4.52 \left( \sigma \mu_{\text{liquid}}^2 / \rho_{\text{gas}} \Delta P^2 \right)^{0.25} (t \cos \theta)^{0.25}$ $+ 0.39 \left( \sigma \rho_{\text{liquid}} / \rho_{\text{gas}} \Delta P \right)^{0.25} (t \cos \theta)^{0.75}$ $t = 0.0114 A_{\text{inj}} \rho_{\text{liquid}}^{1/2} d \cos \theta$	$t$ = film thickness; $\theta$ = cone angle, $d$ = discharge orifice diameter
Twin fluid/air blast	$\text{SMD} = 0.48 d \left( \sigma / \rho_{\text{gas}} U^2 d \right)^{0.4} (1 + 1/\text{ALR})^{0.4}$ $+ 0.15 d \left( \mu_{\text{liquid}}^2 / \sigma \rho_{\text{liquid}} d \right)^{0.5} (1 + 1/\text{ALR})$	ALR = air-to-liquid mass ratio
Prefilming air blast	$\text{SMD} = (1 + 1/\text{ALR}) \left[ 0.33 d_h \left( \sigma / \rho_{\text{gas}} U^2 d_p \right)^{0.6} \right. \\ \left. + 0.068 d_h \left( \mu_{\text{liquid}}^2 / \sigma \rho_{\text{liquid}} d_p \right)^{0.5} \right]$	$d_h$ = hydraulic diameter, $d_p$ = prefilmer diameter, Figure 3.12.9
Ultrasonic	$\text{SMD} = \left( 4\pi^3 \sigma / \rho_{\text{liquid}} \omega^2 \right)^{1/3}$	$\omega$ = vibration frequency

The plain orifice design is also used in twin-fluid-type liquid rocket engines in showerhead and doublet designs (Figures 3.12.5b and 3.12.5c). In the case of doublet nozzles, shown in Figure 3.12.6c, the impinging jets create unstable liquid sheets which break up to produce the sprays. Drop size correlations are available for liquid sheets such as those formed by discharging the liquid through a rectangular slit (see *fan spray*, Table 3.12.1). Thin liquid sheets or slits lead to the production of small drops. The breakup mechanism of liquid sheets is also thought to involve the unstable growth of surface waves due to surface tension and aerodynamic forces.<sup>5</sup>

In *rotary atomizers* centrifugal forces are used to further enhance the breakup process. In this case the liquid is supplied to the center of a spinning disk and liquid sheets or ligaments are thrown off the edges of the disk. The drop size depends on the rotational speed of the disk, as indicated in Table 3.12.1.

A spinning wheel or cup (turbobell) is used in some spray-painting applications. The spray shape is controlled by supplying a coflowing stream of “shaping-air.”

Centrifugal forces also play a role in the breakup mechanism of *pressure swirl atomizers* (*simplex* nozzles). These atomizers give wider spray cone angle than plain orifice nozzles, and are available in hollow cone and solid cone designs. As depicted in [Figure 3.12.3\(b\)](#) the spray liquid enters a swirl chamber tangentially to create a swirling liquid sheet. The air core vortex within the swirl chamber plays an important role in determining the thickness of the liquid sheet or film at the nozzle exit. This type of nozzle produces relatively coarse sprays. A representative SMD correction is listed in [Table 3.12.1](#). The spray cone angle depends on the ratio of the axial and tangential liquid velocity components at the exit of the nozzle. This type of atomizer is not well suited for use in transient applications because it tends to dribble at start-up and to shut down when the air core is not fully formed.

The basic drawback of all pressure atomizers is that the flow rate depends on the square root of  $\Delta P$ . The volumetric flow rate is  $Q = A_{inj} U$ , where  $A_{inj}$  is the liquid flow area at the nozzle exit, so that a factor of 20 increase in flow rate (a typical turndown ratio from idle to full load operation of a gas turbine engine) requires a factor of 400 increase in injection pressure.

This difficulty has led to so-called wide-range atomizer designs such as those shown in [Figure 3.12.6](#). The *duplex* nozzle features two sets of tangential swirl ports; the primary (or pilot) supplies fuel at low flow rates, while the secondary ports become operational at high flow rates. Another variation is the *dual-orifice* nozzle which is conceptually two simplex nozzles arranged concentrically, one supplying the primary flow and the other supplying the secondary flow. The *spill-return* nozzle is a simplex nozzle with a rear passage that returns fuel to the injection pump. In this design the flow rate is controlled by the relative spill amount, and there are no small passages to become plugged. However, the fuel is always supplied at the maximum pressure which increases the demands on the injection pump. But high swirl is always maintained in the swirl chamber and good atomization is achieved even at low flow rates.

**FIGURE 3.12.6** (a) Duplex, (b) dual orifice, and (c) spill-return-type nozzle designs.

In *twin-fluid injectors* atomization is aided by a flow of high-velocity gas through the injector passages. The high-velocity gas stream impinges on a relatively low-velocity liquid either internally (in *internal-mixing* nozzles, [Figure 3.12.7](#)) or externally (in *external-mixing* designs, [Figure 3.12.8](#)). The liquid and gas flows are typically swirled in opposite directions by means of swirl vanes to improve atomization. *Air-assist* refers to designs that use a relatively small amount of air at high (possibly sonic) velocities. *Air-blast* refers to designs that use large quantities of relatively low-velocity air which often supplies some of the air to help decrease soot formation in combustion systems<sup>3</sup>. (see [Figure 3.12.9](#).)

In *flashing* and *effervescent* atomizers a two-phase flow is passed through the injector nozzle exit. In the former the bubbles are generated by means of a phase change which occurs as the liquid, containing a dissolved propellant gas or vapor, undergoes the pressure drop through the nozzle. This process is exploited in many household spray cans, but has the disadvantage of releasing the propellant gas required for atomization into the atmosphere. In the so-called effervescent atomizer, air bubbles are introduced

FIGURE 3.12.7 Internal-mixing twin-fluid injector design.

FIGURE 3.12.8 External-mixing twin-fluid injector design.

FIGURE 3.12.9 Prefilming air blast atomizer.

FIGURE 3.12.10 Internal-mixing, effervescent atomizer.

into the liquid upstream of the exit orifice, as depicted in [Figure 3.12.10](#). The spray quality is found to depend weakly on the air bubble size and is independent of the nozzle exit diameter. This makes internal-mixing, air-assist atomizers very attractive for use with high-viscosity fluids and slurries where nozzle plugging would otherwise be a problem.<sup>3</sup>

In *electrostatic* atomizers the spray liquid is charged by applying a high-voltage drop across the nozzle. The dispersion of the spray drops is increased by exploiting electrical repulsive forces between the droplets. An electrostatic charge on the drops is also helpful in spray-coating applications, such as in automotive spray painting using electrostatic turbobell sprayers, since the charged drops are attracted to an oppositely charged target surface.

Other atomizer types include *vibratory* and *ultrasonic* atomizers (or *nebulizers*), where the drops are formed by vibrating the injector nozzle at high frequencies and at large amplitudes to produce short-wavelength disturbances to the liquid flow. Ultrasonic atomizers are used in inhalation therapy where very fine sprays (submicron sizes) are required, and an available representative drop size correlation is also listed in [Table 3.12.1](#).

## Further Information

Information about recent work in the field of atomization and sprays can be obtained through participation in the Institutes for Liquid Atomization and Spraying Systems (ILASS-Americas, -Europe, -Japan, -Korea). These regional ILASS sections hold annual meetings. An international congress (ICLASS) is also held biennially. More information is available on the ILASS-Americas homepage at <http://ucicl.eng.uci.edu/ilass>. Affiliated with the ILASS organizations is the Institute's Journal publication *Atomization and Sprays* published by Begell House, Inc., New York.

### 3.13 Flow Measurement\*

*Alan T. McDonald and Sherif A. Sherif*

This section deals with the measurement of mass flow rate or volume flow rate of a fluid in an enclosed pipe or duct system. Flow measurement in open channels is treated in Section 3.10 of this book.

The choice of a flow meter type and size depends on the required accuracy, range, cost, ease of reading or data reduction, and service life. Always select the simplest and cheapest device that gives the desired accuracy.

#### Direct Methods

Tanks can be used to determine the flow rate for steady liquid flows by measuring the volume or mass of liquid collected during a known time interval. If the time interval is long enough, flow rates may be determined precisely using tanks. Compressibility must be considered in gas volume measurements. It is not practical to measure the mass of gas, but a volume sample can be collected by placing an inverted “bell” over water and holding the pressure constant by counterweights. No calibration is required when volume measurements are set up carefully; this is a great advantage of direct methods.

Positive-displacement **flow meters** may be used in specialized applications, particularly for remote or recording uses. For example, household water and natural gas meters are calibrated to read directly in units of product. Gasoline metering pumps measure total flow and automatically compute the cost. Many positive-displacement meters are available commercially. Consult manufacturers’ literature or Reference 7 for design and installation details.

#### Restriction Flow Meters for Flow in Ducts

Most restriction flow meters for internal flow (except the laminar flow element) are based on acceleration of a fluid stream through some form of nozzle, shown schematically in Figure 3.13.1. Flow separating from the sharp edge of the nozzle throat forms a recirculation zone shown by the dashed lines downstream from the nozzle. The main flow stream continues to accelerate from the nozzle throat to form a *vena contracta* at section (2) and then decelerates again to fill the duct. At the vena contracta, the flow area is a minimum, the flow streamlines are essentially straight, and the pressure is uniform across the channel section. The theoretical flow rate is

$$\dot{m}_{\text{theoretical}} = \frac{A_2}{\sqrt{1 - (A_2/A_1)^2}} \sqrt{2\rho(p_1 - p_2)} \quad (3.13.1)$$

Equation (3.13.1) shows the general relationship for a **restriction flow meter**: Mass flow rate is proportional to the square root of the pressure differential across the meter taps. This relationship limits the flow rates that can be measured accurately to approximately a 4:1 range.

Several factors limit the utility of Equation (3.13.1) for calculating the actual mass flow rate through a meter. The actual flow area at section (2) is unknown when the vena contracta is pronounced (e.g., for orifice plates when  $D_2$  is a small fraction of  $D_1$ ). The velocity profiles approach uniform flow only at large Reynolds number. Frictional effects can become important (especially downstream from the meter) when the meter contours are abrupt. Finally, the location of the pressure taps influences the differential pressure reading,  $p_1 - p_2$ .

The actual mass flow rate is given by

\* The contributors of this chapter were asked to conform as much as possible to the nomenclature presented below, but define new terms pertaining to their particular area of specialty in the context of the chapter.

**FIGURE 3.13.1** Internal flow through a generalized nozzle, showing control volume used for analysis.

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1 - (A_t/A_1)^2}} \sqrt{2\rho(p_1 - p_2)} \tag{3.13.2}$$

where  $C$  is an empirical *discharge coefficient*.

If  $\beta = D_t/D_1$ , then  $(A_t/A_1)^2 = (D_t/D_1)^4 = \beta^4$ , and

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1 - \beta^4}} \sqrt{2\rho(p_1 - p_2)} \tag{3.13.3}$$

where  $1/(1 - \beta^4)^{1/2}$  is the *velocity correction factor*. Combining the discharge coefficient and velocity correction factor into a single *flow coefficient*,

$$K = \frac{C}{\sqrt{1 - \beta^4}} \tag{3.13.4}$$

yields the mass flow rate in the form:

$$\dot{m}_{\text{actual}} = KA_t \sqrt{2\rho(p_1 - p_2)} \tag{3.13.5}$$

Test data can be used to develop empirical equations to predict flow coefficients vs. pipe diameter and Reynolds number for standard metering systems. The accuracy of the equations (within specified ranges) is often adequate to use the meter without calibration. Otherwise, the coefficients must be measured experimentally.

For the turbulent flow regime ( $Re_D > 4000$ ), the flow coefficient may be expressed by an equation of the form:<sup>7</sup>

$$K = K_\infty + \frac{1}{\sqrt{1 - \beta^4}} \frac{b}{Re_D^n} \tag{3.13.6}$$

where subscript  $\infty$  denotes the flow coefficient at infinite Reynolds number and constants  $b$  and  $n$  allow for scaling to finite Reynolds numbers. Correlating equations and curves of flow coefficients vs. Reynolds number are given for specific metering elements in the next three subsections following the general comparison of the characteristics of orifice plate, flow nozzle, and venturi meters in [Table 3.13.1](#) (see Reference 4).

Flow meter coefficients reported in the literature have been measured with fully developed turbulent velocity distributions at the meter inlet (Section 3.1). When a flow meter is installed downstream from

**TABLE 3.13.1. Characteristics of Orifice, Flow Nozzle, and Venturi Flow Meters**

Flow Meter Type	Diagram	Head Loss	Cost
Orifice		High	Low
Flow nozzle		Intermediate	Intermediate
Venturi		Low	High

a valve, elbow, or other disturbance, a straight section of pipe must be placed in front of the meter. Approximately 10 diameters of straight pipe upstream are required for venturi meters, and up to 40 diameters for orifice plate or flow nozzle meters. Some design data for incompressible flow are given below. The same basic methods can be extended to compressible flows.<sup>7</sup>

**Orifice Plates**

The orifice plate (Figure 3.13.2) may be clamped between pipe flanges. Since its geometry is simple, it is low in cost and easy to install or replace. The sharp edge of the orifice will not foul with scale or suspended matter. However, suspended matter can build up at the inlet side of a concentric orifice in a horizontal pipe; an eccentric orifice may be placed flush with the bottom of the pipe to avoid this difficulty. The primary disadvantages of the orifice are its limited capacity and the high permanent head loss caused by uncontrolled expansion downstream from the metering element.

**FIGURE 3.13.2** Orifice geometry and pressure tap locations.

Pressure taps for orifices may be placed in several locations as shown in Figure 3.13.2 (see Reference 7 for additional details). Since the location of the pressure taps influences the empirically determined flow coefficient, one must select handbook values of *K* consistent with the pressure tap locations.

The correlating equation recommended for a concentric orifice with corner taps is

$$C = 0.5959 + 0.0312\beta^{2.1} - 0.184\beta^8 + \frac{91.71\beta^{2.5}}{Re_{D_1}^{0.75}} \tag{3.13.7}$$

FIGURE 3.13.3 Flow coefficients for concentric orifices with corner taps.

FIGURE 3.13.4 Typical installations of nozzle flow meters. (a) In plenum, (b) In duct.

Equation (3.13.7) predicts orifice discharge coefficients within  $\pm 0.6\%$  for  $0.2 < \beta < 0.75$  and for  $10^4 < Re_{D_1} < 10^7$ . Some flow coefficients calculated from Equation (3.13.7) are presented in Figure 3.13.3. Flow coefficients are relatively insensitive to Reynolds number for  $Re_{D_1} > 10^5$  when  $\beta > 0.5$ .

A similar correlating equation is available for orifice plates with  $D$  and  $D/2$  taps. Flange taps require a different correlation for every line size. Pipe taps, located at  $2\frac{1}{2}D$  and  $8D$ , no longer are recommended.

**Flow Nozzles**

Flow nozzles may be used as metering elements in either plenums or ducts, as shown in Figure 3.13.4; the nozzle section is approximately a quarter ellipse. Design details and recommended locations for pressure taps are given in Reference 7.

The correlating equation recommended for an ASME long-radius flow nozzles<sup>7</sup> is

$$C = 0.9975 - \frac{6.53\beta^{0.5}}{Re_{D_1}^{0.5}} \quad (3.13.8)$$

Equation (3.13.8) predicts discharge coefficients for flow nozzles within  $\pm 2.0\%$  for  $0.25 < \beta < 0.75$  for  $10^4 < Re_{D_1} < 10^7$ . Some flow coefficients calculated from Equation 3.13.8 are presented in [Figure 3.13.5](#). ( $K$  can be greater than 1 when the velocity correction factor exceeds 1.) For plenum installation, nozzles may be fabricated from spun aluminum, molded fiberglass, or other inexpensive materials. Typical flow coefficients are in the range  $0.95 < K < 0.99$ ; the larger values apply at high Reynolds numbers. Thus, the mass flow rate can be computed within approximately  $\pm 2\%$  using  $K = 0.97$ .

FIGURE 3.13.5 Flow coefficients for ASME long-radius flow nozzles.

### Venturis

Venturi meters are generally made from castings machined to close tolerances to duplicate the performance of the standard design, so they are heavy, bulky, and expensive. The conical diffuser section downstream from the throat gives excellent pressure recovery; overall head loss is low. Venturi meters are self-cleaning because of their smooth internal contours.

Experimentally measured discharge coefficients for venturi meters range from 0.980 to 0.995 at high Reynolds numbers ( $Re_{D_1} > 2 \times 10^5$ ). Thus,  $C = 0.99$  can be used to calculate mass flow rate within about  $\pm 1\%$  at high Reynolds number.<sup>7</sup> Consult manufacturers' literature for specific information at Reynolds numbers below  $10^5$ .

Orifice plates, flow nozzles, and venturis all produce pressure drops proportional to flow rate squared, according to Equation 3.13.4. In practice, a meter must be sized to accommodate the largest flow rate expected. Because the pressure drop vs. flow rate relationship is nonlinear, a limited range of flow rate

can be measured accurately. Flow meters with single throats usually are considered for flow rates over a 4:1 range.<sup>7</sup>

Unrecoverable head loss across a metering element may be expressed as a fraction of the differential pressure across the element. Unrecoverable head losses are shown in Figure 3.13.6.<sup>7</sup>

FIGURE 3.13.6 Permanent head loss produced by various flow metering elements.

**Laminar Flow Elements**

The laminar flow element (LFE)\* produces a pressure differential proportional to flow rate. The LFE contains a metering section subdivided into many passages, each of small enough diameter to assure fully developed laminar flow. Because the pressure drop in laminar duct flow is directly proportional to flow rate, the pressure drop vs. flow rate relationship is linear. The LFE may be used with reasonable accuracy over a 10:1 flow rate range. Because the relationship between pressure drop and flow rate for laminar flow depends on viscosity, which is a strong function of temperature, fluid temperature must be known in order to obtain accurate metering.

An LFE costs approximately as much as a venturi, but is much lighter and smaller. Thus, the LFE is widely used in applications where compactness and extended range are important.

**Linear Flow Meters**

Several flow meter types produce outputs proportional to flow rate. Some meters produce signals without the need to measure differential pressure. The most common linear flow meters are discussed briefly below.

*Float meters* indicate flow rate directly for liquids or gases. An example is shown in Figure 3.13.7. The float is carried upward in the tapered clear tube by the flowing fluid until drag force and float weight are in equilibrium. Float meters (often called rotameters) are available with factory calibration for a number of common fluids and flow rate ranges.

A *turbine flow meter* is a free-running, vaned impeller mounted in a cylindrical section of tube (Figure 3.13.8). With proper design, the rate of rotation of the impeller may be made proportional to volume

\* Patented and manufactured by Meriam Instrument Co., 10920 Madison Ave., Cleveland, OH.

**FIGURE 3.13.7** Float-type variable-area flow meter. (Courtesy of Dwyer Instrument Co., Michigan City, IN.)

flow rate over as much as a 100:1 flow rate range. Rotational speed of the turbine element can be sensed using a magnetic or modulated carrier pickup external to the meter. This sensing method therefore requires no penetrations or seals in the duct. Thus, turbine flow meters can be used safely to measure flow rates in corrosive or toxic fluids. The electrical signal can be displayed, recorded, or integrated to provide total flow information.

**FIGURE 3.13.8** Turbine flow meter. (Courtesy of Potter Aeronautical Corp., Union, NJ.)

*Vortex shedding* from a bluff obstruction may be used to meter flow. Since Strouhal number,  $St = fL/V$ , is approximately constant ( $St \approx 0.21$ ), vortex shedding frequency  $f$  is proportional to flow velocity. Vortex shedding causes velocity and pressure changes. Pressure, thermal, or ultrasonic sensors may be used to detect the vortex shedding frequency, and thus to infer the fluid velocity. (The velocity profile does affect the constancy of the shedding frequency.) Vortex flow meters can be used over a 20:1 flow rate range.<sup>7</sup>

*Electromagnetic flow meters* create a magnetic field across a pipe. When a conductive fluid passes through the field, a voltage is generated at right angles to the field and velocity vectors. Electrodes placed on a pipe diameter detect the resulting signal voltage, which is proportional to the average axial velocity when the profile is axisymmetric. The minimum flow speed should be above about 0.3 m/sec, but there are no restrictions on Reynolds number. The flow rate range normally quoted is 10:1.<sup>7</sup>

Ultrasonic flow meters also respond to average velocity at a pipe cross section. Two principal types of ultrasonic meters measure propagation time for clean liquids, and reflection frequency shift (Doppler effect) for flows carrying particulates. The speed of an acoustic wave increases in the flow direction and decreases when transmitted against the flow. For clean liquids, an acoustic path inclined to the pipe axis is used to infer flow velocity. Multiple paths are used to estimate volume flow rate accurately.

Doppler effect ultrasonic flow meters depend on reflection of sonic waves (in the megahertz range) from scattering particles in the fluid. When the particles move at flow speed, the frequency shift is proportional to flow speed; for a suitably chosen path, output is proportional to volume flow rate; ultrasonic meters may require calibration in place. One or two transducers may be used; the meter may be clamped to the outside of the pipe. Flow rate range is 10:1.<sup>7</sup>

A relatively new type of true mass flow meter is based on the effect of *Coriolis acceleration* on natural frequency of a bent tube carrying fluid. The bent tube is excited and its vibration amplitude measured. The instrument measures mass flow rate directly, and thus is ideal for two-phase or liquid–solid flow measurements. Pressure drop of the Coriolis meter may be high, but its useful flow rate range is 100:1.

### Traversing Methods

In situations such as in air handling or refrigeration equipment, it may be impractical or impossible to install a fixed flow meter, but it may be possible to measure flow rate using a traversing technique.<sup>1</sup> To measure flow rate by **traverse**, the duct cross section is subdivided into segments of equal area. The fluid velocity is measured at the center of each area segment using a pitot tube (see Figure 3.13.9), a total head tube, or a suitable anemometer. The volume flow rate for each segment is approximated by the product of the measured velocity and segment area. Flow rate through the entire duct is the sum of these segmental flow rates. For details of recommended procedures see Reference 1 or 6.

$$V = \sqrt{2(P_T - P_S)/\rho}$$

FIGURE 3.13.9 Pitot tube.

Use of probes for traverse measurements requires direct access to the flow field. Pitot tubes give uncertain results when pressure gradients or streamline curvature are present, and they respond slowly. Two types of anemometers — **thermal anemometers** and **laser Doppler anemometers** — partially overcome these difficulties, although they introduce new complications.

*Thermal anemometers* use electrically heated tiny elements (either hot-wire or hot-film elements). Sophisticated feedback circuits are used to maintain the temperature of the element constant and to sense the input heating rate. The heating rate is related to the local flow velocity by calibration. The primary advantage of thermal anemometers is the small size of the sensing element. Sensors as small as 0.002 mm in diameter and 0.1 mm long are available commercially. Because the thermal mass of such tiny elements is extremely small, their response to fluctuations in flow velocity is rapid. Frequency responses to the 50-kHz range have been quoted.<sup>3</sup> Thus, thermal anemometers are ideal for measuring turbulence quantities. Insulating coatings may be applied to permit their use in conductive or corrosive gases or liquids.

Because of their fast response and small size, thermal anemometers are used extensively for research. Numerous schemes for treating the resulting data have been published. Digital processing techniques, including fast Fourier transforms, can be used to obtain mean values and moments, and to analyze signal frequency content and correlations.

*Laser Doppler anemometers* (LDAs) can be used for specialized applications where direct physical access to the flow field is difficult or impossible.<sup>5</sup> Laser beam(s) are focused to a small volume in the flow at the location of interest; laser light is scattered from particles present in the flow or introduced for this purpose. A frequency shift is caused by the local flow speed (Doppler effect). Scattered light and a reference beam are collected by receiving optics. The frequency shift is proportional to the flow speed; this relationship may be calculated, so there is no need for calibration. Since velocity is measured directly, the signal is unaffected by changes in temperature, density, or composition in the flow field. The primary disadvantages of LDAs are the expensive and fragile optical equipment and the need for careful alignment.

## Viscosity Measurements

Viscometry is the technique of measuring the viscosity of a fluid. Viscometers are classified as rotational, capillary, or miscellaneous, depending on the technique employed. Rotational viscometers use the principle that a rotating body immersed in a liquid experiences a viscous drag which is a function of the viscosity of the liquid, the shape and size of the body, and the speed of its rotation. Rotational viscometers are widely used because measurements can be carried out for extended periods of time. Several types of viscometers are classified as rotational and [Figure 3.13.10](#) is a schematic diagram illustrating a typical instrument of this type.

Capillary viscometry uses the principle that when a liquid passes in laminar flow through a tube, the viscosity of the liquid can be determined from measurements of the volume flow rate, the applied pressure, and the tube dimensions. Viscometers that cannot be classified either as rotational or capillary include the falling ball viscometer. Its method of operation is based on Stokes' law which relates the viscosity of a Newtonian fluid to the velocity of a sphere falling in it. Falling ball viscometers are often employed for reasonably viscous fluids. Rising bubble viscometers utilize the principle that the rise of an air bubble through a liquid medium gives a visual measurement of liquid viscosity. Because of their simplicity, rising bubble viscometers are commonly used to estimate the viscosity of varnish, lacquer, and other similar media.

## Defining Terms

**Flow meter:** Device used to measure mass flow rate or volume flow rate of fluid flowing in a duct.

**Restriction flow meter:** Flow meter that causes flowing fluid to accelerate in a nozzle, creating a pressure change that can be measured and related to flow rate.

**FIGURE 3.13.10** Rotational viscometer.

**Thermal anemometer:** Heated sensor used to infer local fluid velocity by sensing changes in heat transfer from a small electrically heated surface exposed to the fluid flow.

**Traverse:** Systematic procedure used to traverse a probe across a duct cross-section to measure flow rate through the duct.

### Further Information

This section presents only a survey of flow measurement methods. The references contain a wealth of further information. Baker<sup>2</sup> surveys the field and discusses precision, calibration, probe and tracer methods, and likely developments. Miller<sup>7</sup> is the most comprehensive and current reference available for information on restriction flow meters. Goldstein<sup>5</sup> treats a variety of measurement methods in his recently revised and updated book. Spitzer<sup>8</sup> presents an excellent practical discussion of flow measurement. Measurement of viscosity is extensively treated in *Viscosity and Flow Measurement: A Laboratory Handbook of Rheology*, by Van Wazer, J.R., Lyons, J.W., Kim, K.Y., and Colwell, R.E., Interscience Publishers, John Wiley & Sons, New York, 1963.

### 3.14 Micro/Nanotribology

*Bharat Bhushan*

#### Introduction

The emerging field of micro/nanotribology is concerned with processes ranging from atomic and molecular scales to microscale, occurring during adhesion, friction, wear, and thin-film lubrication at sliding surfaces (Bhushan, 1995, 1997; Bhushan et al., 1995). The differences between conventional tribology or macrotribology and micro/nanotribology are contrasted in Figure 3.14.1. In macrotribology, tests are conducted on components with relatively large mass under heavily loaded conditions. In these tests, wear is inevitable and the bulk properties of mating components dominate the tribological performance. In micro/nanotribology, measurements are made on at least one of the mating components, with relatively small mass under lightly loaded conditions. In this situation, negligible wear occurs and the surface properties dominate the tribological performance.

**FIGURE 3.14.1** Comparison between macrotribology and microtribology.

Micro/nanotribological investigations are needed to develop fundamental understanding of interfacial phenomena on a small scale and to study interfacial phenomena in the micro- and nanostructures used in magnetic storage systems, microelectromechanical systems (MEMS), and other industrial applications (Bhushan, 1995, 1996, 1997). Friction and wear of lightly loaded micro/nanocomponents are highly dependent on the surface interactions (few atomic layers). These structures are generally lubricated with molecularly thin films. Micro- and nanotribological studies are also valuable in fundamental understanding of interfacial phenomena in macrostructures to provide a bridge between science and engineering (Bowden and Tabor, 1950, 1964; Bhushan and Gupta, 1997; Bhushan, 1996).

In 1985, Binnig et al. (1986) developed an “atomic force microscope” (AFM) to measure ultrasmall forces (less than  $1 \mu\text{N}$ ) present between the AFM tip surface and the sample surface. AFMs can be used for measurement of *all engineering surfaces* of any surface roughness, which may be either electrically conducting or insulating. AFM has become a popular surface profiler for topographic measurements on micro- to nanoscale. These are also used for scratching, wear, and nanofabrication purposes. AFMs have been modified in order to measure both normal and friction forces and this instrument is generally called a friction force microscope (FFM) or a lateral force microscope (LFM). New transducers in conjunction with an AFM can be used for measurements of elastic/plastic mechanical properties (such as load-displacement curves, indentation hardness, and modulus of elasticity) (Bhushan et al., 1996). A surface force apparatus (SFA) was first developed in 1969 (Tabor and Winterton, 1969) to study both static and dynamic properties of molecularly thin liquid films sandwiched between two molecularly smooth surfaces. SFAs are being used to study rheology of molecularly thin liquid films; however, the liquid under study has to be confined between molecularly smooth surfaces with radii of curvature on the order of 1 mm (leading to poorer lateral resolution as compared with AFMs) (Bhushan, 1995). Only AFMs/FFMs can be used to study *engineering surfaces* in the *dry and wet conditions* with *atomic resolution*. The scope of this section is limited to the applications of AFMs/FFMs.

At most solid–solid interfaces of technological relevance, contact occurs at numerous asperities with a range of radii; a sharp AFM/FFM tip sliding on a surface simulates just one such contact. Surface roughness, adhesion, friction, wear, and lubrication at the interface between two solids with and without liquid films have been studied using the AFM and FFM. The status of current understanding of micro/nanotribology of engineering interfaces follows.

## Experimental Techniques

An AFM relies on a scanning technique to produce very high resolution, three-dimensional images of sample surfaces. The AFM measures ultrasmall forces (less than 1 nN) present between the AFM tip surface and a sample surface. These small forces are measured by measuring the motion of a very flexible cantilever beam having an ultrasmall mass. The deflection can be measured to with  $\pm 0.02$  nm, so for a typical cantilever force constant of 10 N/m, a force as low as 0.2 nN can be detected. An AFM is capable of investigating surfaces of both conductors and insulators on an atomic scale. In the operation of a high-resolution AFM, the sample is generally scanned; however, AFMs are also available where the tip is scanned and the sample is stationary. To obtain atomic resolution with an AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. A cantilever beam with a spring constant of about 1 N/m or lower is desirable. Tips have to be sharp as possible. Tips with a radius ranging from 10 to 100 nm are commonly available.

In the AFM/FFM shown in Figure 3.14.2, the sample is mounted on a PZT tube scanner which consists of separate electrodes to precisely scan the sample in the  $X$ – $Y$  plane in a raster pattern and to move the sample in the vertical ( $Z$ ) direction. A sharp tip at the end of a flexible cantilever is brought in contact with the sample. Normal and frictional forces being applied at the tip–sample interface are measured simultaneously, using a laser beam deflection technique.

**FIGURE 3.14.2** Schematic of a commercial AFM/FFM using laser beam deflection method.

Topographic measurements are typically made using a sharp tip on a cantilever beam with normal stiffness on the order of 0.5 N/m at a normal load of about 10 nN, and friction measurements are carried out in the load range of 10 to 150 nN. The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern. Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. A maximum scan size of  $125 \times 125 \mu\text{m}$  and scan rate of 122 Hz typically can be used. Higher scan rates are used for small scan lengths.

For nanoscale boundary lubrication studies, the samples are typically scanned over an area of  $1 \times 1 \mu\text{m}$  at a normal force of about 300 nN, in a direction orthogonal to the long axis of the cantilever beam (Bhushan, 1997). The samples are generally scanned with a scan rate of 1 Hz and the scanning speed of  $2 \mu\text{m}/\text{sec}$ . The coefficient of friction is monitored during scanning for a desired number of cycles. After the scanning test, a larger area of  $2 \times 2 \mu\text{m}$  is scanned at a normal force of 40 nN to observe for any wear scar.

For microscale scratching, microscale wear, and nano-scale indentation hardness measurements, a sharp single-crystal natural diamond tip mounted on a stainless steel cantilever beam with a normal stiffness on the order of 25 N/m is used at relatively higher loads (1 to 150  $\mu\text{N}$ ). For wear studies, typically an area of  $2 \times 2 \mu\text{m}$  is scanned at various normal loads (ranging from 1 to 100  $\mu\text{N}$ ) for a selected number of cycles. For nanoindentation hardness measurements the scan size is set to zero and then normal load is applied to make the indents. During this procedure, the diamond tip is continuously pressed against the sample surface for about 2 sec at various indentation loads. The sample surface is scanned before and after the scratching, wear, or indentation to obtain the initial and the final surface topography, at a low normal load of about 0.3  $\mu\text{N}$  using the same diamond tip. An area larger than the indentation region is scanned to observe the indentation marks. Nanohardness is calculated by dividing the indentation load by the projected residual area of the indents.

In measurements using conventional AFMs, the hardness value is based on the projected residual area after imaging the indent. Identification of the boundary of the indentation mark is difficult to accomplish with great accuracy, which makes the direct measurement of contact area somewhat inaccurate. A capacitive transducer with the dual capability of depth sensing as well as *in situ* imaging is used in conjunction with an AFM (Bhushan et al., 1996). This indentation system, called nano/picoindentation, is used to make load-displacement measurements and subsequently carry out *in situ* imaging of the indent, if necessary. Indenter displacement at a given load is used to calculate the projected indent area for calculation of the hardness value. Young's modulus of elasticity is obtained from the slope of the unloading portion of the load-displacement curve.

## Surface Roughness, Adhesion, and Friction

Solid surfaces, irrespective of the method of formation, contain surface irregularities or deviations from the prescribed geometrical form. When two nominally flat surfaces are placed in contact, surface roughness causes contact to occur at discrete contact points. Deformation occurs in these points and may be either elastic or plastic, depending on the nominal stress, surface roughness, and material properties. The sum of the areas of all the contact points constitutes the real area that would be in contact, and for most materials at normal loads this will be only a small fraction of the area of contact if the surfaces were perfectly smooth. In general, real area of contact must be minimized to minimize adhesion, friction, and wear (Bhushan and Gupta, 1997; Bhushan, 1996). Characterizing surface roughness is therefore important for predicting and understanding the tribological properties of solids in contact.

Surface roughness most commonly refers to the variations in the height of the surface relative to a reference plane (Bowden and Tabor, 1950; Bhushan, 1996). Commonly measured roughness parameters, such as standard deviation of surface heights (rms), are found to be scale dependent and a function of the measuring instrument, for any given surface, Figure 3.14.3 (Poon and Bhushan, 1995). The topography of most engineering surfaces is fractal, possessing a self-similar structure over a range of scales. By using fractal analysis one can characterize the roughness of surfaces with two scale-independent fractal parameters  $D$  and  $C$  which provide information about roughness at all length scales (Ganti and

**FIGURE 3.14.3** Scale dependence of standard deviation of surface heights (rms) for a glass–ceramic substrate, measured using an AFM, a stylus profiler (SP-P2 and SP- $\alpha$ 200), and a noncontact optical profiler (NOP).

Bhushan, 1995; Bhushan, 1995). These two parameters are instrument independent and are unique for each surface.  $D$  (generally ranging from 1 to 2) primarily relates to distribution of different frequencies in the surface profile, and  $C$  to the amplitude of the surface height variations at all frequencies. A fractal model of elastic plastic contact has been used to predict whether contacts experience elastic or plastic deformation and to predict the statistical distribution of contact points.

Based on atomic-scale friction measurements of a well-characterized freshly cleaved surface of highly oriented pyrolytic graphite (HOPG), the atomic-scale friction force of HOPG exhibits the same periodicity as that of corresponding topography (Figure 3.14.4(a)), but the peaks in friction and those in topography were displaced relative to each other (Figure 3.14.4(b)). A Fourier expansion of the interatomic potential has been used to calculate the conservative interatomic forces between atoms of the FFM tip and those of the graphite surface. Maxima in the interatomic forces in the normal and lateral directions do not occur at the same location, which explains the observed shift between the peaks in the lateral force and those in the corresponding topography. Furthermore, the observed local variations in friction force were explained by variation in the intrinsic lateral force between the sample and the FFM tip, and these variations may not necessarily occur as a result of an atomic-scale stick–slip process.

Friction forces of HOPG have also been studied. Local variations in the microscale friction of cleaved graphite are observed, which arise from structural changes that occur during the cleaving process. The cleaved HOPG surface is largely atomically smooth, but exhibits line-shaped regions in which the coefficient of friction is more than an order of magnitude larger. Transmission electron microscopy indicates that the line-shaped regions consist of graphite planes of different orientation, as well as of amorphous carbon. Differences in friction can also be seen for organic mono- and multilayer films, which again seem to be the result of structural variations in the films. These measurements suggest that the FFM can be used for structural mapping of the surfaces. FFM measurements can be used to map chemical variations, as indicated by the use of the FFM with a modified probe tip to map the spatial arrangement of chemical functional groups in mixed organic monolayer films. Here, sample regions that had stronger interactions with the functionalized probe tip exhibited larger friction. For further details, see Bhushan (1995).

Local variations in the microscale friction of scratched surfaces can be significant and are seen to depend on the local surface slope rather than on the surface height distribution (Bhushan, 1995). Directionality in friction is sometimes observed on the macroscale; on the microscale this is the norm (Bhushan, 1995). This is because most “engineering” surfaces have asymmetric surface asperities so that the interaction of the FFM tip with the surface is dependent on the direction of the tip motion. Moreover, during surface-finishing processes material can be transferred preferentially onto one side of the asperities, which also causes asymmetry and directional dependence. Reduction in local variations and in the directionality of frictional properties therefore requires careful optimization of surface roughness distributions and of surface-finishing processes.

**FIGURE 3.14.4** (a) Gray-scale plots of surface topography (left) and friction profiles (right) of a  $1 \times 1$  nm area of freshly cleaved HOPG, showing the atomic-scale variation of topography and friction, (b) diagram of superimposed topography and friction profiles from (a); the symbols correspond to maxima. Note the spatial shift between the two profiles.

Table 3.14.1 shows the coefficient of friction measured for two surfaces on micro- and macroscales. The coefficient of friction is defined as the ratio of friction force to the normal load. The values on the microscale are much lower than those on the macroscale. When measured for the small contact areas and very low loads used in microscale studies, indentation hardness and modulus of elasticity are higher than at the macroscale. This reduces the degree of wear. In addition, the small apparent areas of contact reduce the number of particles trapped at the interface, and thus minimize the “ploughing” contribution to the friction force.

At higher loads (with contact stresses exceeding the hardness of the softer material), however, the coefficient of friction for microscale measurements increases toward values comparable with those obtained from macroscale measurements, and surface damage also increases (Bhushan et al., 1995; Bhushan and Kulkarni, 1996). Thus, Amontons’ law of friction, which states that the coefficient of

**TABLE 3.14.1 Surface Roughness and Micro- and Macroscale Coefficients of Friction of Various Samples**

Material	rms Roughness, nm	Microscale Coefficient of Friction vs. Si <sub>3</sub> N <sub>4</sub> Tip <sup>a</sup>	Macroscale Coefficient of Friction vs. Alumina Ball <sup>b</sup>
Si(111)	0.11	0.03	0.18
C <sup>+</sup> -implanted Si	0.33	0.02	0.18

<sup>a</sup> Tip radius of about 50 nm in the load range of 10 to 150 nN (2.5 to 6.1 GPa), a scanning speed of 5 m/sec and scan area of  $1 \times 1 \mu\text{m}$ .

<sup>b</sup> Ball radius of 3 mm at a normal load of 0.1 N (0.3 GPa) and average sliding speed of 0.8 mm/sec.

friction is independent of apparent contact area and normal load, does not hold for microscale measurements. These findings suggest that microcomponents sliding under lightly loaded conditions should experience very low friction and near zero wear.

### Scratching, Wear, and Indentation

The AFM can be used to investigate how surface materials can be moved or removed on micro- to nanoscales, for example, in scratching and wear (Bhushan, 1995) (where these things are undesirable) and, in nanomachining/nanofabrication (where they are desirable). The AFM can also be used for measurements of mechanical properties on micro- to nanoscales. Figure 3.14.5 shows microscratches made on Si(111) at various loads after 10 cycles. As expected, the depth of scratch increases with load. Such microscratching measurements can be used to study failure mechanisms on the microscale and to evaluate the mechanical integrity (scratch resistance) of ultrathin films at low loads.

**FIGURE 3.14.5** Surface profiles of Si(111) scratched at various loads. Note that the  $x$  and  $y$  axes are in micrometers and the  $z$  axis is in nanometers.

By scanning the sample in two dimensions with the AFM, wear scars are generated on the surface. The evolution of wear of a diamond-like carbon coating on a polished aluminum substrate is showing in Figure 3.14.6 which illustrates how the microwear profile for a load of  $20 \mu\text{N}$  develops as a function of the number of scanning cycles. Wear is not uniform, but is initiated at the nanoscratches indicating that surface defects (with high surface energy) act as initiation sites. Thus, scratch-free surfaces will be relatively resistant to wear.

Mechanical properties, such as load-displacement curves, hardness, and modulus of elasticity can be determined on micro- to picoscales using an AFM and its modifications (Bhushan, 1995; Bhushan et al., 1995, 1996). Indentability on the scale of picometers can be studied by monitoring the slope of cantilever deflection as a function of sample traveling distance after the tip is engaged and the sample

**FIGURE 3.14.6** Surface profiles of diamond-like carbon-coated thin-film disk showing the worn region; the normal load and number of test cycles are indicated. (From Bhushan, B., *Handbook of Micro/Nanotribology*, CRC Press, Boca Raton, FL, 1995. With permission.)

is pushed against the tip. For a rigid sample, cantilever deflection equals the sample traveling distance; but the former quantity is smaller if the tip indents the sample. The indentation hardness on nanoscale of bulk materials and surface films with an indentation depth as small as 1 nm can be measured. An example of hardness data as a function of indentation depth is shown in Figure 3.14.7. A decrease in hardness with an increase in indentation depth can be rationalized on the basis that, as the volume of deformed materials increases, there is a higher probability of encountering material defects. AFM measurements on ion-implanted silicon surfaces show that ion implantation increases their hardness and, thus, their wear resistance (Bhushan, 1995). Formation of surface alloy films with improved mechanical properties by ion implantation is growing in technological importance as a means of improving the mechanical properties of materials.

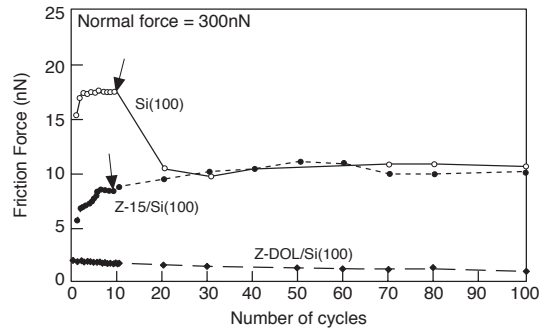

FIGURE 3.14.7 Indentation hardness as a function of residual indentation depth for Si(100).

Young's modulus of elasticity is calculated from the slope of the indentation curve during unloading (Bhushan, 1995; Bhushan et al., 1996). AFM can be used in a *force modulation mode* to measure surface elasticities: an AFM tip is scanned over the modulated sample surface with the feedback loop keeping the average force constant. For the same applied force, a soft area deforms more, and thus causes less cantilever deflection, than a hard area. The ratio of modulation amplitude to the local tip deflection is then used to create a *force modulation image*. The force modulation mode makes it easier to identify soft areas on hard substrates.

Detection of the transfer of material on a nanoscale is possible with the AFM. Indentation of C<sub>60</sub>-rich fullerene films with an AFM tip has been shown to result in the transfer of fullerene molecules to the AFM tip, as indicated by discontinuities in the cantilever deflection as a function of sample traveling distance in subsequent indentation studies (Bhushan, 1995).

## Boundary Lubrication

The "classical" approach to lubrication uses freely supported multimolecular layers of liquid lubricants (Bowden and Tabor, 1950, 1964; Bhushan, 1996). The liquid lubricants are chemically bonded to improve their wear resistance (Bhushan, 1995, 1996). To study depletion of boundary layers, the microscale friction measurements are made as a function of the number of cycles. For an example of the data of virgin Si(100) surface and silicon surface lubricated with about 2-nm-thick Z-15 and Z-Dol perfluoropolyether (PEPE) lubricants, see Figure 3.14.8. Z-Dol is PFPE lubricant with hydroxyl end groups. Its lubricant film was thermally bonded. In Figure 3.14.8, the unlubricated silicon sample shows a slight increase in friction force followed by a drop to a lower steady state value after some cycles. Depletion of native oxide and possible roughening of the silicon sample are responsible for the decrease in this

**FIGURE 3.14.8** Friction force as a function of number of cycles using a silicon nitride tip at a normal force of 300 nN for the unlubricated and lubricated silicon samples.

friction force. The initial friction force for the Z-15-lubricated sample is lower than that of the unlubricated silicon and increases gradually to a friction force value comparable with that of the silicon after some cycles. This suggests the depletion of the Z-15 lubricant in the wear track. In the case of the Z-Dol-coated silicon sample, the friction force starts out to be low and remains low during the entire test. It suggests that Z-Dol does not get displaced/depleted as readily as Z-15. Additional studies of freely supported liquid lubricants showed that either increasing the film thickness or chemically bonding the molecules to the substrate with a mobile fraction improves the lubrication performance (Bhushan, 1997).

For lubrication of microdevices, a more effect approach involves the deposition of organized, dense molecular layers of long-chain molecules on the surface contact. Such monolayers and thin films are commonly produced by Langmuir–Blodgett (LB) deposition and by chemical grafting of molecules into self-assembled monolayers (SAMs). Based on the measurements, SAMs of octadecyl ( $C_{18}$ ) compounds based on aminosilanes on a oxidized silicon exhibited a lower coefficient of friction of (0.018) and greater durability than LB films of zinc arachidate adsorbed on a gold surface coated with octadecylthiol (ODT) (coefficient of friction of 0.03) (Bhushan et al., 1995). LB films are bonded to the substrate by weak van der Waals attraction, whereas SAMs are chemically bound via covalent bonds. Because of the choice of chain length and terminal linking group that SAMs offer, they hold great promise for boundary lubrication of microdevices.

Measurement of ultrathin lubricant films with nanometer lateral resolution can be made with the AFM (Bhushan, 1995). The lubricant thickness is obtained by measuring the force on the tip as it approaches, contacts, and pushes through the liquid film and ultimately contacts the substrate. The distance between the sharp “snap-in” (owing to the formation of a liquid of meniscus between the film and the tip) at the liquid surface and the hard repulsion at the substrate surface is a measure of the liquid film thickness. This technique is now used routinely in the information-storage industry for thickness measurements (with nanoscale spatial resolution) of lubricant films, a few nanometers thick, in rigid magnetic disks.

**FIGURE 3.8.7** Transition at minimum fluidization. (From Chen, J.C. 1996. In *Annual Review of Heat Transfer*, Vol. VII, Begal House, Washington, D.C. With permission.)

where  $\phi$  = sphericity of particles (unity for spherical particles)

$\alpha_{mf}$  = volumetric fraction of fluid at minimum fluidization

Small, light particles have minimum fluidization voidage ( $\alpha_{mf}$ ) of the order 0.6, while larger particles such as sand have values closer to 0.4.

An alternative correlation for estimating the point of minimum fluidization is that of Wen and Yu (1966):

$$\frac{U_{mf} d_p \rho_f}{\mu_f} = (33.7 + 0.041 Ga)^{0.5} - 33.7 \quad (3.8.31)$$

where  $Ga = \rho_f d_p^3 (\rho_s - \rho_f) g / \mu_f^2$ .

When the fluid velocity exceeds  $U_{mf}$ , the two-phase mixture exists in the fluidized state in which the pressure gradient is essentially balanced by the gravitational force on the two-phase mixture:

$$\frac{dP}{dz} = g [\alpha_s \rho_s + \alpha_f \rho_f] \quad (3.8.32)$$

This fluidized state exists until the fluid velocity reaches a significant fraction of the terminal slip velocity, beyond which significant entrainment and transport of the solid particles occur.

### Terminal Slip Velocity

For an isolated single particle the maximum velocity relative to an upflowing fluid is the terminal slip velocity. At this condition, the interfacial drag of the fluid on the particle exactly balances the gravitational body force on the particle:

$$U_t = (U_f - U_s)_t = \left[ \frac{4d_p (\rho_s - \rho_f)}{3\rho_f} \cdot \frac{1}{C_D} \right]^{1/2} \quad (3.8.33)$$

where  $C_D$  = coefficient of drag on the particle.

The coefficient of drag on the particle ( $C_D$ ) depends on the particle Reynolds number:

$$\text{Re}_p = \frac{\rho_f d_p (U_f - U_s)}{\mu_f} \quad (3.8.34)$$

The following expressions may be used to estimate  $C_D$  as appropriate:

$$\begin{aligned} C_D &= \frac{32}{\text{Re}_p}, & \text{Re}_p &\leq 1 \\ C_D &= \frac{18.5}{\text{Re}_p^{0.67}}, & 1 &\leq \text{Re}_p \leq 10^3 \end{aligned} \quad (3.8.35)$$

### Pneumatic Conveying

A desirable mode of pneumatic conveying is two-phase flow with solid particles dispersed in the concurrent flowing fluid. Such dispersed flows can be obtained if the fluid velocity is sufficiently high. For both horizontal and vertical flows, there are minimum fluid velocities below which saltation of the solid particles due to gravitational force occurs, leading to settling of the solid particles in horizontal channels and choking of the particles in vertical channels. [Figures 3.8.8 and 3.8.9](#) for Zenz and Othmer (1960) show these different regimes of pneumatic conveying for horizontal and vertical transport, respectively. [Figure 3.8.8](#) shows that for a given rate of solids flow ( $W$ ) there is a minimum superficial fluid velocity below which solid particles tend to settle into a dense layer at the bottom of the horizontal channels. Above this saltation threshold, fully dispersed two-phase flow is obtained. In the case of

FIGURE 3.8.8 Flow characteristics in horizontal pneumatic conveying.

FIGURE 3.8.9 Flow characteristics in vertical pneumatic conveying.

vertical transport illustrated in [Figure 3.8.9](#), there is a minimum fluid velocity below which solid particles tend to detrain from the two-phase suspension. This choking limit varies not only with particle properties but also with the actual rate of particle flow. Well-designed transport systems must operate with superficial fluid velocities greater than these limiting saltation and choking velocities.

Zenz and Othmer (1960) recommend the empirical correlations represented in [Figure 3.8.10](#) estimating limiting superficial fluid velocities at incipient saltation or choking, for liquid or gas transport of uniformly sized particles. Note that these correlations are applicable for either horizontal or vertical concurrent flow. [Figure 3.8.10](#) is duplicated from the original source and is based on parameters in engineering units, as noted in the figure. To operate successfully in dispersed pneumatic conveying of solid particles, the superficial fluid velocity must exceed that determined from the empirical correlations of [Figure 3.8.10](#).

## Nomenclature

$A_c$	cross-sectional flow area of channel
$C_o$	Wallis' distribution coefficient
$d_p$	diameter of solid particles
$f_D$	Darcy friction factor
$G$	mass flow flux, $\text{kg}/\text{m}^2 \cdot \text{sec}$
$j$	volumetric flow flux, $\text{m}/\text{sec}$
$\dot{m}$	mass flow rate, $\text{kg}/\text{sec}$
$P$	pressure, $\text{N}/\text{m}^2$
$u$	velocity in axial flow direction, $\text{m}/\text{sec}$
$v$	superficial velocity in axial flow direction, $\text{m}/\text{sec}$
$x$	mass flow quality
$z$	axial coordinate

## Greek Letters

## 3.9 New-Newtonian Flows

*Thomas F. Irvine Jr. and Massimo Capobianchi*

### Introduction

An important class of fluids exists which differ from Newtonian fluids in that the relationship between the shear stress and the flow field is more complicated. Such fluids are called non-Newtonian or rheological fluids. Examples include various suspensions such as coal–water or coal–oil slurries, food products, inks, glues, soaps, polymer solutions, etc.

An interesting characteristic of rheological fluids is their large “apparent viscosities”. This results in laminar flow situations in many applications, and consequently the engineering literature is concentrated on laminar rather than turbulent flows. It should also be mentioned that knowledge of non-Newtonian fluid mechanics and heat transfer is still in an early stage and many aspects of the field remain to be clarified.

In the following sections, we will discuss the definition and classification of non-Newtonian fluids, the special problems of thermophysical properties, and the prediction of pressure drops in both laminar and turbulent flow in ducts of various cross-sectional shapes for different classes of non-Newtonian fluids.

### Classification of Non-Newtonian Fluids

It is useful to first define a Newtonian fluid since all other fluids are non-Newtonian. Newtonian fluids possess a property called viscosity and follow a law analogous to the Hookian relation between the stress applied to a solid and its strain. For a one-dimensional Newtonian fluid flow, the shear stress at a point is proportional to the rate of strain (called in the literature the *shear rate*) which is the velocity gradient at that point. The constant of proportionality is the dynamic viscosity, i.e.,

$$\tau_{y,x} = \mu \frac{du}{dy} = \mu \dot{\gamma} \quad (3.9.1)$$

where  $x$  refers to the direction of the shear stress  $y$  the direction of the velocity gradient, and  $\dot{\gamma}$  is the shear rate. The important characteristic of a Newtonian fluid is that the dynamic viscosity is independent of the shear rate.

Equation (3.9.1) is called a constitutive equation, and if  $\tau_{x,y}$  is plotted against  $\dot{\gamma}$ , the result is a linear relation whose slope is the dynamic viscosity. Such a graph is called a *flow curve* and is a convenient way to illustrate the viscous properties of various types of fluids.

Fluids which do not obey Equation (3.9.1) are called non-Newtonian. Their classifications are illustrated in [Figure 3.9.1](#) where they are separated into various categories of purely viscous time-independent or time-dependent fluids and viscoelastic fluids. Viscoelastic fluids, which from their name possess both viscous and elastic properties (as well as memory), have received considerable attention because of their ability to reduce both drag and heat transfer in channel flows. They will be discussed in a later subsection.

Purely viscous time-dependent fluids are those in which the shear stress is a function only of the shear rate but in a more complicated manner than that described in Equation (3.9.1). [Figure 3.9.2](#) illustrates the characteristics of purely viscous time-independent fluids. In the figure, (a) and (b) are fluids where the shear stress depends only on the shear rate but in a nonlinear way. Fluid (a) is called pseudoplastic (or shear thinning), and fluid (b) is called dilatant (or shear thickening). Curve (c) is one which has an initial yield stress after which it acts as a Newtonian fluid, called Buckingham plastic, and curve (d), called Hershel-Buckley, also has a yield stress after which it becomes pseudoplastic. Curve (e) depicts a Newtonian fluid.

[Figure 3.9.3](#) shows flow curves for two common classes of purely viscous time-dependent non-Newtonian fluids. It is seen that such fluids have a hysteresis loop or memory whose shape depends

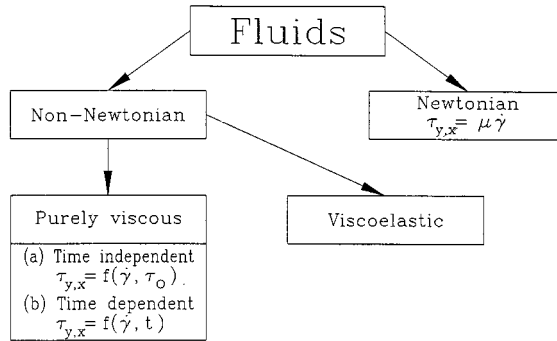

FIGURE 3.9.1 Classification of fluids.

FIGURE 3.9.2 Flow curves of purely viscous, time-independent fluids: (a) pseudoplastic; (b) dilatant; (c) Bingham plastic; (d) Hershel–Buckley; (e) Newtonian.

FIGURE 3.9.3 Flow curves for purely viscous, time-dependent fluids: (a) thixotropic; (b) rheopectic.

upon the time-dependent rate at which the shear stress is applied. Curve (a) illustrates a pseudoplastic time-dependent fluid and curve (b) a dilatant time-dependent fluid. They are called, respectively, thixotropic and rheopectic fluids and are complicated by the fact that their flow curves are difficult to characterize for any particular application.

## Apparent Viscosity

Although non-Newtonian fluids do not have the property of viscosity, in the Newtonian fluid sense, it is convenient to define an apparent viscosity which is the ratio of the local shear stress to the shear rate at that point.

$$\mu_a = \frac{\tau}{\dot{\gamma}} \quad (3.9.2)$$

The apparent viscosity is not a true property for non-Newtonian fluids because its value depends upon the flow field, or shear rate. Nevertheless, it is a useful quantity and flow curves are often constructed with the apparent viscosity as the ordinate and shear rate as the abscissa. Such a flow curve will be illustrated in a later subsection.

## Constitutive Equations

A constitutive equation is one that expresses the relation between the shear stress or apparent viscosity and the shear rate through the rheological properties of the fluid. For example, Equation (3.9.1) is the constitutive equation for a Newtonian fluid.

Many constitutive equations have been developed for non-Newtonian fluids with some of them having as many as five rheological properties. For engineering purposes, simpler equations are normally satisfactory and two of the most popular will be considered here.

Since many of the non-Newtonian fluids in engineering applications are pseudoplastic, such fluids will be used in the following to illustrate typical flow curves and constitutive equations. Figure 3.9.4 is a qualitative flow curve for a typical pseudoplastic fluid plotted with logarithmic coordinates. It is seen in the figure that at low shear rates, region (a), the fluid is Newtonian with a constant apparent viscosity of  $\mu_0$  (called the *zero shear rate viscosity*). At higher shear rates, region (b), the apparent viscosity begins to decrease until it becomes a straight line, region (c). This region (c) is called the power law region and is an important region in fluid mechanics and heat transfer. At higher shear rates than the power law region, there is another transition region (d) until again the fluid becomes Newtonian in region (e). As discussed below, regions (a), (b), and (c) are where most of the engineering applications occur.

**FIGURE 3.9.4** Illustrative flow curve for a pseudoplastic fluid (a) Newtonian region; (b) transition region I; (c) power law region; (d) transition region II; (e) high-shear-rate Newtonian region.

### Power Law Constitutive Equation

Region (c) in [Figure 3.9.4](#), which was defined above as the power law region, has a simple constitutive equation:

$$\tau = K\dot{\gamma}^n \quad (3.9.3)$$

or, from Equation (3.9.2):

$$\mu_a = K\dot{\gamma}^{n-1} \quad (3.9.4)$$

Here,  $K$  is called the fluid consistency and  $n$  the flow index. Note that if  $n = 1$ , the fluid becomes Newtonian and  $K$  becomes the dynamic viscosity. Because of its simplicity, the power law constitutive equation has been most often used in rheological studies, but at times it is inappropriate because it has several inherent flaws and anomalies. For example, if one considers the flow of a pseudoplastic fluid ( $n < 1$ ) through a circular duct, because of symmetry at the center of the duct the shear rate (velocity gradient) becomes zero and thus the apparent viscosity from Equation (3.9.4) becomes infinite. This poses conceptual difficulties especially when performing numerical analyses on such systems. Another difficulty arises when the flow field under consideration is not operating in region (c) of [Figure 3.9.4](#) but may have shear rates in region (a) and (b). In this case, the power law equation is not applicable and a more general constitutive equation is needed.

### Modified Power Law Constitutive Equation

A generalization of the power law equation which extends the shear rate range to regions (a) and (b) is given by

$$\mu_a = \frac{\mu_o}{1 + \frac{\mu_o}{K}\dot{\gamma}^{1-n}} \quad (3.9.5)$$

Examination of Equation (3.9.5) reveals that at low shear rates, the second term in the denominator becomes small compared with unity and the apparent viscosity becomes a constant equal to  $\mu_o$ . This represents the Newtonian region in [Figure 3.9.4](#). On the other hand, as the second term in the denominator becomes large compared with unity, Equation (3.9.5) becomes Equation (3.9.4) and represents region (c), the power law region. When both denominator terms must be considered, Equation (3.9.5) represents region (b) in [Figure 3.9.4](#).

An important advantage of the modified power law equation is that it retains the rheological properties  $K$  and  $n$  of the power law model plus the additional property  $\mu_o$ . Thus, as will be shown later, in the flow and heat transfer equations, the same dimensionless groups as in the power law model will appear plus an additional dimensionless parameter which describes in which of the regions (a), (b), or (c) a particular system is operating. Also, solutions using the modified power law model will have Newtonian and power law solutions as asymptotes.

Equation (3.9.5) describes the flow curve for a pseudoplastic fluid ( $n < 1$ ). For a dilatant fluid, ( $n > 1$ ), an appropriate modified power law model is given by

$$\mu_a = \mu_o \left[ 1 + \frac{K}{\mu_o} \dot{\gamma}^{n-1} \right] \quad (3.9.6)$$

Many other constitutive equations have been proposed in the literature (Skelland, 1967; Cho and Hartnett, 1982; Irvine and Karni, 1987), but the ones discussed above are sufficient for a large number of engineering applications and agree well with the experimental determinations of rheological properties.

## Rheological Property Measurements

For non-Newtonian fluids, specifying the appropriate rheological properties for a particular fluid is formidable because such fluids are usually not pure substances but various kinds of mixtures. This means that the properties are not available in handbooks or other reference materials but must be measured for each particular application. A discussion of the various instruments for measuring rheological properties is outside the scope of the present section, but a number of sources are available which describe different rheological property measurement techniques and instruments: Skelland (1967), Whorlow (1980), Irvine and Karni (1987), and Darby (1988). Figure 3.9.5 is an illustration of experimental flow curves measured with a falling needle viscometer and a square duct viscometer for polymer solutions of different concentrations. Also known in the figure as solid lines is the modified power law equation used to represent the experimental data. It is seen that Equation (3.9.5) fits the experimental data within  $\pm 2\%$ . Table 3.9.1 lists the rheological properties used in the modified power law equations in Figure 3.9.5. It must be emphasized that a proper knowledge of these properties is vital to the prediction of fluid mechanics and heat transfer phenomena in rheological fluids.

**TABLE 3.9.1 Rheological Properties Used in the Modified Power Law Equations in Figure 3.9.5 for Three Polymer Solutions of CMC-7H4**

## Fully Developed Laminar Pressure Drops for Time-Independent Non-Newtonian Fluids

### Modified Power Law Fluids

This important subject will be considered by first discussing modified power law fluids. The reason is that such solutions include both friction factor–Reynolds number relations and a shear rate parameter. The latter allows the designer to determine the shear rate region in which his system is operating and thus the appropriate solution to be used, i.e., regions (a), (b), or (c) in Figure 3.9.4.

For laminar fully developed flow of a modified power law fluid in a circular duct, the product of the friction factor and a certain Reynolds number is a constant depending on the flow index,  $n$ , and the shear rate parameter,  $\beta$ .

$$f_D \cdot \text{Re}_m = \text{constant}(n, \beta) \quad (3.9.7)$$

where  $f_D$  is the Darcy friction factor and  $\text{Re}_m$  the modified power law Reynolds number, i.e.,

$$f_D = \frac{2 \Delta p D_H}{L \rho \bar{u}^2} \quad (\text{Darcy friction factor})^*$$

\* It should be noted that the Fanning friction factor is also used in the technical literature. The Fanning friction factor is  $1/4$  of the Darcy friction factor, and will be characterized by the symbol  $f_F$ .

**FIGURE 3.9.5** Experimental measurements of apparent viscosity vs. shear rate for polymer solutions (CMC-7H4) at different concentrations. (From Park, S. et al., in *Proc. Third World Conf. Heat Transfer, Fluid Mechanics, and Thermodynamics*, Vol. 1, Elsevier, New York, 1993, 900-908.).

$$Re_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

$$\mu^* = \frac{\mu_o}{1 + \beta}$$

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n}$$

where  $\beta$  is the shear rate parameter mentioned previously which can be calculated by the designer for a certain operating duct ( $\bar{u}$  and  $d$ ) and a certain pseudoplastic fluid ( $\mu_o$ ,  $K$ ,  $n$ ). The solution for a circular tube has been calculated by Brewster and Irvine (1987) and the results are shown in [Figure 3.9.6](#) and in [Table 3.9.2](#). Referring to 3.9.6, we can see that when the  $\log_{10} \beta$  is less than approximately  $-2$ , the duct is operating in region (a) of [Figure 3.9.4](#) which is the Newtonian region and therefore classical Newtonian solutions can be used. Note that in the Newtonian region,  $Re_m$  reverts to the Newtonian Reynolds number given by

**FIGURE 3.9.6** Product of friction factor and modified Reynolds number vs.  $\log_{10} \beta$  for a circular duct.

**TABLE 3.9.2** Summary of Computed Values of  $f_D \cdot Re_m$  for Various Values of  $n$  and  $\beta$  for a Circular Duct

Exact solution	64.000	53.282	44.323	36.829	30.557	25.298

Source: Brewster, R.A. and Irvine, T.F., Jr., *Wärme und Stoffübertragung*, 21, 83–86, 1987. With permission.

$$\text{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o} \quad (3.9.8)$$

When the value of  $\log_{10} \beta$  is approximately in the range  $-2 \leq \log_{10} \beta \leq 2$ , the duct is operating in the transition region (b) of Figure 3.9.4 and the values of  $f_D \cdot \text{Re}_m$  must be obtained from Figure 3.9.6 or from Table 3.9.2.

When  $\log_{10} \beta$  is greater than approximately 2, the duct is operating in the power law region (c) of Figure 3.9.4 and power law friction factor Reynolds number relations can be used. They are also indicated in Figure 3.9.6 and Table 3.9.2. In this region,  $\text{Re}_m$  becomes the power law Reynolds number given by

$$\text{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K} \quad (3.9.9)$$

For convenience, Brewster and Irvine (1987) have presented a correlation equation which agrees within 0.1% with the results tabulated in Table 3.9.2.

$$f_D \cdot \text{Re}_m = \frac{1 + \beta}{\frac{1}{64} + \frac{\beta}{2^{3n+3} \left(\frac{3n+1}{4n}\right)^n}} \quad (3.9.10)$$

Thus, Equation (3.9.10) contains all of the information required to calculate the circular tube laminar fully developed pressure drop for a pseudoplastic fluid depending upon the shear rate region(s) under consideration, i.e., regions (a), (b), or (c) of Figure 3.9.4. Note that in scaling such non-Newtonian systems, both  $\text{Re}_m$  and  $\beta$  must be held constant. Modified power law solutions have been reported for two other duct shapes. Park et al. (1993) have presented the friction factor–Reynolds number relations for rectangular ducts and Capobianchi and Irvine (1992) for concentric annular ducts.

### Power Law Fluids

Since the power law region of modified power law fluids ( $\log_{10} \beta \geq 2$ ) is often encountered, the friction factor–Reynolds number relations will be discussed in detail in this subsection.

An analysis of power law fluids which is most useful has been presented by Kozicki et al. (1967). Although the method is approximate, its overall accuracy ( $\pm 5\%$ ) is usually sufficient for many engineering calculations. His expression for the friction factor–Reynolds number product is given by

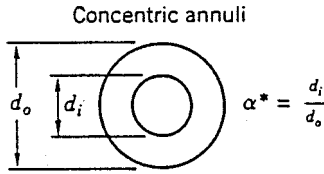

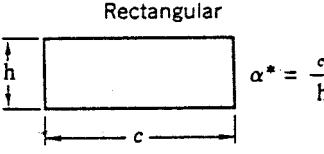

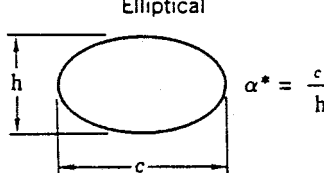

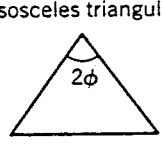

$$f_D \cdot \text{Re}^* = 2^{6n} \quad (3.9.11)$$

where

$$\text{Re}^* = \text{Kozicki Reynolds number}, \quad \text{Re}^* = \frac{\text{Re}_g}{\left[\frac{a + bn}{n}\right]^n 8^{n-1}} \quad (3.9.12)$$

and  $a$  and  $b$  are geometric constants which depend on the cross-sectional shape of the duct. For example, for a circular duct,  $a = 0.25$  and  $b = 0.75$ . Values of  $a$  and  $b$  for other duct shapes are tabulated in Table 3.9.3. For additional duct shapes in both closed and open channel flows, Kozicki et al. (1967) may be consulted.

### Fully Developed Turbulent Flow Pressure Drops

In a number of engineering design calculations for turbulent flow, the shear rate range falls in region (c) of Figure 3.9.4. Thus, power law relations are appropriate for such pressure drop calculations.

Hartnett and Kostic (1990) have investigated the various correlations which have appeared in the literature for circular tubes and have concluded that for a circular tube the relation proposed by Dodge and Metzner (1959) is the most reliable for pseudoplastic fluids. It is given by

$$\frac{1}{f_F^{1/2}} = \frac{4.0}{n^{0.75}} \cdot \log_{10} \left[ \text{Re}'_g (f_F)^{1-(1/2n)} \right] - \frac{0.40}{n^{1.2}} \tag{3.9.13}$$

where  $f_F$  is the Fanning friction factor and

$$\text{Re}'_g = \text{Re}_g \left[ \frac{8^{1-n}}{\left[ \frac{3n+1}{4n} \right]^n} \right] \tag{3.9.14}$$

Figure 3.9.7 is a graphical representation of Equation (3.9.13) which indicates the Dodge and Metzner experimental regions by solid lines, and by dashed lines where the data are extrapolated outside of their experiments.

**FIGURE 3.9.7** Dodge and Metzner relation between Fanning friction factor and  $\text{Re}'_g$ . (From Dodge, D.W. and Metzner, A.B., *AIChE J.*, 5, 189–204, 1959.)

For noncircular ducts in turbulent fully developed flow, only a limited amount of experimental data are available. Kostic and Hartnett (1984) suggest the correlation:

$$\frac{1}{f_F^{1/2}} = \frac{4}{n^{0.75}} \cdot \log_{10} \left[ \text{Re}^* (f_F)^{1-(1/2n)} \right] - \frac{0.40}{n^{0.5}} \tag{3.9.15}$$

where  $f_F$  is again the Fanning friction factor and  $\text{Re}^*$  is the Kozicki Reynolds number:

$$\text{Re}^* = \frac{\text{Re}_g}{\left[ \frac{a+bn}{n} \right]^n 8^{n-1}} \tag{3.9.16}$$

and  $a$  and  $b$  are geometric constants given in Table 3.9.3.

## Viscoelastic Fluids

### Fully Developed Turbulent Flow Pressure Drops

Viscoelastic fluids are of interest in engineering applications because of reductions of pressure drop and heat transfer which occur in turbulent channel flows. Such fluids can be prepared by dissolving small amounts of high-molecular-weight polymers, e.g., polyacrylamide, polyethylene oxide (Polyox), etc., in water. Concentrations as low as 5 parts per million by weight (wppm) result in significant pressure drop reductions. Figure 3.9.8 from Cho and Hartnett (1982) illustrates the reduction in friction factors for Polyox solutions in a small-diameter capillary tube. It is seen that at zero polymer concentration the data agree with the Blasius equation for Newtonian turbulent flow. With the addition of only 7 wppm of Polyox, there is a significant pressure drop reduction and for concentrations of 70 wppm and greater all the data fall on the Virk line which is the maximum drag-reduction asymptote. The correlations for the Blasius and Virk lines as reported by Cho and Hartnett (1982) are

$$f_F = \frac{0.079}{\text{Re}^{1/4}} \quad (\text{Blasius}) \quad (3.9.17)$$

$$f_F = 0.20 \text{Re}_a^{-0.48} \quad (\text{Virk}) \quad (3.9.18)$$

**FIGURE 3.9.8** Reduction in friction factors for polyethylene oxide (Polyox) solutions in a small-diameter capillary tube. (From Cho, Y.I. and Hartnett, J.P., *Adv. Heat Transfer*, 15, 59–141, 1982. With permission.)

At the present time, no generally accepted method exists to predict the drag reduction between the Blasius and Virk lines. Kwack and Hartnett (1983) have proposed that the amount of drag reduction between those two correlations is a function of the Weissenberg number, defined as

$$w_s = \frac{\lambda \bar{u}}{D_H} \quad (3.9.19)$$

where  $\lambda$  = characteristic time of the viscoelastic fluid. They present correlations which allow the friction factor to be estimated at several Reynolds numbers between the Blasius and Virk lines.

### Fully Developed Laminar Flow Pressure Drops

The above discussion on viscoelastic fluids has only considered fully developed turbulent flows. Laminar fully developed flows can be considered as nonviscoelastic but purely viscous non-Newtonian. Therefore, the method of Kozicki et al. (1967) may be applied to such situations once the appropriate rheological properties have been determined.

### Nomenclature

- $a$  = duct shape geometric constant  
 $b$  = duct shape geometric constant  
 $c$  = duct width (see Table 3.9.3) (m)  
 $d_i$  = concentric annuli inner diameter (see Table 3.9.3) (m)  
 $d_o$  = concentric annuli outer diameter (see Table 3.9.3) (m)  
 $f_D$  = Darcy friction factor  
 $f_F$  = Fanning friction factor  
 $h$  = duct height (see Table 3.9.3) (m)  
 $K$  = fluid consistency ( $\text{Ns}^n/\text{m}^2$ )  
 $n$  = flow index  
 $N$  = number of sides in polygon (see Table 3.9.3)  
 $\text{Re}_g$  = generalized Reynolds number,

$$\text{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K}$$

$\text{Re}_m$  = modified power law Reynolds number,

$$\text{Re}_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

$\text{Re}_N$  = modified power law Reynolds number Newtonian asymptote,

$$\text{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o}$$

$\text{Re}_a$  = apparent Reynolds number

$$\text{Re}_a = \frac{\text{Re}_g}{\left(\frac{3n+1}{4n}\right)^{n-1} 8^{n-1}}$$

$\text{Re}^*$  = Kozicki Reynolds number

$$\text{Re}^* = \frac{\rho \bar{u}^{2-n} D_H^n}{K \left[\frac{a+bn}{n}\right]^n 8^{n-1}}$$

$Re'_g =$  Metzner Reynolds number

$$Re'_g = Re_g \left[ \frac{8^{1-n}}{\left[ \frac{3n+1}{4n} \right]^n} \right]$$

$\bar{u}$  = average streamwise velocity (m/sec)

$t$  = time (sec)

$w_s$  = Weissenberg number

$x$  = direction of shear stress (m)

$y$  = direction of velocity gradient (m)

## Greek

$\alpha^*$  = duct aspect ratio in [Table 3.9.3](#)

$\beta$  = shear rate parameter

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n}$$

$\dot{\gamma}$  = shear rate (L/sec)

$\Delta P$  = pressure drop (N/m<sup>2</sup>)

$\lambda$  = characteristic time of viscoelastic fluid (sec)

$\mu_a$  = apparent viscosity (N · sec/m<sup>2</sup>)

$\mu_o$  = zero shear rate viscosity (N · sec/m<sup>2</sup>)

$\mu_\infty$  = high shear rate viscosity (N · sec/m<sup>2</sup>)

$\mu^*$  = reference viscosity

$$\mu^* = \frac{\mu_o}{1 + \beta} \left( \text{N} \cdot \text{sec/m}^2 \right)$$

$\tau_o$  = yield stress (N/m<sup>2</sup>)

$\tau_{y,x}$  = shear stress (N/m<sup>2</sup>)

$\phi$  = half apex angle (see [Table 3.9.3](#)) (°)

### Further Information

It is not possible to include all of the interesting non-Newtonian topics in a section of this scope. Other items which may be of interest and importance are listed below along with appropriate references: hydrodynamic and thermal entrance lengths, Cho and Hartnett (1982); non-Newtonian flow over external surfaces, Irvine and Karni (1987); chemical, solute, and degradation effects in viscoelastic fluids, Cho and Hartnett (1982); general references, Skelland (1967), Whorlow (1980), and Darby (1988).

## 3.10 Tribology, Lubrication, and Bearing Design

*Francis E. Kennedy, E. Richard Booser, and Donald F. Wilcock*

### Introduction

Tribology, the science and technology of contacting surfaces involving friction, wear, and lubrication, is extremely important in nearly all mechanical components. A major focus of the field is on friction, its consequences, especially wear and its reduction through lubrication and material surface engineering. The improper solution of tribological problems is responsible for huge economic losses in our society, including shortened component lives, excessive equipment downtime, and large expenditures of energy. It is particularly important that engineers use appropriate means to reduce friction and wear in mechanical systems through the proper selection of bearings, lubricants, and materials for all contacting surfaces. The aim of this section is to assist in that endeavor.

### Sliding Friction and its Consequences

#### Coefficient of Friction

If two stationary contacting bodies are held together by a normal force  $W$  and a tangential force is applied to one of them, the tangential force can be increased until it reaches a magnitude sufficient to initiate sliding. The ratio of the friction force at incipient sliding to the normal force is known as the static coefficient of friction,  $f_s$ . After sliding begins, the friction force always acts in the direction opposing motion and the ratio between that friction force and the applied normal force is the kinetic coefficient of friction,  $f_k$ .

Generally,  $f_k$  is slightly smaller than  $f_s$  and both coefficients are independent of the size or shape of the contacting surfaces. Both coefficients are very much dependent on the materials and cleanliness of the two contacting surfaces. For ordinary metallic surfaces, the friction coefficient is not very sensitive to surface roughness. For ultrasmooth or very rough surfaces, however, the friction coefficient can be larger. Typical friction coefficient values are given in Table 3.10.1. Generally, friction coefficients are greatest when the two surfaces are identical metals, slightly lower with dissimilar but mutually soluble metals, still lower for metal against nonmetal, and lowest for dissimilar nonmetals.

**TABLE 3.10.1 Some Typical Friction Coefficients<sup>a</sup>**

Material Pair	Static Friction Coefficient $f_s$		Kinetic Friction Coefficient $f_k$	
	In Air	In Vacuo	In Air, Dry	Oiled
Mild steel vs. mild steel	0.75	—	0.57	0.16
Mild steel vs. copper	0.53	0.5 (oxidized) 2.0 (clean)	0.36	0.18
Copper vs. copper	1.3	21.0	0.8	0.1
Tungsten carbide vs. copper	0.35	—	0.4	—
Tungsten carbide vs. tungsten carbide	0.2	0.4	0.15	—
Mild steel vs. polytetrafluoroethylene	0.04	—	0.05	0.04

<sup>a</sup> The friction coefficient values listed in this table were compiled from several of the references listed at the end of this section.

The kinetic coefficient of friction,  $f_k$ , for metallic or ceramic surfaces is relatively independent of sliding velocity at low and moderate velocities, although there is often a slight decrease in  $f_k$  at higher velocities. With polymers and soft metals there may be an increase in the friction coefficient with increasing velocity until a peak is reached, after which friction may decrease with further increases in velocity or temperature. The decrease in kinetic friction coefficient with increasing velocity, which may become especially pronounced at higher sliding velocities, can be responsible for friction-induced

vibrations (stick–slip oscillations) of the sliding systems. Such vibrations are an important design consideration for clutches and braking systems, and can also be important in the accurate control and positioning of robotic mechanisms and precision manufacturing systems.

### Wear

Wear is the unwanted removal of material from solid surfaces by mechanical means; it is one of the leading reasons for the failure and replacement of manufactured products. It has been estimated that the costs of wear, which include repair and replacement, along with equipment downtime, constitute up to 6% of the U.S. gross national product (Rabinowicz, 1995). Wear can be classified into four primary types: sliding wear, abrasion, erosion, and corrosive wear. Owing to its importance, wear and its control have been the subject of several handbooks (Peterson and Winer, 1980; Blau, 1992), which the interested reader may consult for further information.

*Types of Wear.* *Sliding wear* occurs to some degree whenever solid surfaces are in sliding contact. There are two predominant sliding wear mechanisms, adhesion and surface fatigue. *Adhesive wear* is caused by strong adhesive forces between the two surfaces within the real area of contact. It results in the removal of small particles from at least one of the surfaces, usually the softer one. These particles can then transfer to the other surface or mix with other material from both surfaces before being expelled as loose wear debris. Adhesive wear can be particularly severe for surfaces which have a strong affinity for each other, such as those made from identical metals. *Surface fatigue wear* occurs when repeated sliding or rolling/sliding over a wear track results in the initiation of surface or subsurface cracks, and the propagation of those cracks produces wear particles in ductile materials by a process that has been called delamination. With brittle materials, sliding wear often occurs by a *surface fracture* process.

After an initial transition or “running-in” period, sliding wear tends to reach a steady state rate which is approximated by the following Archard (or Holm/Archard) wear equation:

$$V = K * W * s / H \quad (3.10.1)$$

where  $V$  = volume of worn material,  $K$  = dimensionless wear coefficient,  $s$  = sliding distance,  $W$  = normal load between the surfaces, and  $H$  = hardness of the softer of the two contacting surfaces.

The dimensionless wear coefficient gives an indication of the tendency of a given material combination to wear; relative wear coefficient values are given in Figure 3.10.1. In general, wear coefficients are highest for identical metals sliding without lubrication, and wear is decreased by adding a lubricant and by having material pairs which are dissimilar.

*Abrasive wear* occurs when a hard, rough surface slides against a softer surface (*two-body abrasion*) or when hard particles slide between softer surfaces (*three-body abrasion*). This process usually results in material removal by plowing or chip formation, especially when the abraded surface is metallic; surface fracture can occur during abrasion of brittle surfaces. In fact, abrasion mechanisms are similar to those of grinding and lapping, which could be considered as intentional abrasion. Consideration of the cutting and plowing processes shows that abrasive wear obeys the same equation (3.10.1) as sliding wear (Archard, 1980; Rabinowicz, 1995). Typical wear coefficients for abrasive wear are given in Figure 3.10.1. Since the relative size, hardness, and sharpness of the abrading particles, or surface asperities, also affect abrasive wear rates, the wear coefficients for abrasion must include recognition of those factors (Rabinowicz, 1995).

*Erosion* occurs when solid particles or liquid droplets impinge on a solid surface. When impingement is on a ductile metallic surface, the wear process is similar to that caused by abrasion, and is dominated by plastic deformation. Brittle surfaces, on the other hand, tend to erode by surface fracture mechanisms. The material removal rate is dependent on the angle of attack of the particles, with erosion reaching a peak at low angles (about 20°) for ductile surfaces and at high angles (90°) for brittle materials. In either case, the wear rate is proportional to the mass rate of flow of the particles and to their kinetic energy; it is inversely proportional to the hardness of the surface and the energy-absorbing potential (or toughness)

**FIGURE 3.10.1** Typical values of wear coefficient for sliding and abrasive wear. (Modified from Rabinowicz, 1980, 1995.)

of the impinged surface (Schmitt, 1980). Although erosion is usually detrimental, it can be used beneficially in such material removal processes as sandblasting and abrasive water jet machining.

*Corrosive wear* results from a combination of chemical and mechanical action. It involves the synergistic effects of chemical attack (corrosion) of the surface, followed by removal of the corrosion products by a wear mechanism to expose the metallic surface, and then repetition of those processes. Since many corrosion products act to protect the surfaces from further attack, the removal of those films by wear acts to accelerate the rate of material removal. Corrosive wear can become particularly damaging when it acts in a low-amplitude oscillatory contact, which may be vibration induced, in which case it is called *fretting corrosion*.

#### Means for Wear Reduction.

The following actions can be taken to limit sliding wear:

- Insure that the sliding surfaces are well lubricated. This can best be accomplished by a liquid lubricant (see sub-section on effect of lubrication on friction and wear), but grease, or solid lubricants such as graphite or molybdenum disulfide, can sometimes be effective when liquid lubricants cannot be used.
- Choose dissimilar materials for sliding pairs.
- Use hardened surfaces.
- Add wear-resistant coatings to the contacting surfaces (see the following subsection).
- Reduce normal loads acting on the contact.
- Reduce surface temperatures. This is particularly important for polymer surfaces.

To reduce abrasive wear:

- Use hardened surfaces.
- Add a hard surface coating.
- Reduce the roughness of hard surfaces that are in contact with softer surfaces.
- Provide for the removal of abrasive particles from contacting surfaces. This can be done by flushing surfaces with liquid and/or filtering liquid coolants and lubricants.
- Reduce the size of abrasive particles.

To reduce erosion:

- Modify the angle of impingement of solid particles or liquid droplets.
- Provide for the removal of solid particles from the stream of fluid.
- Use hardened surfaces.
- Use tough materials for surfaces.
- Add protective coating to surfaces.

### Surface Engineering for Friction and Wear Reduction

Surface treatments have long been an important remedy for wear problems, and that importance has grown in recent years with the introduction of new techniques to harden surfaces or apply hard surface coatings. Available processes and characteristics for treating a steel substrate are listed in Table 3.10.2.

*Thermal transformation hardening* processes are used to harden ferrous (primarily steel) surfaces by heating the surface rapidly, transforming it to austenite, and then quenching it to form martensite. The source of heat can be one of the following: an oxyacetylene or oxypropane flame (*flame hardening*), eddy currents induced by a high-frequency electric field (*induction hardening*), a beam from a high-power laser (*laser hardening*), or a focused electron beam (*electron beam hardening*). The depth and uniformity of the hard layer depend on the rate and method of heating. These processes are characterized by a short process time and all except electron beam hardening (which requires a moderate vacuum) can be done in air.

**TABLE 3.10.2 Characteristics of Surface Treatment Processes for Steel**

Process	Coating or Treated Layer		Substrate Temperature (°C)
	Hardness (HV)	Thickness (μm)	
Surface hardening			
Flame or induction hardening	500–700	250–6000	800–1000
Laser or electron beam hardening	500–700	200–1000	950–1050
Carburizing	650–900	50–1500	800–950
Carbonitriding	650–900	25–500	800–900
Nitriding	700–1200	10–200	500–600
Boronizing	1400–1600	50–100	900–1100
Coating			
Chrome plating	850–1250	1–500	25–100
Electroless nickel	500–700	0.1–500	25–100
Hardfacing	800–2000	500–50000	1300–1400
Thermal spraying	400–2000	50–1500	<250
Physical vapor deposition	100–3000	0.05–10	100–300
Chemical vapor deposition	1000–3000	0.5–100	150–2200
Plasma-assisted chemical vapor deposition	1000–5000	0.5–10	<300
Ion implantation	750–1250	0.01–0.25	<200

*Thermal diffusion processes* involve the diffusion of atoms into surfaces to create a hard layer. In the most widely used of these processes, *carburizing* (or case hardening), carbon diffuses into a low-carbon steel surface to produce a hard, carbon-rich case. The hardness and thickness of the case depend on the temperature, exposure time, and source of carbon (either a hydrocarbon gas, a salt bath, or a packed bed of carbon). *Carbonitriding* is a process similar to carburizing which involves the simultaneous diffusion of carbon and nitrogen atoms into carbon steel surfaces. In the *nitriding* process, nitrogen atoms diffuse into the surface of a steel which contains nitride-forming elements (such as Al, Cr, Mo, V, W, or Ti) and form fine precipitates of nitride compounds in a near-surface layer. The hardness of the surface layer depends on the types of nitrides formed. The source of nitrogen can be a hot gas (usually ammonia) or a plasma. *Nitrocarburizing* and *boronizing* are related processes in which nitrogen or boron atoms diffuse

into steel surfaces and react with the iron to form a hard layer of iron carbonitride or iron boride, respectively.

Thin, hard metallic coatings can be very effective in friction and wear reduction and can be applied most effectively by *electroplating processes* (Weil and Sheppard, 1992). The most common of such coatings are *chromium*, which is plated from a chromic acid bath, and *electroless nickel*, which is deposited without electric current from a solution containing nickel ions and a reducing agent. Chromium coatings generally consist of fine-grained chromium with oxide inclusions, while electroless nickel coatings contain up to 10% of either phosphorus or boron, depending on the reducing agent used.

*Thermal spray processes* (Kushner and Novinski, 1992) enable a large variety of coating materials, including metals, ceramics and polymers, to be deposited rapidly on a wide range of substrates. Four different thermal spray processes are commercially available: *oxyfuel* (or flame) spraying of metallic wire or metallic or ceramic powder, *electric arc* spraying of metallic wire, *plasma arc* spraying of powder (metallic or ceramic), and *high-velocity oxyfuel* (or detonation gun) powder spray. In each thermal spray process the coating material, in either wire or powder form, is heated to a molten or plastic state, and the heated particles are propelled toward the surface to be coated where they adhere and rapidly solidify to form a coating. The hardness of the coating depends on both the sprayed material and the process parameters.

*Weld hardfacing processes* (Crook and Farmer, 1992) involve the application of a wear-resistant material to the surface of a part by means of a weld overlay. Weld overlay materials include ferrous alloys (such as martensitic air-hardening steel or high-chromium cast iron), nonferrous alloys (primarily cobalt- or nickel-based alloys containing hard carbide, boride, or intermetallic particles), and cemented carbides (usually tungsten carbide/cobalt cermets). In each case the surface being coated is heated to the same temperature as the molten weld layer, thus posing a limitation to the process. Weld hardfacing is best used when abrasion or sliding wear cannot be avoided (as with earthmoving or mining equipment) and the goal is to limit the wear rate.

*Vapor deposition processes* for wear-resistant coatings include *physical vapor deposition* (PVD), *chemical vapor deposition* (CVD), and several variants of those basic processes (Bhushan and Gupta, 1991). Each of the processes consists of three steps: (1) creation of a vapor phase of the coating material, (2) transportation of the vapor from source to substrate, and (3) condensation of the vapor phase on the substrate and growth of a thin solid film. In PVD processes the vapor is produced by either evaporation (by heating of the coating source) or sputtering (in which coating material is dislodged and ejected from the source as a result of bombardment by energetic particles). In some PVD processes the vapor becomes ionized or reacts with a gas or plasma en route to the substrate, thus modifying the structure or composition of the deposited film. In CVD processes a gas composed of a volatile component of the coating material is activated either thermally or by other means in the vicinity of the substrate, and it reacts to form a solid deposit on the surface of the hot substrate.

Both PVD and CVD methods can be used to produce a wide variety of coatings, including metals, alloys, and refractory compounds. Among the most popular vapor-deposited hard coatings for wear resistance are titanium nitride and titanium carbide. Deposition rates are relatively low compared with some other coating processes, ranging from  $<0.1 \mu\text{m}/\text{min}$  for some ion beam-sputtering or ion-plating processes, up to  $25 \mu\text{m}/\text{min}$  or more for activated reactive evaporation or CVD processes. Most PVD processes are done in a vacuum, while CVD processes are done in a reaction chamber which may be at atmospheric pressure. *Plasma-assisted chemical vapor deposition* (PACVD) is a hybrid process in which the constituents of the vapor phase react to form a solid film when assisted by a glow discharge plasma. The advantages of PACVD over other CVD processes include lower substrate temperatures, higher deposition rates, and a wider variety of coating possibilities.

*Ion implantation* (Fenske, 1992) is a process in which charged particles are created in an ion source, accelerated toward the surface at high velocity, and then injected into the substrate surface. The most commonly implanted ions for surface engineering are nitrogen, carbon, boron, and titanium, although virtually any element could be implanted. The microstructure of the near-surface region is changed by

the presence of the implanted ions and the result can be high near-surface hardness and wear resistance. The affected layer is very thin ( $<1 \mu\text{m}$ ).

### Effect of Lubrication on Friction and Wear

Whenever lubricated surfaces slide together at low sliding speeds or with a high applied normal load, the lubricant may not separate the two solid surfaces completely. However, the lubricant can still significantly reduce the friction coefficient by reducing the shear strength of adhesive junctions between the two surfaces. In this so-called boundary lubrication regime, the effectiveness of the lubricant can be improved if the lubricant molecules adhere well to the solid surfaces. This is best accomplished by introducing a lubricant or additive that forms a surface film through adsorption, chemisorption, or chemical reaction with the surface. The ensuing reduced shear strength of the surface film can lower the friction coefficient by as much as an order of magnitude from the dry friction value.

When a good supply of a viscous lubricant is available, the separation between the surfaces will increase as the sliding speed increases or the normal load decreases. As the separation increases, the amount of solid/solid contact between the surfaces will decrease, as will the friction coefficient and wear rate. In this “mixed friction” regime, friction is determined by the amount of plowing deformation on the softer surface by the harder surface asperities and by adhesion within the solid/solid contacts. When the surfaces become completely separated by a self-acting or externally pressurized lubricant film, the lubricating regime is hydrodynamic, wear is reduced to nearly zero, and friction reaches a low value governed by viscous shear of the lubricant. Friction coefficients in such cases can be 0.001 or lower, depending on the surface velocities and the lubricant viscosity. This is the case for most journal or thrust bearings (see subsection on fluid film bearings).

### Bearings for Friction Reduction

Most mechanical systems contain moving components, such as shafts, which must be supported and held in position by stationary members. This is best done by appropriate design or selection of bearings to be used wherever the moving member is to be supported. Most bearings may be classified as either fluid film bearings, dry or semilubricated bearings, or rolling element bearings.

*Fluid film bearings* (see subsection below) have a conformal geometry, with a thin film of fluid separating the two surfaces. The fluid lubricant could be a liquid, such as oil, or a gas, such as air. Fluid film bearings are commonly used to support rotating cylindrical shafts, and the load on such a bearing could be either radial, in which case the bearing is called a journal bearing, or axial, for a thrust bearing. In most cases the fluid film is generated by the motion within the bearing itself, so the bearing is called self-acting or hydrodynamic. Whether or not a self-acting bearing can develop a fluid film sufficient to separate and support the two surfaces is determined by magnitude of the quantity  $\mu U/W$ , where  $\mu$  is the (absolute) fluid viscosity,  $U$  is the relative sliding velocity, and  $W$  is the normal load. If that quantity is too small, the fluid film will be too thin and high friction will occur. This can be a problem during start-up of equipment when sliding velocities are low. That problem can be overcome by pressurizing the fluid film from an external pressure source to create a hydrostatic bearing. Whether the fluid film is externally pressurized (hydrostatic) or self-acting (hydrodynamic), separation of the solid surfaces allows wear to be essentially eliminated and friction to be very low, even when very large loads are carried by the pressurized lubricant.

*Dry and semilubricated bearings* (see subsection below) have conformal surfaces which are in direct contact with each other. This category includes bearings which run dry (without liquid lubrication) or those which have been impregnated with a lubricant. Dry bearings are made of a material such as a polymer or carbon-graphite which has a low friction coefficient, and they are generally used in low-load and low-speed applications. Semilubricated bearings are made of a porous material, usually metal, and are impregnated with a lubricant which resides within the pores. The lubricant, which could be oil or grease, cannot provide a complete fluid film, but usually acts as a boundary lubricant. Semilubricated bearings can carry greater loads at greater speeds than dry bearings, but not as high as either fluid film or rolling element bearings. The failure mechanism for both dry and semilubricated bearings is wear.

*Rolling element bearings* (see subsection below) have the advantage that rolling friction is lower than sliding friction. These bearings include rolling elements, either balls or rollers, between hardened and ground rings or plates. Their main advantage over fluid film bearings is that they have low friction both during start-up and at operating velocities, although the friction can be higher than that of fluid film bearings during steady state operation. Ball and roller bearings are most commonly lubricated by either oil or grease. In either case the lubricating film at the concentrated contacts between rolling elements and rings is very thin and the pressures in the film are very high; this is the condition known as elastohydrodynamic lubrication. Rolling element bearings fail by a number of mechanisms, often stemming from improper installation or use or from poor lubrication, but the overriding failure mechanism is rolling contact fatigue.

Each type of bearing has advantages and disadvantages, and these are summarized in [Table 3.10.3](#). The Engineering Sciences Data Unit (ESDU) (1965; 1967) has developed some general guides to the selection of bearing type for different load and speed conditions, and those guides for journal and thrust bearing selection are given in [Figures 3.10.2 and 3.10.3](#).

**TABLE 3.10.3 Bearing Characteristics**

	Fluid Film Bearings	Dry Bearings	Semilubricated	Rolling Element Bearings
Start-up friction coefficient	0.25	0.15	0.10	0.002
Running friction coefficient	0.001	0.10	0.05	0.001

Cost	High	Low	Low	Medium

## Lubricant Properties

### Petroleum Oils

The vast majority of lubricants in use today are mineral oils which are obtained through the distillation of crude petroleum. Mineral oils are composed primarily of three types of hydrocarbon structures: paraffinic, aromatic, and alicyclic (naphthenic). The molecular weights of the hydrocarbons range from about 250 for low-viscosity grades, up to nearly 1000 for more-viscous lubricants.

Mineral oils by themselves do not have all of the properties required of modern lubricants. For that reason, almost all current lubricants are fortified with a chemical additive package which consists of some of the following:

*Oxidation inhibitors* limit oxidation of hydrocarbon molecules by interrupting the hydroperoxide chain reaction.

*Rust inhibitors* are surface-active additives that preferentially adsorb on iron or steel surfaces and prevent their corrosion by moisture.

*Antiwear and extreme pressure agents* form low shear strength films on metallic surfaces which limit friction and wear, particularly in concentrated contacts.

*Friction modifiers* form adsorbed or chemisorbed surface films which are effective in reducing friction of bearings during low-speed operation (boundary lubrication regime).

*Detergents and dispersants* reduce deposits of oil-insoluble compounds (e.g., sludge) in internal combustion engines.

**FIGURE 3.10.2** General guide to journal bearing-type selection. Except for rolling element bearings, curves are drawn for bearings with width/diameter = 1. A medium-viscosity mineral oil is assumed for hydrodynamic bearings. From ESDU, *General Guide to the Choice of Journal Bearing Type*, Item 67073, Institution of Mechanical Engineers, London, 1965. With permission.

*Pour-point depressants* lower the temperature at which petroleum oils become immobilized by crystallized wax.

*Foam inhibitors* are silicone polymers which enhance the separation of air bubbles from the oil.

*Viscosity-index improvers* are long-chain polymer molecules which reduce the effect of temperature on viscosity. They are used in multigrade lubricants.

**Properties of Petroleum Oils**

The lubricating oil property which is of most significance to bearing performance is viscosity. The absolute viscosity, designated as  $\mu$ , could be given in SI units as pascal second ( $\text{Pa} \cdot \text{sec} = \text{N} \cdot \text{sec}/\text{m}^2$ ) or centipoise ( $1 \text{ cP} = 0.001 \text{ Pa} \cdot \text{sec}$ ) or in English units as  $\text{lb} \cdot \text{sec}/\text{in}^2$  (or reyn). Kinematic viscosity, designated here as  $\nu$ , is defined as absolute viscosity divided by density. It is given in SI units as  $\text{m}^2/\text{sec}$  or centistokes ( $1 \text{ cSt} = 10^{-6} \text{ m}^2/\text{sec}$ ) and in English units as  $\text{in}^2/\text{sec}$ .

Viscosity data in [Table 3.10.4](#) are representative of typical petroleum “turbine” and “hydraulic” oils which are widely used in industry and closely correspond to properties of most other commercially available petroleum oils. [Table 3.10.5](#) gives equivalent viscosity grades for common automotive (SAE), gear (SAE and AGMA), and reciprocating aircraft engine (SAE) oils (Booser, 1995). Equivalent ISO viscosity grades are listed for the single-graded SAE automotive oils such as SAE 10W and SAE 30.

**FIGURE 3.10.3** General guide to thrust bearing type selection. Except for rolling element bearings, curves are drawn for a ratio of inside diameter to outside diameter equal to 2 and for a nominal life of 10,000 hr. A medium-viscosity mineral oil is assumed for hydrodynamic bearings. (Based on ESDU, *General Guide to the Choice of Journal Bearing Type*, Item 67073, Institution of Mechanical Engineers, London, 1965, and Neale, M.J., *Bearings*, Butterworth-Heinemann, Oxford, 1993.)

For multigrade oils such as SAE 10W–30, however, the added viscosity-index improvers provide unique viscosity–temperature characteristics. Typical properties of a number of these multigrade SAE oils are included in [Table 3.10.4](#).

ISO viscosity grade 32 and the equivalent SAE 10W are most widely used industrially. Lower-viscosity oils often introduce evaporation and leakage problems, along with diminished load capacity. Higher viscosity may lead to high temperature rise, unnecessary power loss, and start-up problems at low temperature. For low-speed machines, however, higher-viscosity oils ranging up to ISO 150, SAE 40 and sometimes higher are often used to obtain higher load capacity.

**TABLE 3.10.4 Representative Oil Properties**

	Viscosity				Density	
	Centistokes		10 <sup>-6</sup> reyns(lb·sec/in <sup>2</sup> )		gm/cc	lb/in <sup>3</sup>

<sup>a</sup> Comparisons are nominal since SAE grades are not specified at 40°C viscosity; VI of lubes could change some of the comparisons.

Oil viscosity decreases significantly with increasing temperature as shown in Fig. 3.10.4. While Figure 3.10.4 provides viscosity data suitable for most bearing calculations, oil suppliers commonly provide only the 40°C and 100°C values of kinematic viscosity in centistokes (mm<sup>2</sup>/sec). The viscosity at other temperatures can be found by the following ASTM D341 equation relating kinematic viscosity  $\nu$  in centistokes (mm<sup>2</sup>/sec) to temperature  $T$  in degrees F:

$$\log \log(\nu + 0.7) = A - B \log(460 + T) \tag{3.10.2}$$

**FIGURE 3.10.4** Viscosity–temperature chart for industrial petroleum oils (Ramondi and Szeri, 1984).

where  $A$  and  $B$  are constants for any particular (petroleum or synthetic) oil. For ISO VG-32 oil in Table 3.10.4, for example,  $A = 10.54805$  and  $B = 3.76834$  based on the 104 and 212°F (40 and 100°C) viscosities. This gives a viscosity of 10.78 cSt at a bearing operating temperature of 160°F.

Conversion of kinematic to absolute viscosity requires use of density, which also varies with temperature. A coefficient of expansion of 0.0004/°F is typical for most petroleum oils, so the variation of density with temperature is in accordance with the following relation:

$$\rho_T = \rho_{104} [1 - 0.0004(T - 104)] \tag{3.10.3}$$

For the ISO-VG-32 oil with its density of 0.857 g/cc at 100°F (40°C), this equation gives 0.838 g/cc at 160°F. Multiplying 10.78 cSt by 0.838 then gives an absolute viscosity of 9.03 cP. Multiplying by the conversion factor of  $1.45 \times 10^{-7}$  gives  $1.31 \times 10^{-6}$  lb·sec/in.<sup>2</sup> (reyns).

Heat capacity  $C_p$  of petroleum oils used in bearing calculations is given by (Klaus and Tewksburg, 1984)

$$C_p = 3860 + 4.5(T) \text{ in.} \cdot \text{lb}/(\text{lb} \cdot ^\circ\text{F}) \tag{3.10.4}$$

The viscosity of petroleum oils is also affected significantly by pressure, and that increase can become important in concentrated contacts such as rolling element bearings where elastohydrodynamic lubrication occurs. The following relationship can be used for many oils to find the viscosity at elevated pressure:

$$\mu_p = \mu_o e^{\alpha p} \tag{3.10.5}$$

where  $\mu_o$  is the viscosity at atmospheric pressure,  $\mu_p$  is the viscosity at pressure  $p$ , and  $\alpha$  is the pressure–viscosity exponent. The pressure–viscosity exponent can be obtained from lubricant suppliers.

### Synthetic Oils

Synthetic oils of widely varying characteristics are finding increasing use for applications at extreme temperatures and for their unique physical and chemical characteristics. Table 3.10.6 gives a few representative examples of synthetic oils which are commercially available. Cost of the synthetics, ranging up to many times that of equivalent petroleum oils, is a common deterrent to their use where petroleum products give satisfactory performance

**TABLE 3.10.6 Properties of Representative Synthetic Oils**

### Greases

Grease is essentially a suspension of oil in a thickening agent, along with appropriate additives. The oil generally makes up between 75 and 90% of the weight of a grease, and it is held in place by the gel structure of the thickener to carry out its lubricating function. The simplicity of the lubricant supply system, ease of sealing, and corrosion protection make grease the first choice for many ball-and-roller bearings, small gear drives, and slow-speed sliding applications (Booser, 1995). Consistencies of greases vary from soap-thickened oils that are fluid at room temperature to hard brick-types that may be cut with a knife. Greases of NLGI Grade 2 stiffness (ASTM D217) are most common. Softer greases down to grade 000 provide easier feeding to multiple-row roller bearings and gear mechanisms. Stiffer Grade 3 is used in some prepacked ball bearings to avoid mechanical churning as the seals hold the grease in close proximity with the rotating balls.

Petroleum oils are used in most greases; the oils generally are in the SAE 30 range, with a viscosity of about 100 to 130 cSt at 40°C. Lower-viscosity oil grades are used for some high-speed applications and for temperatures below about -20°C. Higher-viscosity oils are used in greases for high loads and low speeds. Synthetic oils are used only when their higher cost is justified by the need for special properties, such as capability for operation below -20°C or above 125 to 150°C.

The most common gelling agents are the fatty acid metallic soaps of lithium, calcium, sodium, or aluminum in concentrations of 8 to 25%. Of these, the most popular is lithium 12-hydroxystearate; greases based on this lithium thickener are suitable for use at temperatures up to 110°C, where some lithium soaps undergo a phase change. Greases based on calcium or aluminum soaps generally have an upper temperature limit of 65 to 80°C, but this limit can be significantly raised to the 120 to 125°C range through new complex soap formulations. Calcium-complex soaps with improved high-temperature stability, for instance, are prepared by reacting both a high-molecular-weight fatty acid (e.g., stearic acid) and a low-molecular-weight fatty acid (acetic acid) with calcium hydroxide dispersed in mineral oil.

Inorganic thickeners, such as fine particles of bentonite clay, are inexpensively applied by simple mixing with oil to provide nonmelting greases for use up to about 140°C. Polyurea nonmelting organic powders are used in premium petroleum greases for applications up to about 150 to 170°C.

Additives, such as those mentioned in the subsection on petroleum oils, are added to grease to improve oxidation resistance, rust protection, or extreme pressure properties. Because of the incompatibility of oils, thickeners, and additives, greases of different types should be mixed only with caution.

### Solid Lubricants

Solid lubricants provide thin solid films on sliding or rolling/sliding surfaces to reduce friction and wear. They are particularly useful for applications involving high operating temperatures, vacuum, nuclear radiation, or other environments which limit the use of oils or greases. Solid lubricant films do not prevent moving surfaces from contacting each other, so they cannot eliminate wear and their lives are limited by wear. The properties of some of the most common solid lubricants are given in Table 3.10.7.

**TABLE 3.10.7 Properties of Selected Solid Lubricants**

Material	Acceptable Usage Temperature, °C				Average Friction Coefficient, <i>f</i>		Remarks
	Minimum		Maximum		In Air	In N <sub>2</sub> or Vacuum	
	In Air	In N <sub>2</sub> or Vacuum	In Air	In N <sub>2</sub> or Vacuum			
Molybdenum disulfide, MoS <sub>2</sub>	-240	-240	370	820	0.10–0.25	0.05–0.10	Low <i>f</i> , carries high load, good overall lubricant, can promote metal corrosion
Graphite	-240	—	540	Unstable in vacuum	0.10–0.30	0.02–0.45	Low <i>f</i> and high load capacity in air, high <i>f</i> and wear in vacuum, conducts electricity
PTFE	-70	-70	290	290	0.02–0.15	0.02–0.15	Lowest <i>f</i> of solid lubricants, load capacity moderate and decreases at elevated temperature
Calcium fluoride–barium fluoride eutectic, CaF <sub>2</sub> –BaF <sub>2</sub>	430	430	820	820	0.10–0.25 above 540°C 0.25–0.40 below 540°C	Same as in air	Can be used at higher temperature than other solid lubricants, high <i>f</i> below 540°C

Modified from Booser, E.R., in *Encyclopedia of Chemical Technology*, 4th ed., Vol. 15, John Wiley & Sons, New York, 1995, 463–517.

The most important inorganic solid lubricants are layer–lattice solids such as molybdenum disulfide (MoS<sub>2</sub>) and graphite. These materials are characterized by strong covalent or ionic bonding between atoms in individual layers, but relatively weak van der Waals bonds between layers, enabling the layers

to slide easily relative to one another. Graphite is a very effective lubricant film when moisture or water vapor is present, since adsorbed water vapor lubricates the sliding layers, but it has poor friction properties in vacuum or other low-humidity applications. Molybdenum disulfide does not require the presence of adsorbed water vapor, so it is widely used in vacuum or space applications.

The most commonly used organic solid lubricant is polytetrafluoroethylene (PTFE) which can be used either as a fused surface coating or as a self-lubricating material (see subsection on plastics). Its low friction is attributed to the smooth profile of the PTFE molecule. The chemical inertness of PTFE makes it attractive for chemical and food-processing applications.

New ceramic-based solid lubricants have been developed for high-temperature applications, such as heat engines or space uses. One of the most promising of these is a calcium fluoride–barium fluoride eutectic, which can be used at temperatures exceeding 800°C.

## Fluid Film Bearings

### Journal Bearings

A journal bearing consists of an approximately cylindrical bearing body or sleeve around a rotating cylindrical shaft. In general, journal bearings are found in motors, pumps, generators, appliances, and internal combustion engines in which a fluid lubricant is used; and in smaller mechanisms such as switches, clocks, small motors, and circuit breakers in which a solid lubricant such as graphite, grease, or certain plastics serves to reduce friction. Air (gas) bearings are designed to utilize both fluid mechanics principles when operating and solid lubricant–surfaced materials for start, stop, and emergency operations.

A hydrodynamic journal bearing maintains separation of shaft from bearing because the lubricant viscosity and the speed of the shaft create pressure in the converging portion of the fluid film which carries load. The governing equations were first developed by Reynolds (1886). Their solution has led to numerous computer solutions, including those used for this section.

*Journal Bearing Design.* Figure 3.10.5 shows schematics of frequently used types of journal bearing in which one or more lobes of cylindrical shape are positioned around the shaft, their axis being assumed parallel to the shaft axis. The features of each design and applications where it is often found are listed in Table 3.10.8.

Noncontact journal bearings are designed to assure a continuous supply of lubricant to the load-carrying section, and the bearing grooves in Figure 3.10.5 are designed for that purpose. Oil must be resupplied to the bearing because of the continuous loss of lubricant as it is forced from the bearing by the load-carrying pressures generated within it. The subsection on lubricant supply methods describes some of the many systems designed to assure this supply and to cool the lubricant at the same time.

*Controlling Variables.* Definitions of the variables involved in journal bearing analysis are contained in Table 3.10.9. Because of the large range of many variables, nondimensional quantities are often used which are independent of the dimensional unit system involved. Examples are given in the English system unless otherwise stated.

*Calculating Bearing Performance.* Journal bearing performance can be calculated directly from dedicated computer codes which take account of load, speed, oil type, and delivery system, as well as bearing dimensions. This subsection presents two approximate solutions: a simple thermal approach and a set of interpolation tables based on computer solutions.

*Thermal Approach.* It is assumed that the bearing is operating at a constant but elevated temperature. A predicted operating temperature can then be found as a function of an assumed viscosity. A solution is found when the assumed viscosity equals the lubricant viscosity at that temperature. Three equations are used for this method. For radial loads, the power dissipation is

$$H_p = j\pi^3\mu(N/60)^2 D^3L/C \quad \text{in} \cdot \text{lb}/\text{sec} \quad (3.10.6)$$

**FIGURE 3.10.5** Types of pressure-fed journal bearings: (a) Partial arc. (b) Circumferential groove. (c) Cylindrical bearing–axial groove. (d) Pressure dam. (e) Cylindrical overshot. (f) Elliptical. (g) Multilobe. (h) Tilting pad.

$\mu$	Viscosity	lb·sec/in. <sup>2</sup>
$\omega$	Shaft velocity	rad/sec
$\theta$	Angle in direction of rotation, from bottom dead center	—
$\Phi$	Energy dissipation	in.·lb/sec

$$Q = Q_o + qCR^2\omega/2 \text{ in.}^3/\text{sec} \tag{3.10.7}$$

where  $q$  is the proportion of side flow to circulating flow, and the zero speed flow,  $Q_o$  (in<sup>3</sup>/sec), represents other flows such as from the ends of the feed grooves which are not related to the load-carrying film itself.  $Q_o$  can usually be neglected for rough estimation, and this approximation is useful for eccentricities as high as 0.7. Note that both  $q$  and  $j$  are functions of specific design as well as load and speed. The average operating temperature for a given viscosity is

$$T_2 = T_f + \frac{(H_p - \Phi)}{(\rho C_p Q)} \text{ °F} \tag{3.10.8}$$

where  $T_f$  is the feed temperature and  $\Phi$  is the energy loss due to conduction and radiation. For diameters of 2" or more,  $\Phi$  can usually be assumed to be 0. Plotting  $T_2$  vs. viscosity for several values of  $\mu$  on a plot of the viscosity vs.  $T$  for the lubricant shows the operating temperature for the bearing as the intersection.

*Flow Dynamics Solution.* A more general solution for journal bearing performance is based on prediction of flow characteristics in the bearing, and of physical behavior of the bearing based on the Reynolds equation. A common two-pad journal bearing with pressurized oil feed will be used to provide specific design information. The Reynolds equation is the differential equation expressing the physical behavior of the fluid film between shaft and bearing, as written for cylindrical bearings:

$$1/R^2 \left[ \frac{\partial}{\partial \Theta} \left( h^3 / \mu \right) \frac{\partial p}{\partial \Theta} \right] + \frac{\partial}{\partial z} \left( h^3 / \mu \right) \frac{\partial p}{\partial z} = 6(U/R) \frac{\partial h}{\partial \Theta} \quad (3.10.9)$$

where  $z$  is the axial coordinate and  $\Theta$  is the angular coordinate.

*Bearing Configuration.* A cross section through a common type of two-pad cylindrical bearing is shown in Figure 3.10.6. Two pads having a radius of  $R + C$  and an angular extent of  $150^\circ$ , and with load applied vertically to the lower half through a shaft, make up the bearing. Lubricant is admitted under moderate feed pressure to the two  $30^\circ$  grooves formed at the split as shown in Figure 3.10.6. The shaft rotates counterclockwise, and lubricant pressures are balanced when the shaft center is displaced down and to the right.

FIGURE 3.10.6 Geometry of split cylindrical journal bearing.

*Lubricant Properties.* Pressures in the lubricant film are generated as a function of the local shear rates and the local viscosity as described by the Reynolds equation. The local temperature rise is given by the local energy dissipation divided by the local flow rate:

$$\Delta T = \left[ 2\mu\omega R^2 \Delta\theta \right] / \left[ h^2 \rho C_p \right] \quad (3.10.10)$$

As an alternative to Equation 3.10.2, an exponential relation between viscosity and temperature is used:

$$\mu = \mu_0 e^{-\beta(T-T_0)} \quad (3.10.11)$$

Assuming an ISO 32 oil, viscosity  $\mu_0$  at  $104^\circ\text{F}$  is 3.98 reyns, density is 0.0310, and  $\beta$  is 0.0170 for the range from  $104$  to  $212^\circ\text{F}$ . The value for  $\beta$  may be determined from Figure 3.10.4. A nondimensional

coefficient,  $C_\alpha$ , the *adiabatic coefficient*, is used as an indicator of the severity of thermal heating in a design. It contains the several factors responsible for temperature rise.

$$C_\alpha = 2\mu_f \beta \omega (R/C)^2 / \rho C_p \tag{3.10.12}$$

*Bearing Performance Tables.* Using computer-generated solutions of the Reynolds equation for the pressure field over the bearing surface, the relevant performance properties of the bearing/lubricant system can be determined. A number of programs are commercially available for this purpose. In order to illustrate how the behavior of a journal bearing can be determined, a two-pad split cylindrical bearing with an  $L/D$  of 0.5 has been selected, and a proprietary computer code has been used to develop a group of performance quantities for such a bearing. The code accounts for the internal lubricant circulation, including mixing in the inlet groove of feed lubricant with warm lubricant from the upper half, resulting in the viscosity  $\mu_f$ . The primary characteristics of the bearing are load, stiffness, and damping. Each of these factors is presented in nondimensional terms in [Table 3.10.10](#), and the corresponding dimensional and other quantities are given as follows:

Film thickness, in.  $h = C(1 + e \cos \Theta)$  (3.10.13a)

Shaft eccentricity, in.  $e = \epsilon C$  (3.10.13b)

Load, lb  $W = w \left[ 6\mu\omega (R/C)^2 DL \right]$  (3.10.13c)

Flow, in.<sup>3</sup>/sec  $Q = q \left( CR^2 \omega / 2 \right)$  (3.10.13d)

Power loss, in. · lb/sec  $H_p = j \left( 2\pi\mu\omega^2 R^3 L/C \right)$  (3.10.13e)

Stiffness, lb/in.  $S_{xx} = K_{xx} 6\mu\omega R (R/C)^2$  (3.10.13f)

Damping, lb · sec/in.  $D_{xx} = B_{xx} 12\mu R (R/C)^3$  (3.10.13g)

The axial length/diameter ratio also influences the performance of a journal bearing. To illustrate this, [Table 3.10.11](#) presents the performance of longer bearings ( $L/D = 0.75$  and  $1.00$ ) for comparison to the more common  $L/D = 0.5$  results in [Table 3.10.10](#).

Comparing [Tables 3.10.10](#) and [3.10.11](#), the use of longer bearings has several important effects on operation and performance. Comparing key variables, the effects at an eccentricity of ratio of 0.7 are as follows:

Variable	L/D = 0.5	L/D = 0.75	L/D = 1.00
Load, $w$	0.28	0.69	1.21
Flow, $q$	0.69	0.82	0.88
Attitude angle, $\phi$	36.4	36.1	35.8
Power ratio, $j$	1.00	1.15	1.17
Stiffness, $K_{xx}$	1.38	3.06	5.03
Damping, $B_{xx}$	0.99	2.52	4.31

*Effect of Turbulence.* Turbulence is a mixing phenomenon that occurs in larger high-speed bearings. When this behavior occurs, the simple viscous drag behavior that has been assumed in the preceding

subsections is broken up by numerous eddies which increase the drag. The Reynolds number is a nondimensional quantity that expresses this factor:

$$R_e = hU\rho/\mu \quad (3.10.14)$$

where  $h$  is the local film thickness,  $U$  is the relative velocity of one surface with respect to the other,  $\rho$  is the fluid density, and  $\mu$  is the local viscosity.

The influence of turbulence on an  $L/D = 0.5$  bearing is shown in Table 3.10.12. Examination of Table 3.10.12 shows that the principal effects of operation in the turbulent regime with a Reynolds number above about 1000 are in the greater power required ( $j$ ) and the maximum bearing temperature. Load capacity and flow are only moderately affected.

*Example Calculation.* The problem is to design a two-pad cylindrical bearing for support of a rotor having a bearing load of 8000 lb, a shaft diameter of 6 in., and a speed of 3600 rpm. Assume use of ISO VG-32 oil fed at a temperature of  $120^\circ\text{F}$ . Compute operating characteristics for a 3-in.-long bearing. Assume a radial clearance of 0.0044 in.

Feed viscosity,  $\mu_f = 3.98 \times 10^{-6} e^{-0.00170(120-104)} = 3.03 \times 10^{-6}$  reyn

Angular velocity,  $\omega = 3600 \times 2\pi/60 = 377$  rad/sec

Adiabatic coefficient:  $C_\alpha = 2 \times 3.03 \times 10^{-6} \times 0.0170 \times 377 \times (3/0.0044)^2/0.0310/4320 = 0.1345$

Load coefficient (from Equation 3.10.13c:  $w = 8000/[6 \times 3.03 \times 10^{-6} \times 377 \times 3 \times 6 \times (33/0.0044)^2] = 0.139$

The desired solution lies between Part 2 and Part 3 of Table 3.10.10. By using linear interpolation between the tabulated values for  $C_\alpha$  of 0.1 and 0.2, and values of  $\epsilon$  of 0.7 and 0.8, an approximate operating point of  $C_\alpha = 0.1345$  yields the following coefficients:  $\epsilon = 0.729$ ,  $w = 0.279$ ,  $q = 0.733$ ,  $j = 0.860$ , and  $\Delta T_b = 0.915$ .

By using Equations 3.10.13, the dimensional operating results are:

Shaft velocity:  $\omega = 3600 \times 2\pi/60 = 377$  rad/sec

Flow:  $Q = 0.733 \times 0.0044 \times 3^2 \times 377 = 5.47$  in<sup>3</sup>/sec

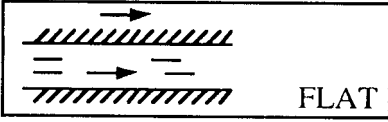

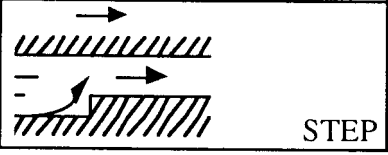

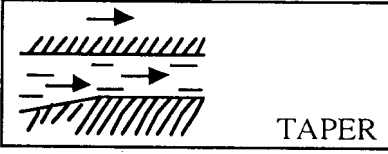

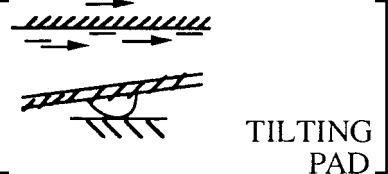

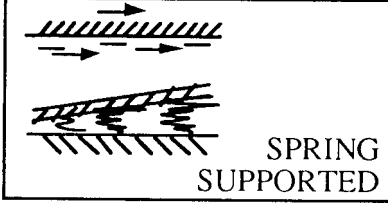

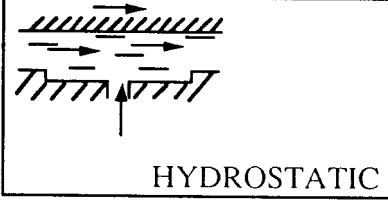

Power loss:  $H_p = 0.860 \times 2\pi \times 3.03 \times 10^{-6} \times 377^2 \times 3^3 \times 3/0.0044 = 42.8$  in. $\cdot$ lb/sec

Oil temperature:  $T_b = 120 + 0.915/0.0170 = 174^\circ\text{F}$

## Thrust Bearings

*Types of Thrust Bearings.* Oil film thrust bearings range from coin-size flat washers to sophisticated assemblies many feet in diameter. Of the six common types of thrust bearings shown in Table 3.10.13, the first five are hydrodynamic. As with journal bearings, each of these generates oil film pressure when

**TABLE 3.10.13 Common Thrust Bearings and Their Range of Application**

Type	O.D., in.	Unit Load, psi
 <p>FLAT</p>	0.5–20	20–100
 <p>STEP</p>	0.5–10	100–300
 <p>TAPER</p>	2–35	150–300
 <p>TILTING PAD</p>	4–120	250–700
 <p>SPRING SUPPORTED</p>	50–120	350–700
 <p>HYDROSTATIC</p>	3–50	500–3000

Source: Booser, E.R. and Wilcock, D.F., *Machine Design*, June 20, 1991, 69–72. With permission.

a rotating thrust face pumps oil by shear into a zone of reduced downstream clearance. When thrust load increases, film thickness drops until a new balance is reached between inflow and outflow, raising pressure until the higher bearing load is balanced. The hydrostatic bearing uses a separate oil pump to supply the pressurized flow.

*Flat-land bearings*, simplest to fabricate and least costly, are the first choice for simple positioning of a rotor and for light loads in electric motors, appliances, pumps, crankshafts, and other machinery. They carry less load than the other types because flat parallel planes do not directly provide the required pumping action. Instead, their action depends on thermal expansion of the oil and warping of the bearing

material induced by heating from the passing oil film. The resulting slight oil wedge then gives a load rating of about 10 to 20% of that for the other types.

*Step bearings* also offer relatively simple design. With a coined or etched step, they lend themselves to mass production as small-size bearings and thrust washers. Step height for optimum load capacity approximately equals the minimum film thickness, often 0.001 in. or less. Circumferential length beyond the step is ideally 45% of the total bearing segment (Wilcock and Booser, 1956). Step thrust bearings are well suited for low-viscosity fluids such as water, gasoline, fuels, and solvents. Minimum film thickness in these applications is so small that features such as pivots and tapers are usually impractical. Step height must be small enough for good load capacity, yet large enough to accommodate some wear without becoming worn away. Step erosion by contaminants is sometimes a problem.

*Tapered-land bearings* provide reliable, compact designs for mid- to large-size high-speed machines such as turbines, compressors, and pumps. Taper height normally should be about one to three times the minimum film thickness. For greater load capacity and to minimize wear during starting, stopping, and at low speeds, a flat land is commonly machined at the trailing edge to occupy from 10 to 30% of the circumferential length of each segment. Because operation of these bearings is sensitive to load, speed, and lubricant viscosity, they are typically designed for the rated range of operating conditions for specific machines.

*Tilting-pad thrust bearings* are used increasingly in turbines, compressors, pumps, and marine drives in much the same range of applications as tapered-land designs. They usually have a central supporting pivot for each of their three to ten bearing segments. Each of these thrust pad segments is free to adjust its position to form a nearly optimum oil wedge for widely varying loads, speeds, and lubricants, and with rotation in both directions. A secondary leveling linkage system is commonly introduced to support the individual pads; this provides a further advantage over tapered-land designs by accommodating some misalignment. Off-the-shelf units are available to match rotor shaft diameters from about 2 to 12 in., and custom designs range up to 120 to 170 in. in outside diameter. Recent trends to increase load capacity have led to offsetting pivots from the circumferential midpoint of a pad to about 60% beyond the leading edge, to substituting copper for steel as the backing for a tin babbitt bearing surface, and to nonflooded lubrication to minimize parasitic power loss from useless churning of oil passing through the bearing housing.

*Springs or other flexible supports* for thrust segments are employed for bearings ranging up to 10 ft or more in outside diameter and carrying millions of pounds of thrust. This flexible mounting avoids the high load concentration encountered by pivots in supporting large tilting-pads. Rubber backing can provide this flexible mounting for smaller thrust pads.

*Hydrostatic thrust bearings* are used where sufficient load support cannot be generated by oil film action within the bearing itself. This may be the case with low-viscosity fluids, or for load support on an oil film at standstill and very low speeds. The fluid is first pressurized by an external pump and then introduced into pockets in the bearing surface to float the load. A compact hydrostatic thrust bearing can sometimes be constructed with a single pocket at the end of a rotor. Larger bearings usually use three or more pressurized pockets to resist misalignment or to support off-center loads. Hydraulic flow resistance in the supply line to each pocket, or constant flow to each pocket (as with ganged gear pumps) then provides any asymmetric pressure distribution needed to support an off-center load. Bearing unit load is commonly limited to about 0.5 (0.75 with fixed flow systems) times the hydrostatic fluid supply pressure—up to 5000 psi with conventional lubricating oils.

*Design Factors for Thrust Bearings.* In preliminary sizing, the inside diameter  $d$  of a thrust bearing is made sufficiently larger than the shaft to allow for assembly, and to provide for any required oil flow to the thrust bearing inside diameter (see [Figure 3.10.7](#)). This clearance typically ranges from about  $1/8$  in. for a 2-in. shaft to  $1/2$  in. for a 10-in. shaft. Bearing outside diameter  $D$  is then set to provide bearing

**FIGURE 3.10.7** Sector for tapered land thrust bearing.

area sufficient to support total thrust load  $W$  (lb or N) with an average loading  $P$  (psi or  $N/m^2$ ), using typical values from [Table 3.10.13](#):

$$D = \left( \frac{4W}{\pi k_g P} + d^2 \right)^{0.5} \tag{3.10.15}$$

where  $k_g$  (typically 0.80 to 0.85) is the fraction of area between  $d$  and  $D$  not occupied by oil-distributing grooves. This bearing area is then divided by radial oil-feed groove passages, usually into “square” sectors with circumferential breadth  $B$  at their mean diameter equal to their radial length  $L$ .

While square pads usually produce optimum oil film performance, other proportions may be advantageous. With very large bearing diameters, for instance, square sectors may involve such a long circumferential dimension that the oil film overheats before reaching the next oil-feed groove. With a radially narrow thrust face, on the other hand, square sectors may become so numerous as to introduce excessive oil groove area, and their short circumferential length would interfere with hydrodynamic oil film action.

*Performance Analysis.* Performance analyses for sector thrust bearings using a fixed taper also hold approximately for most thrust bearing shapes (other than flat lands) with the same ratio of inlet to outlet oil film thickness (Wilcock and Booser, 1956; Neale, 1970; Fuller, 1984). Both for centrally pivoted pad thrust bearings and for spring-supported thrust bearings, use of an inlet-to-outlet film thickness ratio of two is usually appropriate in such an analysis.

While computer analyses in polar coordinates and with local oil film viscosity calculated over the whole oil film area gives more-exact solutions, the following constant viscosity approximations are made by relating a rectangular bearing sector (width  $B$ , length  $L$ ) to the circular configuration of [Figure 3.10.7](#). This rectangular representation allows more ready evaluation of a range of variables and gives results which are quite similar to a more accurate polar coordinate analysis.

Employing the nomenclature of [Figure 3.10.7](#), the following relations give minimum film thickness  $h_2$ , frictional power loss  $H$ , and oil flow into a sector  $Q$ . The dimensionless coefficients involved are given in [Table 3.10.14](#) for a range of sector proportions  $L/B$  and ratios of inlet to outlet film thicknesses  $h_1/h_2$ .

$$h_2 = K_h (\mu UB/P)^{0.5} \quad \text{in. (m)} \tag{3.10.16a}$$

$$H = K_f \mu U^2 BL/h_2 \quad \text{lb} \cdot \text{in./sec (N} \cdot \text{m/sec)} \tag{3.10.16b}$$

$$Q = K_q ULh_2 \quad \text{in.}^3/\text{sec} \left( \text{m}^3/\text{sec} \right) \quad (3.10.16c)$$

$$\Delta T = H / (Q \rho C_p) = \frac{K_f}{K_q K_h^2 \rho C_p} P \quad ^\circ\text{F} \left( ^\circ\text{C} \right) \quad (3.10.16d)$$

where  $B$  = circumferential breadth of sector at mean radius, in. (m)

$K_h, K_f, K_q$  = dimensionless coefficients

$L$  = radial length of sector, in. (m)

$P$  = unit loading on projected area of sector,  $W/BL$ , lb/in.<sup>2</sup> (N/m<sup>2</sup>)

$U$  = surface velocity at mean diameter of sector, in./sec (m/sec)

$W$  = load on a sector, lb (N)

$C_p$  = oil specific heat, in.·lb/(lb·°F) (J/(kg·°C))

$h_1, h_2$  = leading edge and trailing edge film thicknesses, in. (m)

$\rho$  = oil density, lb/in.<sup>3</sup> (n/m<sup>3</sup>)

$\mu$  = oil viscosity at the operating temperature, lb·sec/in.<sup>2</sup> (N·sec/m<sup>2</sup>)

*Example.* The following example involves a bearing for 25,000 lb thrust load in a 1200 rpm compressor whose rotor has a 5-in.-diameter journal. ISO-32 viscosity grade oil is to be fed at 120°F. Allowing  $3/8$  in. radial clearance along the shaft sets thrust bearing bore  $d = 5.75$  in. Taking unit loading  $P = 300$  psi allows a margin for uncertainty in expected thrust load, and outside diameter  $D$  is given by Equation 3.10.14):

$$D = \left( \frac{4 \times 25000}{\pi(0.85)(300)} + 5.75^2 \right)^{0.5} = 12.6 \text{ in.}$$

With 15% of the area used for oil feed passages,  $k_g = 0.85$ . Thrust bearing segment radial length  $L = (12.6 - 5.75)/2 = 3.425$  in. With mean diameter  $(5.75 + 12.6)/2 = 9.175$  in., total circumferential breadth of all pads at the mean diameter =  $\pi D_m k_g = 24.5$  in. The number of sectors (and grooves) for  $B = L$  is then  $24.5/3.425 = 7.2$ . Using seven lands, adjusted circumferential breadth  $B$  for each sector =  $24.5/7 = 3.5$  in. (For simpler fabrication, six or eight sectors should also be considered.) Runner velocity at the mean diameter,  $U = \pi(9.175)(1200/60) = 576.5$  in./sec.

For square pads ( $L/B = 1$ ) in a pivoted-pad bearing with  $h_1/h_2 = 2$ , which represents experience with centrally pivoted pads, Table 3.10.14 gives the following performance coefficients:

$$K_h = 0.261, \quad K_f = 0.727, \quad K_q = 0.849$$

Temperature rise is given by Equation (3.10.16d) which assumes that the total frictional power loss  $H$  goes into heating the total oil flow  $Q$  passing over the pad.

$$\Delta T = \frac{K_f P}{K_q K_h^2 \rho C_p} = \frac{0.727(300)}{0.849(0.261)^2(0.0313)(4535)} = 27^\circ\text{F}$$

Adding this  $\Delta T$  to the 120°F feed temperature gives 147°F as the representative oil operating temperature with a viscosity from Figure 3.10.4 of  $1.6 \times 10^{-6}$  lb·sec/in.<sup>2</sup>. Temperature rise to the maximum oil film temperature would be expected to be about 53°F, twice the 27°F. If this bearing were in a housing fully flooded with oil, feed temperature to each pad would become the housing oil temperature, essentially the same as oil draining from the housing.

After Khonsari, M.M., in *Tribology Data Handbook*, CRC Press, Boca Raton, FL, 1997.

Minimum film thickness  $h_2$  becomes, from Equation (3.10.16a)

$$h_2 = 0.261 \left[ (1.6 \times 10^{-6})(576.5)(3.5)/300 \right]^{0.5} = 0.00086 \text{ in.}$$

With a fixed tapered land, rather than a centrally pivoted pad for which it could be assumed that  $h_1/h_2 = 2$ , several iterations might be required with different assumed values of the  $h_1/h_2$  ratio in order to determine the performance coefficients in Table 3.10.14. The proper value of  $h_1/h_2$  will be the one that gives the same final calculated value of  $h_2$  from the above equation as was assumed in the preliminary selection of  $K_h$ ,  $K_f$ , and  $K_q$ .

After finding the values for  $h_2$  and  $K_f$ , the power loss  $H$  can be determined using Equation (3.10.16b). For this example the power loss would be  $H = 5510 \text{ lb-in./sec}$ .

The total oil feed to the bearing should satisfy two requirements: (1) provide a full oil film over the bearing segment and (2) maintain reasonably cool operation with no more than 30 to 40°F rise in the

oil temperature from feed to drain. Equation (3.10.16c) can be used to find the oil feed  $Q$  needed at the sector inlet to form a full film. The oil feed needed for a 40°F rise is given by the following heat balance using typical density and specific heat values for petroleum oil:

$$Q = H / (\rho C_p \Delta T) \quad (3.10.17)$$

The required oil feed will be the larger of the values determined by (3.10.16c) and (3.10.17).

The above calculations are for a single sector; power loss and oil feed would be multiplied by the number of sectors (seven) to obtain values for the total bearing. Consideration would normally follow for other pad geometries, and possibly other lubricants and oil flow patterns, in a search for the most-promising design. More-detailed calculations of film thickness, film temperatures, oil flow, and power loss could then be obtained by one of a number of computer codes available from bearing suppliers or other sources.

### Oil Film Bearing Materials

Selection of the material for use in a journal or thrust bearing depends on matching its properties to the load, temperature, contamination, lubricant, and required life.

*Babbitts.* Of the common bearing materials, listed in Table 3.10.15, first consideration for rotating machines is usually a babbitt alloy containing about 85% tin or lead together with suitable alloying elements. With their low hardness, they have excellent ability to embed dirt, conform to shaft misalignment, and rate highest for compatibility with steel journals. Tin babbitts, containing about 3 to 8% copper and 5 to 8% antimony, are usually the first choice for their excellent corrosion resistance. SAE 12 (ASTM Grade 2) tin babbitt is widely used in both automotive and industrial bearings. The much lower cost of lead babbitt, however, with 9 to 16% antimony and as much as 12% tin for improved corrosion resistance, brings SAE 13, 14, and 15 grades into wide use for both general automotive and industrial applications (Booser, 1992).

TABLE 3.10.15 Characteristics of Oil Film Bearing Materials

Material	Brinell Hardness	Load Capacity, psi	Max Operating Temp., °F	Compati-bility <sup>a</sup>	Conforma-bility and Embed-dability <sup>a</sup>	Corrosion Resistance <sup>a</sup>	Fatigue Strength <sup>a</sup>
Tin babbitt	20–30	800–1500	300	1	1	1	5
Lead babbitt	15–25	800–1200	300	1	1	3	5
Copper lead	20–30	1500–2500	350	2	2	5	4
Leaded bronze	60–65	3000–4500	450	3	4	4	3
Tin bronze	65–80	5000+	500	5	5	2	2
Aluminum alloy	45–65	4000+	300	4	3	1	2
Zinc alloy	90–125	3000	250	4	5	5	3
Silver overplated	—	5000+	300	2	4	2	1
Two-component, babbitt surfaced	—	3000+	300	2	4	2	3
Three-component, babbitt surfaced	—	4000+	300	1	2	2	1

<sup>a</sup> Arbitrary scale: 1 = best, 5 = worst.

To achieve the high fatigue strength needed in reciprocating engines, only a very thin layer (commonly 0.001") of babbitt is used so that much of the reciprocating load is taken on a stronger backing material (DeHart, 1984; Kingsbury, 1992). For bimetal bushings such as those used in automobile engines, oil

grooves and feed holes are formed in a continuous steel strip coated with babbitt. The strip is then cut to size and the individual segments are rolled into finished bearings.

For heavy-duty reciprocating engines, three-layer bearings are common. By using a steel strip backing, a thin overlay of SAE 19 or 190 lead babbitt is either electroplated or precision cast on an intermediate layer about 0.1 to 0.3" thick of copper–nickel, copper–lead, leaded bronze, aluminum, or electroplated silver.

*Copper Alloys.* Copper–lead alloys containing 20 to 50% lead, either cast or sintered on a steel back, provide good fatigue resistance for heavy-duty main and connecting rod bearings for automotive, truck, diesel, and aircraft engines. The 10% lead–10% tin leaded bronze has been a traditional selection for bearings in steel mills, appliances, pumps, automotive piston pins, and trunions. This has been replaced in many applications by CA932 (SAE 660) containing 3% zinc for easier casting. The harder tin bronzes require reliable lubrication, good alignment, and 300 to 400 Brinell minimum shaft hardness. Cast tin bronze bushings are used at high loads and low speeds in farm machinery, earthmoving equipment, rolling mills, and in automotive engines for connecting rod bearings.

Utility of copper alloy bearings is limited to relatively low surface speeds by the tendency to form a copper transfer film on a steel shaft. Above about 1500 to 3000 ft/min, selective plucking of softer copper material from hotter load zones in the bearing may result in welded lumps forming on the cooler, stronger transfer layer on the mating steel shaft.

*Zinc Alloys.* Zinc alloys containing about 10 to 30% aluminum find some use for lower cost and better wear life in replacing leaded bronzes. They are used for both oscillating and rotating applications involving speeds up to 1400 ft/min and temperatures up to 250°F.

*Aluminum Alloys* (DeHart, 1984; Shabel et al., 1992). Although finding only minor use in general industrial applications because of their limited compatibility with steel journals, aluminum alloys containing 6.5% tin, 1% copper, and up to 4% silicon are used as solid, bimetal, and trimetal bearings in automotive engines, reciprocating compressors, and aircraft equipment. Good journal finish and shaft hardness of Rockwell B 85 or higher are required. The good fatigue and corrosion resistance of aluminum alloys have led to use of a number of unique alloys containing major additions of silicon, lead, or tin to provide better compatibility characteristics.

## Dry and Semilubricated Bearings

Various plastics, porous bronze and porous iron, carbon–graphite, rubber, and wood are widely used for bearings operating dry or with sparse lubrication (Booser, 1992). Unique properties of these materials have led to their broad use in applications once employing oil film and ball and roller bearings. While these materials provide good performance under conditions of poor or nonexistent lubrication at low speeds, performance commonly improves the closer the approach to full film lubrication.

### Plastics

Most commercial plastics find some use both dry and lubricated in slow-speed bearings at light loads (Jamison, 1994). The most commonly used thermoplastics for bearings are PTFE, nylon, and acetal resins. Thermosetting plastics used for bearings include phenolics, polyesters, and polyimides. [Table 3.10.16](#) compares characteristics of typical plastic bearings with those of carbon–graphite, wood, and rubber which are used in similar applications.

In addition to the maximum temperature which can be tolerated, three operating limits shown in [Table 3.10.16](#) are normally defined for plastic bearings: (1) maximum load at low speed, which reflects the compressive yield strength, (2) maximum speed for running under very light load, and (3) a  $Pv$  load-speed limit at intermediate speeds, which serves as a measure of the maximum tolerable surface temperature. Since wear volume in dry sliding is approximately proportional to total load and the distance of sliding,  $Pv$  also gives a measure of wear depth  $d$  in the modified form of Archard's relation (3.10.1),  $d = k(Pv)t$ , where  $t$  is the operating time and wear factor  $k =$  wear coefficient  $K/\text{hardness } H$ .

**TABLE 3.10.16. Representative Limiting Conditions for Nonmetallic Bearing Materials**

Material	Maximum Temperature, °C	$P_v$ Limit, MN/(m <sup>2</sup> ·sec) <sup>a</sup>	Maximum Pressure, $P$ , MN/m <sup>2b</sup>	Maximum speed, $v$ , m/sec

<sup>b</sup> To convert MN/m<sup>2</sup> to psi, multiply by 145.

Typical values of this wear factor  $k$  are given in Table 3.10.17. Since  $k$  values involve substantial variability, prototype tests are highly desirable for any planned application. Added fillers can reduce the wear factor for the base polymer by a factor of 10 to 1000 and more (Blanchet and Kennedy, 1992). Common fillers include inorganic powders such as clay, glass fibers, graphite, molybdenum disulfide, and powdered metal, and also silicone fluid as an internally available lubricant.

<sup>c</sup> 15% glass fiber.

### Porous Metals

Bearings of compressed and sintered bronze, iron, and aluminum alloy powder are produced at the rate of millions per week for shaft sizes ranging from about 1.6 to 150 mm. These sleeve bearings and thrust washers are used in a wide variety of small electric motors, appliances, business machines, machine tools, automotive accessories, and farm and construction equipment (Morgan, 1984; Cusano, 1994). Traditional powder metal bearings consist of 90% copper and 10% tin (Table 3.10.18). The common pore volume of 20 to 30% is usually impregnated with a petroleum oil of SAE 30 viscosity. To promote

formation of an oil film, high porosity with its high oil content is employed for higher speeds, often with an oil wick or grease providing a supplementary lubricant supply. Lower porosity with up to 3.5% added graphite is used for lower speeds and oscillation where oil film formation is difficult.

Porous iron bearings are used for lower cost, often with some copper and graphite added for high load capacity at low speed. Iron with up to 40% of added 90–10 bronze powder provides many of the characteristics of porous bronze bearings while enjoying the lower cost of the iron. Porous aluminum containing 3 to 5% copper, tin, and lead finds limited use for providing cooler operation, better conformability, and lower weight.

Table 3.10.18 gives approximate operating limits for porous metal bearings. Generally, maximum  $P$  values for sleeve bearings range up to 50,000 psi-ft/min.  $Pv$  levels for thrust bearings should generally not exceed about 20% of this value.

**TABLE 3.10.18 Operating Limits for Porous Metal Bearings**

Porous Metal	Nominal Composition, wt%	Pressure limit, $P$ , MN/m <sup>2</sup>		Speed Limit $v$ , m/sec	$Pv$ Limit MN/(m·sec)
		Static	Dynamic		
Bronze	Cu 90, Sn 10	59	28	6.1	1.8 <sup>a</sup>
Iron		52	25	2.0	1.3

Bronze–iron	Fe 60, Cu 36, Sn 4	72	17	4.1	1.2
Aluminum		28	14	6.1	1.8

Note: To convert MN/m<sup>2</sup> to psi, multiply by 145.

<sup>a</sup> Approximately equivalent to 50,000 psi · ft/min limit often quoted by U.S. suppliers.

## Rolling Element Bearings

### Types of Rolling Element Bearings

Rolling element bearings may be classified according to the type of rolling element, i.e., ball or roller, and the loading direction. Ball and roller bearings can be designed to carry either radial or thrust loads, or a combination of the two. Standard rolling element bearing configurations are shown in Figure 3.10.8, and the capabilities of the different types are summarized in Figure 3.10.9.

*Ball bearings* usually consist of a number of hardened and precisely ground balls interposed between two grooved and hardened rings or races. A cage or separator is used to keep the balls equally spaced around the groove. The most common *radial ball bearing* is a deep groove, or Conrad, type which is designed to carry large radial loads, with a small thrust load capability. The radial capacity of a deep groove bearing can be increased by inserting more balls in the bearing, by means of either a face-located filling notch (which decreases the thrust capacity) or a split inner or outer ring (which requires a means to hold the ring halves axially together). The thrust capability of a radial ball bearing can be increased by inducing angular contact between ball and rings. A single-row angular contact bearing can carry thrust load in only one direction, with the thrust load capacity being dependent on the contact angle (angle between the line of action of the force and the plane perpendicular to the shaft axis). Duplex angular contact bearings consist of two angular contact bearings mounted together so they can carry thrust loads in either direction with little axial play, or they can be mounted in tandem to double the axial and radial load-carrying capacity. Self-aligning ball bearings are designed to accommodate more shaft misalignment than is possible with other radial ball bearings.

*Thrust ball bearings* are used primarily in machinery with a vertically oriented shaft which requires a stiff axial support. Many such bearings have a 90° contact angle and, as a result, can carry essentially no radial load; they also have limited high-speed capability. If thrust loads in both directions are to be carried, a second row of balls must be added.

**FIGURE 3.10.8** Major types of rolling element bearings.

*Roller bearings* can be made with cylindrical, tapered, or spherical rollers. As with ball bearings, the rollers are contained between two rings, with a cage or separator used to keep the rollers separated. The cage can be guided by either the rollers or one of the rings. Since roller bearings operate with line contacts, as opposed to the point (or elliptical) contacts that occur in ball bearings, roller bearings are stiffer (less radial displacement per unit load) and have a greater load-carrying capacity than a ball bearing of similar size. Roller bearings are more expensive than ball bearings of comparable size.

CHARACTERISTICS OF STANDARD ROLLING ELEMENT BEARING CONFIGURATIONS

	TYPE	SIZE RANGE IN INCHES		AVERAGE RELATIVE RATINGS				DIMENSIONS	
				Capacity		Limiting Speed	Permissible Misalignment	Metric	Inch
		Bore	O.D.	Radial	Thrust				
BALL BEARINGS	CONRAD TYPE 	.1181 to 41.7323	.3750 to 55.1181	Good	Fair $\longleftrightarrow$	Conrad is basis for comparison 1.00	$\pm 0^\circ 8'$	X	X

FIGURE 3.10.9 Characteristics of standard rolling element bearing configurations.

Radial cylindrical roller bearings are designed to carry primarily radial loads. Cylindrical roller bearings have a high radial load capacity and low friction, so they are suitable for high-speed operation. Their thrust load capacity is limited to that which can be carried by contact (sliding) between the ends of the rollers and the flange or shoulder on the ring which contains them. The rollers in many cylindrical

roller bearings are actually slightly crowned to relieve stress concentrations which would otherwise occur at the ends of the rollers and to compensate for misalignment of the bearing. In order to increase the load-carrying capacity of roller bearings, a second row of rollers is added instead of using longer rollers. This is because long rollers (i.e., length/diameter > 1.7) tend to skew in the roller path, thus limiting their high-speed capability and sometimes shortening their life. Needle bearings have long rollers, however, and they are useful when there are severe radial space limitations and when neither high load capacity nor high speeds are required.

*Spherical roller bearings* usually have an outer ring with a spherical inside diameter, within which are barrel-shaped rollers. This makes these bearings self-aligning, and also gives them a larger contact area between roller and ring than is the case for other rolling element bearings. Because of this, spherical roller bearings have a very high radial load-carrying capacity, along with some ability to carry thrust loads. They have higher friction between roller and ring, and this limits their high-speed capability.

*Tapered roller bearings* have tapered rollers, ideally shaped like truncated cones, contained between two mating cones of different angles, the inner cone and the outer cup. The contact angle of the bearing determines its thrust load capability; a steeper angle is chosen for more thrust capacity. If a single row of rollers is used, the bearing is separable and can carry thrust loads in only one direction. If the thrust is double acting, a second bearing can be mounted in a back-to-back configuration or a double row bearing can be selected. In tapered roller bearings there is sliding contact between the ends of the rollers and the guide flange on the inner cone, and this sliding contact requires lubrication to prevent wear and reduce friction.

*Thrust roller bearings* can be either cylindrical, needle, tapered, or spherical (Figure 3.10.9). In each case there is high load-carrying capacity, but the sliding that occurs between rollers and rings requires lubrication and cooling.

### Rolling Element Bearing Materials

Ball and roller bearings require materials with excellent resistance to rolling contact fatigue and wear, as well as good dimensional stability and impact resistance. The rolling elements are subjected to cyclic contact pressures which can range from 70 to 3500 MPa (100 to 500 ksi) or more, and the bearing materials must be hard enough to resist surface fatigue under those conditions. Of the through-hardening steels which meet these requirements, the most popular is AISI 52100, which contains about 1% carbon and 1.5% chromium. In general, balls and rollers made from 52100 are hardened to about Rockwell C60. Standard bearings made from 52100 may suffer from unacceptable dimensional changes resulting from metallurgical transformations at operating temperatures above 140°C (285°F). Special stabilization heat treatments enable operation at higher temperatures, with successful operation at temperatures as high as 200°C (390°F) having been achieved in cases involving low loads. The strength and fatigue resistance of the material diminish if the bearing temperature increases above about 175°C (350°F), however, so above that temperature materials with better hot-hardness, such as M50 tool steel, are required. Carburizing steels such as AISI 8620 have been developed for tapered roller bearings and other heavily loaded types that benefit from the tougher core and case compressive residual stress developed during carburizing. For applications in oxidative or corrosive environments, a hardened martensitic stainless steel such as SAE 440C may be chosen. For the highest operating temperatures, ceramic materials may be used in bearings. The most promising of the ceramics for rolling element bearing applications is silicon nitride. Its major use so far in bearings has been in hybrid bearings with ceramic balls or rollers and metallic rings, but all-ceramic bearings have also been developed.

The temperature limits of these bearing materials are given in Table 3.10.19. For all bearing materials, great care must be taken in the processing and production stages to ensure that no defects or inclusions are present that could serve as an initiation site for fatigue cracks. For most high-performance metallic bearings, this requires a very clean steel production process, such as vacuum arc remelting. Heat treatment of the material is also important to produce the required dimensional stability. The production process for ceramic bearings is even more critical, because a defect in a ceramic bearing element could result in catastrophic fracture of the brittle material.

**TABLE 3.10.19 Temperature Limits for Rolling Element Bearing Materials**

Material	Maximum Operating Temperature	
	°C	°F
AISI 52100	140–175	285–350
AISI 8620 (carburized)	150	300
440C stainless steel	170	340
M50 tool steel	315	600
Hybrid Si <sub>3</sub> N <sub>4</sub> -M50	425	800
All-ceramic (Si <sub>3</sub> N <sub>4</sub> )	650	1200

Bearing cages or retainers have as their primary purpose the separation of the rolling elements. In some cases, they also provide some solid lubrication to the bearing. Low-carbon steel is the most common cage material, but bronze (silicon iron bronze or aluminum bronze) and polymers (particularly nylon 6-6) are used in many applications.

**Selection of Rolling Element Bearings**

It has been stated that if a rolling element bearing in service is properly lubricated, properly aligned, kept free of abrasive particles, moisture, and corrosive agents, and properly loaded, then all causes of damage will be eliminated except one, contact fatigue (Harris, 1991). The fatigue process results in a spall which may originate on or just beneath the contact surface. Studies of rolling contact fatigue life by Lundberg and Palmgren (1947; 1952) and others showed that most rolling element bearings have fatigue lives which follow a Weibull statistical distribution, wherein the dependence of strength on volume is explained by the dispersion in material strength. Most bearings today are designed according to the Lundberg–Palmgren model, which has been standardized by international (ISO, 1990) and national standards (e.g., ANSI/AFBMA, 1990), although recent work (Ioannides and Harris, 1985) has found that modern bearings have longer lives than those predicted by the standard methods.

The basic rating life of rolling element bearings is the  $L_{10}$  life, which is the number of revolutions at constant speed for which there is a 10% probability of failure (or 90% reliability). The basic dynamic load-carrying capacity, or load rating, of a bearing is the constant load  $C$  which corresponds to an  $L_{10}$  life of one million revolutions. For any other bearing load  $F$ , the  $L_{10}$  life can be determined by the following relationship:

$$L_{10} = (C/F)^n \tag{3.10.18}$$

where the load-life exponent  $n = 3$  for ball bearings, and  $n = 10/3$  for roller bearings.

The equivalent bearing load includes contributions from both radial and thrust loads, and can be calculated by the following expression:

$$F = XF_r + YF_a \tag{3.10.19}$$

where  $X$  is a radial load factor,  $Y$  is a thrust load factor,  $F_r$  is the radial load applied to the bearing, and  $F_a$  is the applied thrust (or axial) load.

Values for the dynamic load rating  $C$ , as well as the load factors  $X$  and  $Y$  for any bearing configuration can be found in manufacturers’ catalogs, or they can be calculated according to formulas given in bearing texts by Harris (1991) or Eschmann et al. (1985). Those references also give life adjustment factors which can be used to adjust the desired  $L_{10}$  life to account for special operating conditions, special material selections, special lubrication conditions, or for a reliability different from 90%.

The bearing user will generally select a commercially available bearing by the following procedure:

1. Determine the axial and thrust loads acting at the bearing location.
2. Determine the required bearing life ( $L_{10}$ ).

3. Select the most appropriate bearing type from among those given in [Figure 3.10.9](#).
4. Use the  $X$  and  $Y$  values appropriate to the type of bearing and loading conditions in Equation (3.10.19) to find the equivalent dynamic bearing load  $F$ .
5. Determine the required dynamic load capacity  $C$  from Equation (3.10.18).
6. Select a bearing with a dynamic load capacity at least as large as the required value from a manufacturer's catalog.
7. Provide an appropriate mounting arrangement for the bearing. Manufacturers' catalogs can be consulted for guidance in designing the mounting and selecting appropriate fits for the bearing. The importance of the fit cannot be overemphasized, since improper fit can result in considerable reduction in bearing life.
8. Provide adequate lubrication for the bearing (see below). Seals and/or shields may be integrated into the bearing to retain or protect the lubricant in the bearing.

### Rolling Bearing Lubrication

The primary load-carrying contacts between rolling elements and rings exhibit nearly pure rolling. There are many sliding contacts in rolling element bearings, however, including those where roller ends contact the internal flanges of rings, where rolling elements contact separator/cage, and where the separator contacts the guiding (piloting) ring of the bearing. All of those contacts must be lubricated to limit friction and wear, and either a grease or an oil can be used for that purpose.

Under most normal operating conditions, rolling element bearings can be grease lubricated. *Greases* coat surfaces with a thin boundary lubricant film of oil, thickener, and additive molecules, thus providing protection against sliding wear, and provide oil to lubricate the concentrated rolling contacts (see below). The selection of a grease depends on its effective temperature range, oil viscosity, consistency, and rust-inhibiting properties. For normal applications, a bearing should be filled with grease up to 30 to 50% of its free volume. Overfilling will cause overheating, particularly at high speeds. Grease will deteriorate with time and will leak out. For that reason, there should be a relubrication schedule, with grease being added at intervals which can be estimated by the following expression (Neale, 1993):

$$\text{relubrication interval (hours)} = \left(k/d^{1/2}\right) \left[ \left(14 \times 10^6/n\right) - 4d^{1/2} \right] \quad (3.10.20)$$

where  $k = 10$  for radial ball bearings, 5 for cylindrical roller bearings, and 1 for spherical or tapered roller bearings;  $d =$  bearing bore diameter (mm); and  $n =$  speed (rpm)

*Oil lubrication* is required when high speed or high operating temperatures preclude the use of grease. It is necessary to choose an oil of proper viscosity and appropriate viscosity–temperature characteristics in order to insure sufficient thickness of oil film in the lubricated concentrated contacts. If viscosity is too low, the film thickness will not prevent metal/metal contact, but if the viscosity is too high, excessive friction will occur. Oil can be applied to a bearing by one of several methods (listed in order of increasing effectiveness at increasing bearing speed): *oil bath*, in which the rolling elements carry the oil through the bearing; *oil circulating system*, in which the oil is pumped from the bearing through an external filter and heat exchanger and back to the bearing; *oil mist*, in which an airstream carries oil droplets to the bearing; and *oil jets*, in which the oil is injected into the bearing through carefully positioned nozzles. The quantity and entry velocity of the oil must be carefully selected and controlled in order to dissipate the heat generated in the bearing.

The lubrication mechanism in the concentrated contacts of rolling element bearings is *elastohydrodynamic lubrication* (EHL). EHL typically occurs in lubricated, nonconforming elastic contacts, such as the elliptical contact that occurs between ball and raceway or the rectangular contact between roller and ring. These lubricated contacts have a very small area and the contact pressures are very high. Because of those high pressures, the contacting surfaces deform and the lubricant viscosity increases, thereby aiding its ability to sustain heavy loading without oil-film breakdown. A diagram of these phenomena is shown in [Figure 3.10.10](#). The most important parameter of the concentrated contact, from

the point of view of rolling element bearing performance, is minimum EHL film thickness,  $h_o$ . The following expression can be used to find minimum film thickness in most rolling element bearing contacts (Hamrock and Dowson, 1977):

$$h_o = 3.63R_x U^{0.68} G^{-0.49} W_p^{-0.73} (1 - e^{-0.68\kappa}) \tag{3.10.21}$$

where  $R_x = (R_{x1} R_{x2}) / (R_{x1} + R_{x2})$ ,  $R_y = (R_{y1} R_{y2}) / (R_{y1} + R_{y2})$ , ellipticity parameter  $\kappa = R_x / R_y$ ,  $U = \mu (u_1 + u_2) / 2E'R_x$ ,  $\mu$  = absolute viscosity,  $u_1$  and  $u_2$  are velocities of rolling element and ring,  $E' = E / (1 - \nu^2)$ ,  $E$  = modulus of elasticity,  $\nu$  = Poisson's ratio,  $G = \alpha E'$ ,  $\alpha$  = pressure-viscosity exponent,  $W_p = W / E' R_x^2$ , and  $W$  = radial load.

**FIGURE 3.10.10** Typical pressure and film thickness distributions in elastohydrodynamic contact.

The minimum film thickness must be large enough to prevent metal/metal contact within the lubricated conjunctions. The criterion for this is stated as

$$h_o \geq 1.5 (r_{q1}^2 + r_{q2}^2)^{0.5} \tag{3.10.22}$$

where  $r_{q1}$  and  $r_{q2}$  are the rms surface roughness of the rolling element and ring, respectively. If the minimum film thickness is less than this value, complete EHL will not occur, and this could result in wear, surface fatigue, and eventual early bearing failure (i.e., well before the predicted  $L_{10}$  life).

An alternative to oil or grease lubrication for rolling element bearings operating under severe conditions is *solid lubrication*. Solid lubricants can be used effectively in high temperatures or vacuum conditions where liquid lubricants are impractical or would provide marginal performance. Solid lubricants do not prevent solid/solid contact, so wear of the lubricant coating can be expected; bearing life is governed by the depletion of the solid lubricant film.

### Lubricant Supply Methods

Lubrication systems for oil film bearings can generally be grouped into three classifications: self contained devices for small machines; centralized systems, common in manufacturing plants; and circulating systems dedicated to a single piece of equipment such as a motor, turbine, or compressor. Upper speed limits for common journal bearing lubrication methods are indicated in [Figure 3.10.11](#) (Wilcock and Booser, 1987). Submerging the bearing directly in an oil bath is a common alternative for vertical machines.

**FIGURE 3.10.11** Upper limits for journal bearing lubrication methods. (From Wilcock, D.F. and Booser, E.R., *Mach. Des.*; April 23, 101–107, 1987. With permission.)

**Self-Contained Units**

Lifting of oil by *capillary action* from a small reservoir is used to feed small bearings in business machines, household appliances, electrical instruments, controls, and timer motors. In capillary tubes, the height *h* to which oil will rise is (Wilcock and Booser, 1987)

$$h = 2\sigma \cos\theta / (r\rho) \tag{3.10.23}$$

where  $\sigma$  = surface tension, lb/in.,  $r$  = capillary radius (or spacing between two parallel plates), in.;  $\rho$  = oil density, lb/in.<sup>3</sup>. Because oils wet most surfaces readily, the cosine of the contact angle can be taken as unity. As an example, with  $\sigma = 1.7 \times 10^{-4}$  lb/in. for a petroleum oil, the rise in an 0.005-in.-radius capillary will be  $h = 2(1.7 \times 10^{-4})(1)/(0.005)(0.0307) = 2.2$  in.

*Wick lubrication* is applied in millions of fractional horsepower motors annually. Although wicks generally are not efficient at raising oil more than about 2 in., lift may be up to 5 in. in railway journal bearings. By referring to [Figure 3.10.12](#), petroleum oil delivery by a typical wick can be estimated by the following equation (Elwell, 1994):

$$Q = kAF_o(h_u - h) / (\mu L) \text{ in.}^3/\text{min} \tag{3.10.24}$$

where the constant  $k$  reflects both the capillary spacing in the wick and the surface tension of the oil;  $A$  is the wick cross-section area, in.<sup>2</sup>;  $F_o$  is volume fraction of oil in the saturated wick (often about 0.75);  $h_u$  is the ultimate wicking height, about 7.5 in. for SAE Grade F-1 felt;  $h$  is oil delivery height above the reservoir surface, in.;  $L$  is wick length, in.; and  $\mu$  is viscosity at the wick temperature, lb-sec/in.<sup>2</sup>  $\times 10^6$ .  $k$  is approximately 0.26 for SAE Grade F-1 felt.

*Oil rings* hanging over a journal, as illustrated in [Figure 3.10.13](#) and [Table 3.10.20](#), are used to lift oil to journal bearings in electric motors, pumps, and medium-size industrial machines (Elwell, 1994).

**FIGURE 3.10.12** Wick-lubricated journal bearing. (From Elwell, R.C., in *Handbook of Lubrication and Tribology*, Vol. 3, CRC Press, Boca Raton, FL, 1994, 515–533. With permission.)

At very low journal surface speeds below about 2 to 3 ft/sec, the ring will run synchronously with its journal. At higher speeds, increasing viscous drag on the ring in its reservoir will slow the ring surface velocity; oil ring rpm at higher speeds is often in the range of  $1/10$  the journal rpm. Above about 45 ft/sec journal surface velocity, oil delivery drops to an unusably low level as centrifugal throw-off and windage interfere.

These self-contained systems usually supply much less oil to a bearing than needed to form a full hydrodynamic oil film (Elwell, 1994). With the starved oil supply generating an oil wedge of reduced circumferential extent, power loss will be lowered at the expense of reduced load capacity (smaller minimum film thickness).

### Centralized Distribution Systems

Limitations with individual localized lubricating devices have led to widespread use of centralized systems for factory production-line equipment, construction and mining machines, and small applications. Oil or soft grease is pumped from a central reservoir in pulses or as metered continuous feed. Oil mist is piped for distances up to 300 ft for machines in petrochemical plants and steel mills. Polymer additives in the 50,000 to 150,000 molecular-weight range greatly reduce the escape of stray oil mist into the atmosphere.

### Circulating Systems

Where bearing design, reliability requirements, or equipment considerations preclude use of a simpler oil feed, a circulating system is employed involving an oil reservoir, pump, cooler, and filter (Twidale and Williams, 1984). These systems become quite compact with the space limitations in aircraft, marine, or automobile engines where the reservoir may simply be the machine sump with capacity to hold only a 20- to 60-sec oil supply. Characteristics of typical oil-circulating systems for industrial use are given in [Table 3.10.21](#) (Wilcock and Booser, 1987).

### Dynamic Seals

Fluid seals commonly accompany bearings in a wide variety of machinery, both to control leakage of lubricating oil and process fluids and to minimize contamination. Static seals, such as O-rings and gaskets, provide sealing between surfaces which do not move relative to each other. Dynamic seals, which will be the focus of this discussion, restrain flow of fluid between surfaces in relative motion. Most dynamic seals could be classified as either contact or clearance seals. Contact seals are used when the surfaces are in sliding contact, while clearance seals imply that the surfaces are in close proximity to each other but do not contact. The major types of dynamic seals are listed in [Table 3.10.22](#). Further details about the design and analysis of dynamic sealing elements can be found in the handbook article by Stair (1984) and in the book by Lebeck (1991).

As an example of a contact seal, ball bearings are often sealed to retain their lubricant and to keep out contaminants over a long lifetime. For small grease-lubricated bearings, the sealing function is often accomplished by lightly loaded contact between a rubber lip seal component and the bearing ring. For shafts ranging up to about 2 in. (5 cm) in diameter, the lip seal may be replaced by a closely fitted, but noncontacting, shield which helps contain the grease and restricts intrusion of dirt and other contaminants.

H = High, M = Moderate, L = Low.

Modified from Stair, W.K., in *Handbook of Lubrication*, Vol. 2, CRC Press, Boca Raton, FL 1984, 581–622.

For more severe sealing requirements in rolling element bearings, labyrinth clearance seals may be used (Harris, 1991).

The most common seals for rotating shafts passing through fixed housings, such as pumps or gear-boxes, are radial lip seals and mechanical face seals. These contact seals can be designed to handle a wide range of sealed fluids, temperatures, velocities, and pressures (Stair, 1984; Lebeck, 1991). Material selection and surface finish considerations are similar to those discussed in the subsections on sliding friction and its consequences and on dry and semilubricated bearings.

When high surface speeds are encountered, wear and frictional heating may prohibit use of rubbing contact seals. For such applications, clearance seals such as close-fitting labyrinth seals or controlled-clearance fluid film seals can be used. Fluid film seals can be either hydrostatic or hydrodynamic; both types have a pressurized film of fluid which prevents contact between the sealed surfaces and use pressure balancing to restrain leakage. The principles governing their operation are similar to those discussed in the subsection on fluid film bearings. Details of fluid film seals can be found in Shapiro (1995).

## 3.11 Pumps and Fans

---

*Robert F. Boehm*

### Introduction

Pumps are devices that impart a pressure increase to a liquid. Fans are used to increase the velocity of a gas, but this is also accomplished through an increase in pressure. The pressure rise found in pumps can vary tremendously, and this is a very important design parameter along with the liquid flow rate. This pressure rise can range from simply increasing the elevation of the liquid to increasing the pressure hundreds of atmospheres. Fan applications, on the other hand, generally deal with small pressure increases. In spite of this seemingly significant distinction between pumps and fans, there are many similarities in the fundamentals of certain types of these machines as well as with their application and theory of operation.

The appropriate use of pumps and fans depends upon the proper choice of device and the proper design and installation for the application. A check of sources of commercial equipment shows that many varieties of pumps and fans exist. Each of these had special characteristics that must be appreciated for achieving proper function. Preliminary design criteria for choosing between different types is given by Boehm (1987).

As is to be expected, the wise applications of pumps and fans requires knowledge of fluid flow fundamentals. Unless the fluid mechanics of a particular application are understood, the design could be less than desirable.

In this section, pump and fan types are briefly defined. In addition, typical application information is given. Also, some ideas from fluid mechanics that are especially relevant to pump and fan operation are reviewed.

### Pumps

Raising of water from wells and cisterns is the earliest form of pumping (a very detailed history of early applications is given by Ewbank, 1842). Modern applications are much broader, and these find a wide variety of machines in use. Modern pumps function on one of two principles. By far the majority of pump installations are of the *velocity head* type. In these devices, the pressure rise is achieved by giving the fluid a movement. At the exit of the machine, this movement is translated into a pressure increase. The other major type of pump is called *positive displacement*. These devices are designed to increase the pressure of the liquid while essentially trying to compress the volume. A categorization of pump types has been given by Krutzsch (1986), and an adaptation of this is shown below.

- I. Velocity head
  - A. Centrifugal
    - 1. Axial flow (single or multistage)
    - 2. Radial flow (single or double suction)
    - 3. Mixed flow (single or double suction)
    - 4. Peripheral (single or multistage)
  - B. Special Effect
    - 1. Gas lift
    - 2. Jet
    - 3. Hydraulic ram
    - 4. Electromagnetic
- II. Positive displacement
  - A. Reciprocating
    - 1. Piston, plunger
      - a. Direct acting (simplex or duplex)

- b. Power (single or double acting, simplex, duplex, triplex, multiplex)
- 2. Diaphragm (mechanically or fluid driven, simplex or multiplex)
- B. Rotary
  - 1. Single rotor (vane, piston, screw, flexible member, peristaltic)
  - 2. Multiple rotor (gear, lobe, screw, circumferential piston)

In the next subsection, some of the more common pumps are described.

### Centrifugal and Other Velocity Head Pumps

Centrifugal pumps are used in more industrial applications than any other kind of pump. This is primarily because these pumps offer low initial and upkeep costs. Traditionally, pumps of this type have been limited to low-pressure-head applications, but modern pump designs have overcome this problem unless very high pressures are required. Some of the other good characteristics of these types of devices include smooth (nonpulsating) flow and the ability to tolerate nonflow conditions.

The most important parts of the centrifugal pump are the *impeller* and *volute*. An impeller can take on many forms, ranging from essentially a spinning disk to designs with elaborate vanes. The latter is usual. Impeller design tends to be somewhat unique to each manufacturer, as well as finding a variety of designs for a variety of applications. An example of an impeller is shown in Figure 3.11.1. This device imparts a radial velocity to the fluid that has entered the pump perpendicular to the impeller. The volute (there may be one or more) performs the function of slowing the fluid and increasing the pressure. A good discussion of centrifugal pumps is given by Lobanoff and Ross (1992).

**FIGURE 3.11.1.** A schematic of a centrifugal pump is shown. The liquid enters perpendicular to the figure, and a radial velocity is imparted by clockwise spin of the impeller.

A very important factor in the specification of a centrifugal pump is the *casing orientation* and *type*. For example, the pump can be oriented vertically or horizontally. Horizontal mounting is most common. Vertical pumps usually offer benefits related to ease of priming and reduction in required net positive suction head (see discussion below). This type also requires less floor space. Submersible and immersible pumps are always of the vertical type. Another factor in the design is the way the casing is split, and this has implications about ease of manufacture and repair. Casings that are split perpendicular to the shaft are called *radially split*, while those split parallel to the shaft axis are denoted as *axially split*. The latter can be *horizontally split* or *vertically split*. The number of *stages* in the pump greatly affects the pump-output characteristics. Several stages can be incorporated into the same casing, with an associated increase in pump output. Multistage pumps are often used for applications with total developed head over 50 atm.

Whether or not a pump is self-priming can be important. If a centrifugal pump is filled with air when it is turned on, the initiation of pumping action may not be sufficient to bring the fluid into the pump. Pumps can be specified with features that can minimize priming problems.

There are other types of velocity head pumps. *Jet pumps* increase pressure by imparting momentum from a high-velocity liquid stream to a low-velocity or stagnant body of liquid. The resulting flow then

goes through a diffuser to achieve an overall pressure increase. *Gas lifts* accomplish a pumping action by a drag on gas bubbles that rise through a liquid.

### Positive-Displacement Pumps

Positive-displacement pumps demonstrate high discharge pressures and low flow rates. Usually, this is accomplished by some type of pulsating device. A piston pump is a classic example of positive-displacement machines. Rotary pumps are one type of positive-displacement device that do not impart pulsations to the existing flow (a full description of these types of pumps is given by Turton, 1994). Several techniques are available for dealing with pulsating flows, including use of double-acting pumps (usually of the reciprocating type) and installation of pulsation dampeners.

Positive-displacement pumps usually require special seals to contain the fluid. Costs are higher both initially and for maintenance compared with most pumps that operate on the velocity head basis. Positive-displacement pumps demonstrate an efficiency that is nearly independent of flow rate, in contrast to the velocity head type (see [Figure 3.11.2](#) and the discussion related to it below).

Reciprocating pumps offer very high efficiencies, reaching 90% in larger sizes. These types of pumps are more appropriate for pumping abrasive liquids (e.g., slurries) than are centrifugal pumps.

A characteristic of positive displacement pumps which may be valuable is that the output flow is proportional to pump speed. This allows this type of pump to be used for metering applications. Also a positive aspect of these pumps is that they are self-priming, except at initial start-up.

Very high head pressures (often damaging to the pump) can be developed in positive-displacement pumps if the downstream flow is blocked. For this reason, a pressure-relief-valve bypass must always be used with positive-displacement pumps.

### Pump/Flow Considerations

Performance characteristics of the pump must be considered in system design. Simple diagrams of pump applications are shown in [Figure 3.11.2](#). First, consider the left-hand figure. This represents a flow circuit, and the pressure drops related to the piping, fittings, valves, and any other flow devices found in the circuit must be estimated using the laws of fluid mechanics. Usually, these resistances (pressure drops) are found to vary approximately with the square of the liquid flow rate. Typical characteristics are shown in [Figure 3.11.3](#). Most pumps demonstrate a flow vs. pressure rise variation that is a positive value at zero flow and decreases to zero at some larger flow. Positive-displacement pumps, as shown on the right-hand side of [Figure 3.11.3](#), are an exception to this in that these devices usually cannot tolerate a zero flow. An important aspect to note is that a closed system can presumably be pressurized. A contrasting situation and its implications are discussed below.

The piping diagram shown on the right-hand side of [Figure 3.11.2](#) is a once-through system, another frequently encountered installation. However, the leg of piping through “pressure drop 1” shown there can have some very important implications related to *net positive suction head*, often denoted as **NPSH**. In simple terms, NPSH indicates the difference between the local pressure and the thermodynamic saturation pressure at the fluid temperature. If  $NPSH = 0$ , the liquid can vaporize, and this can result in a variety of outcomes from noisy pump operation to outright failure of components. This condition is called **cavitation**. Cavitation, if it occurs, will first take place at the lowest pressure point within the piping arrangement. Often this point is located at, or inside, the inlet to the pump. Most manufacturers specify how much NPSH is required for satisfactory operation of their pumps. Hence, the actual NPSH (denoted as **NPSHA**) experienced by the pump must be larger than the manufacturer’s required NPSH (called **NPSHR**). If a design indicates insufficient NPSH, changes should be made in the system, possibly including alternative piping layout, including elevation and/or size, or use of a pump with smaller NPSH requirements.

The manufacturer should be consulted for a map of operational information for a given pump. A typical form is shown in [Figure 3.11.4](#). This information will allow the designer to select a pump that satisfied the circuit operational requirements while meeting the necessary NPSH and most-efficient-operation criteria.

**FIGURE 3.11.2.** Typical pump applications, either in circuits or once-through arrangements, can be represented as combined fluid resistances as shown. The resistances are determined from fluid mechanics analyses.

**FIGURE 3.11.3.** An overlay of the pump flow vs. head curve with the circuit piping characteristics gives the operating state of the circuit. A typical velocity head pump characteristic is shown on the left, while a positive-displacement pump curve is shown on the right.

**FIGURE 3.11.4.** A full range of performance information should be available from the pump manufacturer, and this may include the parameters shown.

Several options are available to the designer for combining pumps in systems. Consider a comparison of the net effect between operating pumps in series or operating the same two pumps in parallel. Examples of this for pumps with characteristics such as centrifugal units are shown in [Figure 3.11.5](#). It is clear that one way to achieve high pumping pressures with centrifugal pumps is to place a number of units in series. This is a related effect to what is found in *multistage* designs.

**FIGURE 3.11.5.** Series (a) and parallel (b) operation of centrifugal pumps are possible. The resultant characteristics for two identical pumps are shown.

## Fans

As noted earlier, fans are devices that cause air to move. This definition is broad and can include a flapping palm branch, but the discussion here deals only with devices that impart air movement due to *rotation of an impeller inside a fixed casing*. In spite of this limiting definition, a large variety of commercial designs are included.

Fans find application in many engineering systems. Along with the chillers and boilers, they are the heart of heating, ventilating, and air conditioning (HVAC) systems. When large physical dimensions of a unit are not a design concern (usually the case), centrifugal fans are favored over axial flow units for HVAC applications. Many types of fans are found in *power plants*. Very large fans are used to furnish air to the boiler, as well as to draw or force air through cooling towers and pollution-control equipment. *Electronic cooling* finds applications for small units. Even automobiles have several fans in them. Because of the great engineering importance of fans, several organizations publish rating and testing criteria (see, for example, ASME, 1990).

Generally fans are classified according to how the air flows through the impeller. These flows may be *axial* (essentially a propeller in a duct), *radial* (conceptually much like the centrifugal pumps discussed earlier), *mixed*, and *cross*. While there are many other fan designations, all industrial units fit one of these classifications. Mixed-flow fans are so named because both axial and radial flow occur on the vanes. Casings for these devices are essentially like those for axial-flow machines, but the inlet has a radial-flow component. On cross-flow impellers, the gas traverses the blading twice.

Characteristics of fans are shown in [Figure 3.11.6](#). Since velocities can be high in fans, often both the total and the static pressure increases are considered. While both are not shown on this figure, the curves have similar variations. Of course the total  $\Delta P$  will be greater than will the static value, the difference being the velocity head. This difference increases as the volume flow increases. At zero flow (the shutoff point), the static and total pressure difference values are the same. Efficiency variation shows a sharp optimum value at the design point. For this reason, it is critical that fan designs be carefully tuned to the required conditions.

A variety of vane type are found on fans, and the type of these is also used for fan classification. Axial fans usually have vanes of airfoil shape or vanes of uniform thickness. Some vane types that might be found on a centrifugal (radial-flow) fan are shown in [Figure 3.11.7](#).

One aspect that is an issue in choosing fans for a particular application is fan efficiency. Typical efficiency comparisons of the effect of blade type on a centrifugal fan are shown in [Figure 3.11.8](#). Since velocities can be high, the value of aerodynamic design is clear. Weighing against this are cost and other factors.

An additional aspect that may be important in the choice of fans is noise generation. This may be most critical in HVAC applications. It is difficult to describe noise characteristics in brief terms because of the frequency-dependent nature of these phenomena. However, a comparison of specific sound power

**FIGURE 3.11.6.** Shown are characteristics of a centrifugal fan. The drawbacks to operating away from optimal conditions are obvious from the efficiency variation.

**FIGURE 3.11.7.** A variety of vane types that might be used on a centrifugal fan are shown.

**FIGURE 3.11.8.** Efficiency variation with volume flow of centrifugal fans for a variety of vane types is shown.

level (usually denoted by  $K_w$ ) shows backward-curved centrifugal fans with aerodynamic blades perform best among the designs. Details of noise characteristics are given elsewhere (ASHRAE, 1991).

While each type of fan has some specific qualities for certain applications, most installations use centrifugal (radial-flow) fans. A primary exception is for very-high-flow, low-pressure-rise situations where axial (propeller) fans are used.

Similarities exist between fans and pumps because the fluid density essentially does not vary through either type of machine. Of course, in pumps this is because a liquid can be assumed to be incompressible. In fans, a gas (typically air) is moved with little pressure change. As a result, the gas density can be taken to be constant. Since most fans operate near atmospheric pressure, the ideal gas assumptions can be used in determining gas properties.

Flow control in fan applications, where needed, is a very important design concern. Methods for accomplishing this involve use of dampers (either on the inlet or on the outlet of the fan), variable pitch vanes, or variable speed control. Dampers are the least expensive to install, but also the most inefficient in terms of energy use. Modern solid state controls for providing a variable frequency power to the drive motor is becoming the preferred control method, when a combination of initial and operating costs is considered.

## Defining Terms

**Cavitation:** Local liquid conditions allow vapor voids to form (boiling).

**NPSH:** Net positive suction head is the difference between the local absolute pressure of a liquid and the thermodynamic saturation pressure of the liquid based upon the temperature of the liquid. Applies to the inlet of a pump.

**NPSHA:** Actual net positive suction head is the NPSH at the given state of operation of a pump.

**NPSHR:** Required net positive suction head is the amount of NPSH required by a specific pump for a given application.

### 3.12 Liquid Atomization and Spraying

Rolf D. Reitz

Sprays are involved in many practical applications, including in the process industries (e.g., spray drying, spray cooling, powdered metals); in treatment applications (e.g., humidification, gas scrubbing); in coating applications (e.g., surface treatment, spray painting, and crop spraying); in spray combustion (e.g., burners, furnaces, rockets, gas turbines, diesel and port fuel injected engines); and in medicinal and printing applications. To be able to describe sprays it is necessary to obtain a detailed understanding of spray processes.

In the simplest case, the liquid to be sprayed is injected at a high velocity through a small orifice. Atomization is the process whereby the injected liquid is broken up into droplets. Atomization has a strong influence on spray vaporization rates because it increases the total surface area of the injected liquid greatly. Fast vaporization may be desirable in certain applications, but undesirable in others, where the liquid is required to impinge on a target. The trajectories of the spray drops are governed by the injected momentum of the drop, drag forces, and interactions between the drops and the surrounding gas. Control of these and other spray processes can lead to significant improvements in performance and in quality of product, and to reduction of emission of pollutants.

#### Spray Characterization

Practical atomizers generate sprays with a distribution of drop sizes, with average sizes in the diameter range from a few microns ( $1 \mu\text{m} = 10^{-6} \text{m}$ ) to as large as 0.5 mm. It is important to quantify the details of the distribution depending on the application. For example, the smaller drops in a spray vaporize fast, and this is helpful to control ignition processes in some combustion systems. On the other hand, the large drops carry most of the mass and momentum of the injected liquid and these drops are able to penetrate into the high-pressure gases in engine combustion chambers. Typical average drop sizes for broad classes of sprays are shown schematically in Figure 3.12.1. It should be noted that the terminology used to describe sprays in Figure 3.12.1 is qualitative and is not universally agreed upon.

**FIGURE 3.12.1** Typical average spray drop sizes for various classes of sprays. A representative size distribution is depicted for the diesel spray.

Methods for characterizing the size distribution of spray drops are discussed in References 1 and 2. A probability distribution function,  $F(D)$ , is introduced that represents the fraction of drops per unit diameter range about the diameter,  $D$ , as shown in Figure 3.12.2. The spray drop sizes span a range from a minimum diameter,  $D_{\min}$ , to a maximum diameter,  $D_{\max}$ . It is also convenient to introduce a mean or average drop diameter instead of having to specify the complete drop size distribution. The number median drop diameter (NMD) represents that drop whose diameter is such that 50% of the drops in the spray have sizes less than this size. Spray drop size distribution data can also be represented as a volume

**FIGURE 3.12.2** Cumulative spray drop number and volume distributions.

(or mass) distribution function,  $F(D^3)$ ; this gives more weight to the large drops in the distribution. In this case, a volume median diameter (VMD) or a mass median diameter (MMD) can also be defined, as indicated in Figure 3.12.2.

Various other mean diameters are also in common use. These are summarized using the standard notation of Mugele and Evans<sup>2</sup> as

$$(D_{jk})^{j-k} = \frac{\int_{D_{\min}}^{D_{\max}} D^j f(D) dD}{\int_{D_{\min}}^{D_{\max}} D^k f(D) dD} \quad (3.12.1)$$

where  $f(D) = dF(D)/dD$  is the drop size probability density function (usually normalized such that  $\int_{D_{\min}}^{D_{\max}} f(D)dD = 1$ ). Commonly used mean diameters are  $D_{10}$  (i.e.,  $j = 1, k = 0$ , sometimes called the length mean diameter<sup>3</sup> and  $D_{32}$  (i.e.,  $j = 3, k = 2$ , called the Sauter mean diameter or SMD). The Sauter mean diameter has a useful physical interpretation in combustion applications since drop vaporization rates are proportional to the surface area of the drop. It represents the size of that drop that has the same volume-to-surface area ratio as that of the entire spray.

Several distribution functions have been found to fit experimental data reasonably well. Among these are the Nukiyama–Tanasawa and the Rosin–Rammler distributions which have the general form<sup>3</sup>  $f(D) = aD^p \exp\{-bD\}^q$ , where the constants  $a, p, b$ , and  $q$  characterize the size distribution. The higher the parameter,  $q$ , the more uniform the distribution, and typically  $1.5 < q < 4$ . Other distributions have been proposed which consist of logarithmic transformations of the normal distribution, such as  $f(D) = a \exp(-y^2/2)$ , where  $y = \delta \ln(\eta D / (D_{\max} - D))$ , and  $a, \delta$ , and  $\eta$  are constants. In this case, the smaller  $\delta$ , the more uniform the size distribution. It should be noted that there is no theoretical justification for any of these size distributions. Spray drop size distributions can be measured nonintrusively by using optical laser diffraction and phase/Doppler instruments. A discussion of these techniques and their accuracy is reviewed by Chigier.<sup>4</sup>

## Atomizer Design Considerations

Atomization is generally achieved by forcing a liquid or a liquid–gas mixture through a small hole or slit under pressure to create thin liquid sheets or jets moving at a high relative velocity with respect to the surrounding ambient gas. Desirable characteristics of atomizers include the ability to atomize the

liquid over a wide range of flow rates, low power requirements, and low susceptibility to blockage or fouling. In addition, atomizers should produce consistent sprays with uniform flow patterns in operation.

Atomizers can be broadly characterized as those producing hollow cone or solid cone sprays, as depicted in Figure 3.12.3. In solid cone (or full cone) sprays the spray liquid is concentrated along the spray axis, Figure 3.12.3(a). These sprays are useful in applications requiring high spray penetration, such as in diesel engines. In hollow cone sprays the axis region is relatively free of drops, giving wide spray dispersal, Figure 3.12.3(b). These sprays are often used in furnaces, gas turbines, and spray-coating applications.

FIGURE 3.12.3 Schematic diagram of (a) solid cone and (b) hollow cone pressure atomizer sprays.

Many different atomizer designs are found in applications. Common atomizer types include pressure, rotary, twin-fluid (air-assist, air-blast, effervescent), flashing, electrostatic, vibratory, and ultrasonic atomizers, as discussed next.

### Atomizer Types

In *pressure atomizers* atomization is achieved by means of a pressure difference,  $\Delta P = P_{res} - P_{gas}$ , between the liquid in the supply reservoir pressure,  $P_{res}$ , and the ambient medium pressure,  $P_{gas}$ , across a nozzle. The simplest design is the plain orifice nozzle with exit hole diameter,  $d$ , depicted in Figure 3.12.3(a). The liquid emerges at the theoretical velocity  $U = \sqrt{2\Delta P/\rho_{liquid}}$ , the (Bernoulli) velocity along the streamline A–B in Figure 3.12.3(a), where  $\rho_{liquid}$  is the density of the liquid. The actual injection velocity is less than the ideal velocity by a factor called the discharge coefficient,  $C_D$ , which is between 0.6 and 0.9 for plain hole nozzles.  $C_D$  accounts for flow losses in the nozzle.

Four main jet breakup regimes have been identified, corresponding to different combinations of liquid inertia, surface tension, and aerodynamic forces acting on the jet, as shown in Figure 3.12.4. At low injection pressures the low-velocity liquid jet breaks up due to the unstable growth of long-wavelength waves driven by surface tension forces (Rayleigh regime). As the jet velocity is increased, the growth of disturbances on the liquid surface is enhanced because of the interaction between the liquid and the ambient gas (the first and second wind-induced breakup regimes). At high injection pressures the high-velocity jet disintegrates into drops immediately after leaving the nozzle exit (atomization regime). Criteria for the boundaries between the regimes are available.<sup>5</sup> Aerodynamic effects are found to become very important relative to inertial effects when the jet Weber number,  $We_j > 40$ , where  $We_j = \rho_{gas}U^2d/\sigma$ ,  $\rho_{gas}$  is the gas density, and  $\sigma$  is the liquid surface tension.

Experiments show that the unstable growth of surface waves is aided by high relative velocities between the liquid and the gas, and also by high turbulence and other disturbances in the liquid and gas flows, and by the use of spray liquids with low viscosity and low surface tension.

**FIGURE 3.12.4** (a) Rayleigh breakup. Drop diameters are larger than the jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (b) First wind-induced regime. Drops with diameters of the order of jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (c) Second wind-induced regime. Drop sizes smaller than the jet diameter. Breakup starts some distance downstream of nozzle. (d) Atomization regime. Drop sizes much smaller than the jet diameter. Breakup starts at nozzle exit.

Liquid breakup characteristics such as the spray drop size, the jet breakup length, and the spray angle have been related to the unstable wave growth mechanism. The wavelengths and growth rates of the waves can be predicted using results from a linear stability analysis with<sup>6</sup>

$$\frac{\Lambda}{2} = 9.02 \frac{(1 + 0.45Z^{0.5})(1 + 0.4T^{0.7})}{(1 + 0.87We_2^{1.67})^{0.6}} \quad (3.12.2a)$$

$$\Omega \left( \frac{\rho_1 a^3}{\sigma} \right)^{0.5} = \frac{0.34 + 0.38We_2^{1.5}}{(1 + Z)(1 + 1.4T^{0.6})} \quad (3.12.2b)$$

where  $\Lambda$  is the wavelength,  $\Omega$  is the growth rate of the most unstable surface wave, and  $a$  is the liquid jet radius. The maximum wave growth rate increases, and the corresponding wavelength decreases with increasing Weber number,  $We_2 = \rho_{\text{gas}} U^2 a / \sigma$ , where  $U$  is the relative velocity between the liquid and the gas. The liquid viscosity appears in the Ohnesorge number,  $Z = We_1^{1/2} / Re_1$ . Here, the Weber number  $We_1$  is based on the liquid density, the Reynolds number is  $Re_1 = Ua/\nu_1$ ,  $\nu_1$  is the liquid viscosity, and the parameter  $T = ZWe_2^{1/2}$ . The wave growth rate is reduced and the wavelength is increased as the liquid viscosity increases.

The size of the drops formed from the breakup process is often assumed to be proportional to the wavelength of the unstable surface waves in modeling studies.<sup>6</sup> However, the drop sizes in the primary breakup region near the nozzle exist have also been found to be influenced by the length scale of the energy-containing eddies in the turbulent liquid flow.<sup>7</sup> There is uncertainty about atomization mechanisms since spray measurements are complicated by the high optical density of the spray in the breakup region

(e.g., see Figure 3.12.4(d)). As the drops penetrate into the ambient gas, they interact with each other through collisions and coalescence, and the spray drop size changes dynamically within the spray as a result of secondary breakup and vaporization effects. The drop trajectories are determined by complex drop drag, breakup, and vaporization phenomena, and by interactions with the turbulent gas flow.<sup>6</sup>

High-pressure diesel sprays are intermittent and are required to start and stop quickly without dribble between injections. This is accomplished by means of a plunger arrangement that is actuated by a cam and spring system in mechanical “jerk” pump systems (see Figure 3.12.5). Modern electronic injectors include electromagnetic solenoids that permit the duration and injection pressure to be varied independently of each other and of engine speed. Experiments on diesel-type injector nozzles show that the penetration distance,  $S$ , of the tip of the spray at time,  $t$ , after the beginning of the injection is given by<sup>8</sup>

$$S = 0.39Ut \left( \rho_{\text{liquid}} / \rho_{\text{gas}} \right)^{1/2} \quad \text{for } t < t_b$$

$$S = 2.46 \sqrt{U} dt \left( \rho_{\text{liquid}} / \rho_{\text{gas}} \right)^{1/4} \quad \text{for } t > t_b$$
(3.12.3)

where the “breakup time” is  $t_b = 40.5d(\rho_{\text{liquid}}/\rho_{\text{gas}})^{1/2}/U$ . The jet breakup length (see Figure 3.12.3(a)),  $L = Ut_b$  is independent of the injection velocity. On the other hand, for low-speed jets, or for jets injected into a low-gas-density environment,  $t_b = 1.04C (\rho_{\text{liquid}} d^3/\sigma)^{1/2}$ , where  $C$  is a constant typically between 12 and 16 and  $\sigma$  is the surface tension. In this case  $L$  increases with the injection velocity.<sup>9</sup> The functional form of the above jet breakup time and length correlations can be derived for an inviscid liquid in the limits of large and small Weber number,  $We_2$  from the unstable wave growth rate in Equation (3.12.2) with  $t_b \sim \Omega^{-1}$ .

**FIGURE 3.12.5** (a) Diesel injector multihole spray nozzle, (b) showerhead, and (c) doublet impingement nozzles.

For high-speed diesel-type jets in the atomization regime the resulting spray diverges in the form of a cone with cone angle,  $\theta$ , that is usually in the range from 5 to 20°.  $\theta$  increases with gas density following  $\tan \theta = A(\rho_{\text{gas}}/\rho_{\text{liquid}})^{1/2}$ , where  $A$  is a constant that depends on the nozzle passage length and (weakly) on the injection velocity.<sup>9</sup> Very high injection pressures are required to produce small drops. In diesel engines  $\Delta P$  is typically as high as 200 Mpa, and drops are produced with mean diameters of the order of 10  $\mu\text{m}$  (see Figure 3.12.1). Drop size correlations have been proposed for plain-orifice sprays, such as that presented in Table 3.12.1.<sup>3</sup> Note, however, that these correlations do not account for the fact that the spray drop size varies with time, and from place to place in the spray. Moreover, experimental correlations often do not include some parameters that are known to influence spray drop sizes, such as the nozzle passage length and its entrance geometry. Therefore, overall drop size correlations should only be used with caution.

**TABLE 3.12.1 Representative Drop Size Correlations for Various Spray Devices**  
(Dimensional quantities are in SI units, kg, m, s)

Device	Correlation	Notes
Plain orifice	$\text{SMD} = 3.08 v_i^{0.385} (\rho_{\text{liquid}} \sigma)^{0.737} \rho_{\text{gas}}^{0.06} \Delta P^{-0.54}$	Use SI units
Fan spray	$\text{SMD} = 2.83 d_h \left( \sigma \mu_{\text{liquid}}^2 / \rho_{\text{gas}} d_h^3 \Delta P^2 \right)^{0.25}$ $+ 0.26 d_h \left( \sigma \rho_{\text{liquid}} / \rho_{\text{gas}} d_h \Delta P \right)^{0.25}$	$d_h$ = nozzle hydraulic diameter
Rotary atomizer	$\text{SMD} = 0.119 Q^{0.1} \sigma^{0.5} / N d^{0.5} \rho_{\text{liquid}}^{0.4} \mu_{\text{liquid}}^{0.1}$	$N$ = rotational speed (rev/sec), $Q$ = volumetric flow rate, $A_{\text{inj}} U$
Pressure swirl	$\text{SMD} = 4.52 \left( \sigma \mu_{\text{liquid}}^2 / \rho_{\text{gas}} \Delta P^2 \right)^{0.25} (t \cos \theta)^{0.25}$ $+ 0.39 \left( \sigma \rho_{\text{liquid}} / \rho_{\text{gas}} \Delta P \right)^{0.25} (t \cos \theta)^{0.75}$ $t = 0.0114 A_{\text{inj}} \rho_{\text{liquid}}^{1/2} d \cos \theta$	$t$ = film thickness; $\theta$ = cone angle, $d$ = discharge orifice diameter
Twin fluid/air blast	$\text{SMD} = 0.48 d \left( \sigma / \rho_{\text{gas}} U^2 d \right)^{0.4} (1 + 1/\text{ALR})^{0.4}$ $+ 0.15 d \left( \mu_{\text{liquid}}^2 / \sigma \rho_{\text{liquid}} d \right)^{0.5} (1 + 1/\text{ALR})$	ALR = air-to-liquid mass ratio
Prefilming air blast	$\text{SMD} = (1 + 1/\text{ALR}) \left[ 0.33 d_h \left( \sigma / \rho_{\text{gas}} U^2 d_p \right)^{0.6} \right. \\ \left. + 0.068 d_h \left( \mu_{\text{liquid}}^2 / \sigma \rho_{\text{liquid}} d_p \right)^{0.5} \right]$	$d_h$ = hydraulic diameter, $d_p$ = prefilmer diameter, Figure 3.12.9
Ultrasonic	$\text{SMD} = \left( 4\pi^3 \sigma / \rho_{\text{liquid}} \omega^2 \right)^{1/3}$	$\omega$ = vibration frequency

The plain orifice design is also used in twin-fluid-type liquid rocket engines in showerhead and doublet designs (Figures 3.12.5b and 3.12.5c). In the case of doublet nozzles, shown in Figure 3.12.6c, the impinging jets create unstable liquid sheets which break up to produce the sprays. Drop size correlations are available for liquid sheets such as those formed by discharging the liquid through a rectangular slit (see *fan spray*, Table 3.12.1). Thin liquid sheets or slits lead to the production of small drops. The breakup mechanism of liquid sheets is also thought to involve the unstable growth of surface waves due to surface tension and aerodynamic forces.<sup>5</sup>

In *rotary atomizers* centrifugal forces are used to further enhance the breakup process. In this case the liquid is supplied to the center of a spinning disk and liquid sheets or ligaments are thrown off the edges of the disk. The drop size depends on the rotational speed of the disk, as indicated in Table 3.12.1.

A spinning wheel or cup (turbobell) is used in some spray-painting applications. The spray shape is controlled by supplying a coflowing stream of “shaping-air.”

Centrifugal forces also play a role in the breakup mechanism of *pressure swirl* atomizers (*simplex* nozzles). These atomizers give wider spray cone angle than plain orifice nozzles, and are available in hollow cone and solid cone designs. As depicted in [Figure 3.12.3\(b\)](#) the spray liquid enters a swirl chamber tangentially to create a swirling liquid sheet. The air core vortex within the swirl chamber plays an important role in determining the thickness of the liquid sheet or film at the nozzle exit. This type of nozzle produces relatively coarse sprays. A representative SMD correction is listed in [Table 3.12.1](#). The spray cone angle depends on the ratio of the axial and tangential liquid velocity components at the exit of the nozzle. This type of atomizer is not well suited for use in transient applications because it tends to dribble at start-up and to shut down when the air core is not fully formed.

The basic drawback of all pressure atomizers is that the flow rate depends on the square root of  $\Delta P$ . The volumetric flow rate is  $Q = A_{inj} U$ , where  $A_{inj}$  is the liquid flow area at the nozzle exit, so that a factor of 20 increase in flow rate (a typical turndown ratio from idle to full load operation of a gas turbine engine) requires a factor of 400 increase in injection pressure.

This difficulty has led to so-called wide-range atomizer designs such as those shown in [Figure 3.12.6](#). The *duplex* nozzle features two sets of tangential swirl ports; the primary (or pilot) supplies fuel at low flow rates, while the secondary ports become operational at high flow rates. Another variation is the *dual-orifice* nozzle which is conceptually two simplex nozzles arranged concentrically, one supplying the primary flow and the other supplying the secondary flow. The *spill-return* nozzle is a simplex nozzle with a rear passage that returns fuel to the injection pump. In this design the flow rate is controlled by the relative spill amount, and there are no small passages to become plugged. However, the fuel is always supplied at the maximum pressure which increases the demands on the injection pump. But high swirl is always maintained in the swirl chamber and good atomization is achieved even at low flow rates.

**FIGURE 3.12.6** (a) Duplex, (b) dual orifice, and (c) spill-return-type nozzle designs.

In *twin-fluid injectors* atomization is aided by a flow of high-velocity gas through the injector passages. The high-velocity gas stream impinges on a relatively low-velocity liquid either internally (in *internal-mixing* nozzles, [Figure 3.12.7](#)) or externally (in *external-mixing* designs, [Figure 3.12.8](#)). The liquid and gas flows are typically swirled in opposite directions by means of swirl vanes to improve atomization. *Air-assist* refers to designs that use a relatively small amount of air at high (possibly sonic) velocities. *Air-blast* refers to designs that use large quantities of relatively low-velocity air which often supplies some of the air to help decrease soot formation in combustion systems<sup>3</sup>. (see [Figure 3.12.9](#).)

In *flashing* and *effervescent* atomizers a two-phase flow is passed through the injector nozzle exit. In the former the bubbles are generated by means of a phase change which occurs as the liquid, containing a dissolved propellant gas or vapor, undergoes the pressure drop through the nozzle. This process is exploited in many household spray cans, but has the disadvantage of releasing the propellant gas required for atomization into the atmosphere. In the so-called effervescent atomizer, air bubbles are introduced

FIGURE 3.12.7 Internal-mixing twin-fluid injector design.

FIGURE 3.12.8 External-mixing twin-fluid injector design.

FIGURE 3.12.9 Prefilming air blast atomizer.

FIGURE 3.12.10 Internal-mixing, effervescent atomizer.

into the liquid upstream of the exit orifice, as depicted in [Figure 3.12.10](#). The spray quality is found to depend weakly on the air bubble size and is independent of the nozzle exit diameter. This makes internal-mixing, air-assist atomizers very attractive for use with high-viscosity fluids and slurries where nozzle plugging would otherwise be a problem.<sup>3</sup>

In *electrostatic* atomizers the spray liquid is charged by applying a high-voltage drop across the nozzle. The dispersion of the spray drops is increased by exploiting electrical repulsive forces between the droplets. An electrostatic charge on the drops is also helpful in spray-coating applications, such as in automotive spray painting using electrostatic turbobell sprayers, since the charged drops are attracted to an oppositely charged target surface.

Other atomizer types include *vibratory* and *ultrasonic* atomizers (or *nebulizers*), where the drops are formed by vibrating the injector nozzle at high frequencies and at large amplitudes to produce short-wavelength disturbances to the liquid flow. Ultrasonic atomizers are used in inhalation therapy where very fine sprays (submicron sizes) are required, and an available representative drop size correlation is also listed in [Table 3.12.1](#).

## Further Information

Information about recent work in the field of atomization and sprays can be obtained through participation in the Institutes for Liquid Atomization and Spraying Systems (ILASS-Americas, -Europe, -Japan, -Korea). These regional ILASS sections hold annual meetings. An international congress (ICLASS) is also held biennially. More information is available on the ILASS-Americas homepage at <http://ucicl.eng.uci.edu/ilass>. Affiliated with the ILASS organizations is the Institute's Journal publication *Atomization and Sprays* published by Begell House, Inc., New York.

### 3.13 Flow Measurement\*

*Alan T. McDonald and Sherif A. Sherif*

This section deals with the measurement of mass flow rate or volume flow rate of a fluid in an enclosed pipe or duct system. Flow measurement in open channels is treated in Section 3.10 of this book.

The choice of a flow meter type and size depends on the required accuracy, range, cost, ease of reading or data reduction, and service life. Always select the simplest and cheapest device that gives the desired accuracy.

#### Direct Methods

Tanks can be used to determine the flow rate for steady liquid flows by measuring the volume or mass of liquid collected during a known time interval. If the time interval is long enough, flow rates may be determined precisely using tanks. Compressibility must be considered in gas volume measurements. It is not practical to measure the mass of gas, but a volume sample can be collected by placing an inverted “bell” over water and holding the pressure constant by counterweights. No calibration is required when volume measurements are set up carefully; this is a great advantage of direct methods.

Positive-displacement **flow meters** may be used in specialized applications, particularly for remote or recording uses. For example, household water and natural gas meters are calibrated to read directly in units of product. Gasoline metering pumps measure total flow and automatically compute the cost. Many positive-displacement meters are available commercially. Consult manufacturers’ literature or Reference 7 for design and installation details.

#### Restriction Flow Meters for Flow in Ducts

Most restriction flow meters for internal flow (except the laminar flow element) are based on acceleration of a fluid stream through some form of nozzle, shown schematically in Figure 3.13.1. Flow separating from the sharp edge of the nozzle throat forms a recirculation zone shown by the dashed lines downstream from the nozzle. The main flow stream continues to accelerate from the nozzle throat to form a *vena contracta* at section (2) and then decelerates again to fill the duct. At the vena contracta, the flow area is a minimum, the flow streamlines are essentially straight, and the pressure is uniform across the channel section. The theoretical flow rate is

$$\dot{m}_{\text{theoretical}} = \frac{A_2}{\sqrt{1 - (A_2/A_1)^2}} \sqrt{2\rho(p_1 - p_2)} \quad (3.13.1)$$

Equation (3.13.1) shows the general relationship for a **restriction flow meter**: Mass flow rate is proportional to the square root of the pressure differential across the meter taps. This relationship limits the flow rates that can be measured accurately to approximately a 4:1 range.

Several factors limit the utility of Equation (3.13.1) for calculating the actual mass flow rate through a meter. The actual flow area at section (2) is unknown when the vena contracta is pronounced (e.g., for orifice plates when  $D_2$  is a small fraction of  $D_1$ ). The velocity profiles approach uniform flow only at large Reynolds number. Frictional effects can become important (especially downstream from the meter) when the meter contours are abrupt. Finally, the location of the pressure taps influences the differential pressure reading,  $p_1 - p_2$ .

The actual mass flow rate is given by

\* The contributors of this chapter were asked to conform as much as possible to the nomenclature presented below, but define new terms pertaining to their particular area of specialty in the context of the chapter.

**FIGURE 3.13.1** Internal flow through a generalized nozzle, showing control volume used for analysis.

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1 - (A_t/A_1)^2}} \sqrt{2\rho(p_1 - p_2)} \quad (3.13.2)$$

where  $C$  is an empirical *discharge coefficient*.

If  $\beta = D_t/D_1$ , then  $(A_t/A_1)^2 = (D_t/D_1)^4 = \beta^4$ , and

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1 - \beta^4}} \sqrt{2\rho(p_1 - p_2)} \quad (3.13.3)$$

where  $1/(1 - \beta^4)^{1/2}$  is the *velocity correction factor*. Combining the discharge coefficient and velocity correction factor into a single *flow coefficient*,

$$K = \frac{C}{\sqrt{1 - \beta^4}} \quad (3.13.4)$$

yields the mass flow rate in the form:

$$\dot{m}_{\text{actual}} = KA_t \sqrt{2\rho(p_1 - p_2)} \quad (3.13.5)$$

Test data can be used to develop empirical equations to predict flow coefficients vs. pipe diameter and Reynolds number for standard metering systems. The accuracy of the equations (within specified ranges) is often adequate to use the meter without calibration. Otherwise, the coefficients must be measured experimentally.

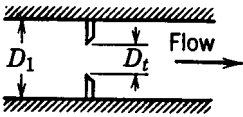

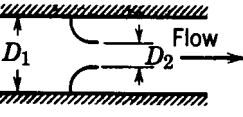

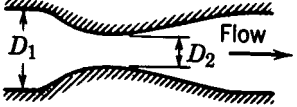

For the turbulent flow regime ( $Re_D > 4000$ ), the flow coefficient may be expressed by an equation of the form:<sup>7</sup>

$$K = K_\infty + \frac{1}{\sqrt{1 - \beta^4}} \frac{b}{Re_D^n} \quad (3.13.6)$$

where subscript  $\infty$  denotes the flow coefficient at infinite Reynolds number and constants  $b$  and  $n$  allow for scaling to finite Reynolds numbers. Correlating equations and curves of flow coefficients vs. Reynolds number are given for specific metering elements in the next three subsections following the general comparison of the characteristics of orifice plate, flow nozzle, and venturi meters in [Table 3.13.1](#) (see Reference 4).

Flow meter coefficients reported in the literature have been measured with fully developed turbulent velocity distributions at the meter inlet (Section 3.1). When a flow meter is installed downstream from

**TABLE 3.13.1. Characteristics of Orifice, Flow Nozzle, and Venturi Flow Meters**

Flow Meter Type	Diagram	Head Loss	Cost
Orifice		High	Low
Flow nozzle		Intermediate	Intermediate
Venturi		Low	High

a valve, elbow, or other disturbance, a straight section of pipe must be placed in front of the meter. Approximately 10 diameters of straight pipe upstream are required for venturi meters, and up to 40 diameters for orifice plate or flow nozzle meters. Some design data for incompressible flow are given below. The same basic methods can be extended to compressible flows.<sup>7</sup>

**Orifice Plates**

The orifice plate (Figure 3.13.2) may be clamped between pipe flanges. Since its geometry is simple, it is low in cost and easy to install or replace. The sharp edge of the orifice will not foul with scale or suspended matter. However, suspended matter can build up at the inlet side of a concentric orifice in a horizontal pipe; an eccentric orifice may be placed flush with the bottom of the pipe to avoid this difficulty. The primary disadvantages of the orifice are its limited capacity and the high permanent head loss caused by uncontrolled expansion downstream from the metering element.

**FIGURE 3.13.2** Orifice geometry and pressure tap locations.

Pressure taps for orifices may be placed in several locations as shown in Figure 3.13.2 (see Reference 7 for additional details). Since the location of the pressure taps influences the empirically determined flow coefficient, one must select handbook values of *K* consistent with the pressure tap locations.

The correlating equation recommended for a concentric orifice with corner taps is

$$C = 0.5959 + 0.0312\beta^{2.1} - 0.184\beta^8 + \frac{91.71\beta^{2.5}}{Re_{D_1}^{0.75}} \tag{3.13.7}$$

FIGURE 3.13.3 Flow coefficients for concentric orifices with corner taps.

FIGURE 3.13.4 Typical installations of nozzle flow meters. (a) In plenum, (b) In duct.

Equation (3.13.7) predicts orifice discharge coefficients within  $\pm 0.6\%$  for  $0.2 < \beta < 0.75$  and for  $10^4 < Re_{D_1} < 10^7$ . Some flow coefficients calculated from Equation (3.13.7) are presented in Figure 3.13.3. Flow coefficients are relatively insensitive to Reynolds number for  $Re_{D_1} > 10^5$  when  $\beta > 0.5$ .

A similar correlating equation is available for orifice plates with  $D$  and  $D/2$  taps. Flange taps require a different correlation for every line size. Pipe taps, located at  $2\frac{1}{2}D$  and  $8D$ , no longer are recommended.

### Flow Nozzles

Flow nozzles may be used as metering elements in either plenums or ducts, as shown in Figure 3.13.4; the nozzle section is approximately a quarter ellipse. Design details and recommended locations for pressure taps are given in Reference 7.

The correlating equation recommended for an ASME long-radius flow nozzles<sup>7</sup> is

$$C = 0.9975 - \frac{6.53\beta^{0.5}}{Re_{D_1}^{0.5}} \quad (3.13.8)$$

Equation (3.13.8) predicts discharge coefficients for flow nozzles within  $\pm 2.0\%$  for  $0.25 < \beta < 0.75$  for  $10^4 < Re_{D_1} < 10^7$ . Some flow coefficients calculated from Equation 3.13.8 are presented in Figure 3.13.5. ( $K$  can be greater than 1 when the velocity correction factor exceeds 1.) For plenum installation, nozzles may be fabricated from spun aluminum, molded fiberglass, or other inexpensive materials. Typical flow coefficients are in the range  $0.95 < K < 0.99$ ; the larger values apply at high Reynolds numbers. Thus, the mass flow rate can be computed within approximately  $\pm 2\%$  using  $K = 0.97$ .

FIGURE 3.13.5 Flow coefficients for ASME long-radius flow nozzles.

### Venturis

Venturi meters are generally made from castings machined to close tolerances to duplicate the performance of the standard design, so they are heavy, bulky, and expensive. The conical diffuser section downstream from the throat gives excellent pressure recovery; overall head loss is low. Venturi meters are self-cleaning because of their smooth internal contours.

Experimentally measured discharge coefficients for venturi meters range from 0.980 to 0.995 at high Reynolds numbers ( $Re_{D_1} > 2 \times 10^5$ ). Thus,  $C = 0.99$  can be used to calculate mass flow rate within about  $\pm 1\%$  at high Reynolds number.<sup>7</sup> Consult manufacturers' literature for specific information at Reynolds numbers below  $10^5$ .

Orifice plates, flow nozzles, and venturis all produce pressure drops proportional to flow rate squared, according to Equation 3.13.4. In practice, a meter must be sized to accommodate the largest flow rate expected. Because the pressure drop vs. flow rate relationship is nonlinear, a limited range of flow rate

can be measured accurately. Flow meters with single throats usually are considered for flow rates over a 4:1 range.<sup>7</sup>

Unrecoverable head loss across a metering element may be expressed as a fraction of the differential pressure across the element. Unrecoverable head losses are shown in Figure 3.13.6.<sup>7</sup>

FIGURE 3.13.6 Permanent head loss produced by various flow metering elements.

**Laminar Flow Elements**

The laminar flow element (LFE)\* produces a pressure differential proportional to flow rate. The LFE contains a metering section subdivided into many passages, each of small enough diameter to assure fully developed laminar flow. Because the pressure drop in laminar duct flow is directly proportional to flow rate, the pressure drop vs. flow rate relationship is linear. The LFE may be used with reasonable accuracy over a 10:1 flow rate range. Because the relationship between pressure drop and flow rate for laminar flow depends on viscosity, which is a strong function of temperature, fluid temperature must be known in order to obtain accurate metering.

An LFE costs approximately as much as a venturi, but is much lighter and smaller. Thus, the LFE is widely used in applications where compactness and extended range are important.

**Linear Flow Meters**

Several flow meter types produce outputs proportional to flow rate. Some meters produce signals without the need to measure differential pressure. The most common linear flow meters are discussed briefly below.

*Float meters* indicate flow rate directly for liquids or gases. An example is shown in Figure 3.13.7. The float is carried upward in the tapered clear tube by the flowing fluid until drag force and float weight are in equilibrium. Float meters (often called rotameters) are available with factory calibration for a number of common fluids and flow rate ranges.

A *turbine flow meter* is a free-running, vaned impeller mounted in a cylindrical section of tube (Figure 3.13.8). With proper design, the rate of rotation of the impeller may be made proportional to volume

flow rate over as much as a 100:1 flow rate range. Rotational speed of the turbine element can be sensed using a magnetic or modulated carrier pickup external to the meter. This sensing method therefore requires no penetrations or seals in the duct. Thus, turbine flow meters can be used safely to measure flow rates in corrosive or toxic fluids. The electrical signal can be displayed, recorded, or integrated to provide total flow information.

**FIGURE 3.13.8** Turbine flow meter. (Courtesy of Potter Aeronautical Corp., Union, NJ.)

*Vortex shedding* from a bluff obstruction may be used to meter flow. Since Strouhal number,  $St = fL/V$ , is approximately constant ( $St \approx 0.21$ ), vortex shedding frequency  $f$  is proportional to flow velocity. Vortex shedding causes velocity and pressure changes. Pressure, thermal, or ultrasonic sensors may be used to detect the vortex shedding frequency, and thus to infer the fluid velocity. (The velocity profile does affect the constancy of the shedding frequency.) Vortex flow meters can be used over a 20:1 flow rate range.<sup>7</sup>

*Electromagnetic flow meters* create a magnetic field across a pipe. When a conductive fluid passes through the field, a voltage is generated at right angles to the field and velocity vectors. Electrodes placed on a pipe diameter detect the resulting signal voltage, which is proportional to the average axial velocity when the profile is axisymmetric. The minimum flow speed should be above about 0.3 m/sec, but there are no restrictions on Reynolds number. The flow rate range normally quoted is 10:1.<sup>7</sup>

Ultrasonic flow meters also respond to average velocity at a pipe cross section. Two principal types of ultrasonic meters measure propagation time for clean liquids, and reflection frequency shift (Doppler effect) for flows carrying particulates. The speed of an acoustic wave increases in the flow direction and decreases when transmitted against the flow. For clean liquids, an acoustic path inclined to the pipe axis is used to infer flow velocity. Multiple paths are used to estimate volume flow rate accurately.

Doppler effect ultrasonic flow meters depend on reflection of sonic waves (in the megahertz range) from scattering particles in the fluid. When the particles move at flow speed, the frequency shift is proportional to flow speed; for a suitably chosen path, output is proportional to volume flow rate; ultrasonic meters may require calibration in place. One or two transducers may be used; the meter may be clamped to the outside of the pipe. Flow rate range is 10:1.<sup>7</sup>

A relatively new type of true mass flow meter is based on the effect of *Coriolis acceleration* on natural frequency of a bent tube carrying fluid. The bent tube is excited and its vibration amplitude measured. The instrument measures mass flow rate directly, and thus is ideal for two-phase or liquid–solid flow measurements. Pressure drop of the Coriolis meter may be high, but its useful flow rate range is 100:1.

### Traversing Methods

In situations such as in air handling or refrigeration equipment, it may be impractical or impossible to install a fixed flow meter, but it may be possible to measure flow rate using a traversing technique.<sup>1</sup> To measure flow rate by **traverse**, the duct cross section is subdivided into segments of equal area. The fluid velocity is measured at the center of each area segment using a pitot tube (see Figure 3.13.9), a total head tube, or a suitable anemometer. The volume flow rate for each segment is approximated by the product of the measured velocity and segment area. Flow rate through the entire duct is the sum of these segmental flow rates. For details of recommended procedures see Reference 1 or 6.

$$V = \sqrt{2(P_T - P_S)/\rho}$$

FIGURE 3.13.9 Pitot tube.

Use of probes for traverse measurements requires direct access to the flow field. Pitot tubes give uncertain results when pressure gradients or streamline curvature are present, and they respond slowly. Two types of anemometers — **thermal anemometers** and **laser Doppler anemometers** — partially overcome these difficulties, although they introduce new complications.

*Thermal anemometers* use electrically heated tiny elements (either hot-wire or hot-film elements). Sophisticated feedback circuits are used to maintain the temperature of the element constant and to sense the input heating rate. The heating rate is related to the local flow velocity by calibration. The primary advantage of thermal anemometers is the small size of the sensing element. Sensors as small as 0.002 mm in diameter and 0.1 mm long are available commercially. Because the thermal mass of such tiny elements is extremely small, their response to fluctuations in flow velocity is rapid. Frequency responses to the 50-kHz range have been quoted.<sup>3</sup> Thus, thermal anemometers are ideal for measuring turbulence quantities. Insulating coatings may be applied to permit their use in conductive or corrosive gases or liquids.

Because of their fast response and small size, thermal anemometers are used extensively for research. Numerous schemes for treating the resulting data have been published. Digital processing techniques, including fast Fourier transforms, can be used to obtain mean values and moments, and to analyze signal frequency content and correlations.

*Laser Doppler anemometers* (LDAs) can be used for specialized applications where direct physical access to the flow field is difficult or impossible.<sup>5</sup> Laser beam(s) are focused to a small volume in the flow at the location of interest; laser light is scattered from particles present in the flow or introduced for this purpose. A frequency shift is caused by the local flow speed (Doppler effect). Scattered light and a reference beam are collected by receiving optics. The frequency shift is proportional to the flow speed; this relationship may be calculated, so there is no need for calibration. Since velocity is measured directly, the signal is unaffected by changes in temperature, density, or composition in the flow field. The primary disadvantages of LDAs are the expensive and fragile optical equipment and the need for careful alignment.

## Viscosity Measurements

Viscometry is the technique of measuring the viscosity of a fluid. Viscometers are classified as rotational, capillary, or miscellaneous, depending on the technique employed. Rotational viscometers use the principle that a rotating body immersed in a liquid experiences a viscous drag which is a function of the viscosity of the liquid, the shape and size of the body, and the speed of its rotation. Rotational viscometers are widely used because measurements can be carried out for extended periods of time. Several types of viscometers are classified as rotational and [Figure 3.13.10](#) is a schematic diagram illustrating a typical instrument of this type.

Capillary viscometry uses the principle that when a liquid passes in laminar flow through a tube, the viscosity of the liquid can be determined from measurements of the volume flow rate, the applied pressure, and the tube dimensions. Viscometers that cannot be classified either as rotational or capillary include the falling ball viscometer. Its method of operation is based on Stokes' law which relates the viscosity of a Newtonian fluid to the velocity of a sphere falling in it. Falling ball viscometers are often employed for reasonably viscous fluids. Rising bubble viscometers utilize the principle that the rise of an air bubble through a liquid medium gives a visual measurement of liquid viscosity. Because of their simplicity, rising bubble viscometers are commonly used to estimate the viscosity of varnish, lacquer, and other similar media.

## Defining Terms

**Flow meter:** Device used to measure mass flow rate or volume flow rate of fluid flowing in a duct.

**Restriction flow meter:** Flow meter that causes flowing fluid to accelerate in a nozzle, creating a pressure change that can be measured and related to flow rate.

**FIGURE 3.13.10** Rotational viscometer.

**Thermal anemometer:** Heated sensor used to infer local fluid velocity by sensing changes in heat transfer from a small electrically heated surface exposed to the fluid flow.

**Traverse:** Systematic procedure used to traverse a probe across a duct cross-section to measure flow rate through the duct.

### Further Information

This section presents only a survey of flow measurement methods. The references contain a wealth of further information. Baker<sup>2</sup> surveys the field and discusses precision, calibration, probe and tracer methods, and likely developments. Miller<sup>7</sup> is the most comprehensive and current reference available for information on restriction flow meters. Goldstein<sup>5</sup> treats a variety of measurement methods in his recently revised and updated book. Spitzer<sup>8</sup> presents an excellent practical discussion of flow measurement. Measurement of viscosity is extensively treated in *Viscosity and Flow Measurement: A Laboratory Handbook of Rheology*, by Van Wazer, J.R., Lyons, J.W., Kim, K.Y., and Colwell, R.E., Interscience Publishers, John Wiley & Sons, New York, 1963.

### 3.14 Micro/Nanotribology

*Bharat Bhushan*

#### Introduction

The emerging field of micro/nanotribology is concerned with processes ranging from atomic and molecular scales to microscale, occurring during adhesion, friction, wear, and thin-film lubrication at sliding surfaces (Bhushan, 1995, 1997; Bhushan et al., 1995). The differences between conventional tribology or macrotribology and micro/nanotribology are contrasted in Figure 3.14.1. In macrotribology, tests are conducted on components with relatively large mass under heavily loaded conditions. In these tests, wear is inevitable and the bulk properties of mating components dominate the tribological performance. In micro/nanotribology, measurements are made on at least one of the mating components, with relatively small mass under lightly loaded conditions. In this situation, negligible wear occurs and the surface properties dominate the tribological performance.

**FIGURE 3.14.1** Comparison between macrotribology and microtribology.

Micro/nanotribological investigations are needed to develop fundamental understanding of interfacial phenomena on a small scale and to study interfacial phenomena in the micro- and nanostructures used in magnetic storage systems, microelectromechanical systems (MEMS), and other industrial applications (Bhushan, 1995, 1996, 1997). Friction and wear of lightly loaded micro/nanocomponents are highly dependent on the surface interactions (few atomic layers). These structures are generally lubricated with molecularly thin films. Micro- and nanotribological studies are also valuable in fundamental understanding of interfacial phenomena in macrostructures to provide a bridge between science and engineering (Bowden and Tabor, 1950, 1964; Bhushan and Gupta, 1997; Bhushan, 1996).

In 1985, Binnig et al. (1986) developed an “atomic force microscope” (AFM) to measure ultrasmall forces (less than  $1 \mu\text{N}$ ) present between the AFM tip surface and the sample surface. AFMs can be used for measurement of *all engineering surfaces* of any surface roughness, which may be either electrically conducting or insulating. AFM has become a popular surface profiler for topographic measurements on micro- to nanoscale. These are also used for scratching, wear, and nanofabrication purposes. AFMs have been modified in order to measure both normal and friction forces and this instrument is generally called a friction force microscope (FFM) or a lateral force microscope (LFM). New transducers in conjunction with an AFM can be used for measurements of elastic/plastic mechanical properties (such as load-displacement curves, indentation hardness, and modulus of elasticity) (Bhushan et al., 1996). A surface force apparatus (SFA) was first developed in 1969 (Tabor and Winterton, 1969) to study both static and dynamic properties of molecularly thin liquid films sandwiched between two molecularly smooth surfaces. SFAs are being used to study rheology of molecularly thin liquid films; however, the liquid under study has to be confined between molecularly smooth surfaces with radii of curvature on the order of 1 mm (leading to poorer lateral resolution as compared with AFMs) (Bhushan, 1995). Only AFMs/FFMs can be used to study *engineering surfaces* in the *dry and wet conditions* with *atomic resolution*. The scope of this section is limited to the applications of AFMs/FFMs.

At most solid–solid interfaces of technological relevance, contact occurs at numerous asperities with a range of radii; a sharp AFM/FFM tip sliding on a surface simulates just one such contact. Surface roughness, adhesion, friction, wear, and lubrication at the interface between two solids with and without liquid films have been studied using the AFM and FFM. The status of current understanding of micro/nanotribology of engineering interfaces follows.

## Experimental Techniques

An AFM relies on a scanning technique to produce very high resolution, three-dimensional images of sample surfaces. The AFM measures ultrasmall forces (less than 1 nN) present between the AFM tip surface and a sample surface. These small forces are measured by measuring the motion of a very flexible cantilever beam having an ultrasmall mass. The deflection can be measured to with  $\pm 0.02$  nm, so for a typical cantilever force constant of 10 N/m, a force as low as 0.2 nN can be detected. An AFM is capable of investigating surfaces of both conductors and insulators on an atomic scale. In the operation of a high-resolution AFM, the sample is generally scanned; however, AFMs are also available where the tip is scanned and the sample is stationary. To obtain atomic resolution with an AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. A cantilever beam with a spring constant of about 1 N/m or lower is desirable. Tips have to be sharp as possible. Tips with a radius ranging from 10 to 100 nm are commonly available.

In the AFM/FFM shown in Figure 3.14.2, the sample is mounted on a PZT tube scanner which consists of separate electrodes to precisely scan the sample in the  $X$ – $Y$  plane in a raster pattern and to move the sample in the vertical ( $Z$ ) direction. A sharp tip at the end of a flexible cantilever is brought in contact with the sample. Normal and frictional forces being applied at the tip–sample interface are measured simultaneously, using a laser beam deflection technique.

FIGURE 3.14.2 Schematic of a commercial AFM/FFM using laser beam deflection method.

Topographic measurements are typically made using a sharp tip on a cantilever beam with normal stiffness on the order of 0.5 N/m at a normal load of about 10 nN, and friction measurements are carried out in the load range of 10 to 150 nN. The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern. Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. A maximum scan size of  $125 \times 125 \mu\text{m}$  and scan rate of 122 Hz typically can be used. Higher scan rates are used for small scan lengths.

For nanoscale boundary lubrication studies, the samples are typically scanned over an area of  $1 \times 1 \mu\text{m}$  at a normal force of about 300 nN, in a direction orthogonal to the long axis of the cantilever beam (Bhushan, 1997). The samples are generally scanned with a scan rate of 1 Hz and the scanning speed of  $2 \mu\text{m}/\text{sec}$ . The coefficient of friction is monitored during scanning for a desired number of cycles. After the scanning test, a larger area of  $2 \times 2 \mu\text{m}$  is scanned at a normal force of 40 nN to observe for any wear scar.

For microscale scratching, microscale wear, and nano-scale indentation hardness measurements, a sharp single-crystal natural diamond tip mounted on a stainless steel cantilever beam with a normal stiffness on the order of 25 N/m is used at relatively higher loads (1 to 150  $\mu\text{N}$ ). For wear studies, typically an area of  $2 \times 2 \mu\text{m}$  is scanned at various normal loads (ranging from 1 to 100  $\mu\text{N}$ ) for a selected number of cycles. For nanoindentation hardness measurements the scan size is set to zero and then normal load is applied to make the indents. During this procedure, the diamond tip is continuously pressed against the sample surface for about 2 sec at various indentation loads. The sample surface is scanned before and after the scratching, wear, or indentation to obtain the initial and the final surface topography, at a low normal load of about 0.3  $\mu\text{N}$  using the same diamond tip. An area larger than the indentation region is scanned to observe the indentation marks. Nanohardness is calculated by dividing the indentation load by the projected residual area of the indents.

In measurements using conventional AFMs, the hardness value is based on the projected residual area after imaging the indent. Identification of the boundary of the indentation mark is difficult to accomplish with great accuracy, which makes the direct measurement of contact area somewhat inaccurate. A capacitive transducer with the dual capability of depth sensing as well as *in situ* imaging is used in conjunction with an AFM (Bhushan et al., 1996). This indentation system, called nano/picoindentation, is used to make load-displacement measurements and subsequently carry out *in situ* imaging of the indent, if necessary. Indenter displacement at a given load is used to calculate the projected indent area for calculation of the hardness value. Young's modulus of elasticity is obtained from the slope of the unloading portion of the load-displacement curve.

## Surface Roughness, Adhesion, and Friction

Solid surfaces, irrespective of the method of formation, contain surface irregularities or deviations from the prescribed geometrical form. When two nominally flat surfaces are placed in contact, surface roughness causes contact to occur at discrete contact points. Deformation occurs in these points and may be either elastic or plastic, depending on the nominal stress, surface roughness, and material properties. The sum of the areas of all the contact points constitutes the real area that would be in contact, and for most materials at normal loads this will be only a small fraction of the area of contact if the surfaces were perfectly smooth. In general, real area of contact must be minimized to minimize adhesion, friction, and wear (Bhushan and Gupta, 1997; Bhushan, 1996). Characterizing surface roughness is therefore important for predicting and understanding the tribological properties of solids in contact.

Surface roughness most commonly refers to the variations in the height of the surface relative to a reference plane (Bowden and Tabor, 1950; Bhushan, 1996). Commonly measured roughness parameters, such as standard deviation of surface heights (rms), are found to be scale dependent and a function of the measuring instrument, for any given surface, Figure 3.14.3 (Poon and Bhushan, 1995). The topography of most engineering surfaces is fractal, possessing a self-similar structure over a range of scales. By using fractal analysis one can characterize the roughness of surfaces with two scale-independent fractal parameters  $D$  and  $C$  which provide information about roughness at all length scales (Ganti and

**FIGURE 3.14.3** Scale dependence of standard deviation of surface heights (rms) for a glass–ceramic substrate, measured using an AFM, a stylus profiler (SP-P2 and SP- $\alpha$ 200), and a noncontact optical profiler (NOP).

Bhushan, 1995; Bhushan, 1995). These two parameters are instrument independent and are unique for each surface.  $D$  (generally ranging from 1 to 2) primarily relates to distribution of different frequencies in the surface profile, and  $C$  to the amplitude of the surface height variations at all frequencies. A fractal model of elastic plastic contact has been used to predict whether contacts experience elastic or plastic deformation and to predict the statistical distribution of contact points.

Based on atomic-scale friction measurements of a well-characterized freshly cleaved surface of highly oriented pyrolytic graphite (HOPG), the atomic-scale friction force of HOPG exhibits the same periodicity as that of corresponding topography (Figure 3.14.4(a)), but the peaks in friction and those in topography were displaced relative to each other (Figure 3.14.4(b)). A Fourier expansion of the interatomic potential has been used to calculate the conservative interatomic forces between atoms of the FFM tip and those of the graphite surface. Maxima in the interatomic forces in the normal and lateral directions do not occur at the same location, which explains the observed shift between the peaks in the lateral force and those in the corresponding topography. Furthermore, the observed local variations in friction force were explained by variation in the intrinsic lateral force between the sample and the FFM tip, and these variations may not necessarily occur as a result of an atomic-scale stick–slip process.

Friction forces of HOPG have also been studied. Local variations in the microscale friction of cleaved graphite are observed, which arise from structural changes that occur during the cleaving process. The cleaved HOPG surface is largely atomically smooth, but exhibits line-shaped regions in which the coefficient of friction is more than an order of magnitude larger. Transmission electron microscopy indicates that the line-shaped regions consist of graphite planes of different orientation, as well as of amorphous carbon. Differences in friction can also be seen for organic mono- and multilayer films, which again seem to be the result of structural variations in the films. These measurements suggest that the FFM can be used for structural mapping of the surfaces. FFM measurements can be used to map chemical variations, as indicated by the use of the FFM with a modified probe tip to map the spatial arrangement of chemical functional groups in mixed organic monolayer films. Here, sample regions that had stronger interactions with the functionalized probe tip exhibited larger friction. For further details, see Bhushan (1995).

Local variations in the microscale friction of scratched surfaces can be significant and are seen to depend on the local surface slope rather than on the surface height distribution (Bhushan, 1995). Directionality in friction is sometimes observed on the macroscale; on the microscale this is the norm (Bhushan, 1995). This is because most “engineering” surfaces have asymmetric surface asperities so that the interaction of the FFM tip with the surface is dependent on the direction of the tip motion. Moreover, during surface-finishing processes material can be transferred preferentially onto one side of the asperities, which also causes asymmetry and directional dependence. Reduction in local variations and in the directionality of frictional properties therefore requires careful optimization of surface roughness distributions and of surface-finishing processes.

**FIGURE 3.14.4** (a) Gray-scale plots of surface topography (left) and friction profiles (right) of a  $1 \times 1$  nm area of freshly cleaved HOPG, showing the atomic-scale variation of topography and friction, (b) diagram of superimposed topography and friction profiles from (a); the symbols correspond to maxima. Note the spatial shift between the two profiles.

Table 3.14.1 shows the coefficient of friction measured for two surfaces on micro- and macroscales. The coefficient of friction is defined as the ratio of friction force to the normal load. The values on the microscale are much lower than those on the macroscale. When measured for the small contact areas and very low loads used in microscale studies, indentation hardness and modulus of elasticity are higher than at the macroscale. This reduces the degree of wear. In addition, the small apparent areas of contact reduce the number of particles trapped at the interface, and thus minimize the “ploughing” contribution to the friction force.

At higher loads (with contact stresses exceeding the hardness of the softer material), however, the coefficient of friction for microscale measurements increases toward values comparable with those obtained from macroscale measurements, and surface damage also increases (Bhushan et al., 1995; Bhushan and Kulkarni, 1996). Thus, Amontons’ law of friction, which states that the coefficient of

**TABLE 3.14.1 Surface Roughness and Micro- and Macroscale Coefficients of Friction of Various Samples**

Material	rms Roughness, nm	Microscale Coefficient of Friction vs. Si <sub>3</sub> N <sub>4</sub> Tip <sup>a</sup>	Macroscale Coefficient of Friction vs. Alumina Ball <sup>b</sup>
Si(111)	0.11	0.03	0.18

<sup>a</sup> Tip radius of about 50 nm in the load range of 10 to 150 nN (2.5 to 6.1 GPa), a scanning speed of 5 m/sec and scan area of  $1 \times 1 \mu\text{m}$ .

<sup>b</sup> Ball radius of 3 mm at a normal load of 0.1 N (0.3 GPa) and average sliding speed of 0.8 mm/sec.

friction is independent of apparent contact area and normal load, does not hold for microscale measurements. These findings suggest that microcomponents sliding under lightly loaded conditions should experience very low friction and near zero wear.

### Scratching, Wear, and Indentation

The AFM can be used to investigate how surface materials can be moved or removed on micro- to nanoscales, for example, in scratching and wear (Bhushan, 1995) (where these things are undesirable) and, in nanomachining/nanofabrication (where they are desirable). The AFM can also be used for measurements of mechanical properties on micro- to nanoscales. Figure 3.14.5 shows microscratches made on Si(111) at various loads after 10 cycles. As expected, the depth of scratch increases with load. Such microscratching measurements can be used to study failure mechanisms on the microscale and to evaluate the mechanical integrity (scratch resistance) of ultrathin films at low loads.

**FIGURE 3.14.5** Surface profiles of Si(111) scratched at various loads. Note that the  $x$  and  $y$  axes are in micrometers and the  $z$  axis is in nanometers.

By scanning the sample in two dimensions with the AFM, wear scars are generated on the surface. The evolution of wear of a diamond-like carbon coating on a polished aluminum substrate is showing in Figure 3.14.6 which illustrates how the microwear profile for a load of  $20 \mu\text{N}$  develops as a function of the number of scanning cycles. Wear is not uniform, but is initiated at the nanoscratches indicating that surface defects (with high surface energy) act as initiation sites. Thus, scratch-free surfaces will be relatively resistant to wear.

Mechanical properties, such as load-displacement curves, hardness, and modulus of elasticity can be determined on micro- to picoscales using an AFM and its modifications (Bhushan, 1995; Bhushan et al., 1995, 1996). Indentability on the scale of picometers can be studied by monitoring the slope of cantilever deflection as a function of sample traveling distance after the tip is engaged and the sample

**FIGURE 3.14.6** Surface profiles of diamond-like carbon-coated thin-film disk showing the worn region; the normal load and number of test cycles are indicated. (From Bhushan, B., *Handbook of Micro/Nanotribology*, CRC Press, Boca Raton, FL, 1995. With permission.)

is pushed against the tip. For a rigid sample, cantilever deflection equals the sample traveling distance; but the former quantity is smaller if the tip indents the sample. The indentation hardness on nanoscale of bulk materials and surface films with an indentation depth as small as 1 nm can be measured. An example of hardness data as a function of indentation depth is shown in Figure 3.14.7. A decrease in hardness with an increase in indentation depth can be rationalized on the basis that, as the volume of deformed materials increases, there is a higher probability of encountering material defects. AFM measurements on ion-implanted silicon surfaces show that ion implantation increases their hardness and, thus, their wear resistance (Bhushan, 1995). Formation of surface alloy films with improved mechanical properties by ion implantation is growing in technological importance as a means of improving the mechanical properties of materials.

FIGURE 3.14.7 Indentation hardness as a function of residual indentation depth for Si(100).

Young's modulus of elasticity is calculated from the slope of the indentation curve during unloading (Bhushan, 1995; Bhushan et al., 1996). AFM can be used in a *force modulation mode* to measure surface elasticities: an AFM tip is scanned over the modulated sample surface with the feedback loop keeping the average force constant. For the same applied force, a soft area deforms more, and thus causes less cantilever deflection, than a hard area. The ratio of modulation amplitude to the local tip deflection is then used to create a *force modulation image*. The force modulation mode makes it easier to identify soft areas on hard substrates.

Detection of the transfer of material on a nanoscale is possible with the AFM. Indentation of C<sub>60</sub>-rich fullerene films with an AFM tip has been shown to result in the transfer of fullerene molecules to the AFM tip, as indicated by discontinuities in the cantilever deflection as a function of sample traveling distance in subsequent indentation studies (Bhushan, 1995).

## Boundary Lubrication

The "classical" approach to lubrication uses freely supported multimolecular layers of liquid lubricants (Bowden and Tabor, 1950, 1964; Bhushan, 1996). The liquid lubricants are chemically bonded to improve their wear resistance (Bhushan, 1995, 1996). To study depletion of boundary layers, the microscale friction measurements are made as a function of the number of cycles. For an example of the data of virgin Si(100) surface and silicon surface lubricated with about 2-nm-thick Z-15 and Z-Dol perfluoropolyether (PEPE) lubricants, see Figure 3.14.8. Z-Dol is PFPE lubricant with hydroxyl end groups. Its lubricant film was thermally bonded. In Figure 3.14.8, the unlubricated silicon sample shows a slight increase in friction force followed by a drop to a lower steady state value after some cycles. Depletion of native oxide and possible roughening of the silicon sample are responsible for the decrease in this

**FIGURE 3.14.8** Friction force as a function of number of cycles using a silicon nitride tip at a normal force of 300 nN for the unlubricated and lubricated silicon samples.

friction force. The initial friction force for the Z-15-lubricated sample is lower than that of the unlubricated silicon and increases gradually to a friction force value comparable with that of the silicon after some cycles. This suggests the depletion of the Z-15 lubricant in the wear track. In the case of the Z-Dol-coated silicon sample, the friction force starts out to be low and remains low during the entire test. It suggests that Z-Dol does not get displaced/depleted as readily as Z-15. Additional studies of freely supported liquid lubricants showed that either increasing the film thickness or chemically bonding the molecules to the substrate with a mobile fraction improves the lubrication performance (Bhushan, 1997).

For lubrication of microdevices, a more effect approach involves the deposition of organized, dense molecular layers of long-chain molecules on the surface contact. Such monolayers and thin films are commonly produced by Langmuir–Blodgett (LB) deposition and by chemical grafting of molecules into self-assembled monolayers (SAMs). Based on the measurements, SAMs of octadecyl ( $C_{18}$ ) compounds based on aminosilanes on a oxidized silicon exhibited a lower coefficient of friction of (0.018) and greater durability than LB films of zinc arachidate adsorbed on a gold surface coated with octadecylthiol (ODT) (coefficient of friction of 0.03) (Bhushan et al., 1995). LB films are bonded to the substrate by weak van der Waals attraction, whereas SAMs are chemically bound via covalent bonds. Because of the choice of chain length and terminal linking group that SAMs offer, they hold great promise for boundary lubrication of microdevices.

Measurement of ultrathin lubricant films with nanometer lateral resolution can be made with the AFM (Bhushan, 1995). The lubricant thickness is obtained by measuring the force on the tip as it approaches, contacts, and pushes through the liquid film and ultimately contacts the substrate. The distance between the sharp “snap-in” (owing to the formation of a liquid of meniscus between the film and the tip) at the liquid surface and the hard repulsion at the substrate surface is a measure of the liquid film thickness. This technique is now used routinely in the information-storage industry for thickness measurements (with nanoscale spatial resolution) of lubricant films, a few nanometers thick, in rigid magnetic disks.

## 3.1 Fluid Statics

---

*Stanley A. Berger*

### Equilibrium of a Fluid Element

If the sum of the external forces acting on a fluid element is zero, the fluid will be either at rest or moving as a solid body — in either case, we say the fluid element is in equilibrium. In this section we consider fluids in such an equilibrium state. For fluids in equilibrium the only internal stresses acting will be normal forces, since the shear stresses depend on velocity gradients, and all such gradients, by the definition of equilibrium, are zero. If one then carries out a balance between the normal surface stresses and the body forces, assumed proportional to volume or mass, such as gravity, acting on an elementary prismatic fluid volume, the resulting equilibrium equations, after shrinking the volume to zero, show that the normal stresses at a point are the same in all directions, and since they are known to be negative, this common value is denoted by  $-p$ ,  $p$  being the pressure.

### Hydrostatic Pressure

If we carry out an equilibrium of forces on an elementary volume element  $dx dy dz$ , the forces being pressures acting on the faces of the element and gravity acting in the  $-z$  direction, we obtain

$$\frac{\partial p}{\partial x} = \frac{\partial p}{\partial y} = 0, \quad \text{and} \quad \frac{\partial p}{\partial z} = -\rho g = -\gamma \quad (3.1.1)$$

The first two of these imply that the pressure is the same in all directions at the same vertical height in a gravitational field. The third, where  $\gamma$  is the specific weight, shows that the pressure increases with depth in a gravitational field, the variation depending on  $\rho(z)$ . For homogeneous fluids, for which  $\rho$  = constant, this last equation can be integrated immediately, yielding

$$p_2 - p_1 = -\rho g(z_2 - z_1) = -\rho g(h_2 - h_1) \tag{3.1.2}$$

or

$$p_2 + \rho g h_2 = p_1 + \rho g h_1 = \text{constant} \tag{3.1.3}$$

where  $h$  denotes the elevation. These are the equations for the hydrostatic pressure distribution.

When applied to problems where a liquid, such as the ocean, lies below the atmosphere, with a constant pressure  $p_{\text{atm}}$ ,  $h$  is usually measured from the ocean/atmosphere interface and  $p$  at any distance  $h$  below this interface differs from  $p_{\text{atm}}$  by an amount

$$p - p_{\text{atm}} = \rho g h \tag{3.1.4}$$

Pressures may be given either as *absolute pressure*, pressure measured relative to absolute vacuum, or *gauge pressure*, pressure measured relative to atmospheric pressure.

### Manometry

The hydrostatic pressure variation may be employed to measure pressure differences in terms of heights of liquid columns — such devices are called manometers and are commonly used in wind tunnels and a host of other applications and devices. Consider, for example the U-tube manometer shown in Figure 3.1.1 filled with liquid of specific weight  $\gamma$ , the left leg open to the atmosphere and the right to the region whose pressure  $p$  is to be determined. In terms of the quantities shown in the figure, in the left leg

$$p_0 - \rho g h_2 = p_{\text{atm}} \tag{3.1.5a}$$

and in the right leg

$$p_0 - \rho g h_1 = p \tag{3.1.5b}$$

the difference being

$$p - p_{\text{atm}} = -\rho g(h_1 - h_2) = -\rho g d = -\gamma d \tag{3.1.6}$$

FIGURE 3.1.1 U-tube manometer.

and determining  $p$  in terms of the height difference  $d = h_1 - h_2$  between the levels of the fluid in the two legs of the manometer.

### Hydrostatic Forces on Submerged Objects

We now consider the force acting on a submerged object due to the hydrostatic pressure. This is given by

$$\mathbf{F} = \iint p \, d\mathbf{A} = \iint p \cdot \mathbf{n} \, dA = \iint \rho g h \, d\mathbf{A} + p_0 \iint d\mathbf{A} \quad (3.1.7)$$

where  $h$  is the variable vertical depth of the element  $d\mathbf{A}$  and  $p_0$  is the pressure at the surface. In turn we consider plane and nonplanar surfaces.

#### Forces on Plane Surfaces

Consider the planar surface  $A$  at an angle  $\theta$  to a free surface shown in [Figure 3.1.2](#). The force on one side of the planar surface, from Equation (3.1.7), is

$$\mathbf{F} = \rho g n \iint_A h \, d\mathbf{A} + p_0 A \mathbf{n} \quad (3.1.8)$$

but  $h = y \sin \theta$ , so

$$\iint_A h \, d\mathbf{A} = \sin \theta \iint_A y \, dA = y_c A \sin \theta = h_c A \quad (3.1.9)$$

where the subscript  $c$  indicates the distance measured to the centroid of the area  $A$ . Thus, the total force (on one side) is

$$\mathbf{F} = \gamma h_c A + p_0 A \quad (3.1.10)$$

Thus, the magnitude of the force is independent of the angle  $\theta$ , and is equal to the pressure at the centroid,  $\gamma h_c + p_0$ , times the area. If we use gauge pressure, the term  $p_0 A$  in Equation (3.1.10) can be dropped.

Since  $p$  is not evenly distributed over  $A$ , but varies with depth,  $\mathbf{F}$  does not act through the centroid. The point action of  $\mathbf{F}$ , called the *center of pressure*, can be determined by considering moments in [Figure 3.1.2](#). The moment of the hydrostatic force acting on the elementary area  $dA$  about the axis perpendicular to the page passing through the point  $O$  on the free surface is

$$y \, dF = y(\gamma y \sin \theta \, dA) = \gamma y^2 \sin \theta \, dA \quad (3.1.11)$$

so if  $y_{cp}$  denotes the distance to the center of pressure,

$$y_{cp} F = \gamma \sin \theta \iint y^2 \, dA = \gamma \sin \theta I_x \quad (3.1.12)$$

where  $I_x$  is the moment of inertia of the plane area with respect to the axis formed by the intersection of the plane containing the planar surface and the free surface (say  $Ox$ ). Dividing by  $F = \gamma h_c A = \gamma y_c \sin \theta A$  gives

FIGURE 3.1.2 Hydrostatic force on a plane surface.

$$y_{cp} = \frac{I_x}{y_c A} \tag{3.1.13}$$

By using the parallel axis theorem  $I_x = I_{xc} + Ay_c^2$ , where  $I_{xc}$  is the moment of inertia with respect to an axis parallel to  $0x$  passing through the centroid, Equation (3.1.13) becomes

$$y_{cp} = y_c + \frac{I_{xc}}{y_c A} \tag{3.1.14}$$

which shows that, in general, the center of pressure lies below the centroid.

Similarly, we find  $x_{cp}$  by taking moments about the  $y$  axis, specifically

$$x_{cp} F = \gamma \sin \theta \iint xy \, dA = \gamma \sin \theta I_{xy} \tag{3.1.15}$$

or

$$x_{cp} = \frac{I_{xy}}{y_c A} \tag{3.1.16}$$

where  $I_{xy}$  is the product of inertia with respect to the  $x$  and  $y$  axes. Again, the parallel axis theorem  $I_{xy} = I_{xyc} + Ax_c y_c$ , where the subscript  $c$  denotes the value at the centroid, allows Equation (3.1.16) to be written

$$x_{cp} = x_c + \frac{I_{xyc}}{y_c A} \tag{3.1.17}$$

This completes the determination of the center of pressure  $(x_{cp}, y_{cp})$ . Note that if the submerged area is symmetrical with respect to an axis passing through the centroid and parallel to either the  $x$  or  $y$  axes that  $I_{xyc} = 0$  and  $x_{cp} = x_c$ ; also that as  $y_c$  increases,  $y_{cp} \rightarrow y_c$ .

Centroidal moments of inertia and centroidal coordinates for some common areas are shown in [Figure 3.1.3](#).

**FIGURE 3.1.3** Centroidal moments of inertia and coordinates for some common areas.

**Forces on Curved Surfaces**

On a curved surface the forces on individual elements of area differ in direction so a simple summation of them is not generally possible, and the most convenient approach to calculating the pressure force on the surface is by separating it into its horizontal and vertical components.

A free-body diagram of the forces acting on the volume of fluid lying above a curved surface together with the conditions of static equilibrium of such a column leads to the results that:

1. The horizontal components of force on a curved submerged surface are equal to the forces exerted on the planar areas formed by the projections of the curved surface onto vertical planes normal to these components, the lines of action of these forces calculated as described earlier for planar surfaces; and
2. The vertical component of force on a curved submerged surface is equal in magnitude to the weight of the entire column of fluid lying above the curved surface, and acts through the center of mass of this volume of fluid.

Since the three components of force, two horizontal and one vertical, calculated as above, need not meet at a single point, there is, in general, no single resultant force. They can, however, be combined into a single force at any arbitrary point of application together with a moment about that point.

**Hydrostatic Forces in Layered Fluids**

All of the above results which employ the linear hydrostatic variation of pressure are valid only for homogeneous fluids. If the fluid is heterogeneous, consisting of individual layers each of constant density, then the pressure varies linearly with a different slope in each layer and the preceding analyses must be remedied by computing and summing the separate contributions to the forces and moments.

## Buoyancy

The same principles used above to compute hydrostatic forces can be used to calculate the net pressure force acting on completely submerged or floating bodies. These laws of buoyancy, the principles of Archimedes, are that:

1. A completely submerged body experiences a vertical upward force equal to the weight of the displaced fluid; and
2. A floating or partially submerged body displaces its own weight in the fluid in which it floats (i.e., the vertical upward force is equal to the body weight).

The line of action of the buoyancy force in both (1) and (2) passes through the centroid of the displaced volume of fluid; this point is called the *center of buoyancy*. (This point need not correspond to the center of mass of the body, which could have nonuniform density. In the above it has been assumed that the displaced fluid has a constant  $\gamma$ . If this is not the case, such as in a layered fluid, the magnitude of the buoyant force is still equal to the weight of the displaced fluid, but the line of action of this force passes through the center of gravity of the displaced volume, not the centroid.)

If a body has a weight exactly equal to that of the volume of fluid it displaces, it is said to be *neutrally buoyant* and will remain at rest at any point where it is immersed in a (homogeneous) fluid.

## Stability of Submerged and Floating Bodies

### Submerged Body

A body is said to be in stable equilibrium if, when given a slight displacement from the equilibrium position, the forces thereby created tend to restore it back to its original position. The forces acting on a submerged body are the buoyancy force,  $F_B$ , acting through the center of buoyancy, denoted by CB, and the weight of the body,  $W$ , acting through the center of gravity denoted by CG (see Figure 3.1.4). We see from Figure 3.1.4 that if the CB lies above the CG a rotation from the equilibrium position creates a restoring couple which will rotate the body back to its original position — thus, this is a *stable* equilibrium situation. The reader will readily verify that when the CB lies below the CG, the couple that results from a rotation from the vertical increases the displacement from the equilibrium position — thus, this is an *unstable* equilibrium situation.

FIGURE 3.1.4 Stability for a submerged body.

### Partially Submerged Body

The stability problem is more complicated for floating bodies because as the body rotates the location of the center of buoyancy may change. To determine stability in these problems requires that we determine the location of the *metacenter*. This is done for a symmetric body by tilting the body through a small angle  $\Delta\theta$  from its equilibrium position and calculating the new location of the center of buoyancy  $CB'$ ; the point of intersection of a vertical line drawn upward from  $CB'$  with the line of symmetry of the floating body is the metacenter, denoted by  $M$  in Figure 3.1.5, and it is independent of  $\Delta\theta$  for small angles. If  $M$  lies above the CG of the body, we see from Figure 3.1.5 that rotation of the body leads to

**FIGURE 3.1.5** Stability for a partially submerged body.

a restoring couple, whereas  $M$  lying below the  $CG$  leads to a couple which will increase the displacement. Thus, the stability of the equilibrium depends on whether  $M$  lies above or below the  $CG$ . The directed distance from  $CG$  to  $M$  is called the *metacentric height*, so equivalently the equilibrium is stable if this vector is positive and unstable if it is negative; stability increases as the metacentric height increases. For geometrically complex bodies, such as ships, the computation of the metacenter can be quite complicated.

### Pressure Variation in Rigid-Body Motion of a Fluid

In rigid-body motion of a fluid all the particles translate and rotate as a whole, there is no relative motion between particles, and hence no viscous stresses since these are proportional to velocity gradients. The equation of motion is then a balance among pressure, gravity, and the fluid acceleration, specifically.

$$\nabla p = \rho(\mathbf{g} - \mathbf{a}) \tag{3.1.18}$$

where  $\mathbf{a}$  is the uniform acceleration of the body. Equation (3.1.18) shows that the lines of constant pressure, including a free surface if any, are perpendicular to the direction  $\mathbf{g} - \mathbf{a}$ . Two important applications of this are to a fluid in uniform linear translation and rigid-body rotation. While such problems are not, strictly speaking, fluid statics problems, their analysis and the resulting pressure variation results are similar to those for static fluids.

#### Uniform Linear Acceleration

For a fluid partially filling a large container moving to the right with constant acceleration  $\mathbf{a} = (a_x, a_y)$  the geometry of Figure 3.1.6 shows that the magnitude of the pressure gradient in the direction  $\mathbf{n}$  normal to the accelerating free surface, in the direction  $\mathbf{g} - \mathbf{a}$ , is

$$\frac{dp}{dn} = \rho \left[ a_x^2 + (g + a_y)^2 \right]^{1/2} \tag{3.1.19}$$

and the free surface is oriented at an angle to the horizontal

$$\theta = \tan^{-1} \left( \frac{a_x}{g + a_y} \right) \tag{3.1.20}$$

FIGURE 3.1.6 A fluid with a free surface in uniform linear acceleration.

**Rigid-Body Rotation**

Consider the fluid-filled circular cylinder rotating uniformly with angular velocity  $\Omega = \Omega e_r$  (Figure 3.1.7). The only acceleration is the centripetal acceleration  $\Omega \times \Omega \times r = -r\Omega^2 e_r$ , so Equation 3.1.18 becomes

FIGURE 3.1.7 A fluid with a free surface in rigid-body rotation.

$$\nabla p = \frac{\partial p}{\partial r} \mathbf{e}_r + \frac{\partial p}{\partial z} \mathbf{e}_z = \rho(\mathbf{g} - \mathbf{a}) = \rho(r\Omega^2 \mathbf{e}_r - g\mathbf{e}_z) \quad (3.1.21)$$

or

$$\frac{\partial p}{\partial r} = \rho r \Omega^2, \quad \frac{\partial p}{\partial z} = -\rho g = -\gamma \quad (3.1.22)$$

Integration of these equations leads to

$$p = p_o - \gamma z + \frac{1}{2} \rho r^2 \Omega^2 \quad (3.1.23)$$

where  $p_o$  is some reference pressure. This result shows that at any fixed  $r$  the pressure varies hydrostatically in the vertical direction, while the constant pressure surfaces, including the free surface, are paraboloids of revolution.

### Further Information

The reader may find more detail and additional information on the topics in this section in any one of the many excellent introductory texts on fluid mechanics, such as

White, F.M. 1994. *Fluid Mechanics*, 3rd ed., McGraw-Hill, New York.

Munson, B.R., Young, D.F., and Okiishi, T.H. 1994. *Fundamentals of Fluid Mechanics*, 2nd ed., John Wiley & Sons, New York.

## 3.2 Equations of Motion and Potential Flow

Stanley A. Berger

### Integral Relations for a Control Volume

Like most physical conservation laws those governing motion of a fluid apply to material particles or systems of such particles. This so-called Lagrangian viewpoint is generally not as useful in practical fluid flows as an analysis through fixed (or deformable) control volumes — the Eulerian viewpoint. The relationship between these two viewpoints can be deduced from the Reynolds transport theorem, from which we also most readily derive the governing integral and differential equations of motion.

### Reynolds Transport Theorem

The *extensive* quantity  $B$ , a scalar, vector, or tensor, is defined as any property of the fluid (e.g., momentum, energy) and  $b$  as the corresponding value per unit mass (the *intensive* value). The Reynolds transport theorem for a moving and arbitrarily deforming control volume CV, with boundary CS (see Figure 3.2.1), states that

$$\frac{d}{dt}(B_{\text{system}}) = \frac{d}{dt} \left( \iiint_{\text{CV}} \rho b \, dv \right) + \iint_{\text{CS}} \rho b (\mathbf{V}_r \cdot \mathbf{n}) \, dA \quad (3.2.1)$$

where  $B_{\text{system}}$  is the total quantity of  $B$  in the system (any mass of fixed identity),  $\mathbf{n}$  is the outward normal to the CS,  $\mathbf{V}_r = \mathbf{V}(\mathbf{r}, t) - \mathbf{V}_{\text{CS}}(\mathbf{r}, t)$ , the velocity of the fluid particle,  $\mathbf{V}(\mathbf{r}, t)$ , relative to that of the CS,  $\mathbf{V}_{\text{CS}}(\mathbf{r}, t)$ , and  $d/dt$  on the left-hand side is the derivative following the fluid particles, i.e., the fluid mass comprising the system. The theorem states that the time rate of change of the total  $B$  in the system is equal to the rate of change within the CV plus the net flux of  $B$  through the CS. To distinguish between the  $d/dt$  which appears on the two sides of Equation (3.2.1) but which have different interpretations, the derivative on the left-hand side, following the system, is denoted by  $D/Dt$  and is called the material derivative. This notation is used in what follows. For any function  $f(x, y, z, t)$ ,

$$\frac{Df}{Dt} = \frac{\partial f}{\partial t} + \mathbf{V} \cdot \nabla f$$

For a CV fixed with respect to the reference frame, Equation (3.2.1) reduces to

$$\frac{D}{Dt}(B_{\text{system}}) = \frac{d}{dt} \iiint_{\text{CV}} (\rho b) \, dv + \iint_{\text{CS}} \rho b (\mathbf{V} \cdot \mathbf{n}) \, dA \quad (3.2.2)$$

(fixed)

(The time derivative operator in the first term on the right-hand side may be moved inside the integral, in which case it is then to be interpreted as the partial derivative  $\partial/\partial t$ .)

### Conservation of Mass

If we apply Equation (3.2.2) for a fixed control volume, with  $B_{\text{system}}$  the total mass in the system, then since conservation of mass requires that  $DB_{\text{system}}/Dt = 0$  there follows, since  $b = B_{\text{system}}/m = 1$ ,

FIGURE 3.2.1 Control volume.

$$\iiint_{\substack{CV \\ (\text{fixed})}} \frac{\partial \rho}{\partial t} dv + \iint_{CS} \rho (\mathbf{V} \cdot \mathbf{n}) dA = 0 \quad (3.2.3)$$

This is the integral form of the conservation of mass law for a fixed control volume. For a steady flow, Equation (3.2.3) reduces to

$$\iint_{CS} \rho (\mathbf{V} \cdot \mathbf{n}) dA = 0 \quad (3.2.4)$$

whether compressible or incompressible. For an incompressible flow,  $\rho = \text{constant}$ , so

$$\iint_{CS} (\mathbf{V} \cdot \mathbf{n}) dA = 0 \quad (3.2.5)$$

whether the flow is steady or unsteady.

### Conservation of Momentum

The conservation of (linear) momentum states that

$$\mathbf{F}_{\text{total}} \equiv \sum (\text{external forces acting on the fluid system}) = \frac{D\mathbf{M}}{Dt} \equiv \frac{D}{Dt} \left( \iiint_{\text{system}} \rho \mathbf{V} dv \right) \quad (3.2.6)$$

where  $\mathbf{M}$  is the total system momentum. For an arbitrarily moving, deformable control volume it then follows from Equation (3.2.1) with  $b$  set to  $\mathbf{V}$ ,

$$\mathbf{F}_{\text{total}} = \frac{d}{dt} \left( \iiint_{CV} \rho \mathbf{V} dv \right) + \iint_{CS} \rho \mathbf{V} (\mathbf{V}_r \cdot \mathbf{n}) dA \quad (3.2.7)$$

This expression is only valid in an inertial coordinate frame. To write the equivalent expression for a noninertial frame we must use the relationship between the acceleration  $\mathbf{a}_i$  in an inertial frame and the acceleration  $\mathbf{a}_r$  in a noninertial frame,

$$\mathbf{a}_I = \mathbf{a}_R + \frac{d^2\mathbf{R}}{dt^2} + 2\boldsymbol{\Omega} \times \mathbf{V} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{r}) + \frac{d\boldsymbol{\Omega}}{dt} \times \mathbf{r} \quad (3.2.8)$$

where  $\mathbf{R}$  is the position vector of the origin of the noninertial frame with respect to that of the inertial frame,  $\boldsymbol{\Omega}$  is the angular velocity of the noninertial frame, and  $\mathbf{r}$  and  $\mathbf{V}$  the position and velocity vectors in the noninertial frame. The third term on the right-hand side of Equation (3.2.8) is the Coriolis acceleration, and the fourth term is the centrifugal acceleration. For a noninertial frame Equation (3.2.7) is then

$$\begin{aligned} \mathbf{F}_{\text{total}} - \iiint_{\text{system}} \left[ \frac{d^2\mathbf{R}}{dt^2} + 2\boldsymbol{\Omega} \times \mathbf{V} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{r}) + \frac{d\boldsymbol{\Omega}}{dt} \times \mathbf{r} \right] \rho \, dv &= \frac{D}{Dt} \left( \iiint_{\text{system}} \rho \mathbf{V} \, dv \right) \\ &= \frac{d}{dt} \left( \iiint_{\text{CV}} \rho \mathbf{V} \, dv \right) + \iint_{\text{CS}} \rho \mathbf{V} \cdot (\mathbf{V}_r \cdot \mathbf{n}) \, dA \end{aligned} \quad (3.2.9)$$

where the frame acceleration terms of Equation (3.2.8) have been brought to the left-hand side because to an observer in the noninertial frame they act as “apparent” body forces.

For a fixed control volume in an inertial frame for steady flow it follows from the above that

$$\mathbf{F}_{\text{total}} = \iint_{\text{CS}} \rho \mathbf{V} (\mathbf{V} \cdot \mathbf{n}) \, dA \quad (3.2.10)$$

This expression is the basis of many control volume analyses for fluid flow problems.

The cross product of  $\mathbf{r}$ , the position vector with respect to a convenient origin, with the momentum Equation (3.2.6) written for an elementary particle of mass  $dm$ , noting that  $(d\mathbf{r}/dt) \times \mathbf{V} = 0$ , leads to the integral moment of momentum equation

$$\sum \mathbf{M} - \mathbf{M}_I = \frac{D}{Dt} \iiint_{\text{system}} \rho (\mathbf{r} \times \mathbf{V}) \, dv \quad (3.2.11)$$

where  $\sum \mathbf{M}$  is the sum of the moments of all the external forces acting on the system about the origin of  $\mathbf{r}$ , and  $\mathbf{M}_I$  is the moment of the apparent body forces (see Equation (3.2.9)). The right-hand side can be written for a control volume using the appropriate form of the Reynolds transport theorem.

### Conservation of Energy

The conservation of energy law follows from the first law of thermodynamics for a moving system

$$\mathcal{Q} - \mathcal{W} = \frac{D}{Dt} \left( \iiint_{\text{system}} \rho e \, dv \right) \quad (3.2.12)$$

where  $\mathcal{Q}$  is the rate at which heat is added to the system,  $\mathcal{W}$  the rate at which the system works on its surroundings, and  $e$  is the total energy per unit mass. For a particle of mass  $dm$  the contributions to the specific energy  $e$  are the internal energy  $u$ , the kinetic energy  $V^2/2$ , and the potential energy, which in the case of gravity, the only body force we shall consider, is  $gz$ , where  $z$  is the vertical displacement opposite to the direction of gravity. (We assume no energy transfer owing to chemical reaction as well

as no magnetic or electric fields.) For a fixed control volume it then follows from Equation (3.2.2) [with  $b = e = u + (V^2/2) + gz$ ] that

$$\dot{Q} - \dot{W} = \frac{d}{dt} \left( \iiint_{CV} \rho \left( u + \frac{1}{2} V^2 + gz \right) dv \right) + \iint_{CS} \rho \left( u + \frac{1}{2} V^2 + gz \right) (\mathbf{V} \cdot \mathbf{n}) dA \quad (3.2.13)$$

**Problem**

An incompressible fluid flows through a pump at a volumetric flow rate  $\dot{Q}$ . The (head) loss between sections 1 and 2 (see Figure 3.2.2 ) is equal to  $\beta \rho V_1^2 / 2$  ( $V$  is the average velocity at the section). Calculate the power that must be delivered by the pump to the fluid to produce a given increase in pressure,  $\Delta p = p_2 - p_1$ .

**FIGURE 3.2.2** Pump producing pressure increase.

*Solution:* The principal equation needed is the energy Equation (3.2.13). The term  $\dot{W}$ , the rate at which the system does work on its surroundings, for such problems has the form

$$\dot{W} = -\dot{W}_{shaft} + \iint_{CS} p \mathbf{V} \cdot \mathbf{n} dA \quad (P.3.2.1)$$

where  $\dot{W}_{shaft}$  represents the work done on the fluid by a moving shaft, such as by turbines, propellers, fans, etc., and the second term on the right side represents the rate of working by the normal stress, the pressure, at the boundary. For a steady flow in a control volume coincident with the physical system boundaries and bounded at its ends by sections 1 and 2, Equation (3.2.13) reduces to ( $u = 0$ ),

$$\dot{Q} + \dot{W}_{shaft} - \iint_{CS} p \mathbf{V} \cdot \mathbf{n} dA = \iint_{CS} \left( \frac{1}{2} \rho V^2 + \gamma z \right) (\mathbf{V} \cdot \mathbf{n}) dA \quad (P.3.2.2)$$

Using average quantities at sections 1 and 2, and the continuity Equation (3.2.5), which reduces in this case to

$$V_1 A_1 = V_2 A_2 = \dot{Q} \quad (P.3.2.3)$$

We can write Equation (P.3.2.2) as

$$\dot{Q} + \dot{W}_{shaft} - (p_2 - p_1) \dot{Q} = \left[ \frac{1}{2} \rho (V_2^2 - V_1^2) + \gamma (z_2 - z_1) \right] \dot{Q} \quad (P.3.2.4)$$

$\mathcal{Q}$ , the rate at which heat is added to the system, is here equal to  $-\beta\rho V_1^2/2$ , the head loss between sections 1 and 2. Equation (P.3.2.4) then can be rewritten

$$\mathcal{W}_{\text{shaft}} = \beta\rho \frac{V_1^2}{2} + (\Delta p)\mathcal{Q}' + \frac{1}{2}\rho(V_2^2 - V_1^2)\mathcal{Q}' + \gamma(z_2 - z_1)\mathcal{Q}'$$

or, in terms of the given quantities,

$$\mathcal{W}_{\text{shaft}} = \frac{\beta\rho\mathcal{Q}'^2}{A_1^2} + (\Delta p)\mathcal{Q}' + \frac{1}{2}\rho\frac{\mathcal{Q}'^3}{A_2^2}\left(1 - \frac{A_2^2}{A_1^2}\right) + \gamma(z_2 - z_1)\mathcal{Q}' \tag{P.3.2.5}$$

Thus, for example, if the fluid is water ( $\rho \approx 1000 \text{ kg/m}^3$ ,  $\gamma = 9.8 \text{ kN/m}^3$ ),  $\mathcal{Q}' = 0.5 \text{ m}^3/\text{sec}$ , the heat loss is  $0.2\rho V_1^2/2$ , and  $\Delta p = p_2 - p_1 = 2 \times 10^5 \text{ N/m}^2 = 200 \text{ kPa}$ ,  $A_1 = 0.1 \text{ m}^2 = A_2/2$ ,  $(z_2 - z_1) = 2 \text{ m}$ , we find, using Equation (P.3.2.5)

$$\begin{aligned} \mathcal{W}_{\text{shaft}} &= \frac{0.2(1000)(0.5)^2}{(0.1)^2} + (2 \times 10^5)(0.5) + \frac{1}{2}(1000)\frac{(0.5)^3}{(0.2)^2}(1 - 4) + (9.8 \times 10^3)(2)(0.5) \\ &= 5,000 + 10,000 - 4,688 + 9,800 = 20,112 \text{ Nm/sec} \\ &= 20,112 \text{ W} = \frac{20,112}{745.7} \text{ hp} = 27 \text{ hp} \end{aligned}$$

### Differential Relations for Fluid Motion

In the previous section the conservation laws were derived in integral form. These forms are useful in calculating, generally using a control volume analysis, gross features of a flow. Such analyses usually require some *a priori* knowledge or assumptions about the flow. In any case, an approach based on integral conservation laws cannot be used to determine the point-by-point variation of the dependent variables, such as velocity, pressure, temperature, etc. To do this requires the use of the differential forms of the conservation laws, which are presented below.

### Mass Conservation–Continuity Equation

Applying Gauss’s theorem (the divergence theorem) to Equation (3.2.3) we obtain

$$\iiint_{\text{CV (fixed)}} \left[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{V}) \right] dv = 0 \tag{3.2.14}$$

which, because the control volume is arbitrary, immediately yields

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{V}) = 0 \tag{3.2.15}$$

This can also be written as

$$\frac{D\rho}{Dt} + \rho \nabla \cdot \mathbf{V} = 0 \tag{3.2.16}$$

using the fact that

$$\frac{D\rho}{Dt} = \frac{\partial\rho}{\partial t} + \mathbf{V} \cdot \nabla\rho \quad (3.2.17)$$

Special cases:

1. Steady flow  $[(\partial/\partial t) (\ ) = 0]$

$$\nabla \cdot (\rho\mathbf{V}) = 0 \quad (3.2.18)$$

2. Incompressible flow  $(D\rho/Dt = 0)$

$$\nabla \cdot \mathbf{V} = 0 \quad (3.2.19)$$

## Momentum Conservation

We note first, as a consequence of mass conservation for a system, that the right-hand side of Equation (3.2.6) can be written as

$$\frac{D}{Dt} \left( \iiint_{\text{system}} \rho\mathbf{V} \, dv \right) = \iiint_{\text{system}} \rho \frac{D\mathbf{V}}{Dt} \, dv \quad (3.2.20)$$

The total force acting on the system which appears on the left-hand side of Equation (3.2.6) is the sum of body forces  $\mathbf{F}_b$  and surface forces  $\mathbf{F}_s$ . The body forces are often given as forces per unit mass (e.g., gravity), and so can be written

$$\mathbf{F}_b = \iiint_{\text{system}} \rho \mathbf{f} \, dv \quad (3.2.21)$$

The surface forces are represented in terms of the second-order stress tensor\*  $\underline{\underline{\sigma}} = \{\sigma_{ij}\}$ , where  $\sigma_{ij}$  is defined as the force per unit area in the  $i$  direction on a planar element whose normal lies in the  $j$  direction. From elementary angular momentum considerations for an infinitesimal volume it can be shown that  $\sigma_{ij}$  is a symmetric tensor, and therefore has only six independent components. The total surface force exerted on the system by its surroundings is then

$$\mathbf{F}_s = \iint_{\text{system surface}} \underline{\underline{\sigma}} \cdot \mathbf{n} \, dA, \quad \text{with } i\text{-component } F_{s_i} = \iint \sigma_{ij} n_j \, dA \quad (3.2.22)$$

The integral momentum conservation law Equation (3.2.6) can then be written

$$\iiint_{\text{system}} \rho \frac{D\mathbf{V}}{Dt} \, dv = \iiint_{\text{system}} \rho \mathbf{f} \, dv + \iint_{\text{system surface}} \underline{\underline{\sigma}} \cdot \mathbf{n} \, dA \quad (3.2.23)$$

---

\* We shall assume the reader is familiar with elementary Cartesian tensor analysis and the associated subscript notation and conventions. The reader for whom this is not true should skip the details and concentrate on the final principal results and equations given at the ends of the next few subsections.

The application of the divergence theorem to the last term on the right-side of Equation (3.2.23) leads to

$$\iiint_{\text{system}} \rho \frac{DV}{Dt} dv = \iiint_{\text{system}} \rho f dv + \iiint_{\text{system}} \nabla \cdot \underline{\underline{\sigma}} dv \quad (3.2.24)$$

where  $\nabla \cdot \underline{\underline{\sigma}} \equiv \{\partial \sigma_{ij} / \partial x_j\}$ . Since Equation (3.2.24) holds for any material volume, it follows that

$$\rho \frac{DV}{Dt} = \rho f + \nabla \cdot \underline{\underline{\sigma}} \quad (3.2.25)$$

(With the decomposition of  $F_{\text{total}}$  above, Equation (3.2.10) can be written

$$\iiint_{\text{CV}} \rho f dv + \iint_{\text{CS}} \underline{\underline{\sigma}} \cdot \mathbf{n} dA = \iint_{\text{CS}} \rho \mathbf{V} (\mathbf{V} \cdot \mathbf{n}) dA \quad (3.2.26)$$

If  $\rho$  is uniform and  $f$  is a conservative body force, i.e.,  $f = -\nabla \Psi$ , where  $\Psi$  is the force potential, then Equation (3.2.26), after application of the divergence theorem to the body force term, can be written

$$\iint_{\text{CS}} (-\rho \Psi \mathbf{n} + \underline{\underline{\sigma}} \cdot \mathbf{n}) dA = \iint_{\text{CS}} \rho \mathbf{V} (\mathbf{V} \cdot \mathbf{n}) dA \quad (3.2.27)$$

It is in this form, involving only integrals over the surface of the control volume, that the integral form of the momentum equation is used in control volume analyses, particularly in the case when the body force term is absent.)

### Analysis of Rate of Deformation

The principal aim of the following two subsections is to derive a relationship between the stress and the rate of strain to be used in the momentum Equation (3.2.25). The reader less familiar with tensor notation may skip these sections, apart from noting some of the terms and quantities defined therein, and proceed directly to Equations (3.2.38) or (3.2.39).

The relative motion of two neighboring points  $P$  and  $Q$ , separated by a distance  $\eta$ , can be written (using  $\mathbf{u}$  for the local velocity)

$$\mathbf{u}(Q) = \mathbf{u}(P) + (\nabla \mathbf{u}) \eta$$

or, equivalently, writing  $\nabla \mathbf{u}$  as the sum of antisymmetric and symmetric tensors,

$$\mathbf{u}(Q) = \mathbf{u}(P) + \frac{1}{2} \left( (\nabla \mathbf{u}) - (\nabla \mathbf{u})^* \right) \eta + \frac{1}{2} \left( (\nabla \mathbf{u}) + (\nabla \mathbf{u})^* \right) \eta \quad (3.2.28)$$

where  $\nabla \mathbf{u} = \{\partial u_i / \partial x_j\}$ , and the superscript  $*$  denotes transpose, so  $(\nabla \mathbf{u})^* = \{\partial u_j / \partial x_i\}$ . The second term on the right-hand side of Equation (3.2.28) can be rewritten in terms of the *vorticity*,  $\nabla \times \mathbf{u}$ , so Equation (3.2.28) becomes

$$\mathbf{u}(Q) = \mathbf{u}(P) + \frac{1}{2} (\nabla \times \mathbf{u}) \times \eta + \frac{1}{2} \left( (\nabla \mathbf{u}) + (\nabla \mathbf{u})^* \right) \eta \quad (3.2.29)$$

which shows that the local rate of deformation consists of a rigid-body translation, a rigid-body rotation with angular velocity  $1/2 (\nabla \times \mathbf{u})$ , and a velocity or rate of deformation. The coefficient of  $\underline{e}$  in the last term in Equation (3.2.29) is defined as the rate-of-strain tensor and is denoted by  $\underline{e}$ , in subscript form

$$e_{ij} = \frac{1}{2} \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \quad (3.2.30)$$

From  $\underline{e}$  we can define a rate-of-strain central quadric, along the principal axes of which the deforming motion consists of a pure extension or compression.

## Relationship Between Forces and Rate of Deformation

We are now in a position to determine the required relationship between the stress tensor  $\underline{\sigma}$  and the rate of deformation. Assuming that in a static fluid the stress reduces to a (negative) hydrostatic or thermodynamic pressure, equal in all directions, we can write

$$\underline{\sigma} = -p\underline{I} + \underline{\tau} \quad \text{or} \quad \underline{\sigma}_{ij} = -p\delta_{ij} + \tau_{ij} \quad (3.2.31)$$

where  $\underline{\tau}$  is the viscous part of the total stress and is called the deviatoric stress tensor,  $\underline{I}$  is the identity tensor, and  $\delta_{ij}$  is the corresponding Kronecker delta ( $\delta_{ij} = 0$  if  $i \neq j$ ;  $\delta_{ij} = 1$  if  $i = j$ ). We make further assumptions that (1) the fluid exhibits no preferred directions; (2) the stress is independent of any previous history of distortion; and (3) that the stress depends only on the local thermodynamic state and the kinematic state of the immediate neighborhood. Precisely, we assume that  $\underline{\tau}$  is linearly proportional to the first spatial derivatives of  $\mathbf{u}$ , the coefficient of proportionality depending only on the local thermodynamic state. These assumptions and the relations below which follow from them are appropriate for a Newtonian fluid. Most common fluids, such as air and water under most conditions, are Newtonian, but there are many other fluids, including many which arise in industrial applications, which exhibit so-called non-Newtonian properties. The study of such non-Newtonian fluids, such as viscoelastic fluids, is the subject of the field of rheology.

With the Newtonian fluid assumptions above, and the symmetry of  $\underline{\tau}$  which follows from the symmetry of  $\underline{\sigma}$ , one can show that the viscous part  $\underline{\tau}$  of the total stress can be written as

$$\underline{\tau} = \lambda(\nabla \cdot \mathbf{u})\underline{I} + 2\mu\underline{e} \quad (3.2.32)$$

so the total stress for a Newtonian fluid is

$$\underline{\sigma} = -p\underline{I} + \lambda(\nabla \cdot \mathbf{u})\underline{I} + 2\mu\underline{e} \quad (3.2.33)$$

or, in subscript notation

$$\sigma_{ij} = -p\delta_{ij} + \lambda \left( \frac{\partial u_k}{\partial x_k} \right) \delta_{ij} + \mu \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \quad (3.2.34)$$

(the Einstein summation convention is assumed here, namely, that a repeated subscript, such as in the second term on the right-hand side above, is summed over; note also that  $\nabla \cdot \mathbf{u} = \partial u_k / \partial x_k = e_{kk}$ .) The coefficient  $\lambda$  is called the “second viscosity” and  $\mu$  the “absolute viscosity,” or more commonly the “dynamic viscosity,” or simply the “viscosity.” For a Newtonian fluid  $\lambda$  and  $\mu$  depend only on local thermodynamic state, primarily on the temperature.

We note, from Equation (3.2.34), that whereas in a fluid at rest the pressure is an isotropic normal stress, this is not the case for a moving fluid, since in general  $\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$ . To have an analogous quantity to  $p$  for a moving fluid we define the pressure in a moving fluid as the negative mean normal stress, denoted, say, by  $\bar{p}$

$$\bar{p} = -\frac{1}{3}\sigma_{ii} \tag{3.2.35}$$

( $\sigma_{ii}$  is the trace of  $\underline{\underline{\sigma}}$  and an invariant of  $\underline{\underline{\sigma}}$ , independent of the orientation of the axes). From Equation (3.2.34)

$$\bar{p} = -\frac{1}{3}\sigma_{ii} = p - \left(\lambda + \frac{2}{3}\mu\right)\nabla \cdot \mathbf{u} \tag{3.2.36}$$

For an incompressible fluid  $\nabla \cdot \mathbf{u} = 0$  and hence  $\bar{p} \equiv p$ . The quantity  $(\lambda + \frac{2}{3}\mu)$  is called the bulk viscosity. If one assumes that the deviatoric stress tensor  $\tau_{ij}$  makes no contribution to the mean normal stress, it follows that  $\lambda + \frac{2}{3}\mu = 0$ , so again  $\bar{p} = p$ . This condition,  $\lambda = -\frac{2}{3}\mu$ , is called the Stokes assumption or hypothesis. If neither the incompressibility nor the Stokes assumptions are made, the difference between  $\bar{p}$  and  $p$  is usually still negligibly small because  $(\lambda + \frac{2}{3}\mu)\nabla \cdot \mathbf{u} \ll p$  in most fluid flow problems. If the Stokes hypothesis is made, as is often the case in fluid mechanics, Equation (3.2.34) becomes

$$\sigma_{ij} = -p\delta_{ij} + 2\mu\left(e_{ij} - \frac{1}{3}e_{kk}\delta_{ij}\right) \tag{3.2.37}$$

### The Navier–Stokes Equations

Substitution of Equation (3.2.33) into (3.2.25), since  $\nabla \cdot (\phi \underline{\underline{I}}) = \nabla\phi$ , for any scalar function  $\phi$ , yields (replacing  $\mathbf{u}$  in Equation (3.2.33) by  $\mathbf{V}$ )

$$\rho \frac{DV}{Dt} = \rho \mathbf{f} - \nabla p + \nabla(\lambda \nabla \cdot \mathbf{V}) + \nabla \cdot (2\mu \underline{\underline{e}}) \tag{3.2.38}$$

These equations are the Navier–Stokes equations (although the name is as often given to the full set of governing conservation equations). With the Stokes assumption ( $\lambda = -\frac{2}{3}\mu$ ), Equation (3.2.38) becomes

$$\rho \frac{DV}{Dt} = \rho \mathbf{f} - \nabla p + \nabla \cdot \left[ 2\mu \left( \underline{\underline{e}} - \frac{1}{3}e_{kk}\underline{\underline{I}} \right) \right] \tag{3.2.39}$$

If the Eulerian frame is not an inertial frame, then one must use the transformation to an inertial frame either using Equation (3.2.8) or the “apparent” body force formulation, Equation (3.2.9).

### Energy Conservation — The Mechanical and Thermal Energy Equations

In deriving the differential form of the energy equation we begin by assuming that heat enters or leaves the material or control volume by heat conduction across the boundaries, the heat flux per unit area being  $\mathbf{q}$ . It then follows that

$$\mathcal{Q} = -\iint \mathbf{q} \cdot \mathbf{n} \, dA = -\iiint \nabla \cdot \mathbf{q} \, dv \tag{3.2.40}$$

The work-rate term  $\dot{W}$  can be decomposed into the rate of work done against body forces, given by

$$- \iiint \rho \mathbf{f} \cdot \mathbf{V} \, dv \quad (3.2.41)$$

and the rate of work done against surface stresses, given by

$$- \iint_{\text{system surface}} \mathbf{V} \cdot (\underline{\underline{\sigma}} \mathbf{n}) \, dA \quad (3.2.42)$$

Substitution of these expressions for  $\dot{Q}$  and  $\dot{W}$  into Equation (3.2.12), use of the divergence theorem, and conservation of mass lead to

$$\rho \frac{D}{Dt} \left( u + \frac{1}{2} V^2 \right) = -\nabla \cdot \mathbf{q} + \rho \mathbf{f} \cdot \mathbf{V} + \nabla \cdot (\mathbf{V} \underline{\underline{\sigma}}) \quad (3.2.43)$$

(note that a potential energy term is no longer included in  $e$ , the total specific energy, as it is accounted for by the body force rate-of-working term  $\rho \mathbf{f} \cdot \mathbf{V}$ ).

Equation (3.2.43) is the total energy equation showing how the energy changes as a result of working by the body and surface forces and heat transfer. It is often useful to have a purely thermal energy equation. This is obtained by subtracting from Equation (3.2.43) the dot product of  $\mathbf{V}$  with the momentum Equation (3.2.25), after expanding the last term in Equation (3.2.43), resulting in

$$\rho \frac{Du}{Dt} = \frac{\partial V_i}{\partial x_j} \sigma_{ij} - \nabla \cdot \mathbf{q} \quad (3.2.44)$$

With  $\sigma_{ij} = -p\delta_{ij} + \tau_{ij}$ , and the use of the continuity equation in the form of Equation (3.2.16), the first term on the right-hand side of Equation (3.2.44) may be written

$$\frac{\partial V_i}{\partial x_j} \sigma_{ij} = -\rho \frac{D}{Dt} \left( \frac{p}{\rho} \right) + \frac{Dp}{Dt} + \Phi \quad (3.2.45)$$

where  $\Phi$  is the rate of dissipation of mechanical energy per unit mass due to viscosity, and is given by

$$\Phi \equiv \frac{\partial V_i}{\partial x_j} \tau_{ij} = 2\mu \left( e_{ij} e_{ij} - \frac{1}{3} e_{kk}^2 \right) = 2\mu \left( e_{ij} - \frac{1}{3} e_{kk} \delta_{ij} \right)^2 \quad (3.2.46)$$

With the introduction of Equation (3.2.45), Equation (3.2.44) becomes

$$\rho \frac{De}{Dt} = -p \nabla \cdot \mathbf{V} + \Phi - \nabla \cdot \mathbf{q} \quad (3.2.47)$$

or

$$\rho \frac{Dh}{Dt} = \frac{Dp}{Dt} + \Phi - \nabla \cdot \mathbf{q} \quad (3.2.48)$$

where  $h = e + (p/\rho)$  is the specific enthalpy. Unlike the other terms on the right-hand side of Equation (3.2.47), which can be negative or positive,  $\Phi$  is always nonnegative and represents the increase in internal energy (or enthalpy) owing to irreversible degradation of mechanical energy. Finally, from elementary thermodynamic considerations

$$\frac{Dh}{Dt} = T \frac{DS}{Dt} + \frac{1}{\rho} \frac{Dp}{Dt}$$

where  $S$  is the entropy, so Equation (3.2.48) can be written

$$\rho T \frac{DS}{Dt} = \Phi - \nabla \cdot \mathbf{q} \tag{3.2.49}$$

If the heat conduction is assumed to obey the Fourier heat conduction law, so  $\mathbf{q} = -k\nabla T$ , where  $k$  is the thermal conductivity, then in all of the above equations

$$-\nabla \cdot \mathbf{q} = \nabla \cdot (k\nabla T) = k\nabla^2 T \tag{3.2.50}$$

the last of these equalities holding only if  $k = \text{constant}$ .

In the event the thermodynamic quantities vary little, the coefficients of the constitutive relations for  $\underline{\sigma}$  and  $\mathbf{q}$  may be taken to be constant and the above equations simplified accordingly.

We note also that if the flow is incompressible, then the mass conservation, or continuity, equation simplifies to

$$\nabla \cdot \mathbf{V} = 0 \tag{3.2.51}$$

and the momentum Equation (3.2.38) to

$$\rho \frac{D\mathbf{V}}{Dt} = \rho \mathbf{f} - \nabla p + \mu \nabla^2 \mathbf{V} \tag{3.2.52}$$

where  $\nabla^2$  is the Laplacian operator. The small temperature changes, compatible with the incompressibility assumption, are then determined, for a perfect gas with constant  $k$  and specific heats, by the energy equation rewritten for the temperature, in the form

$$\rho c_v \frac{DT}{Dt} = k\nabla^2 T + \Phi \tag{3.2.53}$$

## Boundary Conditions

The appropriate boundary conditions to be applied at the boundary of a fluid in contact with another medium depends on the nature of this other medium — solid, liquid, or gas. We discuss a few of the more important cases here in turn:

1. *At a solid surface:*  $\mathbf{V}$  and  $T$  are continuous. Contained in this boundary condition is the “no-slip” condition, namely, that the tangential velocity of the fluid in contact with the boundary of the solid is equal to that of the boundary. For an inviscid fluid the no-slip condition does not apply, and only the normal component of velocity is continuous. If the wall is permeable, the tangential velocity is continuous and the normal velocity is arbitrary; the temperature boundary condition for this case depends on the nature of the injection or suction at the wall.

2. *At a liquid/gas interface:* For such cases the appropriate boundary conditions depend on what can be assumed about the gas the liquid is in contact with. In the classical liquid free-surface problem, the gas, generally atmospheric air, can be ignored and the necessary boundary conditions are that (a) the normal velocity in the liquid at the interface is equal to the normal velocity of the interface and (b) the pressure in the liquid at the interface exceeds the atmospheric pressure by an amount equal to

$$\Delta p = p_{\text{liquid}} - p_{\text{atm}} = \sigma \left( \frac{1}{R_1} + \frac{1}{R_2} \right) \quad (3.2.54)$$

where  $R_1$  and  $R_2$  are the radii of curvature of the intercepts of the interface by two orthogonal planes containing the vertical axis. If the gas is a vapor which undergoes nonnegligible interaction and exchanges with the liquid in contact with it, the boundary conditions are more complex. Then, in addition to the above conditions on normal velocity and pressure, the shear stress (momentum flux) and heat flux must be continuous as well.

For interfaces in general the boundary conditions are derived from continuity conditions for each “transportable” quantity, namely continuity of the appropriate intensity across the interface and continuity of the normal component of the flux vector. Fluid momentum and heat are two such transportable quantities, the associated intensities are velocity and temperature, and the associated flux vectors are stress and heat flux. (The reader should be aware of circumstances where these simple criteria do not apply, for example, the velocity slip and temperature jump for a rarefied gas in contact with a solid surface.)

### Vorticity in Incompressible Flow

With  $\mu = \text{constant}$ ,  $\rho = \text{constant}$ , and  $\mathbf{f} = -\mathbf{g} = -g\mathbf{k}$  the momentum equation reduces to the form (see Equation (3.2.52))

$$\rho \frac{D\mathbf{V}}{Dt} = -\nabla p - \rho g\mathbf{k} + \mu \nabla^2 \mathbf{V} \quad (3.2.55)$$

With the vector identities

$$(\mathbf{V} \cdot \nabla) \mathbf{V} = \nabla \left( \frac{V^2}{2} \right) - \mathbf{V} \times (\nabla \times \mathbf{V}) \quad (3.2.56)$$

and

$$\nabla^2 \mathbf{V} = \nabla(\nabla \cdot \mathbf{V}) - \nabla \times (\nabla \times \mathbf{V}) \quad (3.2.57)$$

and defining the *vorticity*

$$\boldsymbol{\xi} \equiv \nabla \times \mathbf{V} \quad (3.2.58)$$

Equation (3.2.55) can be written, noting that for incompressible flow  $\nabla \cdot \mathbf{V} = 0$ ,

$$\rho \frac{\partial \mathbf{V}}{\partial t} + \nabla \left( p + \frac{1}{2} \rho V^2 + \rho g z \right) = \rho \mathbf{V} \times \boldsymbol{\xi} - \mu \nabla \times \boldsymbol{\xi} \quad (3.2.59)$$

The flow is said to be *irrotational* if

$$\boldsymbol{\zeta} \equiv \nabla \times \mathbf{V} = 0 \tag{3.2.60}$$

from which it follows that a *velocity potential*  $\Phi$  can be defined

$$\mathbf{V} = \nabla\Phi \tag{3.2.61}$$

Setting  $\boldsymbol{\zeta} = 0$  in Equation (3.2.59), using Equation (3.2.61), and then integrating with respect to all the spatial variables, leads to

$$\rho \frac{\partial\Phi}{\partial t} + \left( p + \frac{1}{2}\rho V^2 + \rho gz \right) = F(t) \tag{3.2.62}$$

(the arbitrary function  $F(t)$  introduced by the integration can either be absorbed in  $\Phi$ , or is determined by the boundary conditions). Equation (3.2.62) is the unsteady *Bernoulli equation* for irrotational, incompressible flow. (Irrotational flows are always potential flows, even if the flow is compressible. Because the viscous term in Equation (3.2.59) vanishes identically for  $\boldsymbol{\zeta} = 0$ , it would appear that the above Bernoulli equation is valid even for viscous flow. Potential solutions of hydrodynamics are in fact exact solutions of the full Navier–Stokes equations. Such solutions, however, are not valid near solid boundaries or bodies because the no-slip condition generates vorticity and causes nonzero  $\boldsymbol{\zeta}$ ; the potential flow solution is invalid in all those parts of the flow field that have been “contaminated” by the spread of the vorticity by convection and diffusion. See below.)

The curl of Equation (3.2.59), noting that the curl of any gradient is zero, leads to

$$\rho \frac{\partial\boldsymbol{\zeta}}{\partial t} = \rho \nabla \times (\mathbf{V} \times \boldsymbol{\zeta}) - \mu \nabla \times \nabla \times \boldsymbol{\zeta} \tag{3.2.63}$$

but

$$\begin{aligned} \nabla^2\boldsymbol{\zeta} &= \nabla(\nabla \cdot \boldsymbol{\zeta}) - \nabla \times \nabla \times \boldsymbol{\zeta} \\ &= -\nabla \times \nabla \times \boldsymbol{\zeta} \end{aligned} \tag{3.2.64}$$

since  $\text{div curl}(\ ) \equiv 0$ , and therefore also

$$\nabla \times (\mathbf{V} \times \boldsymbol{\zeta}) \equiv \boldsymbol{\zeta}(\nabla\mathbf{V}) + \mathbf{V}\nabla \cdot \boldsymbol{\zeta} - \mathbf{V}\nabla\boldsymbol{\zeta} - \boldsymbol{\zeta}\nabla \cdot \mathbf{V} \tag{3.2.65}$$

$$= \boldsymbol{\zeta}(\nabla\mathbf{V}) - \mathbf{V}\nabla\boldsymbol{\zeta} \tag{3.2.66}$$

Equation (3.2.63) can then be written

$$\frac{D\boldsymbol{\zeta}}{Dt} = (\boldsymbol{\zeta} \cdot \nabla)\mathbf{V} + \nu \nabla^2\boldsymbol{\zeta} \tag{3.2.67}$$

where  $\nu = \mu/\rho$  is the kinematic viscosity. Equation (3.2.67) is the vorticity equation for incompressible flow. The first term on the right, an inviscid term, increases the vorticity by vortex stretching. In inviscid, two-dimensional flow both terms on the right-hand side of Equation (3.2.67) vanish, and the equation reduces to  $D\boldsymbol{\zeta}/Dt = 0$ , from which it follows that the vorticity of a fluid particle remains constant as it moves. This is Helmholtz’s theorem. As a consequence it also follows that if  $\boldsymbol{\zeta} = 0$  initially,  $\boldsymbol{\zeta} \equiv 0$  always;

i.e., initially irrotational flows remain irrotational (for inviscid flow). Similarly, it can be proved that  $D\Gamma/Dt = 0$ ; i.e., the circulation around a material closed circuit remains constant, which is Kelvin's theorem.

If  $\mathbf{v} \neq 0$ , Equation (3.2.67) shows that the vorticity generated, say, at solid boundaries, diffuses and stretches as it is convected.

We also note that for steady flow the Bernoulli equation reduces to

$$p + \frac{1}{2}\rho V^2 + \rho gz = \text{constant} \quad (3.2.68)$$

valid for steady, irrotational, incompressible flow.

## Stream Function

For two-dimensional flows the continuity equation, e.g., for plane, incompressible flows ( $\mathbf{V} = (u, v)$ )

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (3.2.69)$$

can be identically satisfied by introducing a stream function  $\psi$ , defined by

$$u = \frac{\partial \psi}{\partial y}, \quad v = -\frac{\partial \psi}{\partial x} \quad (3.2.70)$$

Physically  $\psi$  is a measure of the flow between streamlines. (Stream functions can be similarly defined to satisfy identically the continuity equations for incompressible cylindrical and spherical axisymmetric flows; and for these flows, as well as the above planar flow, also when they are compressible, but only then if they are steady.) Continuing with the planar case, we note that in such flows there is only a single nonzero component of vorticity, given by

$$\boldsymbol{\zeta} = (0, 0, \zeta_z) = \left(0, 0, \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) \quad (3.2.71)$$

With Equation (3.2.70)

$$\zeta_z = -\frac{\partial^2 \psi}{\partial x^2} - \frac{\partial^2 \psi}{\partial y^2} = -\nabla^2 \psi \quad (3.2.72)$$

For this two-dimensional flow Equation (3.2.67) reduces to

$$\frac{\partial \zeta_z}{\partial t} + u \frac{\partial \zeta_z}{\partial x} + v \frac{\partial \zeta_z}{\partial y} = \mathbf{v} \cdot \left( \frac{\partial^2 \zeta_z}{\partial x^2} + \frac{\partial^2 \zeta_z}{\partial y^2} \right) \quad (3.2.73)$$

Substitution of Equation (3.2.72) into Equation (3.2.73) yields an equation for the stream function

$$\frac{\partial(\nabla^2 \psi)}{\partial t} + \frac{\partial \psi}{\partial y} \frac{\partial(\nabla^2 \psi)}{\partial x} - \frac{\partial \psi}{\partial x} \frac{\partial(\nabla^2 \psi)}{\partial y} = \mathbf{v} \nabla^4 \psi \quad (3.2.74)$$

where  $\nabla^4 = \nabla^2 (\nabla^2)$ . For uniform flow past a solid body, for example, this equation for  $\Psi$  would be solved subject to the boundary conditions:

$$\begin{aligned} \frac{\partial \psi}{\partial x} = 0, \quad \frac{\partial \psi}{\partial y} = V_\infty \quad \text{at infinity} \\ \frac{\partial \psi}{\partial x} = 0, \quad \frac{\partial \psi}{\partial y} = 0 \quad \text{at the body (no-slip)} \end{aligned} \tag{3.2.75}$$

For the special case of irrotational flow it follows immediately from Equations (3.2.70) and (3.2.71) with  $\zeta_z = 0$ , that  $\psi$  satisfies the Laplace equation

$$\nabla^2 \psi = \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0 \tag{3.2.76}$$

### Inviscid Irrotational Flow: Potential Flow

For irrotational flows we have already noted that a velocity potential  $\Phi$  can be defined such that  $\mathbf{V} = \nabla\Phi$ . If the flow is also incompressible, so  $\nabla \cdot \mathbf{V} = 0$ , it then follows that

$$\nabla \cdot (\nabla\Phi) = \nabla^2\Phi = 0 \tag{3.2.77}$$

so  $\Phi$  satisfies Laplace’s equation. (Note that unlike the stream function  $\psi$ , which can only be defined for two-dimensional flows, the above considerations for  $\Phi$  apply to flow in two and three dimensions. On the other hand, the existence of  $\psi$  does not require the flow to be irrotational, whereas the existence of  $\Phi$  does.)

Since Equation (3.2.77) with appropriate conditions on  $\mathbf{V}$  at boundaries of the flow completely determines the velocity field, and the momentum equation has played no role in this determination, we see that inviscid irrotational flow — *potential theory* — is a purely kinematic theory. The momentum equation only enters after  $\Phi$  is known in order to calculate the pressure field consistent with the velocity field  $\mathbf{V} = \nabla\Phi$ .

For both two- and three-dimensional flows the determination of  $\Phi$  makes use of the powerful techniques of potential theory, well developed in the mathematical literature. For two-dimensional planar flows the techniques of complex variable theory are available, since  $\Phi$  may be considered as either the real or imaginary part of an analytic function (the same being true for  $\psi$ , since for such two-dimensional flows  $\Phi$  and  $\psi$  are conjugate variables.)

Because the Laplace equation, obeyed by both  $\Phi$  and  $\psi$ , is linear, complex flows may be built up from the superposition of simple flows; this property of inviscid irrotational flows underlies nearly all solution techniques in this area of fluid mechanics.

#### Problem

A two-dimensional inviscid irrotational flow has the velocity potential

$$\Phi = x^2 - y^2 \tag{P.3.2.6}$$

What two-dimensional potential flow does this represent?

*Solution.* It follows from Equations (3.2.61) and (3.2.70) that for two-dimensional flows, in general

$$u = \frac{\partial \Phi}{\partial x} = \frac{\partial \psi}{\partial y}, \quad v = \frac{\partial \Phi}{\partial y} = -\frac{\partial \psi}{\partial x} \tag{P.3.2.7}$$

It follows from using Equation (P.3.2.6) that

$$u = \frac{\partial \psi}{\partial y} = 2x, \quad v = -\frac{\partial \psi}{\partial x} = -2y \quad (\text{P.3.2.8})$$

Integration of Equation (P.3.2.8) yields

$$\psi = 2xy \quad (\text{P.3.2.9})$$

The streamlines,  $\psi = \text{constant}$ , and equipotential lines,  $\Phi = \text{constant}$ , both families of hyperbolas and each family the orthogonal trajectory of the other, are shown in Figure 3.2.3. Because the  $x$  and  $y$  axes are streamlines, Equations (P.3.2.6) and (P.3.2.9) represent the inviscid irrotational flow in a right-angle corner. By symmetry, they also represent the planar flow in the upper half-plane directed toward a stagnation point at  $x = y = 0$  (see Figure 3.2.4). In polar coordinates  $(r, \theta)$ , with corresponding velocity components  $(u_r, u_\theta)$ , this flow is represented by

$$\Phi = r^2 \cos 2\theta, \quad \psi = r^2 \sin 2\theta \quad (\text{P.3.2.10})$$

with

$$u_r = \frac{\partial \Phi}{\partial r} = \frac{1}{r} \frac{\partial \psi}{\partial \theta} = 2r \cos 2\theta \quad (\text{P.3.2.11})$$

$$u_\theta = \frac{1}{r} \frac{\partial \Phi}{\partial \theta} = -\frac{\partial \psi}{\partial r} = -2r \sin 2\theta$$

For two-dimensional planar potential flows we may also use complex variables, writing the complex potential  $f(z) = \Phi + i\psi$  as a function of the complex variable  $z = x + iy$ , where the complex velocity is given by  $f'(z) = w(z) = u - iv$ . For the flow above

**FIGURE 3.2.3** Potential flow in a  $90^\circ$  corner.

**FIGURE 3.2.4** Potential flow impinging against a flat ( $180^\circ$ ) wall (plane stagnation-point flow).

$$f(z) = z^2 \quad (\text{P.3.2.12})$$

Expressions such as Equation (P.3.2.12), where the right-hand side is an analytic function of  $z$ , may also be regarded as a conformal mapping, which makes available as an aid in solving two-dimensional potential problems all the tools of this branch of mathematics.

### Further Information

More detail and additional information on the topics in this section may be found in more advanced books on fluid dynamics, such as

Sherman, F.S. 1990. *Viscous Flow*, McGraw-Hill, New York.

Panton, R.L. 1984. *Incompressible Flow*, John Wiley & Sons, New York.

### 3.3 Similitude: Dimensional Analysis and Data Correlation

---

*Stuart W. Churchill*

#### Dimensional Analysis

*Similitude* refers to the formulation of a description for physical behavior that is general and independent of the individual dimensions, physical properties, forces, etc. In this subsection the treatment of similitude is restricted to *dimensional analysis*; for a more general treatment see Zlokarnik (1991). The full power and utility of dimensional analysis is often underestimated and underutilized by engineers. This technique may be applied to a complete mathematical model or to a simple listing of the variables that define the behavior. Only the latter application is described here. For a description of the application of dimensional analysis to a mathematical model see Hellums and Churchill (1964).

#### General Principles

Dimensional analysis is based on the principle that all additive or equated terms of a complete relationship between the variables must have the same net dimensions. The analysis starts with the preparation of a list of the individual dimensional variables (dependent, independent, and parametric) that are presumed to define the behavior of interest. The performance of dimensional analysis in this context is reasonably simple and straightforward; the principal difficulty and uncertainty arise from the identification of the variables to be included or excluded. If one or more important variables are inadvertently omitted, the reduced description achieved by dimensional analysis will be incomplete and inadequate as a guide for the correlation of a full range of experimental data or theoretical values. The familiar band of plotted values in many graphical correlations is more often a consequence of the omission of one or more variables than of inaccurate measurements. If, on the other hand, one or more irrelevant or unimportant variables are included in the listing, the consequently reduced description achieved by dimensional analysis will result in one or more unessential dimensionless groupings. Such excessive dimensionless groupings are generally less troublesome than missing ones because the redundancy will ordinarily be revealed by the process of correlation. Excessive groups may, however, suggest unnecessary experimental work or computations, or result in misleading correlations. For example, real experimental scatter may inadvertently and incorrectly be correlated in all or in part with the variance of the excessive grouping.

In consideration of the inherent uncertainty in selecting the appropriate variables for dimensional analysis, it is recommended that this process be interpreted as a *speculative* and subject to correction of the basis of experimental data or other information. Speculation may also be utilized as a formal technique to identify the effect of eliminating a variable or of combining two or more. The latter aspect of speculation, which may be applied either to the original listing of dimensional variables or to the resulting set of dimensionless groups, is often of great utility in identifying possible limiting behavior or dimensionless groups of marginal significance. The systematic speculative elimination of all but the most certain variables, one at a time, followed by regrouping, is recommended as a general practice. The additional effort as compared with the original dimensional analysis is minimal, but the possible return is very high. A general discussion of this process may be found in Churchill (1981).

The minimum number of independent dimensionless groups  $i$  required to describe the fundamental and parametric behavior is (Buckingham, 1914)

$$i = n - m \quad (3.3.1)$$

where  $n$  is the number of variables and  $m$  is the number of fundamental dimensions such as mass  $M$ , length  $L$ , time  $\theta$ , and temperature  $T$  that are introduced by the variables. The inclusion of redundant dimensions such as force  $F$  and energy  $E$  that may be expressed in terms of mass, length, time, and

temperature is at the expense of added complexity and is to be avoided. (Of course, mass could be replaced by force or temperature by energy as alternative fundamental dimensions.) In some rare cases  $i$  is actually greater than  $n - m$ . Then

$$i = n - k \quad (3.3.2)$$

where  $k$  is the maximum number of the chosen variables that cannot be combined to form a dimensionless group. Determination of the minimum number of dimensionless groups is helpful if the groups are to be chosen by inspection, but is unessential if the algebraic procedure described below is utilized to determine the groups themselves since the number is then obvious from the final result.

The *particular* minimal set of dimensionless groups is arbitrary in the sense that two or more of the groups may be multiplied together to any positive, negative, or fractional power as long as the number of independent groups is unchanged. For example, if the result of a dimensional analysis is

$$\phi\{XY^{1/2}, Z/Y^2, Z\} = 0 \quad (3.3.3)$$

where  $X$ ,  $Y$ , and  $Z$  are independent dimensionless groups, an equally valid expression is

$$\phi\{X, Y, Z\} = 0 \quad (3.3.4)$$

Dimensional analysis itself does not provide any insight as to the best choice of equivalent dimensionless groupings, such as between those of Equations (3.3.3) and (3.3.4). However, isolation of each of the variables that are presumed to be the most important in a separate group may be convenient in terms of interpretation and correlation. Another possible criterion in choosing between alternative groupings may be the relative invariance of a particular one. The functional relationship provided by Equation (3.3.3) may equally well be expressed as

$$X = \phi\{Y, Z\} \quad (3.3.5)$$

where  $X$  is implied to be the dependent grouping and  $Y$  and  $Z$  to be independent or parametric groupings.

Three primary methods of determining a minimal set of dimensionless variables are (1) by inspection; (2) by combination of the residual variables, one at a time, with the set of chosen variables that cannot be combined to obtain a dimensionless group; and (3) by an algebraic procedure. These methods are illustrated in the examples that follow.

### Example 3.3.1: Fully Developed Flow of Water Through a Smooth Round Pipe

*Choice of Variables.* The shear stress  $\tau_w$  on the wall of the pipe may be postulated to be a function of the density  $\rho$  and the dynamic viscosity  $\mu$  of the water, the inside diameter  $D$  of the pipe, and the space-mean of the time-mean velocity  $u_m$ . The limitation to fully developed flow is equivalent to a postulate of independence from distance  $x$  in the direction of flow, and the specification of a smooth pipe is equivalent to the postulate of independence from the roughness  $e$  of the wall. The choice of  $\tau_w$  rather than the pressure drop per unit length  $-dP/dx$  avoids the need to include the acceleration due to gravity  $g$  and the elevation  $z$  as variables. The choice of  $u_m$  rather than the volumetric rate of flow  $V$ , the mass rate of flow  $w$ , or the mass rate of flow per unit area  $G$  is arbitrary but has some important consequences as noted below. The postulated dependence may be expressed functionally as  $\phi\{\tau_w, \rho, \mu, D, u_m\} = 0$  or  $\tau_w = \phi\{\rho, \mu, D, u_m\}$ .

*Tabulation.* Next prepare a tabular listing of the variables and their dimensions:

	$\tau_w$	$\rho$	$\mu$	$D$	$u_m$
$M$	1	1	1	0	0
$L$	-1	-3	-1	1	1
$\theta$	-2	0	-1	0	-1
$T$	0	0	0	0	0

*Minimal Number of Groups.* The number of postulated variables is 5. Since the temperature does not occur as a dimension for any of the variables, the number of fundamental dimensions is 3. From Equation (3.3.1), the minimal number of dimensionless groups is  $5 - 3 = 2$ . From inspection of the above tabulation, a dimensionless group cannot be formed from as many as three variables such as  $D$ ,  $\mu$ , and  $\rho$ . Hence, Equation (3.3.2) also indicates that  $i = 5 - 3 = 2$ .

*Method of Inspection.* By inspection of the tabulation or by trial and error it is evident that only two independent dimensionless groups may be formed. One such set is

$$\phi \left\{ \frac{\tau_w}{\rho u_m^2}, \frac{Du_m \rho}{\mu} \right\} = 0$$

*Method of Combination.* The residual variables  $\tau_w$  and  $\mu$  may be combined in turn with the noncombining variables  $\rho$ ,  $D$ , and  $u_m$  to obtain two groups such as those above.

*Algebraic Method.* The algebraic method makes formal use of the postulate that the functional relationship between the variables may in general be represented by a power series. In this example such a power series may be expressed as

$$\tau_w = \sum_{i=1}^N A_i \rho^{a_i} \mu^{b_i} D^{c_i} u_m^{d_i}$$

where the coefficients  $A_i$  are dimensionless. Each additive term on the right-hand side of this expression must have the same net dimensions as  $\tau_w$ . Hence, for the purposes of dimensional analysis, only the first term need be considered and the indexes may be dropped. The resulting highly restricted expression is  $\tau_w = A \rho^a \mu^b D^c u_m^d$ . Substituting the dimensions for the variables gives

$$\frac{M}{L\theta^2} = A \left( \frac{M}{L^3} \right)^a \left( \frac{M}{L\theta} \right)^b L^c \left( \frac{L}{\theta} \right)^d$$

Equating the sum of the exponents of  $M$ ,  $L$ , and  $\theta$  on the right-hand side of the above expression with those of the left-hand side produces the following three simultaneous linear algebraic equations:  $1 = a + b$ ;  $-1 = -3a - b + c + d$ ; and  $-2 = -b - d$ , which may be solved for  $a$ ,  $c$ , and  $d$  in terms of  $b$  to obtain  $a = 1 - b$ ,  $c = -b$ , and  $d = 2 - b$ . Substitution then gives  $\tau_w = A \rho^{1-b} \mu^b D^{-b} u_m^{2-b}$  which may be regrouped as

$$\frac{\tau_w}{\rho u_m^2} = A \left( \frac{\mu}{Du_m \rho} \right)^b$$

Since this expression is only the first term of a power series, it should *not* be interpreted to imply that  $\tau_w / \rho u_m^2$  is necessarily proportional to some power at  $\mu / Du_m \rho$  but instead only the equivalent of the expression derived by the method of inspection. The inference of a power dependence between the

dimensionless groups is the most common and serious error in the use of the algebraic method of dimensional analysis.

*Speculative Reductions.* Eliminating  $\rho$  as a variable on speculative grounds to

$$\phi \left\{ \frac{\tau_w D}{\mu u_m} \right\} = 0$$

or its exact equivalent:

$$\frac{\tau_w D}{\mu u_m} = A$$

The latter expression with  $A = 8$  is actually the exact solution for the laminar regime ( $Du_m\rho/\mu < 1800$ ). A relationship that does not include  $\rho$  may alternatively be derived directly from the solution by the method of inspection as follows. First,  $\rho$  is eliminated from one group, say  $\tau_w/\rho u_m^2$ , by multiplying it with  $Du_m\rho/\mu$  to obtain

$$\phi \left\{ \frac{\tau_w D}{\mu u_m}, \frac{Du_m\rho}{\mu} \right\} = 0$$

The remaining group containing  $\rho$  is now simply dropped. Had the original expression been composed of three independent groups each containing  $\rho$ , that variable would have to be eliminated from two of them before dropping the third one.

The relationships that are obtained by the speculative elimination of  $\mu$ ,  $D$ , and  $u_m$ , one at a time, do not appear to have any range of physical validity. Furthermore, if  $w$  or  $G$  had been chosen as the independent variable rather than  $u_m$ , the limited relationship for the laminar regime would not have been obtained by the elimination of  $\rho$ .

*Alternative Forms.* The solution may also be expressed in an infinity of other forms such as

$$\phi \left\{ \frac{\tau_w D^2 \rho}{\mu^2}, \frac{Du_m\rho}{\mu} \right\} = 0$$

If  $\tau_w$  is considered to be the principal dependent variable and  $u_m$  the principal independent variable, this latter form is preferable in that these two quantities do not then appear in the same grouping. On the other hand, if  $D$  is considered to be the principal independent variable, the original formulation is preferable. The variance of  $\tau_w/\rho u_m^2$  is less than that of  $\tau_w D/\mu u_m$  and  $\tau_w D^2\rho/\mu^2$  in the turbulent regime while that of  $\tau_w D/\mu u_m$  is zero in the laminar regime. Such considerations may be important in devising convenient graphical correlations.

*Alternative Notations.* The several solutions above are more commonly expressed as

$$\phi \left\{ \frac{f}{2}, \text{Re} \right\} = 0$$

$$\phi \left\{ \frac{f\text{Re}}{2}, \text{Re} \right\} = 0$$

or

$$\phi \left\{ \frac{fRe^2}{2}, Re \right\} = 0$$

where  $f = 2 \tau_w / \rho u_m^2$  is the *Fanning friction factor* and  $Re = Du_m \rho / \mu$  is the *Reynolds number*.

The more detailed forms, however, are to be preferred for purposes of interpretation or correlation because of the explicit appearance of the individual, physically measurable variables.

*Addition of a Variable.* The above results may readily be extended to incorporate the roughness  $e$  of the pipe as a variable. If two variables have the same dimensions, they will always appear as a dimensionless group in the form of a ratio, in this case  $e$  appears most simply as  $e/D$ . Thus, the solution becomes

$$\phi \left\{ \frac{\tau_w}{\rho u_m^2}, \frac{Du_m \rho}{\mu}, \frac{e}{D} \right\} = 0$$

Surprisingly, as contrasted with the solution for a smooth pipe, the speculative elimination of  $\mu$  and hence of the group  $Du_m \rho / \mu$  now results in a valid asymptote for  $Du_m \rho / \mu \rightarrow \infty$  and all finite values of  $e/D$ , namely,

$$\phi \left\{ \frac{\tau_w}{\rho u_m^2}, \frac{e}{D} \right\} = 0$$

### Example 3.3.2: Fully Developed Forced Convection in Fully Developed Flow in a Round Tube

It may be postulated for this process that  $h = \phi\{D, u_m, \rho, \mu, k, c_p\}$ , where here  $h$  is the local heat transfer coefficient, and  $c_p$  and  $k$  are the specific heat capacity and thermal conductivity, respectively, of the fluid. The corresponding tabulation is

	$h$	$D$	$u_m$	$\rho$	$\mu$	$k$	$c_p$
$M$	1	0	0	1	1	1	0
$L$	0	1	1	-3	-1	1	2
$\theta$	-3	0	-1	0	-1	-3	-2
$T$	-1	0	0	0	0	-1	-1

The number of variables is 7 and the number of independent dimensions is 4, as is the number of variables such as  $D$ ,  $u_m$ ,  $\rho$ , and  $k$  that cannot be combined to obtain a dimensionless group. Hence, the minimal number of dimensionless groups is  $7 - 4 = 3$ . The following acceptable set of dimensionless groups may be derived by any of the procedures illustrated in Example 1:

$$\frac{hD}{k} = \phi \left\{ \frac{Du_m \rho}{\mu}, \frac{c_p \mu}{k} \right\}$$

Speculative elimination of  $\mu$  results in

$$\frac{hD}{k} = \phi \left\{ \frac{Du_m \rho c_p}{k} \right\}$$

which has often erroneously been inferred to be a valid asymptote for  $c_p \mu / k \rightarrow 0$ . Speculative elimination of  $D$ ,  $u_m$ ,  $\rho$ ,  $k$ , and  $c_p$  individually also does not appear to result in expressions with any physical validity. However, eliminating  $c_p$  and  $\rho$  or  $u_m$  gives a valid result for the laminar regime, namely,

$$\frac{hD}{k} = A$$

The general solutions for flow and convection in a smooth pipe may be combined to obtain

$$\frac{hD}{k} = \phi \left\{ \frac{\tau_w D^2 \rho}{\mu^2}, \frac{c_p \mu}{k} \right\}$$

which would have been obtained directly had  $u_m$  been replaced by  $\tau_w$  in the original tabulation. This latter expression proves to be superior in terms of speculative reductions. Eliminating  $D$  results in

$$\frac{h\mu}{k(\tau_w \rho)^{1/2}} = \phi \left\{ \frac{c_p \mu}{k} \right\}$$

which may be expressed in the more conventional form of

$$\text{Nu} = \text{Re} \left( \frac{f}{2} \right)^{1/2} \phi \{ \text{Pr} \}$$

where  $\text{Nu} = hD/k$  is the *Nusselt number* and  $\text{Pr} = c_p \mu / k$  is the *Prandtl number*. This result appears to be a valid asymptote for  $\text{Re} \rightarrow \infty$  and a good approximation for even moderate values ( $>5000$ ) for large values of  $\text{Pr}$ . Elimination of  $\mu$  as well as  $D$  results in

$$\frac{h}{c_p (\tau_w \rho)^{1/2}} = A$$

or

$$\text{Nu} = A \text{Re} \text{Pr} \left( \frac{f}{2} \right)^{1/2}$$

which appears to be an approximate asymptote for  $\text{Re} \rightarrow \infty$  and  $\text{Pr} \rightarrow 0$ . Elimination of both  $c_p$  and  $\rho$  again yields the appropriate result for laminar flow, indicating that  $\rho$  rather than  $u_m$  is the meaningful variable to eliminate in this respect.

The numerical value of the coefficient  $A$  in the several expressions above depends on the mode of heating, a true variable, but one from which the purely functional expressions are independent. If  $j_w$  the heat flux density at the wall, and  $T_w - T_m$ , the temperature difference between the wall and the bulk of the fluid, were introduced as variables in place of  $h \equiv j_w / (T_w - T_m)$ , another group such as  $c_p (T_w - T_m) (D\rho/\mu)^2$  or  $\rho c_p (T_w - T_m) / \tau_w$  or  $c_p (T_w - T_m) / u_m^2$ , which represents the effect of viscous dissipation, would be obtained. This effect is usually but not always negligible. (See Chapter 4.)

**Example 3.3.3: Free Convection from a Vertical Isothermal Plate**

The behavior for this process may be postulated to be represented by

$$h = \phi \left\{ g, \beta, T_w - T_\infty, x, \mu, \rho, c_p, k \right\}$$

where  $g$  is the acceleration due to gravity,  $\beta$  is the volumetric coefficient of expansion with temperature,  $T_\infty$  is the unperturbed temperature of the fluid, and  $x$  is the vertical distance along the plate. The corresponding tabulation is

	$h$	$g$	$\beta$	$T_w - T_\infty$	$x$	$\mu$	$\rho$	$c_p$	$k$
$M$	1	0	0	0	0	1	1	0	1
$L$	0	1	0	0	1	-1	-3	2	1
$\theta$	-3	-2	0	0	0	-1	0	-2	-3
$T$	-1	0	-1	1	0	0	0	-1	1

The minimal number of dimensionless groups indicated by both methods is  $9 - 4 = 5$ . A satisfactory set of dimensionless groups, as found by any of the methods illustrated in Example 1 is

$$\frac{hx}{k} = \phi \left\{ \frac{\rho^2 g x^3}{\mu^2}, \frac{c_p \mu}{k}, \beta(T_w - T_\infty), c_p(T_w - T_\infty) \left( \frac{\rho x}{\mu} \right)^2 \right\}$$

It may be reasoned that the buoyant force which generates the convective motion must be proportional to  $\rho g \beta(T_w - T_\infty)$ , thus,  $g$  in the first term on the right-hand side must be multiplied by  $\beta(T_w - T_\infty)$ , resulting in

$$\frac{hx}{k} = \phi \left\{ \frac{\rho^2 g \beta(T_w - T_\infty) x^3}{\mu^2}, \frac{c_p \mu}{k}, \beta(T_w - T_\infty), c_p(T_w - T_\infty) \left( \frac{\rho x}{\mu} \right)^2 \right\}$$

The effect of expansion other than on the buoyancy is now represented by  $\beta(T_w - T_\infty)$ , and the effect of viscous dissipation by  $c_p(T_w - T_\infty)(\rho x/\mu)^2$ . Both effects are negligible for all practical circumstances. Hence, this expression may be reduced to

$$\frac{hx}{k} = \phi \left\{ \frac{\rho^2 g \beta(T_w - T_\infty) x^3}{\mu^2}, \frac{c_p \mu}{k} \right\}$$

or

$$\text{Nu}_x = \phi \{ \text{Gr}_x, \text{Pr} \}$$

where  $\text{Nu}_x = hx/k$  and  $\text{Gr}_x = \rho^2 g \beta(T_w - T_\infty) x^3 / \mu^2$  is the *Grashof number*.

Elimination of  $x$  speculatively now results in

$$\frac{hx}{k} = \left( \frac{\rho^2 g \beta(T_w - T_\infty) x^3}{\mu^2} \right)^{1/3} \phi \{ \text{Pr} \}$$

or

$$\text{Nu}_x = \text{Gr}_x^{1/3} \phi \{ \text{Pr} \}$$

This expression appears to be a valid asymptote for  $\text{Gr}_x \rightarrow \infty$  and a good approximation for the entire turbulent regime. Eliminating  $\mu$  speculatively rather than  $x$  results in

$$\frac{hx}{k} = \phi \left\{ \frac{\rho^2 c_p^2 g \beta (T_w - T_\infty) x^3}{k^2} \right\}$$

or

$$\text{Nu}_x = \phi \left\{ \text{Gr}_x \text{Pr}^2 \right\}$$

The latter expression appears to be a valid asymptote for  $\text{Pr} \rightarrow 0$  for all  $\text{Gr}_x$ , that is, for both the laminar and the turbulent regimes. The development of a valid asymptote for large values of  $\text{Pr}$  requires more subtle reasoning. First  $c_p \mu / k$  is rewritten as  $\mu / \rho \alpha$  where  $\alpha = k / \rho c_p$ . Then  $\rho$  is eliminated speculatively except as it occurs in  $\rho g \beta (T_w - T_\infty)$  and  $k / \rho c_p$ . The result is

$$\frac{hx}{k} = \phi \left\{ \frac{c_p \rho^2 g \beta (T_w - T_\infty) x^3}{\mu k} \right\}$$

or

$$\text{Nu}_x = \phi \left\{ \text{Ra}_x \right\}$$

where

$$\text{Ra}_x = \frac{c_p \rho^2 g \beta (T_w - T_\infty) x^3}{\mu k} = \text{Gr}_x \text{Pr}$$

is the *Rayleigh number*. The expression appears to be a valid asymptote for  $\text{Pr} \rightarrow \infty$  and a reasonable approximation for even moderate values of  $\text{Pr}$  for all  $\text{Gr}_x$ , that is, for both the laminar and the turbulent regimes.

Eliminating  $x$  speculatively from the above expressions for small and large values of  $\text{Pr}$  results in

$$\text{Nu}_x = A \left( \text{Gr}_x \text{Pr}^2 \right)^{1/3} = A \left( \text{Ra}_x \text{Pr} \right)^{1/3}$$

and

$$\text{Nu}_x = B \left( \text{Gr}_x \text{Pr} \right)^{1/3} = B \left( \text{Ra}_x \right)^{1/3}$$

The former appears to be a valid asymptote for  $\text{Pr} \rightarrow 0$  and  $\text{Gr}_x \rightarrow \infty$  and a reasonable approximation for very small values of  $\text{Pr}$  in the turbulent regime, while the latter is well confirmed as a valid asymptote for  $\text{Pr} \rightarrow \infty$  and  $\text{Gr}_x \rightarrow \infty$  and as a good approximation for moderate and large values of  $\text{Pr}$  over the entire turbulent regime. The expressions in terms of  $\text{Gr}_x$  are somewhat more complicated than those in terms of  $\text{Ra}_x$ , but are to be preferred since  $\text{Gr}_x$  is known to characterize the transition from laminar to turbulent motion in natural convection just as  $\text{Re}_D$  does in forced flow in a channel. The power of speculation combined with dimensional analysis is well demonstrated by this example in which valid asymptotes are thereby attained for several regimes.

## Correlation of Experimental Data and Theoretical Values

Correlations of experimental data are generally developed in terms of dimensionless groups rather than in terms of the separate dimensional variables in the interests of compactness and in the hope of greater generality. For example, a complete set of graphical correlations for the heat transfer coefficient  $h$  of Example 3.3.2 above in terms of each of the six individual independent variables and physical properties might approach book length, whereas the dimensionless groupings both imply that a single plot with one parameter should be sufficient. Furthermore, the reduced expression for the turbulent regime implies that a plot of  $\text{Nu}/\text{Re} f^{1/2}$  vs.  $\text{Pr}$  should demonstrate only a slight parametric dependence on  $\text{Re}$  or  $\text{Re} f^{1/2}$ . Of course, the availability of a separate correlation for  $f$  as a function of  $\text{Re}$  is implied.

Theoretical values, that is, ones obtained by numerical solution of a mathematical model in terms of either dimensional variables or dimensionless groups, are presumably free from imprecision. Even so, because of their discrete form, the construction of a correlation or correlations for such values may be essential for the same reasons as for experimental data.

Graphical correlations have the merit of revealing general trends, of providing a basis for evaluation of the choice of coordinates, and most of all of displaying visually the scatter of the individual experimental values about a curve representing a correlation or their behavior on the mean. (As mentioned in the previous subsection, the omission of a variable may give the false impression of experimental error in such a plot.) On the other hand, correlating equations are far more convenient as an input to a computer than is a graphical correlation. These two formats thus have distinct and complementary roles; both should generally be utilized. The merits and demerits of various graphical forms of correlations are discussed in detail by Churchill (1979), while the use of logarithmic and arithmetic coordinates, the effects of the appearance of a variable in both coordinates, and the effects of the distribution of error between the dependent and independent variable are further illustrated by Wilkie (1985).

Churchill and Usagi (1972; 1974) proposed general usage of the following expression for the formulation of correlating equations:

$$y^n\{x\} = y_0^n\{x\} + y_\infty^n\{x\} \quad (3.3.6)$$

where  $y_0\{x\}$  and  $y_\infty\{x\}$  denote asymptotes for small and large values of  $x$ , respectively, and  $n$  is an arbitrary exponent. For convenience and simplicity, Equation (3.3.6) may be rearranged in either of the following two forms:

$$(Y(x))^n = 1 + Z^n\{x\} \quad (3.3.7)$$

or

$$\left(\frac{Y\{x\}}{Z\{x\}}\right)^n = 1 + \frac{1}{Z^n\{x\}} \quad (3.3.8)$$

where  $Y\{x\} \equiv y\{x\}/y_0\{x\}$  and  $Z\{x\} \equiv y_\infty\{x\}/y_0\{x\}$ . Equations (3.3.6), (3.3.7), and (3.3.9) are hereafter denoted collectively as the CUE (Churchill–Usagi equation). The principle merits of the CUE as a canonical expression for correlation are its simple form, generality, and minimal degree of explicit empiricism, namely, only that of the exponent  $n$ , since the asymptotes  $y_0\{x\}$  and  $y_\infty\{x\}$  are ordinarily known in advance from theoretical considerations or well-established correlations. Furthermore, as will be shown, the CUE is quite insensitive to the numerical value of  $n$ . Although the CUE is itself very simple in form, it is remarkably successful in representing closely very complex behavior, even including the dependence on secondary variables and parameters, by virtue of the introduction of such dependencies through  $y_0\{x\}$  and  $y_\infty\{x\}$ . In the rare instances in which such dependencies are not represented in the asymptotes,  $n$  may be correlated as a function of the secondary variables and/or parameters. Although

the CUE usually produces very close representations, it is empirical and not exact. In a few instances, numerical values of  $n$  have been derived or rationalized on theoretical grounds, but even then some degree of approximation is involved. Furthermore, the construction of a correlating expression in terms of the CUE is subject to the following severe limitations:

1. The asymptotes  $y_o\{x\}$  and  $y_\infty\{x\}$  must intersect once and only once;
2. The asymptotes  $y_o\{x\}$  and  $y_\infty\{x\}$  must be free of singularities. Even though a singularity occurs beyond the asserted range of the asymptote, it will persist and disrupt the prediction of the CUE, which is intended to encompass all values of the independent variable  $x$ ; and
3. The asymptotes must both be upper or lower bounds.

In order to avoid or counter these limitations it may be necessary to modify or replace the asymptotes with others. Examples of this process are provided below. A different choice for the dependent variable may be an option in this respect. The suitable asymptotes for use in Equation (3.3.6) may not exist in the literature and therefore may need to be devised or constructed. See, for example, Churchill (1988b) for guidance in this respect. Integrals and derivatives of the CUE are generally awkward and inaccurate, and may include singularities not present or troublesome in the CUE itself. It is almost always preferable to develop a separate correlating equation for such quantities using derivatives or integrals of  $y_o\{x\}$  and  $y_\infty\{x\}$ , simplified or modified as appropriate.

**The Evaluation of  $n$**

Equation (3.3.6) may be rearranged as

$$n = - \frac{\ln \left\{ 1 + \left( \frac{y_\infty\{x\}}{y_o\{x\}} \right)^n \right\}}{\ln \left\{ \frac{y\{x\}}{y_o\{x\}} \right\}} \tag{3.3.9}$$

and solved for  $n$  by iteration for any known value of  $y\{x\}$ , presuming that  $y_o\{x\}$  and  $y_\infty\{x\}$  are known. If  $y\{x^*\}$  is known, where  $x^*$  represents the value of  $x$  at the point of intersection of the asymptotes, that is, for  $y_o\{x\} = y_\infty\{x\}$ , Equation (3.3.9) reduces to

$$n = \frac{\ln\{2\}}{\ln \left\{ \frac{y\{x^*\}}{y_o\{x^*\}} \right\}} \tag{3.3.10}$$

and iterative determination of  $n$  is unnecessary.

A graphical and visual method of evaluation of  $n$  is illustrated in Figure 3.3.1 in which  $Y\{Z\}$  is plotted vs.  $Z$  for  $0 \leq Z \leq 1$  and  $Y\{Z\}/Z$  vs.  $1/Z$  for  $0 \leq 1/Z \leq 1$  in arithmetic coordinates with  $n$  as a parameter. Values of  $y\{x\}$  may be plotted in this form and the best overall value of  $n$  selected visually (as illustrated in Figure 3.3.2). A logarithmic plot of  $Y\{Z\}$  vs.  $Z$  would have less sensitivity relative to the dependence on  $n$ . (See, for example, Figure 1 of Churchill and Usagi, 1972.) Figure 3.3.1 explains in part the success of the CUE. Although  $y$  and  $x$  may both vary from 0 to  $\infty$ , the composite variables plotted in Figure 3.3.1 are highly constrained in that the compound independent variables  $Z$  and  $1/Z$  vary only between 0 and 1, while for  $n \geq 1$ , the compound dependent variables  $Y\{Z\}$  and  $Y\{Z\}/Z$  vary only from 1 to 2.

Because of the relative insensitivity of the CUE to the numerical value of  $n$ , an integer or a ratio of two small integers may be chosen in the interest of simplicity and without significant loss of accuracy. For example, the maximum variance in  $Y$  (for  $0 \leq Z \leq 1$ ) occurs at  $Z = 1$  and increases only  $100(2^{1/20} - 1) = 3.5\%$  if  $n$  is decreased from 5 to 4. If  $y_o\{x\}$  and  $y_\infty\{x\}$  are both lower bounds,  $n$  will be positive,

**FIGURE 3.3.1** Arithmetic, split-coordinate plot of Equation 3.3.10. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1123, 1972. With permission from the American Institute of Chemical Engineers.)

**FIGURE 3.3.2** Arithmetic, split-coordinate plot of computed values and experimental data for laminar free convection from an isothermal vertical plate. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1124, 1972. With permission from the American Institute of Chemical Engineers.)

and if they are both upper bounds,  $n$  will be negative. To avoid extending Figure 3.3.1 for negative values of  $n$ ,  $1/y\{x\}$  may simply be interpreted as the dependent variable.

**Intermediate Regimes**

Equations (3.3.6), (3.3.7), and (3.3.8) imply a slow, smooth transition between  $y_o\{x\}$  and  $y_x\{x\}$  and, moreover, one that is symmetrical with respect to  $x^*(Z = 1)$ . Many physical systems demonstrate instead a relatively abrupt transition, as for example from laminar to turbulent flow in a channel or along a flat plate. The CUE may be applied serially as follows to represent such behavior if an expression  $y_i\{x\}$  is

postulated for the intermediate regime. First, the transition from the initial to the intermediate regime is represented by

$$y_1^n = y_0^n + y_i^n \tag{3.3.11}$$

Then the transition from this combined regime to the final regime by

$$y^m = y_1^m + y_\infty^m = (y_0^n + y_i^n)^{m/n} + y_\infty^m \tag{3.3.12}$$

Here, and throughout the balance of this subsection, in the interests of simplicity and clarity, the functional dependence of all the terms on  $x$  is implied rather than written out explicitly. If  $y_0$  is a lower bound and  $y_i$  is implied to be one,  $y_1$  and  $y_\infty$  must be upper bounds. Hence,  $n$  will then be positive and  $m$  negative. If  $y_0$  and  $y_i$  are upper bounds,  $y_1$  and  $y_\infty$  must be lower bounds; then  $n$  will be negative and  $m$  positive. The reverse formulation starting with  $y_\infty$  and  $y_1$  leads by the same procedure to

$$y^n = y_0^n + (y_i^m + y_\infty^m)^{n/m} \tag{3.3.13}$$

If the intersections of  $y_i$  with  $y_0$  and  $y_\infty$  are widely separated with respect to  $x$ , essentially the same pair of values for  $n$  and  $m$  will be determined for Equations (3.3.12) and (3.3.13), and the two representations for  $y$  will not differ significantly. On the other hand, if these intersections are close in terms of  $x$ , the pair of values of  $m$  and  $n$  may differ significantly and one representation may be quite superior to the other. In some instances a singularity in  $y_0$  or  $y_\infty$  may be tolerable in either Equation (3.3.12) or (3.3.13) because it is overwhelmed by the other terms. Equations (3.3.12) and (3.3.13) have one hidden flaw. For  $x \rightarrow 0$ , Equation (3.3.12) reduces to

$$y \rightarrow y_0 \left[ 1 + \left( \frac{y_\infty}{y_0} \right)^m \right]^{1/m} \tag{3.3.14}$$

If  $y_0$  is a lower bound,  $m$  is necessarily negative, and values of  $y$  less than  $y_0$  are predicted. If  $y_0/y_\infty$  is sufficiently small or if  $m$  is sufficiently large in magnitude, this discrepancy may be tolerable. If not, the following alternative expression may be formulated, again starting from Equation (3.3.11):

$$(y^n - y_0^n)^m = y_i^{nm} + (y_\infty^n - y_0^n)^m \tag{3.3.15}$$

Equation (3.3.15) is free from the flaw identified by means of Equation (3.3.14) and invokes no additional empiricism, but a singularity may occur at  $y_\infty = y_0$ , depending on the juxtapositions of  $y_0$ ,  $y_i$ , and  $y_\infty$ . Similar anomalies occur for Equation (3.3.13) and the corresponding analog of Equation (3.3.14), as well as for behavior for which  $n < 0$  and  $m > 0$ . The preferable form among these four is best chosen by trying each of them.

One other problem with the application of the CUE for a separate transitional regime is the formulation of an expression for  $y_i\{x\}$ , which is ordinarily not known from theoretical considerations. Illustrations of the empirical determination of such expressions for particular cases may be found in Churchill and Usagi (1974), Churchill and Churchill (1975), and Churchill (1976; 1977), as well as in Example 3.3.5 below.

**Example 3.3.4: The Pressure Gradient in Flow through a Packed Bed of Spheres**

The pressure gradient at asymptotically low rates of flow (the creeping regime) can be represented by the Kozeny–Carman equation,  $\Phi = 150 \text{ Re}_p$ , and at asymptotically high rates of flow (the inertial regime)

by the Burke–Plummer equation,  $\Phi = 1.75 (\text{Re}_p)^2$ , where  $\Phi = \rho \varepsilon^2 d_p (-dP_f/dx) \mu^2 (1 - \varepsilon)$ ,  $\text{Re}_p = d_p u_o \rho / \mu (1 - \varepsilon)$ ,  $d_p =$  diameter of spherical particles, m,  $\varepsilon =$  void fraction of bed of spheres,  $dP_f/dx =$  dynamic pressure gradient (due to friction), Pa/m, and  $u_o =$  superficial velocity (in absence of the spheres), m/sec. For the origin of these two asymptotic expressions see Churchill (1988a). They both have a theoretical structure, but the numerical coefficients of 150 and 1.75 are basically empirical. These equations are both lower bounds and have one intersection. Experimental data are plotted in Figure 3.3.3, which has the form of Figure 3.3.1 with  $Y = \Phi/150 \text{Re}_p$ ,  $Y/Z = \Phi/(1.75 \text{Re}_p)^2$  and  $Z = 1.75 \text{Re}_p^2/150 \text{Re}_p = \text{Re}_p/85.7$ . A value of  $n = 1$  is seen to represent these data reasonably well on the mean, resulting in

$$\Phi = 150 \text{Re}_p + 1.75 (\text{Re}_p)^2$$

which was originally proposed as a correlating equation by Ergun (1952) on the conjecture that the volumetric fraction of the bed in “turbulent” flow is proportional to  $\text{Re}_p$ . The success of this expression in conventional coordinates is shown in Figure 3.3.4. The scatter, which is quite evident in the arithmetic split coordinates of Figure 3.3.3, is strongly suppressed in a visual sense in the logarithmic coordinates of Figure 3.3.4.

**FIGURE 3.3.3** Arithmetic, split-coordinate plot of experimental data for the pressure drop in flow through a packed bed of spheres. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1123, 1972. With permission from the American Institute of Chemical Engineers.)

**Example 3.3.5: The Friction Factor for Commercial Pipes for All Conditions**

The serial application of the CUE is illustrated here by the construction of a correlating equation for both smooth and rough pipes in the turbulent regime followed by combination of that expression with ones for the laminar and transitional regimes.

*The Turbulent Regime.* The Fanning friction factor,  $f_F$ , for turbulent flow in a smooth round pipe for asymptotically large rates of flow (say  $\text{Re}_D > 5000$ ) may be represented closely by the empirical expression:

**FIGURE 3.3.4** Logarithmic correlation of experimental data for the pressure drop in flow through a packed bed of spheres. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1123, 1972. With permission from the American Institute of Chemical Engineers.)

$$\left(\frac{2}{f_F}\right)^{1/2} = 0.256 + 2.5 \ln \left\{ \left(\frac{f_F}{2}\right)^{1/2} \text{Re}_D \right\}$$

A corresponding empirical representation for naturally rough pipe is

$$\left(\frac{2}{f_F}\right)^{1/2} = 3.26 + 2.5 \ln \left\{ \frac{D}{e} \right\}$$

Direct combination of these two expressions in the form of the CUE does not produce a satisfactory correlating equation, but their combination in the following rearranged forms:

$$e^{(1/2.5)(2/f_F)^{1/2}} = 1.108 \left(\frac{f_F}{2}\right)^{1/2} \text{Re}_D$$

and

$$e^{(1/2.5)(2/f_F)^{1/2}} = 3.68 \left(\frac{D}{e}\right)$$

with  $n = -1$  results in, after the reverse rearrangement,

$$\left(\frac{2}{f_F}\right)^{1/2} = 0.256 + 2.5 \ln \left\{ \frac{\left(\frac{f_F}{2}\right)^{1/2} \text{Re}_D}{1 + 0.3012 \left(\frac{e}{D}\right) \left(\frac{f_F}{2}\right)^{1/2} \text{Re}_D} \right\}$$

The exact equivalent of this expression in structure but with the slightly modified numerical coefficients of 0.300, 2.46, and 0.304 was postulated by Colebrook (1938–1939) to represent his own experimental data. The coefficients of the expression given here are presumed to be more accurate, but the difference in the predictions of  $f_F$  with the two sets of coefficients is within the band of uncertainty of the

experimental data. The turbulent regime of the “friction-factor” plot in most current textbooks and handbooks is simply a graphical representation of the Colebrook equation. Experimental values are not included in such plots since  $e$ , the effective roughness of commercial pipes, is simply a correlating factor that forces agreement with the Colebrook equation. Values of  $e$  for various types of pipe in various services are usually provided in an accompanying table, that thereby constitutes an integral part of the correlation.

*The Laminar Region.* The Fanning friction factor in the laminar regime of a round pipe ( $Re_d < 1800$ ) is represented exactly by the following theoretical expression known as Poiseuille’s law:  $f_F = 16/Re_D$ . This equation may be rearranged as follows for convenience in combination with that for turbulent flow:

$$\left(\frac{2}{f_F}\right)^{1/2} = \frac{Re_D(f_F/2)^{1/2}}{8}$$

*The Transitional Regime.* Experimental data as well as semitheoretical computed values for the limiting behavior in the transition may be represented closely by  $(f_F/2) = (Re_D/37500)^2$ . This expression may be rewritten, in terms of  $(2/f_F)^{1/2}$  and  $Re_D(f_F/2)^{1/2}$ , as follows:

$$\left(\frac{f_F}{2}\right)^{1/2} = \left(\frac{37500}{Re_D(f_F/2)^{1/2}}\right)^{1/2}$$

*Overall Correlation.* The following correlating equation for all  $Re_D(f_F/2)^{1/2}$  and  $e/D$  may now be constructed by the combination of the expressions for the turbulent and transition regimes in the form of the CUE with  $n = 8$ , and then that expression and that for the laminar regime with  $n = -12$ , both components being chosen on the basis of experimental data and predicted values for the full regime of transition:

$$\left(\frac{2}{f_F}\right)^{1/2} = \left[\left(\frac{8}{Re_D(f_F/2)^{1/2}}\right)^{12} + \left[\left(\frac{37500}{Re_D(f_F/2)^{1/2}}\right)^4 + \left|2.5 \ln \left\{\frac{1.108 Re_D(f_F/2)^{1/2}}{1 + 0.3012 \left(\frac{e}{a}\right) Re_D(f_F/2)^{1/2}}\right\}\right|^8\right]^{-3/2}\right]^{-1/2}$$

The absolute value signs are only included for aesthetic reasons; the negative values of the logarithmic term for very small values of  $Re_D(f_F/2)^{1/2}$  do not affect the numerical value of  $(2/f_F)^{1/2}$  in the regime in which they occur. This overall expression appears to have a complicated structure, but it may readily be recognized to reduce to its component parts when the corresponding term is large with respect to the other two. It is insensitive to the numerical values of the two arbitrary exponents. For example, doubling their values would have almost no effect on the predictions of  $(f_F/2)^{1/2}$ . The principal uncertainty is associated with the expression for the transition regime, but the overall effect of the corresponding term is very small. The uncertainties associated with this correlating equation are common to most graphical correlations and algebraic expressions for the friction factor, and are presumed to be fairly limited in magnitude and to be associated primarily with the postulated value of  $e$ . Although the overall expression is explicit in  $Re_D(f_F/2)^{1/2}$  rather than  $Re_D$ , the latter quantity may readily be obtained simply by multiplying the postulated value of  $Re_D(f_F/2)^{1/2}$  by the computed values of  $(2/f_F)^{1/2}$ .

## 3.4 Hydraulics of Pipe Systems

*J. Paul Tullis*

### Basic Computations

#### Equations

Solving fluid flow problems involves the application of one or more of the three basic equations: continuity, momentum, and energy. These three basic tools are developed from the law of conservation of mass, Newton's second law of motion, and the first law of thermodynamics.

The simplest form of the continuity equation is for one-dimensional incompressible steady flow in a conduit. Applying continuity between any two sections gives

$$A_1 V_1 = A_2 V_2 = Q \quad (3.4.1)$$

For a variable density the equation can be written

$$\rho_1 A_1 V_1 = \rho_2 A_2 V_2 = \dot{m} \quad (3.4.2)$$

in which  $A$  is the cross-sectional area of the pipe,  $V$  is the mean velocity at that same location,  $Q$  is the flow rate,  $\rho$  is the fluid density, and  $\dot{m}$  is the mass flow rate. The equations are valid for any rigid conduit as long as there is no addition or loss of liquid between the sections.

For steady state pipe flow, the momentum equation relates the net force in a given direction ( $F_x$ ) acting on a control volume (a section of the fluid inside the pipe), to the net momentum flux through the control volume.

$$F_x = \rho_2 A_2 V_2 V_{2x} - \rho_1 A_1 V_1 V_{1x} \quad (3.4.3)$$

For incompressible flow this equation can be reduced to

$$F_x = \rho Q (V_{2x} - V_{1x}) \quad (3.4.4)$$

These equations can easily be applied to a three-dimensional flow problem by adding equations in the  $y$  and  $z$  directions.

A general form of the energy equation (see Chapter 2) applicable to incompressible pipe or duct flow

$$\frac{P_1}{\gamma} + Z_1 + \frac{V_1^2}{2g} = \frac{P_2}{\gamma} + Z_2 + \frac{V_2^2}{2g} - H_p + H_t + H_f \quad (3.4.5)$$

The units are energy per unit weight of liquid:  $\text{ft} \cdot \text{lb}/\text{lb}$  or  $\text{N} \cdot \text{m}/\text{N}$  which reduce to  $\text{ft}$  or  $\text{m}$ . The first three terms are pressure head ( $P/\gamma$ ), elevation head ( $Z$ ) (above some datum), and velocity head ( $V^2/2g$ ). The last three terms on the right side of the equation are the total dynamic head added by a pump ( $H_p$ ) or removed by a turbine ( $H_t$ ) and the friction plus minor head losses ( $H_f$ ). The sum of the first three terms in Equation 3.4.5 is defined as the total head, and the sum of the pressure and elevation heads is referred to as the piezometric head.

The purpose of this section is to determine the pressure changes resulting from incompressible flow in pipe systems. Since pipes of circular cross sections are most common in engineering application, the analysis in this section will be performed for circular geometry. However, the results can be generalized for a pipe of noncircular geometry by substituting for the diameter  $D$  in any of the equations, the hydraulic diameter,  $D_h$ , defined as

$$D_h = 4 \times \frac{\text{the cross sectional area}}{\text{the wetted perimeter}}$$

The analysis in this section can also be applied to gases and vapors, provided the Mach number in the duct does not exceed 0.3. For greater values of the Mach number, the compressibility effect becomes significant and the reader is referred to Section 3.7 on compressible flow.

### Fluid Friction

The calculation of friction loss in pipes and ducts depends on whether the flow is laminar or turbulent. The Reynolds number is the ratio of inertia forces to viscous forces and is a convenient parameter for predicting if a flow condition will be laminar or turbulent. It is defined as

$$\text{Re}_D = \frac{\rho VD}{\mu} = \frac{VD}{\nu} \quad (3.4.6)$$

in which  $V$  is the mean flow velocity,  $D$  diameter,  $\rho$  fluid density,  $\mu$  dynamic viscosity, and  $\nu$  kinematic viscosity.

Friction loss ( $H_f$ ) depends on pipe diameter ( $d$ ), length ( $L$ ), roughness ( $e$ ), fluid density ( $\rho$ ) or specific weight ( $\gamma$ ), viscosity ( $\nu$ ), and flow velocity ( $V$ ). Dimensional analysis can be used to provide a functional relationship between the friction loss  $H_f$ , pipe dimensions, fluid properties, and flow parameters. The resulting equation is called the Darcy–Weisbach equation:

$$H_f = \frac{fLV^2}{2gd} = \frac{fLQ^2}{1.23gD^5} \quad (3.4.7)$$

The friction factor  $f$  is a measure of pipe roughness. It has been evaluated experimentally for numerous pipes. The data were used to create the Moody friction factor chart shown as [Figure 3.4.1](#). For  $\text{Re} < 2000$ , the flow in a pipe will be laminar and  $f$  is only a function of  $\text{Re}_D$ . It can be calculated by

$$f = \frac{64}{\text{Re}_D} \quad (3.4.8)$$

At Reynolds numbers between about 2000 and 4000 the flow is unstable as a result of the onset of turbulence (critical zone in [Figure 3.4.1](#)). In this range, friction loss calculations are difficult because it is impossible to determine a unique value of  $f$ . For  $\text{Re} > 4000$  the flow becomes turbulent and  $f$  is a function of both  $\text{Re}$  and relative pipe roughness ( $e/d$ ). At high  $\text{Re}$ ,  $f$  eventually depends only on  $e/d$ ; defining the region referred to as fully turbulent flow. This is the region in [Figure 3.4.1](#) where the lines for different  $e/d$  become horizontal ( $e$  is the equivalent roughness height and  $d$  pipe diameter). The  $\text{Re}_D$  at which this occurs depends on the pipe roughness. Laminar flow in pipes is unusual. For example, for water flowing in a 0.3-m-diameter pipe, the velocity would have to be below 0.02 m/sec for laminar flow to exist. Therefore, most practical pipe flow problems are in the turbulent region.

Using the Moody chart in [Figure 3.4.1](#) to get  $f$  requires that  $\text{Re}$  and  $e/d$  be known. Calculating  $\text{Re}$  is direct if the water temperature, velocity, and pipe diameter are known. The problem is obtaining a good value for  $e$ . Typical values of  $e$  are listed in [Figure 3.4.1](#). These values should be considered as guides only and not used if more-exact values can be obtained from the pipe supplier.

Since roughness may vary with time due to buildup of solid deposits or organic growths,  $f$  is also time dependent. Manufacturing tolerances also cause variations in the pipe diameter and surface roughness. Because of these factors, the friction factor for any pipe can only be approximated. A designer is required to use good engineering judgment in selecting a design value for  $f$  so that proper allowance is made for these uncertainties.

FIGURE 3.4.1 The Moody diagram.

For noncircular pipes, the only change in the friction loss equation is the use of an equivalent diameter — based on the hydraulic radius ( $R$ ), i.e.,  $d = 4R$  — in place of the circular pipe diameter  $d$ .  $R$  is the ratio of the flow area to the wetter perimeter.

Wood (1966) developed equations which can be used in place of the Moody diagram to estimate  $f$  for  $Re > 10^4$  and  $10^{-5} < k < 0.04$  ( $k = e/d$ ).

$$f = a + bRe^{-c} \tag{3.4.9}$$

$$a = 0.094k^{0.225} + 0.53k, \quad b = 88k^{0.44}, \quad c = 1.62k^{0.134}$$

The practical problem is still obtaining a reliable value for  $e$ . It cannot be directly measured but must be determined from friction loss tests of the pipe.

An exact solution using the Darcy–Weisbach equation can require a trial-and-error solution because of the dependency of  $f$  on  $Re$  if either the flow or pipe diameter are not known. A typical approach to solving this problem is to estimate a reasonable fluid velocity to calculate  $Re$  and obtain  $f$  from the Moody chart or Equation (3.4.9). Next, calculate a new velocity and repeat until the solution converges. Converging on a solution is greatly simplified with programmable calculators and a variety of software available for computer.

For long gravity flow pipelines, the starting point in selecting the pipe diameter is to determine the smallest pipe that can pass the required flow without friction loss exceeding the available head. For pumped systems, the selection must be based on an economic analysis that compares the pipe cost with the cost of building and operating the pumping plant.

**Local Losses**

Flow through valves, orifices, elbows, transitions, etc. causes flow separation which results in the generation and dissipation of turbulent eddies. For short systems containing many bends, valves, tees,

etc. local or minor losses can exceed friction losses. The head loss  $h_l$  associated with the dissipation caused by a minor loss is proportional to the velocity head and can be accounted for as a minor or local loss using the following equation.

$$h_l = K_l \frac{Q^2}{(2gA_m^2)} \quad (3.4.10)$$

in which  $K_l$  is the minor loss coefficient and  $A_m$  is the area of the pipe at the inlet to the local loss. The loss coefficient  $K_l$  is analogous to  $fL/d$  in Equation 3.4.7.

The summation of all friction and local losses in a pipe system can be expressed as

$$H_f = h_f + h_l \quad (3.4.11)$$

$$H_f = \left[ \sum \left( \frac{fL}{2gdA_p^2} \right) + \sum \left( \frac{K_l}{2gA_m^2} \right) \right] Q^2 = CQ^2 \quad (3.4.12)$$

in which

$$C = \sum \left( \frac{fL}{2gdA_p^2} \right) + \sum \left( \frac{K_l}{2gA_m^2} \right) \quad (3.4.13)$$

It is important to use the correct pipe diameter for each pipe section and local loss.

In the past some have expressed the local losses as an equivalent pipe length:  $L/d = K_l/f$ . It simply represents the length of pipe that produces the same head loss as the local or minor loss. This is a simple, but not a completely accurate method of including local losses. The problem with this approach is that since the friction coefficient varies from pipe to pipe, the equivalent length will not have a unique value. When local losses are truly minor, this problem becomes academic because the error only influences losses which make up a small percentage of the total. For cases where accurate evaluation of all losses is important, it is recommended that the minor loss coefficients  $K_l$  be used rather than an equivalent length.

The challenging part of making minor loss calculations is obtaining reliable values of  $K_l$ . The final results cannot be any more accurate than the input data. If the pipe is long, the friction losses may be large compared with the minor losses and approximate values of  $K_l$  will be sufficient. However, for short systems with many pipe fittings, the local losses can represent a significant portion of the total system losses, and they should be accurately determined. Numerous factors influence  $K_l$ . For example, for elbows,  $K_l$  is influenced by the shape of the conduit (rectangular vs. circular), by the radius of the bend, the bend angle, the Reynolds number, and the length of the outlet pipe. For dividing or combining tees or Y-branches, the percent division of flow and the change in pipe diameter must also be included when estimating  $K_l$ . One factor which is important for systems where local losses are significant is the interaction between components placed close together. Depending on the type, orientation, and spacing of the components, the total loss coefficient may be greater or less than the simple sum of the individual  $K_l$  values.

Comparing the magnitude of  $\Sigma(fL/2gA^2)$  to  $\Sigma(K_l/2gA_m^2)$  will determine how much care should be given to the selection of the  $K_l$  values. Typical values of  $K_l$  are listed in Table 3.4.1 (Tullis, 1989). When more comprehensive information on loss coefficients is needed, the reader is referred to Miller (1990).

**TABLE 3.4.1 Minor Loss Coefficients**

Item	$K_l$									
	Typical Value					Typical Range				
Pipe inlets										
Inward projecting pipe	0.78					0.5–0.9				
Sharp corner-flush	0.50					—				
Slightly rounded	0.20					0.04–0.5

## Pipe Design

### Pipe Materials

Materials commonly used for pressure pipe transporting liquids are ductile iron, concrete, steel, fiberglass, PVC, and polyolefin. Specifications have been developed by national committees for each of these pipe materials. The specifications discuss external loads, internal design pressure, available sizes, quality of materials, installation practices, and information regarding linings. Standards are available from the following organizations:

- American Water Works Association (AWWA)
- American Society for Testing and Materials (ASTM)
- American National Standards Institute (ANSI)
- Canadian Standards Association (CSA)

Federal Specifications (FED)  
Plastic Pipe Institute (PPI)

In addition, manuals and other standards have been published by various manufacturers and manufacturer's associations. All of these specifications and standards should be used to guide the selection of pipe material. ASCE (1992) contains a description of each of these pipe materials and a list of the specifications for the various organizations which apply to each material. It also discusses the various pipe-lining materials available for corrosion protection.

For air- and low-pressure liquid applications one can use unreinforced concrete, corrugated steel, smooth sheet metal, spiral rib (sheet metal), and HDPE (high-density polyethylene) pipe. The choice of a material for a given application depends on pipe size, pressure requirements, resistance to collapse from internal vacuums, external loads, resistance to internal and external corrosion, ease of handling and installing, useful life, and economics.

### Pressure Class Guidelines

Procedures for selecting the pressure class of pipe vary with the type of pipe material. Guidelines for different types of materials are available from AWWA, ASTM, ANSI, CSA, FED, PPI and from the pipe manufacturers. These specifications should be obtained and studied for the pipe materials being considered.

The primary factors governing the selection of a pipe pressure class are (1) the maximum steady state operating pressure, (2) surge and transient pressures, (3) external earth loads and live loads, (4) variation of pipe properties with temperature or long-time loading effects, and (5) damage that could result from handling, shipping, and installing or reduction in strength due to chemical attack or other aging factors. The influence of the first three items can be quantified, but the last two are very subjective and are generally accounted for with a safety factor which is the ratio of the burst pressure to the rated pressure.

There is no standard procedure on how large the safety factor should be or on how the safety factor should be applied. Some may feel that it is large enough to account for all of the uncertainties. Past failures of pipelines designed using this assumption prove that it is not always a reliable approach. The procedure recommended by the author is to select a pipe pressure class based on the internal design pressure (IDP) defined as

$$\text{IDP} = (P_{\max} + P_s) \text{SF} \quad (3.4.14)$$

in which  $P_{\max}$  is the maximum steady state operating pressure,  $P_s$  is the surge or water hammer pressure, and SF is the safety factor applied to take care of the unknowns (items 3 to 5) just enumerated. A safety factor between 3 and 4 is typical.

The maximum steady state operating pressure ( $P_{\max}$ ) in a gravity flow system is usually the difference between the maximum reservoir elevation and the lowest elevation of the pipe. For a pumped system it is usually the pump shutoff head calculated based on the lowest elevation of the pipe.

Surge and transient pressures depend on the specific pipe system design and operation. Accurately determining  $P_s$  requires analyzing the system using modern computer techniques. The most commonly used method is the "Method of Characteristics" (Tullis, 1989; Wylie and Streeter, 1993). Some of the design standards give general guidelines to predict  $P_s$  that can be used if a detailed transient analysis is not made. However, transients are complex enough that simple "rules of thumb" are seldom accurate enough. Transients are discussed again in a later subsection.

Selection of wall thickness for larger pipes is often more dependent on collapse pressure and handling loads than it is on burst pressure. A thin-wall, large-diameter pipe may be adequate for resisting relatively high internal pressures but may collapse under negative internal pressure or, if the pipe is buried, the soil and groundwater pressure plus live loads may be sufficient to cause collapse even if the pressure inside the pipe is positive.

## External Loads

There are situations where the external load is the controlling factor determining if the pipe will collapse. The magnitude of the external load depends on the diameter of the pipe, the pipe material, the ovality (out of roundness) of the pipe cross section, the trench width, the depth of cover, the specific weight of the soil, the degree of soil saturation, the type of backfill material, the method used to backfill, the degree of compaction, and live loads. The earth load increases with width and depth of the trench, and the live load reduces with depth of cover. The cumulative effect of all these sources of external loading requires considerable study and analysis.

There are no simple guidelines for evaluating external pipe loads. Because of the complexity of this analysis, the default is to assume that the safety factor is adequate to account for external loads as well as the other factors already mentioned. One should not allow the safety factor to replace engineering judgment and calculations. One option to partially compensate for the lack of a detailed analysis is to use a higher-pressure class of pipe in areas where there will be large live loads or where the earth loading is unusually high. One should consider the cost of a pipe failure caused by external loads compared with the cost of using a thicker pipe or the cost of performing a detailed analysis. Those interested in the details of performing calculations of earth loading should be Spranger and Handy, 1973.

## Limiting Velocities

There are concerns about upper and lower velocity limits. If the velocity is too low, problems may develop due to settling of suspended solids and air being trapped at high points and along the crown of the pipe. The safe lower velocity limit to avoid collecting air and sediment depends on the amount and type of sediment and on the pipe diameter and pipe profile. Velocities greater than about 1 m/sec (3 ft/sec) are usually sufficient to move trapped air to air release valves and keep the sediment in suspension.

Problems associated with high velocities are (1) erosion of the pipe wall or liner (especially if coarse suspended sediment is present), (2) cavitation at control valves and other restrictions, (3) increased pumping costs, (4) removal of air at air release valves, (5) increased operator size and concern about valve shaft failures due to excessive flow torques, and (6) an increased risk of hydraulic transients. Each of these should be considered before making the final pipe diameter selection. A typical upper velocity for many applications is 6 m/sec (20 ft/sec). However, with proper pipe design and analysis (of the preceding six conditions), plus proper valve selection, much higher velocities can be tolerated. A typical upper velocity limit for standard pipes and valves is about 6 m/sec (20 ft/sec). However, with proper design and analysis, much higher velocities can be tolerated.

## Valve Selection

Valves serve a variety of functions. Some function as isolation or block valves that are either full open or closed. Control valves are used to regulate flow or pressure and must operate over a wide range of valve openings. Check valves prevent reverse flow, and air valves release air during initial filling and air that is collected during operation and admit air when the pipe is drained.

## Control Valves

For many flow control applications it is desirable to select a valve that has linear control characteristics. This means that if you close the valve 10%, the flow reduces about 10%. Unfortunately, this is seldom possible since the ability of a valve to control flow depends as much on the system as it does on the design of the valve. The same valve that operates linearly in one system may not in another.

Selecting the proper flow control valve should consider the following criteria:

1. The valve should not produce excessive pressure drop when full open.
2. The valve should control over at least 50% of its movement.
3. At maximum flow, the operating torque must not exceed the capacity of the operator or valve shaft and connections.
4. The valve should not be subjected to excessive cavitation.

5. Pressure transients should not exceed the safe limits of the system.
6. Some valves should not be operated at very small openings. Other valves should be operated near full open.

*Controllability.* To demonstrate the relationship between a valve and system, consider a butterfly valve that will be used to control the flow between two reservoirs with an elevation difference of  $\Delta Z$ . System A is a short pipe (0.3 m dia., 100 m long,  $\Delta Z = 10$  m) where pipe friction is small  $fL/2gdA_p^2 = 46.9$ , and System B is a long pipe (0.3 m dia., 10,000 m long,  $\Delta Z = 200$  m) with high friction  $fL/2gdA_p^2 = 4690$ . Initially, assume that the same butterfly valve will be used in both pipes and it will be the same size as the pipe. The flow can be calculated using the energy equation (Equation 3.4.5) and the system loss equation (Equation (3.4.12):

$$Q = \sqrt{\frac{\Delta Z}{\left[ \sum \left( \frac{fL}{2gdA_p^2} \right) + \sum \left( \frac{K_l}{2gA_m^2} \right) \right]}} \tag{3.4.15}$$

For the valve, assume that the  $K_l$  full open is 0.2 and at 50% open it is 9.0. Correspondingly,  $K_l/2gA_m^2 = 1.905$  and 85.7. For System A, the flow with the valve full open will be 0.453 m<sup>3</sup>/sec and at 50% open 0.275 m<sup>3</sup>/sec, a reduction of 39%. Repeating these calculations over the full range of valve openings would show that the flow for System A reduces almost linearly as the valve closes.

For System B, the flow with the valve full open will be 0.206 m<sup>3</sup>/sec and at 50% open 0.205 m<sup>3</sup>/sec, a reduction of less than 1%. For System B the valve does not control until the valve loss, expressed by  $K_l/2gA_m^2$  becomes a significant part of the friction term (4690). The same valve in System B will not start to control the flow until it has closed more than 50%. A line-size butterfly valve is obviously not a good choice for a control valve in System B. One solution to this problem is to use a smaller valve. If the butterfly valve installed in System B was half the pipe diameter, it would control the flow over more of the stroke of the valve.

The range of opening over which the valve controls the flow also has a significant effect on the safe closure time for control valves. Transient pressures are created when there is a sudden change in the flow. Most valve operators close the valve at a constant speed. If the valve does not control until it is more than 50% closed, over half of the closing time is wasted and the effective valve closure time is less than half the total closing time. This will increase the magnitude of the transients that will be generated.

*Torque.* To be sure that the valve shaft, connections, and operator are properly sized, the maximum torque or thrust must be known. If the maximum force exceeds operator capacity, it will not be able to open and close the valve under extreme flow conditions. If the shaft and connectors are underdesigned, the valve may fail and slam shut causing a severe transient.

For quarter-turn valves, the force required to operate a valve consists of seating, bearing, and packing friction, hydrodynamic (flow) forces, and inertial forces. These forces are best determined experimentally. A key step in applying experimental torque information is the determination of the flow condition creating maximum torque. This requires that the system be analyzed for all possible operating conditions and valve openings. For a given size and type of valve, the flow torque depends on the torque coefficient (which is dependent on the specific valve design) and the pressure drop which, in turn, depends on the flow. In short systems where there is little friction loss and high velocities, a quarter-turn valve will see maximum torques at large openings where the flow is high. In long systems with high reservoir heads and smaller velocities, the same valve will see maximum torque at small openings where the pressure drop is high.

One situation where it is easy to overlook the condition causing maximum torque is with parallel pumps. Each pump normally will have a discharge control valve. The maximum system flow occurs with all three pumps operating. However, the flow and the torque for any of the pump discharge valves

is maximum for only one pump operating. One specific example (Tullis, 1989) showed that the torque on a butterfly valve was three times higher when one pump was operating compared with three pumps operating in parallel.

*Cavitation.* Cavitation is frequently an important consideration in selection and operation of control valves. It is necessary to determine if cavitation will exist, evaluate its intensity, and estimate its effect on the system and environment. Cavitation can cause noise, vibration, and erosion damage and can decrease performance. The analysis should consider the full range of operation. Some valves cavitate worst at small openings and others cavitate heavily near full open. It depends on both the system and the valve design. If cavitation is ignored in the design and selection of the valves, repairs and replacement of the valves may be necessary. Information for making a complete cavitation analysis is beyond the scope of this section. Detailed information on the process to design for cavitation is contained in Tullis (1989; 1993).

The first step in a cavitation analysis is selecting the acceptable level of cavitation. Experimental data are available for four limits: incipient (light, intermittent noise), critical (light, steady noise), incipient damage (pitting damage begins), and choking (very heavy damage and performance drops off). Limited cavitation data are available for each of these limits (Tullis, 1989; 1993). Choosing a cavitation limit depends on several factors related to the operating requirements, expected life, location of the device, details of the design, and economics. For long-term operation of a control valve in a system where noise can be tolerated, the valve should never operate beyond incipient damage. In systems where noise is objectionable, critical cavitation would be a better operating limit.

Using a choking cavitation as a design limit is often misused. It is generally appropriate as a design limit for valves that only operate for short periods of time, such as a pressure relief valve. The intensity of cavitation and the corresponding noise vibration and erosion damage at the valve are at their maximum just before a valve chokes. If the valve operates beyond choking (sometimes referred to as supercavitation), the collapse of the vapor cavities occurs remote from the valve. Little damage is likely to occur at the valve, but farther downstream serious vibration and material erosion problems can occur.

If the cavitation analysis indicates that the valve, orifice, or other device will be operating at a cavitation level greater than can be tolerated, various techniques can be used to limit the level of cavitation. One is to select a different type of valve. Recent developments in valve design have produced a new generation of valves that are more resistant to cavitation. Most of them operate on the principle of dropping the pressure in stages. They usually have multiple paths with numerous sharp turns or orifices in series. Two limitations to these valves are that they often have high pressure drops (even when full open), and they are only usable with clean fluids.

A similar approach is to place multiple conventional valves in series or a valve in series with orifice plates. Proper spacing of valves and orifices placed in series is important. The spacing between valves depends upon the type. For butterfly valves it is necessary to have between five and eight diameters of pipe between valves to prevent flutter of the leaf of the downstream valve and to obtain the normal pressure drop at each valve. For globe, cone, and other types of valves, it is possible to bolt them flange to flange and have satisfactory operation.

For some applications another way to suppress cavitation is to use a free-discharge valve that is vented so cavitation cannot occur. There are valves specifically designed for this application. Some conventional valves can also be used for free discharge, if they can be adequately vented.

Cavitation damage can be suppressed by plating critical areas of the pipe and valve with cavitation-resistant materials. Based on tests using a magnetostriction device, data show that there is a wide variation in the resistance of the various types of material. Limited testing has been done on the erosion resistance of different materials and coating to cavitation in flowing systems. The available data show that there is less variation in the damage resistance of materials in actual flowing systems. However, experience has shown the plating parts of the valve with the right material will extend valve life.

Injecting air to suppress cavitation is a technique which has been used for many years with varying degrees of success. The most common mistake is placing the air injection port in the wrong location so

the air does not get to the cavitation zone. If an adequate amount of air is injected into the proper region, the noise, vibrations, and erosion damage can be significantly reduced. The air provides a cushioning effect reducing the noise, vibration, and erosion damage. If the system can tolerate some air being injected, aeration is usually the cheapest and best remedy for cavitation.

*Transients.* Transient pressures can occur during filling and flushing air from the line, while operating valves, and when starting or stopping pumps. If adequate design provisions and operational procedures are not established, the transient pressure can easily exceed the safe operating pressure of the pipe. A system should be analyzed to determine the type and magnitudes of possible hydraulic transients. The basic cause is rapid changes in velocity. The larger the incremental velocity change and the faster that change takes place, the greater will be the transient pressure. If the piping system is not designed to withstand the high transient pressures, or if controls are not included to limit the pressure, rupture of the pipe or damage to equipment can result.

All pipelines experience transients. Whether or not the transient creates operational problems or pipe failure depends upon its magnitude and the ability of the pipes and mechanical equipment to tolerate high pressures without damage. For example, an unreinforced concrete pipeline may have a transient pressure head allowance of only a meter above its operating pressure before damage can occur. For such situations even slow closing of control valves or minor interruptions of flow due to any cause may create sufficient transient pressures to rupture the pipeline. In contrast, steel and plastic pipes can take relatively high transient pressures without failure.

Transients caused by slow velocity changes, such as the rise and fall of the water level in a surge tank, are called surges. Surge analysis, or “rigid column theory” involves mathematical or numerical solution of simple ordinary differential equations. The compressibility of the fluid and the elasticity of the conduit are ignored, and the entire column of fluid is assumed to move as a rigid body.

When changes in velocity occur rapidly, both the compressibility of the liquid and the elasticity of the pipe must be included in the analysis. This procedure is often called “elastic” or “waterhammer” analysis and involves tracking acoustic pressure waves through the pipe. The solution requires solving partial differential equations.

An equation predicting the head rise  $\Delta H$  caused by a sudden change of velocity  $\Delta V = V_2 - V_1$  can be derived by applying the unsteady momentum equation to a control volume of a section of the pipe where the change of flow is occurring. Consider a partial valve closure which instantly reduces the velocity by an amount  $\Delta V$ . Reduction of the velocity can only be accomplished by an increase in the pressure upstream from the valve. This creates a pressure wave of magnitude  $\Delta H$  which travels up the pipe at the acoustic velocity  $a$ . The increased pressure compresses the liquid and expands the pipe. The transient head rise due to an incremental change in velocity is

$$\Delta H = -a\Delta V/g, \quad \text{for } a \gg \Delta V \quad (3.4.16)$$

This equation is easy to use for multiple incremental changes of velocity as long as the first wave has not been reflected back to the point of origin.

The derivation of Equation (3.4.16) is based on an assumption of an instant velocity change. For a valve closing at the end of the pipe, instant closure actually refers to a finite time. It is the longest time that a valve can be closed and still cause a pressure rise equal to that of an instant closure. Normally, it is equal to  $2L/a$  sec (which is the time required for the first pressure wave to travel to and from the other end of the pipe of length  $L$ ); the head rise at the valve will be the same as if the valve were closed instantly. The  $2L/a$  time is therefore often the instant closure time.

For a valve at the end of a long pipeline, the instant closure time can be considerably greater than  $2L/a$ . This is because when the friction loss coefficient  $fL/d$  is much greater than the loss coefficient for the valve  $K_v$ , the valve can be closed a long way before the flow changes. This dead time must be added to the  $2L/a$  time to identify the actual instant closure time. To avoid the maximum potential transient pressure rise, the valve must be closed much slower than the instant closure time.

Computational techniques for estimating transient pressures caused by unsteady flow in pipelines are too complex to be done with simple hand calculations. The solution involves solving partial differential equations based on the equations of motion and continuity. These equations are normally solved by the method of characteristics. This technique transforms the equations into total differential equations. After integration, the equations can be solved numerically by finite differences. This analysis provides equations that can be used to predict the flow and head at any interior pipe section at any time (Tullis, 1989; Wiley and Streeter, 1993).

To complete the analysis, equations describing the boundary conditions are required. Typical boundary conditions are the connection of a pipe to a reservoir, a valve, changes in pipe diameter or material, pipe junctions, etc. Friction loss is included in the development of the basic equations and minor losses are handled as boundary conditions. The analysis properly models friction and the propagation and reflections of the pressure wave. It can also be used for surge calculations.

It is recommended that every pipe system should have at least a cursory transient analysis performed to identify the possibility of serious transients and decide whether or not a detailed analysis is necessary. If an analysis indicates that transients are a problem, the types of solutions available to the engineer include

1. Increasing the closing time of control valves.
2. Using a smaller valve to provide better control.
3. Designing special facilities for filling, flushing, and removing air from pipelines.
4. Increasing the pressure class of the pipeline.
5. Limiting the flow velocity.
6. Using pressure relief valves, surge tanks, air chambers, etc.

### Check Valves

Selecting the wrong type or size of check valve can result in poor performance, severe transients, and frequent repairs (Kalsi, 1993). Proper check valve selection requires understanding the characteristics of the various types of check valves and analyzing how they will function as a part of the system in which they will be installed. A check valve that operates satisfactorily in one system may be totally inadequate in another. Each valve type has unique characteristics that give it advantages or disadvantages compared with the others. The characteristics of check valves that describe their hydraulic performance and which should be considered in the selection process include

1. Opening characteristics, i.e., velocity vs. disk position data.
2. Velocity required to fully open and firmly backseat the disk.
3. Pressure drop at maximum flow.
4. Stability of the disk at partial openings.
5. Sensitivity of disk flutter to upstream disturbances.
6. Speed of valve closure compared with the rate of flow reversal of the system.

Disk stability varies with flow rate, disk position, and upstream disturbances and is an important factor in determining the useful life of a check valve. For most applications it is preferable to size the check valve so that the disk is fully open and firmly backseated at normal flow rates. One of the worst design errors is to oversize a check valve that is located just downstream from a disturbance such as a pump, elbow, or control valve. If the disk does not fully open, it will be subjected to severe motion that will accelerate wear. To avoid this problem, it may be necessary to select a check valve that is smaller than the pipe size.

The transient pressure rise generated at check valve closure is another important consideration. The pressure rise is a function of how fast the valve disk closes compared with how fast the flow in the system reverses. The speed that the flow in a system reverses depends on the system. In systems where rapid flow reversals occur, the disk can slam shut causing a pressure transient (Thorley, 1989).

The closing speed of a valve is determined by the mass of the disk, the forces closing the disk, and the distance of travel from full open to closed. Fast closing valves have the following properties: the disk (including all moving parts) is lightweight, closure is assisted by springs, and the full stroke of the disk is short. Swing check valves are the slowest-closing valves because they violate all three of these criteria; i.e., they have heavy disks, no springs, and long disk travel. The nozzle check valve is one of the fastest-closing valves because the closing element is light, is spring loaded, and has a short stroke. The silent, duo, double door, and lift check valves with springs are similar to nozzle valves in their closing times, mainly because of the closing force of the spring.

Systems where rapid flow reversals occur include parallel pumps, where one pump is stopped while the others are still operating, and systems that have air chambers or surge tanks close to the check valve. For these systems there is a high-energy source downstream from the check valve to cause the flow to quickly reverse. As the disk nears its seat, it starts to restrict the reverse flow. This builds up the pressure, accelerates the disk, and slams it into the seat. Results of laboratory experiments, field tests, and computer simulations show that dramatic reductions in the transient pressures at disk closure can be achieved by replacing a slow-closing swing check valve with a fast-acting check valve. For example, in a system containing parallel pumps where the transient was generated by stopping one of the pumps, the peak transient pressure was reduced from 745 to 76 kPa when a swing check was replaced with a nozzle check valve. Such a change improved performance and significantly reduced maintenance.

### Air Valves

There are three types of automatic air valves: (1) air/vacuum valves, (2) air release valves, and (3) combination valves. The air/vacuum valve is designed for releasing air while the pipe is being filled and for admitting air when the pipe is being drained. The valve must be large enough that it can admit and expel large quantities of air at a low pressure differential. The outlet orifice is generally the same diameter as the inlet pipe.

These valves typically contain a float, which rises and closes the orifice as the valve body fills with water. Once the line is pressurized, this type of valve cannot reopen to remove air that may subsequently accumulate until the pressure becomes negative, allowing the float to drop. If the pressure becomes negative during a transient or while draining, the float drops and admits air into the line. For thin-walled pipes that can collapse under internal vacuums, the air/vacuum valves should be sized for a full pipe break at the lowest pipe elevation. The vacuum valve must supply an air flow equal to the maximum drainage rate of the water from the pipe break and at an internal pipe pressure above the pipe collapse pressure.

The critical factor in sizing air/vacuum valves is usually the air flow rate to protect the pipe from a full pipe break. Since a pipe is filled much slower than it would drain during a full break, the selected valve will be sized so that the air is expelled during filling without pressurizing the pipe. Sizing charts are provided by manufacturers.

Air release valves contain a small orifice and are designed to release small quantities of pressurized air that are trapped during filling and that accumulate after initial filling and pressurization. The small orifice is controlled by a plunger activated by a float at the end of a lever arm. As air accumulates in the valve body, the float drops and opens the orifice. As the air is expelled, the float rises and closes off the orifice. Sizing air release valves requires an estimate of the amount of pressurized air that must be expelled. This is determined by the filling procedure and any source of air that can be admitted into the pipe or be degassed from the liquid during operation.

The combination valve is actually two valves: a large valve that functions as an air/vacuum valve and a small one that functions as an air release valve. The installation can either consist of an air/vacuum valve and an air release valve plumbed in parallel, or the two can be housed in a single valve body. Most air valve installations require combination valves.

One caution is that manual air release valves should be avoided because improper operation of them can be very dangerous. If the system is pressurized with the manual air valves closed, the trapped air

will be pressurized to full system pressure. When the air valve is manually opened, the pressurized air can cause rapid acceleration of the liquid and generate serious transients when the water is decelerated as it hits the air valve. If manual air valves are installed, they should be very small so the air release rate is controlled to a safe rate.

Locating air valves in a piping system depends on the pipe profile, pipe length, and flow rates. Preferably, pipes should be laid to grade with valves placed at the high points or at intervals if there are no high points. One should use engineering judgment when defining a high point. If the pipe has numerous high points that are close together, or if the high points are not pronounced, it will not be necessary to have an air valve at each high point. If the liquid flow velocity is above about 1 m/sec (3 ft/sec), the flowing water can move the entrained air past intermediate high points to a downstream air valve. Releasing the air through an air valve prevents any sizable air pockets under high pressure from forming in the pipe. Trapped air under high pressure is extremely dangerous.

Velocity of the flow during filling is important. A safe way to fill a pipe is to limit the initial fill rate to an average flow velocity of about 0.3 m/sec (1 ft/sec) until most of the air is released and the air/vacuum valves close. The next step is to flush the system at about 1 m/sec (3 ft/sec), at a low system pressure, to flush the remaining air to an air release valve. It is important that the system not be pressurized until the air has been removed. Allowing large quantities of air under high pressure to accumulate and move through the pipe can generate severe transients. This is especially true if the compressed air is allowed to pass through a control valve or manual air release valve. When pressurized air flows through a partially open valve, the sudden acceleration and deceleration of the air and liquid can generate high pressure transients.

## Pump Selection

Optimizing the life of a water supply system requires proper selection, operation, and maintenance of the pumps. During the selection process, the designer must be concerned about matching the pump performance to the system requirements and must anticipate problems that will be encountered when the pumps are started or stopped and when the pipe is filled and drained. The design should also consider the effect of variations in flow requirements, and also anticipate problems that will be encountered due to increased future demands and details of the installation of the pumps.

Selecting a pump for a particular service requires matching the system requirements to the capabilities of the pump. The process consists of developing a system equation by applying the energy equation to evaluate the pumping head required to overcome the elevation difference, friction, and minor losses. For a pump supplying water between two reservoirs, the pump head required to produce a given discharge can be expressed as

$$H_p = \Delta Z + H_f \quad (3.4.17)$$

or

$$H_p = \Delta Z + CQ^2 \quad (3.4.18)$$

in which the constant  $C$  is defined by Equation (3.4.13).

Figure 3.4.2 shows a system curve for a pipe having an 82-m elevation lift and moderate friction losses. If the elevation of either reservoir is a variable, then there is not a single curve but a family of curves corresponding to differential reservoir elevations.

The three pump curves shown in Figure 3.4.2 represent different impeller diameters. The intersections of the system curve with the pump curves identify the flow that each pump will supply if installed in that system. For this example both A and B pumps would be a good choice because they both operate at or near their best efficiency range. Figure 3.4.2 shows the head and flow that the B pump will produce

FIGURE 3.4.2 Pump selection for a single pump.

when operating in that system are 97 m and 450 L/m. The net positive suction head (NPSH) and brake horsepower (bhp) are obtained as shown in the figure.

The selection process is more complex when the system demand varies, either due to variations in the water surface elevation or to changing flow requirements. If the system must operate over a range of reservoir elevations, the pump should be selected so that the system curve, based on the mean (or the most frequently encountered) water level, intersects the pump curve near the midpoint of the best efficiency range. If the water level variation is not too great, the pump may not be able to operate efficiently over the complete flow range.

The problem of pump selection also becomes more difficult when planning for future demands or if the pumps are required to supply a varying flow. If the flow range is large, multiple pumps or a variable-speed drive may be needed. Recent developments in variable-frequency drives for pumps make them a viable alternative for systems with varying flows. Selection of multiple pumps and the decision about installing them in parallel or in series depend on the amount of friction in the system. Parallel installations are most effective for low-friction systems. Series pumps work best in high-friction systems.

For parallel pump operation the combined two pump curve is constructed by adding the flow of each pump. Such a curve is shown in Figure 3.4.3 (labeled 2 pumps). The intersection of the two-pump curve with the system curve identifies the combined flow for the two pumps. The pump efficiency for each pump is determined by projecting horizontally to the left to intersect the single-pump curve. For this example, a C pump, when operating by itself, will have an efficiency of 83%. With two pumps operating, the efficiency of each will be about 72%. For the two pumps to operate in the most efficient way, the selection should be made so the system curve intersects the single-pump curve to the right of its best efficiency point.

Starting a pump with the pipeline empty will result in filling at a very rapid rate because initially there is little friction to build backpressure. As a result, the pump will operate at a flow well above the design flow. This may cause the pump to cavitate, but the more serious problem is the possibility of high pressures generated by the rapid filling of the pipe. Provisions should be made to control the rate of filling to a safe rate. Start-up transients are often controlled by starting the pump against a partially open discharge valve located near the pump and using a bypass line around the pump. This allows the system to be filled slowly and safely. If the pipe remains full and no air is trapped, after the initial filling, subsequent start-up of the pumps generally does not create any serious problem. Adequate air release valves should be installed to release the air under low pressure.

**FIGURE 3.4.3** Selection of parallel pumps.

For some systems, stopping the pump, either intentionally or accidentally, can generate high pressures that can damage the pipe and controls. If the design process does not consider these potential problems, the system may not function trouble free. Downtime and maintenance costs may be high. Not all systems will experience start-up and shutdown problems, but the design should at least consider the possibility. The problem is more severe for pipelines that have a large elevation change and multiple high points. The magnitude of the transient is related to the length and profile of the pipeline, the pump characteristics, the magnitude of the elevation change, and the type of check valve used. The downsurge caused by stopping the pump can cause column separation and high pressures due to flow reversals and closure of the check valves. Surge-protection equipment can be added to such systems to prevent damage and excessive maintenance.

Another operational problem occurs with parallel pumps. Each pump must have a check valve to prevent reverse flow. When one of the pumps is turned off, the flow reverses almost immediately in that line because of the high manifold pressure supplied by the operating pumps. This causes the check valve to close. If a slow-closing check valve is installed, the flow can attain a high reverse velocity before the valve closes, generating high pressure transients.

Numerous mechanical devices and techniques have been used to suppress pump shutdown transients. These include increasing the rotational inertia of the pump, use of surge tanks or air chambers near the pump, pressure relief valves, vacuum-breaking valves, and surge-anticipating valves. Selection of the proper transient control device will improve reliability, extend the economic life of the system, and reduce maintenance. Failure to complete a transient analysis and include the required controls will have the opposite effect. A system is only as good as it is designed to be.

## Other Considerations

### Feasibility Study

Designing pipelines, especially long transmission lines, involves more than just determining the required type and size of pipe. A starting point for major projects is usually a feasibility study which involves

social, environmental, political, and legal issues, as well as an economic evaluation of the engineering alternatives developed during the preliminary design. The preliminary design should identify the scope of the project and all major features that influence the cost or viability. Since local laws, social values, and environmental concerns vary significantly between geographic areas, the engineer must be aware of the problems unique to the area.

Choices that affect the economics of the project include alternative pipe routes, amount of storage and its effect on reliability and controllability of flow, choice of pipe material, diameter and pressure class, provision for future demands, etc. In making decisions one must consider both the engineering and economic advantages of the alternatives. Reliability, safety, maintenance, operating, and replacement costs must all be given their proper value. The analysis should consider (1) expected life of the pipe, which is a function of the type of pipe material and the use of linings or protective coatings; (2) economic life, meaning how long the pipe will supply the demand; (3) planning for future demand; (4) pumping cost vs. pipe cost; and (5) provisions for storage.

During the feasibility study only a general design has been completed so a detailed analysis of all hydraulic problems and their solutions is not available. Even so, it is necessary to anticipate the need for special facilities or equipment and problems such as safe filling, provisions for draining, cavitation at control valves, and transient problems caused by valve or pump operation. Provisions should be made for the cost of the detailed analysis, design, and construction costs required to control special operational problems. Attention should also be given to costs associated with winterizing, stream crossings, highways crossing, special geologic or topographic problems, and any other items that would have a significant influence on the cost, reliability, or safety of the project.

### **Storage**

The purposes of storage tanks and intermediate reservoirs include (1) to supply water when there is a temporary interruption of flow from the supply, (2) to provide supplemental water during peak periods, (3) to sectionalize the pipe to reduce mean and transient pressures, (4) to maintain pressure (elevated storage), and (5) to simplify control. Storage also has a significant impact on the control structures, pumping plants, and general operation of the pipeline. If there is adequate storage, large fluctuations in demand can be tolerated. Any mismatch in supply and demand is made up for by an increase or decrease in storage, and valves in the transmission main will require only infrequent adjustments to maintain storage. Pumps can be activated by level controls at the storage tank and not by fluctuations in demand so they can operate for long periods near their design point.

If there is no storage, the system may have to provide continuous fine adjustment of the flow to provide the required flow within safe pressure limits. For gravity systems this may require automatic pressure- or flow-regulating valves. For pumped systems, the variations in flow can cause constant-speed centrifugal pumps to operate both below and above their design point where power consumption is high, efficiency is low, and where there is more chance of operational problems. Selection of a variable-frequency drive can avoid these problems. The selection of multiple pumps vs. a variable-speed pump is primarily a economic decision.

### **Thrust Blocks**

Any time there is a change of pipe alignment, an unbalanced force is developed. The force required to restrain the pipe can be calculated with the two-dimensional, steady state momentum equation. For buried pipelines, this force can be transmitted to the soil with a thrust block. Determining the size of the block and, consequently, the bearing surface area depends on pipe diameter, fluid pressure, deflection angle of the pipe, and bearing capacity of the soil. A convenient monograph for sizing thrust blocks was published in the *Civil Engineering* in 1969 (Morrison, 1969).

### 3.5 Open Channel Flow\*

Frank M. White

#### Definition

The term *open channel flow* denotes the gravity-driven flow of a liquid with a free surface. Technically, we may study any flowing liquid and any gas interface. In practice, the vast majority of open channel flows concern water flowing beneath atmospheric air in artificial or natural channels.

The geometry of an arbitrary channel is shown in **Figure 3.5.1**. The area  $A$  is for the water cross section only, and  $b$  is its top width. The wetted perimeter  $P$  covers only the bottom and sides, as shown, not the surface (whose air resistance is neglected). The water depth at any location is  $y$ , and the channel slope is  $\theta$ , often denoted as  $S_o = \sin \theta$ . All of these parameters may vary with distance  $x$  along the channel. In unsteady flow (not discussed here) they may also vary with time.

**FIGURE 3.5.1** Definition sketch for an open channel.

#### Uniform Flow

A simple reference condition, called *uniform flow*, occurs in a long straight prismatic channel of constant slope  $S_o$ . There is no acceleration, and the water flows at constant depth with fluid weight exactly balancing the wetted wall shear force:  $\rho gLA \sin \theta = \tau_w PL$ , where  $L$  is the channel length. Thus,  $\tau_w = \rho g R_h S_o$ , where  $R_h = A/P$  is called the *hydraulic radius* of the channel. If we relate wall shear stress to the Darcy friction factor  $f$ ,  $\tau_w = (f/8)\rho V^2$ , we obtain the basic uniform flow open channel relation:

$$\text{Uniform flow: } V = \sqrt{\frac{8g}{f}} \sqrt{R_h S_o}, \text{ where } \sqrt{\frac{8g}{f}} = C = \text{Chézy coefficient} \quad (3.5.1)$$

Antoine Chézy first derived this formula in 1769. It is satisfactory to base  $f$  upon the pipe-flow Moody diagram (**Figure 3.4.1**) using the hydraulic diameter,  $D_h = 4R_h$ , as a length scale. That is,  $f = fcn(VD_h/\nu, \epsilon/D_h)$  from the Moody chart. In ordinary practice, however, engineers assume fully rough, high-Reynolds-number flow and use Robert Manning’s century-old correlation:

$$C \approx \frac{\zeta}{n} R_h^{1/6}, \text{ or } V_{\text{uniform}} \approx \frac{\zeta}{n} R_h^{2/3} S_o^{1/2} \text{ and } Q = VA \quad (3.5.2)$$

where  $\zeta$  is a conversion factor equal to 1.0 in SI units and 1.486 in English units. The quantity  $n$  is Manning’s roughness parameter, with typical values, along with the associated roughness heights  $\epsilon$ , listed in **Table 3.5.1**.

### Critical Flow

Since the surface is always atmospheric, pressure head is not important in open channel flows. Total energy  $E$  relates only to velocity and elevation:

$$\text{Specific energy } E = y + \frac{V^2}{2g} = y + \frac{Q^2}{2gA^2}$$

At a given volume flow rate  $Q$ , the energy passes through a minimum at a condition called *critical flow*, where  $dE/dy = 0$ , or  $dA/dy = b = gA^3/Q^2$ :

$$A_{\text{crit}} = \left( \frac{bQ^2}{g} \right)^{1/3} \quad V_{\text{crit}} = \frac{Q}{A_{\text{crit}}} = \left( \frac{gA_{\text{crit}}}{b} \right)^{1/2} \tag{3.5.3}$$

where  $b$  is the top-surface width as in [Figure 3.5.1](#). The velocity  $V_{\text{crit}}$  equals the speed of propagation of a surface wave along the channel. Thus, we may define the Froude number  $Fr$  of a channel flow, for any cross section, as  $Fr = V/V_{\text{crit}}$ . The three regimes of channel flow are

$Fr < 1$ : subcritical flow;     $Fr = 1$ : critical flow;     $Fr > 1$ : supercritical flow

There are many similarities between Froude number in channel flow and Mach number in variable-area duct flow (see Section 3.6).

For a rectangular duct,  $A = by$ , we obtain the simplified formulas

$$V_{\text{crit}} = \sqrt{gy} \quad \text{Fr} = \frac{V}{\sqrt{gy}} \tag{3.5.4}$$

independent of the width of the channel.

**Example 3.5.1**

Water ( $\rho = 998 \text{ kg/m}^3$ ,  $\mu = 0.001 \text{ kg/m} \cdot \text{sec}$ ) flows uniformly down a half-full brick 1-m-diameter circular channel sloping at  $1^\circ$ . Estimate (a)  $Q$ ; and (b) the Froude number.

*Solution 3.5.1 (a).* First compute the geometric properties of a half-full circular channel:

$$A = \frac{\pi}{8}(1 \text{ m})^2 = 0.393 \text{ m}^2; \quad P = \frac{\pi}{2}(1 \text{ m}) = 1.57 \text{ m}; \quad R = \frac{A}{P} = \frac{0.393}{1.57} = 0.25 \text{ m}$$

From Table 3.5.1, for brickwork,  $n \approx 0.015$ . Then, Manning’s formula, Equation (3.5.2) predicts

$$V = \frac{\zeta}{n} R_h^{1/6} S_o^{1/2} = \frac{1.0}{0.015} (0.25)^{1/6} (\sin 1^\circ)^{1/2} \approx 3.49 \frac{\text{m}}{\text{sec}}; \quad Q = 3.49(0.393) \approx \mathbf{1.37 \frac{\text{m}^3}{\text{sec}}} \text{ Solution 3.5.1(a)}$$

The uncertainty in this result is about  $\pm 10\%$ . The flow rate is quite large (21,800 gal/min) because  $1^\circ$ , although seemingly small, is a substantial slope for a water channel.

One can also use the Moody chart. with  $V \approx 3.49 \text{ m/sec}$ , compute  $\text{Re} = \rho V D_h / \mu \approx 3.49 \text{ E6}$  and  $\epsilon / D_h \approx 0.0037$ , then compute  $f \approx 0.0278$  from the Moody chart. Equation (3.5.1) then predicts

$$V = \sqrt{\frac{8g}{f} R_h S_o} = \sqrt{\frac{8(9.81)}{0.0278} (0.25)(\sin 1^\circ)} \approx 3.51 \frac{\text{m}}{\text{sec}}; \quad Q = VA \approx \mathbf{1.38 \frac{\text{m}^3}{\text{sec}}}$$

*Solution 3.5.1 (b).* With  $Q$  known from part (a), compute the critical conditions from Equation (3.5.3):

$$A_{\text{crit}} = \left( \frac{bQ^2}{g} \right)^{1/3} = \left[ \frac{1.0(1.37)^2}{9.81} \right]^{1/3} = 0.576 \text{ m}^2, \quad V_{\text{crit}} = \frac{Q}{A_{\text{crit}}} = \frac{1.37}{0.576} = 2.38 \frac{\text{m}}{\text{sec}}$$

Hence

$$\text{Fr} = \frac{V}{V_{\text{crit}}} = \frac{3.49}{2.38} \approx \mathbf{1.47} \text{ (supercritical) Solution 3.5.1(b)}$$

Again the uncertainty is approximately  $\pm 10\%$ , primarily because of the need to estimate the brick roughness.

**Hydraulic Jump**

In gas dynamics (Section 3.6), a supersonic gas flow may pass through a thin normal shock and exit as a subsonic flow at higher pressure and temperature. By analogy, a supercritical open channel flow may pass through a *hydraulic jump* and exit as a subcritical flow at greater depth, as in Figure 3.5.2. Application of continuity and momentum to a jump in a rectangular channel yields

FIGURE 3.5.2 A two-dimensional hydraulic jump.

$$V_2 = V_1 \frac{y_1}{y_2} \quad y_2 = \frac{y_1}{2} \left[ -1 + \sqrt{1 + 8Fr_1^2} \right] \quad \text{where } Fr_1 = \frac{V_1}{\sqrt{gy_1}} > 1 \quad (3.5.5)$$

Both the normal shock and the hydraulic jump are dissipative processes: the entropy increases and the effective energy decreases. For a rectangular jump,

$$\Delta E = E_1 - E_2 = \frac{(y_2 - y_1)^3}{4y_1y_2} > 0 \quad (3.5.6)$$

For strong jumps, this loss in energy can be up to 85% of  $E_1$ . The second law of thermodynamics requires  $\Delta E > 0$  and  $y_2 > y_1$  or, equivalently,  $Fr_1 > 1$ ,

Note from Figure 3.5.2 that a hydraulic jump is not thin. Its total length is approximately four times the downstream depth. Jumps also occur in nonrectangular channels, and the theory is much more algebraically laborious.

### Weirs

If an open channel flow encounters a significant obstruction, it will undergo rapidly varied changes which are difficult to model analytically but can be correlated with experiment. An example is the *weir* in Figure 3.5.3 (colloquially called a *dam*), which forces the flow to deflect over the top. If  $L \ll Y$ , the weir is termed *sharp-crested*; if  $L = O(Y)$  it is *broad-crested*. Small details, such as the upper front corner radius or the crest roughness, may be significant. The crest is assumed level and of width  $b$  into the paper.

FIGURE 3.5.3 Geometry and notation for flow over a weir.

If there is a free overfall, as in [Figure 3.5.3](#), the flow accelerates from subcritical upstream to critical over the crest to supercritical in the overfall. There is no flow when the excess upstream depth  $H = 0$ . A simple Bernoulli-type analysis predicts that the flow rate  $Q$  over a wide weir is approximately proportional to  $bg^{1/2}H^{3/2}$ . An appropriate correlation is thus

$$Q_{\text{weir}} = C_d b g^{1/2} H^{3/2}, \quad \text{where } C_d = \text{dimensionless weir coefficient} \quad (3.5.7)$$

If the upstream flow is turbulent, the weir coefficient depends only upon geometry, and Reynolds number effects are negligible. If the weir has sidewalls and is narrow, replace width  $b$  by  $(b - 0.1H)$ .

Two recommended empirical correlations for Equation (3.5.7) are as follows:

$$\begin{aligned} \text{Sharp-crested:} \quad C_d &\approx 0.564 + 0.0846 \frac{H}{Y} \quad \text{for } \frac{L}{Y} < 0.07 \\ \text{Broad-crested:} \quad C_d &\approx 0.462 \quad \text{for } 0.08 < \frac{H}{L} < 0.33 \end{aligned} \quad (3.5.8)$$

These data are for wide weirs with a sharp upper corner in front. Many other weir geometries are discussed in the references for this section. Of particular interest is the sharp-edged vee-notch weir, which has no length scale  $b$ . If  $2\theta$  is the total included angle of the notch, the recommended correlation is

$$\text{Vee-notch, angle } 2\theta: \quad Q \approx 0.44 \tan \theta g^{1/2} H^{5/2} \quad \text{for } 10^\circ < \theta \leq 50^\circ \quad (3.5.9)$$

The vee-notch is more sensitive at low flow rates (large  $H$  for a small  $Q$ ) and thus is popular in laboratory measurements of channel flow rates.

A weir in the field will tend to spring free and form a natural *nappe*, or air cavity, as in [Figure 3.5.3](#). Narrow weirs, with sidewalls, may need to be aerated artificially to form a nappe and keep the flow from sliding down the face of the weir. The correlations above assume nappe formation.

### Gradually Varied Flow

Return to [Figure 3.5.1](#) and suppose that  $(y, A, b, P, S_o)$  are all variable functions of horizontal position  $x$ . If these parameters are slowly changing, with no hydraulic jumps, the flow is termed *gradually varied* and satisfies a simple one-dimensional first-order differential equation if  $Q = \text{constant}$ :

$$\frac{dy}{dx} \approx \frac{S_o - S}{1 - \frac{V^2 b}{gA}}, \quad \text{where } V = \frac{Q}{A} \quad \text{and} \quad S = \frac{f}{D_h} \frac{V^2}{2g} = \frac{n^2 V^2}{\zeta^2 R_h^{4/3}} \quad (3.5.10)$$

The conversion factor  $\zeta^2 = 1.0$  for SI units and 2.208 for English units. If flow rate, bottom slope, channel geometry, and surface roughness are known, we may solve for  $y(x)$  for any given initial condition  $y = y_o$  at  $x = x_o$ . The solution is computed by any common numerical method, e.g., Runge-Kutta.

Recall from Equation (3.5.3) that the term  $V^2 b / (gA) \equiv Fr^2$ , so the sign of the denominator in Equation (3.5.10) depends upon whether the flow is sub- or supercritical. The mathematical behavior of Equation (3.5.10) differs also. If  $Fr$  is near unity, the change  $dy/dx$  will be very large, which probably violates the basic assumption of “gradual” variation.

For a given flow rate and local bottom slope, two reference depths are useful and may be computed in advance:

- (a) The *normal* depth  $y_n$  for which Equation (3.5.2) yields the flow rate:  
 (b) The *critical* depth  $y_c$  for which Equation (3.5.3) yields the flow rate.

Comparison of these two, and their relation to the actual local depth  $y$ , specifies the type of solution curve being computed. The five bottom-slope regimes (mild  $M$ , critical  $C$ , steep  $S$ , horizontal  $H$ , and adverse  $A$ ) create 12 different solution curves, as illustrated in [Figure 3.5.4](#). All of these may be readily generated by a computer solution of Equation 3.5.10. The following example illustrates a typical solution to a gradually varied flow problem.

### Example 3.5.2

Water, flowing at  $2.5 \text{ m}^3/\text{sec}$  in a rectangular gravelly earth channel 2 m wide, encounters a broad-crested weir 1.5 m high. Using gradually varied theory, estimate the water depth profile back to 1 km upstream of the weir. The bottom slope is  $0.1^\circ$ .

*Solution.* We are given  $Q$ ,  $Y = 1.5 \text{ m}$ , and  $b = 2 \text{ m}$ . We may calculate excess water level  $H$  at the weir (see [Figure 3.5.3](#)) from Equations (3.5.7) and (3.5.8):

$$Q = 2.5 \frac{\text{m}^3}{\text{sec}} = C_d b_{\text{eff}} g^{1/2} H^{3/2} = 0.462(2.0 - 0.1H)(9.81)^{1/2} H^{3/2}, \quad \text{solve for } H \approx \mathbf{0.94 \text{ m}}$$

Since the weir is not too wide, we have subtracted  $0.1 H$  from  $b$  as recommended. The weir serves as a “control structure” which sets the water depth just upstream. This is our initial condition for gradually varied theory:  $y(0) = Y + H = 1.5 + 0.94 \approx 2.44 \text{ m}$  at  $x = 0$ . Before solving Equation (3.5.10), we find the normal and critical depths to get a feel for the problem:

$$\text{Normal depth: } Q = 2.5 \frac{\text{m}^3}{\text{sec}} = \frac{1.0}{0.025} (2.0 y_n) \left( \frac{2.0 y_n}{2.0 + 2 y_n} \right)^{3/2} \sqrt{\sin 0.1^\circ}, \quad \text{solve } y_n \approx \mathbf{1.14 \text{ m}}$$

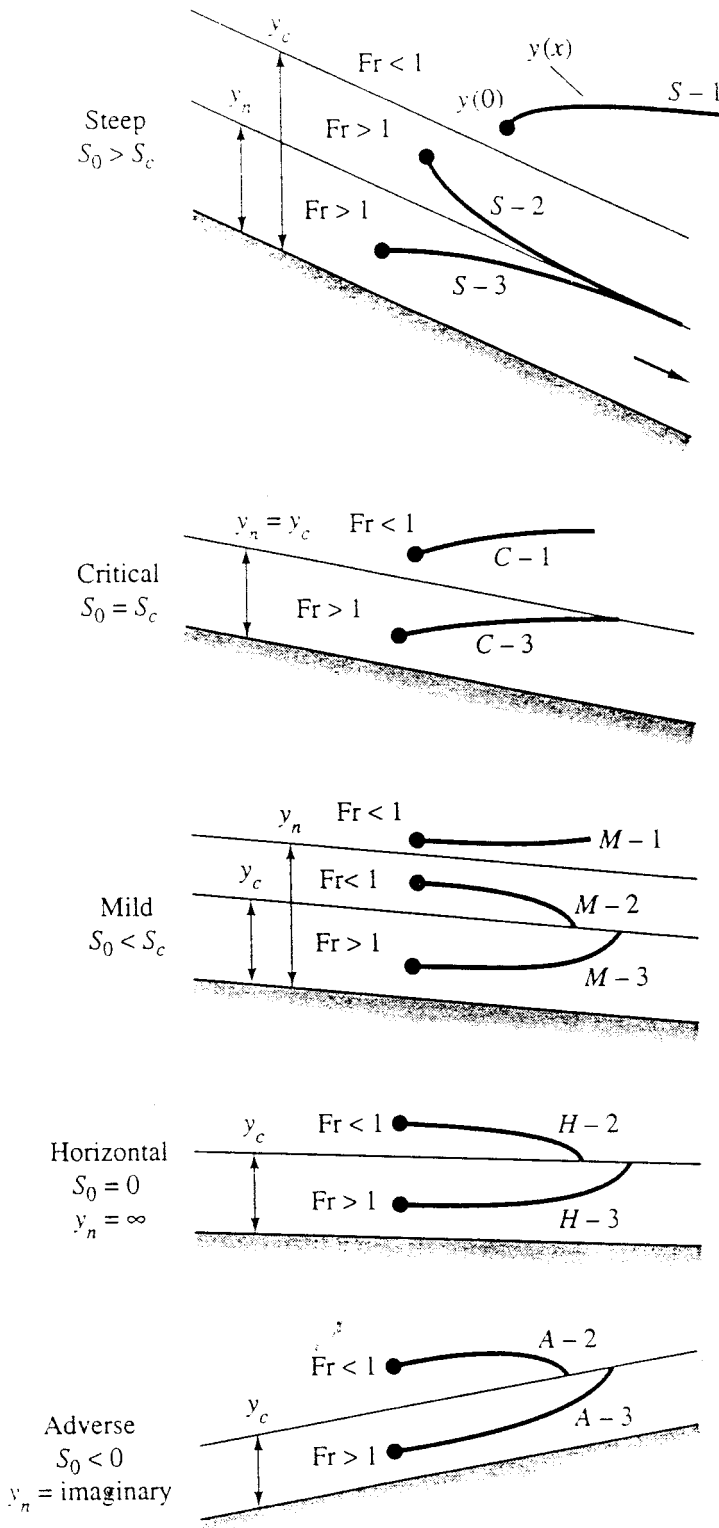

$$\text{Critical depth: } A_c = 2.0 y_c - \left( \frac{b Q^2}{g} \right)^{1/3} = \left[ \frac{2.0 (2.5)^2}{9.81} \right]^{1/3}, \quad \text{solve } y_c \approx \mathbf{0.54 \text{ m}}$$

We have taken  $n \approx 0.025$  for gravelly earth, from [Table 3.5.1](#). Since  $y(0) > y_n > y_c$ , we are on a mild slope  $M - 1$  “backwater” curve, as in [Figure 3.5.4](#). For our data, Equation (3.5.10) becomes

$$\frac{dy}{dx} \approx \frac{S_o - n^2 Q^2 / (\xi^2 A^2 R_h^{4/3})}{1 - Q^2 b / (g A^3)}$$

where  $Q = 2.5$ ,  $b = 2$ ,  $\xi = 1$ ,  $A = 2y$ ,  $S_o = \sin 0.1^\circ$ ,  $R_h = 2y/(2 + 2y)$ ,  $g = 9.81$ ,  $y(0) = 2.44$  at  $x = 0$ .

Integrate numerically backward, that is, for  $\Delta x < 0$ , until  $x = -1 \text{ km} = -1000 \text{ m}$ . The complete solution curve is shown in [Figure 3.5.5](#). The water depth decreases upstream and is approximately  $y \approx 1.31 \text{ m}$  at  $x = -1000 \text{ m}$ . If slope and channel width remain constant, the water depth asymptotically approaches the normal depth  $y_n$  far upstream.

**FIGURE 3.5.4** Classification of solution curves for gradually varied flow.

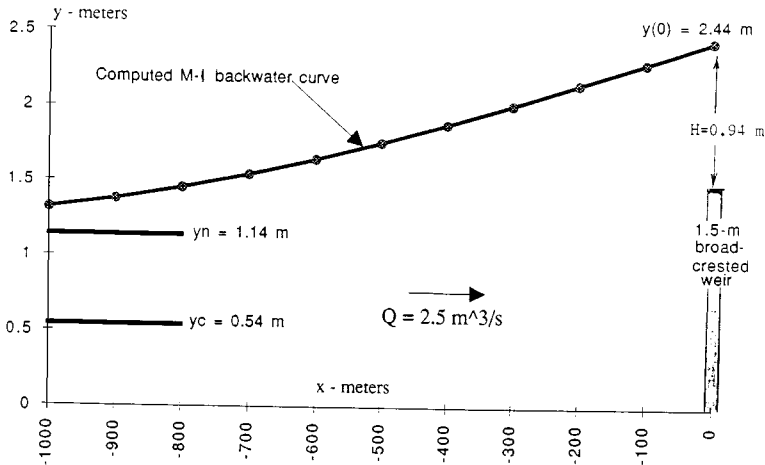

FIGURE 3.5.5 Backwater solution curve for Example 3.5.2.

## Nomenclature

### English symbols

- $A$  = water cross section area  
 $b$  = channel upper-surface width  
 $C$  = Chézy coefficient, Equation (3.5.1)  
 $C_d$  = weir discharge coefficient, Equation (3.5.7)  
 $D_h$  = hydraulic diameter,  $= 4R_h$   
 $E$  = specific energy,  $= y + V^2/2g$   
 $f$  = Moody friction factor  
 $Fr$  = Froude number,  $= V/V_{crit}$   
 $g$  = acceleration of gravity  
 $H$  = excess water level above weir, Figure 3.5.3  
 $L$  = weir length, Figure 3.5.3  
 $n$  = Manning roughness factor, Table 3.5.1  
 $P$  = wetted perimeter  
 $Q$  = volume flow rate  
 $R_h$  = hydraulic radius,  $= A/P$   
 $S$  = frictional slope, Equation (3.5.10)  
 $S_o$  = bottom slope  
 $V$  = average velocity  
 $x$  = horizontal distance along the channel  
 $y$  = water depth  
 $Y$  = weir height, Figure (3.5.3)

### Greek Symbols

- $\varepsilon$  = wall roughness height, Table 3.5.1  
 $\rho$  = fluid density  
 $\mu$  = fluid viscosity  
 $\nu$  = fluid kinematic viscosity,  $= \mu/\rho$   
 $\zeta$  = conversion factor,  $= 1.0$  (SI) and  $1.486$  (English)

### Subscripts

- $c, crit$  = critical, at  $Fr = 1$   
 $n$  = normal, in uniform flow

## 3.6 External Incompressible Flows

*Alan T. McDonald*

### Introduction and Scope

Potential flow theory (Section 3.2) treats an incompressible *ideal fluid* with zero viscosity. There are no shear stresses; pressure is the only stress acting on a fluid particle. Potential flow theory predicts no drag force when an object moves through a fluid, which obviously is not correct, because all real fluids are viscous and cause drag forces. The objective of this section is to consider the behavior of viscous, incompressible fluids flowing over objects.

A number of phenomena that occur in external flow at high Reynolds number over an object are shown in Figure 3.6.1. The freestream flow divides at the stagnation point and flows around the object. Fluid at the object surface takes on the velocity of the body as a result of the no-slip condition. Boundary layers form on the upper and lower surfaces of the body; flow in the boundary layers is initially laminar, then **transition** to turbulent flow may occur (points “T”).

**FIGURE 3.6.1** Viscous flow around an airfoil (boundary layer thickness exaggerated for clarity).

Boundary layers thickening on the surfaces cause only a slight displacement of the streamlines of the external flow (their thickness is greatly exaggerated in the figure). **Separation** may occur in the region of increasing pressure on the rear of the body (points “S”); after separation boundary layer fluid no longer remains in contact with the surface. Fluid that was in the boundary layers forms the viscous *wake* behind the object.

The Bernoulli equation is valid for steady, incompressible flow without viscous effects. It may be used to predict pressure variations outside the boundary layer. Stagnation pressure is constant in the uniform inviscid flow far from an object, and the Bernoulli equation reduces to

$$p_\infty + \frac{1}{2}\rho V^2 = \text{constant} \quad (3.6.1)$$

where  $p_\infty$  is pressure far upstream,  $\rho$  is density, and  $V$  is velocity. Therefore, the local pressure can be determined if the local freestream velocity,  $U$ , is known.

## Boundary Layers

### The Boundary Layer Concept

The **boundary layer** is the thin region near the surface of a body in which viscous effects are important. By recognizing that viscous effects are concentrated near the surface of an object, Prandtl showed that only the Euler equations for inviscid flow need be solved in the region outside the boundary layer. Inside the boundary layer, the elliptic Navier-Stokes equations are simplified to boundary layer equations with parabolic form that are easier to solve. The thin boundary layer has negligible pressure variation across it; pressure from the freestream is impressed upon the boundary layer.

Basic characteristics of all laminar and turbulent boundary layers are shown in the developing flow over a flat plate in a semi-infinite fluid. Because the boundary layer is thin, there is negligible disturbance of the inviscid flow outside the boundary layer, and the **pressure gradient** along the surface is close to zero. Transition from laminar to turbulent boundary layer flow on a flat plate occurs when Reynolds number based on  $x$  exceeds  $Re_x = 500,000$ . Transition may occur earlier if the surface is rough, pressure increases in the flow direction, or separation occurs. Following transition, the turbulent boundary layer thickens more rapidly than the laminar boundary layer as a result of increased shear stress at the body surface.

### Boundary Layer Thickness Definitions

Boundary layer disturbance thickness,  $\delta$ , is usually defined as the distance,  $y$ , from the surface to the point where the velocity within the boundary layer,  $u$ , is within 1% of the local freestream velocity,  $U$ . As shown in **Figure 3.6.2**, the boundary layer velocity profile merges smoothly and asymptotically into the freestream, making  $\delta$  difficult to measure. For this reason and for their physical significance, we define two integral measures of boundary layer thickness. Displacement thickness,  $\delta^*$ , is defined as

$$\frac{\delta^*}{\delta} = \int_0^\infty \left(1 - \frac{u}{U}\right) d\left(\frac{y}{\delta}\right) \tag{3.6.2}$$

**FIGURE 3.6.2** Boundary layer on a flat plate (vertical thickness exaggerated for clarity).

Physically,  $\delta^*$  is the distance the solid boundary would have to be displaced into the freestream in a frictionless flow to produce the mass flow deficit caused by the viscous boundary layer. Momentum thickness,  $\theta$ , is defined as

$$\frac{\theta}{\delta} = \int_0^\infty \frac{u}{U} \left(1 - \frac{u}{U}\right) d\left(\frac{y}{\delta}\right) \tag{3.6.3}$$

Physically,  $\theta$  is the thickness of a fluid layer, having velocity  $U$ , for which the momentum flux is the same as the deficit in momentum flux within the boundary layer (momentum flux is momentum per unit time passing a cross section).

Because  $\delta^*$  and  $\theta$  are defined in terms of integrals for which the integrand vanishes in the freestream, they are easier to evaluate experimentally than disturbance thickness  $\delta$ .

### Exact Solution of the Laminar Flat-Plate Boundary Layer

Blasius obtained an exact solution for laminar boundary layer flow on a flat plate. He assumed a thin boundary layer to simplify the streamwise momentum equation. He also assumed *similar* velocity profiles in the boundary layer, so that when written as  $u/U = f(y/\delta)$ , velocity profiles do not vary with  $x$ . He used a similarity variable to reduce the partial differential equations of motion and continuity to a single third-order ordinary differential equation.

Blasius used numerical methods to solve the ordinary differential equation. Unfortunately, the velocity profile must be expressed in tabular form. The principal results of the Blasius solution may be expressed as

$$\frac{\delta}{x} = \frac{5}{\sqrt{\text{Re}_x}} \quad (3.6.4)$$

and

$$C_f = \frac{\tau_w}{\frac{1}{2}\rho U^2} = \frac{0.664}{\sqrt{\text{Re}_x}} \quad (3.6.5)$$

These results characterize the laminar boundary layer on a flat plate; they show that laminar boundary layer thickness varies as  $x^{1/2}$  and wall shear stress varies as  $1/x^{1/2}$ .

### Approximate Solutions

The Blasius solution cannot be expressed in closed form and is limited to laminar flow. Therefore, approximate methods that give solutions for both laminar and turbulent flow in closed form are desirable. One such method is the *momentum integral equation* (MIE), which may be developed by integrating the boundary layer equation across the boundary layer or by applying the streamwise momentum equation to a differential control volume (Fox and McDonald, 1992). The result is the ordinary differential equation

$$\frac{d\theta}{dx} = \frac{\tau_w}{\rho U^2} - \left( \frac{\delta^*}{\theta} + 2 \right) \frac{\theta}{U} \frac{dU}{dx} \quad (3.6.6)$$

The first term on the right side of Equation (3.6.6) contains the influence of wall shear stress. Since  $\tau_w$  is always positive, it always causes  $\theta$  to increase. The second term on the right side contains the pressure gradient, which can have either sign. Therefore, the effect of the pressure gradient can be to either increase or decrease the rate of growth of boundary layer thickness.

Equation (3.6.6) is an ordinary differential equation that can be solved for  $\theta$  as a function of  $x$  on a flat plate (zero pressure gradient), provided a reasonable shape is assumed for the boundary layer velocity profile and shear stress is expressed in terms of the other variables. Results for laminar and turbulent flat-plate boundary layer flows are discussed below.

**Laminar Boundary Layers.** A reasonable approximation to the laminar boundary layer velocity profile is to express  $u$  as a polynomial in  $y$ . The resulting solutions for  $\delta$  and  $\tau_w$  have the same dependence on  $x$  as the exact Blasius solution. Numerical results are presented in Table 3.6.1. Comparing the approximate and exact solutions shows remarkable agreement in view of the approximations used in the analysis. The trends are predicted correctly and the approximate values are within 10% of the exact values.

**Turbulent Boundary Layers.** The turbulent velocity profile may be expressed well using a power law,  $u/U = (y/\delta)^{1/n}$ , where  $n$  is an integer between 6 and 10 (frequently 7 is chosen). For turbulent flow it is

**TABLE 3.6.1 Exact and Approximate Solutions for Laminar Boundary Layer Flow over a Flat Plate at Zero Incidence**

Velocity Distribution				
$\frac{u}{U} = f\left(\frac{y}{\delta}\right) = f(\eta)$	$\frac{\theta}{\delta}$	$\frac{\delta^*}{\delta}$	$a = \frac{\delta}{x} \sqrt{\text{Re}_x}$	$b = C_f \sqrt{\text{Re}_x}$
$f(\eta) = 2\eta - \eta^2$	2/15	1/3	5.48	0.730
$f(\eta) = 3/2 \eta - 1/2 \eta^3$	39/280	3/8	4.64	0.647
$f(\eta) = \sin(\pi/2 \eta)$	$(4 - \pi)/2\pi$	$(\pi - 2)/\pi$	4.80	0.654
Exact	0.133	0.344	5.00	0.664

not possible to express shear stress directly in terms of a simple velocity profile; an empirical correlation is required. Using a pipe flow data correlation gives

$$\frac{\delta}{x} = \frac{0.382}{\text{Re}_x^{1/5}} \tag{3.6.7}$$

and

$$C_f = \frac{\tau_w}{\frac{1}{2} \rho U^2} = \frac{0.0594}{\text{Re}_x^{1/5}} \tag{3.6.8}$$

These results characterize the turbulent boundary layer on a flat plate. They show that turbulent boundary layer thickness varies as  $x^{4/5}$  and wall shear stress varies as  $1/x^{1/5}$ .

Approximate results for laminar and turbulent boundary layers are compared in Table 3.6.2. At a Reynolds number of 1 million, wall shear stress for the turbulent boundary layer is nearly six times as large as for the laminar layer. For a turbulent boundary layer, thickness increases five times faster with distance along the surface than for a laminar layer. These approximate results give a physical feel for relative magnitudes in the two cases.

**TABLE 3.6.2 Thickness and Skin Friction Coefficient for Laminar and Turbulent Boundary Layers on a Flat Plate**

Note: BL = boundary layer.

The MIE cannot be solved in closed form for flows with nonzero pressure gradients. However, the role of the pressure gradient can be understood qualitatively by studying the MIE.

**Effect of Pressure Gradient**

Boundary layer flow with favorable, zero, and adverse pressure gradients is depicted schematically in Figure 3.6.3. (Assume a thin boundary layer, so flow on the lower surface behaves as external flow on

**FIGURE 3.6.3** Boundary layer flow with pressure gradient (thickness exaggerated for clarity).

a surface, with the pressure gradient impressed on the boundary layer.) The pressure gradient is favorable when  $\partial p/\partial x < 0$ , zero when  $\partial p/\partial x = 0$ , and adverse when  $\partial p/\partial x > 0$ , as indicated for Regions 1, 2, and 3.

Viscous shear always causes a net retarding force on any fluid particle within the boundary layer. For zero pressure gradient, shear forces alone can never bring the particle to rest. (Recall that for laminar and turbulent boundary layers the shear stress varied as  $1/x^{1/2}$  and  $1/x^{1/5}$ , respectively; shear stress never becomes zero for finite  $x$ .) Since shear stress is given by  $\tau_w = \mu \left. \partial u / \partial y \right|_{y=0}$ , the velocity gradient cannot be zero. Therefore, flow cannot separate in a zero pressure gradient; shear stresses alone can never cause flow separation.

In the favorable pressure gradient of Region 1, pressure forces tend to maintain the motion of the particle, so flow cannot separate. In the adverse pressure gradient of Region 3, pressure forces oppose the motion of a fluid particle. An adverse pressure gradient is a necessary condition for flow separation.

Velocity profiles for laminar and turbulent boundary layers are shown in Figure 3.6.2. It is easy to see that the turbulent velocity profile has much more momentum than the laminar profile. Therefore, the turbulent velocity profile can resist separation in an adverse pressure gradient better than the laminar profile.

The freestream velocity distribution must be known before the MIE can be applied. We obtain a first approximation by applying potential flow theory to calculate the flow field around the object. Much effort has been devoted to calculation of velocity distributions over objects of known shape (the “direct” problem) and to determination of shapes to produce a desired pressure distribution (the “inverse” problem). Detailed discussion of such calculation schemes is beyond the scope of this section; the state of the art continues to progress rapidly.

## Drag

Any object immersed in a viscous fluid flow experiences a net force from the shear stresses and pressure differences caused by the fluid motion. *Drag* is the force component parallel to, and *lift* is the force component perpendicular to, the flow direction. *Streamlining* is the art of shaping a body to reduce fluid dynamic drag. Airfoils (hydrofoils) are designed to produce lift in air (water); they are streamlined to reduce drag and thus to attain high lift–drag ratios.

In general, lift and drag cannot be predicted analytically for flows with separation, but progress continues on computational fluid dynamics methods. For many engineering purposes, drag and lift forces are calculated from experimentally derived coefficients, discussed below.

**Drag coefficient** is defined as

$$C_D = \frac{F_D}{\frac{1}{2}\rho V^2 A} \tag{3.6.9}$$

where  $\frac{1}{2}\rho V^2$  is dynamic pressure and  $A$  is the area upon which the coefficient is based. Common practice is to base drag coefficients on projected *frontal area* (Fox and McDonald, 1992).

Similitude was treated in Section 3.3. In general, the drag coefficient may be expressed as a function of Reynolds number, Mach number, Froude number, relative roughness, submergence divided by length, and so forth. In this section we consider neither high-speed flow nor free-surface effects, so we will consider only Reynolds number and roughness effects on drag coefficient.

**Friction Drag**

The total friction drag force acting on a plane surface aligned with the flow direction can be found by integrating the shear stress distribution along the surface. The drag coefficient for this case is defined as friction force divided by dynamic pressure and *wetted area* in contact with the fluid. Since shear stress is a function of Reynolds number, so is drag coefficient (see Figure 3.6.4). In Figure 3.6.4, transition occurs at  $Re_x = 500,000$ ; the dashed line represents the drag coefficient at larger Reynolds numbers. A number of empirical correlations may be used to model the variation in  $C_D$  shown in Figure 3.6.4 (Schlichting, 1979).

**FIGURE 3.6.4** Drag coefficient vs. Reynolds number for a smooth flat plate parallel to the flow.

Extending the laminar boundary layer line to higher Reynolds numbers shows that it is beneficial to delay transition to the highest possible Reynolds number. Some results are presented in Table 3.6.3; drag is reduced more than 50% by extending laminar boundary layer flow to  $Re_L = 10^6$ .

**Pressure Drag**

A thin flat surface normal to the flow has no area parallel to the flow direction. Therefore, there can be no friction force parallel to the flow; all drag is caused by pressure forces. Drag coefficients for objects with sharp edges tend to be independent of Reynolds number (for  $Re > 1000$ ), because the separation points are fixed by the geometry of the object. Drag coefficients for selected objects are shown in Table 3.6.4.

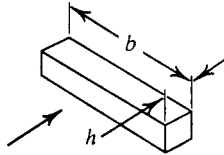

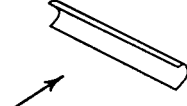

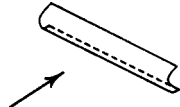

Rounding the edges that face the flow reduces drag markedly. Compare the drag coefficients for the hemisphere and C-section shapes facing into and away from the flow. Also note that the drag coefficient

**TABLE 3.6.3 Drag Coefficients for Laminar, Turbulent, and Transition Boundary Layers on a Flat Plate**

<sup>b</sup> Based on ring area.

for a two-dimensional object (long square cylinder) is about twice that for the corresponding three-dimensional object (square cylinder with  $b/h = 1$ ).

**Friction and Pressure Drag: Bluff Bodies**

Both friction and pressure forces contribute to the drag of *bluff bodies* (see Shapiro, 1960, for a good discussion of the mechanisms of drag). As an example, consider the drag coefficient for a smooth sphere shown in Figure 3.6.5. Transition from laminar to turbulent flow in the boundary layers on the forward portion of the sphere causes a dramatic dip in drag coefficient at the *critical Reynolds number* ( $Re_D \approx 2 \times 10^5$ ). The turbulent boundary layer is better able to resist the adverse pressure gradient on the rear of the sphere, so separation is delayed and the wake is smaller, causing less pressure drag.

**FIGURE 3.6.5** Drag coefficient vs. Reynolds number for a smooth sphere.

Surface roughness (or freestream disturbances) can reduce the critical Reynolds number. Dimples on a golf ball cause the boundary layer to become turbulent and, therefore, lower the drag coefficient in the range of speeds encountered in a drive.

**Streamlining**

Streamlining is adding a faired tail section to reduce the extent of separated flow on the downstream portion of an object (at high Reynolds number where pressure forces dominate drag). The adverse pressure gradient is taken over a longer distance, delaying separation. However, adding a faired tail increases surface area, causing skin friction drag to increase. Thus, streamlining must be optimized for each shape.

Front contours are of principal importance in road vehicle design; the angle of the back glass also is important (in most cases the entire rear end cannot be made long enough to control separation and reduce drag significantly).

**Lift**

**Lift coefficient** is defined as

$$C_L = \frac{F_L}{\frac{1}{2} \rho V^2 A} \tag{3.6.10}$$

Note that lift coefficient is based on projected *planform area*.

## Airfoils

Airfoils are shaped to produce lift efficiently by accelerating flow over the upper surface to produce a low-pressure region. Because the flow must again decelerate, inevitably there must be a region of adverse pressure gradient near the rear of the upper surface (pressure distributions are shown clearly in Hazen, 1965).

Lift and drag coefficients for airfoil sections depend on Reynolds number and *angle of attack* between the chord line and the undisturbed flow direction. The *chord line* is the straight line joining the leading and trailing edges of the airfoil (Abbott and von Doenhoff, 1959).

As the angle of attack is increased, the minimum pressure point moves forward on the upper surface and the minimum pressure becomes lower. This increases the adverse pressure gradient. At some angle of attack, the adverse pressure gradient is strong enough to cause the boundary layer to separate completely from the upper surface, causing the airfoil to *stall*. The separated flow alters the pressure distribution, reducing lift sharply.

Increasing the angle of attack also causes the the drag coefficient to increase. At some angle of attack below stall the ratio of lift to drag, the *lift-drag* ratio, reaches a maximum value.

### Drag Due to Lift

For wings (airfoils of finite span), lift and drag also are functions of aspect ratio. Lift is reduced and drag increased compared with infinite span, because end effects cause the lift vector to rotate rearward. For a given geometric angle of attack, this reduces effective angle of attack, reducing lift. The additional component of lift acting in the flow direction increases drag; the increase in drag due to lift is called *induced drag*.

The effective aspect ratio includes the effect of planform shape. When written in terms of effective aspect ratio, the drag of a finite-span wing is

$$C_D = C_{D,\infty} + \frac{C_L^2}{\pi ar} \quad (3.6.11)$$

where  $ar$  is effective aspect ratio and the subscript  $\infty$  refers to the infinite section drag coefficient at  $C_L$ . For further details consult the references.

The lift coefficient must increase to support aircraft weight as speed is reduced. Therefore, induced drag can increase rapidly at low flight speeds. For this reason, minimum allowable flight speeds for commercial aircraft are closely controlled by the FAA.

## Boundary Layer Control

The major part of the drag on an airfoil or wing is caused by skin friction. Therefore, it is important to maintain laminar flow in the boundary layers as far aft as possible; laminar flow sections are designed to do this. It also is important to prevent flow separation and to achieve high lift to reduce takeoff and landing speeds. These topics fall under the general heading of boundary layer control.

### Profile Shaping

Boundary layer transition on a conventional airfoil section occurs almost immediately after the minimum pressure at about 25% chord aft the leading edge. Transition can be delayed by shaping the profile to maintain a favorable pressure gradient over more of its length. The U.S. National Advisory Committee for Aeronautics (NACA) developed several series of profiles that delayed transition to 60 or 65% of chord, reducing drag coefficients (in the design range) 60% compared with conventional sections of the same thickness ratio (Abbott and von Doenhoff, 1959).

## Flaps and Slats

Flaps are movable sections near the trailing edge of a wing. They extend and/or deflect to increase wing area and/or increase wing camber (curvature), to provide higher lift than the clean wing. Many aircraft also are fitted with leading edge slats which open to expose a slot from the pressure side of the wing to the upper surface. The open slat increases the effective radius of the leading edge, improving maximum lift coefficient. The slot allows energized air from the pressure surface to flow into the low-pressure region atop the wing, energizing the boundary layers and delaying separation and stall.

## Suction and Blowing

Suction removes low-energy fluid from the boundary layer, reducing the tendency for early separation. Blowing via high-speed jets directed along the surface reenergizes low-speed boundary layer fluid. The objective of both approaches is to delay separation, thus increasing the maximum lift coefficient the wing can achieve. Powered systems add weight and complexity; they also require bleed air from the engine compressor, reducing thrust or power output.

## Moving Surfaces

Many schemes have been proposed to utilize moving surfaces for boundary layer control. Motion in the direction of flow reduces skin friction, and thus the tendency to separate; motion against the flow has the opposite effect. The aerodynamic behavior of sports balls — baseballs, golf balls, and tennis balls — depends significantly on aerodynamic side force (lift, down force, or side force) produced by spin. These effects are discussed at length in Fox and McDonald (1992) and its references.

## Computation vs. Experiment

Experiments cannot yet be replaced completely by analysis. Progress in modeling, numerical techniques, and computer power continues to be made, but the role of the experimentalist likely will remain important for the foreseeable future.

## Computational Fluid Dynamics (CFD)

Computation of fluid flow requires accurate mathematical modeling of flow physics and accurate numerical procedures to solve the equations. The basic equations for laminar boundary layer flow are well known. For turbulent boundary layers generally it is not possible to resolve the solution space into sufficiently small cells to allow direct numerical simulation. Instead, empirical models for the turbulent stresses must be used. Advances in computer memory storage capacity and speed (e.g., through use of massively parallel processing) continue to increase the resolution that can be achieved.

A second source of error in CFD work results from the numerical procedures required to solve the equations. Even if the equations are exact, approximations must be made to discretize and solve them using finite-difference or finite-volume methods. Whichever is chosen, the solver must guard against introducing numerical instability, round-off errors, and numerical diffusion (Hoffman, 1992).

## Role of the Wind Tunnel

Traditionally, wind tunnel experiments have been conducted to verify the design and performance of components and complete aircraft. Design verification of a modern aircraft may require expensive scale models, several thousand hours of wind tunnel time at many thousands of dollars an hour, and additional full-scale flight testing.

New wind tunnel facilities continue to be built and old ones refurbished. This indicates a need for continued experimental work in developing and optimizing aircraft configurations.

Many experiments are designed to produce baseline data to validate computer codes. Such systematic experimental data can help to identify the strengths and weaknesses of computational methods.

CFD tends to become only indicative of trends when massive zones of flow separation are present. Takeoff and landing configurations of conventional aircraft, with landing gear, high-lift devices, and

flaps extended, tend to need final experimental confirmation and optimization. Many studies of vertical takeoff and vectored thrust aircraft require testing in wind tunnels.

## Defining Terms

**Boundary layer:** Thin layer of fluid adjacent to a surface where viscous effects are important; viscous effects are negligible outside the boundary layer.

**Drag coefficient:** Force in the flow direction exerted on an object by the fluid flowing around it, divided by dynamic pressure and area.

**Lift coefficient:** Force perpendicular to the flow direction exerted on an object by the fluid flowing around it, divided by dynamic pressure and area.

**Pressure gradient:** Variation in pressure along the surface of an object. For a *favorable* pressure gradient, pressure *decreases* in the flow direction; for an *adverse* pressure gradient, pressure *increases* in the flow direction.

**Separation:** Phenomenon that occurs when fluid layers adjacent to a solid surface are brought to rest and boundary layers depart from the surface contour, forming a low-pressure *wake* region. Separation can occur only in an *adverse pressure gradient*.

**Transition:** Change from laminar to turbulent flow within the boundary layer. The location depends on distance over which the boundary layer has developed, pressure gradient, surface roughness, freestream disturbances, and heat transfer.

## Further Information

A comprehensive source of basic information is the *Handbook of Fluid Dynamics*, edited by Victor L. Streeter (McGraw-Hill, New York, 1960).

Timely reviews of important topics are published in the *Annual Review of Fluid Mechanics* series (Annual Reviews, Inc., Palo Alto, CA.). Each volume contains a cumulative index.

ASME (American Society of Mechanical Engineers, New York, NY) publishes the *Journal of Fluids Engineering* quarterly. *JFE* contains fluid machinery and other engineering applications of fluid mechanics.

The monthly *AIAA Journal* and bimonthly *Journal of Aircraft* (American Institute for Aeronautics and Astronautics, New York) treat aerospace applications of fluid mechanics.

## 3.7 Compressible Flow

Ajay Kumar

### Introduction

This section deals with compressible flow. Only one- or two-dimensional steady, inviscid flows under perfect gas assumption are considered. Readers are referred to other sources of information for unsteady effects, viscous effects, and three-dimensional flows.

The term *compressible flow* is routinely used to define variable density flow which is in contrast to incompressible flow, where the density is assumed to be constant throughout. In many cases, these density variations are principally caused by the pressure changes from one point to another. Physically, the *compressibility* can be defined as the fractional change in volume of the gas element per unit change in pressure. It is a property of the gas and, in general, can be defined as

$$\tau = \frac{1}{\rho} \frac{d\rho}{dp}$$

where  $\tau$  is the compressibility of the gas,  $\rho$  is the density, and  $p$  is the pressure being exerted on the gas. A more precise definition of compressibility is obtained if we take into account the thermal and frictional losses. If during the compression the temperature of the gas is held constant, it is called the isothermal compressibility and can be written as

$$\tau_T = \frac{1}{\rho} \left( \frac{\partial \rho}{\partial p} \right)_T$$

However, if the compression process is reversible, it is called the isentropic compressibility and can be written as

$$\tau_s = \frac{1}{\rho} \left( \frac{\partial \rho}{\partial p} \right)_s$$

Gases in general have high compressibility ( $\tau_T$  for air is  $10^{-5} \text{ m}^2/\text{N}$  at 1 atm) as compared with liquids ( $\tau_T$  for water is  $5 \times 10^{-10} \text{ m}^2/\text{N}$  at 1 atm).

Compressibility is a very important parameter in the analysis of compressible flow and is closely related to the *speed of sound*,  $a$ , which is the velocity of propagation of small pressure disturbances and is defined as

$$a^2 = \left( \frac{\partial p}{\partial \rho} \right)_s \quad \text{or} \quad a = \sqrt{\left( \frac{\partial p}{\partial \rho} \right)_s}$$

In an isentropic process of a perfect gas, the pressure and density are related as

$$\frac{P}{\rho^\gamma} = \text{constant}$$

Using this relation along with the perfect gas relation  $p = \rho RT$ , we can show that for a perfect gas

$$a = \sqrt{\gamma RT} = \sqrt{\frac{\gamma p}{\rho}}$$

where  $\gamma$  is the ratio of specific heats at constant pressure and constant volume,  $R$  is the gas constant, and  $T$  is the temperature. For air under normal conditions,  $\gamma$  is 1.4 and  $R$  is  $287 \text{ m}^2/\text{sec}^2 \text{ K}$  so that the speed of sound for air becomes  $a = 20.045 \sqrt{T}$  m/sec where  $T$  is in kelvin.

Another important parameter in compressible flows is the *Mach number*,  $M$ , which is defined as the ratio of the gas velocity to the speed of sound or

$$M = \frac{V}{a}$$

where  $V$  is the velocity of gas. Depending upon the Mach number of the flow, we can define the following flow regimes:

$M \ll 1$  Incompressible flow

$M < 1$  Subsonic flow

$M \approx 1$  Transonic flow

$M > 1$  Supersonic flow

$M \gg 1$  Hypersonic flow

Subsonic through hypersonic flows are compressible in nature. In these flows, the velocity is appreciable compared with the speed of sound, and the fractional changes in pressure, temperature, and density are all of significant magnitude. We will restrict ourselves in this section to subsonic through flows only.

Before we move on to study these flows, let us define one more term. Let us consider a gas with static pressure  $p$  and temperature  $T$ , traveling at some velocity  $V$  and corresponding Mach number  $M$ . If this gas is brought isentropically to stagnation or zero velocity, the pressure and temperature which the gas achieves are defined as *stagnation pressure*  $p_0$  and *stagnation temperature*  $T_0$  (also called total pressure and total temperature). The speed of sound at stagnation conditions is called the *stagnation speed of sound* and is denoted as  $a_0$ .

## One-Dimensional Flow

In one-dimensional flow, the flow properties vary only in one coordinate direction. Figure 3.7.1 shows two streamtubes in a flow. In a *truly one-dimensional flow* illustrated in Figure 3.7.1(a), the flow variables are a function of  $x$  only and the area of the stream tube is constant. On the other hand, Figure 3.7.1(b) shows a flow where the area of the stream tube is also a function of  $x$  but the flow variables are still a function of  $x$  only. This flow is defined as the *quasi-one-dimensional flow*. We will first discuss the truly one-dimensional flow.

In a steady, truly one-dimensional flow, conservation of mass, momentum, and energy leads to the following simple algebraic equations.

$$\begin{aligned} \rho u &= \text{constant} \\ p + \rho u^2 &= \text{constant} \\ h + \frac{u^2}{2} + q &= \text{constant} \end{aligned} \tag{3.7.1}$$

**FIGURE 3.7.1** (a) One-dimensional flow; (b) quasi-one-dimensional flow.

where  $q$  is the heat added per unit mass of the gas. These equations neglect body forces, viscous stresses, and heat transfer due to thermal conduction and diffusion. These relations given by Equation 3.7.1, when applied at points 1 and 2 in a flow with no heat addition, become

$$\begin{aligned} \rho_1 u_1 &= \rho_2 u_2 \\ p_1 + \rho_1 u_1^2 &= p_2 + \rho_2 u_2^2 \\ h_1 + \frac{u_1^2}{2} &= h_2 + \frac{u_2^2}{2} \end{aligned} \tag{3.7.2}$$

The energy equation for a calorically perfect gas, where  $h = c_p T$ , becomes

$$c_p T_1 + \frac{u_1^2}{2} = c_p T_2 + \frac{u_2^2}{2}$$

Using  $c_p = \gamma R / (\gamma - 1)$  and  $a^2 = \gamma RT$ , the above equation can be written as

$$\frac{a_1^2}{\gamma - 1} + \frac{u_1^2}{2} = \frac{a_2^2}{\gamma - 1} + \frac{u_2^2}{2} \tag{3.7.3}$$

Since Equation (3.7.3) is written for no heat addition, it holds for an adiabatic flow. If the energy equation is applied to the stagnation conditions, it can be written as

$$\begin{aligned} c_p T + \frac{u^2}{2} &= c_p T_0 \\ \frac{T_0}{T} &= 1 + \frac{\gamma - 1}{2} M^2 \end{aligned} \tag{3.7.4}$$

It is worth mentioning that in arriving at Equation (3.7.4), only adiabatic flow condition is used whereas stagnation conditions are defined as those where the gas is brought to rest isentropically. Therefore, the definition of stagnation temperature is less restrictive than the general definition of stagnation conditions. According to the general definition of isentropic flow, it is a reversible adiabatic flow. This definition is needed for the definition of stagnation pressure and density. For an isentropic flow,

$$\frac{p_0}{p} = \left( \frac{\rho_0}{\rho} \right)^\gamma = \left( \frac{T_0}{T} \right)^{\gamma/(\gamma-1)} \quad (3.7.5)$$

From Equations 3.7.4 and 3.7.5, we can write

$$\frac{p_0}{p} = \left( 1 + \frac{\gamma-1}{2} M^2 \right)^{\gamma/(\gamma-1)} \quad (3.7.6)$$

$$\frac{\rho_0}{\rho} = \left( 1 + \frac{\gamma-1}{2} M^2 \right)^{1/(\gamma-1)} \quad (3.7.7)$$

Values of stagnation conditions are tabulated in Anderson (1982) as a function of  $M$  for  $\gamma = 1.4$ .

### Normal Shock Wave

A shock wave is a very thin region (of the order of a few molecular mean free paths) across which the static pressure, temperature, and density increase whereas the velocity decreases. If the shock wave is perpendicular to the flow, it is called a *normal shock wave*. The flow is supersonic ahead of the normal shock wave and subsonic behind it. Figure 3.7.2 shows the flow conditions across a normal shock wave which is treated as a discontinuity. Since there is no heat added or removed, the flow across the shock wave is adiabatic. By using Equations 3.7.2 the normal shock equations can be written as

$$\begin{aligned} \rho_1 u_1 &= \rho_2 u_2 \\ p_1 + \rho_1 u_1^2 &= p_2 + \rho_2 u_2^2 \\ h_1 + \frac{u_1^2}{2} &= h_2 + \frac{u_2^2}{2} \end{aligned} \quad (3.7.8)$$

**FIGURE 3.7.2** Flow conditions across a normal shock.

Equations (3.7.8) are applicable to a general type of flow; however, for a calorically perfect gas, we can use the relations  $p = \rho RT$  and  $h = c_p T$  to derive a number of equations relating flow conditions downstream of the normal shock to those at upstream. These equations (also known as Rankine–Hugoniot relations) are

$$\begin{aligned} \frac{p_2}{p_1} &= 1 + \frac{2\gamma}{\gamma+1} (M_1^2 - 1) \\ \frac{\rho_2}{\rho_1} &= \frac{u_1}{u_2} = \frac{(\gamma+1)M_1^2}{2 + (\gamma-1)M_1^2} \end{aligned} \quad (3.7.9)$$

$$\frac{T_2}{T_1} = \frac{h_2}{h_1} = \left[ 1 + \frac{2\gamma}{\gamma + 1} (M_1^2 - 1) \right] \left[ \frac{2 + (\gamma - 1)M_1^2}{(\gamma + 1)M_1^2} \right]$$

$$M_2^2 = \frac{1 + \frac{\gamma - 1}{2} M_1^2}{\gamma M_1^2 - \frac{\gamma - 1}{2}}$$

Again, the values of  $p_2/p_1$ ,  $\rho_2/\rho_1$ ,  $T_2/T_1$ , etc. are tabulated in Anderson (1982) as a function of  $M_1$  for  $\gamma = 1.4$ . Let us examine some limiting cases. As  $M_1 \rightarrow 1$ , Equations 3.7.9 yield  $M_2 \rightarrow 1$ ,  $p_2/p_1 \rightarrow 1$ ,  $\rho_2/\rho_1 \rightarrow 1$ , and  $T_2/T_1 \rightarrow 1$ . This is the case of an extremely weak normal shock across which no finite changes occur. This is the same as the sound wave. On the other hand, as  $M_1 \rightarrow \infty$ , Equations (3.7.9) yield

$$M_2 \rightarrow \sqrt{\frac{\gamma - 1}{2\gamma}} = 0.378; \quad \frac{\rho_2}{\rho_1} \rightarrow \frac{\gamma + 1}{\gamma - 1} = 6; \quad \frac{p_2}{p_1} \rightarrow \infty; \quad \frac{T_2}{T_1} \rightarrow \infty$$

However, the calorically perfect gas assumption no longer remains valid as  $M_1 \rightarrow \infty$ .

Let us now examine why the flow ahead of a normal shock wave must be supersonic even though Equations (3.7.8) hold for  $M_1 < 1$  as well as  $M_1 > 1$ . From the second law of thermodynamics, the entropy change across the normal shock can be written as

$$s_2 - s_1 = c_p \ln \frac{T_2}{T_1} - R \ln \frac{p_2}{p_1}$$

By using Equations (3.7.9) it becomes

$$s_2 - s_1 = c_p \ln \left\{ \left[ 1 + \frac{2\gamma}{\gamma + 1} (M_1^2 - 1) \right] \left[ \frac{2 + (\gamma - 1)M_1^2}{(\gamma + 1)M_1^2} \right] \right\} - R \ln \left[ 1 + \frac{2\gamma}{\gamma + 1} (M_1^2 - 1) \right] \quad (3.7.10)$$

Equation (3.7.10) shows that the entropy change across the normal shock is also a function of  $M_1$  only. Using Equation (3.7.10) we see that

$$\begin{aligned} s_2 - s_1 &= 0 \quad \text{for } M_1 = 1 \\ &< 0 \quad \text{for } M_1 < 1 \\ &> 0 \quad \text{for } M_1 > 1 \end{aligned}$$

Since it is necessary that  $s_2 - s_1 \geq 0$  from the second law,  $M_1 \geq 1$ . This, in turn, requires that  $p_2/p_1 \geq 1$ ,  $\rho_2/\rho_1 \geq 1$ ,  $T_2/T_1 \geq 1$ , and  $M_2 \leq 1$ .

We now examine how the stagnation conditions change across a normal shock wave. For a calorically perfect gas, the energy equation in Equations (3.7.9) gives

$$c_p T_{01} = c_p T_{02} \quad \text{or} \quad T_{01} = T_{02}$$

In other words, the total temperature remains constant across a stationary normal shock wave.

Let us now apply the entropy change relation across the shock using the stagnation conditions.

$$s_2 - s_1 = c_p \ln \frac{T_{02}}{T_{01}} - R \ln \frac{P_{02}}{P_{01}}$$

Note that entropy at stagnation conditions is the same as at the static conditions since to arrive at stagnation conditions, the gas is brought to rest isentropically. Since  $T_{02} = T_{01}$ ,

$$s_2 - s_1 = -R \ln \frac{P_{02}}{P_{01}}$$

$$\frac{P_{02}}{P_{01}} = e^{-(s_2 - s_1)/R} \quad (3.7.11)$$

Since  $s_2 > s_1$  across the normal shockwave, Equation (3.7.11) gives  $P_{02} < P_{01}$  or, in other words, the total pressure decreases across a shock wave.

### One-Dimensional Flow with Heat Addition

Consider one-dimensional flow through a control volume as shown in Figure 3.7.3. Flow conditions going into this control volume are designated by 1 and coming out by 2. A specified amount of heat per unit mass,  $q$ , is added to the control volume. The governing equations relating conditions 1 and 2 can be written as

$$\begin{aligned} \rho_1 u_1 &= \rho_2 u_2 \\ p_1 + \rho_1 u_1^2 &= p_2 + \rho_2 u_2^2 \\ h_1 + \frac{u_1^2}{2} + q &= h_2 + \frac{u_2^2}{2} \end{aligned} \quad (3.7.12)$$

FIGURE 3.7.3 One-dimensional control volume with heat addition.

The following relations can be derived from Equation (3.7.12) for a calorically perfect gas

$$q = c_p (T_{02} - T_{01}) \quad (3.7.13)$$

$$\frac{p_2}{p_1} = \frac{1 + \gamma M_1^2}{1 + \gamma M_2^2} \quad (3.7.14)$$

$$\frac{T_2}{T_1} = \left( \frac{1 + \gamma M_1^2}{1 + \gamma M_2^2} \right)^2 \left( \frac{M_2}{M_1} \right)^2 \tag{3.7.15}$$

$$\frac{\rho_2}{\rho_1} = \left( \frac{1 + \gamma M_2^2}{1 + \gamma M_1^2} \right)^2 \left( \frac{M_1}{M_2} \right)^2 \tag{3.7.16}$$

Equation (3.7.13) indicates that the effect of heat addition is to directly change the stagnation temperature  $T_0$  of the flow. Table 3.7.1 shows some physical trends which can be obtained with heat addition to subsonic and supersonic flow. With heat extraction the trends in Table 3.7.1 are reversed.

**TABLE 3.7.1 Effect of Heat Addition on Subsonic and Supersonic Flow**

	$M_1 < 1$	$M_1 > 1$
$M_2$	Increases	Decreases
$p_2$	Decreases	Increases
$T_2$	Increases for $M_1 < \gamma^{-1/2}$ and decreases for $M_1 > \gamma^{-1/2}$	
$u_2$	Increases	Decreases
$T_{02}$	Increases	Increases
$p_{02}$	Decreases	Decreases

Figure 3.7.4 shows a plot between enthalpy and entropy, also known as the Mollier diagram, for one-dimensional flow with heat addition. This curve is called the Rayleigh curve and is drawn for a set of given initial conditions. Each point on this curve corresponds to a different amount of heat added or removed. It is seen from this curve that heat addition always drives the Mach numbers toward 1. For a certain amount of heat addition, the flow will become sonic. For this condition, the flow is said to be *choked*. Any further increase in heat addition is not possible without adjustment in initial conditions. For example, if more heat is added in region 1, which is initially supersonic, than allowed for attaining Mach 1 in region 2, then a normal shock will form inside the control volume which will suddenly change the conditions in region 1 to subsonic. Similarly, in case of an initially subsonic flow corresponding to region 1', any heat addition beyond that is needed to attain Mach 1 in region 2, the conditions in region 1' will adjust to a lower subsonic Mach number through a series of pressure waves.

**FIGURE 3.7.4** The Rayleigh curve.

Similar to the preceding heat addition or extraction relationships, we can also develop relationships for one-dimensional steady, adiabatic flow but with frictional effects due to viscosity. In this case, the momentum equation gets modified for frictional shear stress. For details, readers are referred to Anderson (1982).

## Quasi-One-Dimensional Flow

In quasi-one-dimensional flow, in addition to flow conditions, the area of duct also changes with  $x$ . The governing equations for quasi-one-dimensional flow can be written in a differential form as follows using an infinitesimal control volume shown in [Figure 3.7.5](#).

$$d(\rho u A) = 0 \quad (3.7.17)$$

$$dp + \rho u \, du = 0 \quad (3.7.18)$$

$$dh + u \, du = 0 \quad (3.7.19)$$

**FIGURE 3.7.5** Control volume for quasi-one-dimensional flow.

Equation 3.7.17 can be written as

$$\frac{d\rho}{\rho} + \frac{du}{u} + \frac{dA}{A} = 0 \quad (3.7.20)$$

which can be further written as follows for an isentropic flow:

$$\frac{dA}{A} = (M^2 - 1) \frac{du}{u} \quad (3.7.21)$$

Some very useful physical insight can be obtained from this area–velocity relation.

- For subsonic flow ( $0 \leq M < 1$ ), an increase in area results in decrease in velocity, and vice versa.
- For supersonic flow ( $M > 1$ ), an increase in area results in increase in velocity, and vice versa.
- For sonic flow ( $M = 1$ ),  $dA/A = 0$ , which corresponds to a minimum or maximum in the area distribution, but it can be shown that a minimum in area is the only physical solution.

[Figure 3.7.6](#) shows the preceding results in a schematic form.

It is obvious from this discussion that for a gas to go isentropically from subsonic to supersonic, and vice versa, it must flow through a convergent–divergent nozzle, also known as the de Laval nozzle. The minimum area of the nozzle at which the flow becomes sonic is called the throat. This physical observation forms the basis of designing supersonic wind tunnels shown schematically in [Figure 3.7.7](#). In general, in a supersonic wind tunnel, a stagnant gas is first expanded to the desired supersonic Mach number. The supersonic flow enters the test section where it passes over a model being tested. The flow

FIGURE 3.7.6 Compressible flow in converging and diverging ducts.

FIGURE 3.7.7 Schematic of a typical supersonic wind tunnel.

then is slowed down by compressing it through a second convergent–divergent nozzle, also known as a diffuser, before it is exhausted to the atmosphere.

Now, using the equations for quasi-one-dimensional flow and the isentropic flow conditions, we can derive a relation for the area ratio that is needed to accelerate or decelerate the gas to sonic conditions. Denoting the sonic conditions by an asterisk, we can write  $u^* = a^*$ . The area is denoted as  $A^*$ , and it is obviously the minimum area for the throat of the nozzle. From Equation (3.7.17) we have

$$\rho u A = \rho^* u^* A^* \tag{3.7.22}$$

$$\frac{A}{A^*} = \frac{\rho^* u^*}{\rho u} = \frac{\rho^*}{\rho} \frac{\rho_0}{\rho} \frac{u^*}{u}$$

Under isentropic conditions,

$$\frac{\rho_0}{\rho} = \left( 1 + \frac{\gamma - 1}{2} M^2 \right)^{1/(\gamma - 1)} \tag{3.7.23}$$

$$\frac{\rho_0}{\rho^*} = \left( 1 + \frac{\gamma - 1}{2} \right)^{1/(\gamma - 1)} = \left( \frac{\gamma + 1}{2} \right)^{1/(\gamma - 1)} \tag{3.7.24}$$

Also,  $u^*/u = a^*/u$ . Let us define a Mach number  $M^* = u/a^*$ .  $M^*$  is known as the *characteristic Mach number* and it is related to the local Mach number by the following relation:

$$M^{*2} = \frac{\frac{\gamma + 1}{2} M^2}{1 + \frac{\gamma - 1}{2} M^2} \tag{3.7.25}$$

Using Equations (3.7.23) through (3.7.25) in Equation (3.7.22) we can write

$$\left(\frac{A}{A^*}\right)^2 = \frac{1}{M^2} \left[ \left(\frac{2}{\gamma+1}\right) \left(1 + \frac{\gamma-1}{2} M^2\right) \right]^{(\gamma+1)/(\gamma-1)} \quad (3.7.26)$$

Equation (3.7.26) is called the area Mach number relation. Figure 3.7.8 shows a plot of  $A/A^*$  against Mach number.  $A/A^*$  is always  $\geq 1$  for physically viable solutions.

**FIGURE 3.7.8** Variation of area ratio  $A/A^*$  as a function of Mach number for a quasi-one-dimensional flow.

The area Mach number relation says that for a given Mach number, there is only one area ratio  $A/A^*$ . This is a very useful relation and is frequently used to design convergent–divergent nozzles to produce a desired Mach number. Values of  $A/A^*$  are tabulated as a function of  $M$  in Anderson (1982).

Equation (3.7.26) can also be written in terms of pressure as follows:

$$\frac{A}{A^*} = \frac{\left[ 1 - \left(\frac{p}{p_0}\right)^{(\gamma-1)/\gamma} \right]^{1/2} \left(\frac{p}{p_0}\right)^{1/\gamma}}{\left(\frac{\gamma-1}{2}\right)^{1/2} \left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/2(\gamma-1)}} \quad (3.7.27)$$

### Nozzle Flow

Using the area relations, we can now plot the distributions of Mach number and pressure along a nozzle. Figure 3.7.9 shows pressure and Mach number distributions along a given nozzle and the wave configurations for several exit pressures. For curves a and b, the flow stays subsonic throughout and the exit pressure controls the flow in the entire nozzle. On curve c, the throat has just become sonic, and so the pressure at the throat, and upstream of it, can decrease no further. There is another exit pressure corresponding to curve j ( $p_j < p_c$ ) for which a supersonic isentropic solution exists. But if the pressure lies between  $p_c$  and  $p_j$ , there is no isentropic solution possible. For example, for an exit pressure  $p_d$ , a shock will form in the nozzle at location  $s$  which will raise the pressure to  $p_d$  and turn the flow subsonic. The pressure will then rise to  $p_d$  as the subsonic flow goes through an increasing area nozzle. The location,  $s$ , depends on the exit pressure. Various possible situations are shown in Figure 3.7.9. It is clear that if the exit pressure is equal to or below  $p_j$ , the flow within the nozzle is fully supersonic. This is

**FIGURE 3.7.9** Effect of exit pressure on flow through a nozzle.

the principle used in designing supersonic wind tunnels by operating from a high-pressure reservoir or into a vacuum receiver, or both.

**Diffuser**

If a nozzle discharges directly into the receiver, the minimum pressure ratio for full supersonic flow in the test section is

$$\left(\frac{p_0}{p_E}\right)_{\min} = \frac{p_0}{p_f}$$

where  $p_f$  is the value of  $p_E$  at which the normal shock stands right at the nozzle exit. However, by adding an additional diverging section, known as a diffuser, downstream of the test section as shown in Figure 3.7.10 it is possible to operate the tunnel at a lower pressure ratio than  $p_0/p_f$ . This happens because the diffuser can now decelerate the subsonic flow downstream of the shock isentropically to a stagnation pressure  $p'_0$ . The pressure ratio required then is the ratio of stagnation pressures across a normal shock wave at the test section Mach number. In practice, the diffuser gives lower than expected recovery as a result of viscous losses caused by the interaction of shock wave and the boundary layer which are neglected here.

The operation of supersonic wind tunnels can be made even more efficient; i.e., they can be operated at even lower pressure ratios than  $p_0/p'_0$ , by using the approach shown in Figure 3.7.7 where the diffuser has a second throat. It can slow down the flow to subsonic Mach numbers isentropically and, ideally, can provide complete recovery, giving  $p'_0 = p_0$ . However, due to other considerations, such as the starting process of the wind tunnel and viscous effects, it is not realized in real life.

**Two-Dimensional Supersonic Flow**

When supersonic flow goes over a wedge or an expansion corner, it goes through an oblique shock or expansion waves, respectively, to adjust to the change in surface geometry. Figure 3.7.11 shows the two

FIGURE 3.7.10 Normal shock diffuser.

FIGURE 3.7.11 Supersonic flow over a corner.

flow situations. In Figure 3.7.11(a) an oblique shock abruptly turns the flow parallel to the wedge surface. The Mach number behind the shock is less than ahead of it, whereas the pressure, temperature, and density increase. In the case of an expansion corner, oblique expansion waves smoothly turn the flow to become parallel to the surface downstream of the expansion corner. In this case, the Mach number increases, but the pressure, temperature, and density decrease as the flow goes through the expansion corner. Oblique shocks and expansion waves occur in two- and three-dimensional supersonic flows. In this section, we will restrict ourselves to steady, two-dimensional supersonic flows only.

**Oblique Shock Waves**

The oblique shock can be treated in the same way as the normal shock by accounting for the additional velocity component. If a uniform velocity  $v$  is superimposed on the flow field of the normal shock, the resultant velocity ahead of the shock can be adjusted to any flow direction by adjusting the magnitude and direction of  $v$ . If  $v$  is taken parallel to the shock wave, as shown in Figure 3.7.12, the resultant velocity ahead of the shock is  $w_1 = \sqrt{u_1^2 + v_1^2}$  and its direction from the shock is given by  $\beta = \tan^{-1}(u_1/v)$ . On the downstream side of the shock, since  $u_2$  is less than  $u_1$ , the flow always turns toward the shock. The magnitude of  $u_2$  can be determined by the normal shock relations corresponding to velocity  $u_1$  and the magnitude of  $v$  is such that the flow downstream of the shock turns parallel to the surface. Since imposition of a uniform velocity does not affect the pressure, temperature, etc., we can use normal shock relations with Mach number replaced in them to correspond to velocity  $u_1$  or  $u_1/a_1$ , which is nothing but  $M_1 \sin \beta$ . Thus, oblique shock relations become

$$\frac{p_2}{p_1} = 1 + \frac{2\gamma}{\gamma + 1} (M_1^2 \sin^2 \beta - 1) \tag{3.7.28}$$

$$\frac{\rho_2}{\rho_1} = \frac{(\gamma + 1)M_1^2 \sin^2 \beta}{(\gamma - 1)M_1^2 \sin^2 \beta + 2} \tag{3.7.29}$$

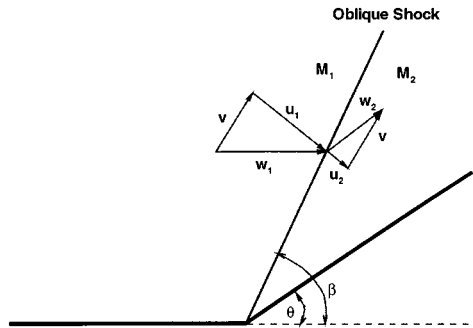

FIGURE 3.7.12 Oblique shock on a wedge.

$$\frac{T_2}{T_1} = \frac{a_2^2}{a_1^2} = \left[ 1 + \frac{2\gamma}{\gamma + 1} (M_1^2 \sin^2 \beta - 1) \right] \left[ \frac{2 + (\gamma - 1)M_1^2 \sin^2 \beta}{(\gamma + 1)M_1^2 \sin^2 \beta} \right] \tag{3.7.30}$$

The Mach number  $M_2 (= w_2/a_2)$  can be obtained by using a Mach number corresponding to velocity  $u_2 (= w_2 \sin(\beta - \theta))$  in the normal shock relation for the Mach number. In other words,

$$M_2^2 \sin^2(\beta - \theta) = \frac{1 + \frac{\gamma - 1}{2} M_1^2 \sin^2 \beta}{\gamma M_1^2 \sin^2 \beta - \frac{\gamma - 1}{2}} \tag{3.7.31}$$

To derive a relation between the wedge angle  $\theta$  and the wave angle  $\beta$ , we have from [Figure 3.7.12](#)

$$\tan \beta = \frac{u_1}{v} \quad \text{and} \quad \tan(\beta - \theta) = \frac{u_2}{v}$$

so that

$$\frac{\tan(\beta - \theta)}{\tan \beta} = \frac{u_2}{u_1} = \frac{\rho_1}{\rho_2} = \frac{(\gamma - 1)M_1^2 \sin^2 \beta + 2}{(\gamma + 1)M_1^2 \sin^2 \beta}$$

This can be simplified to

$$\tan \theta = 2 \cot \beta \frac{M_1^2 \sin^2 \beta - 1}{M_1^2 (\gamma + \cos 2\beta) + 2} \tag{3.7.32}$$

Dennard and Spencer (1964) have tabulated oblique shock properties as a function of  $M_1$ . Let us now make some observations from the preceding relations.

From the normal shock relations,  $M_1 \sin \beta \geq 1$ . This defines a minimum wave angle for a given Mach number. The maximum wave angle, of course, corresponds to the normal shock or  $\beta = \pi/2$ . Therefore, the wave angle  $\beta$  has the following range

FIGURE 3.7.13 Oblique shock characteristics.

$$\sin^{-1} \frac{1}{M} \leq \beta \leq \frac{\pi}{2} \tag{3.7.33}$$

Equation 3.7.32 becomes zero at the two limits of  $\beta$ . Figure 3.7.13 shows a plot of  $\theta$  against  $\beta$  for various values of  $M_1$ . For each value of  $M_1$ , there is a maximum value of  $\theta$ . For  $\theta < \theta_{\max}$ , there are two possible solutions having different values of  $\beta$ . The larger value of  $\beta$  gives the stronger shock in which the flow becomes subsonic. A locus of solutions for which  $M_2 = 1$  is also shown in the figure. It is seen from the figure that with weak shock solution, the flow remains supersonic except for a small range of  $\theta$  slightly smaller than  $\theta_{\max}$ .

Let us now consider the limiting case of  $\theta$  going to zero for the weak shock solution. As  $\theta$  decreases to zero,  $\beta$  decreases to the limiting value  $\mu$ , given by

$$M_1^2 \sin^2 \mu - 1 = 0$$

$$\mu = \sin^{-1} \frac{1}{M_1} \tag{3.7.34}$$

For this angle, the oblique shock relations show no jump in flow quantities across the wave or, in other words, there is no disturbance generated in the flow. This angle  $\mu$  is called the *Mach angle* and the lines at inclination  $\mu$  are called *Mach lines*.

**Thin-Airfoil Theory**

For a small deflection angle  $\Delta\theta$ , it can be shown that the change in pressure in a flow at Mach  $M_1$  is given approximately by

$$\frac{\Delta p}{P_1} \approx \frac{\gamma M_1^2}{\sqrt{M_1^2 - 1}} \Delta\theta \tag{3.7.35}$$

This expression holds for both compression and expansion. If  $\Delta p$  is measured with respect to the freestream pressure,  $p_1$ , and all deflections to the freestream direction, we can write Equation (3.7.35) as

$$\frac{p - p_1}{p_1} = \frac{\gamma M_1^2}{\sqrt{M_1^2 - 1}} \theta \tag{3.7.36}$$

where  $\theta$  is positive for a compression and negative for expansion. Let us define a pressure coefficient  $C_p$ , as

$$C_p = \frac{p - p_1}{q_1}$$

where  $q_1$  is the dynamic pressure and is equal to  $\gamma p_1 M_1^2 / 2$ . Equation (3.7.36) then gives

$$C_p = \mp \frac{2\theta}{\sqrt{M_1^2 - 1}} \tag{3.7.37}$$

Equation (3.7.37) states that the pressure coefficient is proportional to the local flow deflection. This relation can be used to develop supersonic thin-airfoil theory. As an example, for a flat plate at angle of attack  $\alpha_0$  (shown in Figure 3.7.14), the pressure coefficients on the upper and lower surfaces are

$$C_p = \mp \frac{2\alpha_0}{\sqrt{M_1^2 - 1}}$$

**FIGURE 3.7.14** Lifting flat plate.

The lift and drag coefficients can be written as

$$C_L = \frac{(p_L - p_U)c \cos \alpha_0}{q_1 c} = (C_{pL} - C_{pU}) \cos \alpha_0$$

$$C_D = \frac{(p_L - p_U)c \sin \alpha_0}{q_1 c} = (C_{pL} - C_{pU}) \sin \alpha_0$$

where  $c$  is the chord length of the plate. Since  $\alpha_0$  is small, we can write

$$C_L = \frac{4\alpha_0}{\sqrt{M_1^2 - 1}}, \quad C_D = \frac{4\alpha_0^2}{\sqrt{M_1^2 - 1}} \tag{3.7.38}$$

A similar type of expression can be obtained for an arbitrary thin airfoil that has thickness, camber, and angle of attack. Figure 3.7.15 shows such an airfoil. The pressure coefficients on the upper and lower surfaces can be written as

$$C_{pU} = \frac{2}{\sqrt{M_1^2 - 1}} \frac{dy_U}{dx}, \quad C_{pL} = \frac{2}{\sqrt{M_1^2 - 1}} \left( -\frac{dy_L}{dx} \right) \tag{3.7.39}$$

FIGURE 3.7.15 Arbitrary thin airfoil and its components.

For the thin airfoil, the profile may be resolved into three separate components as shown in Figure 3.7.15. The local slope of the airfoil can be obtained by superimposing the local slopes of the three components as

$$\begin{aligned} \frac{dy_U}{dx} &= -(\alpha_0 + \alpha_c(x)) + \frac{dh}{dx} = -\alpha(x) + \frac{dh}{dx} \\ \frac{dy_L}{dx} &= -(\alpha_0 + \alpha_c(x)) - \frac{dh}{dx} = -\alpha(x) - \frac{dh}{dx} \end{aligned} \tag{3.7.40}$$

where  $\alpha = \alpha_0 + \alpha_c(x)$  is the local total angle of attack of the camber line. The lift and drag for the thin airfoil are given by

$$\begin{aligned} L &= q_1 \int_0^c (C_{pL} - C_{pU}) dx \\ D &= q_1 \int_0^c \left[ C_{pL} \left( -\frac{dy_L}{dx} \right) + C_{pU} \left( \frac{dy_U}{dx} \right) \right] dx \end{aligned}$$

Let us define an average value of  $\alpha(x)$  as

$$\bar{\alpha} = \frac{1}{c} \int_0^c \alpha(x) dx$$

Using Equation (3.7.40) and the fact that  $\bar{\alpha}_0 = \alpha$  and  $\bar{\alpha}_c = 0$  by definition, the lift and drag coefficients for the thin airfoil can be written as

$$C_L = \frac{4\alpha_0}{\sqrt{M_1^2 - 1}}$$

$$C_D = \frac{4}{\sqrt{M_1^2 - 1}} \left[ \overline{\left(\frac{dh}{dx}\right)^2} + \overline{\alpha_c^2(x)} + \alpha_0^2 \right] \quad (3.7.41)$$

Equations (3.7.41) show that the lift coefficient depends only on the mean angle of attack whereas the drag coefficient is a linear combination of the drag due to thickness, drag due to camber, and drag due to lift (or mean angle of attack).

## Further Information

As mentioned in the beginning, this section discussed only one- or two-dimensional steady, inviscid compressible flows under perfect gas assumption. Even this discussion was quite brief because of space limitations. For more details on the subject as well as for compressible unsteady viscous flows, readers are referred to Anderson (1982) and Liepmann and Roshko (1966).

## 3.8 Multiphase Flow

---

*John C. Chen*

### Introduction

Classic study of fluid mechanics concentrates on the flow of a single homogeneous phase, e.g., water, air, steam. However, many industrially important processes involve simultaneous flow of multiple phases, e.g., gas bubbles in oil, wet steam, dispersed particles in gas or liquid. Examples include vapor–liquid flow in refrigeration systems, steam–water flows in boilers and condensers, vapor–liquid flows in distillation columns, and pneumatic transport of solid particulates. In spite of their importance, multiphase flows are often neglected in standard textbooks. Fundamental understanding and engineering design procedures for multiphase flows are not nearly so well developed as those for single-phase flows. An added complexity is the need to predict the relative concentrations of the different phases in the multiphase flows, a need that doesn't exist for single-phase flows.

Inadequate understanding notwithstanding, a significant amount of data have been collected and combinations of theoretical models and empirical correlations are used in engineering calculations. This knowledge base is briefly summarized in this section and references are provided for additional information. While discussions are provided of solid–gas flows and solid–liquid flows, primary emphasis is placed on multiphase flow of gas–liquids since this is the most often encountered class of multiphase flows in industrial applications.

A multiphase flow occurs whenever two or more of the following phases occur simultaneously: gas/vapor, solids, single-liquid phase, multiple (immiscible) liquid phases. Every possible combination has been encountered in some industrial process, the most common being the simultaneous flow of vapor/gas and liquid (as encountered in boilers and condensers). All multiphase flow problems have features which are characteristically different from those found in single-phase problems. First, the relative concentration of different phases is usually a dependent parameter of great importance in multiphase flows, while it is a parameter of no consequence in single-phase flows. Second, the spatial distribution of the various phases in the flow channel strongly affects the flow behavior, again a parameter that is of no concern in single-phase flows. Finally, since the density of various phases can differ by orders of magnitude, the influence of gravitational body force on multiphase flows is of much greater importance than in the case of single-phase flows. In any given flow situation, the possibility exists for the various phases to assume different velocities, leading to the phenomena of slip between phases and consequent interfacial momentum transfer. Of course, the complexity of laminar/turbulent characteristics occurs in multiphase flows as in single-phase flows, with the added complexity of interactions between phases altering the laminar/turbulent flow structures. These complexities increase exponentially with the number of phases encountered in the multiphase problem. Fortunately, a large number of applications occur with just two phase flows, or can be treated as pseudo-two-phase flows.

Two types of analysis are used to deal with two-phase flows. The simpler approach utilizes homogeneous models which assume that the separate phases flow with the same identical local velocity at all points in the fluid. The second approach recognizes the possibility that the two phases can flow at different velocities throughout the fluid, thereby requiring separate conservation equations for mass and momentum for each phase. Brief descriptions of both classes of models are given below.

### Fundamentals

Consider  $n$  phases in concurrent flow through a duct with cross-sectional area  $A_c$ . Fundamental quantities that characterize this flow are

$\dot{m}_i$  = mass flow rate of  $i$ th phase

$u_i$  = velocity of  $i$ th phase

$\alpha_i$  = volume fraction of  $i$ th phase in channel

Basic relationships between these and related parameters are

$$\begin{aligned} G_i &= \text{mass flux of } i\text{th phase} \\ &= \frac{\dot{m}_i}{A_c} \end{aligned} \quad (3.8.1)$$

$$\begin{aligned} v_i &= \text{superficial velocity of } i\text{th phase} \\ &= \frac{G_i}{\rho_i} \end{aligned} \quad (3.8.2)$$

$$\begin{aligned} u_i &= \text{actual velocity of } i\text{th phase} \\ &= \frac{v_i}{\alpha_i} \end{aligned} \quad (3.8.3)$$

$$\begin{aligned} x_i &= \text{flow quality of } i\text{th phase} \\ &= \frac{\dot{m}_i}{\sum_i^n \dot{m}_i} = \frac{G_i}{\sum_i^n G_i} \end{aligned} \quad (3.8.4)$$

$$\begin{aligned} \alpha_i &= \text{volume fraction of } i\text{th phase} \\ &= \frac{\left( \frac{x_i}{\rho_i u_i} \right)}{\sum_i^n \left( \frac{x_i}{\rho_i u_i} \right)} \end{aligned} \quad (3.8.5)$$

In most engineering calculations, the above parameters are defined as average quantities across the entire flow area,  $A_c$ . It should be noted, however, that details of the multiphase flow could involve local variations across the flow area. In the latter situation,  $G_i$ ,  $v_i$ , and  $\alpha_i$  are often defined on a local basis, varying with transverse position across the flow area.

Pressure drop along the flow channel is associated with gravitational body force, acceleration forces, and frictional shear at the channel wall. The total pressure gradient along the flow axis can be represented as

$$\frac{dP}{dz} = \left( \frac{dP}{dz} \right)_g + \left( \frac{dP}{dz} \right)_a + \left( \frac{dP}{dz} \right)_f \quad (3.8.6)$$

where

$$\left(\frac{dP}{dz}\right)_g = -g \cos \theta \cdot \sum_{i=1}^n \alpha_i \rho_i \quad (3.8.7)$$

$\theta$  = angle of channel from vertical

and

$$\left(\frac{dP}{dz}\right)_a = -\sum_{i=1}^n G_i \frac{du_i}{dz} \quad (3.8.8)$$

$$\left(\frac{dP}{dz}\right)_f = -\frac{\rho u^2}{2D} f \quad (3.8.9)$$

$\rho$  = density of multiphase mixture

$$= \sum_{i=1}^n \rho_i \alpha_i \quad (3.8.10)$$

$u$  = an average mixture velocity

$$= \frac{1}{\rho} \sum_{i=1}^n G_i \quad (3.8.11)$$

$f$  = equivalent Darcy friction factor for the multiphase flow

In applications, the usual requirement is to determine pressure gradient ( $dP/dz$ ) and the volume fractions ( $\alpha_i$ ). The latter quantities are of particular importance since the volume fraction of individual phases affects all three components of the pressure gradient, as indicated in Equations (3.8.7) to (3.8.11). Correlations of various types have been developed for prediction of the volume fractions, all but the simplest of which utilize empirical parameters and functions.

The simplest flow model is known as the homogeneous equilibrium model (HEM), wherein all phases are assumed to be in neutral equilibrium. One consequence of this assumption is that individual phase velocities are equal for all phases everywhere in the flow system:

$$u_i = u \text{ for all } i \quad (3.8.12)$$

This assumption permits direct calculation of the volume fractions from known mass qualities:

$$\alpha_i = \frac{x_i}{\rho_i \sum_{i=1}^n \left(\frac{x_i}{\rho_i}\right)} \quad (3.8.13)$$

The uniform velocity for all phases is the same as mixture velocity:

$$u = \frac{1}{\rho} \sum_{i=1}^n G_i \quad (3.8.14)$$

where

$$\frac{1}{\rho} = \sum_{i=1}^n \left( \frac{x_i}{\rho_i} \right) \quad (3.8.15)$$

This homogeneous model permits direct evaluation of all three components of axial pressure gradient, if flow qualities ( $x_i$ ) are known:

$$\left( \frac{dP}{dz} \right)_g = - \frac{g \cos \theta}{\sum_{i=1}^n \left( \frac{x_i}{\rho_i} \right)} \quad (3.8.16)$$

$$\left( \frac{dP}{dz} \right)_a = - \left( \sum_{i=1}^n G_i \right) \cdot \frac{du}{dz} \quad (3.8.17)$$

$$\left( \frac{dP}{dz} \right)_f = - \frac{\rho u^2}{2D_f} \cdot f \quad (3.8.18)$$

where  $u$  and  $\rho$  are given by Equations (3.8.14) and (3.8.15).

Predicting the coefficient of friction ( $f$  to clear) remains a problem, even in the homogeneous model. For cases of fully turbulent flows, experience has shown that a value of 0.02 may be used as a first-order approximation for ( $f$  to clear). More-accurate estimates require empirical correlations, specific to particular classes of multiphase flows and subcategories of flow regimes.

The following parts of this section consider the more common situations of two-phase flows and describe improved design methodologies specific to individual situations.

## Gas–Liquid Two-Phase Flow

The most common case of multiphase flow is two-phase flow of gas and liquid, as encountered in steam generators and refrigeration systems. A great deal has been learned about such flows, including delineation of flow patterns in different flow regimes, methods for estimating volume fractions (gas void fractions), and two-phase pressure drops.

### Flow Regimes

A special feature of multiphase flows is their ability to assume different spatial distributions of the phases. These different flow patterns have been classified in flow regimes, which are themselves altered by the direction of flow relative to gravitational acceleration. [Figures 3.8.1](#) and [3.8.2](#) (Delhaye, 1981) show the flow patterns commonly observed for co-current flow of gas and liquid in vertical and horizontal channels, respectively. For a constant liquid flow rate, the gas phase tends to be distributed as small bubbles at low gas flow rates. Increasing gas flow rate causes agglomeration of bubbles into larger slugs and plugs. Further increasing gas flow rate causes separation of the phases into annular patterns wherein liquid concentrates at the channel wall and gas flows in the central core for vertical ducts. For horizontal ducts, gravitational force tends to drain the liquid annulus toward the bottom of the channel, resulting

**FIGURE 3.8.1** Flow patterns in gas-liquid vertical flow. (From Lahey, R.T., Jr. and Moody, F.I. 1977. *The Thermal Hydraulics of a Boiling Water Nuclear Reactor*, The American Nuclear Society, LaGrange, IL. With permission.)

(1) Bubbly flow, (2) Plug flow, (3) Stratified flow, (4) Wavy flow, (5) Slug flow, (6) Annular flow

**FIGURE 3.8.2** Flow patterns in gas-liquid horizontal flow.

in stratified and stratified wavy flows. This downward segregation of the liquid phase can be overcome by kinetic forces at high flow rates, causing stratified flows to revert to annular flows. At high gas flow rates, more of the liquid tends to be entrained as dispersed drops; in the limit one obtains completely dispersed mist flow.

Flow pattern maps are utilized to predict flow regimes for specific applications. The first generally successful flow map was that of Baker (1954) for horizontal flow, reproduced here in Figure 3.8.3. For vertical flows, the map of Hewitt and Roberts (1969), duplicated in Figure 3.8.4, provides a simple method for determining flow regimes. Parameters used for the axial coordinates of these flow maps are defined as follows:

$$\lambda = \left( \frac{\rho_g \rho_\ell}{\rho_a \rho_w} \right)^{1/2} \tag{3.8.19}$$

$$\psi = \left( \frac{\sigma_w}{\sigma} \right) \left[ \left( \frac{\mu_\ell}{\mu_w} \right) \left( \frac{\rho_w}{\rho_\ell} \right)^2 \right]^{1/3} \tag{3.8.20}$$

$$j = \text{volumetric flux, } \frac{G}{\rho} \tag{3.8.21}$$

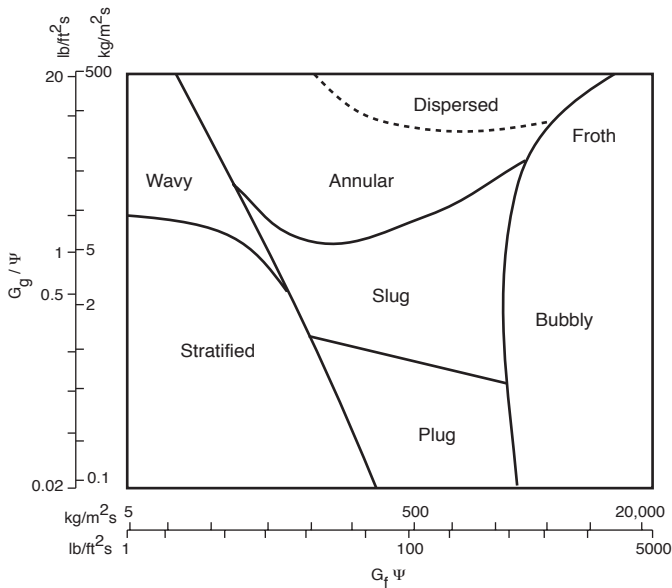

FIGURE 3.8.3 Flow pattern map for horizontal flow (Baker, 1954).

**Void Fractions**

In applications of gas–liquid flows, the volume fraction of gas ( $\alpha_g$ ) is commonly called “void fraction” and is of particular interest. The simplest method to estimate void fraction is by the HEM. From Equation (3.8.13), the void fraction can be estimated as

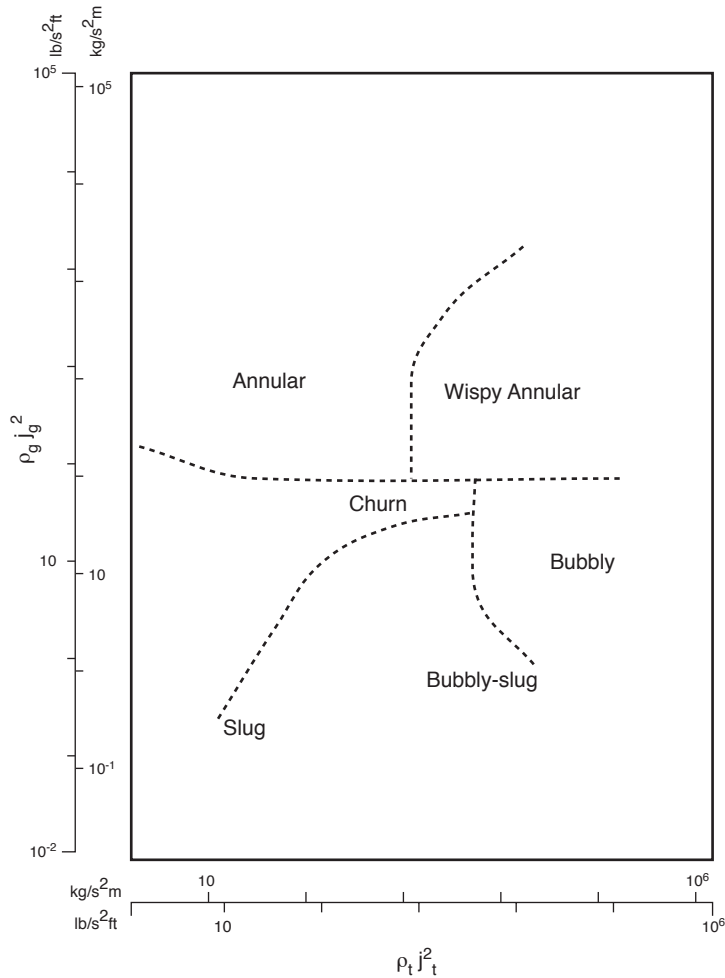

FIGURE 3.8.4 Flow pattern map for vertical flow (Hewitt and Roberts, 1969).

$$\alpha_g = \frac{x_g}{x_g + (1 - x_g) \frac{\rho_g}{\rho_\ell}} \tag{3.8.22}$$

where  $\alpha_g$ ,  $x_g$ ,  $\rho_g$ ,  $\rho_\ell$  are cross-sectional averaged quantities.

In most instances, the homogenous model tends to overestimate the void fraction. Improved estimates are obtained by using separated-phase models which account for the possibility of slip between gas and liquid velocities. A classic separated-phase model is that of Lockhart and Martinelli (1949). The top portion of Figure 3.8.5 reproduces the Lockhart–Martinelli correlation for void fraction (shown as  $\alpha$ ) as a function of the parameter  $X$  which is defined as

$$X = \left[ \left( \frac{dP}{dz} \right)_{fl} \div \left( \frac{dP}{dz} \right)_{fg} \right]^{1/2} \tag{3.8.23}$$

FIGURE 3.8.5 Correlations for void fraction and frictional pressure drop (Lockhart and Martinelli, 1949)

where

$$\left(\frac{dP}{dz}\right)_{f\ell} = \text{frictional pressure gradient of liquid phase flowing alone in channel}$$

$$\left(\frac{dP}{dz}\right)_{fg} = \text{frictional pressure gradient of gas phase flowing alone in channel}$$

Often, flow rates are sufficiently high such that each phase if flowing alone in the channel would be turbulent. In this situation the parameter  $X$  can be shown to be

$$X_{tt} = \left(\frac{1 - x_g}{x_g}\right)^{0.9} \left(\frac{\rho_g}{\rho_\ell}\right)^{0.5} \left(\frac{\mu_\ell}{\mu_g}\right)^{0.1} \tag{3.8.24}$$

Another type of separated-phase model is the drift-flux formulation of Wallis (1969). This approach focuses attention on relative slip between phases and results in slightly different expressions depending on the flow regime. For co-current upflow in two of the more common regimes, the drift-flux model gives the following relationships between void fraction and flow quality:

Bubbly flow or churn-turbulent flow:

$$\alpha_g = \frac{x_g}{\left(\frac{u_o \rho_g}{G}\right) + C_o \left[ x_g + (1 - x_g) \frac{\rho_g}{\rho_\ell} \right]} \quad (3.8.25)$$

Dispersed drop (mist) flow:

$$x_g = \frac{1 - (1 - \alpha_g) \left( \frac{u_o \rho_\ell}{G} \alpha_g^2 + 1 \right)}{1 - (1 - \alpha_g) \left( 1 - \frac{\rho_\ell}{\rho_g} \right)} \quad (3.8.26)$$

where  $u_o$  = terminal rise velocity of bubble, in bubbly flow, or terminal fall velocity of drop in churn-turbulent flow

$C_o$  = an empirical distribution coefficient  $\approx 1.2$

### Pressure Drop

Equations 3.8.16 through 3.8.18 permit calculation of two-phase pressure drop by the homogeneous model, if the friction coefficient ( $f$ ) is known. One useful method for estimating ( $f$ ) is to treat the entire two-phase flow as if it were all liquid, except flowing at the two-phase mixture velocity. By this approach the frictional component of the two-phase pressure drop becomes

$$\left(\frac{dP}{dz}\right)_f = \left[ 1 + x_g \left( \frac{\rho_\ell}{\rho_g} - 1 \right) \right] \cdot \left(\frac{dP}{dz}\right)_{fG} \quad (3.8.27)$$

where  $(dP/dz)_{fG}$  = frictional pressure gradient if entire flow (of total mass flux  $G$ ) flowed as liquid in the channel.

The equivalent frictional pressure drop for the entire flow as liquid,  $(dP/dz)_{fG}$ , can be calculated by standard procedures for single-phase flow. In using Equations (3.8.16) through (3.8.18), the void fraction would be calculated with the equivalent homogeneous expression Equation (3.8.13).

A more accurate method to calculate two-phase pressure drop is by the separated-phases model of Lockhart and Martinelli (1949). The bottom half of Figure 3.8.5 shows empirical curves for the Lockhart–Martinelli frictional multiplier,  $\phi$ :

$$\phi_i = \left[ \left(\frac{dP}{dz}\right)_f \div \left(\frac{dP}{dz}\right)_{fi} \right]^{1/2} \quad (3.8.28)$$

where ( $i$ ) denotes either the fluid liquid phase ( $f$ ) or gas phase ( $g$ ). The single-phase frictional gradient is based on the  $i$ th phase flowing alone in the channel, in either viscous laminar ( $v$ ) or turbulent ( $t$ ) modes. The most common case is where each phase flowing alone would be turbulent, whence one could use Figure 3.8.5 to obtain

$$\begin{aligned} \left(\frac{dP}{dz}\right)_f &= \text{frictional pressure gradient for two-phase flow} \\ &= \phi_{gn}^2 \cdot \left(\frac{dP}{dz}\right)_{fg} \end{aligned} \quad (3.8.29)$$

where  $(dP/dz)_{fg}$  is calculated for gas phase flowing alone and  $X = X_g$  as given by Equation (3.8.24).

The correlation of Lockhart–Martinelli has been found to be adequate for two-phase flows at low-to-moderate pressures, i.e., with reduced pressures less than 0.3. For applications at higher pressures, the revised models of Martinelli and Nelson (1948) and Thom (1964) are recommended.

## Gas–Solid, Liquid–Solid Two-Phase Flows

Two-phase flows can occur with solid particles in gas or liquid. Such flows are found in handling of granular materials and heterogeneous reaction processing. Concurrent flow of solid particulates with a fluid phase can occur with various flow patterns, as summarized below.

### Flow Regimes

Consider vertical upflow of a fluid (gas or liquid) with solid particles. Figure 3.8.6 illustrates the major flow regimes that have been identified for such two-phase flows. At low flow rates, the fluid phase percolates between stationary particles; this is termed flow through a fixed bed. At some higher velocity a point is reached when the particles are all suspended by the upward flowing fluid, the drag force between particles and fluid counterbalancing the gravitational force on the particles. This is the point of minimum fluidization, marking the transition from fixed to fluidized beds. Increase of fluid flow rate beyond minimum fluidization causes instabilities in the two-phase mixture, and macroscopic bubbles or channels of fluid are observed in the case of gaseous fluids. In the case of liquid fluids, the two-phase mixture tends to expand, often without discrete bubbles or channels. Further increase of fluid velocity causes transition to turbulent fluidization wherein discrete regions of separated phases (fluid slugs or channels and disperse suspensions of particles) can coexist. Depending on specific operating conditions (e.g., superficial fluid velocity, particle size, particle density, etc.), net transport of solid particles with the flowing fluid can occur at any velocity equal to or greater than that associated with slug flow and turbulent flow. Further increases in fluid velocity increase the net transport of solid particles. This can occur with large-scale clusters of solid particles (as exemplified by the fast fluidization regime) or with dilute dispersions of solid particles (as often utilized in pneumatic conveying). For engineering application of fluid–solid two-phase flows, the important thresholds between flow regimes are marked by the fluid velocity for minimum fluidization, terminal slip, and saltation threshold.

### Minimum Fluidization

The transition from flow through packed beds to the fluidization regime is marked by the minimum fluidization velocity of the fluid. On a plot pressure drop vs. superficial fluid velocity, the point of minimum fluidization is marked by a transition from a linearly increasing pressure drop to a relatively constant pressure drop as shown in Figure 3.8.7 for typical data, for two-phase flow of gas with sand particles of 280  $\mu\text{m}$  mean diameter (Chen, 1996). The threshold fluid velocity at minimum fluidization is traditionally derived from the Carman–Kozeny equation,

$$U_{mf} = \frac{(\rho_s - \rho_f)(\phi dp)^2 g}{150\mu_f} \cdot \frac{\alpha_{mf}^2}{(1 - \alpha_{mf})} \quad (3.8.30)$$

**FIGURE 3.8.6** Flow patterns for vertical upflow of solid particles and gas or liquid. (From Chen, J.C. 1994. *Proc. Xth Int. Heat Transfer Conf.*, Brighton, U.K., 1:369–386. With permission.)

**FIGURE 3.8.7** Transition at minimum fluidization. (From Chen, J.C. 1996. In *Annual Review of Heat Transfer*, Vol. VII, Begal House, Washington, D.C. With permission.)

where  $\phi$  = sphericity of particles (unity for spherical particles)

$\alpha_{mf}$  = volumetric fraction of fluid at minimum fluidization

Small, light particles have minimum fluidization voidage ( $\alpha_{mf}$ ) of the order 0.6, while larger particles such as sand have values closer to 0.4.

An alternative correlation for estimating the point of minimum fluidization is that of Wen and Yu (1966):

$$\frac{U_{mf} d_p \rho_f}{\mu_f} = (33.7 + 0.041 Ga)^{0.5} - 33.7 \quad (3.8.31)$$

where  $Ga = \rho_f d_p^3 (\rho_s - \rho_f) g / \mu_f^2$ .

When the fluid velocity exceeds  $U_{mf}$ , the two-phase mixture exists in the fluidized state in which the pressure gradient is essentially balanced by the gravitational force on the two-phase mixture:

$$\frac{dP}{dz} = g [\alpha_s \rho_s + \alpha_f \rho_f] \quad (3.8.32)$$

This fluidized state exists until the fluid velocity reaches a significant fraction of the terminal slip velocity, beyond which significant entrainment and transport of the solid particles occur.

### Terminal Slip Velocity

For an isolated single particle the maximum velocity relative to an upflowing fluid is the terminal slip velocity. At this condition, the interfacial drag of the fluid on the particle exactly balances the gravitational body force on the particle:

$$U_t = (U_f - U_s)_t = \left[ \frac{4d_p (\rho_s - \rho_f)}{3\rho_f} \cdot \frac{1}{C_D} \right]^{1/2} \quad (3.8.33)$$

where  $C_D$  = coefficient of drag on the particle.

The coefficient of drag on the particle ( $C_D$ ) depends on the particle Reynolds number:

$$\text{Re}_p = \frac{\rho_f d_p (U_f - U_s)}{\mu_f} \quad (3.8.34)$$

The following expressions may be used to estimate  $C_D$  as appropriate:

$$\begin{aligned} C_D &= \frac{32}{\text{Re}_p}, & \text{Re}_p &\leq 1 \\ C_D &= \frac{18.5}{\text{Re}_p^{0.67}}, & 1 &\leq \text{Re}_p \leq 10^3 \end{aligned} \quad (3.8.35)$$

### Pneumatic Conveying

A desirable mode of pneumatic conveying is two-phase flow with solid particles dispersed in the concurrent flowing fluid. Such dispersed flows can be obtained if the fluid velocity is sufficiently high. For both horizontal and vertical flows, there are minimum fluid velocities below which saltation of the solid particles due to gravitational force occurs, leading to settling of the solid particles in horizontal channels and choking of the particles in vertical channels. [Figures 3.8.8 and 3.8.9](#) for Zenz and Othmer (1960) show these different regimes of pneumatic conveying for horizontal and vertical transport, respectively. [Figure 3.8.8](#) shows that for a given rate of solids flow ( $W$ ) there is a minimum superficial fluid velocity below which solid particles tend to settle into a dense layer at the bottom of the horizontal channels. Above this saltation threshold, fully dispersed two-phase flow is obtained. In the case of

FIGURE 3.8.8 Flow characteristics in horizontal pneumatic conveying.

FIGURE 3.8.9 Flow characteristics in vertical pneumatic conveying.

vertical transport illustrated in [Figure 3.8.9](#), there is a minimum fluid velocity below which solid particles tend to detrain from the two-phase suspension. This choking limit varies not only with particle properties but also with the actual rate of particle flow. Well-designed transport systems must operate with superficial fluid velocities greater than these limiting saltation and choking velocities.

Zenz and Othmer (1960) recommend the empirical correlations represented in [Figure 3.8.10](#) estimating limiting superficial fluid velocities at incipient saltation or choking, for liquid or gas transport of uniformly sized particles. Note that these correlations are applicable for either horizontal or vertical concurrent flow. [Figure 3.8.10](#) is duplicated from the original source and is based on parameters in engineering units, as noted in the figure. To operate successfully in dispersed pneumatic conveying of solid particles, the superficial fluid velocity must exceed that determined from the empirical correlations of [Figure 3.8.10](#).

## Nomenclature

$A_c$	cross-sectional flow area of channel
$C_o$	Wallis' distribution coefficient
$d_p$	diameter of solid particles
$f_D$	Darcy friction factor
$G$	mass flow flux, $\text{kg}/\text{m}^2 \cdot \text{sec}$
$j$	volumetric flow flux, $\text{m}/\text{sec}$
$\dot{m}$	mass flow rate, $\text{kg}/\text{sec}$
$P$	pressure, $\text{N}/\text{m}^2$
$u$	velocity in axial flow direction, $\text{m}/\text{sec}$
$v$	superficial velocity in axial flow direction, $\text{m}/\text{sec}$
$x$	mass flow quality
$z$	axial coordinate

## Greek Letters

---

$\alpha$	volume fraction
$\lambda$	parameter in Baker flow map
$\phi$	sphericity of solid particles
$\phi_i$	frictional multiphase for pressure drag, Equation (3.8.28)
$\psi$	parameter in Baker flow map
$\sigma$	surface tension
$\theta$	angle from vertical

## Subscripts

---

$a$	air
$f$	fluid phase
$g$	gas phase
$l$	liquid phase
mf	minimum fluidization
$p$	particle
$s$	solid phase
$t$	terminal slip
$w$	water

## 3.9 New-Newtonian Flows

*Thomas F. Irvine Jr. and Massimo Capobianchi*

### Introduction

An important class of fluids exists which differ from Newtonian fluids in that the relationship between the shear stress and the flow field is more complicated. Such fluids are called non-Newtonian or rheological fluids. Examples include various suspensions such as coal–water or coal–oil slurries, food products, inks, glues, soaps, polymer solutions, etc.

An interesting characteristic of rheological fluids is their large “apparent viscosities”. This results in laminar flow situations in many applications, and consequently the engineering literature is concentrated on laminar rather than turbulent flows. It should also be mentioned that knowledge of non-Newtonian fluid mechanics and heat transfer is still in an early stage and many aspects of the field remain to be clarified.

In the following sections, we will discuss the definition and classification of non-Newtonian fluids, the special problems of thermophysical properties, and the prediction of pressure drops in both laminar and turbulent flow in ducts of various cross-sectional shapes for different classes of non-Newtonian fluids.

### Classification of Non-Newtonian Fluids

It is useful to first define a Newtonian fluid since all other fluids are non-Newtonian. Newtonian fluids possess a property called viscosity and follow a law analogous to the Hookian relation between the stress applied to a solid and its strain. For a one-dimensional Newtonian fluid flow, the shear stress at a point is proportional to the rate of strain (called in the literature the *shear rate*) which is the velocity gradient at that point. The constant of proportionality is the dynamic viscosity, i.e.,

$$\tau_{y,x} = \mu \frac{du}{dy} = \mu \dot{\gamma} \quad (3.9.1)$$

where  $x$  refers to the direction of the shear stress  $y$  the direction of the velocity gradient, and  $\dot{\gamma}$  is the shear rate. The important characteristic of a Newtonian fluid is that the dynamic viscosity is independent of the shear rate.

Equation (3.9.1) is called a constitutive equation, and if  $\tau_{x,y}$  is plotted against  $\dot{\gamma}$ , the result is a linear relation whose slope is the dynamic viscosity. Such a graph is called a *flow curve* and is a convenient way to illustrate the viscous properties of various types of fluids.

Fluids which do not obey Equation (3.9.1) are called non-Newtonian. Their classifications are illustrated in [Figure 3.9.1](#) where they are separated into various categories of purely viscous time-independent or time-dependent fluids and viscoelastic fluids. Viscoelastic fluids, which from their name possess both viscous and elastic properties (as well as memory), have received considerable attention because of their ability to reduce both drag and heat transfer in channel flows. They will be discussed in a later subsection.

Purely viscous time-dependent fluids are those in which the shear stress is a function only of the shear rate but in a more complicated manner than that described in Equation (3.9.1). [Figure 3.9.2](#) illustrates the characteristics of purely viscous time-independent fluids. In the figure, (a) and (b) are fluids where the shear stress depends only on the shear rate but in a nonlinear way. Fluid (a) is called pseudoplastic (or shear thinning), and fluid (b) is called dilatant (or shear thickening). Curve (c) is one which has an initial yield stress after which it acts as a Newtonian fluid, called Buckingham plastic, and curve (d), called Hershel-Buckley, also has a yield stress after which it becomes pseudoplastic. Curve (e) depicts a Newtonian fluid.

[Figure 3.9.3](#) shows flow curves for two common classes of purely viscous time-dependent non-Newtonian fluids. It is seen that such fluids have a hysteresis loop or memory whose shape depends

FIGURE 3.9.1 Classification of fluids.

FIGURE 3.9.2 Flow curves of purely viscous, time-independent fluids: (a) pseudoplastic; (b) dilatant; (c) Bingham plastic; (d) Hershel-Buckley; (e) Newtonian.

FIGURE 3.9.3 Flow curves for purely viscous, time-dependent fluids: (a) thixotropic; (b) rheopectic.

upon the time-dependent rate at which the shear stress is applied. Curve (a) illustrates a pseudoplastic time-dependent fluid and curve (b) a dilatant time-dependent fluid. They are called, respectively, thixotropic and rheopectic fluids and are complicated by the fact that their flow curves are difficult to characterize for any particular application.

## Apparent Viscosity

Although non-Newtonian fluids do not have the property of viscosity, in the Newtonian fluid sense, it is convenient to define an apparent viscosity which is the ratio of the local shear stress to the shear rate at that point.

$$\mu_a = \frac{\tau}{\dot{\gamma}} \quad (3.9.2)$$

The apparent viscosity is not a true property for non-Newtonian fluids because its value depends upon the flow field, or shear rate. Nevertheless, it is a useful quantity and flow curves are often constructed with the apparent viscosity as the ordinate and shear rate as the abscissa. Such a flow curve will be illustrated in a later subsection.

## Constitutive Equations

A constitutive equation is one that expresses the relation between the shear stress or apparent viscosity and the shear rate through the rheological properties of the fluid. For example, Equation (3.9.1) is the constitutive equation for a Newtonian fluid.

Many constitutive equations have been developed for non-Newtonian fluids with some of them having as many as five rheological properties. For engineering purposes, simpler equations are normally satisfactory and two of the most popular will be considered here.

Since many of the non-Newtonian fluids in engineering applications are pseudoplastic, such fluids will be used in the following to illustrate typical flow curves and constitutive equations. Figure 3.9.4 is a qualitative flow curve for a typical pseudoplastic fluid plotted with logarithmic coordinates. It is seen in the figure that at low shear rates, region (a), the fluid is Newtonian with a constant apparent viscosity of  $\mu_0$  (called the *zero shear rate viscosity*). At higher shear rates, region (b), the apparent viscosity begins to decrease until it becomes a straight line, region (c). This region (c) is called the power law region and is an important region in fluid mechanics and heat transfer. At higher shear rates than the power law region, there is another transition region (d) until again the fluid becomes Newtonian in region (e). As discussed below, regions (a), (b), and (c) are where most of the engineering applications occur.

**FIGURE 3.9.4** Illustrative flow curve for a pseudoplastic fluid (a) Newtonian region; (b) transition region I; (c) power law region; (d) transition region II; (e) high-shear-rate Newtonian region.

### Power Law Constitutive Equation

Region (c) in [Figure 3.9.4](#), which was defined above as the power law region, has a simple constitutive equation:

$$\tau = K\dot{\gamma}^n \quad (3.9.3)$$

or, from Equation (3.9.2):

$$\mu_a = K\dot{\gamma}^{n-1} \quad (3.9.4)$$

Here,  $K$  is called the fluid consistency and  $n$  the flow index. Note that if  $n = 1$ , the fluid becomes Newtonian and  $K$  becomes the dynamic viscosity. Because of its simplicity, the power law constitutive equation has been most often used in rheological studies, but at times it is inappropriate because it has several inherent flaws and anomalies. For example, if one considers the flow of a pseudoplastic fluid ( $n < 1$ ) through a circular duct, because of symmetry at the center of the duct the shear rate (velocity gradient) becomes zero and thus the apparent viscosity from Equation (3.9.4) becomes infinite. This poses conceptual difficulties especially when performing numerical analyses on such systems. Another difficulty arises when the flow field under consideration is not operating in region (c) of [Figure 3.9.4](#) but may have shear rates in region (a) and (b). In this case, the power law equation is not applicable and a more general constitutive equation is needed.

### Modified Power Law Constitutive Equation

A generalization of the power law equation which extends the shear rate range to regions (a) and (b) is given by

$$\mu_a = \frac{\mu_o}{1 + \frac{\mu_o}{K} \dot{\gamma}^{1-n}} \quad (3.9.5)$$

Examination of Equation (3.9.5) reveals that at low shear rates, the second term in the denominator becomes small compared with unity and the apparent viscosity becomes a constant equal to  $\mu_o$ . This represents the Newtonian region in [Figure 3.9.4](#). On the other hand, as the second term in the denominator becomes large compared with unity, Equation (3.9.5) becomes Equation (3.9.4) and represents region (c), the power law region. When both denominator terms must be considered, Equation (3.9.5) represents region (b) in [Figure 3.9.4](#).

An important advantage of the modified power law equation is that it retains the rheological properties  $K$  and  $n$  of the power law model plus the additional property  $\mu_o$ . Thus, as will be shown later, in the flow and heat transfer equations, the same dimensionless groups as in the power law model will appear plus an additional dimensionless parameter which describes in which of the regions (a), (b), or (c) a particular system is operating. Also, solutions using the modified power law model will have Newtonian and power law solutions as asymptotes.

Equation (3.9.5) describes the flow curve for a pseudoplastic fluid ( $n < 1$ ). For a dilatant fluid, ( $n > 1$ ), an appropriate modified power law model is given by

$$\mu_a = \mu_o \left[ 1 + \frac{K}{\mu_o} \dot{\gamma}^{n-1} \right] \quad (3.9.6)$$

Many other constitutive equations have been proposed in the literature (Skelland, 1967; Cho and Hartnett, 1982; Irvine and Karni, 1987), but the ones discussed above are sufficient for a large number of engineering applications and agree well with the experimental determinations of rheological properties.

## Rheological Property Measurements

For non-Newtonian fluids, specifying the appropriate rheological properties for a particular fluid is formidable because such fluids are usually not pure substances but various kinds of mixtures. This means that the properties are not available in handbooks or other reference materials but must be measured for each particular application. A discussion of the various instruments for measuring rheological properties is outside the scope of the present section, but a number of sources are available which describe different rheological property measurement techniques and instruments: Skelland (1967), Whorlow (1980), Irvine and Karni (1987), and Darby (1988). Figure 3.9.5 is an illustration of experimental flow curves measured with a falling needle viscometer and a square duct viscometer for polymer solutions of different concentrations. Also known in the figure as solid lines is the modified power law equation used to represent the experimental data. It is seen that Equation (3.9.5) fits the experimental data within  $\pm 2\%$ . Table 3.9.1 lists the rheological properties used in the modified power law equations in Figure 3.9.5. It must be emphasized that a proper knowledge of these properties is vital to the prediction of fluid mechanics and heat transfer phenomena in rheological fluids.

## Fully Developed Laminar Pressure Drops for Time-Independent Non-Newtonian Fluids

### Modified Power Law Fluids

This important subject will be considered by first discussing modified power law fluids. The reason is that such solutions include both friction factor–Reynolds number relations and a shear rate parameter. The latter allows the designer to determine the shear rate region in which his system is operating and thus the appropriate solution to be used, i.e., regions (a), (b), or (c) in Figure 3.9.4.

For laminar fully developed flow of a modified power law fluid in a circular duct, the product of the friction factor and a certain Reynolds number is a constant depending on the flow index,  $n$ , and the shear rate parameter,  $\beta$ .

$$f_D \cdot \text{Re}_m = \text{constant}(n, \beta) \quad (3.9.7)$$

where  $f_D$  is the Darcy friction factor and  $\text{Re}_m$  the modified power law Reynolds number, i.e.,

$$f_D = \frac{2 \Delta p D_H}{L \rho \bar{u}^2} \quad (\text{Darcy friction factor})^*$$

\* It should be noted that the Fanning friction factor is also used in the technical literature. The Fanning friction factor is  $1/4$  of the Darcy friction factor, and will be characterized by the symbol  $f_F$ .

**FIGURE 3.9.5** Experimental measurements of apparent viscosity vs. shear rate for polymer solutions (CMC-7H4) at different concentrations. (From Park, S. et al., in *Proc. Third World Conf. Heat Transfer, Fluid Mechanics, and Thermodynamics*, Vol. 1, Elsevier, New York, 1993, 900–908.).

$$Re_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

$$\mu^* = \frac{\mu_o}{1 + \beta}$$

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n}$$

where  $\beta$  is the shear rate parameter mentioned previously which can be calculated by the designer for a certain operating duct ( $\bar{u}$  and  $d$ ) and a certain pseudoplastic fluid ( $\mu_o$ ,  $K$ ,  $n$ ). The solution for a circular tube has been calculated by Brewster and Irvine (1987) and the results are shown in [Figure 3.9.6](#) and in [Table 3.9.2](#). Referring to 3.9.6, we can see that when the  $\log_{10} \beta$  is less than approximately  $-2$ , the duct is operating in region (a) of [Figure 3.9.4](#) which is the Newtonian region and therefore classical Newtonian solutions can be used. Note that in the Newtonian region,  $Re_m$  reverts to the Newtonian Reynolds number given by

**FIGURE 3.9.6** Product of friction factor and modified Reynolds number vs.  $\log_{10} \beta$  for a circular duct.

**TABLE 3.9.2** Summary of Computed Values of  $f_D \cdot Re_m$  for Various Values of  $n$  and  $\beta$  for a Circular Duct

Exact solution	64.000	53.282	44.323	36.829	30.557	25.298

Source: Brewster, R.A. and Irvine, T.F., Jr., *Wärme und Stoffübertragung*, 21, 83–86, 1987. With permission.

$$\text{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o} \quad (3.9.8)$$

When the value of  $\log_{10} \beta$  is approximately in the range  $-2 \leq \log_{10} \beta \leq 2$ , the duct is operating in the transition region (b) of Figure 3.9.4 and the values of  $f_D \cdot \text{Re}_m$  must be obtained from Figure 3.9.6 or from Table 3.9.2.

When  $\log_{10} \beta$  is greater than approximately 2, the duct is operating in the power law region (c) of Figure 3.9.4 and power law friction factor Reynolds number relations can be used. They are also indicated in Figure 3.9.6 and Table 3.9.2. In this region,  $\text{Re}_m$  becomes the power law Reynolds number given by

$$\text{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K} \quad (3.9.9)$$

For convenience, Brewster and Irvine (1987) have presented a correlation equation which agrees within 0.1% with the results tabulated in Table 3.9.2.

$$f_D \cdot \text{Re}_m = \frac{1 + \beta}{\frac{1}{64} + \frac{\beta}{2^{3n+3} \left(\frac{3n+1}{4n}\right)^n}} \quad (3.9.10)$$

Thus, Equation (3.9.10) contains all of the information required to calculate the circular tube laminar fully developed pressure drop for a pseudoplastic fluid depending upon the shear rate region(s) under consideration, i.e., regions (a), (b), or (c) of Figure 3.9.4. Note that in scaling such non-Newtonian systems, both  $\text{Re}_m$  and  $\beta$  must be held constant. Modified power law solutions have been reported for two other duct shapes. Park et al. (1993) have presented the friction factor–Reynolds number relations for rectangular ducts and Capobianchi and Irvine (1992) for concentric annular ducts.

### Power Law Fluids

Since the power law region of modified power law fluids ( $\log_{10} \beta \geq 2$ ) is often encountered, the friction factor–Reynolds number relations will be discussed in detail in this subsection.

An analysis of power law fluids which is most useful has been presented by Kozicki et al. (1967). Although the method is approximate, its overall accuracy ( $\pm 5\%$ ) is usually sufficient for many engineering calculations. His expression for the friction factor–Reynolds number product is given by

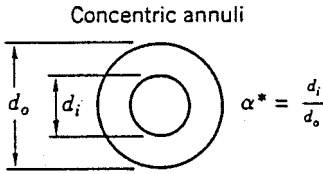

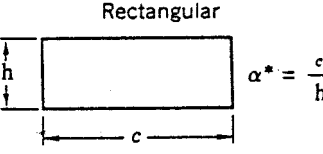

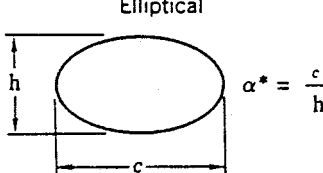

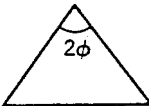

$$f_D \cdot \text{Re}^* = 2^{6n} \quad (3.9.11)$$

where

$$\text{Re}^* = \text{Kozicki Reynolds number}, \quad \text{Re}^* = \frac{\text{Re}_g}{\left[\frac{a + bn}{n}\right]^n 8^{n-1}} \quad (3.9.12)$$

and  $a$  and  $b$  are geometric constants which depend on the cross-sectional shape of the duct. For example, for a circular duct,  $a = 0.25$  and  $b = 0.75$ . Values of  $a$  and  $b$  for other duct shapes are tabulated in Table 3.9.3. For additional duct shapes in both closed and open channel flows, Kozicki et al. (1967) may be consulted.

### Fully Developed Turbulent Flow Pressure Drops

In a number of engineering design calculations for turbulent flow, the shear rate range falls in region (c) of Figure 3.9.4. Thus, power law relations are appropriate for such pressure drop calculations.

Hartnett and Kostic (1990) have investigated the various correlations which have appeared in the literature for circular tubes and have concluded that for a circular tube the relation proposed by Dodge and Metzner (1959) is the most reliable for pseudoplastic fluids. It is given by

$$\frac{1}{f_F^{1/2}} = \frac{4.0}{n^{0.75}} \cdot \log_{10} \left[ \text{Re}'_g (f_F)^{1-(1/2n)} \right] - \frac{0.40}{n^{1.2}} \tag{3.9.13}$$

where  $f_F$  is the Fanning friction factor and

$$\text{Re}'_g = \text{Re}_g \left[ \frac{8^{1-n}}{\left[ \frac{3n+1}{4n} \right]^n} \right] \tag{3.9.14}$$

Figure 3.9.7 is a graphical representation of Equation (3.9.13) which indicates the Dodge and Metzner experimental regions by solid lines, and by dashed lines where the data are extrapolated outside of their experiments.

**FIGURE 3.9.7** Dodge and Metzner relation between Fanning friction factor and  $\text{Re}'_g$ . (From Dodge, D.W. and Metzner, A.B., *AIChE J.*, 5, 189–204, 1959.)

For noncircular ducts in turbulent fully developed flow, only a limited amount of experimental data are available. Kostic and Hartnett (1984) suggest the correlation:

$$\frac{1}{f_F^{1/2}} = \frac{4}{n^{0.75}} \cdot \log_{10} \left[ \text{Re}^* (f_F)^{1-(1/2n)} \right] - \frac{0.40}{n^{0.5}} \tag{3.9.15}$$

where  $f_F$  is again the Fanning friction factor and  $\text{Re}^*$  is the Kozicki Reynolds number:

$$\text{Re}^* = \frac{\text{Re}_g}{\left[ \frac{a+bn}{n} \right]^n 8^{n-1}} \tag{3.9.16}$$

and  $a$  and  $b$  are geometric constants given in Table 3.9.3.

## Viscoelastic Fluids

### Fully Developed Turbulent Flow Pressure Drops

Viscoelastic fluids are of interest in engineering applications because of reductions of pressure drop and heat transfer which occur in turbulent channel flows. Such fluids can be prepared by dissolving small amounts of high-molecular-weight polymers, e.g., polyacrylamide, polyethylene oxide (Polyox), etc., in water. Concentrations as low as 5 parts per million by weight (wppm) result in significant pressure drop reductions. Figure 3.9.8 from Cho and Hartnett (1982) illustrates the reduction in friction factors for Polyox solutions in a small-diameter capillary tube. It is seen that at zero polymer concentration the data agree with the Blasius equation for Newtonian turbulent flow. With the addition of only 7 wppm of Polyox, there is a significant pressure drop reduction and for concentrations of 70 wppm and greater all the data fall on the Virk line which is the maximum drag-reduction asymptote. The correlations for the Blasius and Virk lines as reported by Cho and Hartnett (1982) are

$$f_F = \frac{0.079}{Re^{1/4}} \quad (\text{Blasius}) \tag{3.9.17}$$

$$f_F = 0.20 Re_a^{-0.48} \quad (\text{Virk}) \tag{3.9.18}$$

**FIGURE 3.9.8** Reduction in friction factors for polyethylene oxide (Polyox) solutions in a small-diameter capillary tube. (From Cho, Y.I. and Harnett, J.P., *Adv. Heat Transfer*, 15, 59–141, 1982. With permission.)

At the present time, no generally accepted method exists to predict the drag reduction between the Blasius and Virk lines. Kwack and Hartnett (1983) have proposed that the amount of drag reduction between those two correlations is a function of the Weissenberg number, defined as

$$w_s = \frac{\lambda \bar{u}}{D_H} \tag{3.9.19}$$

where  $\lambda$  = characteristic time of the viscoelastic fluid. They present correlations which allow the friction factor to be estimated at several Reynolds numbers between the Blasius and Virk lines.

### Fully Developed Laminar Flow Pressure Drops

The above discussion on viscoelastic fluids has only considered fully developed turbulent flows. Laminar fully developed flows can be considered as nonviscoelastic but purely viscous non-Newtonian. Therefore, the method of Kozicki et al. (1967) may be applied to such situations once the appropriate rheological properties have been determined.

### Nomenclature

- $a$  = duct shape geometric constant  
 $b$  = duct shape geometric constant  
 $c$  = duct width (see Table 3.9.3) (m)  
 $d_i$  = concentric annuli inner diameter (see Table 3.9.3) (m)  
 $d_o$  = concentric annuli outer diameter (see Table 3.9.3) (m)  
 $f_D$  = Darcy friction factor  
 $f_F$  = Fanning friction factor  
 $h$  = duct height (see Table 3.9.3) (m)  
 $K$  = fluid consistency ( $\text{Ns}^n/\text{m}^2$ )  
 $n$  = flow index  
 $N$  = number of sides in polygon (see Table 3.9.3)  
 $\text{Re}_g$  = generalized Reynolds number,

$$\text{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K}$$

$\text{Re}_m$  = modified power law Reynolds number,

$$\text{Re}_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

$\text{Re}_N$  = modified power law Reynolds number Newtonian asymptote,

$$\text{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o}$$

$\text{Re}_a$  = apparent Reynolds number

$$\text{Re}_a = \frac{\text{Re}_g}{\left(\frac{3n+1}{4n}\right)^{n-1} 8^{n-1}}$$

$\text{Re}^*$  = Kozicki Reynolds number

$$\text{Re}^* = \frac{\rho \bar{u}^{2-n} D_H^n}{K \left[\frac{a+bn}{n}\right]^n 8^{n-1}}$$

$Re'_g$  = Metzner Reynolds number

$$Re'_g = Re_g \left[ \frac{8^{1-n}}{\left[ \frac{3n+1}{4n} \right]^n} \right]$$

$\bar{u}$  = average streamwise velocity (m/sec)

$t$  = time (sec)

$w_s$  = Weissenberg number

$x$  = direction of shear stress (m)

$y$  = direction of velocity gradient (m)

## Greek

$\alpha^*$  = duct aspect ratio in [Table 3.9.3](#)

$\beta$  = shear rate parameter

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n}$$

$\dot{\gamma}$  = shear rate (L/sec)

$\Delta P$  = pressure drop (N/m<sup>2</sup>)

$\lambda$  = characteristic time of viscoelastic fluid (sec)

$\mu_a$  = apparent viscosity (N · sec/m<sup>2</sup>)

$\mu_o$  = zero shear rate viscosity (N · sec/m<sup>2</sup>)

$\mu_\infty$  = high shear rate viscosity (N · sec/m<sup>2</sup>)

$\mu^*$  = reference viscosity

$$\mu^* = \frac{\mu_o}{1 + \beta} \left( \text{N} \cdot \text{sec}/\text{m}^2 \right)$$

$\tau_o$  = yield stress (N/m<sup>2</sup>)

$\tau_{y,x}$  = shear stress (N/m<sup>2</sup>)

$\phi$  = half apex angle (see [Table 3.9.3](#)) (°)

### Further Information

It is not possible to include all of the interesting non-Newtonian topics in a section of this scope. Other items which may be of interest and importance are listed below along with appropriate references: hydrodynamic and thermal entrance lengths, Cho and Hartnett (1982); non-Newtonian flow over external surfaces, Irvine and Karni (1987); chemical, solute, and degradation effects in viscoelastic fluids, Cho and Harnett (1982); general references, Skelland (1967), Whorlow (1980), and Darby (1988).

## 3.10 Tribology, Lubrication, and Bearing Design

*Francis E. Kennedy, E. Richard Booser, and Donald F. Wilcock*

### Introduction

Tribology, the science and technology of contacting surfaces involving friction, wear, and lubrication, is extremely important in nearly all mechanical components. A major focus of the field is on friction, its consequences, especially wear and its reduction through lubrication and material surface engineering. The improper solution of tribological problems is responsible for huge economic losses in our society, including shortened component lives, excessive equipment downtime, and large expenditures of energy. It is particularly important that engineers use appropriate means to reduce friction and wear in mechanical systems through the proper selection of bearings, lubricants, and materials for all contacting surfaces. The aim of this section is to assist in that endeavor.

### Sliding Friction and its Consequences

#### Coefficient of Friction

If two stationary contacting bodies are held together by a normal force  $W$  and a tangential force is applied to one of them, the tangential force can be increased until it reaches a magnitude sufficient to initiate sliding. The ratio of the friction force at incipient sliding to the normal force is known as the static coefficient of friction,  $f_s$ . After sliding begins, the friction force always acts in the direction opposing motion and the ratio between that friction force and the applied normal force is the kinetic coefficient of friction,  $f_k$ .

Generally,  $f_k$  is slightly smaller than  $f_s$  and both coefficients are independent of the size or shape of the contacting surfaces. Both coefficients are very much dependent on the materials and cleanliness of the two contacting surfaces. For ordinary metallic surfaces, the friction coefficient is not very sensitive to surface roughness. For ultrasmooth or very rough surfaces, however, the friction coefficient can be larger. Typical friction coefficient values are given in Table 3.10.1. Generally, friction coefficients are greatest when the two surfaces are identical metals, slightly lower with dissimilar but mutually soluble metals, still lower for metal against nonmetal, and lowest for dissimilar nonmetals.

**TABLE 3.10.1 Some Typical Friction Coefficients<sup>a</sup>**

Material Pair	Static Friction Coefficient $f_s$		Kinetic Friction Coefficient $f_k$	
	In Air	In Vacuo	In Air, Dry	Oiled
Mild steel vs. mild steel	0.75	—	0.57	0.16
Mild steel vs. copper	0.53	0.5 (oxidized) 2.0 (clean)	0.36	0.18
Copper vs. copper	1.3	21.0	0.8	0.1
Tungsten carbide vs. copper	0.35	—	0.4	—
Tungsten carbide vs. tungsten carbide	0.2	0.4	0.15	—
Mild steel vs. polytetrafluoroethylene	0.04	—	0.05	0.04

<sup>a</sup> The friction coefficient values listed in this table were compiled from several of the references listed at the end of this section.

The kinetic coefficient of friction,  $f_k$ , for metallic or ceramic surfaces is relatively independent of sliding velocity at low and moderate velocities, although there is often a slight decrease in  $f_k$  at higher velocities. With polymers and soft metals there may be an increase in the friction coefficient with increasing velocity until a peak is reached, after which friction may decrease with further increases in velocity or temperature. The decrease in kinetic friction coefficient with increasing velocity, which may become especially pronounced at higher sliding velocities, can be responsible for friction-induced

vibrations (stick–slip oscillations) of the sliding systems. Such vibrations are an important design consideration for clutches and braking systems, and can also be important in the accurate control and positioning of robotic mechanisms and precision manufacturing systems.

### Wear

Wear is the unwanted removal of material from solid surfaces by mechanical means; it is one of the leading reasons for the failure and replacement of manufactured products. It has been estimated that the costs of wear, which include repair and replacement, along with equipment downtime, constitute up to 6% of the U.S. gross national product (Rabinowicz, 1995). Wear can be classified into four primary types: sliding wear, abrasion, erosion, and corrosive wear. Owing to its importance, wear and its control have been the subject of several handbooks (Peterson and Winer, 1980; Blau, 1992), which the interested reader may consult for further information.

*Types of Wear.* *Sliding wear* occurs to some degree whenever solid surfaces are in sliding contact. There are two predominant sliding wear mechanisms, adhesion and surface fatigue. *Adhesive wear* is caused by strong adhesive forces between the two surfaces within the real area of contact. It results in the removal of small particles from at least one of the surfaces, usually the softer one. These particles can then transfer to the other surface or mix with other material from both surfaces before being expelled as loose wear debris. Adhesive wear can be particularly severe for surfaces which have a strong affinity for each other, such as those made from identical metals. *Surface fatigue wear* occurs when repeated sliding or rolling/sliding over a wear track results in the initiation of surface or subsurface cracks, and the propagation of those cracks produces wear particles in ductile materials by a process that has been called delamination. With brittle materials, sliding wear often occurs by a *surface fracture* process.

After an initial transition or “running-in” period, sliding wear tends to reach a steady state rate which is approximated by the following Archard (or Holm/Archard) wear equation:

$$V = K * W * s / H \quad (3.10.1)$$

where  $V$  = volume of worn material,  $K$  = dimensionless wear coefficient,  $s$  = sliding distance,  $W$  = normal load between the surfaces, and  $H$  = hardness of the softer of the two contacting surfaces.

The dimensionless wear coefficient gives an indication of the tendency of a given material combination to wear; relative wear coefficient values are given in Figure 3.10.1. In general, wear coefficients are highest for identical metals sliding without lubrication, and wear is decreased by adding a lubricant and by having material pairs which are dissimilar.

*Abrasive wear* occurs when a hard, rough surface slides against a softer surface (*two-body abrasion*) or when hard particles slide between softer surfaces (*three-body abrasion*). This process usually results in material removal by plowing or chip formation, especially when the abraded surface is metallic; surface fracture can occur during abrasion of brittle surfaces. In fact, abrasion mechanisms are similar to those of grinding and lapping, which could be considered as intentional abrasion. Consideration of the cutting and plowing processes shows that abrasive wear obeys the same equation (3.10.1) as sliding wear (Archard, 1980; Rabinowicz, 1995). Typical wear coefficients for abrasive wear are given in Figure 3.10.1. Since the relative size, hardness, and sharpness of the abrading particles, or surface asperities, also affect abrasive wear rates, the wear coefficients for abrasion must include recognition of those factors (Rabinowicz, 1995).

*Erosion* occurs when solid particles or liquid droplets impinge on a solid surface. When impingement is on a ductile metallic surface, the wear process is similar to that caused by abrasion, and is dominated by plastic deformation. Brittle surfaces, on the other hand, tend to erode by surface fracture mechanisms. The material removal rate is dependent on the angle of attack of the particles, with erosion reaching a peak at low angles (about 20°) for ductile surfaces and at high angles (90°) for brittle materials. In either case, the wear rate is proportional to the mass rate of flow of the particles and to their kinetic energy; it is inversely proportional to the hardness of the surface and the energy-absorbing potential (or toughness)

**FIGURE 3.10.1** Typical values of wear coefficient for sliding and abrasive wear. (Modified from Rabinowicz, 1980, 1995.)

of the impinged surface (Schmitt, 1980). Although erosion is usually detrimental, it can be used beneficially in such material removal processes as sandblasting and abrasive water jet machining.

*Corrosive wear* results from a combination of chemical and mechanical action. It involves the synergistic effects of chemical attack (corrosion) of the surface, followed by removal of the corrosion products by a wear mechanism to expose the metallic surface, and then repetition of those processes. Since many corrosion products act to protect the surfaces from further attack, the removal of those films by wear acts to accelerate the rate of material removal. Corrosive wear can become particularly damaging when it acts in a low-amplitude oscillatory contact, which may be vibration induced, in which case it is called *fretting corrosion*.

#### Means for Wear Reduction.

The following actions can be taken to limit sliding wear:

- Insure that the sliding surfaces are well lubricated. This can best be accomplished by a liquid lubricant (see sub-section on effect of lubrication on friction and wear), but grease, or solid lubricants such as graphite or molybdenum disulfide, can sometimes be effective when liquid lubricants cannot be used.
- Choose dissimilar materials for sliding pairs.
- Use hardened surfaces.
- Add wear-resistant coatings to the contacting surfaces (see the following subsection).
- Reduce normal loads acting on the contact.
- Reduce surface temperatures. This is particularly important for polymer surfaces.

To reduce abrasive wear:

- Use hardened surfaces.
- Add a hard surface coating.
- Reduce the roughness of hard surfaces that are in contact with softer surfaces.
- Provide for the removal of abrasive particles from contacting surfaces. This can be done by flushing surfaces with liquid and/or filtering liquid coolants and lubricants.
- Reduce the size of abrasive particles.

To reduce erosion:

- Modify the angle of impingement of solid particles or liquid droplets.
- Provide for the removal of solid particles from the stream of fluid.
- Use hardened surfaces.
- Use tough materials for surfaces.
- Add protective coating to surfaces.

**Surface Engineering for Friction and Wear Reduction**

Surface treatments have long been an important remedy for wear problems, and that importance has grown in recent years with the introduction of new techniques to harden surfaces or apply hard surface coatings. Available processes and characteristics for treating a steel substrate are listed in Table 3.10.2.

*Thermal transformation hardening* processes are used to harden ferrous (primarily steel) surfaces by heating the surface rapidly, transforming it to austenite, and then quenching it to form martensite. The source of heat can be one of the following: an oxyacetylene or oxypropane flame (*flame hardening*), eddy currents induced by a high-frequency electric field (*induction hardening*), a beam from a high-power laser (*laser hardening*), or a focused electron beam (*electron beam hardening*). The depth and uniformity of the hard layer depend on the rate and method of heating. These processes are characterized by a short process time and all except electron beam hardening (which requires a moderate vacuum) can be done in air.

**TABLE 3.10.2 Characteristics of Surface Treatment Processes for Steel**

Process	Coating or Treated Layer		Substrate Temperature (°C)
	Hardness (HV)	Thickness (µm)	
Surface hardening			
Flame or induction hardening	500–700	250–6000	800–1000
Laser or electron beam hardening	500–700	200–1000	950–1050
Carburizing	650–900	50–1500	800–950
Carbonitriding	650–900	25–500	800–900
Nitriding	700–1200	10–200	500–600
Boronizing	1400–1600	50–100	900–1100
Coating			
Chrome plating	850–1250	1–500	25–100
Electroless nickel	500–700	0.1–500	25–100
Hardfacing	800–2000	500–50000	1300–1400
Thermal spraying	400–2000	50–1500	<250
Physical vapor deposition	100–3000	0.05–10	100–300
Chemical vapor deposition	1000–3000	0.5–100	150–2200
Plasma-assisted chemical vapor deposition	1000–5000	0.5–10	<300
Ion implantation	750–1250	0.01–0.25	<200

*Thermal diffusion processes* involve the diffusion of atoms into surfaces to create a hard layer. In the most widely used of these processes, *carburizing* (or case hardening), carbon diffuses into a low-carbon steel surface to produce a hard, carbon-rich case. The hardness and thickness of the case depend on the temperature, exposure time, and source of carbon (either a hydrocarbon gas, a salt bath, or a packed bed of carbon). *Carbonitriding* is a process similar to carburizing which involves the simultaneous diffusion of carbon and nitrogen atoms into carbon steel surfaces. In the *nitriding* process, nitrogen atoms diffuse into the surface of a steel which contains nitride-forming elements (such as Al, Cr, Mo, V, W, or Ti) and form fine precipitates of nitride compounds in a near-surface layer. The hardness of the surface layer depends on the types of nitrides formed. The source of nitrogen can be a hot gas (usually ammonia) or a plasma. *Nitrocarburizing* and *boronizing* are related processes in which nitrogen or boron atoms diffuse

into steel surfaces and react with the iron to form a hard layer of iron carbonitride or iron boride, respectively.

Thin, hard metallic coatings can be very effective in friction and wear reduction and can be applied most effectively by *electroplating processes* (Weil and Sheppard, 1992). The most common of such coatings are *chromium*, which is plated from a chromic acid bath, and *electroless nickel*, which is deposited without electric current from a solution containing nickel ions and a reducing agent. Chromium coatings generally consist of fine-grained chromium with oxide inclusions, while electroless nickel coatings contain up to 10% of either phosphorus or boron, depending on the reducing agent used.

*Thermal spray processes* (Kushner and Novinski, 1992) enable a large variety of coating materials, including metals, ceramics and polymers, to be deposited rapidly on a wide range of substrates. Four different thermal spray processes are commercially available: *oxyfuel* (or flame) spraying of metallic wire or metallic or ceramic powder, *electric arc* spraying of metallic wire, *plasma arc* spraying of powder (metallic or ceramic), and *high-velocity oxyfuel* (or detonation gun) powder spray. In each thermal spray process the coating material, in either wire or powder form, is heated to a molten or plastic state, and the heated particles are propelled toward the surface to be coated where they adhere and rapidly solidify to form a coating. The hardness of the coating depends on both the sprayed material and the process parameters.

*Weld hardfacing processes* (Crook and Farmer, 1992) involve the application of a wear-resistant material to the surface of a part by means of a weld overlay. Weld overlay materials include ferrous alloys (such as martensitic air-hardening steel or high-chromium cast iron), nonferrous alloys (primarily cobalt- or nickel-based alloys containing hard carbide, boride, or intermetallic particles), and cemented carbides (usually tungsten carbide/cobalt cermets). In each case the surface being coated is heated to the same temperature as the molten weld layer, thus posing a limitation to the process. Weld hardfacing is best used when abrasion or sliding wear cannot be avoided (as with earthmoving or mining equipment) and the goal is to limit the wear rate.

*Vapor deposition processes* for wear-resistant coatings include *physical vapor deposition* (PVD), *chemical vapor deposition* (CVD), and several variants of those basic processes (Bhushan and Gupta, 1991). Each of the processes consists of three steps: (1) creation of a vapor phase of the coating material, (2) transportation of the vapor from source to substrate, and (3) condensation of the vapor phase on the substrate and growth of a thin solid film. In PVD processes the vapor is produced by either evaporation (by heating of the coating source) or sputtering (in which coating material is dislodged and ejected from the source as a result of bombardment by energetic particles). In some PVD processes the vapor becomes ionized or reacts with a gas or plasma en route to the substrate, thus modifying the structure or composition of the deposited film. In CVD processes a gas composed of a volatile component of the coating material is activated either thermally or by other means in the vicinity of the substrate, and it reacts to form a solid deposit on the surface of the hot substrate.

Both PVD and CVD methods can be used to produce a wide variety of coatings, including metals, alloys, and refractory compounds. Among the most popular vapor-deposited hard coatings for wear resistance are titanium nitride and titanium carbide. Deposition rates are relatively low compared with some other coating processes, ranging from  $<0.1 \mu\text{m}/\text{min}$  for some ion beam-sputtering or ion-plating processes, up to  $25 \mu\text{m}/\text{min}$  or more for activated reactive evaporation or CVD processes. Most PVD processes are done in a vacuum, while CVD processes are done in a reaction chamber which may be at atmospheric pressure. *Plasma-assisted chemical vapor deposition* (PACVD) is a hybrid process in which the constituents of the vapor phase react to form a solid film when assisted by a glow discharge plasma. The advantages of PACVD over other CVD processes include lower substrate temperatures, higher deposition rates, and a wider variety of coating possibilities.

*Ion implantation* (Fenske, 1992) is a process in which charged particles are created in an ion source, accelerated toward the surface at high velocity, and then injected into the substrate surface. The most commonly implanted ions for surface engineering are nitrogen, carbon, boron, and titanium, although virtually any element could be implanted. The microstructure of the near-surface region is changed by

the presence of the implanted ions and the result can be high near-surface hardness and wear resistance. The affected layer is very thin ( $<1 \mu\text{m}$ ).

### **Effect of Lubrication on Friction and Wear**

Whenever lubricated surfaces slide together at low sliding speeds or with a high applied normal load, the lubricant may not separate the two solid surfaces completely. However, the lubricant can still significantly reduce the friction coefficient by reducing the shear strength of adhesive junctions between the two surfaces. In this so-called boundary lubrication regime, the effectiveness of the lubricant can be improved if the lubricant molecules adhere well to the solid surfaces. This is best accomplished by introducing a lubricant or additive that forms a surface film through adsorption, chemisorption, or chemical reaction with the surface. The ensuing reduced shear strength of the surface film can lower the friction coefficient by as much as an order of magnitude from the dry friction value.

When a good supply of a viscous lubricant is available, the separation between the surfaces will increase as the sliding speed increases or the normal load decreases. As the separation increases, the amount of solid/solid contact between the surfaces will decrease, as will the friction coefficient and wear rate. In this “mixed friction” regime, friction is determined by the amount of plowing deformation on the softer surface by the harder surface asperities and by adhesion within the solid/solid contacts. When the surfaces become completely separated by a self-acting or externally pressurized lubricant film, the lubricating regime is hydrodynamic, wear is reduced to nearly zero, and friction reaches a low value governed by viscous shear of the lubricant. Friction coefficients in such cases can be 0.001 or lower, depending on the surface velocities and the lubricant viscosity. This is the case for most journal or thrust bearings (see subsection on fluid film bearings).

### **Bearings for Friction Reduction**

Most mechanical systems contain moving components, such as shafts, which must be supported and held in position by stationary members. This is best done by appropriate design or selection of bearings to be used wherever the moving member is to be supported. Most bearings may be classified as either fluid film bearings, dry or semilubricated bearings, or rolling element bearings.

*Fluid film bearings* (see subsection below) have a conformal geometry, with a thin film of fluid separating the two surfaces. The fluid lubricant could be a liquid, such as oil, or a gas, such as air. Fluid film bearings are commonly used to support rotating cylindrical shafts, and the load on such a bearing could be either radial, in which case the bearing is called a journal bearing, or axial, for a thrust bearing. In most cases the fluid film is generated by the motion within the bearing itself, so the bearing is called self-acting or hydrodynamic. Whether or not a self-acting bearing can develop a fluid film sufficient to separate and support the two surfaces is determined by magnitude of the quantity  $\mu U/W$ , where  $\mu$  is the (absolute) fluid viscosity,  $U$  is the relative sliding velocity, and  $W$  is the normal load. If that quantity is too small, the fluid film will be too thin and high friction will occur. This can be a problem during start-up of equipment when sliding velocities are low. That problem can be overcome by pressurizing the fluid film from an external pressure source to create a hydrostatic bearing. Whether the fluid film is externally pressurized (hydrostatic) or self-acting (hydrodynamic), separation of the solid surfaces allows wear to be essentially eliminated and friction to be very low, even when very large loads are carried by the pressurized lubricant.

*Dry and semilubricated bearings* (see subsection below) have conformal surfaces which are in direct contact with each other. This category includes bearings which run dry (without liquid lubrication) or those which have been impregnated with a lubricant. Dry bearings are made of a material such as a polymer or carbon-graphite which has a low friction coefficient, and they are generally used in low-load and low-speed applications. Semilubricated bearings are made of a porous material, usually metal, and are impregnated with a lubricant which resides within the pores. The lubricant, which could be oil or grease, cannot provide a complete fluid film, but usually acts as a boundary lubricant. Semilubricated bearings can carry greater loads at greater speeds than dry bearings, but not as high as either fluid film or rolling element bearings. The failure mechanism for both dry and semilubricated bearings is wear.

*Rolling element bearings* (see subsection below) have the advantage that rolling friction is lower than sliding friction. These bearings include rolling elements, either balls or rollers, between hardened and ground rings or plates. Their main advantage over fluid film bearings is that they have low friction both during start-up and at operating velocities, although the friction can be higher than that of fluid film bearings during steady state operation. Ball and roller bearings are most commonly lubricated by either oil or grease. In either case the lubricating film at the concentrated contacts between rolling elements and rings is very thin and the pressures in the film are very high; this is the condition known as elastohydrodynamic lubrication. Rolling element bearings fail by a number of mechanisms, often stemming from improper installation or use or from poor lubrication, but the overriding failure mechanism is rolling contact fatigue.

Each type of bearing has advantages and disadvantages, and these are summarized in [Table 3.10.3](#). The Engineering Sciences Data Unit (ESDU) (1965; 1967) has developed some general guides to the selection of bearing type for different load and speed conditions, and those guides for journal and thrust bearing selection are given in [Figures 3.10.2 and 3.10.3](#).

**TABLE 3.10.3 Bearing Characteristics**

	Fluid Film Bearings	Dry Bearings	Semilubricated	Rolling Element Bearings
Start-up friction coefficient	0.25	0.15	0.10	0.002
Running friction coefficient	0.001	0.10	0.05	0.001
Velocity limit	High	Low	Low	Medium
Load limit	High	Low	Low	High

Cost	High	Low	Low	Medium

## Lubricant Properties

### Petroleum Oils

The vast majority of lubricants in use today are mineral oils which are obtained through the distillation of crude petroleum. Mineral oils are composed primarily of three types of hydrocarbon structures: paraffinic, aromatic, and alicyclic (naphthenic). The molecular weights of the hydrocarbons range from about 250 for low-viscosity grades, up to nearly 1000 for more-viscous lubricants.

Mineral oils by themselves do not have all of the properties required of modern lubricants. For that reason, almost all current lubricants are fortified with a chemical additive package which consists of some of the following:

*Oxidation inhibitors* limit oxidation of hydrocarbon molecules by interrupting the hydroperoxide chain reaction.

*Rust inhibitors* are surface-active additives that preferentially adsorb on iron or steel surfaces and prevent their corrosion by moisture.

*Antiwear and extreme pressure agents* form low shear strength films on metallic surfaces which limit friction and wear, particularly in concentrated contacts.

*Friction modifiers* form adsorbed or chemisorbed surface films which are effective in reducing friction of bearings during low-speed operation (boundary lubrication regime).

*Detergents and dispersants* reduce deposits of oil-insoluble compounds (e.g., sludge) in internal combustion engines.

**FIGURE 3.10.2** General guide to journal bearing-type selection. Except for rolling element bearings, curves are drawn for bearings with width/diameter = 1. A medium-viscosity mineral oil is assumed for hydrodynamic bearings. From ESDU, *General Guide to the Choice of Journal Bearing Type*, Item 67073, Institution of Mechanical Engineers, London, 1965. With permission.

*Pour-point depressants* lower the temperature at which petroleum oils become immobilized by crystallized wax.

*Foam inhibitors* are silicone polymers which enhance the separation of air bubbles from the oil.

*Viscosity-index improvers* are long-chain polymer molecules which reduce the effect of temperature on viscosity. They are used in multigrade lubricants.

**Properties of Petroleum Oils**

The lubricating oil property which is of most significance to bearing performance is viscosity. The absolute viscosity, designated as  $\mu$ , could be given in SI units as pascal second ( $\text{Pa} \cdot \text{sec} = \text{N} \cdot \text{sec}/\text{m}^2$ ) or centipoise ( $1 \text{ cP} = 0.001 \text{ Pa} \cdot \text{sec}$ ) or in English units as  $\text{lb} \cdot \text{sec}/\text{in}^2$  (or reyn). Kinematic viscosity, designated here as  $\nu$ , is defined as absolute viscosity divided by density. It is given in SI units as  $\text{m}^2/\text{sec}$  or centistokes ( $1 \text{ cSt} = 10^{-6} \text{ m}^2/\text{sec}$ ) and in English units as  $\text{in}^2/\text{sec}$ .

Viscosity data in [Table 3.10.4](#) are representative of typical petroleum “turbine” and “hydraulic” oils which are widely used in industry and closely correspond to properties of most other commercially available petroleum oils. [Table 3.10.5](#) gives equivalent viscosity grades for common automotive (SAE), gear (SAE and AGMA), and reciprocating aircraft engine (SAE) oils (Booser, 1995). Equivalent ISO viscosity grades are listed for the single-graded SAE automotive oils such as SAE 10W and SAE 30.

**FIGURE 3.10.3** General guide to thrust bearing type selection. Except for rolling element bearings, curves are drawn for a ratio of inside diameter to outside diameter equal to 2 and for a nominal life of 10,000 hr. A medium-viscosity mineral oil is assumed for hydrodynamic bearings. (Based on ESDU, *General Guide to the Choice of Journal Bearing Type*, Item 67073, Institution of Mechanical Engineers, London, 1965, and Neale, M.J., *Bearings*, Butterworth-Heinemann, Oxford, 1993.)

For multigrade oils such as SAE 10W–30, however, the added viscosity-index improvers provide unique viscosity–temperature characteristics. Typical properties of a number of these multigrade SAE oils are included in [Table 3.10.4](#).

ISO viscosity grade 32 and the equivalent SAE 10W are most widely used industrially. Lower-viscosity oils often introduce evaporation and leakage problems, along with diminished load capacity. Higher viscosity may lead to high temperature rise, unnecessary power loss, and start-up problems at low temperature. For low-speed machines, however, higher-viscosity oils ranging up to ISO 150, SAE 40 and sometimes higher are often used to obtain higher load capacity.

**TABLE 3.10.4 Representative Oil Properties**

	Viscosity				Density	
	Centistokes		10 <sup>-6</sup> reyns(lb·sec/in <sup>2</sup> )		gm/cc	lb/in <sup>3</sup>

<sup>a</sup> Comparisons are nominal since SAE grades are not specified at 40°C viscosity; VI of lubes could change some of the comparisons.

Oil viscosity decreases significantly with increasing temperature as shown in Fig. 3.10.4. While Figure 3.10.4 provides viscosity data suitable for most bearing calculations, oil suppliers commonly provide only the 40°C and 100°C values of kinematic viscosity in centistokes (mm<sup>2</sup>/sec). The viscosity at other temperatures can be found by the following ASTM D341 equation relating kinematic viscosity  $\nu$  in centistokes (mm<sup>2</sup>/sec) to temperature  $T$  in degrees F:

$$\log \log(\nu + 0.7) = A - B \log(460 + T) \tag{3.10.2}$$

**FIGURE 3.10.4** Viscosity–temperature chart for industrial petroleum oils (Ramondi and Szeri, 1984).

where  $A$  and  $B$  are constants for any particular (petroleum or synthetic) oil. For ISO VG-32 oil in Table 3.10.4, for example,  $A = 10.54805$  and  $B = 3.76834$  based on the 104 and 212°F (40 and 100°C) viscosities. This gives a viscosity of 10.78 cSt at a bearing operating temperature of 160°F.

Conversion of kinematic to absolute viscosity requires use of density, which also varies with temperature. A coefficient of expansion of 0.0004/°F is typical for most petroleum oils, so the variation of density with temperature is in accordance with the following relation:

$$\rho_T = \rho_{104} [1 - 0.0004(T - 104)] \tag{3.10.3}$$

For the ISO-VG-32 oil with its density of 0.857 g/cc at 100°F (40°C), this equation gives 0.838 g/cc at 160°F. Multiplying 10.78 cSt by 0.838 then gives an absolute viscosity of 9.03 cP. Multiplying by the conversion factor of  $1.45 \times 10^{-7}$  gives  $1.31 \times 10^{-6}$  lb·sec/in.<sup>2</sup> (reyns).

Heat capacity  $C_p$  of petroleum oils used in bearing calculations is given by (Klaus and Tewksburg, 1984)

$$C_p = 3860 + 4.5(T) \text{ in.} \cdot \text{lb}/(\text{lb} \cdot ^\circ\text{F}) \tag{3.10.4}$$

The viscosity of petroleum oils is also affected significantly by pressure, and that increase can become important in concentrated contacts such as rolling element bearings where elastohydrodynamic lubrication occurs. The following relationship can be used for many oils to find the viscosity at elevated pressure:

$$\mu_p = \mu_o e^{\alpha p} \tag{3.10.5}$$

where  $\mu_o$  is the viscosity at atmospheric pressure,  $\mu_p$  is the viscosity at pressure  $p$ , and  $\alpha$  is the pressure–viscosity exponent. The pressure–viscosity exponent can be obtained from lubricant suppliers.

### Synthetic Oils

Synthetic oils of widely varying characteristics are finding increasing use for applications at extreme temperatures and for their unique physical and chemical characteristics. Table 3.10.6 gives a few representative examples of synthetic oils which are commercially available. Cost of the synthetics, ranging up to many times that of equivalent petroleum oils, is a common deterrent to their use where petroleum products give satisfactory performance

**TABLE 3.10.6 Properties of Representative Synthetic Oils**

### Greases

Grease is essentially a suspension of oil in a thickening agent, along with appropriate additives. The oil generally makes up between 75 and 90% of the weight of a grease, and it is held in place by the gel structure of the thickener to carry out its lubricating function. The simplicity of the lubricant supply system, ease of sealing, and corrosion protection make grease the first choice for many ball-and-roller bearings, small gear drives, and slow-speed sliding applications (Booser, 1995). Consistencies of greases vary from soap-thickened oils that are fluid at room temperature to hard brick-types that may be cut with a knife. Greases of NLGI Grade 2 stiffness (ASTM D217) are most common. Softer greases down to grade 000 provide easier feeding to multiple-row roller bearings and gear mechanisms. Stiffer Grade 3 is used in some prepacked ball bearings to avoid mechanical churning as the seals hold the grease in close proximity with the rotating balls.

Petroleum oils are used in most greases; the oils generally are in the SAE 30 range, with a viscosity of about 100 to 130 cSt at 40°C. Lower-viscosity oil grades are used for some high-speed applications and for temperatures below about -20°C. Higher-viscosity oils are used in greases for high loads and low speeds. Synthetic oils are used only when their higher cost is justified by the need for special properties, such as capability for operation below -20°C or above 125 to 150°C.

The most common gelling agents are the fatty acid metallic soaps of lithium, calcium, sodium, or aluminum in concentrations of 8 to 25%. Of these, the most popular is lithium 12-hydroxystearate; greases based on this lithium thickener are suitable for use at temperatures up to 110°C, where some lithium soaps undergo a phase change. Greases based on calcium or aluminum soaps generally have an upper temperature limit of 65 to 80°C, but this limit can be significantly raised to the 120 to 125°C range through new complex soap formulations. Calcium-complex soaps with improved high-temperature stability, for instance, are prepared by reacting both a high-molecular-weight fatty acid (e.g., stearic acid) and a low-molecular-weight fatty acid (acetic acid) with calcium hydroxide dispersed in mineral oil.

Inorganic thickeners, such as fine particles of bentonite clay, are inexpensively applied by simple mixing with oil to provide nonmelting greases for use up to about 140°C. Polyurea nonmelting organic powders are used in premium petroleum greases for applications up to about 150 to 170°C.

Additives, such as those mentioned in the subsection on petroleum oils, are added to grease to improve oxidation resistance, rust protection, or extreme pressure properties. Because of the incompatibility of oils, thickeners, and additives, greases of different types should be mixed only with caution.

### Solid Lubricants

Solid lubricants provide thin solid films on sliding or rolling/sliding surfaces to reduce friction and wear. They are particularly useful for applications involving high operating temperatures, vacuum, nuclear radiation, or other environments which limit the use of oils or greases. Solid lubricant films do not prevent moving surfaces from contacting each other, so they cannot eliminate wear and their lives are limited by wear. The properties of some of the most common solid lubricants are given in Table 3.10.7.

**TABLE 3.10.7 Properties of Selected Solid Lubricants**

Material	Acceptable Usage Temperature, °C				Average Friction Coefficient, <i>f</i>		Remarks
	Minimum		Maximum		In Air	In N <sub>2</sub> or Vacuum	
	In Air	In N <sub>2</sub> or Vacuum	In Air	In N <sub>2</sub> or Vacuum			
Molybdenum disulfide, MoS <sub>2</sub>	-240	-240	370	820	0.10–0.25	0.05–0.10	Low <i>f</i> , carries high load, good overall lubricant, can promote metal corrosion
Graphite	-240	—	540	Unstable in vacuum	0.10–0.30	0.02–0.45	Low <i>f</i> and high load capacity in air, high <i>f</i> and wear in vacuum, conducts electricity
PTFE	-70	-70	290	290	0.02–0.15	0.02–0.15	Lowest <i>f</i> of solid lubricants, load capacity moderate and decreases at elevated temperature
Calcium fluoride–barium fluoride eutectic, CaF <sub>2</sub> –BaF <sub>2</sub>	430	430	820	820	0.10–0.25 above 540°C 0.25–0.40 below 540°C	Same as in air	Can be used at higher temperature than other solid lubricants, high <i>f</i> below 540°C

Modified from Booser, E.R., in *Encyclopedia of Chemical Technology*, 4th ed., Vol. 15, John Wiley & Sons, New York, 1995, 463–517.

The most important inorganic solid lubricants are layer–lattice solids such as molybdenum disulfide (MoS<sub>2</sub>) and graphite. These materials are characterized by strong covalent or ionic bonding between atoms in individual layers, but relatively weak van der Waals bonds between layers, enabling the layers

to slide easily relative to one another. Graphite is a very effective lubricant film when moisture or water vapor is present, since adsorbed water vapor lubricates the sliding layers, but it has poor friction properties in vacuum or other low-humidity applications. Molybdenum disulfide does not require the presence of adsorbed water vapor, so it is widely used in vacuum or space applications.

The most commonly used organic solid lubricant is polytetrafluoroethylene (PTFE) which can be used either as a fused surface coating or as a self-lubricating material (see subsection on plastics). Its low friction is attributed to the smooth profile of the PTFE molecule. The chemical inertness of PTFE makes it attractive for chemical and food-processing applications.

New ceramic-based solid lubricants have been developed for high-temperature applications, such as heat engines or space uses. One of the most promising of these is a calcium fluoride–barium fluoride eutectic, which can be used at temperatures exceeding 800°C.

## Fluid Film Bearings

### Journal Bearings

A journal bearing consists of an approximately cylindrical bearing body or sleeve around a rotating cylindrical shaft. In general, journal bearings are found in motors, pumps, generators, appliances, and internal combustion engines in which a fluid lubricant is used; and in smaller mechanisms such as switches, clocks, small motors, and circuit breakers in which a solid lubricant such as graphite, grease, or certain plastics serves to reduce friction. Air (gas) bearings are designed to utilize both fluid mechanics principles when operating and solid lubricant–surfaced materials for start, stop, and emergency operations.

A hydrodynamic journal bearing maintains separation of shaft from bearing because the lubricant viscosity and the speed of the shaft create pressure in the converging portion of the fluid film which carries load. The governing equations were first developed by Reynolds (1886). Their solution has led to numerous computer solutions, including those used for this section.

*Journal Bearing Design.* Figure 3.10.5 shows schematics of frequently used types of journal bearing in which one or more lobes of cylindrical shape are positioned around the shaft, their axis being assumed parallel to the shaft axis. The features of each design and applications where it is often found are listed in Table 3.10.8.

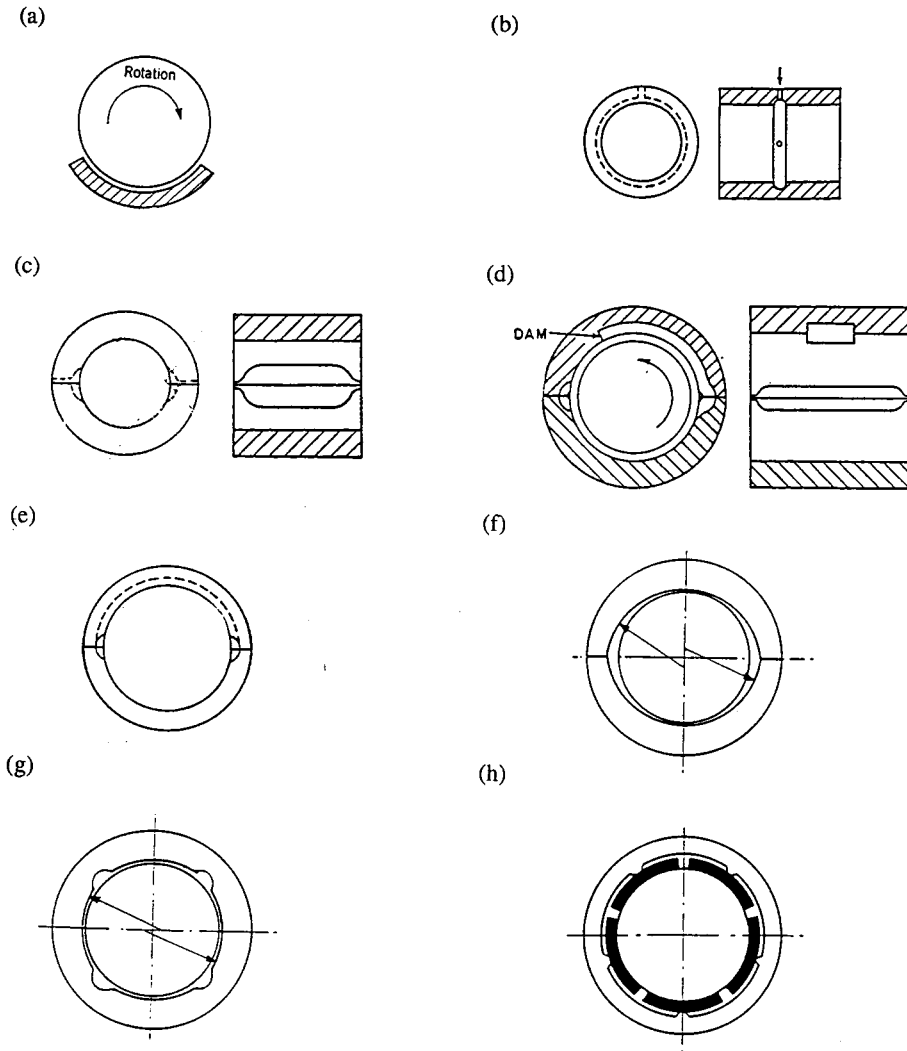

Noncontact journal bearings are designed to assure a continuous supply of lubricant to the load-carrying section, and the bearing grooves in Figure 3.10.5 are designed for that purpose. Oil must be resupplied to the bearing because of the continuous loss of lubricant as it is forced from the bearing by the load-carrying pressures generated within it. The subsection on lubricant supply methods describes some of the many systems designed to assure this supply and to cool the lubricant at the same time.

*Controlling Variables.* Definitions of the variables involved in journal bearing analysis are contained in Table 3.10.9. Because of the large range of many variables, nondimensional quantities are often used which are independent of the dimensional unit system involved. Examples are given in the English system unless otherwise stated.

*Calculating Bearing Performance.* Journal bearing performance can be calculated directly from dedicated computer codes which take account of load, speed, oil type, and delivery system, as well as bearing dimensions. This subsection presents two approximate solutions: a simple thermal approach and a set of interpolation tables based on computer solutions.

*Thermal Approach.* It is assumed that the bearing is operating at a constant but elevated temperature. A predicted operating temperature can then be found as a function of an assumed viscosity. A solution is found when the assumed viscosity equals the lubricant viscosity at that temperature. Three equations are used for this method. For radial loads, the power dissipation is

$$H_p = j\pi^3\mu(N/60)^2 D^3L/C \quad \text{in.} \cdot \text{lb/sec} \quad (3.10.6)$$

**FIGURE 3.10.5** Types of pressure-fed journal bearings: (a) Partial arc. (b) Circumferential groove. (c) Cylindrical bearing–axial groove. (d) Pressure dam. (e) Cylindrical overshoot. (f) Elliptical. (g) Multilobe. (h) Tilting pad.

**TABLE 3.10.8** Journal Bearing Designs

Type	Typical Loading	Applications
Partial arc	Unidirectional load	Shaft guides, dampers
Circumferential groove	Variable load direction	Internal combustion engines
Axial groove types		
Cylindrical	Medium to heavy unidirectional load	General machinery
Pressure dam	Light loads, unidirectional	High-speed turbines, compressors

$W$	Load	lb
$e$	Shaft eccentricity	in.
$h$	Film thickness	in.
$j$	Ratio: power loss/shaft-centered loss	—
$p$	Pressure	psi
$q$	Flow coefficient	—
$w$	Load coefficient	—
$x$	Coordinate in direction of load	in.
$y$	Coordinate orthogonal to load	in.
$\beta$	Exponential temperature coefficient of viscosity	—
$\epsilon$	Shaft eccentricity, nondimensional	—
$\gamma$	Angular extent of film	—
$\phi$	Attitude angle	—
$\rho$	Density	lb/in. <sup>3</sup>
$\mu$	Viscosity	lb·sec/in. <sup>2</sup>
$\omega$	Shaft velocity	rad/sec
$\theta$	Angle in direction of rotation, from bottom dead center	—
$\Phi$	Energy dissipation	in.·lb/sec

$$Q = Q_o + qCR^2\omega/2 \text{ in.}^3/\text{sec} \tag{3.10.7}$$

where  $q$  is the proportion of side flow to circulating flow, and the zero speed flow,  $Q_o$  (in<sup>3</sup>/sec), represents other flows such as from the ends of the feed grooves which are not related to the load-carrying film itself.  $Q_o$  can usually be neglected for rough estimation, and this approximation is useful for eccentricities as high as 0.7. Note that both  $q$  and  $j$  are functions of specific design as well as load and speed. The average operating temperature for a given viscosity is

$$T_2 = T_f + \frac{(H_p - \Phi)}{(\rho C_p Q)} \text{ °F} \tag{3.10.8}$$

where  $T_f$  is the feed temperature and  $\Phi$  is the energy loss due to conduction and radiation. For diameters of 2" or more,  $\Phi$  can usually be assumed to be 0. Plotting  $T_2$  vs. viscosity for several values of  $\mu$  on a plot of the viscosity vs.  $T$  for the lubricant shows the operating temperature for the bearing as the intersection.

*Flow Dynamics Solution.* A more general solution for journal bearing performance is based on prediction of flow characteristics in the bearing, and of physical behavior of the bearing based on the Reynolds equation. A common two-pad journal bearing with pressurized oil feed will be used to provide specific design information. The Reynolds equation is the differential equation expressing the physical behavior of the fluid film between shaft and bearing, as written for cylindrical bearings:

$$1/R^2 \left[ \frac{\partial}{\partial \Theta} \left( h^3 / \mu \right) \frac{\partial p}{\partial \Theta} \right] + \frac{\partial}{\partial z} \left( h^3 / \mu \right) \frac{\partial p}{\partial z} = 6(U/R) \frac{\partial h}{\partial \Theta} \tag{3.10.9}$$

where  $z$  is the axial coordinate and  $\Theta$  is the angular coordinate.

*Bearing Configuration.* A cross section through a common type of two-pad cylindrical bearing is shown in Figure 3.10.6. Two pads having a radius of  $R + C$  and an angular extent of  $150^\circ$ , and with load applied vertically to the lower half through a shaft, make up the bearing. Lubricant is admitted under moderate feed pressure to the two  $30^\circ$  grooves formed at the split as shown in Figure 3.10.6. The shaft rotates counterclockwise, and lubricant pressures are balanced when the shaft center is displaced down and to the right.

**FIGURE 3.10.6** Geometry of split cylindrical journal bearing.

*Lubricant Properties.* Pressures in the lubricant film are generated as a function of the local shear rates and the local viscosity as described by the Reynolds equation. The local temperature rise is given by the local energy dissipation divided by the local flow rate:

$$\Delta T = \left[ 2\mu\omega R^2 \Delta\theta \right] / \left[ h^2 \rho C_p \right] \tag{3.10.10}$$

As an alternative to Equation 3.10.2, an exponential relation between viscosity and temperature is used:

$$\mu = \mu_0 e^{-\beta(T-T_0)} \tag{3.10.11}$$

Assuming an ISO 32 oil, viscosity  $\mu_0$  at  $104^\circ\text{F}$  is 3.98 reyns, density is 0.0310, and  $\beta$  is 0.0170 for the range from  $104$  to  $212^\circ\text{F}$ . The value for  $\beta$  may be determined from Figure 3.10.4. A nondimensional

coefficient,  $C_\alpha$ , the *adiabatic coefficient*, is used as an indicator of the severity of thermal heating in a design. It contains the several factors responsible for temperature rise.

$$C_\alpha = 2\mu_f \beta \omega (R/C)^2 / \rho C_p \tag{3.10.12}$$

*Bearing Performance Tables.* Using computer-generated solutions of the Reynolds equation for the pressure field over the bearing surface, the relevant performance properties of the bearing/lubricant system can be determined. A number of programs are commercially available for this purpose. In order to illustrate how the behavior of a journal bearing can be determined, a two-pad split cylindrical bearing with an  $L/D$  of 0.5 has been selected, and a proprietary computer code has been used to develop a group of performance quantities for such a bearing. The code accounts for the internal lubricant circulation, including mixing in the inlet groove of feed lubricant with warm lubricant from the upper half, resulting in the viscosity  $\mu_f$ . The primary characteristics of the bearing are load, stiffness, and damping. Each of these factors is presented in nondimensional terms in [Table 3.10.10](#), and the corresponding dimensional and other quantities are given as follows:

Film thickness, in.  $h = C(1 + e \cos \Theta)$  (3.10.13a)

Shaft eccentricity, in.  $e = \epsilon C$  (3.10.13b)

Load, lb  $W = w \left[ 6\mu\omega (R/C)^2 DL \right]$  (3.10.13c)

Flow, in.<sup>3</sup>/sec  $Q = q \left( CR^2 \omega / 2 \right)$  (3.10.13d)

Power loss, in. · lb/sec  $H_p = j \left( 2\pi\mu\omega^2 R^3 L / C \right)$  (3.10.13e)

Stiffness, lb/in.  $S_{xx} = K_{xx} 6\mu\omega R \left( R / C \right)^2$  (3.10.13f)

Damping, lb · sec/in.  $D_{xx} = B_{xx} 12\mu R \left( R / C \right)^3$  (3.10.13g)

The axial length/diameter ratio also influences the performance of a journal bearing. To illustrate this, [Table 3.10.11](#) presents the performance of longer bearings ( $L/D = 0.75$  and  $1.00$ ) for comparison to the more common  $L/D = 0.5$  results in [Table 3.10.10](#).

Comparing [Tables 3.10.10](#) and [3.10.11](#), the use of longer bearings has several important effects on operation and performance. Comparing key variables, the effects at an eccentricity of ratio of 0.7 are as follows:

Variable	L/D = 0.5	L/D = 0.75	L/D = 1.00
Load, $w$	0.28	0.69	1.21
Flow, $q$	0.69	0.82	0.88
Attitude angle, $\phi$	36.4	36.1	35.8
Power ratio, $j$	1.00	1.15	1.17
Stiffness, $K_{xx}$	1.38	3.06	5.03
Damping, $B_{xx}$	0.99	2.52	4.31

*Effect of Turbulence.* Turbulence is a mixing phenomenon that occurs in larger high-speed bearings. When this behavior occurs, the simple viscous drag behavior that has been assumed in the preceding

subsections is broken up by numerous eddies which increase the drag. The Reynolds number is a nondimensional quantity that expresses this factor:

$$R_e = hU\rho/\mu \quad (3.10.14)$$

where  $h$  is the local film thickness,  $U$  is the relative velocity of one surface with respect to the other,  $\rho$  is the fluid density, and  $\mu$  is the local viscosity.

The influence of turbulence on an  $L/D = 0.5$  bearing is shown in Table 3.10.12. Examination of Table 3.10.12 shows that the principal effects of operation in the turbulent regime with a Reynolds number above about 1000 are in the greater power required ( $j$ ) and the maximum bearing temperature. Load capacity and flow are only moderately affected.

**TABLE 3.10.12. Influence of Turbulence ( $\epsilon = 0.7$ ,  $C_\alpha = 0.2$ , arc =  $150^\circ$ )**

*Example Calculation.* The problem is to design a two-pad cylindrical bearing for support of a rotor having a bearing load of 8000 lb, a shaft diameter of 6 in., and a speed of 3600 rpm. Assume use of ISO VG-32 oil fed at a temperature of 120°F. Compute operating characteristics for a 3-in.-long bearing. Assume a radial clearance of 0.0044 in.

Feed viscosity,  $\mu_f = 3.98 \times 10^{-6} e^{-0.00170(120-104)} = 3.03 \times 10^{-6}$  reyn

Angular velocity,  $\omega = 3600 \times 2\pi/60 = 377$  rad/sec

Adiabatic coefficient:  $C_\alpha = 2 \times 3.03 \times 10^{-6} \times 0.0170 \times 377 \times (3/0.0044)^2/0.0310/4320 = 0.1345$

Load coefficient (from Equation 3.10.13c:  $w = 8000/[6 \times 3.03 \times 10^{-6} \times 377 \times 3 \times 6 \times (33/0.0044)^2] = 0.139$

The desired solution lies between Part 2 and Part 3 of Table 3.10.10. By using linear interpolation between the tabulated values for  $C_\alpha$  of 0.1 and 0.2, and values of  $\epsilon$  of 0.7 and 0.8, an approximate operating point of  $C_\alpha = 0.1345$  yields the following coefficients:  $\epsilon = 0.729$ ,  $w = 0.279$ ,  $q = 0.733$ ,  $j = 0.860$ , and  $\Delta T_b = 0.915$ .

By using Equations 3.10.13, the dimensional operating results are:

Shaft velocity:  $\omega = 3600 \times 2\pi/60 = 377$  rad/sec

Flow:  $Q = 0.733 \times 0.0044 \times 3^2 \times 377 = 5.47$  in<sup>3</sup>/sec

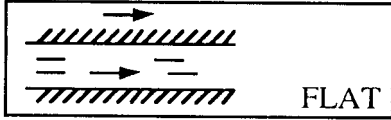

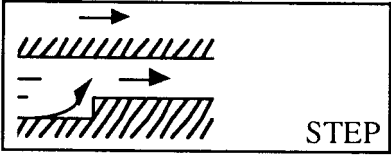

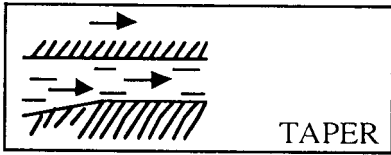

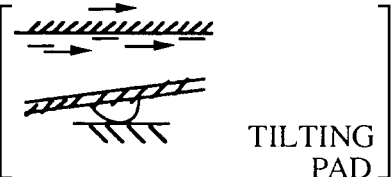

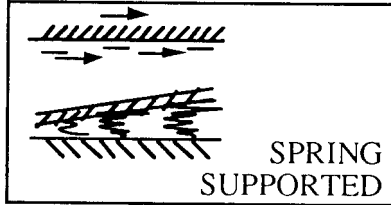

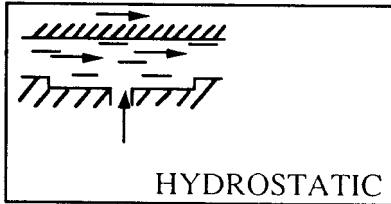

Power loss:  $H_p = 0.860 \times 2\pi \times 3.03 \times 10^{-6} \times 377^2 \times 3^3 \times 3/0.0044 = 42.8$  in. $\cdot$ lb/sec

Oil temperature:  $T_b = 120 + 0.915/0.0170 = 174^\circ\text{F}$

## Thrust Bearings

*Types of Thrust Bearings.* Oil film thrust bearings range from coin-size flat washers to sophisticated assemblies many feet in diameter. Of the six common types of thrust bearings shown in Table 3.10.13, the first five are hydrodynamic. As with journal bearings, each of these generates oil film pressure when

**TABLE 3.10.13 Common Thrust Bearings and Their Range of Application**

Type	O.D., in.	Unit Load, psi
 <p>FLAT</p>	0.5–20	20–100
 <p>STEP</p>	0.5–10	100–300
 <p>TAPER</p>	2–35	150–300
 <p>TILTING PAD</p>	4–120	250–700
 <p>SPRING SUPPORTED</p>	50–120	350–700
 <p>HYDROSTATIC</p>	3–50	500–3000

Source: Booser, E.R. and Wilcock, D.F., *Machine Design*, June 20, 1991, 69–72. With permission.

a rotating thrust face pumps oil by shear into a zone of reduced downstream clearance. When thrust load increases, film thickness drops until a new balance is reached between inflow and outflow, raising pressure until the higher bearing load is balanced. The hydrostatic bearing uses a separate oil pump to supply the pressurized flow.

*Flat-land bearings*, simplest to fabricate and least costly, are the first choice for simple positioning of a rotor and for light loads in electric motors, appliances, pumps, crankshafts, and other machinery. They carry less load than the other types because flat parallel planes do not directly provide the required pumping action. Instead, their action depends on thermal expansion of the oil and warping of the bearing

material induced by heating from the passing oil film. The resulting slight oil wedge then gives a load rating of about 10 to 20% of that for the other types.

*Step bearings* also offer relatively simple design. With a coined or etched step, they lend themselves to mass production as small-size bearings and thrust washers. Step height for optimum load capacity approximately equals the minimum film thickness, often 0.001 in. or less. Circumferential length beyond the step is ideally 45% of the total bearing segment (Wilcock and Booser, 1956). Step thrust bearings are well suited for low-viscosity fluids such as water, gasoline, fuels, and solvents. Minimum film thickness in these applications is so small that features such as pivots and tapers are usually impractical. Step height must be small enough for good load capacity, yet large enough to accommodate some wear without becoming worn away. Step erosion by contaminants is sometimes a problem.

*Tapered-land bearings* provide reliable, compact designs for mid- to large-size high-speed machines such as turbines, compressors, and pumps. Taper height normally should be about one to three times the minimum film thickness. For greater load capacity and to minimize wear during starting, stopping, and at low speeds, a flat land is commonly machined at the trailing edge to occupy from 10 to 30% of the circumferential length of each segment. Because operation of these bearings is sensitive to load, speed, and lubricant viscosity, they are typically designed for the rated range of operating conditions for specific machines.

*Tilting-pad thrust bearings* are used increasingly in turbines, compressors, pumps, and marine drives in much the same range of applications as tapered-land designs. They usually have a central supporting pivot for each of their three to ten bearing segments. Each of these thrust pad segments is free to adjust its position to form a nearly optimum oil wedge for widely varying loads, speeds, and lubricants, and with rotation in both directions. A secondary leveling linkage system is commonly introduced to support the individual pads; this provides a further advantage over tapered-land designs by accommodating some misalignment. Off-the-shelf units are available to match rotor shaft diameters from about 2 to 12 in., and custom designs range up to 120 to 170 in. in outside diameter. Recent trends to increase load capacity have led to offsetting pivots from the circumferential midpoint of a pad to about 60% beyond the leading edge, to substituting copper for steel as the backing for a tin babbitt bearing surface, and to nonflooded lubrication to minimize parasitic power loss from useless churning of oil passing through the bearing housing.

*Springs or other flexible supports* for thrust segments are employed for bearings ranging up to 10 ft or more in outside diameter and carrying millions of pounds of thrust. This flexible mounting avoids the high load concentration encountered by pivots in supporting large tilting-pads. Rubber backing can provide this flexible mounting for smaller thrust pads.

*Hydrostatic thrust bearings* are used where sufficient load support cannot be generated by oil film action within the bearing itself. This may be the case with low-viscosity fluids, or for load support on an oil film at standstill and very low speeds. The fluid is first pressurized by an external pump and then introduced into pockets in the bearing surface to float the load. A compact hydrostatic thrust bearing can sometimes be constructed with a single pocket at the end of a rotor. Larger bearings usually use three or more pressurized pockets to resist misalignment or to support off-center loads. Hydraulic flow resistance in the supply line to each pocket, or constant flow to each pocket (as with ganged gear pumps) then provides any asymmetric pressure distribution needed to support an off-center load. Bearing unit load is commonly limited to about 0.5 (0.75 with fixed flow systems) times the hydrostatic fluid supply pressure—up to 5000 psi with conventional lubricating oils.

*Design Factors for Thrust Bearings.* In preliminary sizing, the inside diameter  $d$  of a thrust bearing is made sufficiently larger than the shaft to allow for assembly, and to provide for any required oil flow to the thrust bearing inside diameter (see [Figure 3.10.7](#)). This clearance typically ranges from about  $1/8$  in. for a 2-in. shaft to  $1/2$  in. for a 10-in. shaft. Bearing outside diameter  $D$  is then set to provide bearing

**FIGURE 3.10.7** Sector for tapered land thrust bearing.

area sufficient to support total thrust load  $W$  (lb or N) with an average loading  $P$  (psi or  $N/m^2$ ), using typical values from [Table 3.10.13](#):

$$D = \left( \frac{4W}{\pi k_g P} + d^2 \right)^{0.5} \tag{3.10.15}$$

where  $k_g$  (typically 0.80 to 0.85) is the fraction of area between  $d$  and  $D$  not occupied by oil-distributing grooves. This bearing area is then divided by radial oil-feed groove passages, usually into “square” sectors with circumferential breadth  $B$  at their mean diameter equal to their radial length  $L$ .

While square pads usually produce optimum oil film performance, other proportions may be advantageous. With very large bearing diameters, for instance, square sectors may involve such a long circumferential dimension that the oil film overheats before reaching the next oil-feed groove. With a radially narrow thrust face, on the other hand, square sectors may become so numerous as to introduce excessive oil groove area, and their short circumferential length would interfere with hydrodynamic oil film action.

*Performance Analysis.* Performance analyses for sector thrust bearings using a fixed taper also hold approximately for most thrust bearing shapes (other than flat lands) with the same ratio of inlet to outlet oil film thickness (Wilcock and Booser, 1956; Neale, 1970; Fuller, 1984). Both for centrally pivoted pad thrust bearings and for spring-supported thrust bearings, use of an inlet-to-outlet film thickness ratio of two is usually appropriate in such an analysis.

While computer analyses in polar coordinates and with local oil film viscosity calculated over the whole oil film area gives more-exact solutions, the following constant viscosity approximations are made by relating a rectangular bearing sector (width  $B$ , length  $L$ ) to the circular configuration of [Figure 3.10.7](#). This rectangular representation allows more ready evaluation of a range of variables and gives results which are quite similar to a more accurate polar coordinate analysis.

Employing the nomenclature of [Figure 3.10.7](#), the following relations give minimum film thickness  $h_2$ , frictional power loss  $H$ , and oil flow into a sector  $Q$ . The dimensionless coefficients involved are given in [Table 3.10.14](#) for a range of sector proportions  $L/B$  and ratios of inlet to outlet film thicknesses  $h_1/h_2$ .

$$h_2 = K_h (\mu UB/P)^{0.5} \quad \text{in. (m)} \tag{3.10.16a}$$

$$H = K_f \mu U^2 BL/h_2 \quad \text{lb} \cdot \text{in./sec (N} \cdot \text{m/sec)} \tag{3.10.16b}$$

$$Q = K_q ULh_2 \quad \text{in.}^3/\text{sec} \left( \text{m}^3/\text{sec} \right) \quad (3.10.16c)$$

$$\Delta T = H / (Q \rho C_p) = \frac{K_f}{K_q K_h^2 \rho C_p} P \quad ^\circ\text{F} \left( ^\circ\text{C} \right) \quad (3.10.16d)$$

where  $B$  = circumferential breadth of sector at mean radius, in. (m)

$K_h, K_f, K_q$  = dimensionless coefficients

$L$  = radial length of sector, in. (m)

$P$  = unit loading on projected area of sector,  $W/BL$ , lb/in.<sup>2</sup> (N/m<sup>2</sup>)

$U$  = surface velocity at mean diameter of sector, in./sec (m/sec)

$W$  = load on a sector, lb (N)

$C_p$  = oil specific heat, in.·lb/(lb·°F) (J/(kg·°C))

$h_1, h_2$  = leading edge and trailing edge film thicknesses, in. (m)

$\rho$  = oil density, lb/in.<sup>3</sup> (n/m<sup>3</sup>)

$\mu$  = oil viscosity at the operating temperature, lb·sec/in.<sup>2</sup> (N·sec/m<sup>2</sup>)

*Example.* The following example involves a bearing for 25,000 lb thrust load in a 1200 rpm compressor whose rotor has a 5-in.-diameter journal. ISO-32 viscosity grade oil is to be fed at 120°F. Allowing  $3/8$  in. radial clearance along the shaft sets thrust bearing bore  $d = 5.75$  in. Taking unit loading  $P = 300$  psi allows a margin for uncertainty in expected thrust load, and outside diameter  $D$  is given by Equation 3.10.14):

$$D = \left( \frac{4 \times 25000}{\pi(0.85)(300)} + 5.75^2 \right)^{0.5} = 12.6 \text{ in.}$$

With 15% of the area used for oil feed passages,  $k_g = 0.85$ . Thrust bearing segment radial length  $L = (12.6 - 5.75)/2 = 3.425$  in. With mean diameter  $(5.75 + 12.6)/2 = 9.175$  in., total circumferential breadth of all pads at the mean diameter =  $\pi D_m k_g = 24.5$  in. The number of sectors (and grooves) for  $B = L$  is then  $24.5/3.425 = 7.2$ . Using seven lands, adjusted circumferential breadth  $B$  for each sector =  $24.5/7 = 3.5$  in. (For simpler fabrication, six or eight sectors should also be considered.) Runner velocity at the mean diameter,  $U = \pi(9.175)(1200/60) = 576.5$  in./sec.

For square pads ( $L/B = 1$ ) in a pivoted-pad bearing with  $h_1/h_2 = 2$ , which represents experience with centrally pivoted pads, Table 3.10.14 gives the following performance coefficients:

$$K_h = 0.261, \quad K_f = 0.727, \quad K_q = 0.849$$

Temperature rise is given by Equation (3.10.16d) which assumes that the total frictional power loss  $H$  goes into heating the total oil flow  $Q$  passing over the pad.

$$\Delta T = \frac{K_f P}{K_q K_h^2 \rho C_p} = \frac{0.727(300)}{0.849(0.261)^2(0.0313)(4535)} = 27^\circ\text{F}$$

Adding this  $\Delta T$  to the 120°F feed temperature gives 147°F as the representative oil operating temperature with a viscosity from Figure 3.10.4 of  $1.6 \times 10^{-6}$  lb·sec/in.<sup>2</sup>. Temperature rise to the maximum oil film temperature would be expected to be about 53°F, twice the 27°F. If this bearing were in a housing fully flooded with oil, feed temperature to each pad would become the housing oil temperature, essentially the same as oil draining from the housing.

After Khonsari, M.M., in *Tribology Data Handbook*, CRC Press, Boca Raton, FL, 1997.

Minimum film thickness *h<sub>2</sub>* becomes, from Equation (3.10.16a)

$$h_2 = 0.261 \left[ (1.6 \times 10^{-6})(576.5)(3.5)/300 \right]^{0.5} = 0.00086 \text{ in.}$$

With a fixed tapered land, rather than a centrally pivoted pad for which it could be assumed that *h<sub>1</sub>/h<sub>2</sub>* = 2, several iterations might be required with different assumed values of the *h<sub>1</sub>/h<sub>2</sub>* ratio in order to determine the performance coefficients in Table 3.10.14. The proper value of *h<sub>1</sub>/h<sub>2</sub>* will be the one that gives the same final calculated value of *h<sub>2</sub>* from the above equation as was assumed in the preliminary selection of *K<sub>h</sub>*, *K<sub>f</sub>*, and *K<sub>q</sub>*.

After finding the values for *h<sub>2</sub>* and *K<sub>f</sub>*, the power loss *H* can be determined using Equation (3.10.16b). For this example the power loss would be *H* = 5510 lb-in./sec.

The total oil feed to the bearing should satisfy two requirements: (1) provide a full oil film over the bearing segment and (2) maintain reasonably cool operation with no more than 30 to 40°F rise in the

oil temperature from feed to drain. Equation (3.10.16c) can be used to find the oil feed  $Q$  needed at the sector inlet to form a full film. The oil feed needed for a 40°F rise is given by the following heat balance using typical density and specific heat values for petroleum oil:

$$Q = H / (\rho C_p \Delta T) \quad (3.10.17)$$

The required oil feed will be the larger of the values determined by (3.10.16c) and (3.10.17).

The above calculations are for a single sector; power loss and oil feed would be multiplied by the number of sectors (seven) to obtain values for the total bearing. Consideration would normally follow for other pad geometries, and possibly other lubricants and oil flow patterns, in a search for the most-promising design. More-detailed calculations of film thickness, film temperatures, oil flow, and power loss could then be obtained by one of a number of computer codes available from bearing suppliers or other sources.

### Oil Film Bearing Materials

Selection of the material for use in a journal or thrust bearing depends on matching its properties to the load, temperature, contamination, lubricant, and required life.

**Babbitts.** Of the common bearing materials, listed in Table 3.10.15, first consideration for rotating machines is usually a babbitt alloy containing about 85% tin or lead together with suitable alloying elements. With their low hardness, they have excellent ability to embed dirt, conform to shaft misalignment, and rate highest for compatibility with steel journals. Tin babbitts, containing about 3 to 8% copper and 5 to 8% antimony, are usually the first choice for their excellent corrosion resistance. SAE 12 (ASTM Grade 2) tin babbitt is widely used in both automotive and industrial bearings. The much lower cost of lead babbitt, however, with 9 to 16% antimony and as much as 12% tin for improved corrosion resistance, brings SAE 13, 14, and 15 grades into wide use for both general automotive and industrial applications (Booser, 1992).

TABLE 3.10.15 Characteristics of Oil Film Bearing Materials

Material	Brinell Hardness	Load Capacity, psi	Max Operating Temp., °F	Compatibility <sup>a</sup>	Conformability and Embeddability <sup>a</sup>	Corrosion Resistance <sup>a</sup>	Fatigue Strength <sup>a</sup>
Tin babbitt	20–30	800–1500	300	1	1	1	5
Lead babbitt	15–25	800–1200	300	1	1	3	5
Copper lead	20–30	1500–2500	350	2	2	5	4
Leaded bronze	60–65	3000–4500	450	3	4	4	3
Tin bronze	65–80	5000+	500	5	5	2	2
Aluminum alloy	45–65	4000+	300	4	3	1	2
Zinc alloy	90–125	3000	250	4	5	5	3
Silver overplated	—	5000+	300	2	4	2	1
Two-component, babbitt surfaced	—	3000+	300	2	4	2	3
Three-component, babbitt surfaced	—	4000+	300	1	2	2	1

<sup>a</sup> Arbitrary scale: 1 = best, 5 = worst.

To achieve the high fatigue strength needed in reciprocating engines, only a very thin layer (commonly 0.001") of babbitt is used so that much of the reciprocating load is taken on a stronger backing material (DeHart, 1984; Kingsbury, 1992). For bimetal bushings such as those used in automobile engines, oil

grooves and feed holes are formed in a continuous steel strip coated with babbitt. The strip is then cut to size and the individual segments are rolled into finished bearings.

For heavy-duty reciprocating engines, three-layer bearings are common. By using a steel strip backing, a thin overlay of SAE 19 or 190 lead babbitt is either electroplated or precision cast on an intermediate layer about 0.1 to 0.3" thick of copper–nickel, copper–lead, leaded bronze, aluminum, or electroplated silver.

*Copper Alloys.* Copper–lead alloys containing 20 to 50% lead, either cast or sintered on a steel back, provide good fatigue resistance for heavy-duty main and connecting rod bearings for automotive, truck, diesel, and aircraft engines. The 10% lead–10% tin leaded bronze has been a traditional selection for bearings in steel mills, appliances, pumps, automotive piston pins, and trunions. This has been replaced in many applications by CA932 (SAE 660) containing 3% zinc for easier casting. The harder tin bronzes require reliable lubrication, good alignment, and 300 to 400 Brinell minimum shaft hardness. Cast tin bronze bushings are used at high loads and low speeds in farm machinery, earthmoving equipment, rolling mills, and in automotive engines for connecting rod bearings.

Utility of copper alloy bearings is limited to relatively low surface speeds by the tendency to form a copper transfer film on a steel shaft. Above about 1500 to 3000 ft/min, selective plucking of softer copper material from hotter load zones in the bearing may result in welded lumps forming on the cooler, stronger transfer layer on the mating steel shaft.

*Zinc Alloys.* Zinc alloys containing about 10 to 30% aluminum find some use for lower cost and better wear life in replacing leaded bronzes. They are used for both oscillating and rotating applications involving speeds up to 1400 ft/min and temperatures up to 250°F.

*Aluminum Alloys* (DeHart, 1984; Shabel et al., 1992). Although finding only minor use in general industrial applications because of their limited compatibility with steel journals, aluminum alloys containing 6.5% tin, 1% copper, and up to 4% silicon are used as solid, bimetal, and trimetal bearings in automotive engines, reciprocating compressors, and aircraft equipment. Good journal finish and shaft hardness of Rockwell B 85 or higher are required. The good fatigue and corrosion resistance of aluminum alloys have led to use of a number of unique alloys containing major additions of silicon, lead, or tin to provide better compatibility characteristics.

## Dry and Semilubricated Bearings

Various plastics, porous bronze and porous iron, carbon–graphite, rubber, and wood are widely used for bearings operating dry or with sparse lubrication (Booser, 1992). Unique properties of these materials have led to their broad use in applications once employing oil film and ball and roller bearings. While these materials provide good performance under conditions of poor or nonexistent lubrication at low speeds, performance commonly improves the closer the approach to full film lubrication.

### Plastics

Most commercial plastics find some use both dry and lubricated in slow-speed bearings at light loads (Jamison, 1994). The most commonly used thermoplastics for bearings are PTFE, nylon, and acetal resins. Thermosetting plastics used for bearings include phenolics, polyesters, and polyimides. [Table 3.10.16](#) compares characteristics of typical plastic bearings with those of carbon–graphite, wood, and rubber which are used in similar applications.

In addition to the maximum temperature which can be tolerated, three operating limits shown in [Table 3.10.16](#) are normally defined for plastic bearings: (1) maximum load at low speed, which reflects the compressive yield strength, (2) maximum speed for running under very light load, and (3) a  $Pv$  load-speed limit at intermediate speeds, which serves as a measure of the maximum tolerable surface temperature. Since wear volume in dry sliding is approximately proportional to total load and the distance of sliding,  $Pv$  also gives a measure of wear depth  $d$  in the modified form of Archard's relation (3.10.1),  $d = k(Pv)t$ , where  $t$  is the operating time and wear factor  $k = \text{wear coefficient } K/\text{hardness } H$ .

**TABLE 3.10.16. Representative Limiting Conditions for Nonmetallic Bearing Materials**

Material	Maximum Temperature, °C	$P_v$ Limit, MN/(m <sup>2</sup> ·sec) <sup>a</sup>	Maximum Pressure, $P$ , MN/m <sup>2b</sup>	Maximum speed, $v$ , m/sec

<sup>a</sup> See Table 3.10.18.

<sup>b</sup> To convert MN/m<sup>2</sup> to psi, multiply by 145.

Typical values of this wear factor  $k$  are given in Table 3.10.17. Since  $k$  values involve substantial variability, prototype tests are highly desirable for any planned application. Added fillers can reduce the wear factor for the base polymer by a factor of 10 to 1000 and more (Blanchet and Kennedy, 1992). Common fillers include inorganic powders such as clay, glass fibers, graphite, molybdenum disulfide, and powdered metal, and also silicone fluid as an internally available lubricant.

<sup>c</sup> 15% glass fiber.

### Porous Metals

Bearings of compressed and sintered bronze, iron, and aluminum alloy powder are produced at the rate of millions per week for shaft sizes ranging from about 1.6 to 150 mm. These sleeve bearings and thrust washers are used in a wide variety of small electric motors, appliances, business machines, machine tools, automotive accessories, and farm and construction equipment (Morgan, 1984; Cusano, 1994). Traditional powder metal bearings consist of 90% copper and 10% tin (Table 3.10.18). The common pore volume of 20 to 30% is usually impregnated with a petroleum oil of SAE 30 viscosity. To promote

formation of an oil film, high porosity with its high oil content is employed for higher speeds, often with an oil wick or grease providing a supplementary lubricant supply. Lower porosity with up to 3.5% added graphite is used for lower speeds and oscillation where oil film formation is difficult.

Porous iron bearings are used for lower cost, often with some copper and graphite added for high load capacity at low speed. Iron with up to 40% of added 90–10 bronze powder provides many of the characteristics of porous bronze bearings while enjoying the lower cost of the iron. Porous aluminum containing 3 to 5% copper, tin, and lead finds limited use for providing cooler operation, better conformability, and lower weight.

Table 3.10.18 gives approximate operating limits for porous metal bearings. Generally, maximum  $P$  values for sleeve bearings range up to 50,000 psi-ft/min.  $Pv$  levels for thrust bearings should generally not exceed about 20% of this value.

**TABLE 3.10.18 Operating Limits for Porous Metal Bearings**

Porous Metal	Nominal Composition, wt%	Pressure limit, $P$ , MN/m <sup>2</sup>		Speed Limit $v$ , m/sec	$Pv$ Limit MN/(m·sec)
		Static	Dynamic		
Bronze	Cu 90, Sn 10	59	28	6.1	1.8 <sup>a</sup>
Iron		52	25	2.0	1.3
Iron–copper	Fe 90, Cu 10	140	28	1.1	1.4

Bronze–iron	Fe 60, Cu 36, Sn 4	72	17	4.1	1.2
Aluminum		28	14	6.1	1.8

Note: To convert MN/m<sup>2</sup> to psi, multiply by 145.

<sup>a</sup> Approximately equivalent to 50,000 psi · ft/min limit often quoted by U.S. suppliers.

## Rolling Element Bearings

### Types of Rolling Element Bearings

Rolling element bearings may be classified according to the type of rolling element, i.e., ball or roller, and the loading direction. Ball and roller bearings can be designed to carry either radial or thrust loads, or a combination of the two. Standard rolling element bearing configurations are shown in Figure 3.10.8, and the capabilities of the different types are summarized in Figure 3.10.9.

*Ball bearings* usually consist of a number of hardened and precisely ground balls interposed between two grooved and hardened rings or races. A cage or separator is used to keep the balls equally spaced around the groove. The most common *radial ball bearing* is a deep groove, or Conrad, type which is designed to carry large radial loads, with a small thrust load capability. The radial capacity of a deep groove bearing can be increased by inserting more balls in the bearing, by means of either a face-located filling notch (which decreases the thrust capacity) or a split inner or outer ring (which requires a means to hold the ring halves axially together). The thrust capability of a radial ball bearing can be increased by inducing angular contact between ball and rings. A single-row angular contact bearing can carry thrust load in only one direction, with the thrust load capacity being dependent on the contact angle (angle between the line of action of the force and the plane perpendicular to the shaft axis). Duplex angular contact bearings consist of two angular contact bearings mounted together so they can carry thrust loads in either direction with little axial play, or they can be mounted in tandem to double the axial and radial load-carrying capacity. Self-aligning ball bearings are designed to accommodate more shaft misalignment than is possible with other radial ball bearings.

*Thrust ball bearings* are used primarily in machinery with a vertically oriented shaft which requires a stiff axial support. Many such bearings have a 90° contact angle and, as a result, can carry essentially no radial load; they also have limited high-speed capability. If thrust loads in both directions are to be carried, a second row of balls must be added.

**FIGURE 3.10.8** Major types of rolling element bearings.

*Roller bearings* can be made with cylindrical, tapered, or spherical rollers. As with ball bearings, the rollers are contained between two rings, with a cage or separator used to keep the rollers separated. The cage can be guided by either the rollers or one of the rings. Since roller bearings operate with line contacts, as opposed to the point (or elliptical) contacts that occur in ball bearings, roller bearings are stiffer (less radial displacement per unit load) and have a greater load-carrying capacity than a ball bearing of similar size. Roller bearings are more expensive than ball bearings of comparable size.

CHARACTERISTICS OF STANDARD ROLLING ELEMENT BEARING CONFIGURATIONS

	TYPE	SIZE RANGE IN INCHES		AVERAGE RELATIVE RATINGS				DIMENSIONS	
				Capacity		Limiting Speed	Permissible Misalignment	Metric	Inch
		Bore	O.D.	Radial	Thrust

FIGURE 3.10.9 Characteristics of standard rolling element bearing configurations.

Radial cylindrical roller bearings are designed to carry primarily radial loads. Cylindrical roller bearings have a high radial load capacity and low friction, so they are suitable for high-speed operation. Their thrust load capacity is limited to that which can be carried by contact (sliding) between the ends of the rollers and the flange or shoulder on the ring which contains them. The rollers in many cylindrical

roller bearings are actually slightly crowned to relieve stress concentrations which would otherwise occur at the ends of the rollers and to compensate for misalignment of the bearing. In order to increase the load-carrying capacity of roller bearings, a second row of rollers is added instead of using longer rollers. This is because long rollers (i.e., length/diameter > 1.7) tend to skew in the roller path, thus limiting their high-speed capability and sometimes shortening their life. Needle bearings have long rollers, however, and they are useful when there are severe radial space limitations and when neither high load capacity nor high speeds are required.

*Spherical roller bearings* usually have an outer ring with a spherical inside diameter, within which are barrel-shaped rollers. This makes these bearings self-aligning, and also gives them a larger contact area between roller and ring than is the case for other rolling element bearings. Because of this, spherical roller bearings have a very high radial load-carrying capacity, along with some ability to carry thrust loads. They have higher friction between roller and ring, and this limits their high-speed capability.

*Tapered roller bearings* have tapered rollers, ideally shaped like truncated cones, contained between two mating cones of different angles, the inner cone and the outer cup. The contact angle of the bearing determines its thrust load capability; a steeper angle is chosen for more thrust capacity. If a single row of rollers is used, the bearing is separable and can carry thrust loads in only one direction. If the thrust is double acting, a second bearing can be mounted in a back-to-back configuration or a double row bearing can be selected. In tapered roller bearings there is sliding contact between the ends of the rollers and the guide flange on the inner cone, and this sliding contact requires lubrication to prevent wear and reduce friction.

*Thrust roller bearings* can be either cylindrical, needle, tapered, or spherical (Figure 3.10.9). In each case there is high load-carrying capacity, but the sliding that occurs between rollers and rings requires lubrication and cooling.

### Rolling Element Bearing Materials

Ball and roller bearings require materials with excellent resistance to rolling contact fatigue and wear, as well as good dimensional stability and impact resistance. The rolling elements are subjected to cyclic contact pressures which can range from 70 to 3500 MPa (100 to 500 ksi) or more, and the bearing materials must be hard enough to resist surface fatigue under those conditions. Of the through-hardening steels which meet these requirements, the most popular is AISI 52100, which contains about 1% carbon and 1.5% chromium. In general, balls and rollers made from 52100 are hardened to about Rockwell C60. Standard bearings made from 52100 may suffer from unacceptable dimensional changes resulting from metallurgical transformations at operating temperatures above 140°C (285°F). Special stabilization heat treatments enable operation at higher temperatures, with successful operation at temperatures as high as 200°C (390°F) having been achieved in cases involving low loads. The strength and fatigue resistance of the material diminish if the bearing temperature increases above about 175°C (350°F), however, so above that temperature materials with better hot-hardness, such as M50 tool steel, are required. Carburizing steels such as AISI 8620 have been developed for tapered roller bearings and other heavily loaded types that benefit from the tougher core and case compressive residual stress developed during carburizing. For applications in oxidative or corrosive environments, a hardened martensitic stainless steel such as SAE 440C may be chosen. For the highest operating temperatures, ceramic materials may be used in bearings. The most promising of the ceramics for rolling element bearing applications is silicon nitride. Its major use so far in bearings has been in hybrid bearings with ceramic balls or rollers and metallic rings, but all-ceramic bearings have also been developed.

The temperature limits of these bearing materials are given in Table 3.10.19. For all bearing materials, great care must be taken in the processing and production stages to ensure that no defects or inclusions are present that could serve as an initiation site for fatigue cracks. For most high-performance metallic bearings, this requires a very clean steel production process, such as vacuum arc remelting. Heat treatment of the material is also important to produce the required dimensional stability. The production process for ceramic bearings is even more critical, because a defect in a ceramic bearing element could result in catastrophic fracture of the brittle material.

**TABLE 3.10.19 Temperature Limits for Rolling Element Bearing Materials**

Material	Maximum Operating Temperature	
	°C	°F
AISI 52100	140–175	285–350
AISI 8620 (carburized)	150	300
440C stainless steel	170	340
M50 tool steel	315	600
Hybrid Si <sub>3</sub> N <sub>4</sub> -M50	425	800
All-ceramic (Si <sub>3</sub> N <sub>4</sub> )	650	1200

Bearing cages or retainers have as their primary purpose the separation of the rolling elements. In some cases, they also provide some solid lubrication to the bearing. Low-carbon steel is the most common cage material, but bronze (silicon iron bronze or aluminum bronze) and polymers (particularly nylon 6-6) are used in many applications.

**Selection of Rolling Element Bearings**

It has been stated that if a rolling element bearing in service is properly lubricated, properly aligned, kept free of abrasive particles, moisture, and corrosive agents, and properly loaded, then all causes of damage will be eliminated except one, contact fatigue (Harris, 1991). The fatigue process results in a spall which may originate on or just beneath the contact surface. Studies of rolling contact fatigue life by Lundberg and Palmgren (1947; 1952) and others showed that most rolling element bearings have fatigue lives which follow a Weibull statistical distribution, wherein the dependence of strength on volume is explained by the dispersion in material strength. Most bearings today are designed according to the Lundberg–Palmgren model, which has been standardized by international (ISO, 1990) and national standards (e.g., ANSI/AFBMA, 1990), although recent work (Ioannides and Harris, 1985) has found that modern bearings have longer lives than those predicted by the standard methods.

The basic rating life of rolling element bearings is the  $L_{10}$  life, which is the number of revolutions at constant speed for which there is a 10% probability of failure (or 90% reliability). The basic dynamic load-carrying capacity, or load rating, of a bearing is the constant load  $C$  which corresponds to an  $L_{10}$  life of one million revolutions. For any other bearing load  $F$ , the  $L_{10}$  life can be determined by the following relationship:

$$L_{10} = (C/F)^n \tag{3.10.18}$$

where the load-life exponent  $n = 3$  for ball bearings, and  $n = 10/3$  for roller bearings.

The equivalent bearing load includes contributions from both radial and thrust loads, and can be calculated by the following expression:

$$F = XF_r + YF_a \tag{3.10.19}$$

where  $X$  is a radial load factor,  $Y$  is a thrust load factor,  $F_r$  is the radial load applied to the bearing, and  $F_a$  is the applied thrust (or axial) load.

Values for the dynamic load rating  $C$ , as well as the load factors  $X$  and  $Y$  for any bearing configuration can be found in manufacturers’ catalogs, or they can be calculated according to formulas given in bearing texts by Harris (1991) or Eschmann et al. (1985). Those references also give life adjustment factors which can be used to adjust the desired  $L_{10}$  life to account for special operating conditions, special material selections, special lubrication conditions, or for a reliability different from 90%.

The bearing user will generally select a commercially available bearing by the following procedure:

1. Determine the axial and thrust loads acting at the bearing location.
2. Determine the required bearing life ( $L_{10}$ ).

3. Select the most appropriate bearing type from among those given in [Figure 3.10.9](#).
4. Use the  $X$  and  $Y$  values appropriate to the type of bearing and loading conditions in Equation (3.10.19) to find the equivalent dynamic bearing load  $F$ .
5. Determine the required dynamic load capacity  $C$  from Equation (3.10.18).
6. Select a bearing with a dynamic load capacity at least as large as the required value from a manufacturer's catalog.
7. Provide an appropriate mounting arrangement for the bearing. Manufacturers' catalogs can be consulted for guidance in designing the mounting and selecting appropriate fits for the bearing. The importance of the fit cannot be overemphasized, since improper fit can result in considerable reduction in bearing life.
8. Provide adequate lubrication for the bearing (see below). Seals and/or shields may be integrated into the bearing to retain or protect the lubricant in the bearing.

### Rolling Bearing Lubrication

The primary load-carrying contacts between rolling elements and rings exhibit nearly pure rolling. There are many sliding contacts in rolling element bearings, however, including those where roller ends contact the internal flanges of rings, where rolling elements contact separator/cage, and where the separator contacts the guiding (piloting) ring of the bearing. All of those contacts must be lubricated to limit friction and wear, and either a grease or an oil can be used for that purpose.

Under most normal operating conditions, rolling element bearings can be grease lubricated. *Greases* coat surfaces with a thin boundary lubricant film of oil, thickener, and additive molecules, thus providing protection against sliding wear, and provide oil to lubricate the concentrated rolling contacts (see below). The selection of a grease depends on its effective temperature range, oil viscosity, consistency, and rust-inhibiting properties. For normal applications, a bearing should be filled with grease up to 30 to 50% of its free volume. Overfilling will cause overheating, particularly at high speeds. Grease will deteriorate with time and will leak out. For that reason, there should be a relubrication schedule, with grease being added at intervals which can be estimated by the following expression (Neale, 1993):

$$\text{relubrication interval (hours)} = \left( k/d^{1/2} \right) \left[ \left( 14 \times 10^6/n \right) - 4d^{1/2} \right] \quad (3.10.20)$$

where  $k = 10$  for radial ball bearings, 5 for cylindrical roller bearings, and 1 for spherical or tapered roller bearings;  $d =$  bearing bore diameter (mm); and  $n =$  speed (rpm)

*Oil lubrication* is required when high speed or high operating temperatures preclude the use of grease. It is necessary to choose an oil of proper viscosity and appropriate viscosity–temperature characteristics in order to insure sufficient thickness of oil film in the lubricated concentrated contacts. If viscosity is too low, the film thickness will not prevent metal/metal contact, but if the viscosity is too high, excessive friction will occur. Oil can be applied to a bearing by one of several methods (listed in order of increasing effectiveness at increasing bearing speed): *oil bath*, in which the rolling elements carry the oil through the bearing; *oil circulating system*, in which the oil is pumped from the bearing through an external filter and heat exchanger and back to the bearing; *oil mist*, in which an airstream carries oil droplets to the bearing; and *oil jets*, in which the oil is injected into the bearing through carefully positioned nozzles. The quantity and entry velocity of the oil must be carefully selected and controlled in order to dissipate the heat generated in the bearing.

The lubrication mechanism in the concentrated contacts of rolling element bearings is *elastohydrodynamic lubrication* (EHL). EHL typically occurs in lubricated, nonconforming elastic contacts, such as the elliptical contact that occurs between ball and raceway or the rectangular contact between roller and ring. These lubricated contacts have a very small area and the contact pressures are very high. Because of those high pressures, the contacting surfaces deform and the lubricant viscosity increases, thereby aiding its ability to sustain heavy loading without oil-film breakdown. A diagram of these phenomena is shown in [Figure 3.10.10](#). The most important parameter of the concentrated contact, from

the point of view of rolling element bearing performance, is minimum EHL film thickness,  $h_o$ . The following expression can be used to find minimum film thickness in most rolling element bearing contacts (Hamrock and Dowson, 1977):

$$h_o = 3.63R_x U^{0.68} G^{-0.49} W_p^{-0.73} (1 - e^{-0.68\kappa}) \tag{3.10.21}$$

where  $R_x = (R_{x1} R_{x2}) / (R_{x1} + R_{x2})$ ,  $R_y = (R_{y1} R_{y2}) / (R_{y1} + R_{y2})$ , ellipticity parameter  $\kappa = R_x / R_y$ ,  $U = \mu (u_1 + u_2) / 2E'R_x$ ,  $\mu$  = absolute viscosity,  $u_1$  and  $u_2$  are velocities of rolling element and ring,  $E' = E / (1 - \nu^2)$ ,  $E$  = modulus of elasticity,  $\nu$  = Poisson's ratio,  $G = \alpha E'$ ,  $\alpha$  = pressure-viscosity exponent,  $W_p = W / E' R_x^2$ , and  $W$  = radial load.

**FIGURE 3.10.10** Typical pressure and film thickness distributions in elastohydrodynamic contact.

The minimum film thickness must be large enough to prevent metal/metal contact within the lubricated conjunctions. The criterion for this is stated as

$$h_o \geq 1.5 (r_{q1}^2 + r_{q2}^2)^{0.5} \tag{3.10.22}$$

where  $r_{q1}$  and  $r_{q2}$  are the rms surface roughness of the rolling element and ring, respectively. If the minimum film thickness is less than this value, complete EHL will not occur, and this could result in wear, surface fatigue, and eventual early bearing failure (i.e., well before the predicted  $L_{10}$  life).

An alternative to oil or grease lubrication for rolling element bearings operating under severe conditions is *solid lubrication*. Solid lubricants can be used effectively in high temperatures or vacuum conditions where liquid lubricants are impractical or would provide marginal performance. Solid lubricants do not prevent solid/solid contact, so wear of the lubricant coating can be expected; bearing life is governed by the depletion of the solid lubricant film.

### Lubricant Supply Methods

Lubrication systems for oil film bearings can generally be grouped into three classifications: self contained devices for small machines; centralized systems, common in manufacturing plants; and circulating systems dedicated to a single piece of equipment such as a motor, turbine, or compressor. Upper speed limits for common journal bearing lubrication methods are indicated in [Figure 3.10.11](#) (Wilcock and Booser, 1987). Submerging the bearing directly in an oil bath is a common alternative for vertical machines.

**FIGURE 3.10.11** Upper limits for journal bearing lubrication methods. (From Wilcock, D.F. and Booser, E.R., *Mach. Des.*; April 23, 101–107, 1987. With permission.)

**Self-Contained Units**

Lifting of oil by *capillary action* from a small reservoir is used to feed small bearings in business machines, household appliances, electrical instruments, controls, and timer motors. In capillary tubes, the height *h* to which oil will rise is (Wilcock and Booser, 1987)

$$h = 2\sigma\cos\theta/(r\rho) \tag{3.10.23}$$

where  $\sigma$  = surface tension, lb/in.,  $r$  = capillary radius (or spacing between two parallel plates), in.;  $\rho$  = oil density, lb/in.<sup>3</sup>. Because oils wet most surfaces readily, the cosine of the contact angle can be taken as unity. As an example, with  $\sigma = 1.7 \times 10^{-4}$  lb/in. for a petroleum oil, the rise in an 0.005-in.-radius capillary will be  $h = 2(1.7 \times 10^{-4})(1)/(0.005)(0.0307) = 2.2$  in.

*Wick lubrication* is applied in millions of fractional horsepower motors annually. Although wicks generally are not efficient at raising oil more than about 2 in., lift may be up to 5 in. in railway journal bearings. By referring to [Figure 3.10.12](#), petroleum oil delivery by a typical wick can be estimated by the following equation (Elwell, 1994):

$$Q = kAF_o(h_u - h)/(\mu L) \text{ in.}^3/\text{min} \tag{3.10.24}$$

where the constant  $k$  reflects both the capillary spacing in the wick and the surface tension of the oil;  $A$  is the wick cross-section area, in.<sup>2</sup>;  $F_o$  is volume fraction of oil in the saturated wick (often about 0.75);  $h_u$  is the ultimate wicking height, about 7.5 in. for SAE Grade F-1 felt;  $h$  is oil delivery height above the reservoir surface, in.;  $L$  is wick length, in.; and  $\mu$  is viscosity at the wick temperature, lb·sec/in.<sup>2</sup>  $\times 10^6$ .  $k$  is approximately 0.26 for SAE Grade F-1 felt.

*Oil rings* hanging over a journal, as illustrated in [Figure 3.10.13](#) and [Table 3.10.20](#), are used to lift oil to journal bearings in electric motors, pumps, and medium-size industrial machines (Elwell, 1994).

**FIGURE 3.10.12** Wick-lubricated journal bearing. (From Elwell, R.C., in *Handbook of Lubrication and Tribology*, Vol. 3, CRC Press, Boca Raton, FL, 1994, 515–533. With permission.)

At very low journal surface speeds below about 2 to 3 ft/sec, the ring will run synchronously with its journal. At higher speeds, increasing viscous drag on the ring in its reservoir will slow the ring surface velocity; oil ring rpm at higher speeds is often in the range of  $1/10$  the journal rpm. Above about 45 ft/sec journal surface velocity, oil delivery drops to an unusably low level as centrifugal throw-off and windage interfere.

These self-contained systems usually supply much less oil to a bearing than needed to form a full hydrodynamic oil film (Elwell, 1994). With the starved oil supply generating an oil wedge of reduced circumferential extent, power loss will be lowered at the expense of reduced load capacity (smaller minimum film thickness).

### Centralized Distribution Systems

Limitations with individual localized lubricating devices have led to widespread use of centralized systems for factory production-line equipment, construction and mining machines, and small applications. Oil or soft grease is pumped from a central reservoir in pulses or as metered continuous feed. Oil mist is piped for distances up to 300 ft for machines in petrochemical plants and steel mills. Polymer additives in the 50,000 to 150,000 molecular-weight range greatly reduce the escape of stray oil mist into the atmosphere.

### Circulating Systems

Where bearing design, reliability requirements, or equipment considerations preclude use of a simpler oil feed, a circulating system is employed involving an oil reservoir, pump, cooler, and filter (Twidale and Williams, 1984). These systems become quite compact with the space limitations in aircraft, marine, or automobile engines where the reservoir may simply be the machine sump with capacity to hold only a 20- to 60-sec oil supply. Characteristics of typical oil-circulating systems for industrial use are given in [Table 3.10.21](#) (Wilcock and Booser, 1987).

### Dynamic Seals

Fluid seals commonly accompany bearings in a wide variety of machinery, both to control leakage of lubricating oil and process fluids and to minimize contamination. Static seals, such as O-rings and gaskets, provide sealing between surfaces which do not move relative to each other. Dynamic seals, which will be the focus of this discussion, restrain flow of fluid between surfaces in relative motion. Most dynamic seals could be classified as either contact or clearance seals. Contact seals are used when the surfaces are in sliding contact, while clearance seals imply that the surfaces are in close proximity to each other but do not contact. The major types of dynamic seals are listed in [Table 3.10.22](#). Further details about the design and analysis of dynamic sealing elements can be found in the handbook article by Stair (1984) and in the book by Lebeck (1991).

As an example of a contact seal, ball bearings are often sealed to retain their lubricant and to keep out contaminants over a long lifetime. For small grease-lubricated bearings, the sealing function is often accomplished by lightly loaded contact between a rubber lip seal component and the bearing ring. For shafts ranging up to about 2 in. (5 cm) in diameter, the lip seal may be replaced by a closely fitted, but noncontacting, shield which helps contain the grease and restricts intrusion of dirt and other contaminants.

H = High, M = Moderate, L = Low.

Modified from Stair, W.K., in *Handbook of Lubrication*, Vol. 2, CRC Press, Boca Raton, FL 1984, 581–622.

For more severe sealing requirements in rolling element bearings, labyrinth clearance seals may be used (Harris, 1991).

The most common seals for rotating shafts passing through fixed housings, such as pumps or gear-boxes, are radial lip seals and mechanical face seals. These contact seals can be designed to handle a wide range of sealed fluids, temperatures, velocities, and pressures (Stair, 1984; Lebeck, 1991). Material selection and surface finish considerations are similar to those discussed in the subsections on sliding friction and its consequences and on dry and semilubricated bearings.

When high surface speeds are encountered, wear and frictional heating may prohibit use of rubbing contact seals. For such applications, clearance seals such as close-fitting labyrinth seals or controlled-clearance fluid film seals can be used. Fluid film seals can be either hydrostatic or hydrodynamic; both types have a pressurized film of fluid which prevents contact between the sealed surfaces and use pressure balancing to restrain leakage. The principles governing their operation are similar to those discussed in the subsection on fluid film bearings. Details of fluid film seals can be found in Shapiro (1995).

## 3.11 Pumps and Fans

---

*Robert F. Boehm*

### Introduction

Pumps are devices that impart a pressure increase to a liquid. Fans are used to increase the velocity of a gas, but this is also accomplished through an increase in pressure. The pressure rise found in pumps can vary tremendously, and this is a very important design parameter along with the liquid flow rate. This pressure rise can range from simply increasing the elevation of the liquid to increasing the pressure hundreds of atmospheres. Fan applications, on the other hand, generally deal with small pressure increases. In spite of this seemingly significant distinction between pumps and fans, there are many similarities in the fundamentals of certain types of these machines as well as with their application and theory of operation.

The appropriate use of pumps and fans depends upon the proper choice of device and the proper design and installation for the application. A check of sources of commercial equipment shows that many varieties of pumps and fans exist. Each of these had special characteristics that must be appreciated for achieving proper function. Preliminary design criteria for choosing between different types is given by Boehm (1987).

As is to be expected, the wise applications of pumps and fans requires knowledge of fluid flow fundamentals. Unless the fluid mechanics of a particular application are understood, the design could be less than desirable.

In this section, pump and fan types are briefly defined. In addition, typical application information is given. Also, some ideas from fluid mechanics that are especially relevant to pump and fan operation are reviewed.

### Pumps

Raising of water from wells and cisterns is the earliest form of pumping (a very detailed history of early applications is given by Ewbank, 1842). Modern applications are much broader, and these find a wide variety of machines in use. Modern pumps function on one of two principles. By far the majority of pump installations are of the *velocity head* type. In these devices, the pressure rise is achieved by giving the fluid a movement. At the exit of the machine, this movement is translated into a pressure increase. The other major type of pump is called *positive displacement*. These devices are designed to increase the pressure of the liquid while essentially trying to compress the volume. A categorization of pump types has been given by Krutzsch (1986), and an adaptation of this is shown below.

- I. Velocity head
  - A. Centrifugal
    - 1. Axial flow (single or multistage)
    - 2. Radial flow (single or double suction)
    - 3. Mixed flow (single or double suction)
    - 4. Peripheral (single or multistage)
  - B. Special Effect
    - 1. Gas lift
    - 2. Jet
    - 3. Hydraulic ram
    - 4. Electromagnetic
- II. Positive displacement
  - A. Reciprocating
    - 1. Piston, plunger
      - a. Direct acting (simplex or duplex)

- b. Power (single or double acting, simplex, duplex, triplex, multiplex)
- 2. Diaphragm (mechanically or fluid driven, simplex or multiplex)
- B. Rotary
  - 1. Single rotor (vane, piston, screw, flexible member, peristaltic)
  - 2. Multiple rotor (gear, lobe, screw, circumferential piston)

In the next subsection, some of the more common pumps are described.

### Centrifugal and Other Velocity Head Pumps

Centrifugal pumps are used in more industrial applications than any other kind of pump. This is primarily because these pumps offer low initial and upkeep costs. Traditionally, pumps of this type have been limited to low-pressure-head applications, but modern pump designs have overcome this problem unless very high pressures are required. Some of the other good characteristics of these types of devices include smooth (nonpulsating) flow and the ability to tolerate nonflow conditions.

The most important parts of the centrifugal pump are the *impeller* and *volute*. An impeller can take on many forms, ranging from essentially a spinning disk to designs with elaborate vanes. The latter is usual. Impeller design tends to be somewhat unique to each manufacturer, as well as finding a variety of designs for a variety of applications. An example of an impeller is shown in Figure 3.11.1. This device imparts a radial velocity to the fluid that has entered the pump perpendicular to the impeller. The volute (there may be one or more) performs the function of slowing the fluid and increasing the pressure. A good discussion of centrifugal pumps is given by Lobanoff and Ross (1992).

**FIGURE 3.11.1.** A schematic of a centrifugal pump is shown. The liquid enters perpendicular to the figure, and a radial velocity is imparted by clockwise spin of the impeller.

A very important factor in the specification of a centrifugal pump is the *casing orientation* and *type*. For example, the pump can be oriented vertically or horizontally. Horizontal mounting is most common. Vertical pumps usually offer benefits related to ease of priming and reduction in required net positive suction head (see discussion below). This type also requires less floor space. Submersible and immersible pumps are always of the vertical type. Another factor in the design is the way the casing is split, and this has implications about ease of manufacture and repair. Casings that are split perpendicular to the shaft are called *radially split*, while those split parallel to the shaft axis are denoted as *axially split*. The latter can be *horizontally split* or *vertically split*. The number of *stages* in the pump greatly affects the pump-output characteristics. Several stages can be incorporated into the same casing, with an associated increase in pump output. Multistage pumps are often used for applications with total developed head over 50 atm.

Whether or not a pump is self-priming can be important. If a centrifugal pump is filled with air when it is turned on, the initiation of pumping action may not be sufficient to bring the fluid into the pump. Pumps can be specified with features that can minimize priming problems.

There are other types of velocity head pumps. *Jet pumps* increase pressure by imparting momentum from a high-velocity liquid stream to a low-velocity or stagnant body of liquid. The resulting flow then

goes through a diffuser to achieve an overall pressure increase. *Gas lifts* accomplish a pumping action by a drag on gas bubbles that rise through a liquid.

### Positive-Displacement Pumps

Positive-displacement pumps demonstrate high discharge pressures and low flow rates. Usually, this is accomplished by some type of pulsating device. A piston pump is a classic example of positive-displacement machines. Rotary pumps are one type of positive-displacement device that do not impart pulsations to the existing flow (a full description of these types of pumps is given by Turton, 1994). Several techniques are available for dealing with pulsating flows, including use of double-acting pumps (usually of the reciprocating type) and installation of pulsation dampeners.

Positive-displacement pumps usually require special seals to contain the fluid. Costs are higher both initially and for maintenance compared with most pumps that operate on the velocity head basis. Positive-displacement pumps demonstrate an efficiency that is nearly independent of flow rate, in contrast to the velocity head type (see [Figure 3.11.2](#) and the discussion related to it below).

Reciprocating pumps offer very high efficiencies, reaching 90% in larger sizes. These types of pumps are more appropriate for pumping abrasive liquids (e.g., slurries) than are centrifugal pumps.

A characteristic of positive displacement pumps which may be valuable is that the output flow is proportional to pump speed. This allows this type of pump to be used for metering applications. Also a positive aspect of these pumps is that they are self-priming, except at initial start-up.

Very high head pressures (often damaging to the pump) can be developed in positive-displacement pumps if the downstream flow is blocked. For this reason, a pressure-relief-valve bypass must always be used with positive-displacement pumps.

### Pump/Flow Considerations

Performance characteristics of the pump must be considered in system design. Simple diagrams of pump applications are shown in [Figure 3.11.2](#). First, consider the left-hand figure. This represents a flow circuit, and the pressure drops related to the piping, fittings, valves, and any other flow devices found in the circuit must be estimated using the laws of fluid mechanics. Usually, these resistances (pressure drops) are found to vary approximately with the square of the liquid flow rate. Typical characteristics are shown in [Figure 3.11.3](#). Most pumps demonstrate a flow vs. pressure rise variation that is a positive value at zero flow and decreases to zero at some larger flow. Positive-displacement pumps, as shown on the right-hand side of [Figure 3.11.3](#), are an exception to this in that these devices usually cannot tolerate a zero flow. An important aspect to note is that a closed system can presumably be pressurized. A contrasting situation and its implications are discussed below.

The piping diagram shown on the right-hand side of [Figure 3.11.2](#) is a once-through system, another frequently encountered installation. However, the leg of piping through “pressure drop 1” shown there can have some very important implications related to *net positive suction head*, often denoted as **NPSH**. In simple terms, NPSH indicates the difference between the local pressure and the thermodynamic saturation pressure at the fluid temperature. If  $NPSH = 0$ , the liquid can vaporize, and this can result in a variety of outcomes from noisy pump operation to outright failure of components. This condition is called **cavitation**. Cavitation, if it occurs, will first take place at the lowest pressure point within the piping arrangement. Often this point is located at, or inside, the inlet to the pump. Most manufacturers specify how much NPSH is required for satisfactory operation of their pumps. Hence, the actual NPSH (denoted as **NPSHA**) experienced by the pump must be larger than the manufacturer’s required NPSH (called **NPSHR**). If a design indicates insufficient NPSH, changes should be made in the system, possibly including alternative piping layout, including elevation and/or size, or use of a pump with smaller NPSH requirements.

The manufacturer should be consulted for a map of operational information for a given pump. A typical form is shown in [Figure 3.11.4](#). This information will allow the designer to select a pump that satisfied the circuit operational requirements while meeting the necessary NPSH and most-efficient-operation criteria.

**FIGURE 3.11.2.** Typical pump applications, either in circuits or once-through arrangements, can be represented as combined fluid resistances as shown. The resistances are determined from fluid mechanics analyses.

**FIGURE 3.11.3.** An overlay of the pump flow vs. head curve with the circuit piping characteristics gives the operating state of the circuit. A typical velocity head pump characteristic is shown on the left, while a positive-displacement pump curve is shown on the right.

**FIGURE 3.11.4.** A full range of performance information should be available from the pump manufacturer, and this may include the parameters shown.

Several options are available to the designer for combining pumps in systems. Consider a comparison of the net effect between operating pumps in series or operating the same two pumps in parallel. Examples of this for pumps with characteristics such as centrifugal units are shown in [Figure 3.11.5](#). It is clear that one way to achieve high pumping pressures with centrifugal pumps is to place a number of units in series. This is a related effect to what is found in *multistage* designs.

**FIGURE 3.11.5.** Series (a) and parallel (b) operation of centrifugal pumps are possible. The resultant characteristics for two identical pumps are shown.

## Fans

As noted earlier, fans are devices that cause air to move. This definition is broad and can include a flapping palm branch, but the discussion here deals only with devices that impart air movement due to *rotation of an impeller inside a fixed casing*. In spite of this limiting definition, a large variety of commercial designs are included.

Fans find application in many engineering systems. Along with the chillers and boilers, they are the heart of heating, ventilating, and air conditioning (HVAC) systems. When large physical dimensions of a unit are not a design concern (usually the case), centrifugal fans are favored over axial flow units for HVAC applications. Many types of fans are found in *power plants*. Very large fans are used to furnish air to the boiler, as well as to draw or force air through cooling towers and pollution-control equipment. *Electronic cooling* finds applications for small units. Even automobiles have several fans in them. Because of the great engineering importance of fans, several organizations publish rating and testing criteria (see, for example, ASME, 1990).

Generally fans are classified according to how the air flows through the impeller. These flows may be *axial* (essentially a propeller in a duct), *radial* (conceptually much like the centrifugal pumps discussed earlier), *mixed*, and *cross*. While there are many other fan designations, all industrial units fit one of these classifications. Mixed-flow fans are so named because both axial and radial flow occur on the vanes. Casings for these devices are essentially like those for axial-flow machines, but the inlet has a radial-flow component. On cross-flow impellers, the gas traverses the blading twice.

Characteristics of fans are shown in [Figure 3.11.6](#). Since velocities can be high in fans, often both the total and the static pressure increases are considered. While both are not shown on this figure, the curves have similar variations. Of course the total  $\Delta P$  will be greater than will the static value, the difference being the velocity head. This difference increases as the volume flow increases. At zero flow (the shutoff point), the static and total pressure difference values are the same. Efficiency variation shows a sharp optimum value at the design point. For this reason, it is critical that fan designs be carefully tuned to the required conditions.

A variety of vane type are found on fans, and the type of these is also used for fan classification. Axial fans usually have vanes of airfoil shape or vanes of uniform thickness. Some vane types that might be found on a centrifugal (radial-flow) fan are shown in [Figure 3.11.7](#).

One aspect that is an issue in choosing fans for a particular application is fan efficiency. Typical efficiency comparisons of the effect of blade type on a centrifugal fan are shown in [Figure 3.11.8](#). Since velocities can be high, the value of aerodynamic design is clear. Weighing against this are cost and other factors.

An additional aspect that may be important in the choice of fans is noise generation. This may be most critical in HVAC applications. It is difficult to describe noise characteristics in brief terms because of the frequency-dependent nature of these phenomena. However, a comparison of specific sound power

**FIGURE 3.11.6.** Shown are characteristics of a centrifugal fan. The drawbacks to operating away from optimal conditions are obvious from the efficiency variation.

**FIGURE 3.11.7.** A variety of vane types that might be used on a centrifugal fan are shown.

**FIGURE 3.11.8.** Efficiency variation with volume flow of centrifugal fans for a variety of vane types is shown.

level (usually denoted by  $K_w$ ) shows backward-curved centrifugal fans with aerodynamic blades perform best among the designs. Details of noise characteristics are given elsewhere (ASHRAE, 1991).

While each type of fan has some specific qualities for certain applications, most installations use centrifugal (radial-flow) fans. A primary exception is for very-high-flow, low-pressure-rise situations where axial (propeller) fans are used.

Similarities exist between fans and pumps because the fluid density essentially does not vary through either type of machine. Of course, in pumps this is because a liquid can be assumed to be incompressible. In fans, a gas (typically air) is moved with little pressure change. As a result, the gas density can be taken to be constant. Since most fans operate near atmospheric pressure, the ideal gas assumptions can be used in determining gas properties.

Flow control in fan applications, where needed, is a very important design concern. Methods for accomplishing this involve use of dampers (either on the inlet or on the outlet of the fan), variable pitch vanes, or variable speed control. Dampers are the least expensive to install, but also the most inefficient in terms of energy use. Modern solid state controls for providing a variable frequency power to the drive motor is becoming the preferred control method, when a combination of initial and operating costs is considered.

## Defining Terms

**Cavitation:** Local liquid conditions allow vapor voids to form (boiling).

**NPSH:** Net positive suction head is the difference between the local absolute pressure of a liquid and the thermodynamic saturation pressure of the liquid based upon the temperature of the liquid. Applies to the inlet of a pump.

**NPSHA:** Actual net positive suction head is the NPSH at the given state of operation of a pump.

**NPSHR:** Required net positive suction head is the amount of NPSH required by a specific pump for a given application.

### 3.12 Liquid Atomization and Spraying

Rolf D. Reitz

Sprays are involved in many practical applications, including in the process industries (e.g., spray drying, spray cooling, powdered metals); in treatment applications (e.g., humidification, gas scrubbing); in coating applications (e.g., surface treatment, spray painting, and crop spraying); in spray combustion (e.g., burners, furnaces, rockets, gas turbines, diesel and port fuel injected engines); and in medicinal and printing applications. To be able to describe sprays it is necessary to obtain a detailed understanding of spray processes.

In the simplest case, the liquid to be sprayed is injected at a high velocity through a small orifice. Atomization is the process whereby the injected liquid is broken up into droplets. Atomization has a strong influence on spray vaporization rates because it increases the total surface area of the injected liquid greatly. Fast vaporization may be desirable in certain applications, but undesirable in others, where the liquid is required to impinge on a target. The trajectories of the spray drops are governed by the injected momentum of the drop, drag forces, and interactions between the drops and the surrounding gas. Control of these and other spray processes can lead to significant improvements in performance and in quality of product, and to reduction of emission of pollutants.

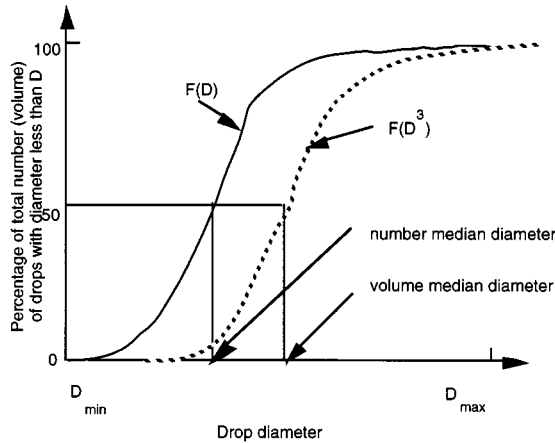

#### Spray Characterization

Practical atomizers generate sprays with a distribution of drop sizes, with average sizes in the diameter range from a few microns ( $1 \mu\text{m} = 10^{-6} \text{m}$ ) to as large as 0.5 mm. It is important to quantify the details of the distribution depending on the application. For example, the smaller drops in a spray vaporize fast, and this is helpful to control ignition processes in some combustion systems. On the other hand, the large drops carry most of the mass and momentum of the injected liquid and these drops are able to penetrate into the high-pressure gases in engine combustion chambers. Typical average drop sizes for broad classes of sprays are shown schematically in Figure 3.12.1. It should be noted that the terminology used to describe sprays in Figure 3.12.1 is qualitative and is not universally agreed upon.

**FIGURE 3.12.1** Typical average spray drop sizes for various classes of sprays. A representative size distribution is depicted for the diesel spray.

Methods for characterizing the size distribution of spray drops are discussed in References 1 and 2. A probability distribution function,  $F(D)$ , is introduced that represents the fraction of drops per unit diameter range about the diameter,  $D$ , as shown in Figure 3.12.2. The spray drop sizes span a range from a minimum diameter,  $D_{\min}$ , to a maximum diameter,  $D_{\max}$ . It is also convenient to introduce a mean or average drop diameter instead of having to specify the complete drop size distribution. The number median drop diameter (NMD) represents that drop whose diameter is such that 50% of the drops in the spray have sizes less than this size. Spray drop size distribution data can also be represented as a volume

**FIGURE 3.12.2** Cumulative spray drop number and volume distributions.

(or mass) distribution function,  $F(D^3)$ ; this gives more weight to the large drops in the distribution. In this case, a volume median diameter (VMD) or a mass median diameter (MMD) can also be defined, as indicated in Figure 3.12.2.

Various other mean diameters are also in common use. These are summarized using the standard notation of Mugele and Evans<sup>2</sup> as

$$(D_{jk})^{j-k} = \frac{\int_{D_{\min}}^{D_{\max}} D^j f(D) dD}{\int_{D_{\min}}^{D_{\max}} D^k f(D) dD} \quad (3.12.1)$$

where  $f(D) = dF(D)/dD$  is the drop size probability density function (usually normalized such that  $\int_{D_{\min}}^{D_{\max}} f(D)dD = 1$ ). Commonly used mean diameters are  $D_{10}$  (i.e.,  $j = 1, k = 0$ , sometimes called the length mean diameter<sup>3</sup> and  $D_{32}$  (i.e.,  $j = 3, k = 2$ , called the Sauter mean diameter or SMD). The Sauter mean diameter has a useful physical interpretation in combustion applications since drop vaporization rates are proportional to the surface area of the drop. It represents the size of that drop that has the same volume-to-surface area ratio as that of the entire spray.

Several distribution functions have been found to fit experimental data reasonably well. Among these are the Nukiyama–Tanasawa and the Rosin–Rammler distributions which have the general form<sup>3</sup>  $f(D) = aD^p \exp\{-bD\}^q$ , where the constants  $a, p, b$ , and  $q$  characterize the size distribution. The higher the parameter,  $q$ , the more uniform the distribution, and typically  $1.5 < q < 4$ . Other distributions have been proposed which consist of logarithmic transformations of the normal distribution, such as  $f(D) = a \exp(-y^2/2)$ , where  $y = \delta \ln(\eta D / (D_{\max} - D))$ , and  $a, \delta$ , and  $\eta$  are constants. In this case, the smaller  $\delta$ , the more uniform the size distribution. It should be noted that there is no theoretical justification for any of these size distributions. Spray drop size distributions can be measured nonintrusively by using optical laser diffraction and phase/Doppler instruments. A discussion of these techniques and their accuracy is reviewed by Chigier.<sup>4</sup>

## Atomizer Design Considerations

Atomization is generally achieved by forcing a liquid or a liquid–gas mixture through a small hole or slit under pressure to create thin liquid sheets or jets moving at a high relative velocity with respect to the surrounding ambient gas. Desirable characteristics of atomizers include the ability to atomize the

liquid over a wide range of flow rates, low power requirements, and low susceptibility to blockage or fouling. In addition, atomizers should produce consistent sprays with uniform flow patterns in operation.

Atomizers can be broadly characterized as those producing hollow cone or solid cone sprays, as depicted in Figure 3.12.3. In solid cone (or full cone) sprays the spray liquid is concentrated along the spray axis, Figure 3.12.3(a). These sprays are useful in applications requiring high spray penetration, such as in diesel engines. In hollow cone sprays the axis region is relatively free of drops, giving wide spray dispersal, Figure 3.12.3(b). These sprays are often used in furnaces, gas turbines, and spray-coating applications.

FIGURE 3.12.3 Schematic diagram of (a) solid cone and (b) hollow cone pressure atomizer sprays.

Many different atomizer designs are found in applications. Common atomizer types include pressure, rotary, twin-fluid (air-assist, air-blast, effervescent), flashing, electrostatic, vibratory, and ultrasonic atomizers, as discussed next.

### Atomizer Types

In *pressure atomizers* atomization is achieved by means of a pressure difference,  $\Delta P = P_{res} - P_{gas}$ , between the liquid in the supply reservoir pressure,  $P_{res}$ , and the ambient medium pressure,  $P_{gas}$ , across a nozzle. The simplest design is the plain orifice nozzle with exit hole diameter,  $d$ , depicted in Figure 3.12.3(a). The liquid emerges at the theoretical velocity  $U = \sqrt{2\Delta P/\rho_{liquid}}$ , the (Bernoulli) velocity along the streamline A–B in Figure 3.12.3(a), where  $\rho_{liquid}$  is the density of the liquid. The actual injection velocity is less than the ideal velocity by a factor called the discharge coefficient,  $C_D$ , which is between 0.6 and 0.9 for plain hole nozzles.  $C_D$  accounts for flow losses in the nozzle.

Four main jet breakup regimes have been identified, corresponding to different combinations of liquid inertia, surface tension, and aerodynamic forces acting on the jet, as shown in Figure 3.12.4. At low injection pressures the low-velocity liquid jet breaks up due to the unstable growth of long-wavelength waves driven by surface tension forces (Rayleigh regime). As the jet velocity is increased, the growth of disturbances on the liquid surface is enhanced because of the interaction between the liquid and the ambient gas (the first and second wind-induced breakup regimes). At high injection pressures the high-velocity jet disintegrates into drops immediately after leaving the nozzle exit (atomization regime). Criteria for the boundaries between the regimes are available.<sup>5</sup> Aerodynamic effects are found to become very important relative to inertial effects when the jet Weber number,  $We_j > 40$ , where  $We_j = \rho_{gas} U^2 d / \sigma$ ,  $\rho_{gas}$  is the gas density, and  $\sigma$  is the liquid surface tension.

Experiments show that the unstable growth of surface waves is aided by high relative velocities between the liquid and the gas, and also by high turbulence and other disturbances in the liquid and gas flows, and by the use of spray liquids with low viscosity and low surface tension.

**FIGURE 3.12.4** (a) Rayleigh breakup. Drop diameters are larger than the jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (b) First wind-induced regime. Drops with diameters of the order of jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (c) Second wind-induced regime. Drop sizes smaller than the jet diameter. Breakup starts some distance downstream of nozzle. (d) Atomization regime. Drop sizes much smaller than the jet diameter. Breakup starts at nozzle exit.

Liquid breakup characteristics such as the spray drop size, the jet breakup length, and the spray angle have been related to the unstable wave growth mechanism. The wavelengths and growth rates of the waves can be predicted using results from a linear stability analysis with<sup>6</sup>

$$\frac{\Lambda}{2} = 9.02 \frac{(1 + 0.45Z^{0.5})(1 + 0.4T^{0.7})}{(1 + 0.87We_2^{1.67})^{0.6}} \quad (3.12.2a)$$

$$\Omega \left( \frac{\rho_1 a^3}{\sigma} \right)^{0.5} = \frac{0.34 + 0.38 We_2^{1.5}}{(1 + Z)(1 + 1.4T^{0.6})} \quad (3.12.2b)$$

where  $\Lambda$  is the wavelength,  $\Omega$  is the growth rate of the most unstable surface wave, and  $a$  is the liquid jet radius. The maximum wave growth rate increases, and the corresponding wavelength decreases with increasing Weber number,  $We_2 = \rho_{\text{gas}} U^2 a / \sigma$ , where  $U$  is the relative velocity between the liquid and the gas. The liquid viscosity appears in the Ohnesorge number,  $Z = We_1^{1/2} / Re_1$ . Here, the Weber number  $We_1$  is based on the liquid density, the Reynolds number is  $Re_1 = Ua / \nu_1$ ,  $\nu_1$  is the liquid viscosity, and the parameter  $T = Z We_2^{1/2}$ . The wave growth rate is reduced and the wavelength is increased as the liquid viscosity increases.

The size of the drops formed from the breakup process is often assumed to be proportional to the wavelength of the unstable surface waves in modeling studies.<sup>6</sup> However, the drop sizes in the primary breakup region near the nozzle exist have also been found to be influenced by the length scale of the energy-containing eddies in the turbulent liquid flow.<sup>7</sup> There is uncertainty about atomization mechanisms since spray measurements are complicated by the high optical density of the spray in the breakup region

(e.g., see Figure 3.12.4(d)). As the drops penetrate into the ambient gas, they interact with each other through collisions and coalescence, and the spray drop size changes dynamically within the spray as a result of secondary breakup and vaporization effects. The drop trajectories are determined by complex drop drag, breakup, and vaporization phenomena, and by interactions with the turbulent gas flow.<sup>6</sup>

High-pressure diesel sprays are intermittent and are required to start and stop quickly without dribble between injections. This is accomplished by means of a plunger arrangement that is actuated by a cam and spring system in mechanical “jerk” pump systems (see Figure 3.12.5). Modern electronic injectors include electromagnetic solenoids that permit the duration and injection pressure to be varied independently of each other and of engine speed. Experiments on diesel-type injector nozzles show that the penetration distance,  $S$ , of the tip of the spray at time,  $t$ , after the beginning of the injection is given by<sup>8</sup>

$$\begin{aligned}
 S &= 0.39Ut \left( \rho_{\text{liquid}} / \rho_{\text{gas}} \right)^{1/2} && \text{for } t < t_b \\
 S &= 2.46 \sqrt{U} dt \left( \rho_{\text{liquid}} / \rho_{\text{gas}} \right)^{1/4} && \text{for } t > t_b
 \end{aligned}
 \tag{3.12.3}$$

where the “breakup time” is  $t_b = 40.5d(\rho_{\text{liquid}}/\rho_{\text{gas}})^{1/2}/U$ . The jet breakup length (see Figure 3.12.3(a)),  $L = Ut_b$  is independent of the injection velocity. On the other hand, for low-speed jets, or for jets injected into a low-gas-density environment,  $t_b = 1.04C (\rho_{\text{liquid}} d^3/\sigma)^{1/2}$ , where  $C$  is a constant typically between 12 and 16 and  $\sigma$  is the surface tension. In this case  $L$  increases with the injection velocity.<sup>9</sup> The functional form of the above jet breakup time and length correlations can be derived for an inviscid liquid in the limits of large and small Weber number,  $We_2$  from the unstable wave growth rate in Equation (3.12.2) with  $t_b \sim \Omega^{-1}$ .

**FIGURE 3.12.5** (a) Diesel injector multihole spray nozzle, (b) showerhead, and (c) doublet impingement nozzles.

For high-speed diesel-type jets in the atomization regime the resulting spray diverges in the form of a cone with cone angle,  $\theta$ , that is usually in the range from 5 to 20°.  $\theta$  increases with gas density following  $\tan \theta = A(\rho_{\text{gas}}/\rho_{\text{liquid}})^{1/2}$ , where  $A$  is a constant that depends on the nozzle passage length and (weakly) on the injection velocity.<sup>9</sup> Very high injection pressures are required to produce small drops. In diesel engines  $\Delta P$  is typically as high as 200 Mpa, and drops are produced with mean diameters of the order of 10  $\mu\text{m}$  (see Figure 3.12.1). Drop size correlations have been proposed for plain-orifice sprays, such as that presented in Table 3.12.1.<sup>3</sup> Note, however, that these correlations do not account for the fact that the spray drop size varies with time, and from place to place in the spray. Moreover, experimental correlations often do not include some parameters that are known to influence spray drop sizes, such as the nozzle passage length and its entrance geometry. Therefore, overall drop size correlations should only be used with caution.

**TABLE 3.12.1 Representative Drop Size Correlations for Various Spray Devices**  
(Dimensional quantities are in SI units, kg, m, s)

Device	Correlation	Notes
Plain orifice	$\text{SMD} = 3.08 v_i^{0.385} (\rho_{\text{liquid}} \sigma)^{0.737} \rho_{\text{gas}}^{0.06} \Delta P^{-0.54}$	Use SI units
Fan spray	$\text{SMD} = 2.83 d_h \left( \sigma \mu_{\text{liquid}}^2 / \rho_{\text{gas}} d_h^3 \Delta P^2 \right)^{0.25}$ $+ 0.26 d_h \left( \sigma \rho_{\text{liquid}} / \rho_{\text{gas}} d_h \Delta P \right)^{0.25}$	$d_h$ = nozzle hydraulic diameter
Rotary atomizer	$\text{SMD} = 0.119 Q^{0.1} \sigma^{0.5} / N d^{0.5} \rho_{\text{liquid}}^{0.4} \mu_{\text{liquid}}^{0.1}$	$N$ = rotational speed (rev/sec), $Q$ = volumetric flow rate, $A_{\text{inj}} U$
Pressure swirl	$\text{SMD} = 4.52 \left( \sigma \mu_{\text{liquid}}^2 / \rho_{\text{gas}} \Delta P^2 \right)^{0.25} (t \cos \theta)^{0.25}$ $+ 0.39 \left( \sigma \rho_{\text{liquid}} / \rho_{\text{gas}} \Delta P \right)^{0.25} (t \cos \theta)^{0.75}$ $t = 0.0114 A_{\text{inj}} \rho_{\text{liquid}}^{1/2} d \cos \theta$	$t$ = film thickness; $\theta$ = cone angle, $d$ = discharge orifice diameter
Twin fluid/air blast	$\text{SMD} = 0.48 d \left( \sigma / \rho_{\text{gas}} U^2 d \right)^{0.4} (1 + 1/\text{ALR})^{0.4}$ $+ 0.15 d \left( \mu_{\text{liquid}}^2 / \sigma \rho_{\text{liquid}} d \right)^{0.5} (1 + 1/\text{ALR})$	ALR = air-to-liquid mass ratio
Prefilming air blast	$\text{SMD} = (1 + 1/\text{ALR}) \left[ 0.33 d_h \left( \sigma / \rho_{\text{gas}} U^2 d_p \right)^{0.6} \right. \\ \left. + 0.068 d_h \left( \mu_{\text{liquid}}^2 / \sigma \rho_{\text{liquid}} d_p \right)^{0.5} \right]$	$d_h$ = hydraulic diameter, $d_p$ = prefilmer diameter, Figure 3.12.9
Ultrasonic	$\text{SMD} = \left( 4\pi^3 \sigma / \rho_{\text{liquid}} \omega^2 \right)^{1/3}$	$\omega$ = vibration frequency

The plain orifice design is also used in twin-fluid-type liquid rocket engines in showerhead and doublet designs (Figures 3.12.5b and 3.12.5c). In the case of doublet nozzles, shown in Figure 3.12.6c, the impinging jets create unstable liquid sheets which break up to produce the sprays. Drop size correlations are available for liquid sheets such as those formed by discharging the liquid through a rectangular slit (see *fan spray*, Table 3.12.1). Thin liquid sheets or slits lead to the production of small drops. The breakup mechanism of liquid sheets is also thought to involve the unstable growth of surface waves due to surface tension and aerodynamic forces.<sup>5</sup>

In *rotary atomizers* centrifugal forces are used to further enhance the breakup process. In this case the liquid is supplied to the center of a spinning disk and liquid sheets or ligaments are thrown off the edges of the disk. The drop size depends on the rotational speed of the disk, as indicated in Table 3.12.1.

A spinning wheel or cup (turbobell) is used in some spray-painting applications. The spray shape is controlled by supplying a coflowing stream of “shaping-air.”

Centrifugal forces also play a role in the breakup mechanism of *pressure swirl atomizers* (*simplex* nozzles). These atomizers give wider spray cone angle than plain orifice nozzles, and are available in hollow cone and solid cone designs. As depicted in [Figure 3.12.3\(b\)](#) the spray liquid enters a swirl chamber tangentially to create a swirling liquid sheet. The air core vortex within the swirl chamber plays an important role in determining the thickness of the liquid sheet or film at the nozzle exit. This type of nozzle produces relatively coarse sprays. A representative SMD correction is listed in [Table 3.12.1](#). The spray cone angle depends on the ratio of the axial and tangential liquid velocity components at the exit of the nozzle. This type of atomizer is not well suited for use in transient applications because it tends to dribble at start-up and to shut down when the air core is not fully formed.

The basic drawback of all pressure atomizers is that the flow rate depends on the square root of  $\Delta P$ . The volumetric flow rate is  $Q = A_{inj} U$ , where  $A_{inj}$  is the liquid flow area at the nozzle exit, so that a factor of 20 increase in flow rate (a typical turndown ratio from idle to full load operation of a gas turbine engine) requires a factor of 400 increase in injection pressure.

This difficulty has led to so-called wide-range atomizer designs such as those shown in [Figure 3.12.6](#). The *duplex* nozzle features two sets of tangential swirl ports; the primary (or pilot) supplies fuel at low flow rates, while the secondary ports become operational at high flow rates. Another variation is the *dual-orifice* nozzle which is conceptually two simplex nozzles arranged concentrically, one supplying the primary flow and the other supplying the secondary flow. The *spill-return* nozzle is a simplex nozzle with a rear passage that returns fuel to the injection pump. In this design the flow rate is controlled by the relative spill amount, and there are no small passages to become plugged. However, the fuel is always supplied at the maximum pressure which increases the demands on the injection pump. But high swirl is always maintained in the swirl chamber and good atomization is achieved even at low flow rates.

**FIGURE 3.12.6** (a) Duplex, (b) dual orifice, and (c) spill-return-type nozzle designs.

In *twin-fluid injectors* atomization is aided by a flow of high-velocity gas through the injector passages. The high-velocity gas stream impinges on a relatively low-velocity liquid either internally (in *internal-mixing* nozzles, [Figure 3.12.7](#)) or externally (in *external-mixing* designs, [Figure 3.12.8](#)). The liquid and gas flows are typically swirled in opposite directions by means of swirl vanes to improve atomization. *Air-assist* refers to designs that use a relatively small amount of air at high (possibly sonic) velocities. *Air-blast* refers to designs that use large quantities of relatively low-velocity air which often supplies some of the air to help decrease soot formation in combustion systems<sup>3</sup>. (see [Figure 3.12.9](#).)

In *flashing* and *effervescent* atomizers a two-phase flow is passed through the injector nozzle exit. In the former the bubbles are generated by means of a phase change which occurs as the liquid, containing a dissolved propellant gas or vapor, undergoes the pressure drop through the nozzle. This process is exploited in many household spray cans, but has the disadvantage of releasing the propellant gas required for atomization into the atmosphere. In the so-called effervescent atomizer, air bubbles are introduced

FIGURE 3.12.7 Internal-mixing twin-fluid injector design.

FIGURE 3.12.8 External-mixing twin-fluid injector design.

FIGURE 3.12.9 Prefilming air blast atomizer.

FIGURE 3.12.10 Internal-mixing, effervescent atomizer.

into the liquid upstream of the exit orifice, as depicted in [Figure 3.12.10](#). The spray quality is found to depend weakly on the air bubble size and is independent of the nozzle exit diameter. This makes internal-mixing, air-assist atomizers very attractive for use with high-viscosity fluids and slurries where nozzle plugging would otherwise be a problem.<sup>3</sup>

In *electrostatic* atomizers the spray liquid is charged by applying a high-voltage drop across the nozzle. The dispersion of the spray drops is increased by exploiting electrical repulsive forces between the droplets. An electrostatic charge on the drops is also helpful in spray-coating applications, such as in automotive spray painting using electrostatic turbobell sprayers, since the charged drops are attracted to an oppositely charged target surface.

Other atomizer types include *vibratory* and *ultrasonic* atomizers (or *nebulizers*), where the drops are formed by vibrating the injector nozzle at high frequencies and at large amplitudes to produce short-wavelength disturbances to the liquid flow. Ultrasonic atomizers are used in inhalation therapy where very fine sprays (submicron sizes) are required, and an available representative drop size correlation is also listed in [Table 3.12.1](#).

## Further Information

Information about recent work in the field of atomization and sprays can be obtained through participation in the Institutes for Liquid Atomization and Spraying Systems (ILASS-Americas, -Europe, -Japan, -Korea). These regional ILASS sections hold annual meetings. An international congress (ICLASS) is also held biennially. More information is available on the ILASS-Americas homepage at <http://ucicl.eng.uci.edu/ilass>. Affiliated with the ILASS organizations is the Institute's Journal publication *Atomization and Sprays* published by Begell House, Inc., New York.

### 3.13 Flow Measurement\*

*Alan T. McDonald and Sherif A. Sherif*

This section deals with the measurement of mass flow rate or volume flow rate of a fluid in an enclosed pipe or duct system. Flow measurement in open channels is treated in Section 3.10 of this book.

The choice of a flow meter type and size depends on the required accuracy, range, cost, ease of reading or data reduction, and service life. Always select the simplest and cheapest device that gives the desired accuracy.

#### Direct Methods

Tanks can be used to determine the flow rate for steady liquid flows by measuring the volume or mass of liquid collected during a known time interval. If the time interval is long enough, flow rates may be determined precisely using tanks. Compressibility must be considered in gas volume measurements. It is not practical to measure the mass of gas, but a volume sample can be collected by placing an inverted “bell” over water and holding the pressure constant by counterweights. No calibration is required when volume measurements are set up carefully; this is a great advantage of direct methods.

Positive-displacement **flow meters** may be used in specialized applications, particularly for remote or recording uses. For example, household water and natural gas meters are calibrated to read directly in units of product. Gasoline metering pumps measure total flow and automatically compute the cost. Many positive-displacement meters are available commercially. Consult manufacturers’ literature or Reference 7 for design and installation details.

#### Restriction Flow Meters for Flow in Ducts

Most restriction flow meters for internal flow (except the laminar flow element) are based on acceleration of a fluid stream through some form of nozzle, shown schematically in Figure 3.13.1. Flow separating from the sharp edge of the nozzle throat forms a recirculation zone shown by the dashed lines downstream from the nozzle. The main flow stream continues to accelerate from the nozzle throat to form a *vena contracta* at section (2) and then decelerates again to fill the duct. At the vena contracta, the flow area is a minimum, the flow streamlines are essentially straight, and the pressure is uniform across the channel section. The theoretical flow rate is

$$\dot{m}_{\text{theoretical}} = \frac{A_2}{\sqrt{1 - (A_2/A_1)^2}} \sqrt{2\rho(p_1 - p_2)} \quad (3.13.1)$$

Equation (3.13.1) shows the general relationship for a **restriction flow meter**: Mass flow rate is proportional to the square root of the pressure differential across the meter taps. This relationship limits the flow rates that can be measured accurately to approximately a 4:1 range.

Several factors limit the utility of Equation (3.13.1) for calculating the actual mass flow rate through a meter. The actual flow area at section (2) is unknown when the vena contracta is pronounced (e.g., for orifice plates when  $D_t$  is a small fraction of  $D_1$ ). The velocity profiles approach uniform flow only at large Reynolds number. Frictional effects can become important (especially downstream from the meter) when the meter contours are abrupt. Finally, the location of the pressure taps influences the differential pressure reading,  $p_1 - p_2$ .

The actual mass flow rate is given by

\* The contributors of this chapter were asked to conform as much as possible to the nomenclature presented below, but define new terms pertaining to their particular area of specialty in the context of the chapter.

**FIGURE 3.13.1** Internal flow through a generalized nozzle, showing control volume used for analysis.

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1 - (A_t/A_1)^2}} \sqrt{2\rho(p_1 - p_2)} \tag{3.13.2}$$

where  $C$  is an empirical *discharge coefficient*.

If  $\beta = D_t/D_1$ , then  $(A_t/A_1)^2 = (D_t/D_1)^4 = \beta^4$ , and

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1 - \beta^4}} \sqrt{2\rho(p_1 - p_2)} \tag{3.13.3}$$

where  $1/(1 - \beta^4)^{1/2}$  is the *velocity correction factor*. Combining the discharge coefficient and velocity correction factor into a single *flow coefficient*,

$$K = \frac{C}{\sqrt{1 - \beta^4}} \tag{3.13.4}$$

yields the mass flow rate in the form:

$$\dot{m}_{\text{actual}} = KA_t \sqrt{2\rho(p_1 - p_2)} \tag{3.13.5}$$

Test data can be used to develop empirical equations to predict flow coefficients vs. pipe diameter and Reynolds number for standard metering systems. The accuracy of the equations (within specified ranges) is often adequate to use the meter without calibration. Otherwise, the coefficients must be measured experimentally.

For the turbulent flow regime ( $Re_D > 4000$ ), the flow coefficient may be expressed by an equation of the form:<sup>7</sup>

$$K = K_\infty + \frac{1}{\sqrt{1 - \beta^4}} \frac{b}{Re_D^n} \tag{3.13.6}$$

where subscript  $\infty$  denotes the flow coefficient at infinite Reynolds number and constants  $b$  and  $n$  allow for scaling to finite Reynolds numbers. Correlating equations and curves of flow coefficients vs. Reynolds number are given for specific metering elements in the next three subsections following the general comparison of the characteristics of orifice plate, flow nozzle, and venturi meters in [Table 3.13.1](#) (see Reference 4).

Flow meter coefficients reported in the literature have been measured with fully developed turbulent velocity distributions at the meter inlet (Section 3.1). When a flow meter is installed downstream from

**TABLE 3.13.1. Characteristics of Orifice, Flow Nozzle, and Venturi Flow Meters**

Flow Meter Type	Diagram	Head Loss	Cost
Orifice		High	Low
Flow nozzle		Intermediate	Intermediate
Venturi		Low	High

a valve, elbow, or other disturbance, a straight section of pipe must be placed in front of the meter. Approximately 10 diameters of straight pipe upstream are required for venturi meters, and up to 40 diameters for orifice plate or flow nozzle meters. Some design data for incompressible flow are given below. The same basic methods can be extended to compressible flows.<sup>7</sup>

**Orifice Plates**

The orifice plate (Figure 3.13.2) may be clamped between pipe flanges. Since its geometry is simple, it is low in cost and easy to install or replace. The sharp edge of the orifice will not foul with scale or suspended matter. However, suspended matter can build up at the inlet side of a concentric orifice in a horizontal pipe; an eccentric orifice may be placed flush with the bottom of the pipe to avoid this difficulty. The primary disadvantages of the orifice are its limited capacity and the high permanent head loss caused by uncontrolled expansion downstream from the metering element.

**FIGURE 3.13.2** Orifice geometry and pressure tap locations.

Pressure taps for orifices may be placed in several locations as shown in Figure 3.13.2 (see Reference 7 for additional details). Since the location of the pressure taps influences the empirically determined flow coefficient, one must select handbook values of *K* consistent with the pressure tap locations.

The correlating equation recommended for a concentric orifice with corner taps is

$$C = 0.5959 + 0.0312\beta^{2.1} - 0.184\beta^8 + \frac{91.71\beta^{2.5}}{Re_{D_1}^{0.75}} \tag{3.13.7}$$

FIGURE 3.13.3 Flow coefficients for concentric orifices with corner taps.

FIGURE 3.13.4 Typical installations of nozzle flow meters. (a) In plenum, (b) In duct.

Equation (3.13.7) predicts orifice discharge coefficients within  $\pm 0.6\%$  for  $0.2 < \beta < 0.75$  and for  $10^4 < Re_{D_1} < 10^7$ . Some flow coefficients calculated from Equation (3.13.7) are presented in Figure 3.13.3. Flow coefficients are relatively insensitive to Reynolds number for  $Re_{D_1} > 10^5$  when  $\beta > 0.5$ .

A similar correlating equation is available for orifice plates with  $D$  and  $D/2$  taps. Flange taps require a different correlation for every line size. Pipe taps, located at  $2\frac{1}{2}D$  and  $8D$ , no longer are recommended.

**Flow Nozzles**

Flow nozzles may be used as metering elements in either plenums or ducts, as shown in Figure 3.13.4; the nozzle section is approximately a quarter ellipse. Design details and recommended locations for pressure taps are given in Reference 7.

The correlating equation recommended for an ASME long-radius flow nozzles<sup>7</sup> is

$$C = 0.9975 - \frac{6.53\beta^{0.5}}{Re_{D_1}^{0.5}} \tag{3.13.8}$$

Equation (3.13.8) predicts discharge coefficients for flow nozzles within  $\pm 2.0\%$  for  $0.25 < \beta < 0.75$  for  $10^4 < Re_{D_1} < 10^7$ . Some flow coefficients calculated from Equation 3.13.8 are presented in Figure 3.13.5. ( $K$  can be greater than 1 when the velocity correction factor exceeds 1.) For plenum installation, nozzles may be fabricated from spun aluminum, molded fiberglass, or other inexpensive materials. Typical flow coefficients are in the range  $0.95 < K < 0.99$ ; the larger values apply at high Reynolds numbers. Thus, the mass flow rate can be computed within approximately  $\pm 2\%$  using  $K = 0.97$ .

FIGURE 3.13.5 Flow coefficients for ASME long-radius flow nozzles.

**Venturis**

Venturi meters are generally made from castings machined to close tolerances to duplicate the performance of the standard design, so they are heavy, bulky, and expensive. The conical diffuser section downstream from the throat gives excellent pressure recovery; overall head loss is low. Venturi meters are self-cleaning because of their smooth internal contours.

Experimentally measured discharge coefficients for venturi meters range from 0.980 to 0.995 at high Reynolds numbers ( $Re_{D_1} > 2 \times 10^5$ ). Thus,  $C = 0.99$  can be used to calculate mass flow rate within about  $\pm 1\%$  at high Reynolds number.<sup>7</sup> Consult manufacturers' literature for specific information at Reynolds numbers below  $10^5$ .

Orifice plates, flow nozzles, and venturis all produce pressure drops proportional to flow rate squared, according to Equation 3.13.4. In practice, a meter must be sized to accommodate the largest flow rate expected. Because the pressure drop vs. flow rate relationship is nonlinear, a limited range of flow rate

can be measured accurately. Flow meters with single throats usually are considered for flow rates over a 4:1 range.<sup>7</sup>

Unrecoverable head loss across a metering element may be expressed as a fraction of the differential pressure across the element. Unrecoverable head losses are shown in Figure 3.13.6.<sup>7</sup>

FIGURE 3.13.6 Permanent head loss produced by various flow metering elements.

**Laminar Flow Elements**

The laminar flow element (LFE)\* produces a pressure differential proportional to flow rate. The LFE contains a metering section subdivided into many passages, each of small enough diameter to assure fully developed laminar flow. Because the pressure drop in laminar duct flow is directly proportional to flow rate, the pressure drop vs. flow rate relationship is linear. The LFE may be used with reasonable accuracy over a 10:1 flow rate range. Because the relationship between pressure drop and flow rate for laminar flow depends on viscosity, which is a strong function of temperature, fluid temperature must be known in order to obtain accurate metering.

An LFE costs approximately as much as a venturi, but is much lighter and smaller. Thus, the LFE is widely used in applications where compactness and extended range are important.

**Linear Flow Meters**

Several flow meter types produce outputs proportional to flow rate. Some meters produce signals without the need to measure differential pressure. The most common linear flow meters are discussed briefly below.

*Float meters* indicate flow rate directly for liquids or gases. An example is shown in Figure 3.13.7. The float is carried upward in the tapered clear tube by the flowing fluid until drag force and float weight are in equilibrium. Float meters (often called rotameters) are available with factory calibration for a number of common fluids and flow rate ranges.

A *turbine flow meter* is a free-running, vaned impeller mounted in a cylindrical section of tube (Figure 3.13.8). With proper design, the rate of rotation of the impeller may be made proportional to volume

\* Patented and manufactured by Meriam Instrument Co., 10920 Madison Ave., Cleveland, OH.

**FIGURE 3.13.7** Float-type variable-area flow meter. (Courtesy of Dwyer Instrument Co., Michigan City, IN.)

flow rate over as much as a 100:1 flow rate range. Rotational speed of the turbine element can be sensed using a magnetic or modulated carrier pickup external to the meter. This sensing method therefore requires no penetrations or seals in the duct. Thus, turbine flow meters can be used safely to measure flow rates in corrosive or toxic fluids. The electrical signal can be displayed, recorded, or integrated to provide total flow information.

**FIGURE 3.13.8** Turbine flow meter. (Courtesy of Potter Aeronautical Corp., Union, NJ.)

*Vortex shedding* from a bluff obstruction may be used to meter flow. Since Strouhal number,  $St = fL/V$ , is approximately constant ( $St \approx 0.21$ ), vortex shedding frequency  $f$  is proportional to flow velocity. Vortex shedding causes velocity and pressure changes. Pressure, thermal, or ultrasonic sensors may be used to detect the vortex shedding frequency, and thus to infer the fluid velocity. (The velocity profile does affect the constancy of the shedding frequency.) Vortex flow meters can be used over a 20:1 flow rate range.<sup>7</sup>

*Electromagnetic flow meters* create a magnetic field across a pipe. When a conductive fluid passes through the field, a voltage is generated at right angles to the field and velocity vectors. Electrodes placed on a pipe diameter detect the resulting signal voltage, which is proportional to the average axial velocity when the profile is axisymmetric. The minimum flow speed should be above about 0.3 m/sec, but there are no restrictions on Reynolds number. The flow rate range normally quoted is 10:1.<sup>7</sup>

Ultrasonic flow meters also respond to average velocity at a pipe cross section. Two principal types of ultrasonic meters measure propagation time for clean liquids, and reflection frequency shift (Doppler effect) for flows carrying particulates. The speed of an acoustic wave increases in the flow direction and decreases when transmitted against the flow. For clean liquids, an acoustic path inclined to the pipe axis is used to infer flow velocity. Multiple paths are used to estimate volume flow rate accurately.

Doppler effect ultrasonic flow meters depend on reflection of sonic waves (in the megahertz range) from scattering particles in the fluid. When the particles move at flow speed, the frequency shift is proportional to flow speed; for a suitably chosen path, output is proportional to volume flow rate; ultrasonic meters may require calibration in place. One or two transducers may be used; the meter may be clamped to the outside of the pipe. Flow rate range is 10:1.<sup>7</sup>

A relatively new type of true mass flow meter is based on the effect of *Coriolis acceleration* on natural frequency of a bent tube carrying fluid. The bent tube is excited and its vibration amplitude measured. The instrument measures mass flow rate directly, and thus is ideal for two-phase or liquid–solid flow measurements. Pressure drop of the Coriolis meter may be high, but its useful flow rate range is 100:1.

### Traversing Methods

In situations such as in air handling or refrigeration equipment, it may be impractical or impossible to install a fixed flow meter, but it may be possible to measure flow rate using a traversing technique.<sup>1</sup> To measure flow rate by **traverse**, the duct cross section is subdivided into segments of equal area. The fluid velocity is measured at the center of each area segment using a pitot tube (see Figure 3.13.9), a total head tube, or a suitable anemometer. The volume flow rate for each segment is approximated by the product of the measured velocity and segment area. Flow rate through the entire duct is the sum of these segmental flow rates. For details of recommended procedures see Reference 1 or 6.

$$V = \sqrt{2(P_T - P_S)/\rho}$$

FIGURE 3.13.9 Pitot tube.

Use of probes for traverse measurements requires direct access to the flow field. Pitot tubes give uncertain results when pressure gradients or streamline curvature are present, and they respond slowly. Two types of anemometers — **thermal anemometers** and **laser Doppler anemometers** — partially overcome these difficulties, although they introduce new complications.

*Thermal anemometers* use electrically heated tiny elements (either hot-wire or hot-film elements). Sophisticated feedback circuits are used to maintain the temperature of the element constant and to sense the input heating rate. The heating rate is related to the local flow velocity by calibration. The primary advantage of thermal anemometers is the small size of the sensing element. Sensors as small as 0.002 mm in diameter and 0.1 mm long are available commercially. Because the thermal mass of such tiny elements is extremely small, their response to fluctuations in flow velocity is rapid. Frequency responses to the 50-kHz range have been quoted.<sup>3</sup> Thus, thermal anemometers are ideal for measuring turbulence quantities. Insulating coatings may be applied to permit their use in conductive or corrosive gases or liquids.

Because of their fast response and small size, thermal anemometers are used extensively for research. Numerous schemes for treating the resulting data have been published. Digital processing techniques, including fast Fourier transforms, can be used to obtain mean values and moments, and to analyze signal frequency content and correlations.

*Laser Doppler anemometers* (LDAs) can be used for specialized applications where direct physical access to the flow field is difficult or impossible.<sup>5</sup> Laser beam(s) are focused to a small volume in the flow at the location of interest; laser light is scattered from particles present in the flow or introduced for this purpose. A frequency shift is caused by the local flow speed (Doppler effect). Scattered light and a reference beam are collected by receiving optics. The frequency shift is proportional to the flow speed; this relationship may be calculated, so there is no need for calibration. Since velocity is measured directly, the signal is unaffected by changes in temperature, density, or composition in the flow field. The primary disadvantages of LDAs are the expensive and fragile optical equipment and the need for careful alignment.

## Viscosity Measurements

Viscometry is the technique of measuring the viscosity of a fluid. Viscometers are classified as rotational, capillary, or miscellaneous, depending on the technique employed. Rotational viscometers use the principle that a rotating body immersed in a liquid experiences a viscous drag which is a function of the viscosity of the liquid, the shape and size of the body, and the speed of its rotation. Rotational viscometers are widely used because measurements can be carried out for extended periods of time. Several types of viscometers are classified as rotational and [Figure 3.13.10](#) is a schematic diagram illustrating a typical instrument of this type.

Capillary viscometry uses the principle that when a liquid passes in laminar flow through a tube, the viscosity of the liquid can be determined from measurements of the volume flow rate, the applied pressure, and the tube dimensions. Viscometers that cannot be classified either as rotational or capillary include the falling ball viscometer. Its method of operation is based on Stokes' law which relates the viscosity of a Newtonian fluid to the velocity of a sphere falling in it. Falling ball viscometers are often employed for reasonably viscous fluids. Rising bubble viscometers utilize the principle that the rise of an air bubble through a liquid medium gives a visual measurement of liquid viscosity. Because of their simplicity, rising bubble viscometers are commonly used to estimate the viscosity of varnish, lacquer, and other similar media.

## Defining Terms

**Flow meter:** Device used to measure mass flow rate or volume flow rate of fluid flowing in a duct.

**Restriction flow meter:** Flow meter that causes flowing fluid to accelerate in a nozzle, creating a pressure change that can be measured and related to flow rate.

**FIGURE 3.13.10** Rotational viscometer.

**Thermal anemometer:** Heated sensor used to infer local fluid velocity by sensing changes in heat transfer from a small electrically heated surface exposed to the fluid flow.

**Traverse:** Systematic procedure used to traverse a probe across a duct cross-section to measure flow rate through the duct.

### Further Information

This section presents only a survey of flow measurement methods. The references contain a wealth of further information. Baker<sup>2</sup> surveys the field and discusses precision, calibration, probe and tracer methods, and likely developments. Miller<sup>7</sup> is the most comprehensive and current reference available for information on restriction flow meters. Goldstein<sup>5</sup> treats a variety of measurement methods in his recently revised and updated book. Spitzer<sup>8</sup> presents an excellent practical discussion of flow measurement. Measurement of viscosity is extensively treated in *Viscosity and Flow Measurement: A Laboratory Handbook of Rheology*, by Van Wazer, J.R., Lyons, J.W., Kim, K.Y., and Colwell, R.E., Interscience Publishers, John Wiley & Sons, New York, 1963.

### 3.14 Micro/Nanotribology

*Bharat Bhushan*

#### Introduction

The emerging field of micro/nanotribology is concerned with processes ranging from atomic and molecular scales to microscale, occurring during adhesion, friction, wear, and thin-film lubrication at sliding surfaces (Bhushan, 1995, 1997; Bhushan et al., 1995). The differences between conventional tribology or macrotribology and micro/nanotribology are contrasted in [Figure 3.14.1](#). In macrotribology, tests are conducted on components with relatively large mass under heavily loaded conditions. In these tests, wear is inevitable and the bulk properties of mating components dominate the tribological performance. In micro/nanotribology, measurements are made on at least one of the mating components, with relatively small mass under lightly loaded conditions. In this situation, negligible wear occurs and the surface properties dominate the tribological performance.

**FIGURE 3.14.1** Comparison between macrotribology and microtribology.

Micro/nanotribological investigations are needed to develop fundamental understanding of interfacial phenomena on a small scale and to study interfacial phenomena in the micro- and nanostructures used in magnetic storage systems, microelectromechanical systems (MEMS), and other industrial applications (Bhushan, 1995, 1996, 1997). Friction and wear of lightly loaded micro/nanocomponents are highly dependent on the surface interactions (few atomic layers). These structures are generally lubricated with molecularly thin films. Micro- and nanotribological studies are also valuable in fundamental understanding of interfacial phenomena in macrostructures to provide a bridge between science and engineering (Bowden and Tabor, 1950, 1964; Bhushan and Gupta, 1997; Bhushan, 1996).

In 1985, Binnig et al. (1986) developed an “atomic force microscope” (AFM) to measure ultrasmall forces (less than  $1 \mu\text{N}$ ) present between the AFM tip surface and the sample surface. AFMs can be used for measurement of *all engineering surfaces* of any surface roughness, which may be either electrically conducting or insulating. AFM has become a popular surface profiler for topographic measurements on micro- to nanoscale. These are also used for scratching, wear, and nanofabrication purposes. AFMs have been modified in order to measure both normal and friction forces and this instrument is generally called a friction force microscope (FFM) or a lateral force microscope (LFM). New transducers in conjunction with an AFM can be used for measurements of elastic/plastic mechanical properties (such as load-displacement curves, indentation hardness, and modulus of elasticity) (Bhushan et al., 1996). A surface force apparatus (SFA) was first developed in 1969 (Tabor and Winterton, 1969) to study both static and dynamic properties of molecularly thin liquid films sandwiched between two molecularly smooth surfaces. SFAs are being used to study rheology of molecularly thin liquid films; however, the liquid under study has to be confined between molecularly smooth surfaces with radii of curvature on the order of 1 mm (leading to poorer lateral resolution as compared with AFMs) (Bhushan, 1995). Only AFMs/FFMs can be used to study *engineering surfaces* in the *dry and wet conditions* with *atomic resolution*. The scope of this section is limited to the applications of AFMs/FFMs.

At most solid–solid interfaces of technological relevance, contact occurs at numerous asperities with a range of radii; a sharp AFM/FFM tip sliding on a surface simulates just one such contact. Surface roughness, adhesion, friction, wear, and lubrication at the interface between two solids with and without liquid films have been studied using the AFM and FFM. The status of current understanding of micro/nanotribology of engineering interfaces follows.

## Experimental Techniques

An AFM relies on a scanning technique to produce very high resolution, three-dimensional images of sample surfaces. The AFM measures ultrasmall forces (less than 1 nN) present between the AFM tip surface and a sample surface. These small forces are measured by measuring the motion of a very flexible cantilever beam having an ultrasmall mass. The deflection can be measured to with  $\pm 0.02$  nm, so for a typical cantilever force constant of 10 N/m, a force as low as 0.2 nN can be detected. An AFM is capable of investigating surfaces of both conductors and insulators on an atomic scale. In the operation of a high-resolution AFM, the sample is generally scanned; however, AFMs are also available where the tip is scanned and the sample is stationary. To obtain atomic resolution with an AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. A cantilever beam with a spring constant of about 1 N/m or lower is desirable. Tips have to be sharp as possible. Tips with a radius ranging from 10 to 100 nm are commonly available.

In the AFM/FFM shown in Figure 3.14.2, the sample is mounted on a PZT tube scanner which consists of separate electrodes to precisely scan the sample in the  $X$ – $Y$  plane in a raster pattern and to move the sample in the vertical ( $Z$ ) direction. A sharp tip at the end of a flexible cantilever is brought in contact with the sample. Normal and frictional forces being applied at the tip–sample interface are measured simultaneously, using a laser beam deflection technique.

FIGURE 3.14.2 Schematic of a commercial AFM/FFM using laser beam deflection method.

Topographic measurements are typically made using a sharp tip on a cantilever beam with normal stiffness on the order of 0.5 N/m at a normal load of about 10 nN, and friction measurements are carried out in the load range of 10 to 150 nN. The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern. Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. A maximum scan size of  $125 \times 125 \mu\text{m}$  and scan rate of 122 Hz typically can be used. Higher scan rates are used for small scan lengths.

For nanoscale boundary lubrication studies, the samples are typically scanned over an area of  $1 \times 1 \mu\text{m}$  at a normal force of about 300 nN, in a direction orthogonal to the long axis of the cantilever beam (Bhushan, 1997). The samples are generally scanned with a scan rate of 1 Hz and the scanning speed of  $2 \mu\text{m}/\text{sec}$ . The coefficient of friction is monitored during scanning for a desired number of cycles. After the scanning test, a larger area of  $2 \times 2 \mu\text{m}$  is scanned at a normal force of 40 nN to observe for any wear scar.

For microscale scratching, microscale wear, and nano-scale indentation hardness measurements, a sharp single-crystal natural diamond tip mounted on a stainless steel cantilever beam with a normal stiffness on the order of 25 N/m is used at relatively higher loads (1 to 150  $\mu\text{N}$ ). For wear studies, typically an area of  $2 \times 2 \mu\text{m}$  is scanned at various normal loads (ranging from 1 to 100  $\mu\text{N}$ ) for a selected number of cycles. For nanoindentation hardness measurements the scan size is set to zero and then normal load is applied to make the indents. During this procedure, the diamond tip is continuously pressed against the sample surface for about 2 sec at various indentation loads. The sample surface is scanned before and after the scratching, wear, or indentation to obtain the initial and the final surface topography, at a low normal load of about 0.3  $\mu\text{N}$  using the same diamond tip. An area larger than the indentation region is scanned to observe the indentation marks. Nanohardness is calculated by dividing the indentation load by the projected residual area of the indents.

In measurements using conventional AFMs, the hardness value is based on the projected residual area after imaging the indent. Identification of the boundary of the indentation mark is difficult to accomplish with great accuracy, which makes the direct measurement of contact area somewhat inaccurate. A capacitive transducer with the dual capability of depth sensing as well as *in situ* imaging is used in conjunction with an AFM (Bhushan et al., 1996). This indentation system, called nano/picoindentation, is used to make load-displacement measurements and subsequently carry out *in situ* imaging of the indent, if necessary. Indenter displacement at a given load is used to calculate the projected indent area for calculation of the hardness value. Young's modulus of elasticity is obtained from the slope of the unloading portion of the load-displacement curve.

## Surface Roughness, Adhesion, and Friction

Solid surfaces, irrespective of the method of formation, contain surface irregularities or deviations from the prescribed geometrical form. When two nominally flat surfaces are placed in contact, surface roughness causes contact to occur at discrete contact points. Deformation occurs in these points and may be either elastic or plastic, depending on the nominal stress, surface roughness, and material properties. The sum of the areas of all the contact points constitutes the real area that would be in contact, and for most materials at normal loads this will be only a small fraction of the area of contact if the surfaces were perfectly smooth. In general, real area of contact must be minimized to minimize adhesion, friction, and wear (Bhushan and Gupta, 1997; Bhushan, 1996). Characterizing surface roughness is therefore important for predicting and understanding the tribological properties of solids in contact.

Surface roughness most commonly refers to the variations in the height of the surface relative to a reference plane (Bowden and Tabor, 1950; Bhushan, 1996). Commonly measured roughness parameters, such as standard deviation of surface heights (rms), are found to be scale dependent and a function of the measuring instrument, for any given surface, Figure 3.14.3 (Poon and Bhushan, 1995). The topography of most engineering surfaces is fractal, possessing a self-similar structure over a range of scales. By using fractal analysis one can characterize the roughness of surfaces with two scale-independent fractal parameters  $D$  and  $C$  which provide information about roughness at all length scales (Ganti and

**FIGURE 3.14.3** Scale dependence of standard deviation of surface heights (rms) for a glass–ceramic substrate, measured using an AFM, a stylus profiler (SP-P2 and SP- $\alpha$ 200), and a noncontact optical profiler (NOP).

Bhushan, 1995; Bhushan, 1995). These two parameters are instrument independent and are unique for each surface.  $D$  (generally ranging from 1 to 2) primarily relates to distribution of different frequencies in the surface profile, and  $C$  to the amplitude of the surface height variations at all frequencies. A fractal model of elastic plastic contact has been used to predict whether contacts experience elastic or plastic deformation and to predict the statistical distribution of contact points.

Based on atomic-scale friction measurements of a well-characterized freshly cleaved surface of highly oriented pyrolytic graphite (HOPG), the atomic-scale friction force of HOPG exhibits the same periodicity as that of corresponding topography (Figure 3.14.4(a)), but the peaks in friction and those in topography were displaced relative to each other (Figure 3.14.4(b)). A Fourier expansion of the interatomic potential has been used to calculate the conservative interatomic forces between atoms of the FFM tip and those of the graphite surface. Maxima in the interatomic forces in the normal and lateral directions do not occur at the same location, which explains the observed shift between the peaks in the lateral force and those in the corresponding topography. Furthermore, the observed local variations in friction force were explained by variation in the intrinsic lateral force between the sample and the FFM tip, and these variations may not necessarily occur as a result of an atomic-scale stick–slip process.

Friction forces of HOPG have also been studied. Local variations in the microscale friction of cleaved graphite are observed, which arise from structural changes that occur during the cleaving process. The cleaved HOPG surface is largely atomically smooth, but exhibits line-shaped regions in which the coefficient of friction is more than an order of magnitude larger. Transmission electron microscopy indicates that the line-shaped regions consist of graphite planes of different orientation, as well as of amorphous carbon. Differences in friction can also be seen for organic mono- and multilayer films, which again seem to be the result of structural variations in the films. These measurements suggest that the FFM can be used for structural mapping of the surfaces. FFM measurements can be used to map chemical variations, as indicated by the use of the FFM with a modified probe tip to map the spatial arrangement of chemical functional groups in mixed organic monolayer films. Here, sample regions that had stronger interactions with the functionalized probe tip exhibited larger friction. For further details, see Bhushan (1995).

Local variations in the microscale friction of scratched surfaces can be significant and are seen to depend on the local surface slope rather than on the surface height distribution (Bhushan, 1995). Directionality in friction is sometimes observed on the macroscale; on the microscale this is the norm (Bhushan, 1995). This is because most “engineering” surfaces have asymmetric surface asperities so that the interaction of the FFM tip with the surface is dependent on the direction of the tip motion. Moreover, during surface-finishing processes material can be transferred preferentially onto one side of the asperities, which also causes asymmetry and directional dependence. Reduction in local variations and in the directionality of frictional properties therefore requires careful optimization of surface roughness distributions and of surface-finishing processes.

**FIGURE 3.14.4** (a) Gray-scale plots of surface topography (left) and friction profiles (right) of a  $1 \times 1$  nm area of freshly cleaved HOPG, showing the atomic-scale variation of topography and friction, (b) diagram of superimposed topography and friction profiles from (a); the symbols correspond to maxima. Note the spatial shift between the two profiles.

Table 3.14.1 shows the coefficient of friction measured for two surfaces on micro- and macroscales. The coefficient of friction is defined as the ratio of friction force to the normal load. The values on the microscale are much lower than those on the macroscale. When measured for the small contact areas and very low loads used in microscale studies, indentation hardness and modulus of elasticity are higher than at the macroscale. This reduces the degree of wear. In addition, the small apparent areas of contact reduce the number of particles trapped at the interface, and thus minimize the “ploughing” contribution to the friction force.

At higher loads (with contact stresses exceeding the hardness of the softer material), however, the coefficient of friction for microscale measurements increases toward values comparable with those obtained from macroscale measurements, and surface damage also increases (Bhushan et al., 1995; Bhushan and Kulkarni, 1996). Thus, Amontons’ law of friction, which states that the coefficient of

**TABLE 3.14.1 Surface Roughness and Micro- and Macroscale Coefficients of Friction of Various Samples**

Material	rms Roughness, nm	Microscale Coefficient of Friction vs. Si <sub>3</sub> N <sub>4</sub> Tip <sup>a</sup>	Macroscale Coefficient of Friction vs. Alumina Ball <sup>b</sup>
Si(111)	0.11	0.03	0.18
C <sup>+</sup> -implanted Si	0.33	0.02	0.18

<sup>a</sup> Tip radius of about 50 nm in the load range of 10 to 150 nN (2.5 to 6.1 GPa), a scanning speed of 5 m/sec and scan area of  $1 \times 1 \mu\text{m}$ .

<sup>b</sup> Ball radius of 3 mm at a normal load of 0.1 N (0.3 GPa) and average sliding speed of 0.8 mm/sec.

friction is independent of apparent contact area and normal load, does not hold for microscale measurements. These findings suggest that microcomponents sliding under lightly loaded conditions should experience very low friction and near zero wear.

### Scratching, Wear, and Indentation

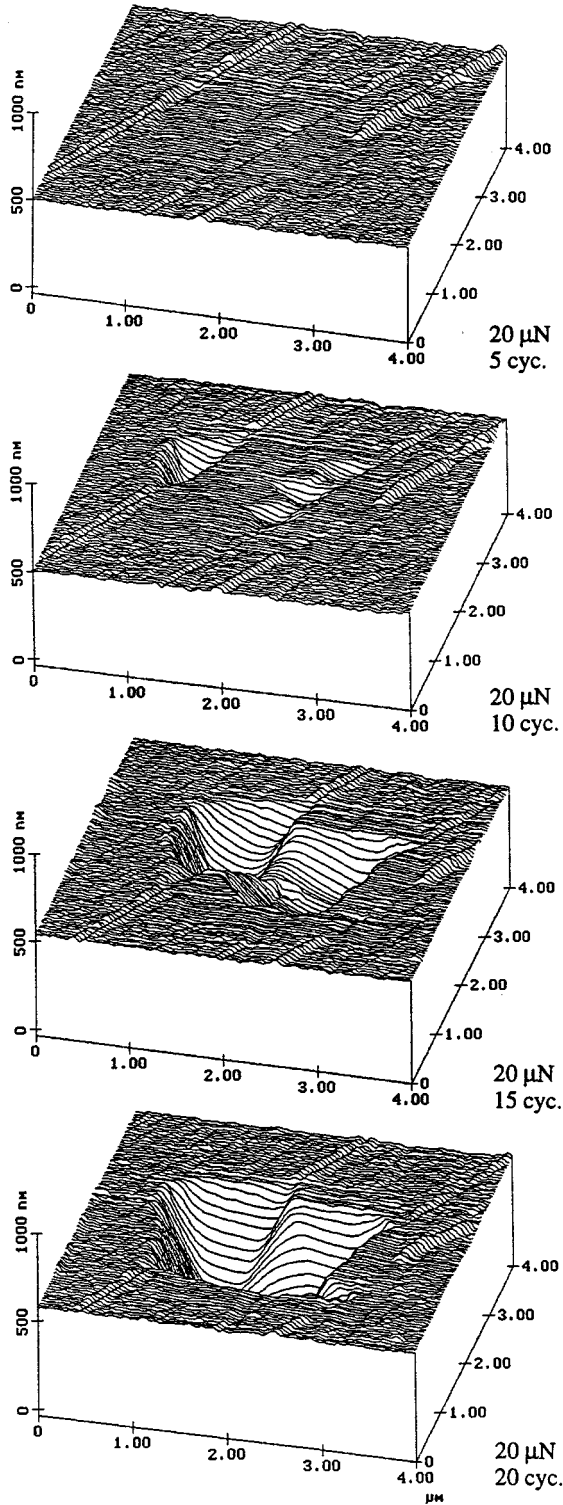

The AFM can be used to investigate how surface materials can be moved or removed on micro- to nanoscales, for example, in scratching and wear (Bhushan, 1995) (where these things are undesirable) and, in nanomachining/nanofabrication (where they are desirable). The AFM can also be used for measurements of mechanical properties on micro- to nanoscales. Figure 3.14.5 shows microscratches made on Si(111) at various loads after 10 cycles. As expected, the depth of scratch increases with load. Such microscratching measurements can be used to study failure mechanisms on the microscale and to evaluate the mechanical integrity (scratch resistance) of ultrathin films at low loads.

**FIGURE 3.14.5** Surface profiles of Si(111) scratched at various loads. Note that the  $x$  and  $y$  axes are in micrometers and the  $z$  axis is in nanometers.

By scanning the sample in two dimensions with the AFM, wear scars are generated on the surface. The evolution of wear of a diamond-like carbon coating on a polished aluminum substrate is showing in Figure 3.14.6 which illustrates how the microwear profile for a load of  $20 \mu\text{N}$  develops as a function of the number of scanning cycles. Wear is not uniform, but is initiated at the nanoscratches indicating that surface defects (with high surface energy) act as initiation sites. Thus, scratch-free surfaces will be relatively resistant to wear.

Mechanical properties, such as load-displacement curves, hardness, and modulus of elasticity can be determined on micro- to picoscales using an AFM and its modifications (Bhushan, 1995; Bhushan et al., 1995, 1996). Indentability on the scale of picometers can be studied by monitoring the slope of cantilever deflection as a function of sample traveling distance after the tip is engaged and the sample

**FIGURE 3.14.6** Surface profiles of diamond-like carbon-coated thin-film disk showing the worn region; the normal load and number of test cycles are indicated. (From Bhushan, B., *Handbook of Micro/Nanotribology*, CRC Press, Boca Raton, FL, 1995. With permission.)

is pushed against the tip. For a rigid sample, cantilever deflection equals the sample traveling distance; but the former quantity is smaller if the tip indents the sample. The indentation hardness on nanoscale of bulk materials and surface films with an indentation depth as small as 1 nm can be measured. An example of hardness data as a function of indentation depth is shown in Figure 3.14.7. A decrease in hardness with an increase in indentation depth can be rationalized on the basis that, as the volume of deformed materials increases, there is a higher probability of encountering material defects. AFM measurements on ion-implanted silicon surfaces show that ion implantation increases their hardness and, thus, their wear resistance (Bhushan, 1995). Formation of surface alloy films with improved mechanical properties by ion implantation is growing in technological importance as a means of improving the mechanical properties of materials.

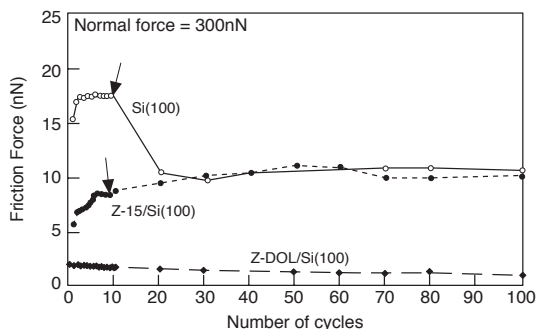

FIGURE 3.14.7 Indentation hardness as a function of residual indentation depth for Si(100).

Young's modulus of elasticity is calculated from the slope of the indentation curve during unloading (Bhushan, 1995; Bhushan et al., 1996). AFM can be used in a *force modulation mode* to measure surface elasticities: an AFM tip is scanned over the modulated sample surface with the feedback loop keeping the average force constant. For the same applied force, a soft area deforms more, and thus causes less cantilever deflection, than a hard area. The ratio of modulation amplitude to the local tip deflection is then used to create a *force modulation image*. The force modulation mode makes it easier to identify soft areas on hard substrates.

Detection of the transfer of material on a nanoscale is possible with the AFM. Indentation of C<sub>60</sub>-rich fullerene films with an AFM tip has been shown to result in the transfer of fullerene molecules to the AFM tip, as indicated by discontinuities in the cantilever deflection as a function of sample traveling distance in subsequent indentation studies (Bhushan, 1995).

## Boundary Lubrication

The "classical" approach to lubrication uses freely supported multimolecular layers of liquid lubricants (Bowden and Tabor, 1950, 1964; Bhushan, 1996). The liquid lubricants are chemically bonded to improve their wear resistance (Bhushan, 1995, 1996). To study depletion of boundary layers, the microscale friction measurements are made as a function of the number of cycles. For an example of the data of virgin Si(100) surface and silicon surface lubricated with about 2-nm-thick Z-15 and Z-Dol perfluoropolyether (PEPE) lubricants, see Figure 3.14.8. Z-Dol is PFPE lubricant with hydroxyl end groups. Its lubricant film was thermally bonded. In Figure 3.14.8, the unlubricated silicon sample shows a slight increase in friction force followed by a drop to a lower steady state value after some cycles. Depletion of native oxide and possible roughening of the silicon sample are responsible for the decrease in this

**FIGURE 3.14.8** Friction force as a function of number of cycles using a silicon nitride tip at a normal force of 300 nN for the unlubricated and lubricated silicon samples.

friction force. The initial friction force for the Z-15-lubricated sample is lower than that of the unlubricated silicon and increases gradually to a friction force value comparable with that of the silicon after some cycles. This suggests the depletion of the Z-15 lubricant in the wear track. In the case of the Z-Dol-coated silicon sample, the friction force starts out to be low and remains low during the entire test. It suggests that Z-Dol does not get displaced/depleted as readily as Z-15. Additional studies of freely supported liquid lubricants showed that either increasing the film thickness or chemically bonding the molecules to the substrate with a mobile fraction improves the lubrication performance (Bhushan, 1997).

For lubrication of microdevices, a more effect approach involves the deposition of organized, dense molecular layers of long-chain molecules on the surface contact. Such monolayers and thin films are commonly produced by Langmuir–Blodgett (LB) deposition and by chemical grafting of molecules into self-assembled monolayers (SAMs). Based on the measurements, SAMs of octadecyl ( $C_{18}$ ) compounds based on aminosilanes on a oxidized silicon exhibited a lower coefficient of friction of (0.018) and greater durability than LB films of zinc arachidate adsorbed on a gold surface coated with octadecylthiol (ODT) (coefficient of friction of 0.03) (Bhushan et al., 1995). LB films are bonded to the substrate by weak van der Waals attraction, whereas SAMs are chemically bound via covalent bonds. Because of the choice of chain length and terminal linking group that SAMs offer, they hold great promise for boundary lubrication of microdevices.

Measurement of ultrathin lubricant films with nanometer lateral resolution can be made with the AFM (Bhushan, 1995). The lubricant thickness is obtained by measuring the force on the tip as it approaches, contacts, and pushes through the liquid film and ultimately contacts the substrate. The distance between the sharp “snap-in” (owing to the formation of a liquid of meniscus between the film and the tip) at the liquid surface and the hard repulsion at the substrate surface is a measure of the liquid film thickness. This technique is now used routinely in the information-storage industry for thickness measurements (with nanoscale spatial resolution) of lubricant films, a few nanometers thick, in rigid magnetic disks.

c.v.	Control volume
$o$	Stagnation or standard state condition
1, 2	Inlet and outlet, respectively, of control volume or machine rotor
$\infty$	Upstream condition far away from body, free stream
T	Total pressure
J	Static pressure

If a single heated element is used within an array of unheated elements, the resulting heat transfer coefficient is implicitly defined as  $h_{\text{adiabatic}}$  and should be identified as such. Heat transfer coefficients measured with single-active-element tests cannot be used with the mixed mean fluid temperature.

When the variation of  $h$  over a surface is required, one common steady-state technique is to stretch a thin foil (stainless steel, or carbon impregnated paper, or gold deposited on polycarbonate) over an insulating substrate, and electrically heat the foil surface. Liquid crystals or infrared techniques can be used to map the surface temperature, from which the heat transfer coefficient distribution can be determined. The “heated foil with liquid crystal” approach was used by Cooper et al. in 1975 to measure heat transfer coefficients, and has since been used by many others. Hippensteele et al. (1985) have made extensive use of the foil technique in studies of gas turbine heat transfer. An example of their work on the end wall of a turbine cascade is shown in [Figure 4.6.15](#).

**FIGURE 4.6.15** Heat transfer coefficient distribution on the end wall of a turbine cascade. (From Hippensteele, S.A. et al., NASA Technical Memorandum 86900, March, 1985. With permission.)

Hollingsworth et al. (1989) used a stainless steel foil heater for a study in air for an electronics cooling application, illustrated in [Figure 4.6.16](#).

**FIGURE 4.6.16** Visualization of the heat transfer coefficient distribution on a heated plate around three unheated cubes.

Another steady-state technique which reveals the distribution of  $h$  on the surface was introduced by den Ouden and Hoogendoorn (1974) and is currently in use by Meinders (1996). It uses a uniform and constant-temperature substrate (originally, a tank of warm water, now a copper block) covered with a layer of known thermal resistance (originally, a plate of glass, now a thin layer of epoxy). The surface was painted with liquid crystals (now visualized using infrared imaging) and the surface-temperature distribution determined. The inner (uniform) and outer (measured) temperature distributions are then used as boundary conditions to a three-dimensional conduction solver which calculates the total heat flux at each point on the surface. The total heat flux is corrected for radiation to yield the net convective transport at each point, from which  $h$  can be determined.

This method appears to have an advantage in accuracy over the heated foil technique because of the more accurate handling of substrate conduction.

*Transient Lumped Parameter Systems.* In the lumped parameter transient method, the specimen is assumed to be uniform in temperature at every instant through the transient. The power,  $\dot{e}_{in}$ , in Equation (4.6.16) is usually zero, although that is not necessary (one could simply change the power level at time zero to initiate the transient). At time zero, a transient is initiated, and the response curve recorded.

The data can be interpreted, and the validity of the first-order assumption tested at the same time by plotting  $(T - T_{final}) / (T_{initial} - T_{final})$  on the log scale of semilog coordinates, with time on the algebraic scale. If the line is straight, then the system is first order and the characteristic time can be determined from any two points on the line by

$$\tau = \frac{(t_2 - t_1)}{\ln \left\{ \frac{T_{fin} - T_1}{T_{fin} - T_2} \right\}} \quad (4.6.17)$$

where  $\tau$  = characteristic time,  $Mc/hA$ , sec

$t_1$  = time at the first instant

$t_2$  = time at the second instant

$T_1$  = specimen temperature at the first instant, °C

$T_2$  = specimen temperature at the second instant, °C

$T_{fin}$  = specimen temperature after a long time (fluid temperature), °C

The heat transfer coefficient is extracted from the time-constant definition.

### Indirect Methods

An increasingly popular method is the extraction of  $h$  from surface-temperature variations after a step in flow temperature using an inverse calculation method (see the section on inferential methods of heat flux measurement). The simplest inverse method assumes one-dimensional conduction into an infinitely thick plate of constant material properties. Even highly irregular geometries can be studied with this technique, if the streamwise extent of the specimen is small and the testing time is short. A short time interval is necessary so the penetration of the thermal wave is limited to a thin layer near the surface. The short streamwise extent is necessary so the temperature response of the surface upstream does not alter the thermal step applied to the downstream surface. This technique has been used to determine the heat transfer coefficient distribution on the inside walls of passages of irregular shape, by making the passage in a transparent material.

*Naphthalene Sublimation.* The equations for mass diffusion are similar to those for heat transfer, except for replacing the Prandtl number in the heat transfer equation by the Schmidt number in the diffusion equation. Thus, one could expect that the distribution of the mass transfer coefficients on a surface would mimic the distribution of the heat transfer coefficients.

The most commonly used analog technique is naphthalene sublimation. As early as 1940, the mass transfer/heat transfer similarity was used to estimate the heat transfer coefficient distribution. Naphthalene

is a solid material which sublimates at a reasonable rate in air at ambient temperature. Specimens can be cast in naphthalene with good precision, and the recession of the surface mapped as a function of position and time using automated or semiautomated measuring equipment. The surface recession over a known interval of time is a measure of the mass transfer rate, from which the mass transfer coefficient can be deduced.

Naphthalene experiments are generally done at uniform temperature; hence, a uniform vapor pressure exists at the surface. This corresponds to the heat transfer situation of heat transfer from a uniform temperature surface. No counterpart of the uniform heat flux situation has been produced using naphthalene, nor have there been experiments corresponding to variable wall temperature.

Naphthalene sublimation experiments do not suffer from any counterpart of the conduction heat transfer in the substrate. Conduction makes it difficult to work near discontinuities in wall temperature in a heat transfer experiment. Details of the fine structure of mass transfer near obstructions and discontinuities can be resolved in naphthalene experiments, but those details might not exist in a heat transfer process. The Prandtl number of air is much lower than the Schmidt number of naphthalene diffusing in air; hence, thermal conduction would tend to blur out sharp gradients in the temperature field more than diffusion would blur out gradients in naphthalene concentration.

The Schmidt number of naphthalene in air is about 2.5, far different than the Prandtl number of air (0.71); hence, the mass transfer coefficient deduced from a naphthalene experiment is not numerically equal to the heat transfer coefficient which would have existed at those conditions. The usual recommendation is to adjust for the Prandtl number of Schmidt number using a relation of the form:

$$\text{St Pr}^{2/3} = f\{\text{Re}\} = \text{Sh}_j \text{Sc}_j^{2/3} \quad (4.6.18)$$

based on laminar results. That recommendation has not been seriously tested by experiments in turbulent and separated flows. By using nominal values of the Schmidt number and Prandtl number, the heat transfer Stanton number would be 2.3 times higher than the measured Sherwood number and an uncertainty of 10% in that ratio would alter the inferred heat transfer coefficient by 23%.

*System Performance Matching.* Sometimes the “effective average heat transfer coefficient” for a system is inferred from the overall behavior of the system, e.g., estimating  $h$  from the effectiveness of a heat exchanger. Values deduced by this means cannot be expected to agree well with direct measurements unless a very sophisticated system description model is used.

## 4.7 Mass Transfer

*Anthony F. Mills*

### Introduction

Mass transfer may occur in a gas mixture, a liquid solution, or a solid solution. There are several physical mechanisms that can transport a chemical species through a phase and transfer it across phase boundaries. The two most important mechanisms are ordinary diffusion and convection. Mass diffusion is analogous to heat conduction and occurs whenever there is a gradient in the concentration of a species. Mass convection is essentially identical to heat convection: a fluid flow that transports heat may also transport a chemical species. The similarity of mechanisms of heat transfer and mass transfer results in the mathematics often being identical, a fact that can be exploited to advantage. But there are some significant differences between the subjects of heat and mass transfer. One difference is the much greater variety of physical and chemical processes that require mass transfer analysis. Another difference is the extent to which the essential details of a given process may depend on the particular chemical system involved, and on temperature and pressure.

In the next subsection, concentrations, velocities, and fluxes are defined, and special attention is paid to phase interfaces where the concentration of a chemical species is almost always discontinuous. Fick's law of ordinary diffusion is introduced in the third section, where other diffusion phenomena are also discussed. The fourth section presents various forms of the species conservation equation. Results for diffusion in a stationary medium are given in the fifth section, and include steady diffusion across a plane wall, transient diffusion in a semi-infinite solid, and diffusion in a porous catalyst. Results for diffusion in a moving medium are given in the sixth section, and the Stefan flow is introduced for diffusion with one component stationary. Also considered are particle combustion, droplet evaporation, and combustion of a volatile liquid hydrocarbon fuel droplet. The last section deals with mass convection. Low mass transfer rate theory is presented and how to exploit the analogy between convective heat and mass transfer is shown. Particular attention is given to situations involving simultaneous heat and mass transfer associated with evaporation or condensation. The section closes by presenting high mass transfer rate theory for convection, and gives engineering calculation methods for boundary layer flows that account for variable property effects.

### Concentrations, Velocities, and Fluxes

#### Definitions of Concentrations

In a gas mixture, or liquid or solid solution, the local *concentration* of a mass species can be expressed in a number of ways. The *number density* of species  $i$  in a mixture or solution of  $n$  species is defined as

$$\begin{aligned} \text{Number density of species } i &\equiv \text{Number of molecules of } i \text{ per unit volume} \\ &\equiv \mathcal{N}_i \text{ molecules/m}^3 \end{aligned} \quad (4.7.1)$$

Alternatively, if the total number of molecules of all species per unit volume is denoted as  $\mathcal{N}$ , then we define the *number fraction* of species  $i$  as

$$n_i \equiv \frac{\mathcal{N}_i}{\mathcal{N}}; \quad \mathcal{N} = \sum \mathcal{N}_i \quad (4.7.2)$$

where the summation is over all species present,  $i = 1, 2, \dots, n$ . Equations (4.7.1) and (4.7.2) describe *microscopic* concepts and are used, for example, when the kinetic theory of gases is used to describe transfer processes.

Whenever possible, it is more convenient to treat matter as a continuum. Then the smallest volume considered is sufficiently large for macroscopic properties such as pressure and temperature to have their usual meanings. For this purpose we also require *macroscopic* definitions of concentration. First, on a mass basis,

$$\begin{aligned} \text{Mass concentration of species } i &\equiv \text{partial density of species } i \\ &\equiv \rho_i \text{ kg/m}^3 \end{aligned} \quad (4.7.3)$$

The total mass concentration is the total mass per unit volume, that is, the density  $\rho = \sum \rho_i$ . The *mass fraction* of species  $i$  is defined as

$$m_i = \frac{\rho_i}{\rho} \quad (4.7.4)$$

Second, on a molar basis,

$$\begin{aligned} \text{Molar concentration of species } i &\equiv \text{number of moles of } i \text{ per unit volume} \\ &\equiv c_i \text{ kmol/m}^3 \end{aligned} \quad (4.7.5)$$

If  $M_i$  (kg/kmol) is the molecular weight of species  $i$ , then

$$c_i = \frac{\rho_i}{M_i} \quad (4.7.6)$$

The total molar concentration is the molar density  $c = \sum c_i$ . The *mole fraction* of species  $i$  is defined as

$$x_i \equiv \frac{c_i}{c} \quad (4.7.7)$$

A number of important relations follow directly from these definitions. The mean molecular weight of the mixture of solution is denoted  $M$  and may be expressed as

$$M = \frac{\rho}{c} = \sum x_i M_i \quad (4.7.8a)$$

or

$$\frac{1}{M} = \sum \frac{m_i}{M_i} \quad (4.7.8b)$$

There are summation rules

$$\sum m_i = 1 \quad (4.7.9a)$$

$$\sum x_i = 1 \quad (4.7.9b)$$

It is often necessary to have the mass fraction of species  $i$  expressed explicitly in terms of mole fractions and molecular weights; this relation is

$$m_i = \frac{x_i M_i}{\sum x_j M_j} = x_i \frac{M_i}{M} \quad (4.7.10a)$$

and the corresponding relation for the mole fraction is

$$x_i = \frac{m_i/M_i}{\sum m_j/M_j} = m_i \frac{M}{M_i} \quad (4.7.10b)$$

Dalton's law of partial pressures for an ideal gas mixture states that

$$P = \sum P_i, \quad \text{where } P_i = \rho_i R_i T \quad (4.7.11)$$

Dividing partial pressure by total pressure and substituting  $R_i = \mathcal{R}/M_i$  gives

$$\frac{P_i}{P} = \frac{\rho_i}{M_i} \frac{\mathcal{R} T}{P} = c_i \frac{\mathcal{R} T}{P} = x_i \frac{c \mathcal{R} T}{P} = x_i \quad (4.7.12)$$

Thus, for an ideal gas mixture, the mole fraction and partial pressure are equivalent measures of concentration (as also is the number fraction).

A commonly used specification of the composition of dry air is 78.1% N<sub>2</sub>, 20.9% O<sub>2</sub>, and 0.9% Ar, by volume. (The next largest component is CO<sub>2</sub>, at 0.3%.) Since equal volumes of gases contain the same number of moles, specifying composition on a volume basis is equivalent to specifying mole fractions, namely,

$$x_{\text{N}_2} = 0.781; \quad x_{\text{O}_2} = 0.209; \quad x_{\text{Ar}} = 0.009$$

The corresponding mass fractions are calculated to be

$$m_{\text{N}_2} = 0.755; \quad m_{\text{O}_2} = 0.231; \quad m_{\text{Ar}} = 0.014$$

### Concentrations at Interfaces

Although temperature is continuous across a phase interface, concentrations are usually discontinuous. In order to define clearly concentrations at interfaces, we introduce imaginary surfaces, denoted  $u$  and  $s$ , on both sides of the real interface, each indefinitely close to the interface, as shown in [Figure 4.7.1](#) for water evaporating into an airstream. Thus, the liquid-phase quantities at the interface are subscripted  $u$ , and gas-phase quantities are subscripted  $s$ . If we ignore the small amount of air dissolved in the water,  $x_{\text{H}_2\text{O},u} = 1$ . Notice that the subscript preceding the comma denotes the chemical species, and the subscript following the comma denotes location. To determine  $x_{\text{H}_2\text{O},s}$  we make use of the fact that, except in extreme circumstances, the water vapor and air mixture at the  $s$ -surface must be in thermodynamic equilibrium with water at the  $u$ -surface. Equilibrium data for this system are found in conventional steam tables: the saturation vapor pressure of steam at the water temperature,  $T_s$ , ( $T_s = T_u$ ), is the required partial pressure  $P_{\text{H}_2\text{O},s}$ . With the total pressure  $P$  known,  $x_{\text{H}_2\text{O},s}$  is calculated as  $P_{\text{H}_2\text{O},s}/P$ . If  $m_{\text{H}_2\text{O},s}$  is required, Equation (4.7.10a) is used.

**FIGURE 4.7.1** Concentrations at a water-air interface.

For example, at  $T_s = 320$  K, the saturation vapor pressure is obtained from steam tables as  $0.10535 \times 10^5$  Pa. If the total pressure is  $1 \text{ atm} = 1.0133 \times 10^5$ ,

$$x_{\text{H}_2\text{O},s} = \frac{0.10535 \times 10^5}{1.0133 \times 10^5} = 0.1040$$

$$m_{\text{H}_2\text{O},s} = \frac{(0.1040)(18)}{(0.1040)(18) + (1 - 0.1040)(29)} = 0.06720$$

For a gas or solid dissolving in a liquid, equilibrium data are often referred to simply as solubility data, found in chemistry handbooks. Many gases are only sparingly soluble, and for such dilute solutions solubility data are conveniently represented by *Henry's law*, which states that the mole fraction of the gas at the *s*-surface is proportional to its mole fraction in solution at the *u*-surface, the constant of proportionality being the *Henry number*,  $\text{He}_i$ . For species *i*,

$$x_{i,s} = \text{He}_i x_{i,u} \tag{4.7.13}$$

The Henry number is inversely proportional to total pressure and is also a function of temperature. The product of Henry number and total pressure is the *Henry constant*,  $C_{\text{He}_i}$ , and for a given species is a function of temperature only:

$$\text{He}_i P = C_{\text{He}_i}(T) \tag{4.7.14}$$

Solubility data are given in [Table 4.7.1](#).

**TABLE 4.7.1** Henry Constants  $C_{\text{He}}$  for Dilute Aqueous Solutions at Moderate Pressures ( $P_{i,s}/x_{i,u}$  in atm, or in bar =  $10^5$  Pa, within the accuracy of the data).

Solute	290 K	300 K	310 K	320 K	330 K	340 K
H <sub>2</sub> S	440	560	700	830	980	1,140
CO <sub>2</sub>	1,280	1,710	2,170	2,720	3,220	—
O <sub>2</sub>	38,000	45,000	52,000	57,000	61,000	65,000
H <sub>2</sub>	67,000	72,000	75,000	76,000	77,000	76,000
CO	51,000	60,000	67,000	74,000	80,000	84,000
Air	62,000	74,000	84,000	92,000	99,000	104,000
N <sub>2</sub>	16,000	89,000	101,000	110,000	118,000	124,000

For example, consider absorption of carbon dioxide from a stream of pure CO<sub>2</sub> at 2 bar pressure into water at 310 K. From Table 4.7.1,  $C_{\text{He}} = 2170$  bar; thus

$$\text{He}_{\text{CO}_2} = \frac{2170}{2} = 1085; \quad x_{\text{CO}_2,u} = \frac{1}{1085} = 9.22 \times 10^{-4}$$

Dissolution of gases into metals is characterized by varied and rather complex interface conditions. Provided temperatures are sufficiently high, hydrogen dissolution is reversible (similar to CO<sub>2</sub> absorption into water); hence, for example, titanium-hydrogen solutions can exist only in contact with a gaseous hydrogen atmosphere. As a result of hydrogen going into solution in atomic form, there is a characteristic square root relation

$$m_{\text{H}_2,u} \propto P_{\text{H}_2,s}^{1/2}$$

The constant of proportionality is strongly dependent on temperature, as well as on the particular titanium alloy: for Ti-6Al-4V alloy it is twice that for pure titanium. In contrast to hydrogen, oxygen dissolution in titanium is irreversible and is complicated by the simultaneous formation of a rutile (TiO<sub>2</sub>) scale on the surface. Provided some oxygen is present in the gas phase, the titanium-oxygen *phase diagram* (found in a metallurgy handbook) shows that  $m_{\text{O}_2,u}$  in alpha-titanium is 0.143, a value essentially independent of temperature and O<sub>2</sub> partial pressure. Dissolution of oxygen in zirconium alloys has similar characteristics to those discussed above for titanium.

All the preceding examples of interface concentrations are situations where thermodynamic equilibrium can be assumed to exist at the interface. Sometimes thermodynamic equilibrium does not exist at an interface: a very common example is when a chemical reaction occurs at the interface, and temperatures are not high enough for equilibrium to be attained. Then the concentrations of the reactants and products at the *s*-surface are dependent both on the rate at which the reaction proceeds — that is, the *chemical kinetics* — as well as on mass transfer considerations.

### Definitions of Fluxes and Velocities

The mass (or molar) flux of species *i* is a vector quantity giving the mass (or moles) of species *i* that pass per unit time through a unit area perpendicular to the vector (Figure 4.7.2). We denote the absolute mass and molar fluxes of species *i*, that is, relative to stationary coordinate axes, as  $\mathbf{n}_i$  (kg/m<sup>2</sup>sec) and  $\mathbf{N}_i$  (kmol/m<sup>2</sup>sec), respectively. The absolute mass flux of the mixture (mass velocity) is

$$\mathbf{n} = \sum \mathbf{n}_i \quad (4.7.15)$$

and the local mass-average velocity is

FIGURE 4.7.2 Flux vectors: (a) mass basis, (b) molar basis.

$$\mathbf{v} = \frac{\mathbf{n}}{\rho} \text{ m/sec} \quad (4.7.16)$$

The velocity  $\mathbf{v}$  is the velocity that would be measured by a Pitot tube and corresponds to the velocity used in considering pure fluids. On a molar basis, the absolute molar flux of the mixture is

$$N = \sum N_i \quad (4.7.17)$$

and the local molar-average velocity is

$$\mathbf{v}^* = \frac{N}{c} \text{ m/sec} \quad (4.7.18)$$

The absolute fluxes at species  $i$  have two components. On a mass basis we write

$$\mathbf{n}_i = \rho_i \mathbf{v} + \mathbf{j}_i \quad (4.7.19)$$

where  $\rho_i \mathbf{n}$  is transport of species  $i$  by bulk motion of the fluid at velocity  $\mathbf{v}$  and is the *convective* component. Thus,  $\mathbf{j}_i$  is transport of species  $i$  relative to the mass average velocity; it is called the *diffusive* component because most commonly it is due to ordinary (concentration) diffusion of the species. On a molar basis the corresponding relation is

$$N_i = c_i \mathbf{v}^* + \mathbf{J}_i^* \quad (4.7.20)$$

Some important relations follow from these definitions:

$$\sum \mathbf{j}_i = \sum \mathbf{J}_i^* = 0 \quad (4.7.21)$$

$$N_i = \frac{\mathbf{n}_i}{M_i} \quad (4.7.22)$$

$$\mathbf{n}_i = \rho_i \mathbf{v} + \mathbf{j}_i = m_i \sum \mathbf{n}_i + \mathbf{j}_i \quad (4.7.23a)$$

$$N_i = c_i \mathbf{v}^* + \mathbf{J}_i^* = x_i \sum N_i + \mathbf{J}_i^* \quad (4.7.23b)$$

## Mechanisms of Diffusion

### Ordinary Diffusion

Fick's law of ordinary diffusion is a linear relation between the rate of diffusion of a chemical species and the local concentration gradient of that species. It is exact for a binary gas mixture, for which the kinetic theory of gases gives

$$\mathbf{j}_1 = -\rho \mathcal{D}_{12} \nabla m_1 \text{ kg/m}^2 \text{ sec} \quad (4.7.24a)$$

on a mass basis, and

$$\mathbf{J}_1^* = -c\mathcal{D}_{12}\nabla x_1 \text{ kg/m}^2 \text{ sec} \quad (4.7.24b)$$

on a molar basis;  $\mathcal{D}_{12}$  (m<sup>2</sup>/sec) is the binary diffusion coefficient (or mass diffusivity), and  $\mathcal{D}_{21} = \mathcal{D}_{12}$ . Equations (4.7.24a) and (4.7.24b) are mathematically equivalent; however, notice that it is incorrect to write

$$\mathbf{j}_i = -\mathcal{D}_{12}\nabla\rho_1 \quad (4.7.25)$$

since  $\nabla\rho_1 \neq \rho \nabla m_1$  in general. Fick's law in the form of Equations (4.7.24a) and (4.7.24b) is also valid for dilute liquid and solid solutions, for which it is often possible to assume  $\rho$  (or  $c$ ) constant, and then Equation (4.7.25) or its molar equivalent are good approximations.

Ordinary diffusion in multicomponent systems is described by the Stefan–Maxwell equations (Hirschfelder et al., 1954). These equations are difficult to use for engineering analysis. In gas mixtures containing species that do not have widely varying molecular weights, it is possible to model approximately the diffusion process by using an effective binary diffusion coefficient in Fick's law. This coefficient is a suitable average over the species in the mixture, and may be calculated from

$$\mathcal{D}_{1m} = \frac{(1-x_1)}{\sum_{i=2}^n (x_i/\mathcal{D}_{1i})}; \quad x_1 \ll 1 \quad (4.7.26)$$

This equation works well for most mixtures of combustion gases (except those containing appreciable concentrations of H or H<sub>2</sub>).

Binary diffusion coefficients at 300 K are of the order of 10<sup>-5</sup> m<sup>2</sup>/sec in gases at 1 atm, 10<sup>-9</sup> m<sup>2</sup>/sec in aqueous solutions, and 10<sup>-10</sup> to 10<sup>-13</sup> m<sup>2</sup>/sec in solids. However, the product  $\rho\mathcal{D}$  or  $(c\mathcal{D})$  is, at most, one order of magnitude different for gases and liquids. Data for diffusion coefficients may be found in [Tables 4.7.2 through 4.7.5](#).

Molecules in a gas mixture, and in a liquid or solid solution, can diffuse by mechanisms other than ordinary diffusion governed by Fick's law. *Thermal diffusion* is diffusion due to a temperature gradient and is often called the *Soret effect*. Thermal diffusion is usually negligible compared with ordinary diffusion, unless the temperature gradient is very large. However, there are some important processes that depend on thermal diffusion, the most well known being the large-scale separation of uranium isotopes. *Pressure diffusion* is diffusion due to a pressure gradient and is also usually negligible unless the pressure gradient is very large. Pressure diffusion is the principle underlying the operation of a centrifuge. Centrifuges are used to separate liquid solutions and are increasingly being used to separate gaseous isotopes as well. *Forced diffusion* results from an external force field acting on a molecule. Gravitational force fields do not cause separation since the force per unit mass of a molecule is constant. Forced diffusion occurs when an electrical field is imposed on an electrolyte (for example, in charging an automobile battery), on a semiconductor, or on an ionized gas (for example, in a neon tube or metal-ion laser). Depending on the strength of the electric field, rates of forced diffusion can be very large.

Some interesting diffusion phenomena occur in porous solids. When a gas mixture is in a porous solid, such as a catalyst pellet or silica–gel particle, the pores can be smaller than the mean free path of the molecules. Then, the molecules collide with the wall more often than with other molecules. In the limit of negligible molecule collisions we have *Knudsen diffusion*, also called *free molecule flow* in the fluid mechanics literature. If the pore size approaches the size of a molecule, then Knudsen diffusion becomes negligible and *surface diffusion*, in which adsorbed molecules move along the pore walls, becomes the dominant diffusion mechanism.

<sup>a</sup> Owing to the practical importance of water vapor-air mixtures, engineers have used convenient empirical formulas for  $\mathcal{D}_{\text{H}_2\text{O air}}$ . A formula that has been widely used for many years is

$$\mathcal{D}_{\text{H}_2\text{O air}} = 1.97 \times 10^{-5} \left( \frac{P_0}{P} \right) \left( \frac{T}{T_0} \right)^{1.685} \text{ m}^2/\text{sec}; \quad 273 \text{ K} < T < 373 \text{ K}$$

where  $P_0 = 1$  atm;  $T_0 = 256$  K. More recently, the following formula has found increasing use. (Marrero, T.R. and Mason, E.A. 1992. Gaseous diffusion coefficients, *J. Phys. Chem. Ref. Data*, 1, 3-118):

$$\begin{aligned} \mathcal{D}_{\text{H}_2\text{O air}} &= 1.87 \times 10^{-10} \frac{T^{2.072}}{P}; \quad 280 \text{ K} < T < 450 \text{ K} \\ &= 2.75 \times 10^{-9} \frac{T^{1.632}}{P}; \quad 450 \text{ K} < T < 1070 \text{ K} \end{aligned}$$

for  $P$  in atmospheres and  $T$  in kelvins. Over the temperature range 290 to 330 K, the discrepancy between the two formulas is less than 2.5%. For small concentrations of water vapor in air, the older formula gives a constant value of  $\text{Sc}_{\text{H}_2\text{O air}} = 0.61$  over the temperature range 273 to 373 K. On the other hand, the Marrero and Mason formula gives values of  $\text{Sc}_{\text{H}_2\text{O air}}$  that vary from 0.63 at 280 K to 0.57 at 373 K.

Very small particles of  $10^{-3}$  to  $10^{-1}$   $\mu\text{m}$  size — for example, smoke, soot, and mist — behave much like large molecules. Ordinary diffusion of such particles is called *Brownian motion* and is described in most elementary physics texts. Diffusion of particles due to a temperature gradient is called *thermophoresis* and plays an important role for larger particles, typically in the size range  $10^{-1}$  to  $1$   $\mu\text{m}$ . Diffusion of particles in a gas mixture due to concentration gradients of molecular species is called *diffusiophoresis*. *Forced diffusion* of a charged particle in an electrical field is similar to that for an ionized molecular species. Thermal and electrostatic precipitators are used to remove particles from power plant and incinerator stack gases, and depend on thermophoresis and forced diffusion, respectively, for their operation. Diffusion phenomena are unimportant for particles of size greater than about  $1$   $\mu\text{m}$  in air at 1 atm; the motion of such particles is governed by the laws of Newtonian mechanics. Transport of particles is dealt with in the *aerosol science* literature.

## Species Conservation Equation

The principle of conservation of a chemical species is used to derive the *species conservation equation*. On a mass basis this equation is

**TABLE 4.7.3 Schmidt Number for Vapors in Dilute Mixture in Air at Normal Temperature, Enthalpy of Vaporization, and Boiling Point at 1 atm<sup>a</sup>**

Vapor	Chemical Formula	Sc <sup>b</sup>	$h_{fg}$ , J/kg $\times 10^{-6}$	$T_{BP}$ , K
Acetone	CH <sub>3</sub> COCH <sub>3</sub>	1.42	0.527	329
Ammonia	NH <sub>3</sub>	0.61	1.370	240
Benzene	C <sub>6</sub> H <sub>6</sub>	1.79	0.395	354
Carbon dioxide	CO <sub>2</sub>	1.00	0.398	194
Carbon monoxide	CO	0.77	0.217	81
Chlorine	Cl <sub>2</sub>	1.42	0.288	238
Ethanol	CH <sub>3</sub> CH <sub>2</sub> OH	1.32	0.854	352
Helium	He	0.22	—	4.3
Heptane	C <sub>7</sub> H <sub>16</sub>	2.0	0.340	372
Hydrogen	H <sub>2</sub>	0.20	0.454	20.3
Hydrogen sulfide	H <sub>2</sub> S	0.94	0.548	213
Methanol	CH <sub>3</sub> OH	0.98	1.110	338
Naphthalene	C <sub>10</sub> H <sub>8</sub>	2.35 <sup>c</sup>	—	491
Nitric oxide	NO	0.87	0.465	121
Octane	C <sub>8</sub> H <sub>18</sub>	2.66	0.303	399
Oxygen	O <sub>2</sub>	0.83	0.214	90.6
Pentane	C <sub>5</sub> H <sub>12</sub>	1.49	0.357	309
Sulfur dioxide	SO <sub>2</sub>	1.24	0.398	263
Water vapor	H <sub>2</sub> O	0.61	2.257	373

<sup>a</sup> With the Clausius-Clapeyron relation, one may estimate vapor pressure as

$$P_{\text{sat}} \approx \exp\left\{-\frac{Mh_{fg}}{\mathcal{R}}\left(\frac{1}{T} - \frac{1}{T_{BP}}\right)\right\} \text{ atm for } T \sim T_{BP}$$

<sup>b</sup> The Schmidt number is defined as  $Sc = \mu/\rho\mathcal{D} = \nu/\mathcal{D}$ . Since the vapors are in small concentrations, values for  $\mu$ ,  $\rho$ , and  $\nu$  can be taken as pure air values.

<sup>c</sup> From a recent study by Cho, C., Irvine, T.F., Jr., and Kami, J. 1992. Measurement of the diffusion coefficient of naphthalene into air, *Int. J. Heat Mass Transfer*, 35, 957–966. Also,  $h_{fg} = 0.567 \times 10^6$  J/kg at 300 K.

$$\frac{\partial \rho_i}{\partial t} + \nabla \cdot \mathbf{n}_i = \dot{r}_i''' \quad (4.7.27)$$

and on a molar basis

$$\frac{\partial c_i}{\partial t} + \nabla \cdot \mathbf{N}_i = \dot{R}_i''' \quad (4.7.28)$$

where  $\dot{r}_i'''$  and  $\dot{R}_i'''$  are the mass and molar rates of production of species  $i$  due to chemical reactions. Summing Equation 4.7.27 over all species gives the mass conservation or continuity equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{v} = 0 \quad (4.7.29)$$

The molar form is

$$\frac{\partial c}{\partial t} + \nabla \cdot c \mathbf{v}^* = \sum_i \dot{R}_i''' \quad (4.7.30)$$

since, in general, moles are not conserved in chemical reactions. A useful alternative form to Equation 4.7.27 can be obtained using Equations (4.7.23a) and (4.7.29) and is

$$\rho \frac{Dm_i}{Dt} = \nabla \cdot (\rho \mathcal{D}_{12} \nabla m_1) + \dot{r}_1''' \quad (4.7.32)$$

When working on a mass basis we define a stationary medium as one in which the mass average velocity  $v$  is zero everywhere. Substituting in Equation (4.7.32) with no chemical reactions and assuming constant properties,

$$\frac{\partial m_1}{\partial t} = \mathcal{D}_{12} \nabla^2 m_1 \quad (4.7.33)$$

which is the *diffusion* equation, and is the mass transfer analog to Fourier's equation for heat conduction. For steady diffusion, Equation (4.7.33) reduces to Laplace's equation

$$\nabla^2 m_1 = 0 \quad (4.7.34)$$

Notice that since properties have been assumed constant, any measure of concentration can be used in Equations (4.7.33) and (4.7.34), for example  $\rho_1$ ,  $c_1$ , and  $x_1$ .

## Diffusion in a Stationary Medium

Many problems involving diffusion in a stationary medium are governed by the diffusion equation (Equation 4.7.33). Often solutions may be obtained from their heat conduction analogs. Some important cases follow.

### Steady Diffusion through a Plane Wall

The mass flow of species 1 across a plane wall of thickness  $L$  and cross-sectional area  $A$  is

$$\dot{m}_1 = \frac{\rho \mathcal{D}_{12} A}{L} (m_{1,u} - m_{1,u'}) \text{ kg/m}^2 \text{ sec} \quad (4.7.35)$$

**FIGURE 4.7.3** Steady diffusion across a plane wall.

where the  $u$ - and  $u'$ -surfaces are shown in [Figure 4.7.3](#). Solubility data are required to relate the  $u$ - and  $u'$ -surface concentrations to  $s$ - and  $s'$ -surface concentrations. Alternatively for systems that obey Henry's law, a solubility  $\mathcal{S}$  can be defined as the volume of solute gas (at STP of 0°C and 1 atm) dissolved in unit volume when the gas is at a partial pressure of 1 atm. Then, defining permeability  $\mathcal{P}_{12}$  as the product  $\mathcal{D}_{12}\mathcal{S}$ , the volume flow of species 1 is

$$\dot{V}_1 = \frac{\mathcal{P}_{12}A}{L}(P_{1,s} - P_{1,s'}) \text{ m}^3 \text{ (STP)/sec} \quad (4.7.36)$$

where the partial pressures  $P_1$  are in atmospheres. The SI units for permeability are  $\text{m}^3 \text{ (STP)/m}^2\text{sec(atm/m)}$ . Permeability and solubility data are given in [Table 4.7.6](#). For example, consider helium at  $10^5$  Pa contained in a 7056-glass vessel with a 1-mm-thick wall at 680 K. For a surface area of  $0.01 \text{ m}^2$ , the leakage rate into ambient air is

$$\dot{V} = \frac{(1.0 \times 10^{-12})(0.01)}{(0.001)}(10^5 - 0) = 1.0 \times 10^{-6} \text{ m}^3 \text{ (STP)/sec}$$

where the value  $\mathcal{P}_{12}$  was obtained from [Table 4.7.6](#).

In general, mass fractions are discontinuous across phase interfaces. Hence, Equation (4.7.35) cannot be generalized to a number of walls in series by simply adding diffusion resistances. However, equilibrium partial pressures  $P_1$  are continuous, and for two walls  $A$  and  $B$ , Equation 4.7.36 becomes

$$\dot{V}_1 = \frac{P_{1,s} - P_{1,s'}}{\frac{L_A}{\mathcal{P}_{1A}A} + \frac{L_B}{\mathcal{P}_{1B}A}} \text{ m}^3 \text{ (STP)/sec} \quad (4.7.37)$$

### Transient Diffusion in a Semi-Infinite Solid

The typically low diffusion coefficients characterizing solids result in many situations where concentration changes are limited to a thin region near the surface (of thickness  $\delta_c \sim (\mathcal{D}_{12}t)^{1/2}$ ). Examples include case-hardening of mild steel and coloring of clear sapphires. Details of the geometry are then unimportant

TABLE 4.7.6 Solubility and Permeability of Gases in Solids

Gas	Solid	Temperature, K	$\mathcal{S}$ (m <sup>3</sup> (STP)/m <sup>3</sup> atm) or $\mathcal{S}'^a$	Permeability <sup>b</sup> m <sup>3</sup> (STP)/m <sup>2</sup> sec (atm/m)
-----	-------	-------------------	--	--

<sup>a</sup> Solubility  $\mathcal{S}$  = volume of solute gas (0°C, 1 atm) dissolved in unit volume of solid when the gas is at 1 atm partial pressure. Solubility coefficient  $\mathcal{S}' = c_{1,u}/c_{1,s}$ .

<sup>b</sup> Permeability  $\mathcal{P}_{12} = \mathcal{D}_{12}\mathcal{S}$ .

From various sources, including Geankoplis, C.J. 1993. *Transport Processes and Unit Operations*, 3rd ed., Prentice-Hall; Englewood Cliffs, N.J.; Doremus, R.H. 1973. *Glass Science*, Wiley, New York; Altemose, V.O. 1961. Helium diffusion through glass, *J. Appl. Phys.*, 32, 1309–1316. With permission.

**FIGURE 4.7.4** Transient diffusion in a plane slab.

and semi-infinite solid model can be used (Figure 4.7.4). For an initial concentration  $m_{1,0}$  and a  $u$ -surface concentration suddenly changed to  $m_{1,u}$  at time  $t = 0$ , the concentration distribution  $m_1(z,t)$  is

$$\frac{m_1 - m_{1,0}}{m_{1,u} - m_{1,0}} = \operatorname{erfc} \frac{z}{(4\mathcal{D}_{12}t)^{1/2}} \quad (4.7.38)$$

and the dissolution rate is

$$\dot{m}_1 = j_{1,u}A = \rho A \left( \frac{\mathcal{D}_{12}}{\pi t} \right)^{1/2} (m_{1,u} - m_{1,0}) \text{ kg/sec} \quad (4.7.39)$$

For example, consider a Pyrex glass slab at 800 K suddenly exposed to helium at  $10^4$  Pa. The molar equivalent to Equation (4.7.39) for an assumed constant solid phase molar concentration  $c$  is

$$\frac{\dot{M}_1}{A} = \left( \frac{\mathcal{D}_{12}}{\pi t} \right)^{1/2} (c_{1,u} - c_{1,0})$$

From Table 4.7.6,  $\mathcal{S}' = c_{1,u}/c_{1,s} \cong 0.024$ ; hence,  $c_{1,u} = (0.024)(10^4)/(8314)(800) = 3.61 \times 10^{-5}$  kmol/m<sup>3</sup>. From Table 4.7.4,  $\mathcal{D}_{12} = 4.76 \times 10^{-8} \exp[-(2.72 \times 10^4)/(10^3)/(8314)(800)] = 7.97 \times 10^{-10}$  m<sup>2</sup>/sec. Hence,

$$\frac{\dot{M}_1}{A} = \left( \frac{7.97 \times 10^{-10}}{\pi t} \right)^{1/2} (3.61 \times 10^{-5} - 0) = 5.75 \times 10^{-10}/t \text{ kmol/sec}$$

### Transient Diffusion in Slabs, Cylinders, and Spheres

Transient heat conduction in slabs, cylinders, and spheres with surface convection is dealt with in Section 4.1. The analogous mass diffusion problem for the slab  $-L < z < L$  is now considered. On a molar basis the governing differential equation is

$$\frac{\partial x_1}{\partial t} = \mathcal{D}_{12} \frac{\partial^2 x_1}{\partial z^2} \quad (4.7.40)$$

with initial condition  $x_1 = x_{1,0}$  at  $t = 0$ . Boundary conditions are  $\partial x_1 / \partial z = 0$  at  $z = 0$ , and at the surface  $z = L$ ,

$$-c\mathcal{D}_{12} \left. \frac{\partial x_1}{\partial z} \right|_{z=L} = \mathcal{G}_{m1} (y_{1,s} - y_{1,e}) \quad (4.7.41)$$

The convective boundary condition is of the same form as Newton's law of cooling, and defines the mole transfer conductance  $\mathcal{G}_{m1}$  (kmol/m<sup>2</sup>sec) (see also the section on mass and mole transfer conductances). Also, we have followed chemical engineering practice and denoted mole fraction  $x$  in the solid (or liquid) phase and  $y$  in the liquid (or gas) phase, to emphasize that generally mole fraction is not continuous across a phase interface. For example, consider absorption of a sparingly soluble gas into a liquid for which Henry's law, Equation (4.7.13), applies: then  $y_{1,s} = \text{Hex}_{1,u}$ .

In using heat conduction charts for mass diffusion problems, particular care must be taken with the evaluation of the Biot number. For heat conduction  $\text{Bi} = h_c L / k$ , where  $k$  is the solid conductivity. For mass diffusion the Biot number accounts for the discontinuity in concentration across the phase interface. Using gas absorption into a plane layer of liquid, for example, when Equation (4.7.41) is put into an appropriate dimensionless form, the mass transfer Biot number is seen to be

$$\text{Bi}_m = \frac{\mathcal{G}_{m1} \text{He} L}{c \mathcal{D}_{12}} \quad (4.7.42)$$

For sparingly soluble gases, e.g., O<sub>2</sub> or CO<sub>2</sub> in water, He, and hence  $\text{Bi}_m$ , are very large, and the absorption process is liquid-side controlled; that is, a uniform gas-phase composition can be assumed. Often interface equilibrium data are in graphical or tabular form; then an effective Biot number at the concentration of concern must be used.

For example, consider a 2-mm-diameter droplet of water at 300 K entrained in an air flow at 1 atm pressure containing 1% by volume CO<sub>2</sub>. From Table 4.7.5,  $\text{He} = C_{\text{He}} = 1710$ . The liquid phase molar density can be approximated by the pure water value of  $c = \rho / M = 996 / 18 = 55.3$  kmol/m<sup>3</sup>. The liquid phase diffusion coefficient is obtained from Table 4.7.4 as  $\mathcal{D}_{12} = \nu_{\text{H}_2\text{O}} / \text{Sc}_{12} = 0.87 \times 10^{-6} / 420 = 2.07 \times 10^{-9}$  m<sup>2</sup>/sec. For negligible relative motion between the droplet and gas, the Sherwood number (see the section on dimensionless groups) is approximately 2.0, and hence the gas phase mole transfer conductance is  $\mathcal{G}_{m1} = 2c\mathcal{D}_{12} / \mathcal{D}$ . For the gas phase, the molar density  $c = \mathcal{P} / \mathcal{R}T = (1.0133 \times 10^5) / (8314)(300) = 0.0406$  kmol/m<sup>3</sup> and  $\mathcal{D}_{12} = 0.157 \times 10^{-4}$  m<sup>2</sup>/sec from Table 4.7.2. Thus,

$$\mathcal{G}_{m1} = \frac{(2)(0.0406)(0.157 \times 10^{-4})}{(0.002)} = 6.37 \times 10^{-4} \text{ kmol/m}^2 \text{ sec}$$

From Equation 4.7.42 with  $L = R$  the droplet radius, the mass transfer Biot number is

$$\text{Bi}_m = \frac{(6.37 \times 10^{-4})(1710)(0.001)}{(55.3)(2.07 \times 10^{-9})} = 9520$$

Thus, even for a small droplet with a relatively large gas-side mole transfer conductance, the absorption process is liquid-side controlled.

### Diffusion in a Porous Catalyst

Porous catalysts are used to give a large surface area per unit volume of catalyst surface. Current practice for automobile catalytic converters is to use a ceramic matrix as a support for a thin porous alumina layer that is impregnated with the catalyst (called a *washcoat*). A typical matrix has passages of hydraulic diameter 1 mm, and the washcoat may be about 20  $\mu\text{m}$  thick. Pore sizes are of the order of 1  $\mu\text{m}$  for which ordinary and Knudsen diffusion resistances are important. A simple model for diffusion in a porous catalyst is

$$J_1 = -c\mathcal{D}_{1,\text{eff}}\nabla x_1 \text{ kmol/m}^2 \text{ sec} \quad (4.7.43)$$

where the subscript eff denotes an effective diffusivity that accounts for the presence of the solid material. Assuming additive resistances,

$$\frac{1}{\mathcal{D}_{1,\text{eff}}} = \frac{1}{\mathcal{D}_{12,\text{eff}}} + \frac{1}{\mathcal{D}_{K1,\text{eff}}} \quad (4.7.44)$$

and

$$\mathcal{D}_{12,\text{eff}} = \frac{\varepsilon_v}{\tau}\mathcal{D}_{12}; \quad \mathcal{D}_{K1,\text{eff}} = \frac{\varepsilon_v}{\tau}\mathcal{D}_{K1,\text{eff}} \quad (4.7.45)$$

where  $\varepsilon_v$  is the volume void fraction and  $\tau$  is the tortuosity factor (usually between 4 and 8). From the kinetic theory of gases the Knudsen diffusion coefficient is

$$\mathcal{D}_{K1} = 97r_e(T/M_1)^{1/2} \text{ m}^2/\text{sec} \quad (4.7.46)$$

for effective pore radius  $r_e$  in meters and  $T$  in kelvins.

When a chemical reaction takes place within a porous layer, a concentration gradient is set up, and surfaces on pores deep within the pellet are exposed to lower reactant concentrations than surfaces near the pore openings. For a first-order reaction it is straightforward to obtain the concentration distribution. The results of such an analysis are conveniently given in the form of an effectiveness  $\eta_p$ , which is defined as the actual consumption rate of the reactant divided by that for an infinite diffusion coefficient. For a layer of thickness  $L$  exposed to reactants on one side, as shown in [Figure 4.7.5](#).

$$\eta_p = \frac{\tanh bL}{bL}; \quad b = \left( \frac{k''a_p}{\mathcal{D}_{1,\text{eff}}} \right)^{1/2} \quad (4.7.47)$$

where  $k''$  (m/sec) is the rate constant for a first-order reaction and  $a_p$  ( $\text{m}^{-1}$ ) is the catalyst area per unit volume. Notice that this effectiveness is analogous to the efficiency of a heat transfer fin.

For example, consider a 30- $\mu\text{m}$ -thick porous alumina washcoat with a volume void fraction  $\varepsilon_v = 0.8$ , a tortuosity factor  $\tau = 4.0$ , average pore radius  $r_e = 1 \mu\text{m}$ , and catalytic surface area per unit volume  $a_p = 7.1 \times 10^5 \text{ cm}^2/\text{cm}^3$ . For carbon monoxide oxidation by copper oxide at 800 K, 1 atm, the rate constant is approximately  $4.2 \times 10^{-4} \text{ m}^2/\text{sec}$ . To calculate the effectiveness of the washcoat, we first need to calculate the effective diffusion coefficient  $\mathcal{D}_{1,\text{eff}}$ :

FIGURE 4.7.5 A catalyst layer.

$$\mathcal{D}_{12,\text{eff}} = \frac{\epsilon_v}{\tau} \mathcal{D}_{12} = \frac{0.8}{4.0} (1.06 \times 10^{-4}) = 2.12 \times 10^{-5} \text{ m}^2/\text{sec}$$

where  $\mathcal{D}_{12}$  is approximated as the CO-air value from Table 4.7.2.

$$\mathcal{D}_{K1,\text{eff}} = \frac{\epsilon_v}{\tau} \mathcal{D}_{12} = \frac{0.8}{4.0} (97) (1 \times 10^{-6}) (800/28)^{1/2} = 1.04 \times 10^{-4} \text{ m}^2/\text{sec}$$

$$\frac{1}{\mathcal{D}_{1,\text{eff}}} = \frac{1}{2.12 \times 10^{-5}} + \frac{1}{1.04 \times 10^{-4}}; \quad \mathcal{D}_{1,\text{eff}} = 1.76 \times 10^{-5} \text{ m}^2/\text{sec}$$

$$b = \left[ \frac{(4.2 \times 10^{-4})(7.1 \times 10^5)(10^2)}{1.76 \times 10^{-5}} \right]^{1/2} = 4.2 \times 10^4 \text{ m}^{-1}; \quad bL = (4.2 \times 10^4)(30 \times 10^{-6}) = 1.236$$

$$\eta_p = \frac{\tanh 1.236}{1.236} = 68.3\%$$

In an automobile catalytic convertor, Equation 4.7.47 applies to the catalyst washcoat. However, the mass transfer problem also involves a convective process for transport of reactants from the bulk flow. Referring to Figure 4.7.6 there are two mass transfer resistances in series, and the consumption rate of species 1 per unit surface area of the washcoat is

$$J_{1,s} = \frac{-x_{1,e}}{\frac{1}{L\eta_p k''c} + \frac{1}{\mathcal{G}_{m1}}} \text{ kmol/m}^2 \text{ sec} \quad (4.7.48)$$

where  $\mathcal{G}_{m1}$  is the mole transfer conductance describing convective transport to the washcoat surface (see the section on mass and mole transfer conductances). Notice that when  $\mathcal{G}_{m1} \ll L\eta_p k''c$  the reaction rate is controlled by mass transfer from the gas stream to the washcoat surface; when  $L\eta_p k''c \ll \mathcal{G}_{m1}$ , the reaction rate is controlled by diffusion within the washcoat and the kinetics of the reaction.

FIGURE 4.7.6 Equivalent circuit for mass transfer in an automobile catalytic convertor.

### Diffusion in a Moving Medium

Net mass transfer across a surface results in a velocity component normal to the surface, and an associated convective flux in the direction of mass transfer. This convective flow is called a *Stefan flow*. The solutions of a number of mass transfer problems, involving a Stefan flow induced by the mass transfer process itself, follow. When necessary to obtain an analytical result, properties are assumed constant. Thus, use of these results requires evaluation of properties at a suitable reference state.

### Diffusion with One Component Stationary

As an example, consider the simple heat pipe shown in Figure 4.7.7 with the evaporator and condenser located at the ends only (a bad design!). Then, if the working fluid is species 1, and a noncondensable gas is species 2, the concentration distribution is

$$\left( \frac{1 - x_1}{1 - x_{1,s}} \right) = \left( \frac{1 - x_{1,e}}{1 - x_{1,s}} \right)^{z/L} \tag{4.7.49}$$

and the vapor flux along the heat pipe is

$$N_1 = \frac{c\mathcal{D}}{L} \ln \frac{1 - x_{1,e}}{1 - x_{1,s}} \text{ kmol/m}^2 \text{ sec} \tag{4.7.50}$$

FIGURE 4.7.7 A simple heat pipe with the evaporator and condenser located at its ends.

Notice that  $N_2 = 0$ ; that is, the gas is stationary. The rate of heat flow for a heat pipe of cross-sectional area of  $A_c$  is  $\dot{Q} = N_1 M_1 h_{fg} A_c$ . Evaluation of the  $c\mathcal{D}$  product at a reference temperature  $T_r = (1/2)(T_s + T_e)$  is adequate for most applications. Equation (4.7.50) applies to any situation where a one-dimensional model of mass transport is appropriate.

### Heterogeneous Combustion

As an example, consider a small carbon particle entrained in a high-temperature airstream, as shown in Figure 4.7.8. The surface reaction is  $2C + O_2 \rightarrow 2CO$  and there are no reactions in the gas phase. The stoichiometric ratio for the reaction is  $r = 4/3$  kg oxygen/kg carbon. The reaction is diffusion controlled at the temperatures under consideration, that is,  $m_{O_2,s} \approx 0$ . The mass transfer rate is  $n_s$ , which we give

the distinctive symbol  $\dot{m}''$  since it is usually the desired result of an analysis; in this situation  $\dot{m}'' = n_{C,u}$  is the combustion rate of carbon, and for a spherical particle of radius  $R$  is given by

$$\dot{m}'' = \frac{\rho \mathcal{D}_{O_2,m}}{R} \ln \left[ 1 + \frac{m_{O_2,e} - m_{O_2,s}}{m_{O_2,s} + 4/3} \right] = 0.160 \frac{\rho \mathcal{D}_{O_2,m}}{R} \text{ kg/m}^2 \text{ sec} \quad (4.7.51)$$

**FIGURE 4.7.8** Combustion of a carbon particle in high-temperature air. The surface reaction is  $2C + O_2 \rightarrow 2CO$ .

The carbon particle temperature depends on its radius, and it is required to evaluate the property product  $\rho \mathcal{D}$  at an appropriate reference temperature: an energy balance on the particle should be performed by this purpose. The resulting particle lifetime  $\tau$  is

$$\tau = \frac{\rho_{\text{solid}} D_0^2}{1.28 (\rho \mathcal{D}_{O_2,m})_r} \text{ sec} \quad (4.7.52)$$

for an initial particle diameter of  $D_0$ . Air properties at an average mean film temperature can be used to evaluate  $\rho \mathcal{D}_{O_2,m}$ .

Consider a 10- $\mu\text{m}$ -diameter carbon particle ignited in an airstream at 1500 K and 1 atm. An energy balance on the particle (including radiation to surroundings at 1500 K) shows that the average temperature of the particle is approximately 2550 K, and, thus,  $T_r = (1/2)(1500 + 2550) = 2025$  K or  $\rho \approx \rho_{\text{air}} = 0.175$  kg/m<sup>3</sup> and  $\mathcal{D}_{O_2,m} \approx \mathcal{D}_{O_2,\text{air}} = 4.89 \times 10^{-4}$  m<sup>2</sup>/sec (from Table 4.7.1). Then

$$\tau = \frac{(1810)(10 \times 10^{-6})^2}{(1.28)(0.175)(4.89 \times 10^{-4})} = 1.65 \times 10^{-3} \text{ sec}$$

### Droplet Evaporation

Consider a small droplet of species 1 entrained in a gas stream, species 2 (Figure 4.7.9). This is a simultaneous heat and mass transfer problem, and the mass transfer rate can be obtained by solving simultaneously

$$\dot{m}'' = \frac{\rho \mathcal{D}_{12}}{R} \ln \left( 1 + \frac{m_{1,e} - m_{1,s}}{m_{1,s} - 1} \right) = \frac{k/c_{p1}}{R} \ln \left( 1 + \frac{c_{p1}(T_e - T_s)}{h_{fg}} \right) \text{ kg/m}^2 \text{ sec} \quad (4.7.53a)$$

$$m_{1,s} = m_{1,s}(T, P) \quad (\text{from vapor-pressure data}) \quad (4.7.53b)$$

FIGURE 4.7.9 Evaporation of a droplet.

Temperature  $T_s$  is the adiabatic vaporization temperature and is essentially the psychrometric wet-bulb temperature. Properties can be evaluated at mean film temperature and composition; alternatively,  $c_{p1}$  can be set equal to the reference specific heat and all properties evaluated using Hubbard's  $1/3$  rule, namely,

$$m_{1,r} = m_{1,s} + (1/3)(m_{1,e} - m_{1,s}) \quad (4.7.54a)$$

$$T_r = T_s + (1/3)(T_e - T_s) \quad (4.7.54b)$$

### Droplet Combustion

Figure 4.7.10 shows a schematic of a volatile liquid hydrocarbon fuel droplet burning in air at zero gravity. The flame diameter is typically four to six times the droplet diameter. Heat is transferred from the flame to the droplet and serves to vaporize the fuel. In the flame the vapor reacts with oxygen to form gaseous products, primarily  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . When a fuel droplet ignites, there is a short initial transient during which the droplet heats up, until further conduction into the droplet is negligible and the droplet attains a steady temperature (approximately the wet-bulb temperature, which is very close to the boiling point for a typical hydrocarbon fuel). The reaction in the flame can be modeled as a single-step reaction with a constant stoichiometric ratio,  $r$ , and heat of combustion  $\Delta h_c$  J/kg of fuel.

The burning (mass transfer) rate of the droplet is given by the Godsave–Spalding formula,

$$\dot{m}'' = \frac{k/c_p}{R} \ln[1 + \mathcal{B}] \text{ kg/m}^2 \text{ sec} \quad (4.7.55)$$

where

$$\mathcal{B} = \frac{m_{\text{ox},e} \Delta h_c / r + c_p (T_e - T_s)}{h_{fg}}$$

is the *mass transfer driving force* (or *transfer number*). The droplet lifetime is then

$$\tau = \frac{\rho_l D_0^2}{8(k/c_p) \ln(1 + \mathcal{B})} \text{ sec} \quad (4.7.56)$$

Based on experimental data for alkane droplets burning in air, Law and Williams (1972) recommend that properties be evaluated at a reference temperature  $T_r = (1/2)(T_{BP} + T_{\text{flame}})$  where  $T_{\text{flame}}$  is the adiabatic flame temperature. The reference specific heat is  $c_{pr} = c_{pfu}$ , and the reference thermal conductivity is  $k_r$ ,

**FIGURE 4.7.10** Combustion of a volatile fuel droplet burning in air: (a) schematic showing the flame, (b) concentration and temperature profiles.

$= 0.4k_{fu} + 0.6k_{air}$ . Radiation has been ignored in the analysis leading to Equation (4.7.55) but is accounted for in using the Law and Williams reference-property scheme.

For example, consider a 1-mm-diameter *n*-octane droplet burning in air at 1 atm and 300 K, at near zero gravity. For *n*-octane ( $n\text{-C}_8\text{H}_{18}$ ),  $\rho_l = 611 \text{ kg/m}^3$ ,  $h_{fg} = 3.03 \times 10^5 \text{ J/kg}$ ,  $\Delta h_c = 4.44 \times 10^7 \text{ J/kg}$ , and  $T_{BP} = 399 \text{ K}$ . The flame temperature is  $T_{\text{flame}} = 2320 \text{ K}$ . At a reference temperature of  $(1/2)(T_{\text{flame}} + T_{BP}) = 1360 \text{ K}$ , property values of *n*-octane vapor include  $k = 0.113 \text{ W/m K}$ ,  $c_p = 4280 \text{ J/kg K}$ . The reaction is

Hence, the stoichiometric ratio  $r = 400/114.2 = 3.50$ . Also  $m_{ox,e} = 0.231$  and  $T_s \cong T_{BP} = 399 \text{ K}$ . Thus, the transfer number is

$$\mathcal{B} = \frac{(0.231)(4.44 \times 10^7)/(3.50) + 4280(300 - 399)}{3.03 \times 10^5} = 8.27$$

At  $T_r = 1360 \text{ K}$ ,  $k_{air} = 0.085 \text{ W/m K}$ . Hence,

$$k_r = 0.4k_{fu} + 0.6k_{air} = (0.4)(0.113) + (0.6)(0.085) = 0.096 \text{ W/m K}$$

and the droplet lifetime is

$$\tau = \frac{(611)(1 \times 10^{-3})^2}{(8)(0.096/4280)\ln(1 + 8.27)} = 1.53 \text{ sec}$$

## Mass Convection

The terms *mass convection* or *convective mass transfer* are generally used to describe the process of mass transfer between a surface and a moving fluid, as shown in Figure 4.7.11. The surface may be that

**FIGURE 4.7.11** Notation for convective mass transfer into an external flow.

of a falling water film in an air humidifier, of a coke particle in a gasifier, or of a silica-phenolic heat shield protecting a reentry vehicle. As is the case for heat convection, the flow can be *forced* or *natural*, *internal* or *external*, and *laminar* or *turbulent*. In addition, the concept of whether the mass transfer rate is *low* or *high* plays an important role: when mass transfer rates are low, there is a simple analogy between heat transfer and mass transfer that can be efficiently exploited in the solution of engineering problems.

### Mass and Mole Transfer Conductances

Analogous to convective heat transfer, the rate of mass transfer by convection is usually a complicated function of surface geometry and  $s$ -surface composition, the fluid composition and velocity, and fluid physical properties. For simplicity, we will restrict our attention to fluids that are either binary mixtures or solutions, or situations in which, although more than two species are present, diffusion can be adequately described using effective binary diffusion coefficients, as was discussed in the section on ordinary diffusion. Referring to [Figure 4.7.11](#), we define the *mass transfer conductance* of species 1,  $g_{m1}$ , by the relation

$$j_{1,s} = g_{m1} \Delta m_1; \quad \Delta m_1 = m_{1,s} - m_{1,e} \quad (4.7.57)$$

and the units of  $g_{m1}$  are seen to be the same as for mass flux ( $\text{kg}/\text{m}^2\text{sec}$ ). Equation (4.7.57) is of a similar form to Newton's law of cooling, which defines the heat transfer coefficient  $h_c$ . Why we should not use a similar name and notation (e.g., mass transfer coefficient and  $h_m$ ) will become clear later. On a molar basis, we define the *mole transfer conductance* of species 1,  $g_{m1}$ , by a corresponding relation,

$$J_{1,s} = g_{m1} \Delta x_1; \quad \Delta x_1 = x_{1,s} - x_{1,e} \quad (4.7.58)$$

where  $g_{m1}$  has units ( $\text{kmol}/\text{m}^2\text{sec}$ ).

### Low Mass Transfer Rate Theory

Consider, as an example, the evaporation of water into air, as shown in [Figure 4.7.12](#). The water–air interface might be the surface of a water reservoir, or the surface of a falling water film in a cooling tower or humidifier. In such situations the mass fraction of water vapor in the air is relatively small; the highest value is at the  $s$ -surface, but even if the water temperature is as high as  $50^\circ\text{C}$ , the corresponding value of  $m_{\text{H}_2\text{O},s}$  at 1 atm total pressure is only 0.077. From Equation 4.7.54 the driving potential for diffusion of water vapor away from the interface is  $\Delta m_1 = m_{1,s} - m_{1,e}$ , and is small compared to unity, even if the free-stream air is very dry such that  $m_{1,e} \approx 0$ . We then say that the mass transfer rate is *low* and the rate of evaporation of the water can be approximated as  $j_{1,s}$ ; for a surface area  $A$ ,

$$\dot{m}_1 = (m_{1,s} n_s + j_{1,s}) A \approx j_{1,s} A \text{ kg/sec} \quad (4.7.59)$$

**FIGURE 4.7.12** Evaporation of water into an air flow.

In contrast, if the water temperature approaches its boiling point,  $m_{1,s}$  is no longer small, and of course, in the limit of  $T_s = T_{BP}$ ,  $m_{1,s} = 1$ . The resulting driving potential for diffusion  $\Delta m_1$  is then large, and we say that the mass transfer rate is *high*. Then, the evaporation rate cannot be calculated from Equation 4.7.59, as will be explained in the section on high mass transfer rate theory. For water evaporation into air, the error incurred in using low mass transfer rate theory is approximately  $(1/2) \Delta m_1$ , and a suitable criterion for application of the theory to engineering problems is  $\Delta m_1 < 0.1$  or  $0.2$ .

A large range of engineering problems can be adequately analyzed assuming low mass transfer rates. These problems include cooling towers and humidifiers as mentioned above, gas absorbers for sparingly soluble gases, and catalysis. In the case of catalysis, the *net* mass transfer rate is actually zero. Reactants diffuse toward the catalyst surface and the products diffuse away, but the catalyst only promotes the reaction and is not consumed. On the other hand, problems that are characterized by high mass transfer rates include condensation of steam containing a small amount of noncondensable gas, as occurs in most power plant condensers; combustion of volatile liquid hydrocarbon fuel droplets in diesel engines and oil-fired power plants, and ablation of phenolic-based heat shields on reentry vehicles.

### Dimensionless Groups

Dimensional analysis of convective mass transfer yields a number of pertinent dimensionless groups that are, in general, analogous to dimensionless groups for convective heat transfer. The most important groups are as follows.

1. The Schmidt number,  $Sc_{12} = \mu/\rho\mathcal{D}_{12}$ , which is a properties group analogous to the Prandtl number. For gas mixtures,  $Sc_{12} = O(1)$ , and for liquid solutions,  $Sc_{12} = O(100)$  to  $O(1000)$ . There are not fluids for which  $Sc_{12} \ll 1$ , as is the case of Prandtl number for liquid metals.
2. The Sherwood number (or mass transfer Nusselt number).  $Sh = g_{m1}L/\rho\mathcal{D}_{12}$  ( $= G_{m1}L/c\mathcal{D}_{12}$ ) is a dimensionless conductance.
3. The mass transfer Stanton number  $St_m = g_{m1}/\rho V$  ( $= G_{m1}/cV$ ) is an alternative dimensionless conductance.

As for convective heat transfer, forced convection flows are characterized by a Reynolds number, and natural convection flows are characterized by a Grashof or Rayleigh number. In the case of Gr or Ra it is not possible to replace  $\Delta\rho$  by  $\beta\Delta T$  since density differences can result from concentration differences (and both concentration and temperature differences for simultaneous heat and mass transfer problems).

### Analogy between Convective Heat and Mass Transfer

A close analogy exists between convective heat and convective mass transfer owing to the fact that conduction and diffusion in a fluid are governed by physical laws of identical form, that is, Fourier's and Fick's laws, respectively. As a result, in many circumstances the Sherwood or mass transfer Stanton number can be obtained in a simple manner from the Nusselt number or heat transfer Stanton number for the same flow conditions. Indeed, in most gas mixtures  $Sh$  and  $St_m$  are nearly equal to their heat transfer counterparts. For dilute mixtures and solutions and low mass transfer rates, the rule for exploiting the analogy is simple: *The Sherwood or Stanton number is obtained by replacing the Prandtl number by the Schmidt number in the appropriate heat transfer correlation.* For example, in the case of fully developed turbulent flow in a smooth pipe

$$Nu_D = 0.023Re_D^{0.8}Pr^{0.4}; \quad Pr > 0.5 \quad (4.7.60a)$$

which for mass transfer becomes

$$Sh_D = 0.023Re_D^{0.8}Sc^{0.4}; \quad Sc > 0.5 \quad (4.7.60b)$$

Also, for natural convection from a heated horizontal surface facing upward,

$$\overline{Nu} = 0.54(Gr_L Pr)^{1/4}; \quad 10^5 < Gr_L Pr < 2 \times 10^7 \quad (\text{laminar}) \quad (4.7.61a)$$

$$\overline{Nu} = 0.14(Gr_L Pr)^{1/3}; \quad 2 \times 10^7 < Gr_L Pr < 3 \times 10^{10} \quad (\text{turbulent}) \quad (4.7.61b)$$

which for isothermal mass transfer with  $\rho_s < \rho_e$  become

$$\overline{Sh} = 0.54(Gr_L Sc)^{1/4}; \quad 10^5 < Gr_L Sc < 2 \times 10^7 \quad (\text{laminar}) \quad (4.7.62a)$$

$$\overline{Sh} = 0.14(Gr_L Sc)^{1/3}; \quad 2 \times 10^7 < Gr_L Sc < 3 \times 10^{10} \quad (\text{turbulent}) \quad (4.7.62b)$$

With evaporation, the condition,  $\rho_s < \rho_e$  will be met when the evaporating species has a smaller molecular weight than the ambient species, for example, water evaporating into air. Mass transfer correlations can be written down in a similar manner for almost all the heat transfer correlations given in Section 4.2. There are some exceptions: for example, there are no fluids with a Schmidt number much less than unity, and thus there are no mass transfer correlations corresponding to those given for heat transfer to liquid metals with  $Pr \ll 1$ . In most cases it is important for the wall boundary conditions to be of analogous form, for example, laminar flow in ducts. A uniform wall temperature corresponds to a uniform concentration  $m_{1,s}$  along the  $s$ -surface, whereas a uniform heat flux corresponds to a uniform diffusive flux  $j_{1,s}$ . In chemical engineering practice, the analogy between convective heat and mass transfer is widely used in a form recommended by Chilton and Colburn in 1934, namely,  $St_m/St = (Sc/Pr)^{-2/3}$ . The Chilton-Colburn form is of adequate accuracy for most external forced flows but is inappropriate for fully developed laminar duct flows.

For example, air at 1 atm and 300 K flows inside a 3-cm-inside-diameter tube at 10 m/sec. Using pure-air properties the Reynolds number is  $VD/\nu = (10)(0.03)/15.7 \times 10^{-6} = 1.911 \times 10^4$ . The flow is turbulent. Using Equation (4.7.60b) with  $Sc_{12} = 0.61$  for small concentrations of  $H_2O$  in air,

$$Sh_D = (0.023)(1.911 \times 10^4)^{0.8} (0.61)^{0.4} = 50.2$$

$$g_{m1} = \rho \mathcal{D}_{12} \text{Sh}/D = \rho v \text{Sh}/\text{Sc}_{12} D = \frac{(1.177)(15.7 \times 10^{-6})(50.2)}{(0.61)(0.03)} = 5.07 \times 10^{-2} \text{ kg/m}^2 \text{ sec}$$

Further insight into this analogy between convective heat and mass transfer can be seen by writing out Equations (4.7.60a) and (4.7.60b) as, respectively,

$$\frac{(h_c/c_p)D}{k/c_p} = 0.023 \text{Re}_D^{0.8} \left( \frac{\mu}{k/c_p} \right)^{0.4} \quad (4.7.63a)$$

$$\frac{g_m D}{\rho \mathcal{D}_{12}} = 0.023 \text{Re}_D^{0.8} \left( \frac{\mu}{\rho \mathcal{D}_{12}} \right)^{0.4} \quad (4.7.63b)$$

When cast in this form, the correlations show that the property combinations  $k/c_p$  and  $\rho \mathcal{D}_{12}$  play analogous roles; these are *exchange coefficients* for heat and mass, respectively, both having units kg/m sec, which are the same as those for dynamic viscosity  $\mu$ . Also, it is seen that the ratio of heat transfer coefficient to specific heat plays an analogous role to the mass transfer conductance, and has the same units (kg/m<sup>2</sup> sec). Thus, it is appropriate to refer to the ratio  $h_c/c_p$  as the *heat transfer conductance*,  $g_h$ , and for this reason we should not refer to  $g_m$  as the mass transfer *coefficient*.

### Simultaneous Heat and Mass Transfer

Often problems involve simultaneous convective heat and mass transfer, for which the surface energy balance must be carefully formulated. Consider, for example, evaporation of water into air, as shown in Figure 4.7.13. With H<sub>2</sub>O denoted as species 1, the steady-flow energy equation applied to a control volume located between the  $u$ - and  $s$ -surfaces requires that

$$\dot{m}(h_{1,s} - h_{1,u}) = A(q''_{\text{cond}} - q''_{\text{conv}} - q''_{\text{rad}}) W \quad (4.7.64)$$

where it has been recognized that only species 1 crosses the  $u$ - and  $s$ -surfaces. Also, the water has been assumed to be perfectly opaque so that all radiation is emitted or absorbed between the  $u$ -surface and the interface.

If we restrict our attention to conditions for which low mass transfer rate theory is valid, we can write  $\dot{m}/A \approx j_{1,s} = g_{m1}(m_{1,s} - m_{1,e})$ . Also, we can then calculate the convective heat transfer as if there were no mass transfer, and write  $q_{\text{conv}} = h_c(T_s - T_e)$ . Substituting in Equation (4.7.64) with  $q_{\text{conv}} = -k\partial T/\partial y|_u$ ,  $h_{1,s} - h_{1,u} = h_{fg}$ , and rearranging, gives

$$-k \frac{\partial T}{\partial y} \Big|_u = h_c(T_s - T_e) + g_{m1}(m_{1,s} - m_{1,e})h_{fg} + q''_{\text{rad}} \text{ W/m}^2 \quad (4.7.65)$$

It is common practice to refer to the convective heat flux  $h_c(T_s - T_e)$  as the *sensible* heat flux, whereas the term  $g_{m1}(m_{1,s} - m_{1,e})h_{fg}$  is called the *evaporative* or *latent* heat flux. Each of the terms in Equation 4.7.65 can be positive or negative, depending on the particular situation. Also, the evaluation of the conduction heat flux at the  $u$ -surface,  $-k\partial T/\partial y|_u$ , depends on the particular situation. Four examples are shown in Figure 4.7.13. For a water film flowing down a packing in a cooling tower (Figure 4.7.13b), this heat flux can be expressed in terms of convective heat transfer from the bulk water at temperature  $T_L$  to the surface of the film,  $-k\partial T/\partial y|_u = h_{cL}(T_L - T_s)$ . If the liquid-side heat transfer coefficient  $h_{cL}$  is large enough, we can simply set  $T_s \approx T_L$ , which eliminates the need to estimate  $h_{cL}$ . The evaporation process is then *gas-side controlled*. Figure 4.7.13c shows film condensation from a steam-air mixture on the outside of a vertical tube. In this case we can write  $k\partial T/\partial y|_u = U(T_s - T_c)$ , where  $T_c$  is the coolant

FIGURE 4.7.13 The surface energy balance for evaporation of water into an air stream.

bulk temperature. The overall heat transfer coefficient  $U$  includes the resistances of the condensate film, the tube wall, and the coolant. Sweat cooling is shown in Figure 4.7.13d, with water from a reservoir (or *plenum chamber*) injected through a porous wall at a rate just sufficient to keep the wall surface wet. In this case, the conduction across the  $u$ -surface can be related to the reservoir conditions by application of the steady-flow energy equation to a control volume located between the  $o$ - and  $u$ -surfaces. Finally, Figure 4.7.13e shows drying of a wet porous material (e.g., a textile or wood). During the constant-rate period of the process, evaporation takes place from the surface with negligible heat conduction into the solid; then  $-k\partial T/\partial y|_u \approx 0$ . The term *adiabatic vaporization* is used to describe evaporation when  $q_{\text{cond}} = 0$ ; constant-rate drying is one example, and the wet-bulb psychrometer is another.

Consider a 1-m-square wet towel on a washline on a day when there is a low overcast and no wind. The ambient air is at 21°C, 1 atm, and 50.5% RH. In the constant-rate drying period the towel temperature is constant, and  $q_{\text{cond}} = 0$ . An iterative calculation is required to obtain the towel temperature using correlations for natural convection on a vertical surface to obtain  $h_c$  and  $g_{m1}$ ;  $q_{\text{rad}}$  is obtained as  $q_{\text{rad}} = \sigma\epsilon(T_s^4 - T_e^4)$  with  $\epsilon = 0.90$ . The results are  $T_s = 17.8^\circ\text{C}$ ,  $h_c = 1.69 \text{ W/m}^2\text{K}$ ,  $g_{m1} = 1.82 \times 10^{-3} \text{ kg/m}^2\text{sec}$ , and the energy balance is

$$q_{\text{cond}} = h_c(T_s - T_e) + g_{m1}(m_{1,s} - m_{1,e})h_{fg} + q_{\text{rad}}$$

$$0 = -5.4 + 21.7 - 16.3 \text{ W/m}^2$$

Evaluation of composition-dependent properties, in particular the mixture specific heat and Prandtl number, poses a problem. In general, low mass transfer rates imply small composition variations across a boundary layer, and properties can be evaluated for a mixture of the free-stream composition at the mean film temperature. In fact, when dealing with evaporation of water into air, use of the properties of dry air at the mean film temperature gives results of adequate engineering accuracy. If there are large composition variations across the boundary layer, as can occur in some catalysis problems, properties should be evaluated at the mean film composition and temperature.

### The Wet- and Dry-Bulb Psychrometer

The wet- and dry-bulb psychrometer is used to measure the moisture content of air. In its simplest form, the air is made to flow over a pair of thermometers, one of which has its bulb covered by a wick whose other end is immersed in a small water reservoir. Evaporation of water from the wick causes the wet bulb to cool and its steady-state temperature is a function of the air temperature measured by the dry bulb and the air humidity. The wet bulb is shown in Figure 4.7.14. In order to determine the water vapor mass fraction  $m_{1,e}$ , the surface energy balance Equation (4.7.66) is used with conduction into the wick and  $q''_{\text{rad}}$  set equal to zero. The result is

$$m_{1,e} = m_{1,s} - \frac{c_p}{h_{fg}} \left( \frac{\text{Pr}}{\text{Sc}_{12}} \right)^{-2/3} (T_e - T_s) \quad (4.7.66)$$

Usually  $m_{1,e}$  is small and we can approximate  $c_p = c_{p, \text{air}}$  and  $(\text{Pr}/\text{Sc}_{12})^{-2/3} = 1/1.08$ . Temperatures  $T_s$  and  $T_e$  are the known measured wet- and dry-bulb temperatures. With  $T_s$  known,  $m_{1,s}$  can be obtained using steam tables in the usual way. For example, consider an air flow at 1000 mbar with measured wet- and dry-bulb temperatures of 305.0 and 310.0 K, respectively. Then  $P_{1,s} = P_{\text{sat}}(T_s) = P_{\text{sat}}(305.0 \text{ K}) = 4714 \text{ Pa}$  from steam tables. Hence,  $x_{1,s} = P_{1,s}/P = 4714/10^5 = 0.04714$ , and

$$m_{1,s} = \frac{0.04714}{0.04714 + (29/18)(1 - 0.04714)} = 0.02979$$

**FIGURE 4.7.14** Wet bulb of a wet- and dry-bulb psychrometer.

Also,  $h_{fg}$  (305 K) =  $2.425 \times 10^6$  J/kg, and  $c_{p, \text{air}} = 1005$  J/kg K; thus

$$m_{1,e} = 0.02979 - \frac{1005}{(1.08)(2.425 \times 10^6)}(310 - 305) = 0.02787$$

$$x_{1,e} = \frac{0.02787}{0.02787 + (18/29)(1 - 0.02787)} = 0.04415$$

$$P_{1,e} = x_{1,e}P = (0.04415)(10^5) = 4412 \text{ Pa}$$

By definition, the relative humidity is  $\text{RH} = P_{1,e}/P_{\text{sat}}(T_e)$ ;  $\text{RH} = 4415/6224 = 70.9\%$ .

In the case of other adiabatic vaporization processes, such as constant-rate drying or evaporation of a water droplet,  $m_{1,e}$  and  $T_e$  are usually known and Equation (4.7.66) must be solved for  $T_s$ . However, the thermodynamic wet-bulb temperature obtained from psychrometric charts or software is accurate enough for engineering purposes.

### High Mass Transfer Rate Theory

When there is net mass transfer across a phase interface, there is a convective component of the absolute flux of a species across the  $s$ -surface. From Equation (4.7.23a) for species 1,

$$n_{1,s} = \rho_{1,s}v_s + j_{1,s} \text{ kg/m}^2 \text{ sec} \quad (4.7.67)$$

During evaporation the convection is directed in the gas phase, with a velocity normal to the surface  $v_s$ . When the convective component cannot be neglected, we say that the mass transfer rate is *high*. There are two issues to consider when mass transfer rates are high. First, the rate at which species 1 is transferred across the  $s$ -surface is not simply the diffusive component  $j_{1,s}$  as assumed in low mass transfer rate theory, but is the sum of the convective and diffusive components shown in Equation 4.7.67. Second, the normal velocity component  $v_s$  has a *blowing* effect on the concentration profiles, and hence on the Sherwood number. The Sherwood number is no longer analogous to the Nusselt number of conventional heat transfer correlations, because those Nusselt numbers are for situations involving impermeable surfaces, e.g., a metal wall, for which  $v_s = 0$ .

Substituting for  $j_{1,s}$  from Equation (4.7.57) into Equation (4.7.67) gives

$$\dot{m}'' = g_{m1} \frac{m_{1,e} - m_{1,s}}{m_{1,s} - n_{1,s}/\dot{m}''} = g_{m1} \mathcal{B}_{m1} \quad (4.7.68)$$

where  $\dot{m}'' = n_s$  is the mass transfer rate introduced in the section on heterogeneous combustion and  $\mathcal{B}_{m1}$  is the *mass transfer driving force*. In the special case where only species 1 is transferred,  $n_{1,s}/\dot{m}'' = 1$ , for example, when water evaporates into air, and dissolution of air in the water is neglected. It is convenient to rewrite Equation (4.7.68) as

$$\dot{m}'' = g_{m1}^* (g_{m1}/g_{m1}^*) \mathcal{B}_{m1} \text{ kg/m}^2 \text{ sec} \quad (4.7.69a)$$

where

$$g_{m1}^* = \lim_{\mathcal{B}_{m1} \rightarrow 0} g_{m1} \quad (4.7.69b)$$

Now  $g_{m1}^*$  is the limit value of  $g_{m1}$  for zero mass transfer (i.e.,  $v_s = 0$ ), and  $\text{Sh}^*$  can be obtained from conventional heat transfer Nusselt number correlations for impermeable surfaces. The ratio  $(g_{m1}/g_{m1}^*)$  is termed a *blowing factor* and accounts for the effect of  $v_s$  on the concentration profiles. Use of Equation (4.7.69) requires appropriate data for the blowing factor. For the constant-property laminar boundary layer on a flat plate, Figure 4.7.15 shows the effect of the Schmidt number on the blowing factor. The abscissa is a *blowing parameter*  $B_m = \dot{m}''/g_{m1}^*$ .

The blowing velocity also affects the velocity and temperature profiles, and hence the wall shear stress and heat transfer. The curve for  $\text{Sc} = 1$  in Figure 4.7.15 also gives the effect of blowing on shear stress as  $\tau_s/\tau_s^*$ , and the curve for  $\text{Sc} = 0.7$  gives the effect of blowing on heat transfer for air injection into air as  $h_c/h_c^*$  (since  $\text{Pr} = 0.7$  for air).

### Variable Property Effects of High Mass Transfer Rates

High mass transfer rate situations are usually characterized by large property variations across the flow, and hence property evaluation for calculating  $g_m$  and  $h_c$  is not straightforward. An often-encountered situation is transfer of a single species into an inert laminar or turbulent boundary layer flow. The effect of variable properties can be very large as shown in Figure 4.7.16 for laminar boundary layers, and Figure 4.7.17 for turbulent boundary layers.

A simple procedure for correlating the effects of flow type and variable properties is to use weighting factors in the exponential functions suggested by a constant-property Couette-flow model (Mills, 1995). Denoting the injected species as species  $i$ , we have

$$\frac{g_{m1}}{g_{m1}^*} = \frac{a_{mi} B_{mi}}{\exp(a_{mi} B_{mi}) - 1}; \quad B_{mi} = \frac{\dot{m}''}{g_{mi}^*} \quad (4.7.70a)$$

or

$$\frac{g_{m1}}{g_{mi}^*} = \frac{\ln(1 + a_{mi} B_{mi})}{a_{mi} B_{mi}}; \quad B_{mi} = \frac{\dot{m}''}{g_{mi}^*} = \frac{m_{i,e} - m_{i,s}}{m_{i,s} - 1}$$

$$\frac{\tau_s}{\tau_s^*} = \frac{a_{fi} B_f}{\exp(a_{fi} B_f) - 1}; \quad B_f = \frac{\dot{m}'' u_e}{\tau_s^*} \quad (4.7.70b)$$

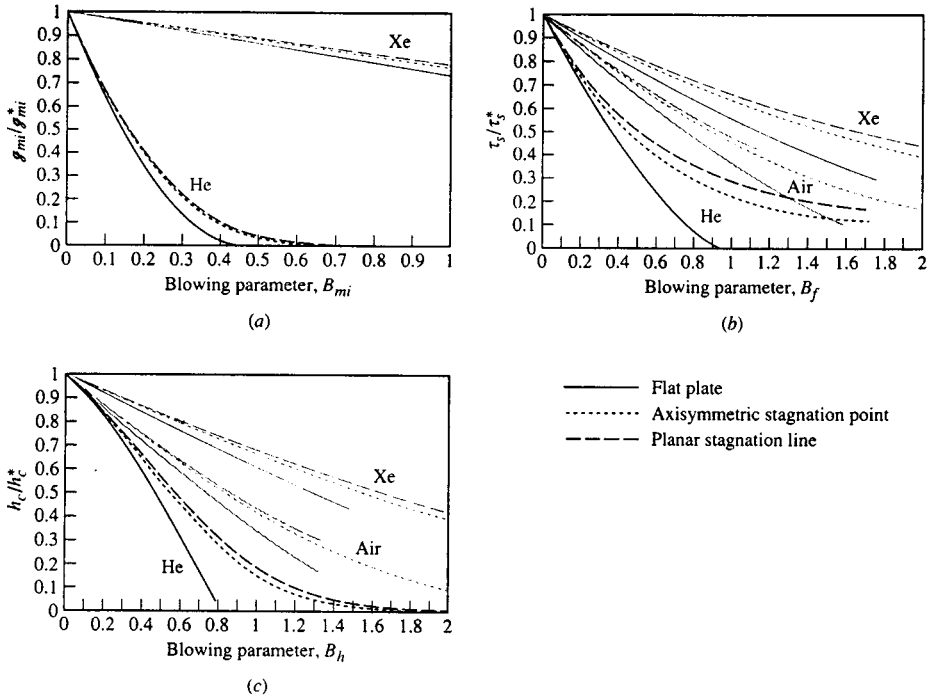

**FIGURE 4.7.15** Effect of mass transfer on the mass transfer conductance for a laminar boundary layer on a flat plate:  $g_m/g_m^*$  vs. blowing parameter  $B_m = \dot{m}''/g_m^*$ .

$$\frac{h_c}{h_c^*} = \frac{a_{hi} B_h}{\exp(a_{hi} B_h) - 1}; \quad B_h = \frac{\dot{m}'' c_{pe}}{h_c^*} \tag{4.7.70c}$$

Notice that  $g_{mi}^*$ ,  $\tau_s^*$ ,  $h_c^*$ , and  $c_{pe}$  are evaluated using properties of the free-stream gas at the mean film temperature. The weighting factor  $a$  may be found from exact numerical solutions of boundary layer equations or from experimental data. Some results for laminar and turbulent boundary layers follow.

1. *Laminar Boundary Layers.* We will restrict our attention to low-speed air flows, for which viscous dissipation and compressibility effects are negligible, and use exact numerical solutions of the self-similar laminar boundary layer equations (Wortman, 1969). Least-squares curve fits of the numerical data were obtained using Equations (4.7.70a) to (4.7.70c). Then, the weighting factors for axisymmetric stagnation-point flow with a cold wall ( $T_s/T_e = 0.1$ ) were correlated as

$$a_{mi} = 1.65(M_{air}/M_i)^{10/12} \tag{4.7.71a}$$

**FIGURE 4.7.16** Numerical results for the effect of pressure gradient and variable properties on blowing factors for laminar boundary layers: low-speed air flow over a cold wall ( $T_s/T_e = 0.1$ ) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Wortman, A., Ph.D. dissertation, University of California, Los Angeles, 1969. With permission.)

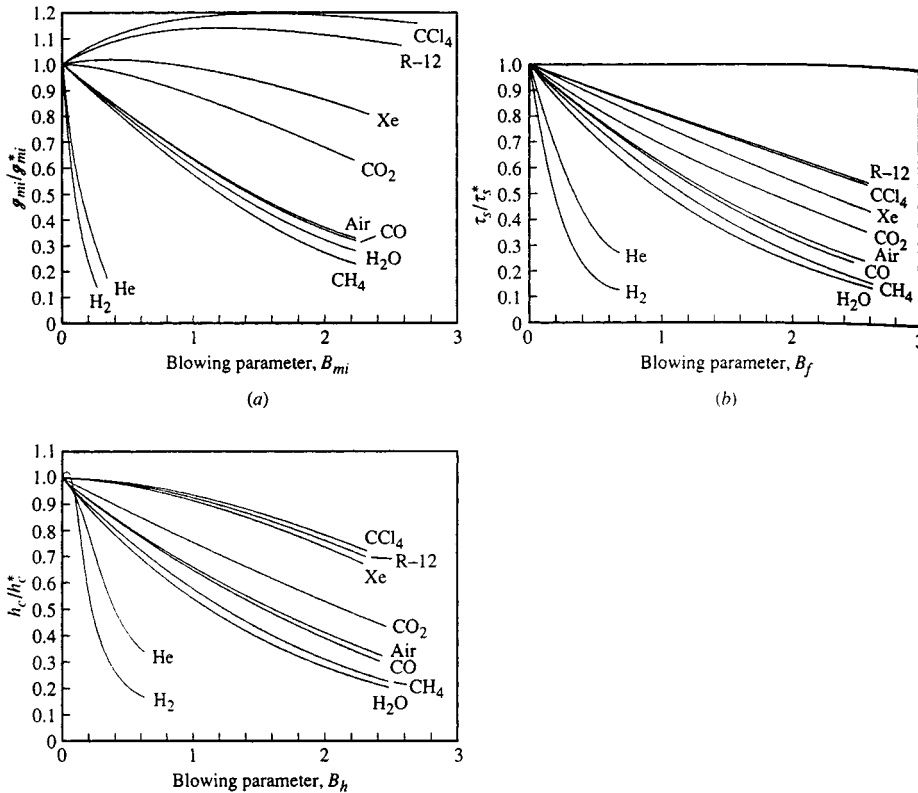

$$a_{fi} = 1.38(M_{air}/M_i)^{5/12} \tag{4.7.71b}$$

$$a_{hi} = 1.30(M_{air}/M_i)^{3/12} \left[ c_{pi} / (2.5\mathcal{R}/M_i) \right] \tag{4.7.71c}$$

Notice that  $c_{pi}/2.5\mathcal{R}/M_i$  is unity for a monatomic species. For the planar stagnation line and the flat plate, and other values of the temperature ratio  $T_s/T_e$ , the values of the species weighting factors are divided by the values given by Equations (4.7.71a,b,c) to give correction factors  $G_{mi}$ ,  $G_{fi}$ , and  $G_{hi}$ , respectively. The correction factors are listed in Table 4.7.7.

The exponential relation blowing factors cannot accurately represent some of the more anomalous effects of blowing. For example, when a light gas such as  $H_2$  is injected, Equation (4.7.70c) indicates that the effect of blowing is always to reduce heat transfer, due to both the low density and high specific heat of hydrogen. However, at very low injection rates, the heat transfer is actually increased, as a result of the high thermal conductivity of  $H_2$ . For a mixture,  $k \approx \sum x_i k_i$  whereas  $c_p = \sum m_i c_{pi}$ . At low rates of injection, the mole fraction of  $H_2$  near the wall is much larger than its mass fraction; thus, there is a substantial increase in the mixture conductivity near the wall, but only a small change in the mixture specific heat. An increase in heat transfer results. At higher injection rates, the mass fraction of  $H_2$  is also large, and the effect of high mixture specific heat dominates to cause a decrease in heat transfer.

2. *Turbulent Boundary Layers.* Here we restrict our attention to air flow along a flat plate for Mach numbers up to 6, and use numerical solutions of boundary layer equations with a mixing length turbulence model (Landis, 1971). Appropriate species weighting factors for  $0.2 < T_s/T_e < 2$  are

**FIGURE 4.7.17** Numerical results for the effect of variable properties on blowing factors for a low-speed turbulent air boundary layer on a cold flat plate ( $T_s/T_e = 0.2$ ) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Landis, R.B., Ph.D. dissertation, University of California, Los Angeles, 1971. With permission.)

$$a_{mi} = 0.79(M_{air}/M_i)^{1.33} \tag{4.7.72a}$$

$$a_{fi} = 0.91(M_{air}/M_i)^{0.76} \tag{4.7.72b}$$

$$a_{hi} = 0.86(M_{air}/M_i)^{0.73} \tag{4.7.72c}$$

In using Equation (4.7.70), the limit values for  $\dot{m}'' = 0$  are elevated at the same location along the plate. Whether the injection rate is constant along the plate or varies as  $x^{-0.2}$  to give a self-similar boundary layer has little effect on the blowing factors. Thus, Equation (4.7.72) has quite general applicability. Notice that the effects of injectant molecular weight are greater for turbulent boundary layers than for laminar ones, which is due to the effect of fluid density on turbulent transport. Also, the injectant specific heat does not appear in  $a_{hi}$  as it did for laminar flows. In general,  $c_{pi}$  decreases with increasing  $M_i$  and is adequately accounted for in the molecular weight ratio.

**Reference State Schemes.** The reference state approach, in which constant-property data are used with properties evaluated at some reference state, is an alternative method for handling variable-property effects. In principle, the reference state is independent of the precise property data used and of the

### Enhancement

*Arthur E. Bergles*

#### Introduction

Energy- and materials-saving considerations, as well as economic incentives, have led to efforts to produce more efficient heat exchange equipment. Common thermal-hydraulic goals are to reduce the size of a heat exchanger required for a specified heat duty, to upgrade the capacity of an existing heat exchanger, to reduce the approach temperature difference for the process streams, or to reduce the pumping power.

The study of improved heat transfer performance is referred to as heat transfer *enhancement*, *augmentation*, or *intensification*. In general, this means an increase in heat transfer coefficient. Attempts to increase “normal” heat transfer coefficients have been recorded for more than a century, and there is a large store of information. A survey (Bergles et al., 1991) cites 4345 technical publications, excluding patents and manufacturers’ literature. The literature has expanded rapidly since 1955.

Enhancement techniques can be classified either as passive methods, which require no direct application of external power (Figure 4.8.1), or as active methods, which require external power. The effectiveness of both types of techniques is strongly dependent on the mode of heat transfer, which may range from single-phase free convection to dispersed-flow film boiling. Brief descriptions of these methods follow.

*Treated surfaces* involve fine-scale alternation of the surface finish or coating (continuous or discontinuous). They are used for boiling and condensing; the roughness height is below that which affects single-phase heat transfer.

*Rough surfaces* are produced in many configurations ranging from random sand-grain-type roughness to discrete protuberances. See Figure 4.8.1a. The configuration is generally chosen to disturb the viscous sublayer rather than to increase the heat transfer surface area. Application of rough surfaces is directed primarily toward single-phase flow.

*Extended surfaces* are routinely employed in many heat exchangers. See Figure 4.8.1a to d. Work of special interest to enhancement is directed toward improvement of heat transfer coefficients on extended surfaces by shaping or perforating the surfaces.

*Displaced enhancement devices* are inserted into the flow channel so as indirectly to improve energy transport at the heated surface. They are used with forced flow. See Figure 4.8.1e and f.

*Swirl-flow devices* include a number of geometric arrangements or tube inserts for forced flow that create rotating and/or secondary flow: coiled tubes, inlet vortex generators, twisted-tape inserts, and axial-core inserts with a screw-type winding.

*Surface-tension devices* consist of wicking or grooved surfaces to direct the flow of liquid in boiling and condensing.

*Additives for liquids* include solid particles and gas bubbles in single-phase flows and liquid trace additives for boiling systems.

*Additives for gases* are liquid droplets or solid particles, either dilute-phase (gas-solid suspensions) or dense-phase (fluidized beds).

*Mechanical aids* involve stirring the fluid by mechanical means or by rotating the surface. Surface “scraping,” widely used for batch processing of viscous liquids in the chemical process industry, is applied to the flow of such diverse fluids as high-viscosity plastics and air. Equipment with rotating heat exchanger ducts is found in commercial practice.

*Surface vibration* at either low or high frequency has been used primarily to improve single-phase heat transfer.

**FIGURE 4.8.1** Enhanced tubes for augmentation of single-phase heat transfer. (a) Corrugated or spirally indented tube with internal protuberances. (b) Integral external fins. (c) Integral internal fins. (d) Deep spirally fluted tube. (e) Static mixer inserts. (f) Wire-wound insert.

*Fluid vibration* is the practical type of vibration enhancement because of the mass of most heat exchangers. The vibrations range from pulsations of about 1 Hz to ultrasound. Single-phase fluids are of primary concern.

*Electrostatic fields* (DC or AC) are applied in many different ways to dielectric fluids. Generally speaking, electrostatic fields can be directed to cause greater bulk mixing or fluid or disruption of fluid flow in the vicinity of the heat transfer surface, which enhances heat transfer.

*Injection* is utilized by supplying gas to a stagnant or flowing liquid through a porous heat transfer surface or by injecting similar fluid upstream of the heat transfer section. Surface degassing of liquids can produce enhancement similar to gas injection. Only single-phase flow is of interest.

*Suction* involves vapor removal, in nucleate or film boiling, or fluid withdrawal, in single-phase flow, through a porous heated surface.

Two or more of the above techniques may be utilized simultaneously to produce an enhancement that is larger than either of the techniques operating separately. This is termed *compound enhancement*.

It should be emphasized that one of the motivations for studying enhanced heat transfer is to assess the effect of an inherent condition on heat transfer. Some practical examples include roughness produced by standard manufacturing, degassing of liquids with high gas content, surface vibration resulting from rotating machinery or flow oscillations, fluid vibration resulting from pumping pulsation, and electrical fields present in electrical equipment.

The surfaces in [Figure 4.8.1](#) have been used for both single-phase and two-phase heat transfer enhancement. The emphasis is on effective and cost-competitive (proved or potential) techniques that have made the transition from the laboratory to commercial heat exchangers.

### Single-Phase Free Convection

With the exception of the familiar technique of providing extended surfaces, the passive techniques have little to offer in the way of enhanced heat transfer for free convection. This is because the velocities are usually too low to cause flow separation or secondary flow.

The restarting of thermal boundary layers in interrupted extended surfaces increases heat transfer so as to more than compensate for the lost area.

Mechanically aided heat transfer is a standard technique in the chemical and food industries when viscous liquids are involved. The predominant geometry for surface vibration has been the horizontal cylinder, vibrated either horizontally or vertically. Heat transfer coefficients can be increased tenfold for both low-frequency/high-amplitude and high-frequency/low-amplitude situations. It is, of course, equally effective and more practical to provide steady forced flow. Furthermore, the mechanical designer is concerned that such intense vibrations could result in equipment failures.

Since it is usually difficult to apply surface vibrations to practical equipment, an alternative technique is utilized whereby vibrations are applied to the fluid and focused toward the heated surface. With proper transducer design, it is also possible to improve heat transfer to simple heaters immersed in gases or liquids by several hundred percent.

Electric fields are particularly effective in increasing heat transfer coefficients in free convection. Dielectrophoretic or electrophoretic (especially with ionization of gases) forces cause greater bulk mixing in the vicinity of the heat transfer surface. Heat transfer coefficients may be improved by as much as a factor of 40 with electrostatic fields up to 100,000 V. Again, the equivalent effect could be produced at lower capital cost and without the voltage hazard by simply providing forced convection with a blower or fan.

### Single-Phase Forced Convection

The present discussion emphasizes enhancement of heat transfer *inside* ducts that are primarily of circular cross section. Typical data for turbulence promoters inserted inside tubes are shown in [Figure 4.8.2](#). As shown in [Figure 4.8.2a](#), the promoters produce a sizable elevation in the Nusselt number, or heat transfer coefficient, at constant Reynolds number, or velocity. However, as shown in [Figure 4.8.2b](#), there is an accompanying large increase in the friction factor.

Surface roughness has been used extensively to enhance forced convection heat transfer. Integral roughness may be produced by the traditional manufacturing processes of machining, forming, casting, or welding. Various inserts can also provide surface protuberances. In view of the infinite number of possible geometric variations, it is not surprising that, even after more than 300 studies, no completely satisfactory unified treatment is available.

In general, the maximum enhancement of laminar flow with many of the techniques is the same order of magnitude, and seems to be independent of the wall boundary condition. The enhancement with some rough tubes, corrugated tubes, inner-fin tubes, various static mixers, and twisted-type inserts is about 200%. The improvements in heat transfer coefficient with turbulent flow in rough tubes (based on nominal surface area) are as much as 250%. Analogy solutions for sand-grain-type roughness and for square-repeated-rib roughness have been proposed. A statistical correlation is also available for heat transfer coefficient and friction factor.

The following correlations are recommended for tubes with transverse or helical repeated ribs ([Figure 4.8.1a](#)) with turbulent flow (Ravigururajan and Bergles, 1985):

$$\text{Nu}_{D_{t,a}}/\text{Nu}_{D_{t,s}} = \left\{ 1 + \left[ 2.64\text{Re}^{0.036} (e/D_i)^{0.212} \left( (p/D_i)^{-0.21} \right) (\alpha/90)^{0.29} (\text{Pr})^{-0.024} \right]^7 \right\}^{1/7} \quad (4.8.1)$$

**FIGURE 4.8.2** Typical data for turbulence promoters inserted inside tubes: (a) heat transfer data, (b) friction data. (From Bergles, 1969. With permission.)

$$\begin{aligned}
 f_a/f_s = & \left\{ 1 + \left[ 29.1 Re_{D_i}^{(0.67-0.06p/D_i-0.49\alpha/90)} \times (e/D_i)^{(0.37-0.157p/D_i)} \times (p/D_i)^{(-1.66 \times 10^{-6} Re_{D_i} - 0.33\alpha/90)} \right. \right. \\
 & \left. \left. \times (\alpha/90)^{(4.59+4.11 \times 10^{-6} Re_{D_i} - 0.15p/D_i)} \times \left( 1 + \frac{2.94}{n} \right) \sin \beta \right]^{15/16} \right\}^{16/15}
 \end{aligned}
 \tag{4.8.2}$$

where the subscript *a* refers to the enhanced tube and the subscript *s* refers to the smooth tube. The special symbols are given as follows: *e* = protuberance height; *p* = repeated-rib pitch;  $\alpha$  = spiral angle for helical ribs,  $^\circ$ ; *n* = number of sharp corners facing the flow; and  $\beta$  = contact angle of rib profile,  $^\circ$ . Also,

$$Nu_s = 0.125 f Re_{D_i} Pr / \left( 1 + 12.7 (0.125 f)^{0.5} Pr^{0.667} - 1 \right)$$

and

$$f_s = \left( 1.82 \log_{10} Re_{D_i} - 1.64 \right)^{-2*}$$

Much work has been done to obtain the enhanced heat transfer of parallel angled ribs in short rectangular channels, simulating the interior of gas turbine blades. Jets are frequently used for heating, cooling, and drying in a variety of industrial applications. A number of studies have reported that roughness elements of the transverse-repeated-rib type mitigate the deterioration in heat transfer downstream of stagnation.

Extended surfaces can be considered “old technology” as far as most applications are concerned. The real interest now is in increasing heat transfer coefficients on the extended surface. Compact heat exchangers of the plate-fin or tube-and-center variety use several enhancement techniques: offset strip fins, louvered fins, perforated fins, or corrugated fins. Coefficients are several hundred percent above the

\* The Fanning friction factor is used throughout this section.

smooth-tube values; however, the pressure drop is also substantially increased, and there may be vibration and noise problems.

For the case of offset strip fins the following correlations are recommended for calculating the  $j$  and  $f$  characteristics (Manglik and Bergles, 1990)

$$j_h = 0.6522 \text{Re}_h^{-0.5403} \alpha^{-0.1541} \delta^{0.1499} \gamma^{-0.0678} \times [1 + 5.269 \times 10^{-5} \text{Re}_h^{1.340} \alpha^{0.504} \delta^{0.456} \gamma^{-1.055}]^{0.1} \quad (4.8.3)$$

$$f_h = 9.6243 \text{Re}_h^{-0.7422} \alpha^{-0.1856} \delta^{0.3053} \gamma^{-0.2659} \times [1 + 7.669 \times 10^{-8} \text{Re}_h^{4.429} \alpha^{0.920} \delta^{3.767} \gamma^{0.236}]^{0.1} \quad (4.8.4)$$

where  $j_H$  (the heat transfer  $j$ -factor  $\text{Nu}_H/\text{Re}_H\text{Pr}^{1/3}$ ), and  $f_h$ , and  $\text{Re}_h$  are based on the hydraulic diameter given by

$$D_h = 4shl/[2(sl + hl + th) + ts] \quad (4.8.5)$$

Special symbols are  $\alpha$  = aspect ratio  $s/h$ ,  $\delta$  = ratio  $t/l$ ,  $\gamma$  = ratio  $t/s$ ,  $s$  = lateral spacing of strip fin,  $h$  = strip fin height,  $l$  = length of one offset module of strip fins, and  $t$  = fin thickness.

These equations are based on experimental data for 18 different offset strip-fin geometries, and they represent the data continuously in the laminar, transition, and turbulent flow regions.

Internally finned circular tubes are available in aluminum and copper (or copper alloys). Correlations (for heat transfer coefficient and friction factor) are available for laminar flow, for both straight and spiral continuous fins.

Turbulent flow in tubes with straight or helical fins (Figure 4.8.1c) was correlated by (Carnavos, 1979)

$$\text{Nu}_h = 0.023 \text{Pr}^{0.4} \text{Re}_h^{0.8} \left[ \frac{A_c}{A_{ci}} \right]^{0.1} \left[ \frac{A_{s,i}}{A_s} \right]^{0.5} (\sec \alpha)^3 \quad (4.8.6)$$

$$f_h = 0.046 \text{Re}_h^{-0.2} \left[ \frac{A_c}{A_{ci}} \right]^{0.5} (\sec \alpha)^{0.75} \quad (4.8.7)$$

where  $A_{c,i}$  is based on the maximum inside (envelope) flow area,  $A_{s,i}$  is based on the maximum inside (envelope) surface area, and  $\alpha$  the spiral angle for helical fins, °.

A numerical analysis of turbulent flow in tubes with idealized straight fins was reported. The necessary constant for the turbulence model was obtained from experimental data for air. Further improvements in numerical techniques are expected, so that a wider range of geometries and fluids can be handled without resort to extensive experimental programs.

Many proprietary surface configurations have been produced by deforming the basic tube. The “convoluted,” “corrugated,” “spiral,” or “spirally fluted” tubes (Figure 4.8.1a) have multiple-start spiral corrugations, which add area, along the tube length. A systematic survey of the single-tube performance of condenser tubes indicates up to 400% increase in the nominal inside heat transfer coefficient (based on diameter of a smooth tube of the same maximum inside diameter); however, pressure drops on the water side are about 20 times higher.

Displaced enhancement devices are typically in the form of inserts, within elements arranged to promote transverse mixing (static mixers, Figure 4.8.1e). They are used primarily for viscous liquids, to promote either heat transfer or mass transfer. Displaced promoters are also used to enhance the radiant heat transfer in high-temperature applications. In the flue-tube of a hot-gas-fired hot water heater, there is a trade-off between radiation and convection. Another type of displaced insert generates vortices, which enhance the downstream flow. Delta-wing and rectangular wing promoters, both co-rotating and

counterrotating, have been studied. Wire-loop inserts (Figure 4.8.1f) have also been used for enhancement of laminar and turbulent flow.

Twisted-tape inserts have been widely used to improve heat transfer in both laminar and turbulent flow. Correlations are available for laminar flow, for both uniform heat flux and uniform wall temperature conditions. Turbulent flow in tubes with twisted-tape inserts has also been correlated. Several studies have considered the heat transfer enhancement of a decaying swirl flow, generated, say, by a short twisted-tape insert.

### Performance Evaluation Criteria for Single-Phase Forced Convection in Tubes

Numerous, and sometimes conflicting, factors enter into the ultimate decision to use an enhancement technique: heat duty increase or area reduction that can be obtained, initial cost, pumping power or operating cost, maintenance cost (especially cleaning), safety, and reliability, among others. These factors are difficult to quantitize, and a generally acceptable selection criterion may not exist. It is possible, however, to suggest some performance criteria for preliminary design guidance. As an example, consider the basic geometry and the pumping power fixed, with the objective of increasing the heat transfer. The following ratio is then of interest

$$R_3 = \left( \frac{h_a}{h_s} \right)_{D_i, L, N, P, T_{in}, \Delta T} = \frac{(\text{Nu}/\text{Pr}^{0.4})_a}{(\text{Nu}/\text{Pr}^{0.4})_s} = \frac{q_a}{q_s} \quad (4.8.8)$$

where  $P$  = pumping power,  $T_{in}$  = inlet bulk temperature of fluid, and  $\Delta T$  = average wall-fluid temperature difference.

With the pumping power (neglecting entrance and exit losses) given as

$$P = NVA_c 4f(L/D)\rho V^2/2 \quad (4.8.9)$$

and

$$f_s = 0.046/\text{Re}_s^{0.2} \quad (4.8.10)$$

$$A_{c,a} f_a \text{Re}_a^3 = 0.046 A_{c,s} \text{Re}_s^{2.8} \quad (4.8.11)$$

The calculation best proceeds by picking  $\text{Re}_{D_i,a}$ , and reading  $\text{Nu}_{D_i,a}/\text{Pr}^{0.4}$  and  $f_a$ .  $\text{Re}_{D_i,s}$  is then obtained from Equation (4.8.11) and  $\text{Nu}_{D_i,s}/\text{Pr}^{0.4}$  obtained from a conventional, empty-tube correlation. The desired ratio of Equation (4.8.8) is then obtained. Typical results are presented in Figure 4.8.3 for a repeated-rib roughness (Bergles et al., 1974).

### Active and Compound Techniques for Single-Phase Forced Convection

Under active techniques, mechanically aided heat transfer in the form of surface scraping can increase forced convection heat transfer. Surface vibration has been demonstrated to improve heat transfer to both laminar and turbulent duct flow of liquids. Fluid vibration has been extensively studied for both air (loudspeakers and sirens) and liquids (flow interrupters, pulsators, and ultrasonic transducers). Pulsations are relatively simple to apply to low-velocity liquid flows, and improvements of several hundred percent can be realized.

Some very impressive enhancements have been recorded with electrical fields, particularly in the laminar-flow region. Improvements of at least 100% were obtained when voltages in the 10-kV range were applied to transformer oil. It is found that even with intense electrostatic fields, the heat transfer enhancement disappears as turbulent flow is approached in a circular tube with a concentric inner electrode.

**FIGURE 4.8.3** Constant pumping power performance criterion applied to repeated rib roughness.

Compound techniques are a slowly emerging area of enhancement that holds promise for practical applications, since heat transfer coefficients can usually be increased above each of the several techniques acting along. Some examples that have been studied are as follows: rough tube wall with twisted-tape inserts, rough cylinder with acoustic vibrations, internally finned tube with twisted-tape inserts, finned tubes in fluidized beds, externally finned tubes subjected to vibrations, rib-roughened passage being rotated, gas-solid suspension with an electrical field, fluidized bed with pulsations of air, and a rib-roughened channel with longitudinal vortex generation.

### Pool Boiling

Selected passive and active enhancement techniques have been shown to be effective for pool boiling and flow boiling/evaporation. Most techniques apply to nucleate boiling; however, some techniques are applicable to transition and film boiling.

It should be noted that phase-change heat transfer coefficients are relatively high. The main thermal resistance in a two-fluid heat exchanger often lies on the non-phase-change side. (Fouling of either side can, of course, represent the dominant thermal resistance.) For this reason, the emphasis is often on enhancement of single-phase flow. On the other hand, the overall thermal resistance may then be reduced to the point where significant improvement in the overall performance can be achieved by enhancing the two-phase flow. Two-phase enhancement would also be important in double-phase-change (boiling/condensing) heat exchangers.

As discussed elsewhere, surface material and finish have a strong effect on nucleate and transition pool boiling. However, reliable control of nucleation on plain surfaces is not easily accomplished. Accordingly, since the earliest days of boiling research, there have been attempts to relocate the boiling curve through use of relatively gross modification of the surface. For many years, this was accomplished simply by area increase in the form of low helical fins. The subsequent tendency was to structure surfaces to improve the nucleate boiling characteristics by a fundamental change in the boiling process. Many of these advanced surfaces are being used in commercial shell-and-tube boilers.

Several manufacturing processes have been employed: machining, forming, layering, and coating. In Figure 4.8.4a standard low-fin tubing is shown. Figure 4.8.4c depicts a tunnel-and-pore arrangement produced by rolling, upsetting, and brushing. An alternative modification of the low fins is shown in Figure 4.8.4d, where the rolled fins have been split and rolled to a T shape. Further modification of the internal, Figure 4.8.4e, or external, Figure 4.8.4f, surface is possible. Knurling and rolling are involved in producing the surface shown in Figure 4.8.4g. The earliest example of a commercial structured surface, shown in Figure 4.8.4b is the porous metallic matrix produced by sintering or brazing small particles. Wall superheat reductions of up to a factor of ten are common with these surfaces. The advantage is not

**FIGURE 4.8.4** Examples of commercial structured boiling surfaces. (From Pate, M.B. et al., in *Compact Heat Exchangers*, Hemisphere Publishing, New York, 1990. With permission.)

only a high nucleate boiling heat transfer coefficient, but the fact that boiling can take place at very low temperature differences.

These structured boiling surfaces, developed for refrigeration and process applications, have been used as “heat sinks” for immersion-cooled microelectronic chips.

The behavior of tube bundles is often different with structured-surface tubes. The enhanced nucleate boiling dominates, and the convective boiling enhancement, found in plain tube bundles, does not occur.

Active enhancement techniques include heated surface rotation, surface wiping, surface vibration, fluid vibration, electrostatic fields, and suction at the heated surface. Although active techniques are effective in reducing the wall superheat and/or increasing the critical heat flux, the practical applications are very limited, largely because of the difficulty of reliably providing the mechanical or electrical effect.

Compound enhancement, which involves two or more techniques applied simultaneously, has also been studied. Electrohydrodynamic enhancement was applied to a finned tube bundle, resulting in nearly a 200% increase in the average boiling heat transfer coefficient of the bundle, with a small power consumption for the field.

### Convective Boiling/Evaporation

The structured surfaces described in the previous section are generally not used for in-tube vaporization, because of the difficulty of manufacture. One notable exception is the high-flux surface in a vertical thermosiphon reboiler. The considerable increase in the low-quality, nucleate boiling coefficient is desirable, but it is also important that more vapor is generated to promote circulation.

Helical repeated ribs and helically coiled wire inserts have been used to increase vaporization coefficients and the dry-out heat flux in once-through boilers.

Numerous tubes with internal fins, either integral or attached, are available for refrigerant evaporators. Original configurations were tightly packed, copper, offset strip fin inserts soldered to the copper tube or aluminum, star-shaped inserts secured by drawing the tube over the insert. Examples are shown in [Figure 4.8.5](#). Average heat transfer coefficients (based on surface area of smooth tube of the same diameter) for typical evaporator conditions are increased by as much as 200%. A cross-sectional view of a typical “microfin” tube is included in [Figure 4.8.5](#). The average evaporation boiling coefficient is

**FIGURE 4.8.5** Inner-fin tubes for refrigerant evaporators: (a) Strip-fin inserts, (b) Star-shaped inserts, (c) Microfin.

increased 30 to 80%. The pressure drop penalties are less; that is, lower percentage increases in pressure drop are frequently observed.

Twisted-tape inserts are generally used to increase the burnout heat flux for subcooled boiling at high imposed heat fluxes  $10^7 - 10^8 \text{ W/m}^2$ , as might be encountered in the cooling of fusion reactor components. Increases in burnout heat flux of up to 200% were obtained at near atmospheric pressure.

### Vapor-Space Condensation

As discussed elsewhere, condensation can be either filmwise or dropwise. In a sense, dropwise condensation is enhancement of the normally occurring film condensation by surface treatment. The only real application is for steam condensers, because nonwetting coatings are not available for most other working fluids. Even after much study, little progress has been made in developing permanently hydrophobic coatings for practical steam condensers. The enhancement of dropwise condensation is pointless, because the heat transfer coefficients are already so high.

Surface extensions are widely employed for enhancement of condensation. The integral low fin tubing (Figure 4.8.4a), used for kettle boilers, is also used for horizontal tube condensers. With proper spacing of the fins to provide adequate condensate drainage, the average coefficients can be several times those of a plain tube with the same base diameter. These fins are normally used with refrigerants and other organic fluids that have low condensing coefficients, but which drain effectively, because of low surface tension.

The fin profile can be altered according to mathematical analysis to take full advantage of the Gregorig effect, whereby condensation occurs mainly at the tops of convex ridges. Surface tension forces then pull the condensate into concave grooves, where it runs off. The average heat transfer coefficient is greater than that for an axially uniform film thickness. The initial application was for condensation of steam on vertical tubes used for reboilers and in desalination. According to numerical solutions, the optimum geometry is characterized by a sharp fin tip, gradually changing curvature of the fin surface from tip to root, wide grooves between fins to collect condensate, and periodic condensate strippers. Figure 4.8.6 schematically presents the configuration.

**FIGURE 4.8.6** Recommended flute profile and schematic of condensate strippers.

Recent interest has centered on three-dimensional surfaces for horizontal-tube condensers. The considerable improvement relative to low fins or other two-dimensional profiles is apparently due to multidimensional drainage at the fin tips. Other three-dimensional shapes include circular pin fins, square pins, and small metal particles that are bonded randomly to the surface.

### Convective Condensation

This final section on enhancement of the various modes of heat transfer focuses on in-tube condensation. The applications include horizontal kettle-type reboilers, moisture separator reheaters for nuclear power plants, and air-conditioner condensers.

Internally grooved or knurled tubes, deep spirally fluted tubes, random roughness, conventional inner-fin tubes have been shown to be effective for condensation of steam and other fluids.

The microfin tubes mentioned earlier have also been applied successfully to in-tube condensing. As in the case of evaporation, the substantial heat transfer improvement is achieved at the expense of a lesser percentage increase in pressure drop. By testing a wide variety of tubes, it has been possible to suggest some guidelines for the geometry, e.g., more fins, longer fins, and sharper tips; however, general correlations are not yet available. Fortunately for heat-pump operation, the tube that performs best for evaporation also performs best for condensation.

Twisted-tape inserts result in rather modest increases in heat transfer coefficient for complete condensation of either steam or refrigerant. The pressure drop increases are large because of the large wetted surface. Coiled tubular condensers provide a modest improvement in average heat transfer coefficient.

## Further Information

This section gives some indication as to why heat transfer enhancement is one of the fastest growing areas of heat transfer. Many techniques are available for improvement of the various modes of heat transfer. Fundamental understanding of the transport mechanism is growing, but, more importantly, design correlations are being established. Many effective and cost-competitive enhancement techniques have made the transition from the laboratory to commercial heat exchangers.

Broad reviews of developments in enhanced heat transfer are available (Bergles, 1985; Bergles, 1988; Thome, 1990; Webb, 1994, Bergles, 1997). Also, several journals, especially *Heat Transfer Engineering*, *Enhanced Heat Transfer*, and *International Journal of Heating, Ventilating, Air-Conditioning and Refrigerating Research*, feature this technology.

## Cooling Towers

*Anthony F. Mills*

### Introduction

In a wet cooling tower, water is evaporated into air with the objective of cooling the water stream. Both natural- and mechanical-draft towers are popular, and examples are shown in [Figure 4.8.7](#). Large natural-draft cooling towers are used in power plants for cooling the water supply to the condenser. Smaller mechanical-draft towers are preferred for oil refineries and other process industries, as well as for central air-conditioning systems and refrigeration plant. [Figure 4.8.7a](#) shows a natural draft *counterflow* unit in which the water flows as thin films down over a suitable packing, and air flows upward. In a natural-draft tower the air flows upward due to the buoyancy of the warm, moist air leaving the top of the packing. In a mechanical-draft tower, the flow is forced or induced by a fan. Since the air inlet temperature is usually lower than the water inlet temperature, the water is cooled both by evaporation and by sensible heat loss. For usual operating conditions the evaporative heat loss is considerably larger than the sensible heat loss. [Figure 4.8.7b](#) shows a mechanical draft cross-flow unit. [Figure 4.8.8](#) shows a natural-draft cross-flow tower for a power plant.

### Packing Thermal Performance

*Counterflow units.* Merkel's method (Merkel, 1925) for calculating the number of transfer units required to cool the water stream, for specified inlet and outlet water temperatures and inlet air condition is (Mills, 1995)

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \int_{h_{L,in}}^{h_{L,out}} \frac{dh_L}{h_s - h_G} \quad (4.8.12)$$

$$h_G = h_{G,in} + (\dot{m}_L / \dot{m}_G)(h_L - h_{L,out}) \quad (4.8.13)$$

$$h_s(P, T_s) = h_s(P, T_L) \quad (4.8.14)$$

It is imperative that the usual enthalpy datum states be used, namely, zero enthalpy for dry air and liquid water at 0°C. [Table 4.8.1](#) gives enthalpy data for 1 atm pressure. The important assumptions required to obtain this result include

1. A Lewis number of unity;
2. Low mass transfer rate theory is valid;
3. The liquid-side heat transfer resistance is negligible, that is,  $T_s \approx T_L$ ;
4. The amount of water evaporated is small compared with the water and air flow rates.

**FIGURE 4.8.7** (a) A natural-draft counterflow cooling tower for a power plant. (b) A cross-flow cooling tower for an air-conditioning system.

The method is accurate up to temperatures of about  $60^{\circ}\text{C}$ ; comparisons with more exact results are usually within 3 to 5%, and seldom show errors greater than 10%. Notice that the method does not give the outlet state of the air; however, in situations encountered in practice, the outlet air can be assumed to be saturated for the purposes of calculating its density. It is possible to extend Merkel's method to include a finite liquid-side heat transfer resistance, but such refinement is seldom warranted. For typical operating conditions the bulk liquid temperature is seldom more than 0.3 K above the interface temperature.

*Cross-flow units.* Figure 4.8.9 shows a schematic of a cross-flow packing. If we assume that both the liquid and gas streams are unidirectional, and that there is no mixing in either stream, then use of Merkel's assumptions leads to the following pair of differential equations (Mills, 1995):

**FIGURE 4.8.8** A natural-draft cross-flow cooling tower for a power plant.

$$\frac{\partial h_G}{\partial x} = \frac{g_m a}{G} (h_s - h_G) \quad (4.8.15)$$

$$\frac{\partial h_L}{\partial y} = -\frac{g_m a}{L} (h_s - h_G) \quad (4.8.16)$$

Also  $h_s = h_s(h_L)$  for a negligible liquid-side heat transfer resistance and the required boundary conditions are the inlet enthalpies of both streams. Equations (4.8.15) and (4.8.16) are solved numerically and the solution used to evaluate the average enthalpy of the outlet liquid,

$$\bar{h}_{L,\text{out}} = \frac{1}{X} \int_0^X h_{L,\text{out}} dx \quad (4.8.17)$$

Substituting in an exchanger energy balance on the liquid stream gives the heat transfer as

$$q = \dot{m}_L (h_{L,\text{in}} - h_{L,\text{out}}) \quad (4.8.18)$$

<sup>a</sup> The enthalpies of dry air and liquid water are set equal to zero at a datum temperature of 0°C.

<sup>b</sup> The enthalpy of an unsaturated water vapor-air mixture can be calculated as  $h = h_{\text{dry air}} + (m_v/m_{v,\text{sat}})(h_{\text{sat}} - h_{\text{dry air}})$ .

*Sample calculation.* Consider a counterflow unit that is required to cool water from 40 to 26°C when the inlet air is at 10°C, 1 atm, and saturated. We will calculate the number of transfer units required for balanced flow, that is,  $\dot{m}_G/\dot{m}_L = 1$ . Equation (4.8.12) is to be integrated numerically, with  $h_G$  obtained from Equation 4.8.13. The required thermodynamic properties can be obtained from Table 4.8.1. Using Table 4.8.1,  $h_{G,\text{in}} = h_{\text{sat}}(10^\circ\text{C}) = 29.15$  kJ/kg,  $h_{L,\text{out}} = h_L(26^\circ\text{C}) = 109.07$  kJ/kg. Substituting in Equation (4.8.13),

$$h_G = 29.15 + (h_L - 109.07)$$

$T_L, ^\circ\text{C}$	$h_L, \text{kJ/kg}$	$h_G, \text{kJ/kg}$	$h_s, \text{kJ/kg}$	$h_s - h_g, \text{kJ/kg}$	$\frac{1}{h_s - h_g}$
26	109.07	29.15	79.12	49.97	0.02001
28	117.43	37.51	87.86	50.35	0.01986
30	125.79	45.87	97.36	51.49	0.01942
32	134.15	54.23	107.67	53.44	0.01871
34	142.50	62.58	118.89	56.31	0.01776
36	150.86	70.94	131.10	60.16	0.01662
38	159.22	79.30	144.39	65.09	0.01536
40	167.58	87.66	158.86	71.20	0.01404

Choosing 2°C intervals for convenient numerical integration, the above table is constructed, with  $h_L$  and  $h_s = h_s(T_L)$  also obtained from Table 4.8.1. Using the trapezoidal rule,

$$\int_{h_{L,out}}^{h_{L,in}} \frac{dh_L}{h_s - h_G} = \frac{8.36}{2} [0.02001 + 2(0.01986 + 0.01942 + 0.01871 + 0.01776 + 0.01662 + 0.01536) + 0.01404]$$

$$= 1.043$$

From Equation (4.8.12),  $N_{tu} = 1.043$ . Also, by using Table 4.8.1,  $T_{G,out} = 27.9^\circ$  for saturated outlet air.

FIGURE 4.8.9 Schematic of a cross-flow cooling tower packing showing the coordinate system.

### Thermal-Hydraulic Design of Cooling Towers

The thermal-hydraulic design of a mechanical-draft cooling tower is relatively straightforward. The flow rate ratio  $\dot{m}_L/\dot{m}_G$  can be specified and varied parametrically to obtain an optimal design, for which the size and cost of the packing is balanced against fan power requirements and operating cost. Data are required for mass transfer conductances and friction for candidate packings. Tables 4.8.2a and b give correlations for a selection of packings. In Table 4.8.2b, the mass transfer conductance is correlated as  $g_m a/L$ , where  $a$  is the transfer area per unit volume and  $L = \dot{m}_L/A_{fr}$  is the superficial mass velocity of the water flow (also called the *water loading* on the packing). Similarly, we define  $G = \dot{m}_G/A_{fr}$ . Typical water loadings are 1.8 to 2.7 kg/m<sup>2</sup> sec, and superficial air velocities fall in the range 1.5 to 4 m/sec. No attempt is made to correlate  $g_m$  and  $a$  separately. The number of transfer units of a packing of height  $H$  is then

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} \quad (4.8.19)$$

7. Marley α-bar, parallel to air flow, 16 × 4 in. spacing
8. Marley ladder, parallel to air flow, 8 × 2 in. spacing

The correlations are in terms of dimensionless mass velocities  $L^+$  and  $G^+$ , and a *hot water correction*  $T_{HW}^+$ . The hot water correction accounts for a number of factors, such as errors associated with Merkel's method, deviations from low mass transfer rate theory at higher values of  $T_s$ , and fluid property dependence on temperature. Frictional resistance to air flow through the packings is correlated as a *loss coefficient*  $N = \Delta P / (\rho V^2 / 2)$  per unit height or depth of packing, as a function of  $L^+$  and  $G^+$ . The velocity  $V$  is superficial gas velocity. No hot water correction is required.

In a natural-draft tower, the thermal and hydraulic performance of the tower are coupled, and the flow rate ratio  $\dot{m}_L / \dot{m}_G$  cannot be specified *a priori*. The buoyancy force producing the air flow depends on the state of the air leaving the packing which in turn depends on  $\dot{m}_L / \dot{m}_G$  and the inlet air and water states. An iterative solution is required to find the operating point of the tower. The buoyancy force available to overcome the shell and packing pressure drops is

$$\Delta P^B = g(\rho_a - \rho_{G,out})H \quad (4.8.20)$$

where  $\rho_a$  is the ambient air density and  $H$  is usually taken as the distance from the bottom of the packing to the top of the shell. The various pressure drops are conveniently expressed as

$$\Delta P_i = N_i \frac{\rho_{Gi} V_i^2}{2} \quad (4.8.21)$$

"Heat transfer and pressure drop data on cooling tower packings, and model studies of the resistance of natural draft towers to airflow" Paper 113, *International Developments in Heat Transfer, Proc. of the International Heat Transfer Conference*, Boulder, CO, ASME, New York; Johnson, B.M., Ed. 1990. *Cooling Tower Performance Prediction and Improvement*, Vols. 1 and 2, EPRI GS-6370, Electric Power Research Institute, Palo Alto, CA. With permission.

Where  $N_i$  is the loss coefficient and  $V_i$  is the air velocity at the corresponding location. The pressure drops are associated with the shell, the packing, the mist eliminators, supports and pipes, and the water spray below the packing. Some sample correlations are given in Table 4.8.3.

Water loadings in counterflow natural-draft towers typically range from 0.8 to 2.4 kg/m<sup>2</sup> sec, and superficial air velocities range from 1 to 2 m/sec. The ratio of base diameter to height may be 0.75 to 0.85, and the ratio of throat to base diameter 0.55 to 0.65. The height of the air inlet is usually 0.10 to 0.12 times the base diameter to facilitate air flow into the tower. In practice the air flow distribution in natural-draft towers is not very uniform. However, the assumption of uniform air and water flows in our model of counterflow packing is adequate for most design purposes.

Cost-optimal design of cooling towers requires consideration of the complete power or refrigeration system. For refrigeration, the economics are determined mainly by the operating cost of the chiller (Kintner-Meyer and Emery, 1955).

**TABLE 4.8.3 Pressure Drop Correlations for Cooling Tower Shells, Sprays, Supports, and Mist Eliminators**

---

1.	Shell (natural draft counterflow):  $N = 0.167 \left( \frac{D_B}{b} \right)^2$ where $D_B$ is the diameter of the shell base and $b$ is the height of the air inlet.
2.	Spray (natural-draft counterflow): $N = 0.526(Z_p[\text{m}] + 1.22) (\dot{m}_L / \dot{m}_G)^{1.32}$
3.	Mist eliminators: $N = 2-4$
4.	Support columns, pipes, etc. (natural-draft counterflow): $N = 2-6$
5.	Fan exit losses for mechanical-draft towers (velocity based on fan exit area): $N = 1.0, \text{ forced draft}$ $\approx 0.5, \text{ induced draft, depending on diffuser design}$
6.	Miscellaneous losses for mechanical-draft towers (velocity based on packing crosssectional area): $N \approx 3$

---

*Note:*  $N$  is the loss coefficient defined by Equation 4.8.21, with velocity based on cross-sectional area for air flow underneath the packing in items 1 through 4.

### Cooling Tower Behavior

There are a number of computer programs available that use variations of Merkel's method to calculate the cooling tower performance, for example, TEFRI (Bourillot, 1983), VERA2D-84 (Mujamdar et al., 1985), CTOWER (Mills, 1995). These programs can be used to perform parametric studies to obtain the response of cooling towers to environmental, duty, and design changes. However, before using such programs, some thought should be given to the important characteristics of cooling tower behavior. For this purpose, it is useful to consider a graphical representation of Merkel's theory for a counterflow tower. Figure 4.8.10 shows a chart with moist air enthalpy plotted vs. water enthalpy (or, equivalently, water temperature) at 1 atm pressure. The *saturation curve*  $h_s(T_s)$  is the enthalpy of saturated air. The *operating lines*  $h_G(h_L)$  are given by Equation (4.8.13) and relate the air enthalpy to the water enthalpy at each location in the packing. The slope of an operating line is  $L/G$ . Since the assumption  $T_s = T_L$  is made in Merkel's method, vertical lines on the chart connect  $h_s$  and  $h_G$  at each location in the packing. The driving force for enthalpy transfer,  $(h_s - h_G)$ , is the vertical distance between the saturation curve and the operating line. The integral in Equation (4.8.12) averages the reciprocal of this distance. By using this chart, a number of observations about cooling tower behavior can be made.

- Figure 4.8.10 shows the effect of  $L/G$  for fixed water inlet and outlet temperatures, and fixed inlet air temperature and humidity. If we imagine  $L$  to be fixed as well, we see that as  $G$  decreases, the driving forces decrease, and so a larger NTU is required.
- The minimum NTU required corresponds to  $L/G = 0$ , that is, an infinite air flow rate, for which the operating line is horizontal.
- Due to the curvature of the operating line, it is possible for the operating line to be tangent to the saturation curve. The indicated NTU is then infinite, which tells us that the air flow rate must be increased in order to achieve the desired water cooling range.

**FIGURE 4.8.10** Counterflow cooling tower operating lines for various water-to-air flow-rate ratios shown on an enthalpy chart.

4. For a mechanical-draft tower, the optimal value of  $L/G$  lies between the two limits described in items 2 and 3 above. If  $L/G$  is large, the required height of packing is large, and the capital cost will be excessive. If  $L/G$  is small, the fan power will be excessive (since fan power is proportional to air volume flow rate times pressure drop).

**Range and Approach**

Cooling tower designers and utility engineers have traditionally used two temperature differences to characterize cooling tower operation. The *range* is the difference between the water inlet and outlet temperatures (also called simply the hot and cold water temperatures). The *approach* is the difference between the outlet water temperature and the wet-bulb temperature of the entering (ambient) air. The approach characterizes cooling tower performance; for a given inlet condition, a larger packing will produce a smaller approach to the ambient wet-bulb temperature, and hence a lower water outlet temperature. (The water cannot be cooled below the ambient wet-bulb temperature.) The approach concept is useful because the ambient dry-bulb temperature has little effect on performance at usual operating conditions (for a specified wet-bulb temperature).

**Cooling Demand Curves**

Electrical utility engineers have found it convenient to use charts of *cooling demand curves* to evaluate packing specifications. Figure 4.8.11 is an example of such a chart, on which the required NTU, for a given inlet air wet-bulb temperature and range, is plotted vs.  $L/G$  with the approach as a parameter. Such a plot is possible since the inlet air dry-bulb temperature has only a small effect under usual operating conditions. Now, if it is possible to correlate the mass transfer conductance as

$$\frac{g_m a}{L} = C \left( \frac{L}{G} \right)^{-n} \tag{4.8.22}$$

the NTU of a packing of height  $H$  is

$$\frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} = C \left( \frac{L}{G} \right)^{-n} H \tag{4.8.23}$$

**FIGURE 4.8.11** Example of cooling demand curves for a specified wet-bulb temperature and range: NTU vs. flow rate ratio for a fixed approach.

Equation (4.8.23) can also be plotted on the chart to give the *packing capability line*. For a required approach, the *operating point* of the tower is the intersection of the cooling demand curve and packing capability line. Charts of cooling demand curves are available (Cooling Tower Institute, 1967; Kelly, 1976). Correlations of the form of Equation (4.8.22) do not necessarily fit experimental data well. A dependence  $g_m a \propto L^{-n} G^n$  is implied and, in the past, experimental data were often forced to fit such a relation. If the  $g_m a$  correlation does not have the form of Equation (4.8.22), the NTU cannot be plotted as a line on a cooling demand chart.

With the almost universal use of computers and the availability of suitable computer programs, one can expect less use of cooling demand charts in the future. The major sources of error in the predictions made by these programs are related to nonuniform air and water flow, and the correlations of packing mass transfer and pressure drop experimental data. The experimental data are obtained in small-scale test rigs, in which it is impossible to simulate many features of full-size towers — for example, nonuniform flow due to entrance configuration, nonuniform wetting of the packing, and, in the case of counterflow towers, the effect of spray above the packing and rain below the packing. Furthermore, since testing of packings in small-scale test rigs is itself not easy, considerable scatter is seen in such test data. Correlations of the data typically have root mean square errors of 10 to 20%.

### Legionnaires' Disease

Legionnaires' disease is a form of pneumonia caused by a strain of legionella bacteria (sero group I). Smokers and sick people are particularly vulnerable to the disease. Major outbreaks have occurred at conventions and in hospitals, for which the source of the bacteria has been traced to cooling towers of air-conditioning systems. The bacteria require nutrients such as algae or dead bacteria in sludge, and thrive if iron oxides are present. However, properly designed, installed, and maintained cooling towers have never been implicated in an outbreak of the disease. Key requirements to be met include the following:

1. Mist (drift) eliminators should be effective.
2. The tower should be located so as to minimize the possibility of mist entering a ventilation system.
3. Corrosion in the tower and water lines should be minimized by use of glass fiber, stainless steel, and coated steel.
4. The design should facilitate inspection and cleaning, to allow early detection and remedy of sludge buildup.
5. Water treatment and filtration procedures should meet recommended standards.

## Heat Pipes

*Larry W. Swanson*

### Introduction

The heat pipe is a vapor-liquid phase-change device that transfers heat from a hot reservoir to a cold reservoir using **capillary forces** generated by a **wick** or porous material and a working fluid. Originally conceived by Gaugler in 1944, the operational characteristics of heat pipes were not widely publicized until 1963 when Grover and his colleagues at Los Alamos Scientific Laboratory independently reinvented the concept. Since then many types of heat pipes have been developed and used by a wide variety of industries.

Figure 4.8.12 shows a schematic of a heat pipe aligned at angle  $\psi$  relative to the vertical axis (gravity vector). The heat pipe is composed of a container lined with a wick that is filled with liquid near its saturation temperature. The vapor-liquid interface, usually found near the inner edge of the wick, separates the liquid in the wick from an open vapor core. Heat flowing into the evaporator is transferred through the container to the liquid-filled wicking material, causing the liquid to evaporate and vapor to flow into the open core portion of the evaporator. The capillary forces generated by the evaporating interface increase the pressure difference between the vapor and liquid. The vapor in the open core flows out of the evaporator through the adiabatic region (insulated region) and into the condenser. The vapor then condenses, generating capillary forces similar, although much less in magnitude, to those in the evaporator. The heat released in the condenser passes through the wet wicking material and container out into the cold reservoir. The condensed liquid is then pumped, by the liquid pressure difference due to the net capillary force between the evaporator and condenser, out of the condenser back into the

FIGURE 4.8.12 Schematic of a typical heat pipe.

evaporator. Proper selection and design of the pipe container, working fluid, and wick structure are essential to the successful operation of a heat pipe. The **heat transfer limitations**, **effective thermal conductivity**, and axial temperature difference define the operational characteristics of the heat pipe.

### Heat Pipe Container, Working Fluid, and Wick Structures

The container, working fluid, and wick structure of a heat pipe determine its operational characteristics. One of the most important considerations in choosing the material for the heat pipe container and wick is its compatibility with the working fluid. Degradation of the container or wick and contamination of the working fluid due to chemical reaction can seriously impair heat pipe performance. For example, noncondensable gas created during a chemical reaction eventually can accumulate near the end of the condenser, decreasing the condensation surface area. This reduces the ability of the heat pipe to transfer heat to the external heat sink. The material and geometry of the heat pipe container also must have a high burst strength, low weight, high thermal conductivity, and low porosity.

Using the proper working fluid for a given application is another critical element of proper heat pipe operation. The working fluid must have good thermal stability properties at the specified operational temperature and pressure. The operational temperature range of the working fluid has to lie between its triple point and its critical point for liquid to exist in the wicking material. The **wettability** of the working fluid contributes to its capillary pumping and priming capability. High-surface-tension fluids are commonly used in heat pipes because they provide the capillary pumping and wetting characteristics necessary for proper operation. Other desirable thermophysical properties include a high liquid thermal

conductivity, high latent heat of vaporization, low liquid viscosity, and a low vapor viscosity. Table 4.8.4 gives the thermophysical properties for three typical heat pipe working fluids that span a fairly wide operating temperature range. The thermophysical properties for other heat pipe working fluids can be obtained from Dunn and Reay (1982) and Peterson (1994).

The wick structure and working fluid generate the capillary forces required to (1) pump liquid from the condenser to the evaporator and (2) keep liquid evenly distributed in the wicking material. Heat pipe wicks can be classified as either homogeneous wicks or composite wicks. Homogeneous wicks are composed of a single material and configuration. The most common types of homogeneous wicks include wrapped screen, sintered metal, axial groove, annular, crescent, and arterial. Composite wicks are composed of two or more materials and configurations. The most common types of composite wicks include variable screen mesh, screen-covered groove, screen slab with grooves, and screen tunnel with

grooves. Regardless of the wick configuration, the desired material properties and structural characteristics of heat pipe wick structures are a high thermal conductivity, high wick porosity, small capillary radius, and high wick permeability. Table 4.8.2 gives the geometric properties of some commonly used homogeneous wicks. The properties of other wick structures, including nonhomogenous types, can be obtained from Peterson (1994). The container, wick structure, and working fluid are used to determine the heat transfer limitations of heat pipes.

### Heat Transfer Limitations

Heat pipes undergo various heat transfer limitations depending on the working fluid, the wick structure, the dimensions of the heat pipe, and the heat pipe operational temperature. Figure 4.8.13 gives a qualitative description of the various heat transfer limitations, which include vapor-pressure, sonic, entrainment, capillary, and boiling limitations. The composite curve enclosing the shaded region in Figure 4.8.13 gives the maximum heat transfer rate of the heat pipe as a function of the operational temperature. The figure shows that as the operational temperature increases, the maximum heat transfer rate of the heat pipe is limited by different physical phenomena. As long as the operational heat transfer rate falls within the shaded region, the heat pipe will function properly.

FIGURE 4.8.13 Heat transfer limitations in heat pipes.

The vapor-pressure limitation (or viscous limitation) in heat pipes develops when the pressure drop in the vapor core reaches the same order of magnitude as the vapor pressure in the evaporator. Under these conditions, the pressure drop due to flow through the vapor core creates an extremely low vapor pressure in the condenser preventing vapor from flowing in the condenser. A general expression for the vapor-pressure limitation is (Dunn and Reay, 1982)

$$Q_{vp,max} = \frac{\pi r_v^4 h_{fg} \rho_{v,e} P_{v,e}}{12 \mu_{v,e} l_{eff}} \quad (4.8.24)$$

where  $r_v$  is the cross-sectional radius of the vapor core (m),  $h_{fg}$  is the latent heat of vaporization (J/kg),  $\rho_{v,e}$  is the vapor density in the evaporator ( $\text{kg/m}^3$ ),  $P_{v,e}$  is the vapor pressure in the evaporator (Pa), and  $\mu_{v,e}$  is the vapor viscosity in the evaporator ( $\text{N sec/m}^2$ ).  $l_{eff}$  is the effective length of the heat pipe (m) equal to  $l_{eff} = 0.5(l_e + 2l_a + l_c)$ . The vapor-pressure limitation can occur during the start-up of heat pipes at the lower end of the working-fluid-temperature range.

The sonic limitation also can occur in heat pipes during start-up at low temperatures. The low temperature produces a low vapor density, thereby reducing the speed of sound in the vapor core. Thus, a sufficiently high mass flow rate in the vapor core can cause sonic flow conditions and generate a shock wave that chokes the flow and restricts the pipes ability to transfer heat to the condenser. Dunn and Reay (1982) give an expression for the sonic limitation that agrees very well with experimental data,

$$Q_{s,\max} = 0.474A_v h_{fg} (\rho_v P_v)^{1/2} \quad (4.8.25)$$

where  $A_v$  is the cross-sectional area of the vapor core ( $m^2$ ). The sonic limitation should be avoided because large temperature gradients occur in heat pipes under choked-flow conditions.

The entrainment limitation in heat pipes develops when the vapor mass flow rate is large enough to shear droplets of liquid off the wick surface causing dry-out in the evaporator. A conservative estimate of the maximum heat transfer rate due to entrainment of liquid droplets has been given by Dunn and Reay (1982) as

$$Q_{e,\max} = A_v h_{fg} \left[ \frac{\rho_v \sigma_l}{2r_{c,\text{ave}}} \right]^{1/2} \quad (4.8.26)$$

where  $\sigma_l$  is the surface tension (N/m) and  $r_{c,\text{ave}}$  is the average capillary radius of the wick. Note that for many applications  $r_{c,\text{ave}}$  is often approximated by  $r_{c,e}$ .

The capillary limitation in heat pipes occurs when the net capillary forces generated by the vapor-liquid interfaces in the evaporator and condenser are not large enough to overcome the frictional pressure losses due to fluid motion. This causes the heat pipe evaporator to dry out and shuts down the transfer of heat from the evaporator to the condenser. For most heat pipes, the maximum heat transfer rate due to the capillary limitation can be expressed as (Chi, 1976).

$$Q_{c,\max} = \left[ \frac{\rho_l \sigma_l h_{fg}}{\mu_l} \right] \left[ \frac{A_w K}{l_{\text{eff}}} \right] \left( \frac{2}{r_{c,e}} - \left[ \frac{\rho_l}{\sigma_l} \right] g L_t \cos \Psi \right) \quad (4.8.27)$$

where  $K$  is the wick permeability ( $m^2$ ),  $A_w$  is the wick cross-sectional area ( $m^2$ ),  $\rho_l$  is the liquid density ( $m^3$ ),  $\mu_l$  is the liquid viscosity (N sec/ $m^2$ ),  $r_{c,e}$  is the wick capillary radius in the evaporator (m),  $g$  is the acceleration due to gravity (9.8 m/sec<sup>2</sup>), and  $L_t$  is the total length of the pipe (m). For most practical operating conditions, this limitation can be used to determine maximum heat transfer rate in heat pipes.

The boiling limitation in heat pipes occurs when the degree of liquid superheat in the evaporator is large enough to cause the nucleation of vapor bubbles on the surface of the wick or the container. Boiling is usually undesirable in heat pipes because local hot spots can develop in the wick, obstructing the flow of liquid in the evaporator. An expression for the boiling limitation is (Chi, 1976)

$$Q_{b,\max} = \frac{4\pi l_{\text{eff}} k_{\text{eff}} T_v \sigma_v}{h_{fg} \rho_l \ln(r_i/r_v)} \left( \frac{1}{r_n} - \frac{1}{r_{c,e}} \right) \quad (4.8.28)$$

where  $k_{\text{eff}}$  is the effective thermal conductivity of the composite wick and working fluid (W/m K),  $T_v$  is the vapor saturation temperature (K),  $r_i$  is the inner container radius (m),  $r_n$  is the nucleation radius (equal to  $2.00 \times 10^{-6}$  m in the absence of noncondensable gas).

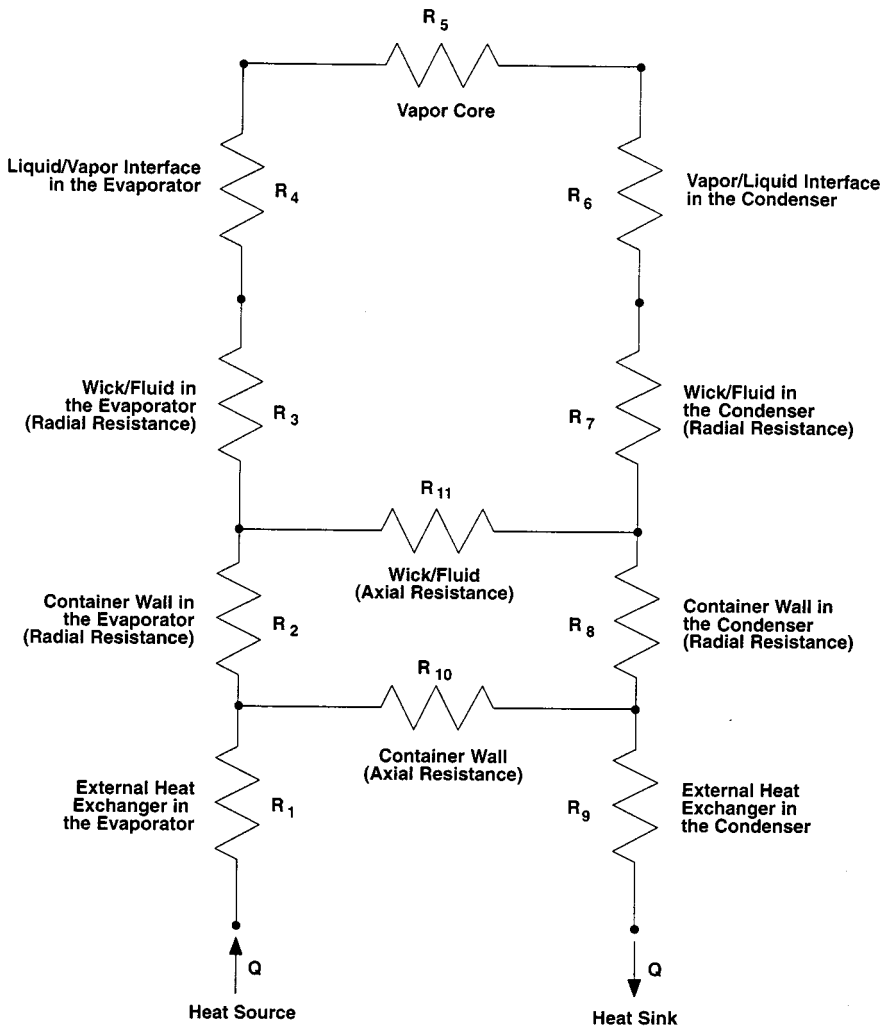

**Effective Thermal Conductivity and Heat Pipe Temperature Difference**

One key attribute of the heat pipe is that it can transfer a large amount of heat while maintaining nearly isothermal conditions. The temperature difference between the external surfaces of the evaporator and the condenser can be determined from the following expression

$$\Delta T = R_t Q \tag{4.8.29}$$

where  $R_t$  is the total thermal resistance (K/W) and  $Q$  is the heat transfer rate (W). Figure 4.8.14 shows the thermal resistance network for a typical heat pipe and the associated thermal resistances. In most cases, the total thermal resistance can be approximated by

$$R_t = R_1 + R_2 + R_3 + R_4 + R_5 + R_6 + R_7 + R_8 + R_9 \tag{4.8.30}$$

**FIGURE 4.8.14** Thermal resistance network in a heat pipe.

The reader is referred to Peterson (1994) for the specific mathematical relationships used to calculate each thermal resistance. The effective thermal conductivity of the heat pipe is defined as the heat transfer rate divided by the temperature difference between the heat source and heat sink,

$$k_{\text{eff}} = \frac{L_t}{R_t A_t} \quad (4.8.31)$$

where  $A_t$  is the overall cross-sectional area of the pipe ( $\text{m}^2$ ). Under normal operating conditions, the total thermal resistance is relatively small, making the external surface temperature in the evaporator approximately equal to that in the condenser. Thus, the effective thermal conductivity in a heat pipe can be very large (at least an order of magnitude larger than that of aluminum).

### Design Example

Design a water heat pipe to transport 80 W of waste heat from an electronics package to cooling water. The heat pipe specifications are

1. Axial orientation — complete gravity-assisted operation (condenser above the evaporator;  $\psi = 180^\circ$ )
2. Maximum heat transfer rate — 80 W
3. Nominal operating temperature —  $40^\circ\text{C}$
4. Inner pipe diameter — 3 cm
5. Pipe length — 25 cm evaporator length, 50 cm adiabatic section, and 25 cm condenser length

The simplest type of wick structure to use is the single-layer wire mesh screen wick shown in [Table 4.8.5](#). The geometric and thermophysical properties of the wick have been selected as (this takes some forethought)

$$d = 2.0 \times 10^{-5} \text{ m}$$

$$w = 6.0 \times 10^{-5} \text{ m}$$

$$\frac{1}{2N} = r_c = 1/2(2.0 \times 10^{-5} + 6 \times 10^{-5}) = 4.0 \times 10^{-5} \text{ m}$$

$$\varepsilon = 1$$

$$k_{\text{eff}} = k_1 = 0.630 \frac{\text{W}}{\text{mK}}$$

$$t_w = 1.0 \times 10^{-3} \text{ m}$$

$$K = \frac{t_w^2}{12} = \frac{(1 \times 10^{-3})^2}{12} = 8.33 \times 10^{-8} \text{ m}^2$$

The other heat pipe geometric properties are

$$r_v = r_i - t_w = 0.015 - 0.001 = 0.014 \text{ m}$$

$$l_{\text{eff}} = \frac{0.25 + 0.25}{2} + 0.5 = 0.75 \text{ m}$$

$$L_t = 0.25 + 0.50 + 0.25 + 1.0 \text{ m}$$

$$A_w = \pi(r_i^2 - r_v^2) = \pi[(0.015)^2 - (0.014)^2] = 9.11 \times 10^{-5} \text{ m}^2$$

$$A_v = \pi r_v^2 = \pi(0.014)^2 = 6.16 \times 10^{-4} \text{ m}^2$$

The thermophysical properties of water at  $40^\circ\text{C}$  are (see [Table 4.8.4](#)):

$$\rho_l = 992.1 \text{ kg/m}^3$$

$$\rho_v = 0.05 \text{ kg/m}^3$$

$$\sigma_l = 2.402 \times 10^6 \text{ J/kg}$$

$$\mu_l = 6.5 \times 10^{-3} \text{ kg/m sec}$$

$$\mu_v = 1.04 \times 10^{-4} \text{ kg/m sec}$$

$$P_v = 7000 \text{ Pa}$$

The various heat transfer limitations can now be determined to ensure the heat pipe meets the 80 W heat transfer rate specification. The vapor-pressure limitation is

$$Q_{vp,\max} = \frac{\pi(0.014)^4 (2.402 \times 10^6)(0.05)(7000)}{12(1.04 \times 10^{-4})(0.75)} = 1.08 \times 10^5 \text{ W} \quad (4.8.32)$$

The sonic limitation is

$$\begin{aligned} Q_{s,\max} &= 0.474(6.16 \times 10^{-4})(2.402 \times 10^6)[(0.05)(7000)]^{1/2} \\ &= 1.31 \times 10^4 \text{ W} \end{aligned} \quad (4.8.33)$$

The entrainment limitation is

$$\begin{aligned} Q_{e,\max} &= (6.16 \times 10^{-4})(2.402 \times 10^6) \left[ \frac{(0.05)(0.07)}{2(4.0 \times 10^{-5})} \right]^{1/2} \\ &= 9.79 \times 10^3 \text{ W} \end{aligned} \quad (4.8.34)$$

Noting that  $\cos \psi = -1$ , the capillary limitation is

$$\begin{aligned} Q_{c,\max} &= \left[ \frac{(992.1)(0.07)(2.402 \times 10^6)}{6.5 \times 10^{-3}} \right] \left[ \frac{(9.11 \times 10^{-5})(8.33 \times 10^{-8})}{0.75} \right] \left[ \frac{2}{4.0 \times 10^{-5}} + \frac{992.1}{0.07} 9.8(1.0) \right] \\ &= 4.90 \times 10^4 \text{ W} \end{aligned} \quad (4.8.35)$$

Finally, the boiling limitation is

$$\begin{aligned} Q_{b,\max} &= \frac{4\pi(0.75)(0.63)(313)(0.07)}{(2.402 \times 10^6)(992.1) \ln\left(\frac{0.015}{0.014}\right)} \left[ \frac{1}{2.0 \times 10^{-6}} - \frac{1}{4.0 \times 10^{-5}} \right] \\ &= 0.376 \text{ W} \end{aligned} \quad (4.8.36)$$

All of the heat transfer limitations, with the exception of the boiling limitation, exceed the specified heat transfer rate of 80 W. The low value of 0.376 W for the boiling limitation strongly suggests that the liquid will boil in the evaporator and possibly cause local dry spots to develop. The reason the liquid boils is because the effective thermal conductivity of the wick is equal to the conductivity of the liquid, which is very low in this case. Because the liquid is saturated at the vapor-liquid interface, a low effective thermal conductivity requires a large amount of wall superheat which, in turn, causes the liquid to boil. This problem can be circumvented by using a high conductivity wire mesh or sintered metal wick, which greatly increases the effective conductivity. It should be noted, however, that because porous wicks have

**TABLE 4.8.5 Physical Properties of Wick Structures**

 <p>Multiple wire mesh screens,<sup>b</sup> plain or sintered (screen dimensions as for single layers illustrated above)</p>	$k_{\text{eff}} = \frac{k_e [k_e + k_s - (1 - \epsilon)(k_e - k_s)]}{k_e + k_s + (1 - \epsilon)(k_e - k_s)}$	<p>Estimated from  <math>\epsilon = 1 - (\pi Nd)/4</math></p>	$r_c = 1/(2N)$	$k = \frac{d^2 \epsilon^2}{122(1 - \epsilon)^2}$

TABLE 4.8.5 Physical Properties of Wick Structures (continued)

	Wick Type <sup>a</sup>	Thermal Conductivity	Porosity	Minimum Capillary Radius	Permeability
	Unconsolidated packed spherical particles ( $d$ = average particle diameter)	Plain $k_{\text{eff}} = \frac{k_e [2k_e + k_s - 2(1-\varepsilon)(k_e - k_s)]}{2k_e + k_s + (1-\varepsilon)(k_e - k_s)}$	Estimated from (assuming cubic packing) $\varepsilon = 0.48$	$r_c = 0.21d$	$k = \frac{d^2 \varepsilon^2}{150(1-\varepsilon)^2}$
	Sintered metal fibers ( $d$ = fiber diameter)	Sintered $k_{\text{eff}} = \frac{k_e [2k_s + k_e - 2\varepsilon(k_s - k_e)]}{2k_s + k_e + \varepsilon(k_s - k_e)}$ $k_{\text{eff}} = \varepsilon^2 k_e (1-\varepsilon)^2 k_s + \frac{4\varepsilon(1-\varepsilon)k_e k_s}{k_e + k_s}$	Use manufacturers data	$r_c = \frac{d}{2(1-\varepsilon)}$	$k = C_1 \frac{y^2 - 1}{y^2 + 1}$ where $y = 1 + \frac{C_2 d^2 \varepsilon^3}{(1-\varepsilon)^2}$ $C_1 = 6.0 \times 10^{-10} \text{ m}^2$ $C_2 = 3.3 \times 10^7 \text{ 1/m}^2$

<sup>a</sup> The axis of the pipe and direction of fluid flow are normal to the paper.

<sup>b</sup> These wicks are positioned so that the layers follow the contours of the inner surface of the pipe wall.

Revised from Peterson, G.P., *An Introduction to Heat Pipes Modeling, Testing, and Applications*, John Wiley & Sons, New York, 1994.

lower permeabilities, the capillary limitation should be lower as well. Let's try a sintered particle wick made of copper with the following properties (see Table 4.8.5):

$$d = 1.91 \times 10^{-4} \text{ m}$$

$$r_{c,3} = 0.21d = 4.0 \times 10^{-5} \text{ m (same as before)}$$

$$\varepsilon = 0.48$$

$$K = \frac{(1.91 \times 10^{-4})^2 (0.48)}{150(1 - 0.48)^2} = 2.07 \times 10^{-10} \text{ m}^2$$

$$k_s = 400 \frac{\text{W}}{\text{mK}} \text{ (copper)}$$

$$k_1 = 0.630 \frac{\text{W}}{\text{mK}} \text{ (water)}$$

$$k_{\text{eff}} = \frac{400[2(400) + 0.63 - 2(0.48)(400 - 0.63)]}{2(400) + 0.63 + 0.48(400 - 0.63)} = 168 \text{ W/mK}$$

All other geometric and thermophysical properties are the same. The heat transfer limitations affected by the change in wick structure are the capillary and boiling limitations. The sintered metal wick produces a capillary limitation of

$$\begin{aligned} Q_{c,\text{max}} &= \left[ \frac{(992.1)(0.07)(2.402 \times 10^6)}{6.5 \times 10^{-3}} \right] \left[ \frac{(9.11 \times 10^{-5})(2.07 \times 10^{-10})}{0.75} \right] \left[ \frac{2}{4.0 \times 10^{-5}} + \frac{992.1}{0.07} 9.8(1.0) \right] \\ &= 122 \text{ W} \end{aligned} \quad (4.8.37)$$

The boiling limitation for the sintered wick is

$$\begin{aligned} Q_{b,\text{max}} &= \frac{4\pi(0.75)(168)(313)(0.07)}{(2.402 \times 10^6)(992.1)\ln\left(\frac{0.015}{0.014}\right)} \left[ \frac{1}{2.0 \times 10^{-6}} - \frac{1}{4.0 \times 10^{-5}} \right] \\ &= 100 \text{ W} \end{aligned} \quad (4.8.38)$$

This design now meets all the specifications defined in the problem statement.

### Application of Heat Pipes

Heat pipes have been applied to a wide variety of thermal processes and technologies. It would be an impossible task to list all the applications of heat pipes; therefore, only a few important industrial applications are given in this section. In the aerospace industry, heat pipes have been used successfully in controlling the temperature of vehicles, instruments, and space suits. Cryogenic heat pipes have been applied in (1) the electronics industry for cooling various devices (e.g., infrared sensors, parametric amplifiers) and (2) the medical field for cryogenic eye and tumor surgery. Heat pipes have been employed to keep the Alaskan tundra frozen below the Alaskan pipeline. Other cooling applications include (1) turbine blades, generators, and motors; (2) nuclear and isotope reactors; and (3) heat collection from exhaust gases, solar and geothermal energy.

In general, heat pipes have advantages over many traditional heat-exchange devices when (1) heat has to be transferred isothermally over relatively short distances, (2) low weight is essential (the heat pipe is a passive pumping device and therefore does not require a pump), (3) fast thermal-response times are required, and (4) low maintenance is mandatory.

## Defining Terms

**Capillary force:** The force caused by a curved vapor-liquid interface. The interfacial curvature is dependent on the surface tension of the liquid, the contact angle between the liquid wick structure, the vapor pressure, and the liquid pressure.

**Effective thermal conductivity:** The heat transfer rate divided by the temperature difference between the evaporator and condenser outer surfaces.

**Heat transfer limitations:** Limitations on the axial heat transfer capacity imposed by different physical phenomena (i.e., vapor pressure, sonic, entrainment, capillary, and boiling limitations).

**Wettability:** The ability of a liquid to spread itself over a surface. A wetting liquid spreads over a surface whereas a nonwetting liquid forms droplets on a surface.

**Wick:** A porous material used to generate the capillary forces that circulate fluid in a heat pipe.

### Introduction

In electronic packages, the thermal resistances to heat transfer from heat source to heat sink are often grouped into an internal resistance and an external resistance. The **internal thermal resistance**  $R_{\text{int}}$  is conductive and exists between the chip and the module case:

$$R_{\text{int}} = \frac{T_{\text{chip}} - T_{\text{case}}}{P_{\text{chip}}} \quad (4.8.39)$$

where  $P_{\text{chip}}$  is the chip power.

The **external thermal resistance**  $R_{\text{ext}}$  is primarily convective and exists between the surface of the case of the module and some reference point, typically the temperature of the cooling fluid near the module. In a multichip module, the module power  $P_m$  is the sum of the individual chip powers, and the external resistance is

$$R_{\text{ext}} = \frac{T_{\text{case}} - T_{\text{coolant}}}{P_m} \quad (4.8.40)$$

The internal and external resistances are related to the chip junction temperature  $T_j$  through the following expression:

$$T_j = \Delta T_{j\text{-chip}} + P_{\text{chip}} R_{\text{int}} + P_m R_{\text{ext}} + \Delta T_{\text{coolant}} + T_{\text{coolant in}} \quad (4.8.41)$$

Many factors are involved in determining the appropriate cooling mode to be used. If the component junction temperature is constrained to approximately 85°C, Table 4.8.6 may be used to make a preliminary selection of the cooling mode. Extended surfaces can often be used to increase the allowable heat fluxes.

**TABLE 4.8.6 Maximum Component Heat Flux for Various Cooling Modes**

Cooling Mode	W/cm <sup>2</sup>
Free convection air	0.05
Forced convection air	0.5
Impingement air	1.0
Free convection immersion	1.0
Forced convection immersion	50
Pool boiling	20
Forced convection boiling	100
Jet immersion (single phase)	40
Boiling jet immersion	90

### Free Convection Air Cooling of Vertical Printed Circuit Boards

Data have been collected from rack-mounted simulated printed circuit boards (PCBs) (see Figure 4.8.15) and from several actual electronic systems at AT&T Bell Laboratories. Results indicated that existing parallel plate correlations for symmetric isoflux plates (separated by distance “b”) could be adapted to PCB conditions. Specifically, for  $Ra_b < 10$  use the equation corresponding to the fully developed laminar boundary layer condition:

$$Nu_b = 0.144 Ra_b^{0.5} \quad (4.8.42)$$

For  $10 < Ra_b < 1000$ , use

$$Nu_b = \left[ \frac{48}{Ra_b} + \frac{2.5}{Ra_b^{0.4}} \right]^{-0.5} \quad (4.8.43)$$

where

$$Ra_b = \frac{g \beta c_p \rho^2 b^5 q''}{\mu k L}$$

For  $Ra > 1000$ , the expression for an isolated plate in infinite media is recommended:

$$Nu_b = 0.524 Ra_b^{0.2} \quad (4.8.44)$$

**FIGURE 4.8.15** Typical PCB array.

In the previous three expressions air properties are evaluated at the average of the module case and ambient temperatures.

The PCB spacing  $b_{\max}$  for a given power dissipation which yields the lowest PCB component case temperatures (or which maximizes the rate of heat transfer while maintaining PCB temperatures below the maximum allowable) occurs when the developing boundary layers from adjacent PCBs do not interfere, i.e., so the isolated plate condition is approached as follows: If heat is transferred from both sides of the PCB, let  $Ra_{ab} = 17,000$  and the recommended PCB spacing is  $b_{\max} = 7.02\xi^{-0.2}$ . If heat is transferred from only one side of the PCB, let  $Ra_{ab} = 5400$  and the recommended PCB spacing is  $b_{\max} = 5.58\xi^{-0.2}$ . In both cases

$$\xi = \frac{g\beta\rho^2\text{Pr}q''}{\mu^2kL} \quad (4.8.45)$$

### Forced Convection Air Cooling of Vertical PCBs

Sparrow et al. (1982, 1984) studied vertical arrays with simulated modules of uniform size, which was 4 modules wide by 17 module rows deep in the flow direction; the modules were 26.7 mm square and 10 mm high; the space between modules was 6.67 mm, and the distance from the top of the module to the adjoining card  $Hc = 16.7$  mm. The Nusselt number as a function of module row position for a fully populated array may be determined from Figure 4.8.16. Correction factors to the fully developed Nusselt numbers for the effect of missing modules and the presence of modules whose height differs from others in the array are presented in the cited references.

In actual electronic packages, conditions differ from the relatively ideal setups in laboratories because in real packages the flow is disturbed by the PCB supporting hardware and may extend the entry region effect.

Data from actual computer hardware with PCBs containing a  $6 \times 4$  array of 28 mm modules (4 in the flow direction) were used to develop the following expressions:

$$\text{Nu}_x = C \left\{ \text{Re}_{D_h} \left[ 1 + x / (D_h)^{-0.836} \right] \right\}^m \quad (4.8.46)$$

**FIGURE 4.8.16** Nusselt number for fully populated array of modules.

For  $Re < 2000$ ,  $C = 0.072$  and  $m = 0.70$ , and for  $2000 < Re < 10,000$ ,  $C = 0.056$  and  $m = 1.02$ , where  $x$  is the distance in the flow direction. Because the array was only 4 modules deep, all the modules on the PCB were in the entry region.

Tests have been conducted on a  $9 \times 7$  array of 25-mm-square by 6.4-mm-high blocks cooled by a  $3 \times 3$  array of air jets directed normal to the face of each block. The spent flow exited along the channel formed by the orifice plate and the heat transfer surfaces. Test results were correlated by the relation:

$$N_d = 0.213(z/d)^{-0.376} Re_d^{0.743} \quad (4.8.47)$$

where  $d$  is the jet orifice diameter,  $s$  is the orifice-to-orifice spacing, and  $z$  is the distance from the orifice outlet to the face of the module.

### Immersion Cooling

The highly inert perfluorinated liquids, called FC coolants by the 3M Company, are frequently used in **immersion cooling** applications. FC coolants are available with boiling points from 30 to 172°C at atmospheric pressure. FC-75 and FC-77 with boiling points of 100°C are often used in single-phase applications, while FC-72 and FC-87, with boiling points of 56 and 30°C, respectively, are used in systems involving phase change.

Data exist for free convection immersion cooling of a  $3 \times 3$  array of simulated chips mounted on a vertical wall in an enclosure filled with FC-75. Each heat source was 8 mm high by 24 mm wide by 6 mm thick. With the Nusselt and modified Rayleigh numbers based on the heater height,  $L$ , the best fit to the data is

$$Nu_L = 0.279 Ra_b^{0.224} \quad (4.8.48)$$

Air cooling expressions have been modified to make them applicable to free convection immersion cooling of vertical PCB arrays with FC coolants. The Nusselt number (based on PCB spacing “b”) at the top of the PCB is

$$\text{Nu}_L = \left[ \frac{C}{\text{Ra}_b} + \frac{2.78}{\text{Ra}_b^{0.4}} \right]^{-0.5} \quad (4.8.49)$$

$C = 24$  when heat transfer is from one side of the PCB, and  $C = 48$  when from both sides.

### Nucleate Pool Boiling

A number of investigators have tested small flush heat sources boiling in a pool of dielectric liquid. The heaters ranged from  $4 \times 4$  mm to  $12.7 \times 12.7$  mm. Typical saturated pool boiling data for FC-72 and FC-87 are shown in Figure 4.8.17. Note that a temperature overshoot up to  $25^\circ\text{C}$  has been regularly observed for silicon chips in dielectric liquid pools. To estimate the temperature excursion at boiling incipience ( $q_i''$ ), the following approximation is recommended

$$\Delta T_{\text{ex}} = T_{\text{sat}} \left( p - \frac{2\sigma}{r_b} - p_g \right) - T_{\text{sat}} - C(q_i'')^n \quad (4.8.50)$$

where

$$C = \mu h_{fg} \left[ \frac{c_p}{h_{fg} \text{Pr}^b C_{sf}} \right]^{1/a} \left[ \frac{\alpha}{g(\rho - \rho_g)} \right]^{0.5} \quad (4.8.51)$$

with  $r_b = 0.25 \mu\text{m}$ ,  $C_{sf} = 0.003$ ,  $a = 0.33$ , and  $b = 1.7$ . (Note that  $n = 1/a = 3$ .)

Park and Bergles (1988) determined the critical heat flux (CHF) as a function of size for flush heaters operating in a saturated pool of R-113. For a 5-mm-wide heater, and for heater heights from 5 to 80 mm, use

$$\frac{q_{c,\text{sat}}''}{q_{c_z}''} = 0.86 \left[ 1 + \frac{152}{L^{*3.29}} \right]^{0.14} \quad (4.8.52)$$

where the CHF prediction of Zuber,  $q_{c_z}'' = \rho_g^{0.5} h_{fg} [\sigma g(\rho_f - \rho_g)]^{0.5}$ , and  $L^* = L[g(\rho_f - \rho_g)/\sigma]^{0.5}$ .

For a 5-mm-high heater, and for heater widths from 2.5 to 70 mm, use

$$\frac{q_{c,\text{sat}}''}{q_{c_z}''} = 0.93 \left[ 1 + \frac{52}{I^{1.02}} \right]^{0.14} \quad (4.8.53)$$

where the induced convection parameter is  $I = (\rho_f W \sigma / \mu^2)^{0.5}$ .

For flush  $12.7 \times 12.7$  mm heaters in FC-72, test data yield  $q_{c,\text{sat}}'' / q_{c_z}'' \approx 1.45$ . These subcooling data were correlated by

$$\frac{q_{c,\text{sub}}''}{q_{c,\text{sat}}''} = 1 + \frac{0.0643 \rho_f c_{p,f}}{\rho_g h_{fg}} \left[ \frac{\rho_g}{\rho_f} \right]^{1/4} \Delta T_{\text{sub}} \quad (4.8.54)$$

### Single-Phase and Boiling Forced Convection in Channel Flow

The average Nusselt numbers for 12 flush  $12.7 \times 12.7$  mm heaters (4 rows of 3 sources per row) operating in FC-77 has been correlated by the following expression:

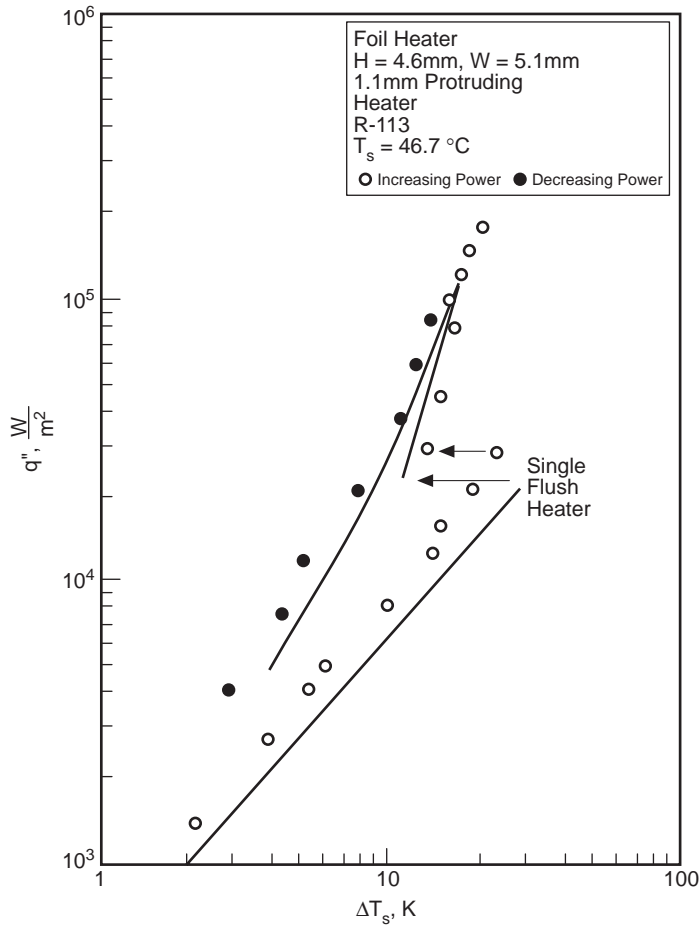

FIGURE 4.8.17 Typical pool boiling curve for small heater.

$$\overline{Nu}_L = C(\text{Re}_{D_h})^m \text{Pr}^{0.11} \tag{4.8.55}$$

For row 1:  $C = 0.194$  and  $m = 0.60$ ; for row 2:  $C = 0.069$  and  $m = 0.69$ ; for row 3:  $C = 0.041$  and  $m = 0.74$ ; and for row 4:  $C = 0.029$  and  $m = 0.78$ . All properties are determined at the inlet temperature except for  $\mu_b$ , which is evaluated at the heater temperature. Note that when heat sinks are employed, forced convection immersion cooling can support a heat flux of approximately  $50 \text{ W/cm}^2$ .

Test data have been obtained for a vertical column of ten  $6.4 \text{ mm} \times 6.4 \text{ mm}$  heaters, with subcooled R-113 flowing in the upward direction. In general, CHF occurred first at the last downstream element in the array, and that CHF values of  $100 \text{ W/cm}^2$  were easily attained. The CHF data yielded the following equation:

$$q_c'' = C_5 \text{We}^n V \rho_f h_{fg} \left( \frac{\rho_f}{\rho_g} \right)^{15/23} \left( \frac{L}{D_h} \right)^{1/23} \left[ 1 + \frac{c_{pf} \Delta T_{\text{sub}}}{h_{fg}} \right]^{7/23} \left[ 1 + \frac{0.021 \rho_f c_{pf} \Delta T_{\text{sub}}}{\rho_g h_{fg}} \right] \tag{4.8.56}$$

where the Weber number,  $\text{We} = \rho_f V^2 L / \sigma$ . Note that for  $\text{We} > 100$ ,  $C_5 = 0.125$  and  $n = -8/23$ , and for  $\text{We} < 10$ ,  $C_5 = 0.254$  and  $n = -1/2$ .

### Immersion Cooling Using Jets

Two modes have been studied. In the first, a dielectric liquid jet discharges into a miscible liquid and is said to be submerged; in the second, a liquid jet discharges into an immiscible gas (air) and is said to be free. In general, the average Nusselt number can be expressed as

$$\overline{Nu} = f(\text{Re}^m, \text{Pr}^n, L/d, z/d) \quad (4.8.57)$$

where  $L/d$  is the ratio of the chip length to orifice diameter, and  $z/d$  is the ratio of the jet to heat source distance to the orifice diameter. A free jet is virtually unaffected by the orifice-to-chip distance, and as a consequence the  $(z/d)$  term drops out.

Data for single-phase forced convection cooling with free jets are available for  $2 \times 2$  and  $3 \times 3$  heat source arrays. The heat sources were  $12.7 \times 12.7$  mm and the cooling fluid was FC-77. Each heat source was cooled either by a single jet or by a  $2 \times 2$  or  $3 \times 3$  array of jets per source. For all the configurations tested, the average Nusselt number was correlated by a single expression:

$$\overline{Nu}_L = 3.84 \left( 0.008 \frac{L}{d} n + 1 \right) \text{Re}^{1/2} \text{Pr}^{1/3} \quad (4.8.58)$$

where fluid properties are to be evaluated at an average of the heat source and jet inlet temperatures.

Data for single-phase forced convection using submerged jets are available for a  $5 \times 5$  mm vertical heat source cooled by a 1.0-mm-diameter submerged jet of R-113. The Nusselt number at the stagnation point was correlated by

$$\text{Nu}_d = 1.29 \text{Re}_d^{1/2} \text{Pr}^{0.4} \quad (4.8.59)$$

Also note that the performance of a submerged liquid jet should be approximately equivalent to gas jet impingement.

Data for two-phase forced convection using free jets have been collected for a single  $12.7 \times 12.7$  mm heat source cooled by either a single jet or a  $2 \times 2$  or  $3 \times 3$  array of jets. The jet diameter, velocity, and jet-to-source distance were varied. The CHF data was correlated by

$$q_c'' = 0.0742 \text{We}^{-0.365} V \rho_f h_{fg} \left( \frac{\rho_g}{\rho_f} \right)^{0.239} \left[ 1 + 0.952 \left( \frac{\rho_f}{\rho_g} \right)^{0.118} \left( \frac{c_{pf} \Delta T_{\text{sub}}}{h_{fg}} \right) \right]^{1.414} \quad (4.8.60)$$

Experimental evidence in two-phase forced convection using submerged jets indicates that (1) the temperature overshoot at incipient boiling was very small compared with pool or forced boiling; (2) the boiling curves at various velocities merge to a single curve and that this curve coincides approximately with an upward extrapolation of the pool boiling curve; (3) the CHF varies as the cube of the jet velocity; (4) the CHF is greatly improved by increasing the subcooling; and (5) powers in excess of 20 W ( $5 \times 5$ -mm chip) could be accommodated within a  $85^\circ\text{C}$  chip temperature.

## Defining Terms

**External thermal resistance:** The thermal resistance from a convenient reference point on the outside of the electronic package to the local ambient.

**Internal thermal resistance:** The thermal resistance from the device junction inside an electronic package to a convenient reference point on the outside surface of the package.

**Immersion cooling:** Concerns applications where the coolant is in direct physical contact with the electronic components.

## 4.9 Non-Newtonian Fluids — Heat Transfer

*Thomas F. Irvine, Jr., and Massimo Capobianchi*

### Introduction

The general characteristics of non-Newtonian fluids are described in Section 3.9 and will not be repeated here. Topics to be included in this section are laminar and turbulent heat transfer in fully developed duct flow, and laminar free convection heat transfer in vertical channels and plates and several other common geometries.

For non-Newtonian flows, except for certain classes of fluids which exhibit a slip phenomenon at solid boundaries, the boundary condition is taken as no-slip or zero velocity at all solid surfaces. For heat transfer analyses, however, the situation is more complicated because there are many different ways to heat a wall, which in turn affects the type of thermal boundary conditions.

In general, the rate of heat transfer from a surface, or the temperature difference between the wall and the fluid, is calculated using the equation  $q_c = h_c A_q \Delta T$ . Since the heat transfer coefficient can vary considerably for different thermal boundary conditions, it is important that the boundary conditions be specified correctly. Although the number of thermal boundary conditions is in principle infinite, several classical types have been identified and are in common use. They are usually identified in terms of the Nusselt number,  $Nu = h_c L/k$ , with a particular subscript. For example, for duct flow, the symbol  $Nu_T$  is used to specify the Nusselt number when the wall temperature is constant in both the flow and peripheral directions. Other thermal boundary conditions are described in Table 4.9.1 for duct heat transfer and will be used throughout this section.

**TABLE 4.9.1 Thermal Boundary Conditions for Duct Heat Transfer**

1.	Constant wall temperature in both the flow and circumferential direction	$Nu_T$
2.	Constant heat flux in the flow direction and constant temperature in the circumferential direction	$Nu_{H1}$
3.	Constant heat flux in the flow and circumferential directions	$Nu_{H2}$
4.	Constant heat flux per unit volume in the wall with circumferential wall heat conduction	$Nu_{H4}$

It should be noted that because of the symmetry in circular and parallel plate ducts,  $Nu_{H1}$  and  $Nu_{H2}$  are identical and are referred to simply as  $Nu_{H1}$ ,  $Nu_{H4}$  with wall conduction is a more-complicated problem where the energy equations must be solved simultaneously in both the wall and the fluid. Such problems are called conjugated. In the  $Nu_{H4}$  situation, the designer has the flexibility of affecting the heat transfer by varying either or both the characteristics of the duct wall or the convective fluid. In the heat transfer relations to be considered later, care will be taken to identify the proper thermal boundary conditions using the nomenclature in Table 4.9.1.

### Laminar Duct Heat Transfer — Purely Viscous, Time-Independent Non-Newtonian Fluids

As discussed in Section 3.9, a convenient and comprehensive constitutive equation for pseudoplastic fluids (flow index,  $n < 1$ ) is the modified power law equation:

$$\mu_a = \frac{\mu_o}{1 + \frac{\mu_o}{K} (\dot{\gamma})^{1-n}} \quad (4.9.1)$$

Equation (4.9.1) has the characteristic that at low shear rates, the equation approaches that for a Newtonian fluid while at large shear rates it describes a power law fluid. In addition, solutions using

Equation (4.9.1) generate a shear rate parameter,  $\beta$ , which describes whether any particular system is in the Newtonian, transitional, or power law region. For duct flow,  $\beta$  is given by

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n} \quad (4.9.2)$$

If  $\log_{10} \beta > 2$ : Power law region

If  $\log_{10} \beta < -2$ : Newtonian region

If  $-2 \leq \log_{10} \beta \leq 2$ : Transition region

For fully developed flow, the characteristic length is the hydraulic diameter,  $D_H$ , and the fluid temperature is the “bulk” temperature defined as

$$T_b = \frac{1}{A_c \bar{u}} \int_{A_c} u T dA_c \quad (4.9.3)$$

Figure 4.9.1 illustrates the values of  $Nu_T$  vs.  $\beta$  for a circular duct with the flow index,  $n$ , as a parameter. It is seen from the figure that the effect of  $\beta$  on  $Nu_T$  is only moderate, but for some applications it may be important to know at what value of  $\beta$  the system is operating. The situation is similar for boundary condition  $Nu_H$ .

Although Figure 4.9.1 shows the Nusselt number relation graphically, it is convenient to have simple correlation equations to represent the solutions for both boundary conditions. For fully developed Nusselt numbers with values of  $0.5 \leq n \leq 1.0$  and  $10^{-4} \leq \beta \leq 10^4$ , Irvine et al. (1988) present the following equation which represents both solutions with a maximum difference of 1.5%:

$$Nu = \frac{Nu_N(1+\beta)}{1 + \frac{Nu_N\beta}{Nu_P}} \quad (4.9.4)$$

The Newtonian Nusselt numbers are  $Nu_N = 3.6568$  for  $Nu_T$ , and  $Nu_N = 4.3638$  for  $Nu_H$ . In addition, Table 4.9.2 lists the power law Nusselt numbers,  $Nu_{TP}$  and  $Nu_{HP}$ , for  $\log_{10} \beta = 4$ .

Graetz solutions for the thermal entrance lengths are also available. They assume that the velocity profile is fully developed at the duct entrance and present the duct lengths required for the Nusselt numbers to reach within 1% of the fully developed values. Figure 4.9.2 shows these thermal entrance lengths for  $Nu_T$  thermal boundary condition. The situation is similar for boundary condition  $Nu_H$ .

A correlation equation for the thermal entrance lengths for both the  $Nu_T$  and  $Nu_H$  boundary conditions by Irvine et al. (1988) represents the numerical solutions within 0.5% for  $0.5 \leq n \leq 1.0$  and  $-4 \leq \log_{10} \beta \leq 4$ . Table 4.9.3 lists the power law thermal entrance lengths which are needed to evaluate the following correlation equation:

$$x_{ent,\beta,n}^+ = \frac{x_{ent,N}^+(1+\beta)}{1 + \frac{x_{ent,N}^+(\beta)}{x_{ent,P}^+}} \quad (4.9.5)$$

where  $x_{ent,\beta,n}^+$  is the modified power law dimensionless entrance length defined as  $x_{ent,\beta,n}^+ = (x_{ent,\beta,n}/D_H)/Pe$ , and  $x_{ent,N}^+$  and  $x_{ent,P}^+$  are the Newtonian and power law values, respectively. The Newtonian dimensionless entrance lengths are  $x_{ent,N}^+ = 0.03347$  for  $Nu_T$  and  $x_{ent,N}^+ = 0.04309$  for  $Nu_H$ .

**FIGURE 4.9.1** Variation of the fully developed circular duct Nusselt numbers,  $Nu_T$ , with the shear rate parameter  $\beta$  and  $n$ . (From Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127. With permission.)

Only one noncircular geometry using the modified power law equation has been published in the archival literature for laminar fully developed heat transfer (Capobianchi and Irvine, 1992). A correlation equation for  $Nu_{H1}$  for annuli with constant heat flux at the inner wall and the outer wall insulated is

$$n < 1 \quad Nu_{H1} = \frac{1 + \beta}{\frac{1}{Nu_{H1,N}} + \frac{\beta}{Nu_{H1,P}}} \quad (4.9.6)$$

Nusselt numbers for square ducts and power law fluids can be found in Chandrupatla and Sastri (1977) and, for isosceles triangular ducts, in Cheng (1984). Thermally developing and thermally developed laminar heat transfer in rectangular channels has been studied by Hartnett and Kostic (1989).

For other cross-sectional shapes, a power law approximate correlation has been proposed by Cheng (1984):

**FIGURE 4.9.2** Thermal entrance lengths vs. shear rate parameter  $\beta$  and  $n$  for  $Nu_T$  in circular ducts. (From Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127. With permission.)

$$Nu_p = Nu_N \left[ \frac{(a + bn)}{(a + b)n} \right]^{1/3} \tag{4.9.7}$$

where  $a$  and  $b$  are the Kozicki geometric constants listed in Table 3.9.3 in the section on non-Newtonian flows. Equation (4.9.7) applies to any thermal boundary condition. For circular ducts, Equation 4.9.7 predicts the correct solution for both  $Nu_T$  and  $Nu_H$ .

### Turbulent Duct Flow for Purely Viscous Time-Independent Non-Newtonian Fluids

It is known that in turbulent flow, the type of thermal boundary conditions has much less effect than in laminar flow. Therefore, turbulent flow heat transfer investigations are often reported without specifying the thermal boundary conditions. Yoo (1974) has presented an empirical correlation for turbulent heat transfer in circular ducts for purely viscous time-independent power law fluids.

$$\text{StPr}_a^{2/3} = 0.0152\text{Re}_a^{-0.155} \quad (4.9.8)$$

Equation (4.9.8) describes all of the experimental data available in the literature at the time with a mean deviation of 2.3%. Equation (4.9.8) is recommended in order to predict the turbulent fully developed heat transfer in the ranges  $0.2 \leq n \leq 0.9$  and  $3000 \leq \text{Re}_a \leq 90,000$ . The Reynolds number and Prandtl numbers in Equation (4.9.8) are based on the apparent viscosity at the wall,  $\mu_a$ , i.e.,

$$\text{Re}_a = \frac{\rho \bar{u} D_H}{\mu_a} \quad (4.9.9)$$

$$\text{Pr}_a = \frac{\mu_a c_p}{k} \quad (4.9.10)$$

In order to evaluate Equations (4.9.9) and (4.9.10) in terms of the rheological properties and operating parameters, an expression must be obtained for  $\mu_a$  in terms of these quantities. The value of  $\mu_a$  is evaluated by considering that  $\mu_a$  is determined from fully developed laminar circular tube power law fluid flow for which it can be shown that (Irvine and Karni, 1987)

$$\mu_a = K \left( \frac{3n+1}{4n} \right)^{n-1} \left( \frac{8\bar{u}}{D_H} \right)^{n-1} \quad (4.9.11)$$

assuming that the quantities  $K$ ,  $n$ ,  $c_p$ , and  $k$  are constant. It is also of interest that the Prandtl number is no longer a thermophysical property for power law fluids but depends upon the average velocity,  $\bar{u}$ , and the hydraulic diameter,  $D_H$ .

Hartnett and Rao (1987) have investigated fully developed turbulent heat transfer for a rectangular duct with a 2:1 aspect ratio and propose the following equation which generally agreed with their experimental data within  $\pm 20\%$ :

$$\text{Nu} = (0.0081 + 0.0149n)\text{Re}_a^{0.8}\text{Pr}_a^{0.4} \quad (4.9.12)$$

## Viscoelastic Fluids

An important characteristic of viscoelastic fluids is their large hydrodynamic and thermal entrance lengths. Cho and Hartnett (1982) have reported hydrodynamic entrance lengths of up to 100 diameters and thermal entrance lengths up to 200 to 800 diameters depending upon the Reynolds and Prandtl numbers. These can be compared with Newtonian fluids entrance lengths which are of the order of 10 to 15 diameters. Therefore, care must be used in applying fully developed relations to practical situations.

Cho et al. (1980) reported heat transfer measurements in the thermal entrance region and recommend the following empirical equation for saturated aqueous polymer solutions for  $6000 \leq \text{Re}_a$  and  $x/D_H$  values up to 450:

$$J_H = 0.13 \left( x/D_H \right)^{-0.24} \text{Re}_a^{-0.45} \quad (4.9.13)$$

where  $J_H = \text{St Pr}_a^{2/3}$  and  $\text{St} = h_c/\rho c_p \bar{u}$ .

All of the reported fully developed turbulent flow heat transfer measurements have been plagued by solute and solvent, thermal entrance, and degradation effects, and thus there is considerable scatter in the results. Degradation effects can be reduced or eliminated by using large amounts of polymer (500

to 10,000 wppm) so that the solution becomes saturated. Cho and Hartnett (1982) attempted to eliminate these effects by using a thermal entrance length of 430 diameters and saturated polymer solutions which should yield maximum heat transfer reductions. Their experimental results for fully developed heat transfer were correlated for a Reynolds number range  $3500 \leq Re_a \leq 40,000$  and concentration solutions of 500 to 5000 wppm of polyacrylamide and polyethylene oxide by

$$J_H = 0.03Re_a^{-0.45} \quad (4.9.14)$$

For viscoelastic fluids in fully developed (hydrodynamically and thermally) *laminar flow in circular ducts* there is no apparent viscoelastic effect. Thus, the heat transfer relations are the same as those for time-independent fluids such as power law or modified power law fluids. The same situation holds for thermal entrance region heat transfer (Graetz problem). Relations for laminar Nusselt numbers in thermal entrance regions are presented by Cho and Hartnett (1982).

### Free Convection Flows and Heat Transfer

Free convection information available in the heat transfer literature up to the present time is concentrated on heat transfer to power law fluids for vertical plates and parallel plate channels. For free convection flows, however, the velocities and thus the shear rates are low and care must be taken that the flow for a particular fluid is in the power law shear rate region before using power law solutions or correlations. Comprehensive review articles on free convection with non-Newtonian fluids have been presented by Shenoy and Mashelkar (1982) and Irvine and Karni (1987).

For a single vertical plate with a modified power law fluid and a thermal boundary condition  $\bar{Nu}_T$ , in laminar flow, the following relation is recommended by Shenoy and Mashelkar (1982):

$$\bar{Nu}_{TL} = T(n)Gr_{TL}^{1/(2n+2)}Pr_{TL}^{n/(3n+1)} \quad (4.9.15)$$

where  $\bar{Nu}_{TL}$  is the average Nusselt number and

$$Gr_{TL} = \frac{\rho^2 L^{n+2}}{K^2} [g\alpha(T_s - T_\infty)]^{2-n} \quad (4.9.16)$$

$$Pr_{TL} = \frac{\rho c_p}{k} \left( \frac{K}{\rho} \right)^{2/(n+1)} L^{(n-1)/(2n+2)} [g\alpha(T_s - T_\infty)]^{(3n-3)/(2n+2)} \quad (4.9.17)$$

where  $\alpha$  is the isobaric thermal expansion coefficient.

In the range  $0.5 \leq n \leq 1$ ,  $T(n)$  can be approximated by

$$T(n) = 0.1636n + 0.5139 \quad (4.9.18)$$

The characteristic dimension in the Nusselt and Grashof numbers is the plate height,  $L$ .

For thermal boundary conditions  $Nu_H$ , the following relation is also recommended by Shenoy and Mashelkar (1982). Since the heat flux,  $q_w$  is specified in this case, the local plate temperature at any  $x$  (measured from the bottom of the plate) can be obtained from the local Nusselt number  $Nu_{Hx}$ . The heat transfer coefficient is defined in terms of the difference between the wall and free-stream temperatures.

$$Nu_{Hx} = 0.619 \left[ Gr_{Hx}^{(3n+2)/(n+4)} Pr_{Hx}^n \right]^{0.213} \quad (4.9.19)$$

where

$$\text{Gr}_{Hx} = \frac{\rho^2 x^4}{k^2} \left( \frac{g\alpha q_w}{k} \right)^{2-n} \quad (4.9.20)$$

$$\text{Pr}_{Hx} = \frac{\rho c_p}{K} \left( \frac{K}{\rho} \right)^{5/(n+4)} x^{(2n-2)/(n+4)} \left( \frac{g\alpha q_w}{k} \right)^{(3n-3)/(n+4)} \quad (4.9.21)$$

### Vertical Parallel Plates

For *power law fluids* and laminar flow, [Figure 4.9.3](#) presents the graphical results of a numerical solution. Of interest are the average Nusselt number  $\bar{Nu}_{Tb}$  and the dimensionless average flow velocity between the plates,  $U_o^+$ . These are shown on the left and right ordinates respectively in [Figure 4.9.3](#) (Irvine et al., 1982). The characteristic dimension in the Nusselt and Grashof numbers is the plate spacing,  $b$ . The dimensionless quantities used in [Figure 4.9.3](#) are defined as follows:

$$\bar{Nu}_{Tb} = \frac{\bar{h}_c b}{k} \quad U_o^+ = \frac{b u_o}{Lu^*}$$

$$\text{Pr}_g = \frac{\rho c_p}{k} \left[ \frac{v_k^{1/(2-n)}}{\left( \frac{L}{b} \right)^{(1-n)/(2-n)} b^{(2n-2)/(2-n)}} \right] \quad v_K = \frac{K}{\rho}$$

$$\text{Gr}_g = \frac{g\alpha(T_s - T_\infty) b^{(n+2)/(2-n)}}{v_K^{2/(2-n)} \left( \frac{L}{b} \right)^{n/(2-n)}} \quad u^* = \frac{v_K^{1/(2-n)} b^{(1-2n)/(2-n)}}{L^{(1-n)/(2-n)}}$$

For vertical parallel plates for the average Nusselt number,  $\bar{Nu}_{Hb}$ , and the between plate average velocity, Schneider and Irvine (1984) have presented graphical results similar to [Figure 4.9.3](#).

Lee (1992) has presented a numerical solution for laminar flow of a *modified power law fluid* between vertical plates. Lee has also calculated thermal entrance regions and shown that if a parallel plate system is actually operating in the transition region and if the power law solution is used, both the total heat transfer and the velocity between plates can differ by over an order of magnitude. It is important to consider the shear rate parameter in order to determine which free convection solution to use.

### Sphere and Horizontal Cylinder — Power Law Fluids

For flow over a sphere, the correlation for power law fluids by Amato and Tien (1976) is

$$\bar{Nu}_{Tr} = CZ^D \quad (4.9.22)$$

where

$$Z = \text{Gr}_{Tr}^{1/(2n+2)} \text{Pr}_{Tr}^{n/(3n+1)} \quad (4.9.23)$$

and

$$C = 0.996 \pm 0.120, \quad D = 0.682 \quad \text{for } Z < 10$$

$$C = 0.489 \pm 0.005, \quad D = 1.10 \quad \text{for } 10 \leq Z \leq 40$$

**FIGURE 4.9.3** Free convection average Nusselt number,  $\bar{Nu}_b$ , and dimensionless average velocity  $U_o^+$  between vertical plates for a power law fluid vs. generalized Rayleigh number for the  $Nu_T$  boundary condition. (From Irvine, T.F., Jr. et al., ASME Paper 82-WA/HT-69, 1982. With permission.)

where the characteristic dimension in all dimensionless variables is the sphere radius,  $r$ , and  $Gr_{Tr}$  and  $Pr_{Tr}$  are defined in Equations (4.9.16) and (4.9.17).

For pseudoplastic fluids flowing over a cylinder, an experimental correlation proposed by Gentry and Worllersheim (1974) for the average Nusselt number,  $\bar{Nu}_{TD}$ , is

$$\bar{Nu}_{TD} = \frac{\bar{h}_c D}{k} = 1.19 (Gr_{TD} Pr_{TD})^{0.2} \tag{4.9.24}$$

where  $Gr_{TD}$  and  $Pr_{TD}$  are defined as in Equations (4.9.16) and (4.9.17) with the cylinder diameter,  $D$ , being used instead of  $L$ .

## Further Information

Other sources which may be consulted for more detailed information are Cho and Hartnett (1982), Shenoy and Mashelkar (1982), Irvine and Karni (1987), and Hartnett and Kostic (1989).

If a single heated element is used within an array of unheated elements, the resulting heat transfer coefficient is implicitly defined as  $h_{\text{adiabatic}}$  and should be identified as such. Heat transfer coefficients measured with single-active-element tests cannot be used with the mixed mean fluid temperature.

When the variation of  $h$  over a surface is required, one common steady-state technique is to stretch a thin foil (stainless steel, or carbon impregnated paper, or gold deposited on polycarbonate) over an insulating substrate, and electrically heat the foil surface. Liquid crystals or infrared techniques can be used to map the surface temperature, from which the heat transfer coefficient distribution can be determined. The “heated foil with liquid crystal” approach was used by Cooper et al. in 1975 to measure heat transfer coefficients, and has since been used by many others. Hippensteele et al. (1985) have made extensive use of the foil technique in studies of gas turbine heat transfer. An example of their work on the end wall of a turbine cascade is shown in [Figure 4.6.15](#).

**FIGURE 4.6.15** Heat transfer coefficient distribution on the end wall of a turbine cascade. (From Hippensteele, S.A. et al., NASA Technical Memorandum 86900, March, 1985. With permission.)

Hollingsworth et al. (1989) used a stainless steel foil heater for a study in air for an electronics cooling application, illustrated in [Figure 4.6.16](#).

**FIGURE 4.6.16** Visualization of the heat transfer coefficient distribution on a heated plate around three unheated cubes.

Another steady-state technique which reveals the distribution of  $h$  on the surface was introduced by den Ouden and Hoogendoorn (1974) and is currently in use by Meinders (1996). It uses a uniform and constant-temperature substrate (originally, a tank of warm water, now a copper block) covered with a layer of known thermal resistance (originally, a plate of glass, now a thin layer of epoxy). The surface was painted with liquid crystals (now visualized using infrared imaging) and the surface-temperature distribution determined. The inner (uniform) and outer (measured) temperature distributions are then used as boundary conditions to a three-dimensional conduction solver which calculates the total heat flux at each point on the surface. The total heat flux is corrected for radiation to yield the net convective transport at each point, from which  $h$  can be determined.

This method appears to have an advantage in accuracy over the heated foil technique because of the more accurate handling of substrate conduction.

*Transient Lumped Parameter Systems.* In the lumped parameter transient method, the specimen is assumed to be uniform in temperature at every instant through the transient. The power,  $\dot{e}_{in}$ , in Equation (4.6.16) is usually zero, although that is not necessary (one could simply change the power level at time zero to initiate the transient). At time zero, a transient is initiated, and the response curve recorded.

The data can be interpreted, and the validity of the first-order assumption tested at the same time by plotting  $(T - T_{final}) / (T_{initial} - T_{final})$  on the log scale of semilog coordinates, with time on the algebraic scale. If the line is straight, then the system is first order and the characteristic time can be determined from any two points on the line by

$$\tau = \frac{(t_2 - t_1)}{\ln \left\{ \frac{T_{fin} - T_1}{T_{fin} - T_2} \right\}} \quad (4.6.17)$$

where  $\tau$  = characteristic time,  $Mc/hA$ , sec

$t_1$  = time at the first instant

$t_2$  = time at the second instant

$T_1$  = specimen temperature at the first instant, °C

$T_2$  = specimen temperature at the second instant, °C

$T_{fin}$  = specimen temperature after a long time (fluid temperature), °C

The heat transfer coefficient is extracted from the time-constant definition.

### Indirect Methods

An increasingly popular method is the extraction of  $h$  from surface-temperature variations after a step in flow temperature using an inverse calculation method (see the section on inferential methods of heat flux measurement). The simplest inverse method assumes one-dimensional conduction into an infinitely thick plate of constant material properties. Even highly irregular geometries can be studied with this technique, if the streamwise extent of the specimen is small and the testing time is short. A short time interval is necessary so the penetration of the thermal wave is limited to a thin layer near the surface. The short streamwise extent is necessary so the temperature response of the surface upstream does not alter the thermal step applied to the downstream surface. This technique has been used to determine the heat transfer coefficient distribution on the inside walls of passages of irregular shape, by making the passage in a transparent material.

*Naphthalene Sublimation.* The equations for mass diffusion are similar to those for heat transfer, except for replacing the Prandtl number in the heat transfer equation by the Schmidt number in the diffusion equation. Thus, one could expect that the distribution of the mass transfer coefficients on a surface would mimic the distribution of the heat transfer coefficients.

The most commonly used analog technique is naphthalene sublimation. As early as 1940, the mass transfer/heat transfer similarity was used to estimate the heat transfer coefficient distribution. Naphthalene

is a solid material which sublimates at a reasonable rate in air at ambient temperature. Specimens can be cast in naphthalene with good precision, and the recession of the surface mapped as a function of position and time using automated or semiautomated measuring equipment. The surface recession over a known interval of time is a measure of the mass transfer rate, from which the mass transfer coefficient can be deduced.

Naphthalene experiments are generally done at uniform temperature; hence, a uniform vapor pressure exists at the surface. This corresponds to the heat transfer situation of heat transfer from a uniform temperature surface. No counterpart of the uniform heat flux situation has been produced using naphthalene, nor have there been experiments corresponding to variable wall temperature.

Naphthalene sublimation experiments do not suffer from any counterpart of the conduction heat transfer in the substrate. Conduction makes it difficult to work near discontinuities in wall temperature in a heat transfer experiment. Details of the fine structure of mass transfer near obstructions and discontinuities can be resolved in naphthalene experiments, but those details might not exist in a heat transfer process. The Prandtl number of air is much lower than the Schmidt number of naphthalene diffusing in air; hence, thermal conduction would tend to blur out sharp gradients in the temperature field more than diffusion would blur out gradients in naphthalene concentration.

The Schmidt number of naphthalene in air is about 2.5, far different than the Prandtl number of air (0.71); hence, the mass transfer coefficient deduced from a naphthalene experiment is not numerically equal to the heat transfer coefficient which would have existed at those conditions. The usual recommendation is to adjust for the Prandtl number of Schmidt number using a relation of the form:

$$\text{St Pr}^{2/3} = f\{\text{Re}\} = \text{Sh}_j \text{Sc}_j^{2/3} \quad (4.6.18)$$

based on laminar results. That recommendation has not been seriously tested by experiments in turbulent and separated flows. By using nominal values of the Schmidt number and Prandtl number, the heat transfer Stanton number would be 2.3 times higher than the measured Sherwood number and an uncertainty of 10% in that ratio would alter the inferred heat transfer coefficient by 23%.

*System Performance Matching.* Sometimes the “effective average heat transfer coefficient” for a system is inferred from the overall behavior of the system, e.g., estimating  $h$  from the effectiveness of a heat exchanger. Values deduced by this means cannot be expected to agree well with direct measurements unless a very sophisticated system description model is used.

## 4.7 Mass Transfer

*Anthony F. Mills*

### Introduction

Mass transfer may occur in a gas mixture, a liquid solution, or a solid solution. There are several physical mechanisms that can transport a chemical species through a phase and transfer it across phase boundaries. The two most important mechanisms are ordinary diffusion and convection. Mass diffusion is analogous to heat conduction and occurs whenever there is a gradient in the concentration of a species. Mass convection is essentially identical to heat convection: a fluid flow that transports heat may also transport a chemical species. The similarity of mechanisms of heat transfer and mass transfer results in the mathematics often being identical, a fact that can be exploited to advantage. But there are some significant differences between the subjects of heat and mass transfer. One difference is the much greater variety of physical and chemical processes that require mass transfer analysis. Another difference is the extent to which the essential details of a given process may depend on the particular chemical system involved, and on temperature and pressure.

In the next subsection, concentrations, velocities, and fluxes are defined, and special attention is paid to phase interfaces where the concentration of a chemical species is almost always discontinuous. Fick's law of ordinary diffusion is introduced in the third section, where other diffusion phenomena are also discussed. The fourth section presents various forms of the species conservation equation. Results for diffusion in a stationary medium are given in the fifth section, and include steady diffusion across a plane wall, transient diffusion in a semi-infinite solid, and diffusion in a porous catalyst. Results for diffusion in a moving medium are given in the sixth section, and the Stefan flow is introduced for diffusion with one component stationary. Also considered are particle combustion, droplet evaporation, and combustion of a volatile liquid hydrocarbon fuel droplet. The last section deals with mass convection. Low mass transfer rate theory is presented and how to exploit the analogy between convective heat and mass transfer is shown. Particular attention is given to situations involving simultaneous heat and mass transfer associated with evaporation or condensation. The section closes by presenting high mass transfer rate theory for convection, and gives engineering calculation methods for boundary layer flows that account for variable property effects.

### Concentrations, Velocities, and Fluxes

#### Definitions of Concentrations

In a gas mixture, or liquid or solid solution, the local *concentration* of a mass species can be expressed in a number of ways. The *number density* of species  $i$  in a mixture or solution of  $n$  species is defined as

$$\begin{aligned} \text{Number density of species } i &\equiv \text{Number of molecules of } i \text{ per unit volume} \\ &\equiv \mathcal{N}_i \text{ molecules/m}^3 \end{aligned} \quad (4.7.1)$$

Alternatively, if the total number of molecules of all species per unit volume is denoted as  $\mathcal{N}$ , then we define the *number fraction* of species  $i$  as

$$n_i \equiv \frac{\mathcal{N}_i}{\mathcal{N}}; \quad \mathcal{N} = \sum \mathcal{N}_i \quad (4.7.2)$$

where the summation is over all species present,  $i = 1, 2, \dots, n$ . Equations (4.7.1) and (4.7.2) describe *microscopic* concepts and are used, for example, when the kinetic theory of gases is used to describe transfer processes.

Whenever possible, it is more convenient to treat matter as a continuum. Then the smallest volume considered is sufficiently large for macroscopic properties such as pressure and temperature to have their usual meanings. For this purpose we also require *macroscopic* definitions of concentration. First, on a mass basis,

$$\begin{aligned} \text{Mass concentration of species } i &\equiv \text{partial density of species } i \\ &\equiv \rho_i \text{ kg/m}^3 \end{aligned} \quad (4.7.3)$$

The total mass concentration is the total mass per unit volume, that is, the density  $\rho = \sum \rho_i$ . The *mass fraction* of species  $i$  is defined as

$$m_i = \frac{\rho_i}{\rho} \quad (4.7.4)$$

Second, on a molar basis,

$$\begin{aligned} \text{Molar concentration of species } i &\equiv \text{number of moles of } i \text{ per unit volume} \\ &\equiv c_i \text{ kmol/m}^3 \end{aligned} \quad (4.7.5)$$

If  $M_i$  (kg/kmol) is the molecular weight of species  $i$ , then

$$c_i = \frac{\rho_i}{M_i} \quad (4.7.6)$$

The total molar concentration is the molar density  $c = \sum c_i$ . The *mole fraction* of species  $i$  is defined as

$$x_i \equiv \frac{c_i}{c} \quad (4.7.7)$$

A number of important relations follow directly from these definitions. The mean molecular weight of the mixture of solution is denoted  $M$  and may be expressed as

$$M = \frac{\rho}{c} = \sum x_i M_i \quad (4.7.8a)$$

or

$$\frac{1}{M} = \sum \frac{m_i}{M_i} \quad (4.7.8b)$$

There are summation rules

$$\sum m_i = 1 \quad (4.7.9a)$$

$$\sum x_i = 1 \quad (4.7.9b)$$

It is often necessary to have the mass fraction of species  $i$  expressed explicitly in terms of mole fractions and molecular weights; this relation is

$$m_i = \frac{x_i M_i}{\sum x_j M_j} = x_i \frac{M_i}{M} \quad (4.7.10a)$$

and the corresponding relation for the mole fraction is

$$x_i = \frac{m_i/M_i}{\sum m_j/M_j} = m_i \frac{M}{M_i} \quad (4.7.10b)$$

Dalton's law of partial pressures for an ideal gas mixture states that

$$P = \sum P_i, \quad \text{where } P_i = \rho_i R_i T \quad (4.7.11)$$

Dividing partial pressure by total pressure and substituting  $R_i = \mathcal{R}/M_i$  gives

$$\frac{P_i}{P} = \frac{\rho_i}{M_i} \frac{\mathcal{R} T}{P} = c_i \frac{\mathcal{R} T}{P} = x_i \frac{c \mathcal{R} T}{P} = x_i \quad (4.7.12)$$

Thus, for an ideal gas mixture, the mole fraction and partial pressure are equivalent measures of concentration (as also is the number fraction).

A commonly used specification of the composition of dry air is 78.1% N<sub>2</sub>, 20.9% O<sub>2</sub>, and 0.9% Ar, by volume. (The next largest component is CO<sub>2</sub>, at 0.3%.) Since equal volumes of gases contain the same number of moles, specifying composition on a volume basis is equivalent to specifying mole fractions, namely,

$$x_{\text{N}_2} = 0.781; \quad x_{\text{O}_2} = 0.209; \quad x_{\text{Ar}} = 0.009$$

The corresponding mass fractions are calculated to be

$$m_{\text{N}_2} = 0.755; \quad m_{\text{O}_2} = 0.231; \quad m_{\text{Ar}} = 0.014$$

### Concentrations at Interfaces

Although temperature is continuous across a phase interface, concentrations are usually discontinuous. In order to define clearly concentrations at interfaces, we introduce imaginary surfaces, denoted  $u$  and  $s$ , on both sides of the real interface, each indefinitely close to the interface, as shown in [Figure 4.7.1](#) for water evaporating into an airstream. Thus, the liquid-phase quantities at the interface are subscripted  $u$ , and gas-phase quantities are subscripted  $s$ . If we ignore the small amount of air dissolved in the water,  $x_{\text{H}_2\text{O},u} = 1$ . Notice that the subscript preceding the comma denotes the chemical species, and the subscript following the comma denotes location. To determine  $x_{\text{H}_2\text{O},s}$  we make use of the fact that, except in extreme circumstances, the water vapor and air mixture at the  $s$ -surface must be in thermodynamic equilibrium with water at the  $u$ -surface. Equilibrium data for this system are found in conventional steam tables: the saturation vapor pressure of steam at the water temperature,  $T_s$ , ( $T_s = T_u$ ), is the required partial pressure  $P_{\text{H}_2\text{O},s}$ . With the total pressure  $P$  known,  $x_{\text{H}_2\text{O},s}$  is calculated as  $P_{\text{H}_2\text{O},s}/P$ . If  $m_{\text{H}_2\text{O},s}$  is required, Equation (4.7.10a) is used.

**FIGURE 4.7.1** Concentrations at a water-air interface.

For example, at  $T_s = 320$  K, the saturation vapor pressure is obtained from steam tables as  $0.10535 \times 10^5$  Pa. If the total pressure is  $1 \text{ atm} = 1.0133 \times 10^5$ ,

$$x_{\text{H}_2\text{O},s} = \frac{0.10535 \times 10^5}{1.0133 \times 10^5} = 0.1040$$

$$m_{\text{H}_2\text{O},s} = \frac{(0.1040)(18)}{(0.1040)(18) + (1 - 0.1040)(29)} = 0.06720$$

For a gas or solid dissolving in a liquid, equilibrium data are often referred to simply as solubility data, found in chemistry handbooks. Many gases are only sparingly soluble, and for such dilute solutions solubility data are conveniently represented by *Henry's law*, which states that the mole fraction of the gas at the  $s$ -surface is proportional to its mole fraction in solution at the  $u$ -surface, the constant of proportionality being the *Henry number*,  $\text{He}_i$ . For species  $i$ ,

$$x_{i,s} = \text{He}_i x_{i,u} \quad (4.7.13)$$

The Henry number is inversely proportional to total pressure and is also a function of temperature. The product of Henry number and total pressure is the *Henry constant*,  $C_{\text{He}_i}$ , and for a given species is a function of temperature only:

$$\text{He}_i P = C_{\text{He}_i}(T) \quad (4.7.14)$$

Solubility data are given in [Table 4.7.1](#).

**TABLE 4.7.1** Henry Constants  $C_{\text{He}}$  for Dilute Aqueous Solutions at Moderate Pressures ( $P_{i,s}/x_{i,u}$  in atm, or in bar =  $10^5$  Pa, within the accuracy of the data).

Solute	290 K	300 K	310 K	320 K	330 K	340 K
H <sub>2</sub> S	440	560	700	830	980	1,140
CO <sub>2</sub>	1,280	1,710	2,170	2,720	3,220	—
O <sub>2</sub>	38,000	45,000	52,000	57,000	61,000	65,000
H <sub>2</sub>	67,000	72,000	75,000	76,000	77,000	76,000
CO	51,000	60,000	67,000	74,000	80,000	84,000
Air	62,000	74,000	84,000	92,000	99,000	104,000
N <sub>2</sub>	16,000	89,000	101,000	110,000	118,000	124,000

For example, consider absorption of carbon dioxide from a stream of pure CO<sub>2</sub> at 2 bar pressure into water at 310 K. From Table 4.7.1,  $C_{\text{He}} = 2170$  bar; thus

$$\text{He}_{\text{CO}_2} = \frac{2170}{2} = 1085; \quad x_{\text{CO}_2,u} = \frac{1}{1085} = 9.22 \times 10^{-4}$$

Dissolution of gases into metals is characterized by varied and rather complex interface conditions. Provided temperatures are sufficiently high, hydrogen dissolution is reversible (similar to CO<sub>2</sub> absorption into water); hence, for example, titanium-hydrogen solutions can exist only in contact with a gaseous hydrogen atmosphere. As a result of hydrogen going into solution in atomic form, there is a characteristic square root relation

$$m_{\text{H}_2,u} \propto P_{\text{H}_2,s}^{1/2}$$

The constant of proportionality is strongly dependent on temperature, as well as on the particular titanium alloy: for Ti-6Al-4V alloy it is twice that for pure titanium. In contrast to hydrogen, oxygen dissolution in titanium is irreversible and is complicated by the simultaneous formation of a rutile (TiO<sub>2</sub>) scale on the surface. Provided some oxygen is present in the gas phase, the titanium-oxygen *phase diagram* (found in a metallurgy handbook) shows that  $m_{\text{O}_2,u}$  in alpha-titanium is 0.143, a value essentially independent of temperature and O<sub>2</sub> partial pressure. Dissolution of oxygen in zirconium alloys has similar characteristics to those discussed above for titanium.

All the preceding examples of interface concentrations are situations where thermodynamic equilibrium can be assumed to exist at the interface. Sometimes thermodynamic equilibrium does not exist at an interface: a very common example is when a chemical reaction occurs at the interface, and temperatures are not high enough for equilibrium to be attained. Then the concentrations of the reactants and products at the *s*-surface are dependent both on the rate at which the reaction proceeds — that is, the *chemical kinetics* — as well as on mass transfer considerations.

### Definitions of Fluxes and Velocities

The mass (or molar) flux of species *i* is a vector quantity giving the mass (or moles) of species *i* that pass per unit time through a unit area perpendicular to the vector (Figure 4.7.2). We denote the absolute mass and molar fluxes of species *i*, that is, relative to stationary coordinate axes, as  $\mathbf{n}_i$  (kg/m<sup>2</sup>sec) and  $\mathbf{N}_i$  (kmol/m<sup>2</sup>sec), respectively. The absolute mass flux of the mixture (mass velocity) is

$$\mathbf{n} = \sum \mathbf{n}_i \quad (4.7.15)$$

and the local mass-average velocity is

FIGURE 4.7.2 Flux vectors: (a) mass basis, (b) molar basis.

$$\mathbf{v} = \frac{\mathbf{n}}{\rho} \text{ m/sec} \quad (4.7.16)$$

The velocity  $\mathbf{v}$  is the velocity that would be measured by a Pitot tube and corresponds to the velocity used in considering pure fluids. On a molar basis, the absolute molar flux of the mixture is

$$N = \sum N_i \quad (4.7.17)$$

and the local molar-average velocity is

$$\mathbf{v}^* = \frac{N}{c} \text{ m/sec} \quad (4.7.18)$$

The absolute fluxes at species  $i$  have two components. On a mass basis we write

$$\mathbf{n}_i = \rho_i \mathbf{v} + \mathbf{j}_i \quad (4.7.19)$$

where  $\rho_i \mathbf{n}$  is transport of species  $i$  by bulk motion of the fluid at velocity  $\mathbf{v}$  and is the *convective* component. Thus,  $\mathbf{j}_i$  is transport of species  $i$  relative to the mass average velocity; it is called the *diffusive* component because most commonly it is due to ordinary (concentration) diffusion of the species. On a molar basis the corresponding relation is

$$N_i = c_i \mathbf{v}^* + \mathbf{J}_i^* \quad (4.7.20)$$

Some important relations follow from these definitions:

$$\sum \mathbf{j}_i = \sum \mathbf{J}_i^* = 0 \quad (4.7.21)$$

$$N_i = \frac{\mathbf{n}_i}{M_i} \quad (4.7.22)$$

$$\mathbf{n}_i = \rho_i \mathbf{v} + \mathbf{j}_i = m_i \sum \mathbf{n}_i + \mathbf{j}_i \quad (4.7.23a)$$

$$N_i = c_i \mathbf{v}^* + \mathbf{J}_i^* = x_i \sum N_i + \mathbf{J}_i^* \quad (4.7.23b)$$

## Mechanisms of Diffusion

### Ordinary Diffusion

Fick's law of ordinary diffusion is a linear relation between the rate of diffusion of a chemical species and the local concentration gradient of that species. It is exact for a binary gas mixture, for which the kinetic theory of gases gives

$$\mathbf{j}_1 = -\rho \mathcal{D}_{12} \nabla m_1 \text{ kg/m}^2 \text{ sec} \quad (4.7.24a)$$

on a mass basis, and

$$\mathbf{J}_1^* = -c\mathcal{D}_{12}\nabla x_1 \text{ kg/m}^2 \text{ sec} \quad (4.7.24b)$$

on a molar basis;  $\mathcal{D}_{12}$  ( $\text{m}^2/\text{sec}$ ) is the binary diffusion coefficient (or mass diffusivity), and  $\mathcal{D}_{21} = \mathcal{D}_{12}$ . Equations (4.7.24a) and (4.7.24b) are mathematically equivalent; however, notice that it is incorrect to write

$$\mathbf{j}_i = -\mathcal{D}_{12}\nabla\rho_1 \quad (4.7.25)$$

since  $\nabla\rho_1 \neq \rho \nabla m_1$  in general. Fick's law in the form of Equations (4.7.24a) and (4.7.24b) is also valid for dilute liquid and solid solutions, for which it is often possible to assume  $\rho$  (or  $c$ ) constant, and then Equation (4.7.25) or its molar equivalent are good approximations.

Ordinary diffusion in multicomponent systems is described by the Stefan–Maxwell equations (Hirschfelder et al., 1954). These equations are difficult to use for engineering analysis. In gas mixtures containing species that do not have widely varying molecular weights, it is possible to model approximately the diffusion process by using an effective binary diffusion coefficient in Fick's law. This coefficient is a suitable average over the species in the mixture, and may be calculated from

$$\mathcal{D}_{1m} = \frac{(1-x_1)}{\sum_{i=2}^n (x_i/\mathcal{D}_{1i})}; \quad x_1 \ll 1 \quad (4.7.26)$$

This equation works well for most mixtures of combustion gases (except those containing appreciable concentrations of H or  $\text{H}_2$ ).

Binary diffusion coefficients at 300 K are of the order of  $10^{-5} \text{ m}^2/\text{sec}$  in gases at 1 atm,  $10^{-9} \text{ m}^2/\text{sec}$  in aqueous solutions, and  $10^{-10}$  to  $10^{-13} \text{ m}^2/\text{sec}$  in solids. However, the product  $\rho\mathcal{D}$  or ( $c\mathcal{D}$ ) is, at most, one order of magnitude different for gases and liquids. Data for diffusion coefficients may be found in [Tables 4.7.2 through 4.7.5](#).

Molecules in a gas mixture, and in a liquid or solid solution, can diffuse by mechanisms other than ordinary diffusion governed by Fick's law. *Thermal diffusion* is diffusion due to a temperature gradient and is often called the *Soret effect*. Thermal diffusion is usually negligible compared with ordinary diffusion, unless the temperature gradient is very large. However, there are some important processes that depend on thermal diffusion, the most well known being the large-scale separation of uranium isotopes. *Pressure diffusion* is diffusion due to a pressure gradient and is also usually negligible unless the pressure gradient is very large. Pressure diffusion is the principle underlying the operation of a centrifuge. Centrifuges are used to separate liquid solutions and are increasingly being used to separate gaseous isotopes as well. *Forced diffusion* results from an external force field acting on a molecule. Gravitational force fields do not cause separation since the force per unit mass of a molecule is constant. Forced diffusion occurs when an electrical field is imposed on an electrolyte (for example, in charging an automobile battery), on a semiconductor, or on an ionized gas (for example, in a neon tube or metal-ion laser). Depending on the strength of the electric field, rates of forced diffusion can be very large.

Some interesting diffusion phenomena occur in porous solids. When a gas mixture is in a porous solid, such as a catalyst pellet or silica–gel particle, the pores can be smaller than the mean free path of the molecules. Then, the molecules collide with the wall more often than with other molecules. In the limit of negligible molecule collisions we have *Knudsen diffusion*, also called *free molecule flow* in the fluid mechanics literature. If the pore size approaches the size of a molecule, then Knudsen diffusion becomes negligible and *surface diffusion*, in which adsorbed molecules move along the pore walls, becomes the dominant diffusion mechanism.

<sup>a</sup> Owing to the practical importance of water vapor-air mixtures, engineers have used convenient empirical formulas for  $\mathcal{D}_{\text{H}_2\text{O air}}$ . A formula that has been widely used for many years is

$$\mathcal{D}_{\text{H}_2\text{O air}} = 1.97 \times 10^{-5} \left( \frac{P_0}{P} \right) \left( \frac{T}{T_0} \right)^{1.685} \text{ m}^2/\text{sec}; \quad 273 \text{ K} < T < 373 \text{ K}$$

where  $P_0 = 1$  atm;  $T_0 = 256$  K. More recently, the following formula has found increasing use. (Marrero, T.R. and Mason, E.A. 1992. Gaseous diffusion coefficients, *J. Phys. Chem. Ref. Data*, 1, 3-118):

$$\begin{aligned} \mathcal{D}_{\text{H}_2\text{O air}} &= 1.87 \times 10^{-10} \frac{T^{2.072}}{P}; \quad 280 \text{ K} < T < 450 \text{ K} \\ &= 2.75 \times 10^{-9} \frac{T^{1.632}}{P}; \quad 450 \text{ K} < T < 1070 \text{ K} \end{aligned}$$

for  $P$  in atmospheres and  $T$  in kelvins. Over the temperature range 290 to 330 K, the discrepancy between the two formulas is less than 2.5%. For small concentrations of water vapor in air, the older formula gives a constant value of  $\text{Sc}_{\text{H}_2\text{O air}} = 0.61$  over the temperature range 273 to 373 K. On the other hand, the Marrero and Mason formula gives values of  $\text{Sc}_{\text{H}_2\text{O air}}$  that vary from 0.63 at 280 K to 0.57 at 373 K.

Very small particles of  $10^{-3}$  to  $10^{-1}$   $\mu\text{m}$  size — for example, smoke, soot, and mist — behave much like large molecules. Ordinary diffusion of such particles is called *Brownian motion* and is described in most elementary physics texts. Diffusion of particles due to a temperature gradient is called *thermophoresis* and plays an important role for larger particles, typically in the size range  $10^{-1}$  to  $1$   $\mu\text{m}$ . Diffusion of particles in a gas mixture due to concentration gradients of molecular species is called *diffusiophoresis*. *Forced diffusion* of a charged particle in an electrical field is similar to that for an ionized molecular species. Thermal and electrostatic precipitators are used to remove particles from power plant and incinerator stack gases, and depend on thermophoresis and forced diffusion, respectively, for their operation. Diffusion phenomena are unimportant for particles of size greater than about  $1$   $\mu\text{m}$  in air at 1 atm; the motion of such particles is governed by the laws of Newtonian mechanics. Transport of particles is dealt with in the *aerosol science* literature.

## Species Conservation Equation

The principle of conservation of a chemical species is used to derive the *species conservation equation*. On a mass basis this equation is

**TABLE 4.7.3 Schmidt Number for Vapors in Dilute Mixture in Air at Normal Temperature, Enthalpy of Vaporization, and Boiling Point at 1 atm<sup>a</sup>**

Vapor	Chemical Formula	Sc <sup>b</sup>	$h_{fg}$ , J/kg $\times 10^{-6}$	$T_{BP}$ , K
Acetone	CH <sub>3</sub> COCH <sub>3</sub>	1.42	0.527	329
Ammonia	NH <sub>3</sub>	0.61	1.370	240

Ethanol	CH <sub>3</sub> CH <sub>2</sub> OH	1.32	0.854	352
Helium	He	0.22	—	4.3
Heptane	C <sub>7</sub> H <sub>16</sub>	2.0	0.340	372
Hydrogen	H <sub>2</sub>	0.20	0.454	20.3
Hydrogen sulfide	H <sub>2</sub> S	0.94	0.548	213
Methanol	CH <sub>3</sub> OH	0.98	1.110	338
Naphthalene	C <sub>10</sub> H <sub>8</sub>	2.35 <sup>c</sup>	—	491
Nitric oxide	NO	0.87	0.465	121
Octane	C <sub>8</sub> H <sub>18</sub>	2.66	0.303	399
Oxygen	O <sub>2</sub>	0.83	0.214	90.6
Pentane	C <sub>5</sub> H <sub>12</sub>	1.49	0.357	309
Sulfur dioxide	SO <sub>2</sub>	1.24	0.398	263
Water vapor	H <sub>2</sub> O	0.61	2.257	373

<sup>a</sup> With the Clausius-Clapeyron relation, one may estimate vapor pressure as

$$P_{\text{sat}} \approx \exp\left\{-\frac{Mh_{fg}}{\mathcal{R}}\left(\frac{1}{T} - \frac{1}{T_{BP}}\right)\right\} \text{ atm for } T \sim T_{BP}$$

<sup>b</sup> The Schmidt number is defined as  $Sc = \mu/\rho\mathcal{D} = \nu/\mathcal{D}$ . Since the vapors are in small concentrations, values for  $\mu$ ,  $\rho$ , and  $\nu$  can be taken as pure air values.

<sup>c</sup> From a recent study by Cho, C., Irvine, T.F., Jr., and Kami, J. 1992. Measurement of the diffusion coefficient of naphthalene into air, *Int. J. Heat Mass Transfer*, 35, 957–966. Also,  $h_{fg} = 0.567 \times 10^6$  J/kg at 300 K.

$$\frac{\partial \rho_i}{\partial t} + \nabla \cdot \mathbf{n}_i = \dot{r}_i''' \quad (4.7.27)$$

and on a molar basis

$$\frac{\partial c_i}{\partial t} + \nabla \cdot \mathbf{N}_i = \dot{R}_i''' \quad (4.7.28)$$

where  $\dot{r}_i'''$  and  $\dot{R}_i'''$  are the mass and molar rates of production of species  $i$  due to chemical reactions. Summing Equation 4.7.27 over all species gives the mass conservation or continuity equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{v} = 0 \quad (4.7.29)$$

The molar form is

$$\frac{\partial c}{\partial t} + \nabla \cdot c \mathbf{v}^* = \sum_i \dot{R}_i''' \quad (4.7.30)$$

since, in general, moles are not conserved in chemical reactions. A useful alternative form to Equation 4.7.27 can be obtained using Equations (4.7.23a) and (4.7.29) and is

Various sources.

$$\rho \frac{Dm_i}{Dt} = \nabla \cdot (\rho \mathcal{D}_{12} \nabla m_1) + \dot{r}_1''' \quad (4.7.32)$$

When working on a mass basis we define a stationary medium as one in which the mass average velocity  $v$  is zero everywhere. Substituting in Equation (4.7.32) with no chemical reactions and assuming constant properties,

$$\frac{\partial m_1}{\partial t} = \mathcal{D}_{12} \nabla^2 m_1 \quad (4.7.33)$$

which is the *diffusion* equation, and is the mass transfer analog to Fourier's equation for heat conduction. For steady diffusion, Equation (4.7.33) reduces to Laplace's equation

$$\nabla^2 m_1 = 0 \quad (4.7.34)$$

Notice that since properties have been assumed constant, any measure of concentration can be used in Equations (4.7.33) and (4.7.34), for example  $\rho_1$ ,  $c_1$ , and  $x_1$ .

## Diffusion in a Stationary Medium

Many problems involving diffusion in a stationary medium are governed by the diffusion equation (Equation 4.7.33). Often solutions may be obtained from their heat conduction analogs. Some important cases follow.

### Steady Diffusion through a Plane Wall

The mass flow of species 1 across a plane wall of thickness  $L$  and cross-sectional area  $A$  is

$$\dot{m}_1 = \frac{\rho \mathcal{D}_{12} A}{L} (m_{1,u} - m_{1,u'}) \text{ kg/m}^2 \text{ sec} \quad (4.7.35)$$

**FIGURE 4.7.3** Steady diffusion across a plane wall.

where the  $u$ - and  $u'$ -surfaces are shown in [Figure 4.7.3](#). Solubility data are required to relate the  $u$ - and  $u'$ -surface concentrations to  $s$ - and  $s'$ -surface concentrations. Alternatively for systems that obey Henry's law, a solubility  $\mathcal{S}$  can be defined as the volume of solute gas (at STP of 0°C and 1 atm) dissolved in unit volume when the gas is at a partial pressure of 1 atm. Then, defining permeability  $\mathcal{P}_{12}$  as the product  $\mathcal{D}_{12}\mathcal{S}$ , the volume flow of species 1 is

$$\dot{V}_1 = \frac{\mathcal{P}_{12}A}{L}(P_{1,s} - P_{1,s'}) \text{ m}^3 \text{ (STP)/sec} \quad (4.7.36)$$

where the partial pressures  $P_1$  are in atmospheres. The SI units for permeability are  $\text{m}^3 \text{ (STP)/m}^2\text{sec(atm/m)}$ . Permeability and solubility data are given in [Table 4.7.6](#). For example, consider helium at  $10^5$  Pa contained in a 7056-glass vessel with a 1-mm-thick wall at 680 K. For a surface area of  $0.01 \text{ m}^2$ , the leakage rate into ambient air is

$$\dot{V} = \frac{(1.0 \times 10^{-12})(0.01)}{(0.001)}(10^5 - 0) = 1.0 \times 10^{-6} \text{ m}^3 \text{ (STP)/sec}$$

where the value  $\mathcal{P}_{12}$  was obtained from [Table 4.7.6](#).

In general, mass fractions are discontinuous across phase interfaces. Hence, Equation (4.7.35) cannot be generalized to a number of walls in series by simply adding diffusion resistances. However, equilibrium partial pressures  $P_1$  are continuous, and for two walls  $A$  and  $B$ , Equation 4.7.36 becomes

$$\dot{V}_1 = \frac{P_{1,s} - P_{1,s'}}{\frac{L_A}{\mathcal{P}_{1A}A} + \frac{L_B}{\mathcal{P}_{1B}A}} \text{ m}^3 \text{ (STP)/sec} \quad (4.7.37)$$

### Transient Diffusion in a Semi-Infinite Solid

The typically low diffusion coefficients characterizing solids result in many situations where concentration changes are limited to a thin region near the surface (of thickness  $\delta_c \sim (\mathcal{D}_{12}t)^{1/2}$ ). Examples include case-hardening of mild steel and coloring of clear sapphires. Details of the geometry are then unimportant

**FIGURE 4.7.4** Transient diffusion in a plane slab.

and semi-infinite solid model can be used (Figure 4.7.4). For an initial concentration  $m_{1,0}$  and a  $u$ -surface concentration suddenly changed to  $m_{1,u}$  at time  $t = 0$ , the concentration distribution  $m_1(z,t)$  is

$$\frac{m_1 - m_{1,0}}{m_{1,u} - m_{1,0}} = \operatorname{erfc} \frac{z}{(4\mathcal{D}_{12}t)^{1/2}} \quad (4.7.38)$$

and the dissolution rate is

$$\dot{m}_1 = j_{1,u}A = \rho A \left( \frac{\mathcal{D}_{12}}{\pi t} \right)^{1/2} (m_{1,u} - m_{1,0}) \text{ kg/sec} \quad (4.7.39)$$

For example, consider a Pyrex glass slab at 800 K suddenly exposed to helium at  $10^4$  Pa. The molar equivalent to Equation (4.7.39) for an assumed constant solid phase molar concentration  $c$  is

$$\frac{\dot{M}_1}{A} = \left( \frac{\mathcal{D}_{12}}{\pi t} \right)^{1/2} (c_{1,u} - c_{1,0})$$

From Table 4.7.6,  $\mathcal{S}' = c_{1,u}/c_{1,s} \cong 0.024$ ; hence,  $c_{1,u} = (0.024)(10^4)/(8314)(800) = 3.61 \times 10^{-5}$  kmol/m<sup>3</sup>. From Table 4.7.4,  $\mathcal{D}_{12} = 4.76 \times 10^{-8} \exp[-(2.72 \times 10^4)/(10^3)/(8314)(800)] = 7.97 \times 10^{-10}$  m<sup>2</sup>/sec. Hence,

$$\frac{\dot{M}_1}{A} = \left( \frac{7.97 \times 10^{-10}}{\pi t} \right)^{1/2} (3.61 \times 10^{-5} - 0) = 5.75 \times 10^{-10}/t \text{ kmol/sec}$$

### Transient Diffusion in Slabs, Cylinders, and Spheres

Transient heat conduction in slabs, cylinders, and spheres with surface convection is dealt with in Section 4.1. The analogous mass diffusion problem for the slab  $-L < z < L$  is now considered. On a molar basis the governing differential equation is

$$\frac{\partial x_1}{\partial t} = \mathcal{D}_{12} \frac{\partial^2 x_1}{\partial z^2} \quad (4.7.40)$$

with initial condition  $x_1 = x_{1,0}$  at  $t = 0$ . Boundary conditions are  $\partial x_1 / \partial z = 0$  at  $z = 0$ , and at the surface  $z = L$ ,

$$-c\mathcal{D}_{12} \left. \frac{\partial x_1}{\partial z} \right|_{z=L} = \mathcal{G}_{m1} (y_{1,s} - y_{1,e}) \quad (4.7.41)$$

The convective boundary condition is of the same form as Newton's law of cooling, and defines the mole transfer conductance  $\mathcal{G}_{m1}$  (kmol/m<sup>2</sup>sec) (see also the section on mass and mole transfer conductances). Also, we have followed chemical engineering practice and denoted mole fraction  $x$  in the solid (or liquid) phase and  $y$  in the liquid (or gas) phase, to emphasize that generally mole fraction is not continuous across a phase interface. For example, consider absorption of a sparingly soluble gas into a liquid for which Henry's law, Equation (4.7.13), applies: then  $y_{1,s} = \text{Hex}_{1,u}$ .

In using heat conduction charts for mass diffusion problems, particular care must be taken with the evaluation of the Biot number. For heat conduction  $\text{Bi} = h_c L / k$ , where  $k$  is the solid conductivity. For mass diffusion the Biot number accounts for the discontinuity in concentration across the phase interface. Using gas absorption into a plane layer of liquid, for example, when Equation (4.7.41) is put into an appropriate dimensionless form, the mass transfer Biot number is seen to be

$$\text{Bi}_m = \frac{\mathcal{G}_{m1} \text{He} L}{c \mathcal{D}_{12}} \quad (4.7.42)$$

For sparingly soluble gases, e.g., O<sub>2</sub> or CO<sub>2</sub> in water, He, and hence  $\text{Bi}_m$ , are very large, and the absorption process is liquid-side controlled; that is, a uniform gas-phase composition can be assumed. Often interface equilibrium data are in graphical or tabular form; then an effective Biot number at the concentration of concern must be used.

For example, consider a 2-mm-diameter droplet of water at 300 K entrained in an air flow at 1 atm pressure containing 1% by volume CO<sub>2</sub>. From Table 4.7.5,  $\text{He} = C_{\text{He}} = 1710$ . The liquid phase molar density can be approximated by the pure water value of  $c = \rho / M = 996 / 18 = 55.3$  kmol/m<sup>3</sup>. The liquid phase diffusion coefficient is obtained from Table 4.7.4 as  $\mathcal{D}_{12} = \nu_{\text{H}_2\text{O}} / \text{Sc}_{12} = 0.87 \times 10^{-6} / 420 = 2.07 \times 10^{-9}$  m<sup>2</sup>/sec. For negligible relative motion between the droplet and gas, the Sherwood number (see the section on dimensionless groups) is approximately 2.0, and hence the gas phase mole transfer conductance is  $\mathcal{G}_{m1} = 2c\mathcal{D}_{12} / \mathcal{D}$ . For the gas phase, the molar density  $c = \mathcal{P} / \mathcal{R}T = (1.0133 \times 10^5) / (8314)(300) = 0.0406$  kmol/m<sup>3</sup> and  $\mathcal{D}_{12} = 0.157 \times 10^{-4}$  m<sup>2</sup>/sec from Table 4.7.2. Thus,

$$\mathcal{G}_{m1} = \frac{(2)(0.0406)(0.157 \times 10^{-4})}{(0.002)} = 6.37 \times 10^{-4} \text{ kmol/m}^2 \text{ sec}$$

From Equation 4.7.42 with  $L = R$  the droplet radius, the mass transfer Biot number is

$$\text{Bi}_m = \frac{(6.37 \times 10^{-4})(1710)(0.001)}{(55.3)(2.07 \times 10^{-9})} = 9520$$

Thus, even for a small droplet with a relatively large gas-side mole transfer conductance, the absorption process is liquid-side controlled.

### Diffusion in a Porous Catalyst

Porous catalysts are used to give a large surface area per unit volume of catalyst surface. Current practice for automobile catalytic converters is to use a ceramic matrix as a support for a thin porous alumina layer that is impregnated with the catalyst (called a *washcoat*). A typical matrix has passages of hydraulic diameter 1 mm, and the washcoat may be about 20  $\mu\text{m}$  thick. Pore sizes are of the order of 1  $\mu\text{m}$  for which ordinary and Knudsen diffusion resistances are important. A simple model for diffusion in a porous catalyst is

$$J_1 = -c\mathcal{D}_{1,\text{eff}}\nabla x_1 \text{ kmol/m}^2 \text{ sec} \quad (4.7.43)$$

where the subscript eff denotes an effective diffusivity that accounts for the presence of the solid material. Assuming additive resistances,

$$\frac{1}{\mathcal{D}_{1,\text{eff}}} = \frac{1}{\mathcal{D}_{12,\text{eff}}} + \frac{1}{\mathcal{D}_{K1,\text{eff}}} \quad (4.7.44)$$

and

$$\mathcal{D}_{12,\text{eff}} = \frac{\varepsilon_v}{\tau} \mathcal{D}_{12}; \quad \mathcal{D}_{K1,\text{eff}} = \frac{\varepsilon_v}{\tau} \mathcal{D}_{K1,\text{eff}} \quad (4.7.45)$$

where  $\varepsilon_v$  is the volume void fraction and  $\tau$  is the tortuosity factor (usually between 4 and 8). From the kinetic theory of gases the Knudsen diffusion coefficient is

$$\mathcal{D}_{K1} = 97r_e(T/M_1)^{1/2} \text{ m}^2/\text{sec} \quad (4.7.46)$$

for effective pore radius  $r_e$  in meters and  $T$  in kelvins.

When a chemical reaction takes place within a porous layer, a concentration gradient is set up, and surfaces on pores deep within the pellet are exposed to lower reactant concentrations than surfaces near the pore openings. For a first-order reaction it is straightforward to obtain the concentration distribution. The results of such an analysis are conveniently given in the form of an effectiveness  $\eta_p$ , which is defined as the actual consumption rate of the reactant divided by that for an infinite diffusion coefficient. For a layer of thickness  $L$  exposed to reactants on one side, as shown in [Figure 4.7.5](#).

$$\eta_p = \frac{\tanh bL}{bL}; \quad b = \left( \frac{k''a_p}{\mathcal{D}_{1,\text{eff}}} \right)^{1/2} \quad (4.7.47)$$

where  $k''$  (m/sec) is the rate constant for a first-order reaction and  $a_p$  ( $\text{m}^{-1}$ ) is the catalyst area per unit volume. Notice that this effectiveness is analogous to the efficiency of a heat transfer fin.

For example, consider a 30- $\mu\text{m}$ -thick porous alumina washcoat with a volume void fraction  $\varepsilon_v = 0.8$ , a tortuosity factor  $\tau = 4.0$ , average pore radius  $r_e = 1 \mu\text{m}$ , and catalytic surface area per unit volume  $a_p = 7.1 \times 10^5 \text{ cm}^2/\text{cm}^3$ . For carbon monoxide oxidation by copper oxide at 800 K, 1 atm, the rate constant is approximately  $4.2 \times 10^{-4} \text{ m}^2/\text{sec}$ . To calculate the effectiveness of the washcoat, we first need to calculate the effective diffusion coefficient  $\mathcal{D}_{1,\text{eff}}$ :

FIGURE 4.7.5 A catalyst layer.

$$\mathcal{D}_{12,\text{eff}} = \frac{\epsilon_v}{\tau} \mathcal{D}_{12} = \frac{0.8}{4.0} (1.06 \times 10^{-4}) = 2.12 \times 10^{-5} \text{ m}^2/\text{sec}$$

where  $\mathcal{D}_{12}$  is approximated as the CO-air value from Table 4.7.2.

$$\mathcal{D}_{K1,\text{eff}} = \frac{\epsilon_v}{\tau} \mathcal{D}_{12} = \frac{0.8}{4.0} (97) (1 \times 10^{-6}) (800/28)^{1/2} = 1.04 \times 10^{-4} \text{ m}^2/\text{sec}$$

$$\frac{1}{\mathcal{D}_{1,\text{eff}}} = \frac{1}{2.12 \times 10^{-5}} + \frac{1}{1.04 \times 10^{-4}}; \quad \mathcal{D}_{1,\text{eff}} = 1.76 \times 10^{-5} \text{ m}^2/\text{sec}$$

$$b = \left[ \frac{(4.2 \times 10^{-4})(7.1 \times 10^5)(10^2)}{1.76 \times 10^{-5}} \right]^{1/2} = 4.2 \times 10^4 \text{ m}^{-1}; \quad bL = (4.2 \times 10^4)(30 \times 10^{-6}) = 1.236$$

$$\eta_p = \frac{\tanh 1.236}{1.236} = 68.3\%$$

In an automobile catalytic convertor, Equation 4.7.47 applies to the catalyst washcoat. However, the mass transfer problem also involves a convective process for transport of reactants from the bulk flow. Referring to Figure 4.7.6 there are two mass transfer resistances in series, and the consumption rate of species 1 per unit surface area of the washcoat is

$$J_{1,s} = \frac{-x_{1,e}}{\frac{1}{L\eta_p k''c} + \frac{1}{\mathcal{G}_{m1}}} \text{ kmol/m}^2 \text{ sec} \quad (4.7.48)$$

where  $\mathcal{G}_{m1}$  is the mole transfer conductance describing convective transport to the washcoat surface (see the section on mass and mole transfer conductances). Notice that when  $\mathcal{G}_{m1} \ll L\eta_p k''c$  the reaction rate is controlled by mass transfer from the gas stream to the washcoat surface; when  $L\eta_p k''c \ll \mathcal{G}_{m1}$ , the reaction rate is controlled by diffusion within the washcoat and the kinetics of the reaction.

FIGURE 4.7.6 Equivalent circuit for mass transfer in an automobile catalytic convertor.

### Diffusion in a Moving Medium

Net mass transfer across a surface results in a velocity component normal to the surface, and an associated convective flux in the direction of mass transfer. This convective flow is called a *Stefan flow*. The solutions of a number of mass transfer problems, involving a Stefan flow induced by the mass transfer process itself, follow. When necessary to obtain an analytical result, properties are assumed constant. Thus, use of these results requires evaluation of properties at a suitable reference state.

### Diffusion with One Component Stationary

As an example, consider the simple heat pipe shown in Figure 4.7.7 with the evaporator and condenser located at the ends only (a bad design!). Then, if the working fluid is species 1, and a noncondensable gas is species 2, the concentration distribution is

$$\left( \frac{1 - x_1}{1 - x_{1,s}} \right) = \left( \frac{1 - x_{1,e}}{1 - x_{1,s}} \right)^{z/L} \tag{4.7.49}$$

and the vapor flux along the heat pipe is

$$N_1 = \frac{c\mathcal{D}}{L} \ln \frac{1 - x_{1,e}}{1 - x_{1,s}} \text{ kmol/m}^2 \text{ sec} \tag{4.7.50}$$

FIGURE 4.7.7 A simple heat pipe with the evaporator and condenser located at its ends.

Notice that  $N_2 = 0$ ; that is, the gas is stationary. The rate of heat flow for a heat pipe of cross-sectional area of  $A_c$  is  $\dot{Q} = N_1 M_1 h_{fg} A_c$ . Evaluation of the  $c\mathcal{D}$  product at a reference temperature  $T_r = (1/2)(T_s + T_e)$  is adequate for most applications. Equation (4.7.50) applies to any situation where a one-dimensional model of mass transport is appropriate.

### Heterogeneous Combustion

As an example, consider a small carbon particle entrained in a high-temperature airstream, as shown in Figure 4.7.8. The surface reaction is  $2C + O_2 \rightarrow 2CO$  and there are no reactions in the gas phase. The stoichiometric ratio for the reaction is  $r = 4/3$  kg oxygen/kg carbon. The reaction is diffusion controlled at the temperatures under consideration, that is,  $m_{O_2,s} \approx 0$ . The mass transfer rate is  $n_s$ , which we give

the distinctive symbol  $\dot{m}''$  since it is usually the desired result of an analysis; in this situation  $\dot{m}'' = n_{C,u}$  is the combustion rate of carbon, and for a spherical particle of radius  $R$  is given by

$$\dot{m}'' = \frac{\rho \mathcal{D}_{O_2,m}}{R} \ln \left[ 1 + \frac{m_{O_2,e} - m_{O_2,s}}{m_{O_2,s} + 4/3} \right] = 0.160 \frac{\rho \mathcal{D}_{O_2,m}}{R} \text{ kg/m}^2 \text{ sec} \quad (4.7.51)$$

**FIGURE 4.7.8** Combustion of a carbon particle in high-temperature air. The surface reaction is  $2C + O_2 \rightarrow 2CO$ .

The carbon particle temperature depends on its radius, and it is required to evaluate the property product  $\rho \mathcal{D}$  at an appropriate reference temperature: an energy balance on the particle should be performed by this purpose. The resulting particle lifetime  $\tau$  is

$$\tau = \frac{\rho_{\text{solid}} D_0^2}{1.28 (\rho \mathcal{D}_{O_2,m})_r} \text{ sec} \quad (4.7.52)$$

for an initial particle diameter of  $D_0$ . Air properties at an average mean film temperature can be used to evaluate  $\rho \mathcal{D}_{O_2,m}$ .

Consider a 10- $\mu\text{m}$ -diameter carbon particle ignited in an airstream at 1500 K and 1 atm. An energy balance on the particle (including radiation to surroundings at 1500 K) shows that the average temperature of the particle is approximately 2550 K, and, thus,  $T_r = (1/2)(1500 + 2550) = 2025$  K or  $\rho \approx \rho_{\text{air}} = 0.175$  kg/m<sup>3</sup> and  $\mathcal{D}_{O_2,m} \approx \mathcal{D}_{O_2,\text{air}} = 4.89 \times 10^{-4}$  m<sup>2</sup>/sec (from Table 4.7.1). Then

$$\tau = \frac{(1810)(10 \times 10^{-6})^2}{(1.28)(0.175)(4.89 \times 10^{-4})} = 1.65 \times 10^{-3} \text{ sec}$$

### Droplet Evaporation

Consider a small droplet of species 1 entrained in a gas stream, species 2 (Figure 4.7.9). This is a simultaneous heat and mass transfer problem, and the mass transfer rate can be obtained by solving simultaneously

$$\dot{m}'' = \frac{\rho \mathcal{D}_{12}}{R} \ln \left( 1 + \frac{m_{1,e} - m_{1,s}}{m_{1,s} - 1} \right) = \frac{k/c_{p1}}{R} \ln \left( 1 + \frac{c_{p1}(T_e - T_s)}{h_{fg}} \right) \text{ kg/m}^2 \text{ sec} \quad (4.7.53a)$$

$$m_{1,s} = m_{1,s}(T, P) \quad (\text{from vapor-pressure data}) \quad (4.7.53b)$$

FIGURE 4.7.9 Evaporation of a droplet.

Temperature  $T_s$  is the adiabatic vaporization temperature and is essentially the psychrometric wet-bulb temperature. Properties can be evaluated at mean film temperature and composition; alternatively,  $c_{p1}$  can be set equal to the reference specific heat and all properties evaluated using Hubbard's  $1/3$  rule, namely,

$$m_{1,r} = m_{1,s} + (1/3)(m_{1,e} - m_{1,s}) \quad (4.7.54a)$$

$$T_r = T_s + (1/3)(T_e - T_s) \quad (4.7.54b)$$

### Droplet Combustion

Figure 4.7.10 shows a schematic of a volatile liquid hydrocarbon fuel droplet burning in air at zero gravity. The flame diameter is typically four to six times the droplet diameter. Heat is transferred from the flame to the droplet and serves to vaporize the fuel. In the flame the vapor reacts with oxygen to form gaseous products, primarily  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . When a fuel droplet ignites, there is a short initial transient during which the droplet heats up, until further conduction into the droplet is negligible and the droplet attains a steady temperature (approximately the wet-bulb temperature, which is very close to the boiling point for a typical hydrocarbon fuel). The reaction in the flame can be modeled as a single-step reaction with a constant stoichiometric ratio,  $r$ , and heat of combustion  $\Delta h_c$  J/kg of fuel.

The burning (mass transfer) rate of the droplet is given by the Godsave–Spalding formula,

$$\dot{m}'' = \frac{k/c_p}{R} \ln[1 + \mathcal{B}] \text{ kg/m}^2 \text{ sec} \quad (4.7.55)$$

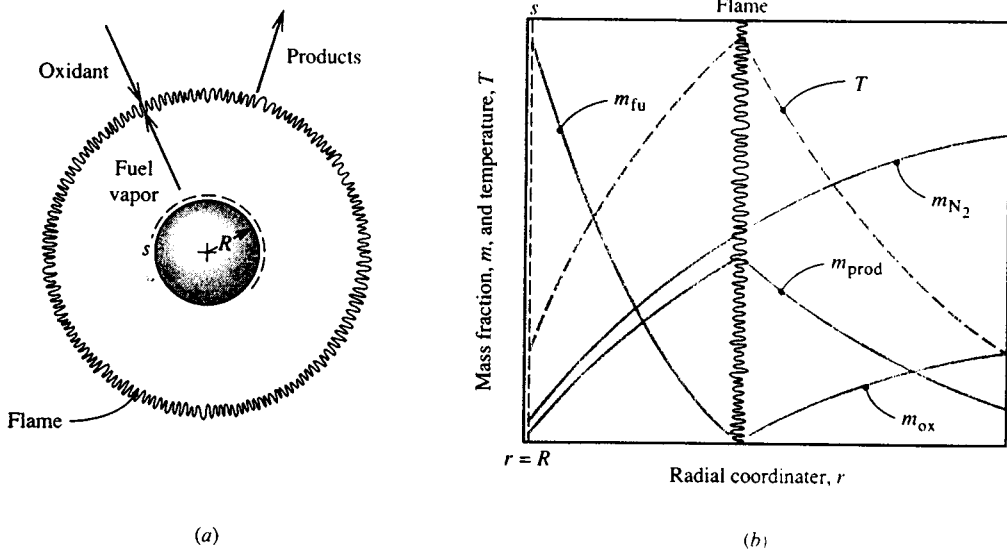

where

$$\mathcal{B} = \frac{m_{\text{ox},e} \Delta h_c / r + c_p (T_e - T_s)}{h_{fg}}$$

is the *mass transfer driving force* (or *transfer number*). The droplet lifetime is then

$$\tau = \frac{\rho_l D_0^2}{8(k/c_p) \ln(1 + \mathcal{B})} \text{ sec} \quad (4.7.56)$$

Based on experimental data for alkane droplets burning in air, Law and Williams (1972) recommend that properties be evaluated at a reference temperature  $T_r = (1/2)(T_{BP} + T_{\text{flame}})$  where  $T_{\text{flame}}$  is the adiabatic flame temperature. The reference specific heat is  $c_{pr} = c_{pfu}$ , and the reference thermal conductivity is  $k_r$ ,

**FIGURE 4.7.10** Combustion of a volatile fuel droplet burning in air: (a) schematic showing the flame, (b) concentration and temperature profiles.

$= 0.4k_{fu} + 0.6k_{air}$ . Radiation has been ignored in the analysis leading to Equation (4.7.55) but is accounted for in using the Law and Williams reference-property scheme.

For example, consider a 1-mm-diameter *n*-octane droplet burning in air at 1 atm and 300 K, at near zero gravity. For *n*-octane ( $n\text{-C}_8\text{H}_{18}$ ),  $\rho_l = 611 \text{ kg/m}^3$ ,  $h_{fg} = 3.03 \times 10^5 \text{ J/kg}$ ,  $\Delta h_c = 4.44 \times 10^7 \text{ J/kg}$ , and  $T_{BP} = 399 \text{ K}$ . The flame temperature is  $T_{\text{flame}} = 2320 \text{ K}$ . At a reference temperature of  $(1/2)(T_{\text{flame}} + T_{BP}) = 1360 \text{ K}$ , property values of *n*-octane vapor include  $k = 0.113 \text{ W/m K}$ ,  $c_p = 4280 \text{ J/kg K}$ . The reaction is

Hence, the stoichiometric ratio  $r = 400/114.2 = 3.50$ . Also  $m_{ox,e} = 0.231$  and  $T_s \cong T_{BP} = 399 \text{ K}$ . Thus, the transfer number is

$$\mathcal{B} = \frac{(0.231)(4.44 \times 10^7)/(3.50) + 4280(300 - 399)}{3.03 \times 10^5} = 8.27$$

At  $T_r = 1360 \text{ K}$ ,  $k_{air} = 0.085 \text{ W/m K}$ . Hence,

$$k_r = 0.4k_{fu} + 0.6k_{air} = (0.4)(0.113) + (0.6)(0.085) = 0.096 \text{ W/m K}$$

and the droplet lifetime is

$$\tau = \frac{(611)(1 \times 10^{-3})^2}{(8)(0.096/4280)\ln(1 + 8.27)} = 1.53 \text{ sec}$$

## Mass Convection

The terms *mass convection* or *convective mass transfer* are generally used to describe the process of mass transfer between a surface and a moving fluid, as shown in Figure 4.7.11. The surface may be that

**FIGURE 4.7.11** Notation for convective mass transfer into an external flow.

of a falling water film in an air humidifier, of a coke particle in a gasifier, or of a silica-phenolic heat shield protecting a reentry vehicle. As is the case for heat convection, the flow can be *forced* or *natural*, *internal* or *external*, and *laminar* or *turbulent*. In addition, the concept of whether the mass transfer rate is *low* or *high* plays an important role: when mass transfer rates are low, there is a simple analogy between heat transfer and mass transfer that can be efficiently exploited in the solution of engineering problems.

### Mass and Mole Transfer Conductances

Analogous to convective heat transfer, the rate of mass transfer by convection is usually a complicated function of surface geometry and  $s$ -surface composition, the fluid composition and velocity, and fluid physical properties. For simplicity, we will restrict our attention to fluids that are either binary mixtures or solutions, or situations in which, although more than two species are present, diffusion can be adequately described using effective binary diffusion coefficients, as was discussed in the section on ordinary diffusion. Referring to [Figure 4.7.11](#), we define the *mass transfer conductance* of species 1,  $g_{m1}$ , by the relation

$$j_{1,s} = g_{m1} \Delta m_1; \quad \Delta m_1 = m_{1,s} - m_{1,e} \quad (4.7.57)$$

and the units of  $g_{m1}$  are seen to be the same as for mass flux ( $\text{kg}/\text{m}^2\text{sec}$ ). Equation (4.7.57) is of a similar form to Newton's law of cooling, which defines the heat transfer coefficient  $h_c$ . Why we should not use a similar name and notation (e.g., mass transfer coefficient and  $h_m$ ) will become clear later. On a molar basis, we define the *mole transfer conductance* of species 1,  $g_{m1}$ , by a corresponding relation,

$$J_{1,s} = g_{m1} \Delta x_1; \quad \Delta x_1 = x_{1,s} - x_{1,e} \quad (4.7.58)$$

where  $g_{m1}$  has units ( $\text{kmol}/\text{m}^2\text{sec}$ ).

### Low Mass Transfer Rate Theory

Consider, as an example, the evaporation of water into air, as shown in [Figure 4.7.12](#). The water–air interface might be the surface of a water reservoir, or the surface of a falling water film in a cooling tower or humidifier. In such situations the mass fraction of water vapor in the air is relatively small; the highest value is at the  $s$ -surface, but even if the water temperature is as high as  $50^\circ\text{C}$ , the corresponding value of  $m_{\text{H}_2\text{O},s}$  at 1 atm total pressure is only 0.077. From Equation 4.7.54 the driving potential for diffusion of water vapor away from the interface is  $\Delta m_1 = m_{1,s} - m_{1,e}$ , and is small compared to unity, even if the free-stream air is very dry such that  $m_{1,e} \approx 0$ . We then say that the mass transfer rate is *low* and the rate of evaporation of the water can be approximated as  $j_{1,s}$ ; for a surface area  $A$ ,

$$\dot{m}_1 = (m_{1,s} n_s + j_{1,s}) A \approx j_{1,s} A \text{ kg/sec} \quad (4.7.59)$$

**FIGURE 4.7.12** Evaporation of water into an air flow.

In contrast, if the water temperature approaches its boiling point,  $m_{1,s}$  is no longer small, and of course, in the limit of  $T_s = T_{BP}$ ,  $m_{1,s} = 1$ . The resulting driving potential for diffusion  $\Delta m_1$  is then large, and we say that the mass transfer rate is *high*. Then, the evaporation rate cannot be calculated from Equation 4.7.59, as will be explained in the section on high mass transfer rate theory. For water evaporation into air, the error incurred in using low mass transfer rate theory is approximately  $(1/2) \Delta m_1$ , and a suitable criterion for application of the theory to engineering problems is  $\Delta m_1 < 0.1$  or  $0.2$ .

A large range of engineering problems can be adequately analyzed assuming low mass transfer rates. These problems include cooling towers and humidifiers as mentioned above, gas absorbers for sparingly soluble gases, and catalysis. In the case of catalysis, the *net* mass transfer rate is actually zero. Reactants diffuse toward the catalyst surface and the products diffuse away, but the catalyst only promotes the reaction and is not consumed. On the other hand, problems that are characterized by high mass transfer rates include condensation of steam containing a small amount of noncondensable gas, as occurs in most power plant condensers; combustion of volatile liquid hydrocarbon fuel droplets in diesel engines and oil-fired power plants, and ablation of phenolic-based heat shields on reentry vehicles.

### Dimensionless Groups

Dimensional analysis of convective mass transfer yields a number of pertinent dimensionless groups that are, in general, analogous to dimensionless groups for convective heat transfer. The most important groups are as follows.

1. The Schmidt number,  $Sc_{12} = \mu/\rho\mathcal{D}_{12}$ , which is a properties group analogous to the Prandtl number. For gas mixtures,  $Sc_{12} = O(1)$ , and for liquid solutions,  $Sc_{12} = O(100)$  to  $O(1000)$ . There are not fluids for which  $Sc_{12} \ll 1$ , as is the case of Prandtl number for liquid metals.
2. The Sherwood number (or mass transfer Nusselt number).  $Sh = g_{m1}L/\rho\mathcal{D}_{12}$  ( $= G_{m1}L/c\mathcal{D}_{12}$ ) is a dimensionless conductance.
3. The mass transfer Stanton number  $St_m = g_{m1}/\rho V$  ( $= G_{m1}/cV$ ) is an alternative dimensionless conductance.

As for convective heat transfer, forced convection flows are characterized by a Reynolds number, and natural convection flows are characterized by a Grashof or Rayleigh number. In the case of Gr or Ra it is not possible to replace  $\Delta\rho$  by  $\beta\Delta T$  since density differences can result from concentration differences (and both concentration and temperature differences for simultaneous heat and mass transfer problems).

### Analogy between Convective Heat and Mass Transfer

A close analogy exists between convective heat and convective mass transfer owing to the fact that conduction and diffusion in a fluid are governed by physical laws of identical form, that is, Fourier's and Fick's laws, respectively. As a result, in many circumstances the Sherwood or mass transfer Stanton number can be obtained in a simple manner from the Nusselt number or heat transfer Stanton number for the same flow conditions. Indeed, in most gas mixtures  $Sh$  and  $St_m$  are nearly equal to their heat transfer counterparts. For dilute mixtures and solutions and low mass transfer rates, the rule for exploiting the analogy is simple: *The Sherwood or Stanton number is obtained by replacing the Prandtl number by the Schmidt number in the appropriate heat transfer correlation.* For example, in the case of fully developed turbulent flow in a smooth pipe

$$Nu_D = 0.023Re_D^{0.8}Pr^{0.4}; \quad Pr > 0.5 \quad (4.7.60a)$$

which for mass transfer becomes

$$Sh_D = 0.023Re_D^{0.8}Sc^{0.4}; \quad Sc > 0.5 \quad (4.7.60b)$$

Also, for natural convection from a heated horizontal surface facing upward,

$$\overline{Nu} = 0.54(Gr_L Pr)^{1/4}; \quad 10^5 < Gr_L Pr < 2 \times 10^7 \quad (\text{laminar}) \quad (4.7.61a)$$

$$\overline{Nu} = 0.14(Gr_L Pr)^{1/3}; \quad 2 \times 10^7 < Gr_L Pr < 3 \times 10^{10} \quad (\text{turbulent}) \quad (4.7.61b)$$

which for isothermal mass transfer with  $\rho_s < \rho_e$  become

$$\overline{Sh} = 0.54(Gr_L Sc)^{1/4}; \quad 10^5 < Gr_L Sc < 2 \times 10^7 \quad (\text{laminar}) \quad (4.7.62a)$$

$$\overline{Sh} = 0.14(Gr_L Sc)^{1/3}; \quad 2 \times 10^7 < Gr_L Sc < 3 \times 10^{10} \quad (\text{turbulent}) \quad (4.7.62b)$$

With evaporation, the condition,  $\rho_s < \rho_e$  will be met when the evaporating species has a smaller molecular weight than the ambient species, for example, water evaporating into air. Mass transfer correlations can be written down in a similar manner for almost all the heat transfer correlations given in Section 4.2. There are some exceptions: for example, there are no fluids with a Schmidt number much less than unity, and thus there are no mass transfer correlations corresponding to those given for heat transfer to liquid metals with  $Pr \ll 1$ . In most cases it is important for the wall boundary conditions to be of analogous form, for example, laminar flow in ducts. A uniform wall temperature corresponds to a uniform concentration  $m_{1,s}$  along the  $s$ -surface, whereas a uniform heat flux corresponds to a uniform diffusive flux  $j_{1,s}$ . In chemical engineering practice, the analogy between convective heat and mass transfer is widely used in a form recommended by Chilton and Colburn in 1934, namely,  $St_m/St = (Sc/Pr)^{-2/3}$ . The Chilton-Colburn form is of adequate accuracy for most external forced flows but is inappropriate for fully developed laminar duct flows.

For example, air at 1 atm and 300 K flows inside a 3-cm-inside-diameter tube at 10 m/sec. Using pure-air properties the Reynolds number is  $VD/\nu = (10)(0.03)/15.7 \times 10^{-6} = 1.911 \times 10^4$ . The flow is turbulent. Using Equation (4.7.60b) with  $Sc_{12} = 0.61$  for small concentrations of  $H_2O$  in air,

$$Sh_D = (0.023)(1.911 \times 10^4)^{0.8} (0.61)^{0.4} = 50.2$$

$$g_{m1} = \rho \mathcal{D}_{12} \text{Sh}/D = \rho v \text{Sh}/\text{Sc}_{12} D = \frac{(1.177)(15.7 \times 10^{-6})(50.2)}{(0.61)(0.03)} = 5.07 \times 10^{-2} \text{ kg/m}^2 \text{ sec}$$

Further insight into this analogy between convective heat and mass transfer can be seen by writing out Equations (4.7.60a) and (4.7.60b) as, respectively,

$$\frac{(h_c/c_p)D}{k/c_p} = 0.023 \text{Re}_D^{0.8} \left( \frac{\mu}{k/c_p} \right)^{0.4} \quad (4.7.63a)$$

$$\frac{g_m D}{\rho \mathcal{D}_{12}} = 0.023 \text{Re}_D^{0.8} \left( \frac{\mu}{\rho \mathcal{D}_{12}} \right)^{0.4} \quad (4.7.63b)$$

When cast in this form, the correlations show that the property combinations  $k/c_p$  and  $\rho \mathcal{D}_{12}$  play analogous roles; these are *exchange coefficients* for heat and mass, respectively, both having units kg/m sec, which are the same as those for dynamic viscosity  $\mu$ . Also, it is seen that the ratio of heat transfer coefficient to specific heat plays an analogous role to the mass transfer conductance, and has the same units (kg/m<sup>2</sup> sec). Thus, it is appropriate to refer to the ratio  $h_c/c_p$  as the *heat transfer conductance*,  $g_h$ , and for this reason we should not refer to  $g_m$  as the mass transfer *coefficient*.

### Simultaneous Heat and Mass Transfer

Often problems involve simultaneous convective heat and mass transfer, for which the surface energy balance must be carefully formulated. Consider, for example, evaporation of water into air, as shown in Figure 4.7.13. With H<sub>2</sub>O denoted as species 1, the steady-flow energy equation applied to a control volume located between the  $u$ - and  $s$ -surfaces requires that

$$\dot{m}(h_{1,s} - h_{1,u}) = A(q''_{\text{cond}} - q''_{\text{conv}} - q''_{\text{rad}}) W \quad (4.7.64)$$

where it has been recognized that only species 1 crosses the  $u$ - and  $s$ -surfaces. Also, the water has been assumed to be perfectly opaque so that all radiation is emitted or absorbed between the  $u$ -surface and the interface.

If we restrict our attention to conditions for which low mass transfer rate theory is valid, we can write  $\dot{m}/A \approx j_{1,s} = g_{m1}(m_{1,s} - m_{1,e})$ . Also, we can then calculate the convective heat transfer as if there were no mass transfer, and write  $q_{\text{conv}} = h_c(T_s - T_e)$ . Substituting in Equation (4.7.64) with  $q_{\text{conv}} = -k\partial T/\partial y|_u$ ,  $h_{1,s} - h_{1,u} = h_{fg}$ , and rearranging, gives

$$-k \frac{\partial T}{\partial y} \Big|_u = h_c(T_s - T_e) + g_{m1}(m_{1,s} - m_{1,e})h_{fg} + q''_{\text{rad}} \text{ W/m}^2 \quad (4.7.65)$$

It is common practice to refer to the convective heat flux  $h_c(T_s - T_e)$  as the *sensible* heat flux, whereas the term  $g_{m1}(m_{1,s} - m_{1,e})h_{fg}$  is called the *evaporative* or *latent* heat flux. Each of the terms in Equation 4.7.65 can be positive or negative, depending on the particular situation. Also, the evaluation of the conduction heat flux at the  $u$ -surface,  $-k\partial T/\partial y|_u$ , depends on the particular situation. Four examples are shown in Figure 4.7.13. For a water film flowing down a packing in a cooling tower (Figure 4.7.13b), this heat flux can be expressed in terms of convective heat transfer from the bulk water at temperature  $T_L$  to the surface of the film,  $-k\partial T/\partial y|_u = h_{cL}(T_L - T_s)$ . If the liquid-side heat transfer coefficient  $h_{cL}$  is large enough, we can simply set  $T_s \approx T_L$ , which eliminates the need to estimate  $h_{cL}$ . The evaporation process is then *gas-side controlled*. Figure 4.7.13c shows film condensation from a steam-air mixture on the outside of a vertical tube. In this case we can write  $k\partial T/\partial y|_u = U(T_s - T_c)$ , where  $T_c$  is the coolant

FIGURE 4.7.13 The surface energy balance for evaporation of water into an air stream.

bulk temperature. The overall heat transfer coefficient  $U$  includes the resistances of the condensate film, the tube wall, and the coolant. Sweat cooling is shown in Figure 4.7.13d, with water from a reservoir (or *plenum chamber*) injected through a porous wall at a rate just sufficient to keep the wall surface wet. In this case, the conduction across the  $u$ -surface can be related to the reservoir conditions by application of the steady-flow energy equation to a control volume located between the  $o$ - and  $u$ -surfaces. Finally, Figure 4.7.13e shows drying of a wet porous material (e.g., a textile or wood). During the constant-rate period of the process, evaporation takes place from the surface with negligible heat conduction into the solid; then  $-k\partial T/\partial y|_u \approx 0$ . The term *adiabatic vaporization* is used to describe evaporation when  $q_{\text{cond}} = 0$ ; constant-rate drying is one example, and the wet-bulb psychrometer is another.

Consider a 1-m-square wet towel on a washline on a day when there is a low overcast and no wind. The ambient air is at 21°C, 1 atm, and 50.5% RH. In the constant-rate drying period the towel temperature is constant, and  $q_{\text{cond}} = 0$ . An iterative calculation is required to obtain the towel temperature using correlations for natural convection on a vertical surface to obtain  $h_c$  and  $g_{m1}$ ;  $q_{\text{rad}}$  is obtained as  $q_{\text{rad}} = \sigma\epsilon(T_s^4 - T_e^4)$  with  $\epsilon = 0.90$ . The results are  $T_s = 17.8^\circ\text{C}$ ,  $h_c = 1.69 \text{ W/m}^2\text{K}$ ,  $g_{m1} = 1.82 \times 10^{-3} \text{ kg/m}^2\text{sec}$ , and the energy balance is

$$q_{\text{cond}} = h_c(T_s - T_e) + g_{m1}(m_{1,s} - m_{1,e})h_{fg} + q_{\text{rad}}$$

$$0 = -5.4 + 21.7 - 16.3 \text{ W/m}^2$$

Evaluation of composition-dependent properties, in particular the mixture specific heat and Prandtl number, poses a problem. In general, low mass transfer rates imply small composition variations across a boundary layer, and properties can be evaluated for a mixture of the free-stream composition at the mean film temperature. In fact, when dealing with evaporation of water into air, use of the properties of dry air at the mean film temperature gives results of adequate engineering accuracy. If there are large composition variations across the boundary layer, as can occur in some catalysis problems, properties should be evaluated at the mean film composition and temperature.

### The Wet- and Dry-Bulb Psychrometer

The wet- and dry-bulb psychrometer is used to measure the moisture content of air. In its simplest form, the air is made to flow over a pair of thermometers, one of which has its bulb covered by a wick whose other end is immersed in a small water reservoir. Evaporation of water from the wick causes the wet bulb to cool and its steady-state temperature is a function of the air temperature measured by the dry bulb and the air humidity. The wet bulb is shown in Figure 4.7.14. In order to determine the water vapor mass fraction  $m_{1,e}$ , the surface energy balance Equation (4.7.66) is used with conduction into the wick and  $q''_{\text{rad}}$  set equal to zero. The result is

$$m_{1,e} = m_{1,s} - \frac{c_p}{h_{fg}} \left( \frac{\text{Pr}}{\text{Sc}_{12}} \right)^{-2/3} (T_e - T_s) \quad (4.7.66)$$

Usually  $m_{1,e}$  is small and we can approximate  $c_p = c_{p, \text{air}}$  and  $(\text{Pr}/\text{Sc}_{12})^{-2/3} = 1/1.08$ . Temperatures  $T_s$  and  $T_e$  are the known measured wet- and dry-bulb temperatures. With  $T_s$  known,  $m_{1,s}$  can be obtained using steam tables in the usual way. For example, consider an air flow at 1000 mbar with measured wet- and dry-bulb temperatures of 305.0 and 310.0 K, respectively. Then  $P_{1,s} = P_{\text{sat}}(T_s) = P_{\text{sat}}(305.0 \text{ K}) = 4714 \text{ Pa}$  from steam tables. Hence,  $x_{1,s} = P_{1,s}/P = 4714/10^5 = 0.04714$ , and

$$m_{1,s} = \frac{0.04714}{0.04714 + (29/18)(1 - 0.04714)} = 0.02979$$

FIGURE 4.7.14 Wet bulb of a wet- and dry-bulb psychrometer.

Also,  $h_{fg}$  (305 K) =  $2.425 \times 10^6$  J/kg, and  $c_{p, \text{air}} = 1005$  J/kg K; thus

$$m_{1,e} = 0.02979 - \frac{1005}{(1.08)(2.425 \times 10^6)}(310 - 305) = 0.02787$$

$$x_{1,e} = \frac{0.02787}{0.02787 + (18/29)(1 - 0.02787)} = 0.04415$$

$$P_{1,e} = x_{1,e}P = (0.04415)(10^5) = 4412 \text{ Pa}$$

By definition, the relative humidity is  $\text{RH} = P_{1,e}/P_{\text{sat}}(T_e)$ ;  $\text{RH} = 4415/6224 = 70.9\%$ .

In the case of other adiabatic vaporization processes, such as constant-rate drying or evaporation of a water droplet,  $m_{1,e}$  and  $T_e$  are usually known and Equation (4.7.66) must be solved for  $T_s$ . However, the thermodynamic wet-bulb temperature obtained from psychrometric charts or software is accurate enough for engineering purposes.

### High Mass Transfer Rate Theory

When there is net mass transfer across a phase interface, there is a convective component of the absolute flux of a species across the  $s$ -surface. From Equation (4.7.23a) for species 1,

$$n_{1,s} = \rho_{1,s}v_s + j_{1,s} \text{ kg/m}^2 \text{ sec} \quad (4.7.67)$$

During evaporation the convection is directed in the gas phase, with a velocity normal to the surface  $v_s$ . When the convective component cannot be neglected, we say that the mass transfer rate is *high*. There are two issues to consider when mass transfer rates are high. First, the rate at which species 1 is transferred across the  $s$ -surface is not simply the diffusive component  $j_{1,s}$  as assumed in low mass transfer rate theory, but is the sum of the convective and diffusive components shown in Equation 4.7.67. Second, the normal velocity component  $v_s$  has a *blowing* effect on the concentration profiles, and hence on the Sherwood number. The Sherwood number is no longer analogous to the Nusselt number of conventional heat transfer correlations, because those Nusselt numbers are for situations involving impermeable surfaces, e.g., a metal wall, for which  $v_s = 0$ .

Substituting for  $j_{1,s}$  from Equation (4.7.57) into Equation (4.7.67) gives

$$\dot{m}'' = g_{m1} \frac{m_{1,e} - m_{1,s}}{m_{1,s} - n_{1,s}/\dot{m}''} = g_{m1} \mathcal{B}_{m1} \quad (4.7.68)$$

where  $\dot{m}'' = n_s$  is the mass transfer rate introduced in the section on heterogeneous combustion and  $\mathcal{B}_{m1}$  is the *mass transfer driving force*. In the special case where only species 1 is transferred,  $n_{1,s}/\dot{m}'' = 1$ , for example, when water evaporates into air, and dissolution of air in the water is neglected. It is convenient to rewrite Equation (4.7.68) as

$$\dot{m}'' = g_{m1}^* (g_{m1}/g_{m1}^*) \mathcal{B}_{m1} \text{ kg/m}^2 \text{ sec} \quad (4.7.69a)$$

where

$$g_{m1}^* = \lim_{\mathcal{B}_{m1} \rightarrow 0} g_{m1} \quad (4.7.69b)$$

Now  $g_{m1}^*$  is the limit value of  $g_{m1}$  for zero mass transfer (i.e.,  $v_s = 0$ ), and  $\text{Sh}^*$  can be obtained from conventional heat transfer Nusselt number correlations for impermeable surfaces. The ratio  $(g_{m1}/g_{m1}^*)$  is termed a *blowing factor* and accounts for the effect of  $v_s$  on the concentration profiles. Use of Equation (4.7.69) requires appropriate data for the blowing factor. For the constant-property laminar boundary layer on a flat plate, Figure 4.7.15 shows the effect of the Schmidt number on the blowing factor. The abscissa is a *blowing parameter*  $B_m = \dot{m}''/g_{m1}^*$ .

The blowing velocity also affects the velocity and temperature profiles, and hence the wall shear stress and heat transfer. The curve for  $\text{Sc} = 1$  in Figure 4.7.15 also gives the effect of blowing on shear stress as  $\tau_s/\tau_s^*$ , and the curve for  $\text{Sc} = 0.7$  gives the effect of blowing on heat transfer for air injection into air as  $h_c/h_c^*$  (since  $\text{Pr} = 0.7$  for air).

### Variable Property Effects of High Mass Transfer Rates

High mass transfer rate situations are usually characterized by large property variations across the flow, and hence property evaluation for calculating  $g_m$  and  $h_c$  is not straightforward. An often-encountered situation is transfer of a single species into an inert laminar or turbulent boundary layer flow. The effect of variable properties can be very large as shown in Figure 4.7.16 for laminar boundary layers, and Figure 4.7.17 for turbulent boundary layers.

A simple procedure for correlating the effects of flow type and variable properties is to use weighting factors in the exponential functions suggested by a constant-property Couette-flow model (Mills, 1995). Denoting the injected species as species  $i$ , we have

$$\frac{g_{m1}}{g_{m1}^*} = \frac{a_{mi} B_{mi}}{\exp(a_{mi} B_{mi}) - 1}; \quad B_{mi} = \frac{\dot{m}''}{g_{mi}^*} \quad (4.7.70a)$$

or

$$\frac{g_{m1}}{g_{mi}^*} = \frac{\ln(1 + a_{mi} \mathcal{B}_{mi})}{a_{mi} \mathcal{B}_{mi}}; \quad \mathcal{B}_{mi} = \frac{\dot{m}''}{g_{mi}^*} = \frac{m_{i,e} - m_{i,s}}{m_{i,s} - 1}$$

$$\frac{\tau_s}{\tau_s^*} = \frac{a_{fi} B_f}{\exp(a_{fi} B_f) - 1}; \quad B_f = \frac{\dot{m}'' u_e}{\tau_s^*} \quad (4.7.70b)$$

**FIGURE 4.7.15** Effect of mass transfer on the mass transfer conductance for a laminar boundary layer on a flat plate:  $g_m/g_m^*$  vs. blowing parameter  $B_m = \dot{m}''/g_m^*$ .

$$\frac{h_c}{h_c^*} = \frac{a_{hi} B_h}{\exp(a_{hi} B_h) - 1}; \quad B_h = \frac{\dot{m}'' c_{pe}}{h_c^*} \tag{4.7.70c}$$

Notice that  $g_{mi}^*$ ,  $\tau_s^*$ ,  $h_c^*$ , and  $c_{pe}$  are evaluated using properties of the free-stream gas at the mean film temperature. The weighting factor  $a$  may be found from exact numerical solutions of boundary layer equations or from experimental data. Some results for laminar and turbulent boundary layers follow.

1. *Laminar Boundary Layers.* We will restrict our attention to low-speed air flows, for which viscous dissipation and compressibility effects are negligible, and use exact numerical solutions of the self-similar laminar boundary layer equations (Wortman, 1969). Least-squares curve fits of the numerical data were obtained using Equations (4.7.70a) to (4.7.70c). Then, the weighting factors for axisymmetric stagnation-point flow with a cold wall ( $T_s/T_e = 0.1$ ) were correlated as

$$a_{mi} = 1.65(M_{air}/M_i)^{10/12} \tag{4.7.71a}$$

**FIGURE 4.7.16** Numerical results for the effect of pressure gradient and variable properties on blowing factors for laminar boundary layers: low-speed air flow over a cold wall ( $T_s/T_e = 0.1$ ) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Wortman, A., Ph.D. dissertation, University of California, Los Angeles, 1969. With permission.)

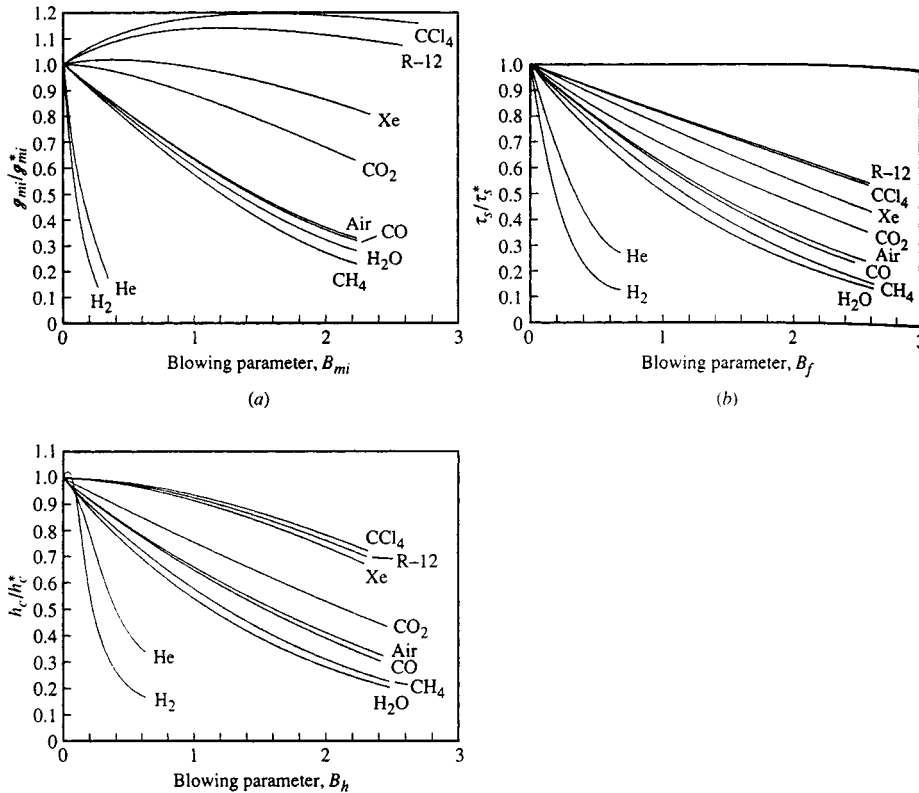

$$a_{fi} = 1.38(M_{air}/M_i)^{5/12} \tag{4.7.71b}$$

$$a_{hi} = 1.30(M_{air}/M_i)^{3/12} \left[ c_{pi} / (2.5\mathcal{R}/M_i) \right] \tag{4.7.71c}$$

Notice that  $c_{pi}/2.5\mathcal{R}/M_i$  is unity for a monatomic species. For the planar stagnation line and the flat plate, and other values of the temperature ratio  $T_s/T_e$ , the values of the species weighting factors are divided by the values given by Equations (4.7.71a,b,c) to give correction factors  $G_{mi}$ ,  $G_{fi}$ , and  $G_{hi}$ , respectively. The correction factors are listed in Table 4.7.7.

The exponential relation blowing factors cannot accurately represent some of the more anomalous effects of blowing. For example, when a light gas such as  $H_2$  is injected, Equation (4.7.70c) indicates that the effect of blowing is always to reduce heat transfer, due to both the low density and high specific heat of hydrogen. However, at very low injection rates, the heat transfer is actually increased, as a result of the high thermal conductivity of  $H_2$ . For a mixture,  $k \approx \sum x_i k_i$  whereas  $c_p = \sum m_i c_{pi}$ . At low rates of injection, the mole fraction of  $H_2$  near the wall is much larger than its mass fraction; thus, there is a substantial increase in the mixture conductivity near the wall, but only a small change in the mixture specific heat. An increase in heat transfer results. At higher injection rates, the mass fraction of  $H_2$  is also large, and the effect of high mixture specific heat dominates to cause a decrease in heat transfer.

2. *Turbulent Boundary Layers.* Here we restrict our attention to air flow along a flat plate for Mach numbers up to 6, and use numerical solutions of boundary layer equations with a mixing length turbulence model (Landis, 1971). Appropriate species weighting factors for  $0.2 < T_s/T_e < 2$  are

**FIGURE 4.7.17** Numerical results for the effect of variable properties on blowing factors for a low-speed turbulent air boundary layer on a cold flat plate ( $T_s/T_e = 0.2$ ) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Landis, R.B., Ph.D. dissertation, University of California, Los Angeles, 1971. With permission.)

$$a_{mi} = 0.79(M_{\text{air}}/M_i)^{1.33} \tag{4.7.72a}$$

$$a_{fi} = 0.91(M_{\text{air}}/M_i)^{0.76} \tag{4.7.72b}$$

$$a_{hi} = 0.86(M_{\text{air}}/M_i)^{0.73} \tag{4.7.72c}$$

In using Equation (4.7.70), the limit values for  $\dot{m}'' = 0$  are elevated at the same location along the plate. Whether the injection rate is constant along the plate or varies as  $x^{-0.2}$  to give a self-similar boundary layer has little effect on the blowing factors. Thus, Equation (4.7.72) has quite general applicability. Notice that the effects of injectant molecular weight are greater for turbulent boundary layers than for laminar ones, which is due to the effect of fluid density on turbulent transport. Also, the injectant specific heat does not appear in  $a_{hi}$  as it did for laminar flows. In general,  $c_{pi}$  decreases with increasing  $M_i$  and is adequately accounted for in the molecular weight ratio.

**Reference State Schemes.** The reference state approach, in which constant-property data are used with properties evaluated at some reference state, is an alternative method for handling variable-property effects. In principle, the reference state is independent of the precise property data used and of the

## 4.8 Applications

---

### Enhancement

*Arthur E. Bergles*

#### Introduction

Energy- and materials-saving considerations, as well as economic incentives, have led to efforts to produce more efficient heat exchange equipment. Common thermal-hydraulic goals are to reduce the size of a heat exchanger required for a specified heat duty, to upgrade the capacity of an existing heat exchanger, to reduce the approach temperature difference for the process streams, or to reduce the pumping power.

The study of improved heat transfer performance is referred to as heat transfer *enhancement*, *augmentation*, or *intensification*. In general, this means an increase in heat transfer coefficient. Attempts to increase “normal” heat transfer coefficients have been recorded for more than a century, and there is a large store of information. A survey (Bergles et al., 1991) cites 4345 technical publications, excluding patents and manufacturers’ literature. The literature has expanded rapidly since 1955.

Enhancement techniques can be classified either as passive methods, which require no direct application of external power (Figure 4.8.1), or as active methods, which require external power. The effectiveness of both types of techniques is strongly dependent on the mode of heat transfer, which may range from single-phase free convection to dispersed-flow film boiling. Brief descriptions of these methods follow.

*Treated surfaces* involve fine-scale alternation of the surface finish or coating (continuous or discontinuous). They are used for boiling and condensing; the roughness height is below that which affects single-phase heat transfer.

*Rough surfaces* are produced in many configurations ranging from random sand-grain-type roughness to discrete protuberances. See Figure 4.8.1a. The configuration is generally chosen to disturb the viscous sublayer rather than to increase the heat transfer surface area. Application of rough surfaces is directed primarily toward single-phase flow.

*Extended surfaces* are routinely employed in many heat exchangers. See Figure 4.8.1a to d. Work of special interest to enhancement is directed toward improvement of heat transfer coefficients on extended surfaces by shaping or perforating the surfaces.

*Displaced enhancement devices* are inserted into the flow channel so as indirectly to improve energy transport at the heated surface. They are used with forced flow. See Figure 4.8.1e and f.

*Swirl-flow devices* include a number of geometric arrangements or tube inserts for forced flow that create rotating and/or secondary flow: coiled tubes, inlet vortex generators, twisted-tape inserts, and axial-core inserts with a screw-type winding.

*Surface-tension devices* consist of wicking or grooved surfaces to direct the flow of liquid in boiling and condensing.

*Additives for liquids* include solid particles and gas bubbles in single-phase flows and liquid trace additives for boiling systems.

*Additives for gases* are liquid droplets or solid particles, either dilute-phase (gas-solid suspensions) or dense-phase (fluidized beds).

*Mechanical aids* involve stirring the fluid by mechanical means or by rotating the surface. Surface “scraping,” widely used for batch processing of viscous liquids in the chemical process industry, is applied to the flow of such diverse fluids as high-viscosity plastics and air. Equipment with rotating heat exchanger ducts is found in commercial practice.

*Surface vibration* at either low or high frequency has been used primarily to improve single-phase heat transfer.

**FIGURE 4.8.1** Enhanced tubes for augmentation of single-phase heat transfer. (a) Corrugated or spirally indented tube with internal protuberances. (b) Integral external fins. (c) Integral internal fins. (d) Deep spirally fluted tube. (e) Static mixer inserts. (f) Wire-wound insert.

*Fluid vibration* is the practical type of vibration enhancement because of the mass of most heat exchangers. The vibrations range from pulsations of about 1 Hz to ultrasound. Single-phase fluids are of primary concern.

*Electrostatic fields* (DC or AC) are applied in many different ways to dielectric fluids. Generally speaking, electrostatic fields can be directed to cause greater bulk mixing or fluid or disruption of fluid flow in the vicinity of the heat transfer surface, which enhances heat transfer.

*Injection* is utilized by supplying gas to a stagnant or flowing liquid through a porous heat transfer surface or by injecting similar fluid upstream of the heat transfer section. Surface degassing of liquids can produce enhancement similar to gas injection. Only single-phase flow is of interest.

*Suction* involves vapor removal, in nucleate or film boiling, or fluid withdrawal, in single-phase flow, through a porous heated surface.

Two or more of the above techniques may be utilized simultaneously to produce an enhancement that is larger than either of the techniques operating separately. This is termed *compound enhancement*.

It should be emphasized that one of the motivations for studying enhanced heat transfer is to assess the effect of an inherent condition on heat transfer. Some practical examples include roughness produced by standard manufacturing, degassing of liquids with high gas content, surface vibration resulting from rotating machinery or flow oscillations, fluid vibration resulting from pumping pulsation, and electrical fields present in electrical equipment.

The surfaces in [Figure 4.8.1](#) have been used for both single-phase and two-phase heat transfer enhancement. The emphasis is on effective and cost-competitive (proved or potential) techniques that have made the transition from the laboratory to commercial heat exchangers.

### Single-Phase Free Convection

With the exception of the familiar technique of providing extended surfaces, the passive techniques have little to offer in the way of enhanced heat transfer for free convection. This is because the velocities are usually too low to cause flow separation or secondary flow.

The restarting of thermal boundary layers in interrupted extended surfaces increases heat transfer so as to more than compensate for the lost area.

Mechanically aided heat transfer is a standard technique in the chemical and food industries when viscous liquids are involved. The predominant geometry for surface vibration has been the horizontal cylinder, vibrated either horizontally or vertically. Heat transfer coefficients can be increased tenfold for both low-frequency/high-amplitude and high-frequency/low-amplitude situations. It is, of course, equally effective and more practical to provide steady forced flow. Furthermore, the mechanical designer is concerned that such intense vibrations could result in equipment failures.

Since it is usually difficult to apply surface vibrations to practical equipment, an alternative technique is utilized whereby vibrations are applied to the fluid and focused toward the heated surface. With proper transducer design, it is also possible to improve heat transfer to simple heaters immersed in gases or liquids by several hundred percent.

Electric fields are particularly effective in increasing heat transfer coefficients in free convection. Dielectrophoretic or electrophoretic (especially with ionization of gases) forces cause greater bulk mixing in the vicinity of the heat transfer surface. Heat transfer coefficients may be improved by as much as a factor of 40 with electrostatic fields up to 100,000 V. Again, the equivalent effect could be produced at lower capital cost and without the voltage hazard by simply providing forced convection with a blower or fan.

### Single-Phase Forced Convection

The present discussion emphasizes enhancement of heat transfer *inside* ducts that are primarily of circular cross section. Typical data for turbulence promoters inserted inside tubes are shown in [Figure 4.8.2](#). As shown in [Figure 4.8.2a](#), the promoters produce a sizable elevation in the Nusselt number, or heat transfer coefficient, at constant Reynolds number, or velocity. However, as shown in [Figure 4.8.2b](#), there is an accompanying large increase in the friction factor.

Surface roughness has been used extensively to enhance forced convection heat transfer. Integral roughness may be produced by the traditional manufacturing processes of machining, forming, casting, or welding. Various inserts can also provide surface protuberances. In view of the infinite number of possible geometric variations, it is not surprising that, even after more than 300 studies, no completely satisfactory unified treatment is available.

In general, the maximum enhancement of laminar flow with many of the techniques is the same order of magnitude, and seems to be independent of the wall boundary condition. The enhancement with some rough tubes, corrugated tubes, inner-fin tubes, various static mixers, and twisted-type inserts is about 200%. The improvements in heat transfer coefficient with turbulent flow in rough tubes (based on nominal surface area) are as much as 250%. Analogy solutions for sand-grain-type roughness and for square-repeated-rib roughness have been proposed. A statistical correlation is also available for heat transfer coefficient and friction factor.

The following correlations are recommended for tubes with transverse or helical repeated ribs ([Figure 4.8.1a](#)) with turbulent flow (Ravigururajan and Bergles, 1985):

$$\text{Nu}_{D_{t,a}}/\text{Nu}_{D_{t,s}} = \left\{ 1 + \left[ 2.64\text{Re}^{0.036} (e/D_i)^{0.212} \left( (p/D_i)^{-0.21} \right) (\alpha/90)^{0.29} (\text{Pr})^{-0.024} \right]^7 \right\}^{1/7} \quad (4.8.1)$$

**FIGURE 4.8.2** Typical data for turbulence promoters inserted inside tubes: (a) heat transfer data, (b) friction data. (From Bergles, 1969. With permission.)

$$f_a/f_s = \left\{ 1 + \left[ 29.1 Re_{D_i}^{(0.67-0.06p/D_i-0.49\alpha/90)} \times (e/D_i)^{(0.37-0.157p/D_i)} \times (p/D_i)^{(-1.66 \times 10^{-6} Re_{D_i} - 0.33\alpha/90)} \right. \right. \\ \left. \left. \times (\alpha/90)^{(4.59+4.11 \times 10^{-6} Re_{D_i} - 0.15p/D_i)} \times \left( 1 + \frac{2.94}{n} \right) \sin \beta \right]^{15/16} \right\}^{16/15} \quad (4.8.2)$$

where the subscript  $a$  refers to the enhanced tube and the subscript  $s$  refers to the smooth tube. The special symbols are given as follows:  $e$  = protuberance height;  $p$  = repeated-rib pitch;  $\alpha$  = spiral angle for helical ribs,  $^\circ$ ;  $n$  = number of sharp corners facing the flow; and  $\beta$  = contact angle of rib profile,  $^\circ$ .

Also,

$$Nu_s = 0.125 f Re_{D_i} Pr / \left( 1 + 12.7 (0.125 f)^{0.5} Pr^{0.667} - 1 \right)$$

and

$$f_s = \left( 1.82 \log_{10} Re_{D_i} - 1.64 \right)^{-2*}$$

Much work has been done to obtain the enhanced heat transfer of parallel angled ribs in short rectangular channels, simulating the interior of gas turbine blades. Jets are frequently used for heating, cooling, and drying in a variety of industrial applications. A number of studies have reported that roughness elements of the transverse-repeated-rib type mitigate the deterioration in heat transfer downstream of stagnation.

Extended surfaces can be considered “old technology” as far as most applications are concerned. The real interest now is in increasing heat transfer coefficients on the extended surface. Compact heat exchangers of the plate-fin or tube-and-center variety use several enhancement techniques: offset strip fins, louvered fins, perforated fins, or corrugated fins. Coefficients are several hundred percent above the

\* The Fanning friction factor is used throughout this section.

smooth-tube values; however, the pressure drop is also substantially increased, and there may be vibration and noise problems.

For the case of offset strip fins the following correlations are recommended for calculating the  $j$  and  $f$  characteristics (Manglik and Bergles, 1990)

$$j_h = 0.6522 \text{Re}_h^{-0.5403} \alpha^{-0.1541} \delta^{0.1499} \gamma^{-0.0678} \times [1 + 5.269 \times 10^{-5} \text{Re}_h^{1.340} \alpha^{0.504} \delta^{0.456} \gamma^{-1.055}]^{0.1} \quad (4.8.3)$$

$$f_h = 9.6243 \text{Re}_h^{-0.7422} \alpha^{-0.1856} \delta^{0.3053} \gamma^{-0.2659} \times [1 + 7.669 \times 10^{-8} \text{Re}_h^{4.429} \alpha^{0.920} \delta^{3.767} \gamma^{0.236}]^{0.1} \quad (4.8.4)$$

where  $j_H$  (the heat transfer  $j$ -factor  $\text{Nu}_H/\text{Re}_H\text{Pr}^{1/3}$ ), and  $f_h$ , and  $\text{Re}_h$  are based on the hydraulic diameter given by

$$D_h = 4shl/[2(sl + hl + th) + ts] \quad (4.8.5)$$

Special symbols are  $\alpha$  = aspect ratio  $s/h$ ,  $\delta$  = ratio  $t/l$ ,  $\gamma$  = ratio  $t/s$ ,  $s$  = lateral spacing of strip fin,  $h$  = strip fin height,  $l$  = length of one offset module of strip fins, and  $t$  = fin thickness.

These equations are based on experimental data for 18 different offset strip-fin geometries, and they represent the data continuously in the laminar, transition, and turbulent flow regions.

Internally finned circular tubes are available in aluminum and copper (or copper alloys). Correlations (for heat transfer coefficient and friction factor) are available for laminar flow, for both straight and spiral continuous fins.

Turbulent flow in tubes with straight or helical fins (Figure 4.8.1c) was correlated by (Carnavos, 1979)

$$\text{Nu}_h = 0.023 \text{Pr}^{0.4} \text{Re}_h^{0.8} \left[ \frac{A_c}{A_{ci}} \right]^{0.1} \left[ \frac{A_{s,i}}{A_s} \right]^{0.5} (\sec \alpha)^3 \quad (4.8.6)$$

$$f_h = 0.046 \text{Re}_h^{-0.2} \left[ \frac{A_c}{A_{c,i}} \right]^{0.5} (\sec \alpha)^{0.75} \quad (4.8.7)$$

where  $A_{c,i}$  is based on the maximum inside (envelope) flow area,  $A_{s,i}$  is based on the maximum inside (envelope) surface area, and  $\alpha$  the spiral angle for helical fins, °.

A numerical analysis of turbulent flow in tubes with idealized straight fins was reported. The necessary constant for the turbulence model was obtained from experimental data for air. Further improvements in numerical techniques are expected, so that a wider range of geometries and fluids can be handled without resort to extensive experimental programs.

Many proprietary surface configurations have been produced by deforming the basic tube. The “convoluted,” “corrugated,” “spiral,” or “spirally fluted” tubes (Figure 4.8.1a) have multiple-start spiral corrugations, which add area, along the tube length. A systematic survey of the single-tube performance of condenser tubes indicates up to 400% increase in the nominal inside heat transfer coefficient (based on diameter of a smooth tube of the same maximum inside diameter); however, pressure drops on the water side are about 20 times higher.

Displaced enhancement devices are typically in the form of inserts, within elements arranged to promote transverse mixing (static mixers, Figure 4.8.1e). They are used primarily for viscous liquids, to promote either heat transfer or mass transfer. Displaced promoters are also used to enhance the radiant heat transfer in high-temperature applications. In the flue-tube of a hot-gas-fired hot water heater, there is a trade-off between radiation and convection. Another type of displaced insert generates vortices, which enhance the downstream flow. Delta-wing and rectangular wing promoters, both co-rotating and

counterrotating, have been studied. Wire-loop inserts (Figure 4.8.1f) have also been used for enhancement of laminar and turbulent flow.

Twisted-tape inserts have been widely used to improve heat transfer in both laminar and turbulent flow. Correlations are available for laminar flow, for both uniform heat flux and uniform wall temperature conditions. Turbulent flow in tubes with twisted-tape inserts has also been correlated. Several studies have considered the heat transfer enhancement of a decaying swirl flow, generated, say, by a short twisted-tape insert.

### Performance Evaluation Criteria for Single-Phase Forced Convection in Tubes

Numerous, and sometimes conflicting, factors enter into the ultimate decision to use an enhancement technique: heat duty increase or area reduction that can be obtained, initial cost, pumping power or operating cost, maintenance cost (especially cleaning), safety, and reliability, among others. These factors are difficult to quantitize, and a generally acceptable selection criterion may not exist. It is possible, however, to suggest some performance criteria for preliminary design guidance. As an example, consider the basic geometry and the pumping power fixed, with the objective of increasing the heat transfer. The following ratio is then of interest

$$R_3 = \left( \frac{h_a}{h_s} \right)_{D_i, L, N, P, T_{in}, \Delta T} = \frac{(\text{Nu}/\text{Pr}^{0.4})_a}{(\text{Nu}/\text{Pr}^{0.4})_s} = \frac{q_a}{q_s} \quad (4.8.8)$$

where  $P$  = pumping power,  $T_{in}$  = inlet bulk temperature of fluid, and  $\Delta T$  = average wall-fluid temperature difference.

With the pumping power (neglecting entrance and exit losses) given as

$$P = NVA_c 4f(L/D)\rho V^2/2 \quad (4.8.9)$$

and

$$f_s = 0.046/\text{Re}_s^{0.2} \quad (4.8.10)$$

$$A_{c,a} f_a \text{Re}_a^3 = 0.046 A_{c,s} \text{Re}_s^{2.8} \quad (4.8.11)$$

The calculation best proceeds by picking  $\text{Re}_{D_i,a}$ , and reading  $\text{Nu}_{D_i,a}/\text{Pr}^{0.4}$  and  $f_a$ .  $\text{Re}_{D_i,s}$  is then obtained from Equation (4.8.11) and  $\text{Nu}_{D_i,s}/\text{Pr}^{0.4}$  obtained from a conventional, empty-tube correlation. The desired ratio of Equation (4.8.8) is then obtained. Typical results are presented in Figure 4.8.3 for a repeated-rib roughness (Bergles et al., 1974).

### Active and Compound Techniques for Single-Phase Forced Convection

Under active techniques, mechanically aided heat transfer in the form of surface scraping can increase forced convection heat transfer. Surface vibration has been demonstrated to improve heat transfer to both laminar and turbulent duct flow of liquids. Fluid vibration has been extensively studied for both air (loudspeakers and sirens) and liquids (flow interrupters, pulsators, and ultrasonic transducers). Pulsations are relatively simple to apply to low-velocity liquid flows, and improvements of several hundred percent can be realized.

Some very impressive enhancements have been recorded with electrical fields, particularly in the laminar-flow region. Improvements of at least 100% were obtained when voltages in the 10-kV range were applied to transformer oil. It is found that even with intense electrostatic fields, the heat transfer enhancement disappears as turbulent flow is approached in a circular tube with a concentric inner electrode.

FIGURE 4.8.3 Constant pumping power performance criterion applied to repeated rib roughness.

Compound techniques are a slowly emerging area of enhancement that holds promise for practical applications, since heat transfer coefficients can usually be increased above each of the several techniques acting along. Some examples that have been studied are as follows: rough tube wall with twisted-tape inserts, rough cylinder with acoustic vibrations, internally finned tube with twisted-tape inserts, finned tubes in fluidized beds, externally finned tubes subjected to vibrations, rib-roughened passage being rotated, gas-solid suspension with an electrical field, fluidized bed with pulsations of air, and a rib-roughened channel with longitudinal vortex generation.

### Pool Boiling

Selected passive and active enhancement techniques have been shown to be effective for pool boiling and flow boiling/evaporation. Most techniques apply to nucleate boiling; however, some techniques are applicable to transition and film boiling.

It should be noted that phase-change heat transfer coefficients are relatively high. The main thermal resistance in a two-fluid heat exchanger often lies on the non-phase-change side. (Fouling of either side can, of course, represent the dominant thermal resistance.) For this reason, the emphasis is often on enhancement of single-phase flow. On the other hand, the overall thermal resistance may then be reduced to the point where significant improvement in the overall performance can be achieved by enhancing the two-phase flow. Two-phase enhancement would also be important in double-phase-change (boiling/condensing) heat exchangers.

As discussed elsewhere, surface material and finish have a strong effect on nucleate and transition pool boiling. However, reliable control of nucleation on plain surfaces is not easily accomplished. Accordingly, since the earliest days of boiling research, there have been attempts to relocate the boiling curve through use of relatively gross modification of the surface. For many years, this was accomplished simply by area increase in the form of low helical fins. The subsequent tendency was to structure surfaces to improve the nucleate boiling characteristics by a fundamental change in the boiling process. Many of these advanced surfaces are being used in commercial shell-and-tube boilers.

Several manufacturing processes have been employed: machining, forming, layering, and coating. In Figure 4.8.4a standard low-fin tubing is shown. Figure 4.8.4c depicts a tunnel-and-pore arrangement produced by rolling, upsetting, and brushing. An alternative modification of the low fins is shown in Figure 4.8.4d, where the rolled fins have been split and rolled to a T shape. Further modification of the internal, Figure 4.8.4e, or external, Figure 4.8.4f, surface is possible. Knurling and rolling are involved in producing the surface shown in Figure 4.8.4g. The earliest example of a commercial structured surface, shown in Figure 4.8.4b is the porous metallic matrix produced by sintering or brazing small particles. Wall superheat reductions of up to a factor of ten are common with these surfaces. The advantage is not

**FIGURE 4.8.4** Examples of commercial structured boiling surfaces. (From Pate, M.B. et al., in *Compact Heat Exchangers*, Hemisphere Publishing, New York, 1990. With permission.)

only a high nucleate boiling heat transfer coefficient, but the fact that boiling can take place at very low temperature differences.

These structured boiling surfaces, developed for refrigeration and process applications, have been used as “heat sinks” for immersion-cooled microelectronic chips.

The behavior of tube bundles is often different with structured-surface tubes. The enhanced nucleate boiling dominates, and the convective boiling enhancement, found in plain tube bundles, does not occur.

Active enhancement techniques include heated surface rotation, surface wiping, surface vibration, fluid vibration, electrostatic fields, and suction at the heated surface. Although active techniques are effective in reducing the wall superheat and/or increasing the critical heat flux, the practical applications are very limited, largely because of the difficulty of reliably providing the mechanical or electrical effect.

Compound enhancement, which involves two or more techniques applied simultaneously, has also been studied. Electrohydrodynamic enhancement was applied to a finned tube bundle, resulting in nearly a 200% increase in the average boiling heat transfer coefficient of the bundle, with a small power consumption for the field.

### Convective Boiling/Evaporation

The structured surfaces described in the previous section are generally not used for in-tube vaporization, because of the difficulty of manufacture. One notable exception is the high-flux surface in a vertical thermosiphon reboiler. The considerable increase in the low-quality, nucleate boiling coefficient is desirable, but it is also important that more vapor is generated to promote circulation.

Helical repeated ribs and helically coiled wire inserts have been used to increase vaporization coefficients and the dry-out heat flux in once-through boilers.

Numerous tubes with internal fins, either integral or attached, are available for refrigerant evaporators. Original configurations were tightly packed, copper, offset strip fin inserts soldered to the copper tube or aluminum, star-shaped inserts secured by drawing the tube over the insert. Examples are shown in [Figure 4.8.5](#). Average heat transfer coefficients (based on surface area of smooth tube of the same diameter) for typical evaporator conditions are increased by as much as 200%. A cross-sectional view of a typical “microfin” tube is included in [Figure 4.8.5](#). The average evaporation boiling coefficient is

**FIGURE 4.8.5** Inner-fin tubes for refrigerant evaporators: (a) Strip-fin inserts, (b) Star-shaped inserts, (c) Microfin.

increased 30 to 80%. The pressure drop penalties are less; that is, lower percentage increases in pressure drop are frequently observed.

Twisted-tape inserts are generally used to increase the burnout heat flux for subcooled boiling at high imposed heat fluxes  $10^7 - 10^8 \text{ W/m}^2$ , as might be encountered in the cooling of fusion reactor components. Increases in burnout heat flux of up to 200% were obtained at near atmospheric pressure.

### Vapor-Space Condensation

As discussed elsewhere, condensation can be either filmwise or dropwise. In a sense, dropwise condensation is enhancement of the normally occurring film condensation by surface treatment. The only real application is for steam condensers, because nonwetting coatings are not available for most other working fluids. Even after much study, little progress has been made in developing permanently hydrophobic coatings for practical steam condensers. The enhancement of dropwise condensation is pointless, because the heat transfer coefficients are already so high.

Surface extensions are widely employed for enhancement of condensation. The integral low fin tubing (Figure 4.8.4a), used for kettle boilers, is also used for horizontal tube condensers. With proper spacing of the fins to provide adequate condensate drainage, the average coefficients can be several times those of a plain tube with the same base diameter. These fins are normally used with refrigerants and other organic fluids that have low condensing coefficients, but which drain effectively, because of low surface tension.

The fin profile can be altered according to mathematical analysis to take full advantage of the Gregorig effect, whereby condensation occurs mainly at the tops of convex ridges. Surface tension forces then pull the condensate into concave grooves, where it runs off. The average heat transfer coefficient is greater than that for an axially uniform film thickness. The initial application was for condensation of steam on vertical tubes used for reboilers and in desalination. According to numerical solutions, the optimum geometry is characterized by a sharp fin tip, gradually changing curvature of the fin surface from tip to root, wide grooves between fins to collect condensate, and periodic condensate strippers. Figure 4.8.6 schematically presents the configuration.

**FIGURE 4.8.6** Recommended flute profile and schematic of condensate strippers.

Recent interest has centered on three-dimensional surfaces for horizontal-tube condensers. The considerable improvement relative to low fins or other two-dimensional profiles is apparently due to multidimensional drainage at the fin tips. Other three-dimensional shapes include circular pin fins, square pins, and small metal particles that are bonded randomly to the surface.

### Convective Condensation

This final section on enhancement of the various modes of heat transfer focuses on in-tube condensation. The applications include horizontal kettle-type reboilers, moisture separator reheaters for nuclear power plants, and air-conditioner condensers.

Internally grooved or knurled tubes, deep spirally fluted tubes, random roughness, conventional inner-fin tubes have been shown to be effective for condensation of steam and other fluids.

The microfin tubes mentioned earlier have also been applied successfully to in-tube condensing. As in the case of evaporation, the substantial heat transfer improvement is achieved at the expense of a lesser percentage increase in pressure drop. By testing a wide variety of tubes, it has been possible to suggest some guidelines for the geometry, e.g., more fins, longer fins, and sharper tips; however, general correlations are not yet available. Fortunately for heat-pump operation, the tube that performs best for evaporation also performs best for condensation.

Twisted-tape inserts result in rather modest increases in heat transfer coefficient for complete condensation of either steam or refrigerant. The pressure drop increases are large because of the large wetted surface. Coiled tubular condensers provide a modest improvement in average heat transfer coefficient.

## Further Information

This section gives some indication as to why heat transfer enhancement is one of the fastest growing areas of heat transfer. Many techniques are available for improvement of the various modes of heat transfer. Fundamental understanding of the transport mechanism is growing, but, more importantly, design correlations are being established. Many effective and cost-competitive enhancement techniques have made the transition from the laboratory to commercial heat exchangers.

Broad reviews of developments in enhanced heat transfer are available (Bergles, 1985; Bergles, 1988; Thome, 1990; Webb, 1994, Bergles, 1997). Also, several journals, especially *Heat Transfer Engineering*, *Enhanced Heat Transfer*, and *International Journal of Heating, Ventilating, Air-Conditioning and Refrigerating Research*, feature this technology.

## Cooling Towers

*Anthony F. Mills*

### Introduction

In a wet cooling tower, water is evaporated into air with the objective of cooling the water stream. Both natural- and mechanical-draft towers are popular, and examples are shown in [Figure 4.8.7](#). Large natural-draft cooling towers are used in power plants for cooling the water supply to the condenser. Smaller mechanical-draft towers are preferred for oil refineries and other process industries, as well as for central air-conditioning systems and refrigeration plant. [Figure 4.8.7a](#) shows a natural draft *counterflow* unit in which the water flows as thin films down over a suitable packing, and air flows upward. In a natural-draft tower the air flows upward due to the buoyancy of the warm, moist air leaving the top of the packing. In a mechanical-draft tower, the flow is forced or induced by a fan. Since the air inlet temperature is usually lower than the water inlet temperature, the water is cooled both by evaporation and by sensible heat loss. For usual operating conditions the evaporative heat loss is considerably larger than the sensible heat loss. [Figure 4.8.7b](#) shows a mechanical draft cross-flow unit. [Figure 4.8.8](#) shows a natural-draft cross-flow tower for a power plant.

### Packing Thermal Performance

*Counterflow units.* Merkel's method (Merkel, 1925) for calculating the number of transfer units required to cool the water stream, for specified inlet and outlet water temperatures and inlet air condition is (Mills, 1995)

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \int_{h_{L,in}}^{h_{L,out}} \frac{dh_L}{h_s - h_G} \quad (4.8.12)$$

$$h_G = h_{G,in} + (\dot{m}_L / \dot{m}_G)(h_L - h_{L,out}) \quad (4.8.13)$$

$$h_s(P, T_s) = h_s(P, T_L) \quad (4.8.14)$$

It is imperative that the usual enthalpy datum states be used, namely, zero enthalpy for dry air and liquid water at 0°C. [Table 4.8.1](#) gives enthalpy data for 1 atm pressure. The important assumptions required to obtain this result include

1. A Lewis number of unity;
2. Low mass transfer rate theory is valid;
3. The liquid-side heat transfer resistance is negligible, that is,  $T_s \approx T_L$ ;
4. The amount of water evaporated is small compared with the water and air flow rates.

**FIGURE 4.8.7** (a) A natural-draft counterflow cooling tower for a power plant. (b) A cross-flow cooling tower for an air-conditioning system.

The method is accurate up to temperatures of about  $60^{\circ}\text{C}$ ; comparisons with more exact results are usually within 3 to 5%, and seldom show errors greater than 10%. Notice that the method does not give the outlet state of the air; however, in situations encountered in practice, the outlet air can be assumed to be saturated for the purposes of calculating its density. It is possible to extend Merkel's method to include a finite liquid-side heat transfer resistance, but such refinement is seldom warranted. For typical operating conditions the bulk liquid temperature is seldom more than 0.3 K above the interface temperature.

*Cross-flow units.* Figure 4.8.9 shows a schematic of a cross-flow packing. If we assume that both the liquid and gas streams are unidirectional, and that there is no mixing in either stream, then use of Merkel's assumptions leads to the following pair of differential equations (Mills, 1995):

**FIGURE 4.8.8** A natural-draft cross-flow cooling tower for a power plant.

$$\frac{\partial h_G}{\partial x} = \frac{g_m a}{G} (h_s - h_G) \quad (4.8.15)$$

$$\frac{\partial h_L}{\partial y} = -\frac{g_m a}{L} (h_s - h_G) \quad (4.8.16)$$

Also  $h_s = h_s(h_L)$  for a negligible liquid-side heat transfer resistance and the required boundary conditions are the inlet enthalpies of both streams. Equations (4.8.15) and (4.8.16) are solved numerically and the solution used to evaluate the average enthalpy of the outlet liquid,

$$\bar{h}_{L,\text{out}} = \frac{1}{X} \int_0^X h_{L,\text{out}} dx \quad (4.8.17)$$

Substituting in an exchanger energy balance on the liquid stream gives the heat transfer as

$$q = \dot{m}_L (h_{L,\text{in}} - h_{L,\text{out}}) \quad (4.8.18)$$

<sup>a</sup> The enthalpies of dry air and liquid water are set equal to zero at a datum temperature of 0°C.

<sup>b</sup> The enthalpy of an unsaturated water vapor-air mixture can be calculated as  $h = h_{\text{dry air}} + (m_v/m_{v,\text{sat}})(h_{\text{sat}} - h_{\text{dry air}})$ .

*Sample calculation.* Consider a counterflow unit that is required to cool water from 40 to 26°C when the inlet air is at 10°C, 1 atm, and saturated. We will calculate the number of transfer units required for balanced flow, that is,  $\dot{m}_G/\dot{m}_L = 1$ . Equation (4.8.12) is to be integrated numerically, with  $h_G$  obtained from Equation 4.8.13. The required thermodynamic properties can be obtained from Table 4.8.1. Using Table 4.8.1,  $h_{G,\text{in}} = h_{\text{sat}}(10^\circ\text{C}) = 29.15$  kJ/kg,  $h_{L,\text{out}} = h_L(26^\circ\text{C}) = 109.07$  kJ/kg. Substituting in Equation (4.8.13),

$$h_G = 29.15 + (h_L - 109.07)$$

$T_L, ^\circ\text{C}$	$h_L, \text{kJ/kg}$	$h_G, \text{kJ/kg}$	$h_s, \text{kJ/kg}$	$h_s - h_g, \text{kJ/kg}$	$\frac{1}{h_s - h_g}$
26	109.07	29.15	79.12	49.97	0.02001
28	117.43	37.51	87.86	50.35	0.01986
30	125.79	45.87	97.36	51.49	0.01942
32	134.15	54.23	107.67	53.44	0.01871
34	142.50	62.58	118.89	56.31	0.01776
36	150.86	70.94	131.10	60.16	0.01662
38	159.22	79.30	144.39	65.09	0.01536
40	167.58	87.66	158.86	71.20	0.01404

Choosing 2°C intervals for convenient numerical integration, the above table is constructed, with  $h_L$  and  $h_s = h_s(T_L)$  also obtained from Table 4.8.1. Using the trapezoidal rule,

$$\int_{h_{L,\text{out}}}^{h_{L,\text{in}}} \frac{dh_L}{h_s - h_G} = \frac{8.36}{2} [0.02001 + 2(0.01986 + 0.01942 + 0.01871 + 0.01776 + 0.01662 + 0.01536) + 0.01404]$$

$$= 1.043$$

From Equation (4.8.12),  $N_{tu} = 1.043$ . Also, by using Table 4.8.1,  $T_{G,\text{out}} = 27.9^\circ$  for saturated outlet air.

FIGURE 4.8.9 Schematic of a cross-flow cooling tower packing showing the coordinate system.

### Thermal-Hydraulic Design of Cooling Towers

The thermal-hydraulic design of a mechanical-draft cooling tower is relatively straightforward. The flow rate ratio  $\dot{m}_L/\dot{m}_G$  can be specified and varied parametrically to obtain an optimal design, for which the size and cost of the packing is balanced against fan power requirements and operating cost. Data are required for mass transfer conductances and friction for candidate packings. Tables 4.8.2a and b give correlations for a selection of packings. In Table 4.8.2b, the mass transfer conductance is correlated as  $g_m a/L$ , where  $a$  is the transfer area per unit volume and  $L = \dot{m}_L/A_{fr}$  is the superficial mass velocity of the water flow (also called the *water loading* on the packing). Similarly, we define  $G = \dot{m}_G/A_{fr}$ . Typical water loadings are 1.8 to 2.7 kg/m<sup>2</sup> sec, and superficial air velocities fall in the range 1.5 to 4 m/sec. No attempt is made to correlate  $g_m$  and  $a$  separately. The number of transfer units of a packing of height  $H$  is then

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} \quad (4.8.19)$$

7. Marley α-bar, parallel to air flow, 16 × 4 in. spacing
8. Marley ladder, parallel to air flow, 8 × 2 in. spacing

The correlations are in terms of dimensionless mass velocities  $L^+$  and  $G^+$ , and a *hot water correction*  $T_{HW}^+$ . The hot water correction accounts for a number of factors, such as errors associated with Merkel's method, deviations from low mass transfer rate theory at higher values of  $T_s$ , and fluid property dependence on temperature. Frictional resistance to air flow through the packings is correlated as a *loss coefficient*  $N = \Delta P / (\rho V^2 / 2)$  per unit height or depth of packing, as a function of  $L^+$  and  $G^+$ . The velocity  $V$  is superficial gas velocity. No hot water correction is required.

In a natural-draft tower, the thermal and hydraulic performance of the tower are coupled, and the flow rate ratio  $\dot{m}_L / \dot{m}_G$  cannot be specified *a priori*. The buoyancy force producing the air flow depends on the state of the air leaving the packing which in turn depends on  $\dot{m}_L / \dot{m}_G$  and the inlet air and water states. An iterative solution is required to find the operating point of the tower. The buoyancy force available to overcome the shell and packing pressure drops is

$$\Delta P^B = g(\rho_a - \rho_{G,out})H \quad (4.8.20)$$

where  $\rho_a$  is the ambient air density and  $H$  is usually taken as the distance from the bottom of the packing to the top of the shell. The various pressure drops are conveniently expressed as

$$\Delta P_i = N_i \frac{\rho_{Gi} V_i^2}{2} \quad (4.8.21)$$

Where  $N_i$  is the loss coefficient and  $V_i$  is the air velocity at the corresponding location. The pressure drops are associated with the shell, the packing, the mist eliminators, supports and pipes, and the water spray below the packing. Some sample correlations are given in Table 4.8.3.

Water loadings in counterflow natural-draft towers typically range from 0.8 to 2.4 kg/m<sup>2</sup> sec, and superficial air velocities range from 1 to 2 m/sec. The ratio of base diameter to height may be 0.75 to 0.85, and the ratio of throat to base diameter 0.55 to 0.65. The height of the air inlet is usually 0.10 to 0.12 times the base diameter to facilitate air flow into the tower. In practice the air flow distribution in natural-draft towers is not very uniform. However, the assumption of uniform air and water flows in our model of counterflow packing is adequate for most design purposes.

Cost-optimal design of cooling towers requires consideration of the complete power or refrigeration system. For refrigeration, the economics are determined mainly by the operating cost of the chiller (Kintner-Meyer and Emery, 1955).

**TABLE 4.8.3 Pressure Drop Correlations for Cooling Tower Shells, Sprays, Supports, and Mist Eliminators**

---

1.	Shell (natural draft counterflow):  $N = 0.167 \left( \frac{D_B}{b} \right)^2$ where $D_B$ is the diameter of the shell base and $b$ is the height of the air inlet.
2.	Spray (natural-draft counterflow):  $N = 0.526(Z_p[\text{m}] + 1.22) (\dot{m}_L / \dot{m}_G)^{1.32}$
3.	Mist eliminators:  $N = 2-4$
4.	Support columns, pipes, etc. (natural-draft counterflow):  $N = 2-6$
5.	Fan exit losses for mechanical-draft towers (velocity based on fan exit area):  $N = 1.0, \text{ forced draft}$ $\approx 0.5, \text{ induced draft, depending on diffuser design}$
6.	Miscellaneous losses for mechanical-draft towers (velocity based on packing crosssectional area):  $N \approx 3$

---

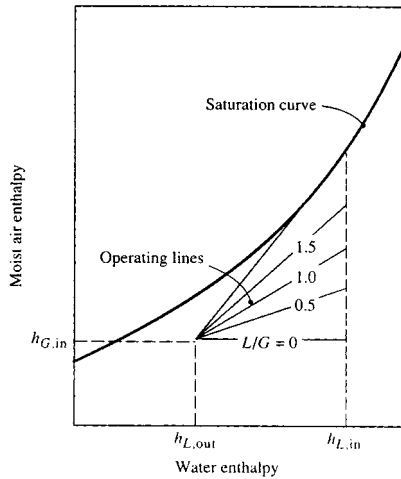

*Note:*  $N$  is the loss coefficient defined by Equation 4.8.21, with velocity based on cross-sectional area for air flow underneath the packing in items 1 through 4.

### Cooling Tower Behavior

There are a number of computer programs available that use variations of Merkel's method to calculate the cooling tower performance, for example, TEFRI (Bourillot, 1983), VERA2D-84 (Mujamdar et al., 1985), CTOWER (Mills, 1995). These programs can be used to perform parametric studies to obtain the response of cooling towers to environmental, duty, and design changes. However, before using such programs, some thought should be given to the important characteristics of cooling tower behavior. For this purpose, it is useful to consider a graphical representation of Merkel's theory for a counterflow tower. Figure 4.8.10 shows a chart with moist air enthalpy plotted vs. water enthalpy (or, equivalently, water temperature) at 1 atm pressure. The *saturation curve*  $h_s(T_s)$  is the enthalpy of saturated air. The *operating lines*  $h_G(h_L)$  are given by Equation (4.8.13) and relate the air enthalpy to the water enthalpy at each location in the packing. The slope of an operating line is  $L/G$ . Since the assumption  $T_s = T_L$  is made in Merkel's method, vertical lines on the chart connect  $h_s$  and  $h_G$  at each location in the packing. The driving force for enthalpy transfer,  $(h_s - h_G)$ , is the vertical distance between the saturation curve and the operating line. The integral in Equation (4.8.12) averages the reciprocal of this distance. By using this chart, a number of observations about cooling tower behavior can be made.
