1. Figure 4.8.10 shows the effect of  $L/G$  for fixed water inlet and outlet temperatures, and fixed inlet air temperature and humidity. If we imagine  $L$  to be fixed as well, we see that as  $G$  decreases, the driving forces decrease, and so a larger NTU is required.
2. The minimum NTU required corresponds to  $L/G = 0$ , that is, an infinite air flow rate, for which the operating line is horizontal.
3. Due to the curvature of the operating line, it is possible for the operating line to be tangent to the saturation curve. The indicated NTU is then infinite, which tells us that the air flow rate must be increased in order to achieve the desired water cooling range.

**FIGURE 4.8.10** Counterflow cooling tower operating lines for various water-to-air flow-rate ratios shown on an enthalpy chart.

4. For a mechanical-draft tower, the optimal value of  $L/G$  lies between the two limits described in items 2 and 3 above. If  $L/G$  is large, the required height of packing is large, and the capital cost will be excessive. If  $L/G$  is small, the fan power will be excessive (since fan power is proportional to air volume flow rate times pressure drop).

**Range and Approach**

Cooling tower designers and utility engineers have traditionally used two temperature differences to characterize cooling tower operation. The *range* is the difference between the water inlet and outlet temperatures (also called simply the hot and cold water temperatures). The *approach* is the difference between the outlet water temperature and the wet-bulb temperature of the entering (ambient) air. The approach characterizes cooling tower performance; for a given inlet condition, a larger packing will produce a smaller approach to the ambient wet-bulb temperature, and hence a lower water outlet temperature. (The water cannot be cooled below the ambient wet-bulb temperature.) The approach concept is useful because the ambient dry-bulb temperature has little effect on performance at usual operating conditions (for a specified wet-bulb temperature).

**Cooling Demand Curves**

Electrical utility engineers have found it convenient to use charts of *cooling demand curves* to evaluate packing specifications. Figure 4.8.11 is an example of such a chart, on which the required NTU, for a given inlet air wet-bulb temperature and range, is plotted vs.  $L/G$  with the approach as a parameter. Such a plot is possible since the inlet air dry-bulb temperature has only a small effect under usual operating conditions. Now, if it is possible to correlate the mass transfer conductance as

$$\frac{g_m a}{L} = C \left( \frac{L}{G} \right)^{-n} \tag{4.8.22}$$

the NTU of a packing of height  $H$  is

$$\frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} = C \left( \frac{L}{G} \right)^{-n} H \tag{4.8.23}$$

**FIGURE 4.8.11** Example of cooling demand curves for a specified wet-bulb temperature and range: NTU vs. flow rate ratio for a fixed approach.

Equation (4.8.23) can also be plotted on the chart to give the *packing capability line*. For a required approach, the *operating point* of the tower is the intersection of the cooling demand curve and packing capability line. Charts of cooling demand curves are available (Cooling Tower Institute, 1967; Kelly, 1976). Correlations of the form of Equation (4.8.22) do not necessarily fit experimental data well. A dependence  $g_m a \propto L^{-n} G^n$  is implied and, in the past, experimental data were often forced to fit such a relation. If the  $g_m a$  correlation does not have the form of Equation (4.8.22), the NTU cannot be plotted as a line on a cooling demand chart.

With the almost universal use of computers and the availability of suitable computer programs, one can expect less use of cooling demand charts in the future. The major sources of error in the predictions made by these programs are related to nonuniform air and water flow, and the correlations of packing mass transfer and pressure drop experimental data. The experimental data are obtained in small-scale test rigs, in which it is impossible to simulate many features of full-size towers — for example, nonuniform flow due to entrance configuration, nonuniform wetting of the packing, and, in the case of counterflow towers, the effect of spray above the packing and rain below the packing. Furthermore, since testing of packings in small-scale test rigs is itself not easy, considerable scatter is seen in such test data. Correlations of the data typically have root mean square errors of 10 to 20%.

### Legionnaires' Disease

Legionnaires' disease is a form of pneumonia caused by a strain of legionella bacteria (sero group I). Smokers and sick people are particularly vulnerable to the disease. Major outbreaks have occurred at conventions and in hospitals, for which the source of the bacteria has been traced to cooling towers of air-conditioning systems. The bacteria require nutrients such as algae or dead bacteria in sludge, and thrive if iron oxides are present. However, properly designed, installed, and maintained cooling towers have never been implicated in an outbreak of the disease. Key requirements to be met include the following:

1. Mist (drift) eliminators should be effective.
2. The tower should be located so as to minimize the possibility of mist entering a ventilation system.
3. Corrosion in the tower and water lines should be minimized by use of glass fiber, stainless steel, and coated steel.
4. The design should facilitate inspection and cleaning, to allow early detection and remedy of sludge buildup.
5. Water treatment and filtration procedures should meet recommended standards.

## Heat Pipes

*Larry W. Swanson*

### Introduction

The heat pipe is a vapor-liquid phase-change device that transfers heat from a hot reservoir to a cold reservoir using **capillary forces** generated by a **wick** or porous material and a working fluid. Originally conceived by Gaugler in 1944, the operational characteristics of heat pipes were not widely publicized until 1963 when Grover and his colleagues at Los Alamos Scientific Laboratory independently reinvented the concept. Since then many types of heat pipes have been developed and used by a wide variety of industries.

Figure 4.8.12 shows a schematic of a heat pipe aligned at angle  $\psi$  relative to the vertical axis (gravity vector). The heat pipe is composed of a container lined with a wick that is filled with liquid near its saturation temperature. The vapor-liquid interface, usually found near the inner edge of the wick, separates the liquid in the wick from an open vapor core. Heat flowing into the evaporator is transferred through the container to the liquid-filled wicking material, causing the liquid to evaporate and vapor to flow into the open core portion of the evaporator. The capillary forces generated by the evaporating interface increase the pressure difference between the vapor and liquid. The vapor in the open core flows out of the evaporator through the adiabatic region (insulated region) and into the condenser. The vapor then condenses, generating capillary forces similar, although much less in magnitude, to those in the evaporator. The heat released in the condenser passes through the wet wicking material and container out into the cold reservoir. The condensed liquid is then pumped, by the liquid pressure difference due to the net capillary force between the evaporator and condenser, out of the condenser back into the

FIGURE 4.8.12 Schematic of a typical heat pipe.

evaporator. Proper selection and design of the pipe container, working fluid, and wick structure are essential to the successful operation of a heat pipe. The **heat transfer limitations**, **effective thermal conductivity**, and axial temperature difference define the operational characteristics of the heat pipe.

### Heat Pipe Container, Working Fluid, and Wick Structures

The container, working fluid, and wick structure of a heat pipe determine its operational characteristics. One of the most important considerations in choosing the material for the heat pipe container and wick is its compatibility with the working fluid. Degradation of the container or wick and contamination of the working fluid due to chemical reaction can seriously impair heat pipe performance. For example, noncondensable gas created during a chemical reaction eventually can accumulate near the end of the condenser, decreasing the condensation surface area. This reduces the ability of the heat pipe to transfer heat to the external heat sink. The material and geometry of the heat pipe container also must have a high burst strength, low weight, high thermal conductivity, and low porosity.

Using the proper working fluid for a given application is another critical element of proper heat pipe operation. The working fluid must have good thermal stability properties at the specified operational temperature and pressure. The operational temperature range of the working fluid has to lie between its triple point and its critical point for liquid to exist in the wicking material. The **wettability** of the working fluid contributes to its capillary pumping and priming capability. High-surface-tension fluids are commonly used in heat pipes because they provide the capillary pumping and wetting characteristics necessary for proper operation. Other desirable thermophysical properties include a high liquid thermal

conductivity, high latent heat of vaporization, low liquid viscosity, and a low vapor viscosity. Table 4.8.4 gives the thermophysical properties for three typical heat pipe working fluids that span a fairly wide operating temperature range. The thermophysical properties for other heat pipe working fluids can be obtained from Dunn and Reay (1982) and Peterson (1994).

The wick structure and working fluid generate the capillary forces required to (1) pump liquid from the condenser to the evaporator and (2) keep liquid evenly distributed in the wicking material. Heat pipe wicks can be classified as either homogeneous wicks or composite wicks. Homogeneous wicks are composed of a single material and configuration. The most common types of homogeneous wicks include wrapped screen, sintered metal, axial groove, annular, crescent, and arterial. Composite wicks are composed of two or more materials and configurations. The most common types of composite wicks include variable screen mesh, screen-covered groove, screen slab with grooves, and screen tunnel with

grooves. Regardless of the wick configuration, the desired material properties and structural characteristics of heat pipe wick structures are a high thermal conductivity, high wick porosity, small capillary radius, and high wick permeability. Table 4.8.2 gives the geometric properties of some commonly used homogeneous wicks. The properties of other wick structures, including nonhomogenous types, can be obtained from Peterson (1994). The container, wick structure, and working fluid are used to determine the heat transfer limitations of heat pipes.

### Heat Transfer Limitations

Heat pipes undergo various heat transfer limitations depending on the working fluid, the wick structure, the dimensions of the heat pipe, and the heat pipe operational temperature. Figure 4.8.13 gives a qualitative description of the various heat transfer limitations, which include vapor-pressure, sonic, entrainment, capillary, and boiling limitations. The composite curve enclosing the shaded region in Figure 4.8.13 gives the maximum heat transfer rate of the heat pipe as a function of the operational temperature. The figure shows that as the operational temperature increases, the maximum heat transfer rate of the heat pipe is limited by different physical phenomena. As long as the operational heat transfer rate falls within the shaded region, the heat pipe will function properly.

FIGURE 4.8.13 Heat transfer limitations in heat pipes.

The vapor-pressure limitation (or viscous limitation) in heat pipes develops when the pressure drop in the vapor core reaches the same order of magnitude as the vapor pressure in the evaporator. Under these conditions, the pressure drop due to flow through the vapor core creates an extremely low vapor pressure in the condenser preventing vapor from flowing in the condenser. A general expression for the vapor-pressure limitation is (Dunn and Reay, 1982)

$$Q_{vp,max} = \frac{\pi r_v^4 h_{fg} \rho_{v,e} P_{v,e}}{12 \mu_{v,e} l_{eff}} \quad (4.8.24)$$

where  $r_v$  is the cross-sectional radius of the vapor core (m),  $h_{fg}$  is the latent heat of vaporization (J/kg),  $\rho_{v,e}$  is the vapor density in the evaporator ( $\text{kg/m}^3$ ),  $P_{v,e}$  is the vapor pressure in the evaporator (Pa), and  $\mu_{v,e}$  is the vapor viscosity in the evaporator ( $\text{N sec/m}^2$ ).  $l_{eff}$  is the effective length of the heat pipe (m) equal to  $l_{eff} = 0.5(l_e + 2l_a + l_c)$ . The vapor-pressure limitation can occur during the start-up of heat pipes at the lower end of the working-fluid-temperature range.

The sonic limitation also can occur in heat pipes during start-up at low temperatures. The low temperature produces a low vapor density, thereby reducing the speed of sound in the vapor core. Thus, a sufficiently high mass flow rate in the vapor core can cause sonic flow conditions and generate a shock wave that chokes the flow and restricts the pipes ability to transfer heat to the condenser. Dunn and Reay (1982) give an expression for the sonic limitation that agrees very well with experimental data,

$$Q_{s,\max} = 0.474A_v h_{fg} (\rho_v P_v)^{1/2} \quad (4.8.25)$$

where  $A_v$  is the cross-sectional area of the vapor core ( $m^2$ ). The sonic limitation should be avoided because large temperature gradients occur in heat pipes under choked-flow conditions.

The entrainment limitation in heat pipes develops when the vapor mass flow rate is large enough to shear droplets of liquid off the wick surface causing dry-out in the evaporator. A conservative estimate of the maximum heat transfer rate due to entrainment of liquid droplets has been given by Dunn and Reay (1982) as

$$Q_{e,\max} = A_v h_{fg} \left[ \frac{\rho_v \sigma_l}{2r_{c,\text{ave}}} \right]^{1/2} \quad (4.8.26)$$

where  $\sigma_l$  is the surface tension (N/m) and  $r_{c,\text{ave}}$  is the average capillary radius of the wick. Note that for many applications  $r_{c,\text{ave}}$  is often approximated by  $r_{c,e}$ .

The capillary limitation in heat pipes occurs when the net capillary forces generated by the vapor-liquid interfaces in the evaporator and condenser are not large enough to overcome the frictional pressure losses due to fluid motion. This causes the heat pipe evaporator to dry out and shuts down the transfer of heat from the evaporator to the condenser. For most heat pipes, the maximum heat transfer rate due to the capillary limitation can be expressed as (Chi, 1976).

$$Q_{c,\max} = \left[ \frac{\rho_l \sigma_l h_{fg}}{\mu_l} \right] \left[ \frac{A_w K}{l_{\text{eff}}} \right] \left( \frac{2}{r_{c,e}} - \left[ \frac{\rho_l}{\sigma_l} \right] g L_t \cos \Psi \right) \quad (4.8.27)$$

where  $K$  is the wick permeability ( $m^2$ ),  $A_w$  is the wick cross-sectional area ( $m^2$ ),  $\rho_l$  is the liquid density ( $m^3$ ),  $\mu_l$  is the liquid viscosity (N sec/ $m^2$ ),  $r_{c,e}$  is the wick capillary radius in the evaporator (m),  $g$  is the acceleration due to gravity (9.8 m/sec<sup>2</sup>), and  $L_t$  is the total length of the pipe (m). For most practical operating conditions, this limitation can be used to determine maximum heat transfer rate in heat pipes.

The boiling limitation in heat pipes occurs when the degree of liquid superheat in the evaporator is large enough to cause the nucleation of vapor bubbles on the surface of the wick or the container. Boiling is usually undesirable in heat pipes because local hot spots can develop in the wick, obstructing the flow of liquid in the evaporator. An expression for the boiling limitation is (Chi, 1976)

$$Q_{b,\max} = \frac{4\pi l_{\text{eff}} k_{\text{eff}} T_v \sigma_v}{h_{fg} \rho_l \ln(r_i/r_v)} \left( \frac{1}{r_n} - \frac{1}{r_{c,e}} \right) \quad (4.8.28)$$

where  $k_{\text{eff}}$  is the effective thermal conductivity of the composite wick and working fluid (W/m K),  $T_v$  is the vapor saturation temperature (K),  $r_i$  is the inner container radius (m),  $r_n$  is the nucleation radius (equal to  $2.00 \times 10^{-6}$  m in the absence of noncondensable gas).

**Effective Thermal Conductivity and Heat Pipe Temperature Difference**

One key attribute of the heat pipe is that it can transfer a large amount of heat while maintaining nearly isothermal conditions. The temperature difference between the external surfaces of the evaporator and the condenser can be determined from the following expression

$$\Delta T = R_t Q \tag{4.8.29}$$

where  $R_t$  is the total thermal resistance (K/W) and  $Q$  is the heat transfer rate (W). Figure 4.8.14 shows the thermal resistance network for a typical heat pipe and the associated thermal resistances. In most cases, the total thermal resistance can be approximated by

$$R_t = R_1 + R_2 + R_3 + R_5 + R_7 + R_8 + R_9 \tag{4.8.30}$$

**FIGURE 4.8.14** Thermal resistance network in a heat pipe.

The reader is referred to Peterson (1994) for the specific mathematical relationships used to calculate each thermal resistance. The effective thermal conductivity of the heat pipe is defined as the heat transfer rate divided by the temperature difference between the heat source and heat sink,

$$k_{\text{eff}} = \frac{L_t}{R_t A_t} \quad (4.8.31)$$

where  $A_t$  is the overall cross-sectional area of the pipe ( $\text{m}^2$ ). Under normal operating conditions, the total thermal resistance is relatively small, making the external surface temperature in the evaporator approximately equal to that in the condenser. Thus, the effective thermal conductivity in a heat pipe can be very large (at least an order of magnitude larger than that of aluminum).

### Design Example

Design a water heat pipe to transport 80 W of waste heat from an electronics package to cooling water. The heat pipe specifications are

1. Axial orientation — complete gravity-assisted operation (condenser above the evaporator;  $\psi = 180^\circ$ )
2. Maximum heat transfer rate — 80 W
3. Nominal operating temperature —  $40^\circ\text{C}$
4. Inner pipe diameter — 3 cm
5. Pipe length — 25 cm evaporator length, 50 cm adiabatic section, and 25 cm condenser length

The simplest type of wick structure to use is the single-layer wire mesh screen wick shown in [Table 4.8.5](#). The geometric and thermophysical properties of the wick have been selected as (this takes some forethought)

$$d = 2.0 \times 10^{-5} \text{ m}$$

$$w = 6.0 \times 10^{-5} \text{ m}$$

$$\frac{1}{2N} = r_c = 1/2(2.0 \times 10^{-5} + 6 \times 10^{-5}) = 4.0 \times 10^{-5} \text{ m}$$

$$\varepsilon = 1$$

$$k_{\text{eff}} = k_1 = 0.630 \frac{\text{W}}{\text{mK}}$$

$$t_w = 1.0 \times 10^{-3} \text{ m}$$

$$K = \frac{t_w^2}{12} = \frac{(1 \times 10^{-3})^2}{12} = 8.33 \times 10^{-8} \text{ m}^2$$

The other heat pipe geometric properties are

$$r_v = r_i - t_w = 0.015 - 0.001 = 0.014 \text{ m}$$

$$l_{\text{eff}} = \frac{0.25 + 0.25}{2} + 0.5 = 0.75 \text{ m}$$

$$L_t = 0.25 + 0.50 + 0.25 + 1.0 \text{ m}$$

$$A_w = \pi(r_i^2 - r_v^2) = \pi[(0.015)^2 - (0.014)^2] = 9.11 \times 10^{-5} \text{ m}^2$$

$$A_v = \pi r_v^2 = \pi(0.014)^2 = 6.16 \times 10^{-4} \text{ m}^2$$

The thermophysical properties of water at  $40^\circ\text{C}$  are (see [Table 4.8.4](#)):

$$\rho_l = 992.1 \text{ kg/m}^3$$

$$\rho_v = 0.05 \text{ kg/m}^3$$

$$\sigma_l = 2.402 \times 10^6 \text{ J/kg}$$

$$\mu_l = 6.5 \times 10^{-3} \text{ kg/m sec}$$

$$\mu_v = 1.04 \times 10^{-4} \text{ kg/m sec}$$

$$P_v = 7000 \text{ Pa}$$

The various heat transfer limitations can now be determined to ensure the heat pipe meets the 80 W heat transfer rate specification. The vapor-pressure limitation is

$$Q_{vp,\max} = \frac{\pi(0.014)^4 (2.402 \times 10^6)(0.05)(7000)}{12(1.04 \times 10^{-4})(0.75)} = 1.08 \times 10^5 \text{ W} \quad (4.8.32)$$

The sonic limitation is

$$\begin{aligned} Q_{s,\max} &= 0.474(6.16 \times 10^{-4})(2.402 \times 10^6)[(0.05)(7000)]^{1/2} \\ &= 1.31 \times 10^4 \text{ W} \end{aligned} \quad (4.8.33)$$

The entrainment limitation is

$$\begin{aligned} Q_{e,\max} &= (6.16 \times 10^{-4})(2.402 \times 10^6) \left[ \frac{(0.05)(0.07)}{2(4.0 \times 10^{-5})} \right]^{1/2} \\ &= 9.79 \times 10^3 \text{ W} \end{aligned} \quad (4.8.34)$$

Noting that  $\cos \psi = -1$ , the capillary limitation is

$$\begin{aligned} Q_{c,\max} &= \left[ \frac{(992.1)(0.07)(2.402 \times 10^6)}{6.5 \times 10^{-3}} \right] \left[ \frac{(9.11 \times 10^{-5})(8.33 \times 10^{-8})}{0.75} \right] \left[ \frac{2}{4.0 \times 10^{-5}} + \frac{992.1}{0.07} 9.8(1.0) \right] \\ &= 4.90 \times 10^4 \text{ W} \end{aligned} \quad (4.8.35)$$

Finally, the boiling limitation is

$$\begin{aligned} Q_{b,\max} &= \frac{4\pi(0.75)(0.63)(313)(0.07)}{(2.402 \times 10^6)(992.1) \ln\left(\frac{0.015}{0.014}\right)} \left[ \frac{1}{2.0 \times 10^{-6}} - \frac{1}{4.0 \times 10^{-5}} \right] \\ &= 0.376 \text{ W} \end{aligned} \quad (4.8.36)$$

All of the heat transfer limitations, with the exception of the boiling limitation, exceed the specified heat transfer rate of 80 W. The low value of 0.376 W for the boiling limitation strongly suggests that the liquid will boil in the evaporator and possibly cause local dry spots to develop. The reason the liquid boils is because the effective thermal conductivity of the wick is equal to the conductivity of the liquid, which is very low in this case. Because the liquid is saturated at the vapor-liquid interface, a low effective thermal conductivity requires a large amount of wall superheat which, in turn, causes the liquid to boil. This problem can be circumvented by using a high conductivity wire mesh or sintered metal wick, which greatly increases the effective conductivity. It should be noted, however, that because porous wicks have

	Sintered metal fibers ( $d$ = fiber diameter)	Sintered $k_{\text{eff}} = \frac{k_e [2k_s + k_e - 2\varepsilon(k_s - k_e)]}{2k_s + k_e + \varepsilon(k_s - k_e)}$ $k_{\text{eff}} = \varepsilon^2 k_e (1-\varepsilon)^2 k_s + \frac{4\varepsilon(1-\varepsilon)k_e k_s}{k_e + k_s}$	Use manufacturers data	$r_c = \frac{d}{2(1-\varepsilon)}$	$k = C_1 \frac{y^2 - 1}{y^2 + 1}$ where $y = 1 + \frac{C_2 d^2 \varepsilon^3}{(1-\varepsilon)^2}$ $C_1 = 6.0 \times 10^{-10} \text{ m}^2$ $C_2 = 3.3 \times 10^7 \text{ 1/m}^2$

<sup>a</sup> The axis of the pipe and direction of fluid flow are normal to the paper.

<sup>b</sup> These wicks are positioned so that the layers follow the contours of the inner surface of the pipe wall.

Revised from Peterson, G.P., *An Introduction to Heat Pipes Modeling, Testing, and Applications*, John Wiley & Sons, New York, 1994.

lower permeabilities, the capillary limitation should be lower as well. Let's try a sintered particle wick made of copper with the following properties (see Table 4.8.5):

$$d = 1.91 \times 10^{-4} \text{ m}$$

$$r_{c,3} = 0.21d = 4.0 \times 10^{-5} \text{ m (same as before)}$$

$$\varepsilon = 0.48$$

$$K = \frac{(1.91 \times 10^{-4})^2 (0.48)}{150(1 - 0.48)^2} = 2.07 \times 10^{-10} \text{ m}^2$$

$$k_s = 400 \frac{\text{W}}{\text{mK}} \text{ (copper)}$$

$$k_1 = 0.630 \frac{\text{W}}{\text{mK}} \text{ (water)}$$

$$k_{\text{eff}} = \frac{400[2(400) + 0.63 - 2(0.48)(400 - 0.63)]}{2(400) + 0.63 + 0.48(400 - 0.63)} = 168 \text{ W/mK}$$

All other geometric and thermophysical properties are the same. The heat transfer limitations affected by the change in wick structure are the capillary and boiling limitations. The sintered metal wick produces a capillary limitation of

$$\begin{aligned} Q_{c,\text{max}} &= \left[ \frac{(992.1)(0.07)(2.402 \times 10^6)}{6.5 \times 10^{-3}} \right] \left[ \frac{(9.11 \times 10^{-5})(2.07 \times 10^{-10})}{0.75} \right] \left[ \frac{2}{4.0 \times 10^{-5}} + \frac{992.1}{0.07} 9.8(1.0) \right] \\ &= 122 \text{ W} \end{aligned} \quad (4.8.37)$$

The boiling limitation for the sintered wick is

$$\begin{aligned} Q_{b,\text{max}} &= \frac{4\pi(0.75)(168)(313)(0.07)}{(2.402 \times 10^6)(992.1)\ln\left(\frac{0.015}{0.014}\right)} \left[ \frac{1}{2.0 \times 10^{-6}} - \frac{1}{4.0 \times 10^{-5}} \right] \\ &= 100 \text{ W} \end{aligned} \quad (4.8.38)$$

This design now meets all the specifications defined in the problem statement.

### Application of Heat Pipes

Heat pipes have been applied to a wide variety of thermal processes and technologies. It would be an impossible task to list all the applications of heat pipes; therefore, only a few important industrial applications are given in this section. In the aerospace industry, heat pipes have been used successfully in controlling the temperature of vehicles, instruments, and space suits. Cryogenic heat pipes have been applied in (1) the electronics industry for cooling various devices (e.g., infrared sensors, parametric amplifiers) and (2) the medical field for cryogenic eye and tumor surgery. Heat pipes have been employed to keep the Alaskan tundra frozen below the Alaskan pipeline. Other cooling applications include (1) turbine blades, generators, and motors; (2) nuclear and isotope reactors; and (3) heat collection from exhaust gases, solar and geothermal energy.

In general, heat pipes have advantages over many traditional heat-exchange devices when (1) heat has to be transferred isothermally over relatively short distances, (2) low weight is essential (the heat pipe is a passive pumping device and therefore does not require a pump), (3) fast thermal-response times are required, and (4) low maintenance is mandatory.

## Defining Terms

**Capillary force:** The force caused by a curved vapor-liquid interface. The interfacial curvature is dependent on the surface tension of the liquid, the contact angle between the liquid wick structure, the vapor pressure, and the liquid pressure.

**Effective thermal conductivity:** The heat transfer rate divided by the temperature difference between the evaporator and condenser outer surfaces.

**Heat transfer limitations:** Limitations on the axial heat transfer capacity imposed by different physical phenomena (i.e., vapor pressure, sonic, entrainment, capillary, and boiling limitations).

**Wettability:** The ability of a liquid to spread itself over a surface. A wetting liquid spreads over a surface whereas a nonwetting liquid forms droplets on a surface.

**Wick:** A porous material used to generate the capillary forces that circulate fluid in a heat pipe.

### Introduction

In electronic packages, the thermal resistances to heat transfer from heat source to heat sink are often grouped into an internal resistance and an external resistance. The **internal thermal resistance**  $R_{\text{int}}$  is conductive and exists between the chip and the module case:

$$R_{\text{int}} = \frac{T_{\text{chip}} - T_{\text{case}}}{P_{\text{chip}}} \quad (4.8.39)$$

where  $P_{\text{chip}}$  is the chip power.

The **external thermal resistance**  $R_{\text{ext}}$  is primarily convective and exists between the surface of the case of the module and some reference point, typically the temperature of the cooling fluid near the module. In a multichip module, the module power  $P_m$  is the sum of the individual chip powers, and the external resistance is

$$R_{\text{ext}} = \frac{T_{\text{case}} - T_{\text{coolant}}}{P_m} \quad (4.8.40)$$

The internal and external resistances are related to the chip junction temperature  $T_j$  through the following expression:

$$T_j = \Delta T_{j\text{-chip}} + P_{\text{chip}} R_{\text{int}} + P_m R_{\text{ext}} + \Delta T_{\text{coolant}} + T_{\text{coolant in}} \quad (4.8.41)$$

Many factors are involved in determining the appropriate cooling mode to be used. If the component junction temperature is constrained to approximately 85°C, Table 4.8.6 may be used to make a preliminary selection of the cooling mode. Extended surfaces can often be used to increase the allowable heat fluxes.

**TABLE 4.8.6 Maximum Component Heat Flux for Various Cooling Modes**

Cooling Mode	W/cm <sup>2</sup>
Free convection air	0.05
Forced convection air	0.5
Impingement air	1.0
Free convection immersion	1.0
Forced convection immersion	50
Pool boiling	20
Forced convection boiling	100
Jet immersion (single phase)	40
Boiling jet immersion	90

### Free Convection Air Cooling of Vertical Printed Circuit Boards

Data have been collected from rack-mounted simulated printed circuit boards (PCBs) (see Figure 4.8.15) and from several actual electronic systems at AT&T Bell Laboratories. Results indicated that existing parallel plate correlations for symmetric isoflux plates (separated by distance “b”) could be adapted to PCB conditions. Specifically, for  $Ra_b < 10$  use the equation corresponding to the fully developed laminar boundary layer condition:

$$Nu_b = 0.144 Ra_b^{0.5} \quad (4.8.42)$$

For  $10 < Ra_b < 1000$ , use

$$Nu_b = \left[ \frac{48}{Ra_b} + \frac{2.5}{Ra_b^{0.4}} \right]^{-0.5} \quad (4.8.43)$$

where

$$Ra_b = \frac{g \beta c_p \rho^2 b^5 q''}{\mu k L}$$

For  $Ra > 1000$ , the expression for an isolated plate in infinite media is recommended:

$$Nu_b = 0.524 Ra_b^{0.2} \quad (4.8.44)$$

**FIGURE 4.8.15** Typical PCB array.

In the previous three expressions air properties are evaluated at the average of the module case and ambient temperatures.

The PCB spacing  $b_{\max}$  for a given power dissipation which yields the lowest PCB component case temperatures (or which maximizes the rate of heat transfer while maintaining PCB temperatures below the maximum allowable) occurs when the developing boundary layers from adjacent PCBs do not interfere, i.e., so the isolated plate condition is approached as follows: If heat is transferred from both sides of the PCB, let  $Ra_{ab} = 17,000$  and the recommended PCB spacing is  $b_{\max} = 7.02\xi^{-0.2}$ . If heat is transferred from only one side of the PCB, let  $Ra_{ab} = 5400$  and the recommended PCB spacing is  $b_{\max} = 5.58\xi^{-0.2}$ . In both cases

$$\xi = \frac{g\beta\rho^2\text{Pr}q''}{\mu^2kL} \quad (4.8.45)$$

### Forced Convection Air Cooling of Vertical PCBs

Sparrow et al. (1982, 1984) studied vertical arrays with simulated modules of uniform size, which was 4 modules wide by 17 module rows deep in the flow direction; the modules were 26.7 mm square and 10 mm high; the space between modules was 6.67 mm, and the distance from the top of the module to the adjoining card  $Hc = 16.7$  mm. The Nusselt number as a function of module row position for a fully populated array may be determined from Figure 4.8.16. Correction factors to the fully developed Nusselt numbers for the effect of missing modules and the presence of modules whose height differs from others in the array are presented in the cited references.

In actual electronic packages, conditions differ from the relatively ideal setups in laboratories because in real packages the flow is disturbed by the PCB supporting hardware and may extend the entry region effect.

Data from actual computer hardware with PCBs containing a  $6 \times 4$  array of 28 mm modules (4 in the flow direction) were used to develop the following expressions:

$$\text{Nu}_x = C \left\{ \text{Re}_{D_h} \left[ 1 + x / (D_h)^{-0.836} \right] \right\}^m \quad (4.8.46)$$

**FIGURE 4.8.16** Nusselt number for fully populated array of modules.

For  $Re < 2000$ ,  $C = 0.072$  and  $m = 0.70$ , and for  $2000 < Re < 10,000$ ,  $C = 0.056$  and  $m = 1.02$ , where  $x$  is the distance in the flow direction. Because the array was only 4 modules deep, all the modules on the PCB were in the entry region.

Tests have been conducted on a  $9 \times 7$  array of 25-mm-square by 6.4-mm-high blocks cooled by a  $3 \times 3$  array of air jets directed normal to the face of each block. The spent flow exited along the channel formed by the orifice plate and the heat transfer surfaces. Test results were correlated by the relation:

$$N_d = 0.213(z/d)^{-0.376} Re_d^{0.743} \quad (4.8.47)$$

where  $d$  is the jet orifice diameter,  $s$  is the orifice-to-orifice spacing, and  $z$  is the distance from the orifice outlet to the face of the module.

### Immersion Cooling

The highly inert perfluorinated liquids, called FC coolants by the 3M Company, are frequently used in **immersion cooling** applications. FC coolants are available with boiling points from 30 to 172°C at atmospheric pressure. FC-75 and FC-77 with boiling points of 100°C are often used in single-phase applications, while FC-72 and FC-87, with boiling points of 56 and 30°C, respectively, are used in systems involving phase change.

Data exist for free convection immersion cooling of a  $3 \times 3$  array of simulated chips mounted on a vertical wall in an enclosure filled with FC-75. Each heat source was 8 mm high by 24 mm wide by 6 mm thick. With the Nusselt and modified Rayleigh numbers based on the heater height,  $L$ , the best fit to the data is

$$Nu_L = 0.279 Ra_b^{0.224} \quad (4.8.48)$$

Air cooling expressions have been modified to make them applicable to free convection immersion cooling of vertical PCB arrays with FC coolants. The Nusselt number (based on PCB spacing “ $b$ ”) at the top of the PCB is

$$\text{Nu}_L = \left[ \frac{C}{\text{Ra}_b} + \frac{2.78}{\text{Ra}_b^{0.4}} \right]^{-0.5} \quad (4.8.49)$$

$C = 24$  when heat transfer is from one side of the PCB, and  $C = 48$  when from both sides.

### Nucleate Pool Boiling

A number of investigators have tested small flush heat sources boiling in a pool of dielectric liquid. The heaters ranged from  $4 \times 4$  mm to  $12.7 \times 12.7$  mm. Typical saturated pool boiling data for FC-72 and FC-87 are shown in Figure 4.8.17. Note that a temperature overshoot up to  $25^\circ\text{C}$  has been regularly observed for silicon chips in dielectric liquid pools. To estimate the temperature excursion at boiling incipience ( $q_i''$ ), the following approximation is recommended

$$\Delta T_{\text{ex}} = T_{\text{sat}} \left( p - \frac{2\sigma}{r_b} - p_g \right) - T_{\text{sat}} - C(q_i'')^n \quad (4.8.50)$$

where

$$C = \mu h_{fg} \left[ \frac{c_p}{h_{fg} \text{Pr}^b C_{sf}} \right]^{1/a} \left[ \frac{\alpha}{g(\rho - \rho_g)} \right]^{0.5} \quad (4.8.51)$$

with  $r_b = 0.25 \mu\text{m}$ ,  $C_{sf} = 0.003$ ,  $a = 0.33$ , and  $b = 1.7$ . (Note that  $n = 1/a = 3$ .)

Park and Bergles (1988) determined the critical heat flux (CHF) as a function of size for flush heaters operating in a saturated pool of R-113. For a 5-mm-wide heater, and for heater heights from 5 to 80 mm, use

$$\frac{q_{c,\text{sat}}''}{q_{c_z}''} = 0.86 \left[ 1 + \frac{152}{L^{*3.29}} \right]^{0.14} \quad (4.8.52)$$

where the CHF prediction of Zuber,  $q_{c_z}'' = \rho_g^{0.5} h_{fg} [\sigma g(\rho_f - \rho_g)]^{0.5}$ , and  $L^* = L[g(\rho_f - \rho_g)/\sigma]^{0.5}$ .

For a 5-mm-high heater, and for heater widths from 2.5 to 70 mm, use

$$\frac{q_{c,\text{sat}}''}{q_{c_z}''} = 0.93 \left[ 1 + \frac{52}{I^{1.02}} \right]^{0.14} \quad (4.8.53)$$

where the induced convection parameter is  $I = (\rho_f W \sigma / \mu^2)^{0.5}$ .

For flush  $12.7 \times 12.7$  mm heaters in FC-72, test data yield  $q_{c,\text{sat}}'' / q_{c_z}'' \approx 1.45$ . These subcooling data were correlated by

$$\frac{q_{c,\text{sub}}''}{q_{c,\text{sat}}''} = 1 + \frac{0.0643 \rho_f c_{p,f}}{\rho_g h_{fg}} \left[ \frac{\rho_g}{\rho_f} \right]^{1/4} \Delta T_{\text{sub}} \quad (4.8.54)$$

### Single-Phase and Boiling Forced Convection in Channel Flow

The average Nusselt numbers for 12 flush  $12.7 \times 12.7$  mm heaters (4 rows of 3 sources per row) operating in FC-77 has been correlated by the following expression:

FIGURE 4.8.17 Typical pool boiling curve for small heater.

$$\overline{Nu}_L = C \left( Re_{D_h} \right)^m Pr^{0.11} \tag{4.8.55}$$

For row 1:  $C = 0.194$  and  $m = 0.60$ ; for row 2:  $C = 0.069$  and  $m = 0.69$ ; for row 3:  $C = 0.041$  and  $m = 0.74$ ; and for row 4:  $C = 0.029$  and  $m = 0.78$ . All properties are determined at the inlet temperature except for  $\mu_b$ , which is evaluated at the heater temperature. Note that when heat sinks are employed, forced convection immersion cooling can support a heat flux of approximately  $50 \text{ W/cm}^2$ .

Test data have been obtained for a vertical column of ten  $6.4 \text{ mm} \times 6.4 \text{ mm}$  heaters, with subcooled R-113 flowing in the upward direction. In general, CHF occurred first at the last downstream element in the array, and that CHF values of  $100 \text{ W/cm}^2$  were easily attained. The CHF data yielded the following equation:

$$q_c'' = C_5 We^n V \rho_f h_{fg} \left( \frac{\rho_f}{\rho_g} \right)^{15/23} \left( \frac{L}{D_h} \right)^{1/23} \left[ 1 + \frac{c_{pf} \Delta T_{sub}}{h_{fg}} \right]^{7/23} \left[ 1 + \frac{0.021 \rho_f c_{pf} \Delta T_{sub}}{\rho_g h_{fg}} \right] \tag{4.8.56}$$

where the Weber number,  $We = \rho_f V^2 L / \sigma$ . Note that for  $We > 100$ ,  $C_5 = 0.125$  and  $n = -8/23$ , and for  $We < 10$ ,  $C_5 = 0.254$  and  $n = -1/2$ .

### Immersion Cooling Using Jets

Two modes have been studied. In the first, a dielectric liquid jet discharges into a miscible liquid and is said to be submerged; in the second, a liquid jet discharges into an immiscible gas (air) and is said to be free. In general, the average Nusselt number can be expressed as

$$\overline{Nu} = f(\text{Re}^m, \text{Pr}^n, L/d, z/d) \quad (4.8.57)$$

where  $L/d$  is the ratio of the chip length to orifice diameter, and  $z/d$  is the ratio of the jet to heat source distance to the orifice diameter. A free jet is virtually unaffected by the orifice-to-chip distance, and as a consequence the  $(z/d)$  term drops out.

Data for single-phase forced convection cooling with free jets are available for  $2 \times 2$  and  $3 \times 3$  heat source arrays. The heat sources were  $12.7 \times 12.7$  mm and the cooling fluid was FC-77. Each heat source was cooled either by a single jet or by a  $2 \times 2$  or  $3 \times 3$  array of jets per source. For all the configurations tested, the average Nusselt number was correlated by a single expression:

$$\overline{Nu}_L = 3.84 \left( 0.008 \frac{L}{d} n + 1 \right) \text{Re}^{1/2} \text{Pr}^{1/3} \quad (4.8.58)$$

where fluid properties are to be evaluated at an average of the heat source and jet inlet temperatures.

Data for single-phase forced convection using submerged jets are available for a  $5 \times 5$  mm vertical heat source cooled by a 1.0-mm-diameter submerged jet of R-113. The Nusselt number at the stagnation point was correlated by

$$\text{Nu}_d = 1.29 \text{Re}_d^{1/2} \text{Pr}^{0.4} \quad (4.8.59)$$

Also note that the performance of a submerged liquid jet should be approximately equivalent to gas jet impingement.

Data for two-phase forced convection using free jets have been collected for a single  $12.7 \times 12.7$  mm heat source cooled by either a single jet or a  $2 \times 2$  or  $3 \times 3$  array of jets. The jet diameter, velocity, and jet-to-source distance were varied. The CHF data was correlated by

$$q_c'' = 0.0742 \text{We}^{-0.365} V \rho_f h_{fg} \left( \frac{\rho_g}{\rho_f} \right)^{0.239} \left[ 1 + 0.952 \left( \frac{\rho_f}{\rho_g} \right)^{0.118} \left( \frac{c_{pf} \Delta T_{\text{sub}}}{h_{fg}} \right) \right]^{1.414} \quad (4.8.60)$$

Experimental evidence in two-phase forced convection using submerged jets indicates that (1) the temperature overshoot at incipient boiling was very small compared with pool or forced boiling; (2) the boiling curves at various velocities merge to a single curve and that this curve coincides approximately with an upward extrapolation of the pool boiling curve; (3) the CHF varies as the cube of the jet velocity; (4) the CHF is greatly improved by increasing the subcooling; and (5) powers in excess of 20 W ( $5 \times 5$ -mm chip) could be accommodated within a  $85^\circ\text{C}$  chip temperature.

## Defining Terms

**External thermal resistance:** The thermal resistance from a convenient reference point on the outside of the electronic package to the local ambient.

**Internal thermal resistance:** The thermal resistance from the device junction inside an electronic package to a convenient reference point on the outside surface of the package.

**Immersion cooling:** Concerns applications where the coolant is in direct physical contact with the electronic components.

## 4.9 Non-Newtonian Fluids — Heat Transfer

*Thomas F. Irvine, Jr., and Massimo Capobianchi*

### Introduction

The general characteristics of non-Newtonian fluids are described in Section 3.9 and will not be repeated here. Topics to be included in this section are laminar and turbulent heat transfer in fully developed duct flow, and laminar free convection heat transfer in vertical channels and plates and several other common geometries.

For non-Newtonian flows, except for certain classes of fluids which exhibit a slip phenomenon at solid boundaries, the boundary condition is taken as no-slip or zero velocity at all solid surfaces. For heat transfer analyses, however, the situation is more complicated because there are many different ways to heat a wall, which in turn affects the type of thermal boundary conditions.

In general, the rate of heat transfer from a surface, or the temperature difference between the wall and the fluid, is calculated using the equation  $q_c = h_c A_q \Delta T$ . Since the heat transfer coefficient can vary considerably for different thermal boundary conditions, it is important that the boundary conditions be specified correctly. Although the number of thermal boundary conditions is in principle infinite, several classical types have been identified and are in common use. They are usually identified in terms of the Nusselt number,  $Nu = h_c L/k$ , with a particular subscript. For example, for duct flow, the symbol  $Nu_T$  is used to specify the Nusselt number when the wall temperature is constant in both the flow and peripheral directions. Other thermal boundary conditions are described in Table 4.9.1 for duct heat transfer and will be used throughout this section.

**TABLE 4.9.1 Thermal Boundary Conditions for Duct Heat Transfer**

1.	Constant wall temperature in both the flow and circumferential direction	$Nu_T$
2.	Constant heat flux in the flow direction and constant temperature in the circumferential direction	$Nu_{H1}$
3.	Constant heat flux in the flow and circumferential directions	$Nu_{H2}$
4.	Constant heat flux per unit volume in the wall with circumferential wall heat conduction	$Nu_{H4}$

It should be noted that because of the symmetry in circular and parallel plate ducts,  $Nu_{H1}$  and  $Nu_{H2}$  are identical and are referred to simply as  $Nu_{H1}$ ,  $Nu_{H4}$  with wall conduction is a more-complicated problem where the energy equations must be solved simultaneously in both the wall and the fluid. Such problems are called conjugated. In the  $Nu_{H4}$  situation, the designer has the flexibility of affecting the heat transfer by varying either or both the characteristics of the duct wall or the convective fluid. In the heat transfer relations to be considered later, care will be taken to identify the proper thermal boundary conditions using the nomenclature in Table 4.9.1.

### Laminar Duct Heat Transfer — Purely Viscous, Time-Independent Non-Newtonian Fluids

As discussed in Section 3.9, a convenient and comprehensive constitutive equation for pseudoplastic fluids (flow index,  $n < 1$ ) is the modified power law equation:

$$\mu_a = \frac{\mu_o}{1 + \frac{\mu_o}{K} (\dot{\gamma})^{1-n}} \quad (4.9.1)$$

Equation (4.9.1) has the characteristic that at low shear rates, the equation approaches that for a Newtonian fluid while at large shear rates it describes a power law fluid. In addition, solutions using

Equation (4.9.1) generate a shear rate parameter,  $\beta$ , which describes whether any particular system is in the Newtonian, transitional, or power law region. For duct flow,  $\beta$  is given by

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n} \quad (4.9.2)$$

If  $\log_{10} \beta > 2$ : Power law region

If  $\log_{10} \beta < -2$ : Newtonian region

If  $-2 \leq \log_{10} \beta \leq 2$ : Transition region

For fully developed flow, the characteristic length is the hydraulic diameter,  $D_H$ , and the fluid temperature is the “bulk” temperature defined as

$$T_b = \frac{1}{A_c \bar{u}} \int_{A_c} u T dA_c \quad (4.9.3)$$

Figure 4.9.1 illustrates the values of  $Nu_T$  vs.  $\beta$  for a circular duct with the flow index,  $n$ , as a parameter. It is seen from the figure that the effect of  $\beta$  on  $Nu_T$  is only moderate, but for some applications it may be important to know at what value of  $\beta$  the system is operating. The situation is similar for boundary condition  $Nu_H$ .

Although Figure 4.9.1 shows the Nusselt number relation graphically, it is convenient to have simple correlation equations to represent the solutions for both boundary conditions. For fully developed Nusselt numbers with values of  $0.5 \leq n \leq 1.0$  and  $10^{-4} \leq \beta \leq 10^4$ , Irvine et al. (1988) present the following equation which represents both solutions with a maximum difference of 1.5%:

$$Nu = \frac{Nu_N(1+\beta)}{1 + \frac{Nu_N\beta}{Nu_P}} \quad (4.9.4)$$

The Newtonian Nusselt numbers are  $Nu_N = 3.6568$  for  $Nu_T$ , and  $Nu_N = 4.3638$  for  $Nu_H$ . In addition, Table 4.9.2 lists the power law Nusselt numbers,  $Nu_{TP}$  and  $Nu_{HP}$ , for  $\log_{10} \beta = 4$ .

Graetz solutions for the thermal entrance lengths are also available. They assume that the velocity profile is fully developed at the duct entrance and present the duct lengths required for the Nusselt numbers to reach within 1% of the fully developed values. Figure 4.9.2 shows these thermal entrance lengths for  $Nu_T$  thermal boundary condition. The situation is similar for boundary condition  $Nu_H$ .

A correlation equation for the thermal entrance lengths for both the  $Nu_T$  and  $Nu_H$  boundary conditions by Irvine et al. (1988) represents the numerical solutions within 0.5% for  $0.5 \leq n \leq 1.0$  and  $-4 \leq \log_{10} \beta \leq 4$ . Table 4.9.3 lists the power law thermal entrance lengths which are needed to evaluate the following correlation equation:

$$x_{ent,\beta,n}^+ = \frac{x_{ent,N}^+(1+\beta)}{1 + \frac{x_{ent,N}^+(\beta)}{x_{ent,P}^+}} \quad (4.9.5)$$

where  $x_{ent,\beta,n}^+$  is the modified power law dimensionless entrance length defined as  $x_{ent,\beta,n}^+ = (x_{ent,\beta,n}/D_H)/Pe$ , and  $x_{ent,N}^+$  and  $x_{ent,P}^+$  are the Newtonian and power law values, respectively. The Newtonian dimensionless entrance lengths are  $x_{ent,N}^+ = 0.03347$  for  $Nu_T$  and  $x_{ent,N}^+ = 0.04309$  for  $Nu_H$ .

**FIGURE 4.9.1** Variation of the fully developed circular duct Nusselt numbers,  $Nu_T$ , with the shear rate parameter  $\beta$  and  $n$ . (From Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127. With permission.)

**TABLE 4.9.2** Power Law  $Nu_T$  and  $Nu_H$   
Solutions for a Circular Duct ( $\log_{10} \beta = 4$ )

$n$	$Nu_{TP}$	$Nu_{HP}$
1.0 (Newtonian)	3.6568	4.3638
0.9	3.6934	4.4109
0.8	3.7377	4.4679
0.7	3.7921	4.5385
0.6	3.8605	4.6281
0.5	3.9494	4.7456

Source: Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127.

Only one noncircular geometry using the modified power law equation has been published in the archival literature for laminar fully developed heat transfer (Capobianchi and Irvine, 1992). A correlation equation for  $Nu_{H1}$  for annuli with constant heat flux at the inner wall and the outer wall insulated is

$$n < 1 \quad Nu_{H1} = \frac{1 + \beta}{\frac{1}{Nu_{H1,N}} + \frac{\beta}{Nu_{H1,P}}} \quad (4.9.6)$$

Nusselt numbers for square ducts and power law fluids can be found in Chandrupatla and Sastri (1977) and, for isosceles triangular ducts, in Cheng (1984). Thermally developing and thermally developed laminar heat transfer in rectangular channels has been studied by Hartnett and Kostic (1989).

For other cross-sectional shapes, a power law approximate correlation has been proposed by Cheng (1984):

**FIGURE 4.9.2** Thermal entrance lengths vs. shear rate parameter  $\beta$  and  $n$  for  $Nu_T$  in circular ducts. (From Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127. With permission.)

**TABLE 4.9.3** Values of Circular Duct Thermal Entrance Lengths for  $Nu_T$  and  $Nu_H$  for Use in Equation 4.9.5

$n$	$Nu_T, x_{ent,p}^+ \times 10^2$	$Nu_H, x_{ent,p}^+ \times 10^2$
1.0 (Newtonian)	3.347	4.309
0.9	3.326	4.281
0.8	3.306	4.248
0.7	3.279	4.210

$$Nu_p = Nu_N \left[ \frac{(a + bn)}{(a + b)n} \right]^{1/3} \tag{4.9.7}$$

where  $a$  and  $b$  are the Kozicki geometric constants listed in Table 3.9.3 in the section on non-Newtonian flows. Equation (4.9.7) applies to any thermal boundary condition. For circular ducts, Equation 4.9.7 predicts the correct solution for both  $Nu_T$  and  $Nu_H$ .

### Turbulent Duct Flow for Purely Viscous Time-Independent Non-Newtonian Fluids

It is known that in turbulent flow, the type of thermal boundary conditions has much less effect than in laminar flow. Therefore, turbulent flow heat transfer investigations are often reported without specifying the thermal boundary conditions. Yoo (1974) has presented an empirical correlation for turbulent heat transfer in circular ducts for purely viscous time-independent power law fluids.

$$\text{StPr}_a^{2/3} = 0.0152\text{Re}_a^{-0.155} \quad (4.9.8)$$

Equation (4.9.8) describes all of the experimental data available in the literature at the time with a mean deviation of 2.3%. Equation (4.9.8) is recommended in order to predict the turbulent fully developed heat transfer in the ranges  $0.2 \leq n \leq 0.9$  and  $3000 \leq \text{Re}_a \leq 90,000$ . The Reynolds number and Prandtl numbers in Equation (4.9.8) are based on the apparent viscosity at the wall,  $\mu_a$ , i.e.,

$$\text{Re}_a = \frac{\rho \bar{u} D_H}{\mu_a} \quad (4.9.9)$$

$$\text{Pr}_a = \frac{\mu_a c_p}{k} \quad (4.9.10)$$

In order to evaluate Equations (4.9.9) and (4.9.10) in terms of the rheological properties and operating parameters, an expression must be obtained for  $\mu_a$  in terms of these quantities. The value of  $\mu_a$  is evaluated by considering that  $\mu_a$  is determined from fully developed laminar circular tube power law fluid flow for which it can be shown that (Irvine and Karni, 1987)

$$\mu_a = K \left( \frac{3n+1}{4n} \right)^{n-1} \left( \frac{8\bar{u}}{D_H} \right)^{n-1} \quad (4.9.11)$$

assuming that the quantities  $K$ ,  $n$ ,  $c_p$ , and  $k$  are constant. It is also of interest that the Prandtl number is no longer a thermophysical property for power law fluids but depends upon the average velocity,  $\bar{u}$ , and the hydraulic diameter,  $D_H$ .

Hartnett and Rao (1987) have investigated fully developed turbulent heat transfer for a rectangular duct with a 2:1 aspect ratio and propose the following equation which generally agreed with their experimental data within  $\pm 20\%$ :

$$\text{Nu} = (0.0081 + 0.0149n)\text{Re}_a^{0.8}\text{Pr}_a^{0.4} \quad (4.9.12)$$

## Viscoelastic Fluids

An important characteristic of viscoelastic fluids is their large hydrodynamic and thermal entrance lengths. Cho and Hartnett (1982) have reported hydrodynamic entrance lengths of up to 100 diameters and thermal entrance lengths up to 200 to 800 diameters depending upon the Reynolds and Prandtl numbers. These can be compared with Newtonian fluids entrance lengths which are of the order of 10 to 15 diameters. Therefore, care must be used in applying fully developed relations to practical situations.

Cho et al. (1980) reported heat transfer measurements in the thermal entrance region and recommend the following empirical equation for saturated aqueous polymer solutions for  $6000 \leq \text{Re}_a$  and  $x/D_H$  values up to 450:

$$J_H = 0.13 \left( x/D_H \right)^{-0.24} \text{Re}_a^{-0.45} \quad (4.9.13)$$

where  $J_H = \text{St Pr}_a^{2/3}$  and  $\text{St} = h_c/\rho c_p \bar{u}$ .

All of the reported fully developed turbulent flow heat transfer measurements have been plagued by solute and solvent, thermal entrance, and degradation effects, and thus there is considerable scatter in the results. Degradation effects can be reduced or eliminated by using large amounts of polymer (500

to 10,000 wppm) so that the solution becomes saturated. Cho and Hartnett (1982) attempted to eliminate these effects by using a thermal entrance length of 430 diameters and saturated polymer solutions which should yield maximum heat transfer reductions. Their experimental results for fully developed heat transfer were correlated for a Reynolds number range  $3500 \leq Re_a \leq 40,000$  and concentration solutions of 500 to 5000 wppm of polyacrylamide and polyethylene oxide by

$$J_H = 0.03Re_a^{-0.45} \quad (4.9.14)$$

For viscoelastic fluids in fully developed (hydrodynamically and thermally) *laminar flow in circular ducts* there is no apparent viscoelastic effect. Thus, the heat transfer relations are the same as those for time-independent fluids such as power law or modified power law fluids. The same situation holds for thermal entrance region heat transfer (Graetz problem). Relations for laminar Nusselt numbers in thermal entrance regions are presented by Cho and Hartnett (1982).

### Free Convection Flows and Heat Transfer

Free convection information available in the heat transfer literature up to the present time is concentrated on heat transfer to power law fluids for vertical plates and parallel plate channels. For free convection flows, however, the velocities and thus the shear rates are low and care must be taken that the flow for a particular fluid is in the power law shear rate region before using power law solutions or correlations. Comprehensive review articles on free convection with non-Newtonian fluids have been presented by Shenoy and Mashelkar (1982) and Irvine and Karni (1987).

For a single vertical plate with a modified power law fluid and a thermal boundary condition  $\bar{Nu}_T$ , in laminar flow, the following relation is recommended by Shenoy and Mashelkar (1982):

$$\bar{Nu}_{TL} = T(n)Gr_{TL}^{1/(2n+2)}Pr_{TL}^{n/(3n+1)} \quad (4.9.15)$$

where  $\bar{Nu}_{TL}$  is the average Nusselt number and

$$Gr_{TL} = \frac{\rho^2 L^{n+2}}{K^2} [g\alpha(T_s - T_\infty)]^{2-n} \quad (4.9.16)$$

$$Pr_{TL} = \frac{\rho c_p}{k} \left( \frac{K}{\rho} \right)^{2/(n+1)} L^{(n-1)/(2n+2)} [g\alpha(T_s - T_\infty)]^{(3n-3)/(2n+2)} \quad (4.9.17)$$

where  $\alpha$  is the isobaric thermal expansion coefficient.

In the range  $0.5 \leq n \leq 1$ ,  $T(n)$  can be approximated by

$$T(n) = 0.1636n + 0.5139 \quad (4.9.18)$$

The characteristic dimension in the Nusselt and Grashof numbers is the plate height,  $L$ .

For thermal boundary conditions  $Nu_H$ , the following relation is also recommended by Shenoy and Mashelkar (1982). Since the heat flux,  $q_w$  is specified in this case, the local plate temperature at any  $x$  (measured from the bottom of the plate) can be obtained from the local Nusselt number  $Nu_{Hx}$ . The heat transfer coefficient is defined in terms of the difference between the wall and free-stream temperatures.

$$Nu_{Hx} = 0.619 \left[ Gr_{Hx}^{(3n+2)/(n+4)} Pr_{Hx}^n \right]^{0.213} \quad (4.9.19)$$

where

$$\text{Gr}_{Hx} = \frac{\rho^2 x^4}{k^2} \left( \frac{g\alpha q_w}{k} \right)^{2-n} \quad (4.9.20)$$

$$\text{Pr}_{Hx} = \frac{\rho c_p}{K} \left( \frac{K}{\rho} \right)^{5/(n+4)} x^{(2n-2)/(n+4)} \left( \frac{g\alpha q_w}{k} \right)^{(3n-3)/(n+4)} \quad (4.9.21)$$

### Vertical Parallel Plates

For *power law fluids* and laminar flow, [Figure 4.9.3](#) presents the graphical results of a numerical solution. Of interest are the average Nusselt number  $\bar{Nu}_{Tb}$  and the dimensionless average flow velocity between the plates,  $U_o^+$ . These are shown on the left and right ordinates respectively in [Figure 4.9.3](#) (Irvine et al., 1982). The characteristic dimension in the Nusselt and Grashof numbers is the plate spacing,  $b$ . The dimensionless quantities used in [Figure 4.9.3](#) are defined as follows:

$$\bar{Nu}_{Tb} = \frac{\bar{h}_c b}{k} \quad U_o^+ = \frac{b u_o}{Lu^*}$$

$$\text{Pr}_g = \frac{\rho c_p}{k} \left[ \frac{v_k^{1/(2-n)}}{\left( \frac{L}{b} \right)^{(1-n)/(2-n)} b^{(2n-2)/(2-n)}} \right] \quad v_K = \frac{K}{\rho}$$

$$\text{Gr}_g = \frac{g\alpha(T_s - T_\infty) b^{(n+2)/(2-n)}}{v_K^{2/(2-n)} \left( \frac{L}{b} \right)^{n/(2-n)}} \quad u^* = \frac{v_K^{1/(2-n)} b^{(1-2n)/(2-n)}}{L^{(1-n)/(2-n)}}$$

For vertical parallel plates for the average Nusselt number,  $\bar{Nu}_{Hb}$ , and the between plate average velocity, Schneider and Irvine (1984) have presented graphical results similar to [Figure 4.9.3](#).

Lee (1992) has presented a numerical solution for laminar flow of a *modified power law fluid* between vertical plates. Lee has also calculated thermal entrance regions and shown that if a parallel plate system is actually operating in the transition region and if the power law solution is used, both the total heat transfer and the velocity between plates can differ by over an order of magnitude. It is important to consider the shear rate parameter in order to determine which free convection solution to use.

### Sphere and Horizontal Cylinder — Power Law Fluids

For flow over a sphere, the correlation for power law fluids by Amato and Tien (1976) is

$$\bar{Nu}_{Tr} = CZ^D \quad (4.9.22)$$

where

$$Z = \text{Gr}_{Tr}^{1/(2n+2)} \text{Pr}_{Tr}^{n/(3n+1)} \quad (4.9.23)$$

and

$$C = 0.996 \pm 0.120, \quad D = 0.682 \quad \text{for } Z < 10$$

$$C = 0.489 \pm 0.005, \quad D = 1.10 \quad \text{for } 10 \leq Z \leq 40$$

**FIGURE 4.9.3** Free convection average Nusselt number,  $\bar{Nu}_b$ , and dimensionless average velocity  $U_o^+$  between vertical plates for a power law fluid vs. generalized Rayleigh number for the  $Nu_T$  boundary condition. (From Irvine, T.F., Jr. et al., ASME Paper 82-WA/HT-69, 1982. With permission.)

where the characteristic dimension in all dimensionless variables is the sphere radius,  $r$ , and  $Gr_{Tr}$  and  $Pr_{Tr}$  are defined in Equations (4.9.16) and (4.9.17).

For pseudoplastic fluids flowing over a cylinder, an experimental correlation proposed by Gentry and Worllersheim (1974) for the average Nusselt number,  $\bar{Nu}_{TD}$ , is

$$\bar{Nu}_{TD} = \frac{\bar{h}_c D}{k} = 1.19 (Gr_{TD} Pr_{TD})^{0.2} \tag{4.9.24}$$

where  $Gr_{TD}$  and  $Pr_{TD}$  are defined as in Equations (4.9.16) and (4.9.17) with the cylinder diameter,  $D$ , being used instead of  $L$ .

## 4.1 Conduction Heat Transfer

*Robert F. Boehm*

### Introduction

Conduction heat transfer phenomena are found throughout virtually all of the physical world and the industrial domain. The analytical description of this heat transfer mode is one of the best understood. Some of the bases of understanding of conduction date back to early history. It was recognized that by invoking certain relatively minor simplifications, mathematical solutions resulted directly. Some of these were very easily formulated. What transpired over the years was a very vigorous development of applications to a broad range of processes. Perhaps no single work better summarizes the wealth of these studies than does the book by Carslaw and Jaeger (1959). They gave solutions to a broad range of problems, from topics related to the cooling of the Earth to the current-carrying capacities of wires. The general analyses given there have been applied to a range of modern-day problems, from laser heating to temperature-control systems.

Today conduction heat transfer is still an active area of research and application. A great deal of interest has developed in recent years in topics like contact resistance, where a temperature difference develops between two solids that do not have perfect contact with each other. Additional issues of current interest include non-Fourier conduction, where the processes occur so fast that the equation described below does not apply. Also, the problems related to transport in miniaturized systems are garnering a great deal of interest. Increased interest has also been directed to ways of handling composite materials, where the ability to conduct heat is very directional.

Much of the work in conduction analysis is now accomplished by use of sophisticated computer codes. These tools have given the heat transfer analyst the capability of solving problems in nonhomogeneous media, with very complicated geometries, and with very involved boundary conditions. It is still important to understand analytical ways of determining the performance of conducting systems. At the minimum these can be used as calibrations for numerical codes.

### Fourier's Law

The basis of conduction heat transfer is **Fourier's Law**. This law involves the idea that the heat flux is proportional to the temperature gradient in any direction  $n$ . **Thermal conductivity**,  $k$ , a property of materials that is temperature dependent, is the constant of proportionality.

$$q_k = -kA \frac{\partial T}{\partial n} \quad (4.1.1)$$

In many systems the area  $A$  is a function of the distance in the direction  $n$ . One important extension is that this can be combined with the first law of thermodynamics to yield the **heat conduction equation**. For constant thermal conductivity, this is given as

$$\nabla^2 T + \frac{\dot{q}_G}{k} = \frac{1}{\alpha} \frac{\partial T}{\partial t} \quad (4.1.2)$$

In this equation,  $\alpha$  is the thermal diffusivity and  $\dot{q}_G$  is the internal heat generation per unit volume. Some problems, typically steady-state, one-dimensional formulations where only the heat flux is desired, can be solved simply from Equation (4.1.1). Most conduction analyses are performed with Equation (4.1.2). In the latter, a more general approach, the temperature distribution is found from this equation and appropriate boundary conditions. Then the heat flux, if desired, is found at any location using Equation (4.1.1). Normally, it is the temperature distribution that is of most importance. For example,

it may be desirable to know through analysis if a material will reach some critical temperature, like its melting point. Less frequently the heat flux is desired.

While there are times when it is simply desired to understand what the temperature response of a structure is, the engineer is often faced with a need to increase or decrease heat transfer to some specific level. Examination of the thermal conductivity of materials gives some insight into the range of possibilities that exist through simple conduction.

Of the more common engineering materials, pure copper exhibits one of the higher abilities to conduct heat with a thermal conductivity approaching  $400 \text{ W/m}^2 \text{ K}$ . Aluminum, also considered to be a good conductor, has a thermal conductivity a little over half that of copper. To increase the heat transfer above values possible through simple conduction, more-involved designs are necessary that incorporate a variety of other heat transfer modes like convection and phase change.

Decreasing the heat transfer is accomplished with the use of insulations. A separate discussion of these follows.

## Insulations

Insulations are used to decrease heat flow and to decrease surface temperatures. These materials are found in a variety of forms, typically *loose fill*, *batt*, and *rigid*. Even a gas, like air, can be a good insulator if it can be kept from moving when it is heated or cooled. A vacuum is an excellent insulator. Usually, though, the engineering approach to insulation is the addition of a low-conducting material to the surface. While there are many chemical forms, costs, and maximum operating temperatures of common forms of insulations, it seems that when a higher operating temperature is required, many times the thermal conductivity and cost of the insulation will also be higher.

Loose-fill insulations include such materials as milled alumina-silica (maximum operating temperature of  $1260^\circ\text{C}$  and thermal conductivities in the range of  $0.1$  to  $0.2 \text{ W/m}^2 \text{ K}$ ) and perlite (maximum operating temperature of  $980^\circ\text{C}$  and thermal conductivities in the range of  $0.05$  to  $1.5 \text{ W/m}^2 \text{ K}$ ). Batt-type insulations include one of the more common types — glass fiber. This type of insulation comes in a variety of densities, which, in turn, have a profound affect on the thermal conductivity. Thermal conductivities for glass fiber insulations can range from about  $0.03$  to  $0.06 \text{ W/m}^2\text{K}$ . Rigid insulations show a very wide range of forms and performance characteristics. For example, a rigid insulation in foam form, polyurethane, is very lightweight, shows a very low thermal conductivity (about  $0.02 \text{ W/m}^2 \text{ K}$ ), but has a maximum operating temperature only up to about  $120^\circ\text{C}$ . Rigid insulations in refractory form show quite different characteristics. For example, high-alumina brick is quite dense, has a thermal conductivity of about  $2 \text{ W/m}^2 \text{ K}$ , but can remain operational to temperatures around  $1760^\circ\text{C}$ . Many insulations are characterized in the book edited by Guyer (1989).

Often, commercial insulation systems designed for high-temperature operation use a layered approach. Temperature tolerance may be critical. Perhaps a refractory is applied in the highest temperature region, an intermediate-temperature foam insulation is used in the middle section, and a high-performance, low-temperature insulation is used on the outer side near ambient conditions.

Analyses can be performed including the effects of temperature variations of thermal conductivity. However, the most frequent approach is to assume that the thermal conductivity is constant at some temperature between the two extremes experienced by the insulation.

## The Plane Wall at Steady State

Consider steady-state heat transfer in a plane wall of thickness  $L$ , but of very large extent in both other directions. The wall has temperature  $T_1$  on one side and  $T_2$  on the other. If the thermal conductivity is considered to be constant, then Equation (4.1.1) can be integrated directly to give the following result:

$$q_k = \frac{kA}{L}(T_1 - T_2) \quad (4.1.3)$$

This can be used to determine the steady-state heat transfer through slabs.

An electrical circuit analog is widely used in conduction analyses. This is realized by considering the temperature difference to be analogous to a voltage difference, the heat flux to be like current flow, and the remainder of Equation (4.1.3) to be like a thermal resistance. The latter is seen to be

$$R_k = \frac{L}{kA} \quad (4.1.4)$$

Heat transfer through walls made of layers of different types of materials can be easily found by summing the resistances in series or parallel form, as appropriate.

In the design of systems, seldom is a surface temperature specified or known. More often, the surface is in contact with a bulk fluid, whose temperature is known at some distance from the surface. Convection from the surface is then represented by Newton's law of cooling:

$$q = \bar{h}_c A (T_s - T_\infty) \quad (4.1.5)$$

This equation can also be represented as a temperature difference divided by a thermal resistance, which is  $1/\bar{h}_{cA}$ . It can be shown that a very low surface resistance, as might be represented by phase change phenomena, has the effect of imposing the fluid temperature directly on the surface. Hence, usually a *known* surface temperature results from a fluid temperature being imposed directly on the surface through a very high heat transfer coefficient. For this reason, in the later results given here, particularly those for transient systems, a convective boundary will be assumed. For steady results this is less important because of the ability to add resistances through the circuit analogy.

### Long, Cylindrical Systems at Steady State

For long ( $L$ ) annular systems at steady-state conditions with constant thermal conductivities, the following two equations are the appropriate counterparts to Equations (4.1.3) and (4.1.4). The heat transfer can be expressed as

$$q_k = \frac{2\pi Lk}{\ln[r_2/r_1]} (T_1 - T_2) \quad (4.1.6)$$

Here,  $r_1$  and  $r_2$  represent the radii of annular section. A thermal resistance for this case is as shown below.

$$R_k = \frac{\ln[r_2/r_1]}{2\pi Lk} \quad (4.1.7)$$

### The Overall Heat Transfer Coefficient

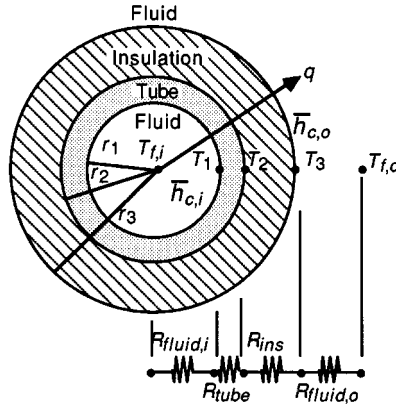

The **overall heat transfer coefficient** concept is valuable in several aspects of heat transfer. It involves a modified form of Newton's law of cooling, as noted above, and it is written as

$$Q = \bar{U} A \Delta T \quad (4.1.8)$$

In this formulation  $\bar{U}$  is the overall heat transfer coefficient based upon the area  $A$ . Because the area for heat transfer in a problem can vary (as with a cylindrical geometry), it is important to note that the  $\bar{U}$  is dependent upon which area is selected. The overall heat transfer coefficient is usually found from a combination of thermal resistances. Hence, for a common series-combination-circuit analog, the  $\bar{U}A$  product is taken as the sum of resistances.

$$\bar{U}A = \frac{1}{\sum_{i=1}^n R_i} = \frac{1}{R_{\text{total}}} \quad (4.1.9)$$

To show an example of the use of this concept, consider [Figure 4.1.1](#).

**FIGURE 4.1.1.** An insulated tube with convective environments on both sides.

For steady-state conditions, the product  $\bar{U}A$  remains constant for a given heat transfer and overall temperature difference. This can be written as

$$\bar{U}_1 A_1 = \bar{U}_2 A_2 = \bar{U}_3 A_3 = \bar{U}A \quad (4.1.10)$$

If the inside area,  $A_1$ , is chosen as the basis, the overall heat transfer coefficient can then be expressed as

$$\bar{U}_1 = \frac{1}{\frac{1}{h_{c,i}} + \frac{r_1 \ln(r_2/r_1)}{k_{\text{pipe}}} + \frac{r_1 \ln(r_3/r_2)}{k_{\text{ins}}} + \frac{r_1}{r_3 h_{c,o}}} \quad (4.1.11)$$

## Critical Thickness of Insulation

Sometimes insulation can cause an increase in heat transfer. This circumstance should be noted in order to apply it when desired and to design around it when an insulating effect is needed. Consider the circumstance shown in [Figure 4.1.1](#). Assume that the temperature is known on the outside of the tube (inside of the insulation). This could be known if the inner heat transfer coefficient is very large and the thermal conductivity of the tube is large. In this case, the inner fluid temperature will be almost the same as the temperature of the inner surface of the insulation. Alternatively, this could be applied to a coating (say an electrical insulation) on the outside of a wire. By forming the expression for the heat transfer in terms of the variables shown in Equation (4.1.11), and examining the change of heat transfer with variations in  $r_3$  (that is, the thickness of insulation) a maximum heat flow can be found. While simple results are given many texts (showing the critical radius as the ratio of the insulation thermal conductivity to the heat transfer coefficient on the outside), Sparrow (1970) has considered a heat transfer coefficient that varies as  $\bar{h}_{c,o} \sim r_3^{-m} |T_3 - T_{f,o}|^n$ . For this case, it is found that the heat transfer is maximized at

$$r_3 = r_{\text{crit}} = \left[ (1-m)/(1+n) \right] \frac{k_{\text{ins}}}{\bar{h}_{c,o}} \quad (4.1.12)$$

By examining the order of magnitudes of  $m$ ,  $n$ ,  $k_{\text{ins}}$ , and  $\bar{h}_{c,o}$  the critical radius is found to be often on the order of a *few millimeters*. Hence, additional insulation on small-diameter cylinders such as small-gauge electrical wires could actually increase the heat dissipation. On the other hand, the addition of insulation to large-diameter pipes and ducts will almost always decrease the heat transfer rate.

### Internal Heat Generation

The analysis of temperature distributions and the resulting heat transfer in the presence of volume heat sources is required in some circumstances. These include phenomena such as nuclear fission processes, joule heating, and microwave deposition. Consider first a slab of material  $2L$  thick but otherwise very large, with internal generation. The outside of the slab is kept at temperature  $T_1$ . To find the temperature distribution within the slab, the thermal conductivity is assumed to be constant. Equation (4.1.2) reduces to the following:

$$\frac{d^2T}{dx^2} + \frac{\dot{q}_G}{k} = 0 \quad (4.1.13)$$

Solving this equation by separating variables, integrating twice, and applying boundary conditions gives

$$T(x) - T_1 = \frac{\dot{q}_G L^2}{2k} \left[ 1 - \left( \frac{x}{L} \right)^2 \right] \quad (4.1.14)$$

A similar type of analysis for a long, cylindrical element of radius  $r_1$  gives

$$T(r) - T_1 = \frac{\dot{q}_G r_1^2}{4k} \left[ 1 - \left( \frac{r}{r_1} \right)^2 \right] \quad (4.1.15)$$

Two additional cases will be given. Both involve the situation when the heat generation rate is dependent upon the local temperature in a linear way (defined by a slope  $\beta$ ), according to the following relationship:

$$\dot{q}_G = \dot{q}_{G,o} \left[ 1 + \beta(T - T_o) \right] \quad (4.1.16)$$

For a plane wall of  $2L$  thickness and a temperature of  $T_1$  specified on each surface

$$\frac{T(x) - T_o + 1/\beta}{T_1 - T_o + 1/\beta} = \frac{\cos \mu x}{\cos \mu L} \quad (4.1.17)$$

For a similar situation in a long cylinder with a temperature of  $T_1$  specified on the outside radius  $r_1$

$$\frac{T(r) - T_o + 1/\beta}{T_1 - T_o + 1/\beta} = \frac{J_o(\mu r)}{J_o(\mu r_1)} \quad (4.1.18)$$

In Equation (4.1.18), the  $J_o$  is the typical notation for the Bessel function. Variations of this function are tabulated in Abramowitz and Stegun (1964). In both cases the following holds:

$$\mu \equiv \sqrt{\frac{\beta \dot{q}_{G,o}}{k}}$$

**Fins**

**Fins** are widely used to enhance the heat transfer (usually convective, but it could also be radiative) from a surface. This is particularly true when the surface is in contact with a gas. Fins are used on air-cooled engines, electronic cooling forms, as well as for a number of other applications. Since the heat transfer coefficient tends to be low in gas convection, area is added in the form of fins to the surface to decrease the convective thermal resistance.

The simplest fins to analyze, and which are usually found in practice, can be assumed to be one-dimensional and constant in cross section. In simple terms, to be one-dimensional, the fins have to be long compared with a transverse dimension. Three cases are normally considered for analysis, and these are shown in Figure 4.1.2. They are the insulated tip, the infinitely long fin, and the convecting tip fin.

**FIGURE 4.1.2.** Three typical cases for one-dimensional, constant-cross-section fins are shown.

For Case, I, the solution to the governing equation and the application of the boundary conditions of the known temperature at the base and the insulated tip yields

$$\text{Case I:} \quad \theta = \theta_b = \frac{\cosh m(L-x)}{\cosh mL} \tag{4.1.19}$$

For the infinitely long case, the following simple form results:

$$\text{Case II:} \quad \theta(x) = \theta_b e^{-mx} \tag{4.1.20}$$

The final case yields the following result:

$$\text{Case III:} \quad \theta(x) = \theta_b \frac{mL \cosh m(L-x) + \text{Bi} \sinh m(L-x)}{mL \cosh mL + \text{Bi} \sinh mL} \tag{4.1.21}$$

where

$$\text{Bi} \equiv \bar{h}_c L/k$$

In all three of the cases given, the following definitions apply:

$$\theta \equiv T(x) - T_\infty, \quad \theta_b \equiv T(x=0) - T_\infty, \quad \text{and} \quad m^2 \equiv \frac{\bar{h}_c P}{kA}$$

Here  $A$  is the cross section of the fin parallel to the wall;  $P$  is the perimeter around that area.

To find the heat removed in any of these cases, the temperature distribution is used in Fourier's law, Equation (4.1.1). For most fins that truly fit the one-dimensional assumption (i.e., long compared with their transverse dimensions), all three equations will yield results that do not differ widely.

Two performance indicators are found in the fin literature. The **fin efficiency** is defined as the ratio of the actual heat transfer to the heat transfer from an ideal fin.

$$\eta \equiv \frac{q_{\text{actual}}}{q_{\text{ideal}}} \quad (4.1.22)$$

The ideal heat transfer is found from convective gain or loss from an area the same size as the fin surface area, all at a temperature  $T_b$ . Fin efficiency is normally used to tabulate heat transfer results for various types of fins, including ones with nonconstant area or which do not meet the one-dimensional assumption. An example of the former can be developed from a result given by Arpaci (1966). Consider a straight fin of triangular profile, as shown in Figure 4.1.3. The solution is found in terms of modified Bessel functions of the first kind. Tabulations are given in Abramowitz and Stegun (1964).

$$\eta = \frac{I_1(2\tilde{m}L^{1/2})}{\tilde{m}L^{1/2}I_0(2\tilde{m}L^{1/2})} \quad (4.1.23)$$

Here,  $\tilde{m} \equiv \sqrt{2\bar{h}_c L/kb}$ .

The **fin effectiveness**,  $\epsilon$ , is defined as the heat transfer from the fin compared with the bare-surface transfer through the same base area.

**FIGURE 4.1.3.** Two examples of fins with a cross-sectional area that varies with distance from the base. (a) Straight triangular fin. (b) Annular fin of constant thickness.

$$\varepsilon = \frac{q_{\text{actual}}}{q_{\text{bare base}}} = \frac{q_f}{\bar{h}_c A (T_b - T_\infty)} \quad (4.1.24)$$

Carslaw and Jaeger (1959) give an expression for the effectiveness of a fin of constant thickness around a tube (see Figure 4.1.3) This is given as ( $\tilde{\mu} \equiv \sqrt{2\bar{h}_c/kb}$ ).

$$\varepsilon = \frac{2}{\tilde{\mu} b} \frac{I_1(\tilde{\mu} r_2) K_1(\tilde{\mu} r_1) - K_1(\tilde{\mu} r_2) I_1(\tilde{\mu} r_1)}{I_0(\tilde{\mu} r_1) K_1(\tilde{\mu} r_2) + K_0(\tilde{\mu} r_1) I_1(\tilde{\mu} r_2)} \quad (4.1.25)$$

Here the notations  $I$  and  $K$  denote Bessel functions that are given in Abramowitz and Stegun (1964).

Fin effectiveness can be used as one indication whether or not fins should be added. A rule of thumb indicates that if the effectiveness is less than about three, fins should not be added to the surface.

## Transient Systems

### Negligible Internal Resistance

Consider the transient cooling or heating of a body with surface area  $A$  and volume  $V$ . This is taking place by convection through a heat transfer coefficient  $\bar{h}_c$  to an ambient temperature of  $T_\infty$ . Assume the thermal resistance to conduction inside the body is significantly less than the thermal resistance to convection (as represented by Newton's law of cooling) on the surface of the body. This ratio is denoted by the **Biot number**,  $Bi$ .

$$Bi = \frac{R_k}{R_c} = \frac{\bar{h}_c (V/A)}{k} \quad (4.1.26)$$

The temperature (which will be uniform throughout the body at any time for this situation) response with time for this system is given by the following relationship. Note that the shape of the body is not important — only the ratio of its volume to its area matters.

$$\frac{T(t) - T_\infty}{T_o - T_\infty} = e^{-\bar{h}_c A t / \rho V c} \quad (4.1.27)$$

Typically, this will hold for the Biot number being less than (about) 0.1.

### Bodies with Significant Internal Resistance

When a body is being heated or cooled transiently in a convective environment, but the internal thermal resistance of the body cannot be neglected, the analysis becomes more complicated. Only simple geometries (a symmetrical plane wall, a long cylinder, a composite of geometric intersections of these geometries, or a sphere) with an imposed step change in ambient temperature are addressed here.

The first geometry considered is a large slab of minor dimension  $2L$ . If the temperature is initially uniform at  $T_o$ , and at time 0+ it begins convecting through a heat transfer coefficient to a fluid at  $T_\infty$ , the temperature response is given by

$$\theta = 2 \sum_{n=1}^{\infty} \left( \frac{\sin \lambda_n L}{\lambda_n L + \sin \lambda_n L \cos \lambda_n L} \right) \exp(-\lambda_n^2 L^2 Fo) \cos(\lambda_n x) \quad (4.1.28)$$

and the  $\lambda_n$  are the roots of the transcendental equation:  $\lambda_n L \tan \lambda_n L = Bi$ . The following definitions hold:

$$\text{Bi} \equiv \frac{\bar{h}_c L}{k} \quad \text{Fo} \equiv \frac{\alpha t}{L^2} \quad \theta \equiv \frac{T - T_\infty}{T_o - T_\infty}$$

The second geometry considered is a very long cylinder of diameter  $2R$ . The temperature response for this situation is

$$\theta = 2\text{Bi} \sum_{n=1}^{\infty} \frac{\exp(-\lambda_n^2 R^2 \text{Fo}) J_o(\lambda_n r)}{(\lambda_n^2 R^2 + \text{Bi}^2) J_o(\lambda_n R)} \quad (4.1.29)$$

Now the  $\lambda_n$  are the roots of  $\lambda_n R J_1(\lambda_n R) + \text{Bi} J_o(\lambda_n R) = 0$ , and

$$\text{Bi} = \frac{\bar{h}_c R}{k} \quad \text{Fo} = \frac{\alpha t}{R^2} \quad \theta = \frac{T - T_\infty}{T_o - T_\infty}$$

The common definition of Bessel's functions applies here.

For the similar situation involving a solid sphere, the following holds:

$$\theta = 2 \sum_{n=1}^{\infty} \frac{\sin(\lambda_n R) - \lambda_n R \cos(\lambda_n R)}{\lambda_n R - \sin(\lambda_n R) \cos(\lambda_n R)} \exp(-\lambda_n^2 R^2 \text{Fo}) \frac{\sin(\lambda_n r)}{\lambda_n r} \quad (4.1.30)$$

and the  $\lambda_n$  are found as the roots of  $\lambda_n R \cos \lambda_n R = (1 - \text{Bi}) \sin \lambda_n R$ . Otherwise, the same definitions as were given for the cylinder hold.

Solids that can be envisioned as the geometric intersection of the simple shapes described above can be analyzed with a simple product of the individual-shape solutions. For these cases, the solution is found as the product of the dimensionless temperature functions for each of the simple shapes with appropriate distance variables taken in each solution. This is illustrated as the right-hand diagram in [Figure 4.1.4](#). For example, a very long rod of rectangular cross section can be seen as the intersection of two large plates. A short cylinder represents the intersection of an infinitely long cylinder and a plate. The temperature at any location within the short cylinder is

$$\theta_{2R,2L \text{ Rod}} = \theta_{\text{Infinite } 2R \text{ Rod}} \theta_{2L \text{ Plate}} \quad (4.1.31)$$

Details of the formulation and solution of the partial differential equations in heat conduction are found in the text by Arpaci (1966).

## Finite-Difference Analysis of Conduction

Today, numerical solution of conduction problems is the most-used analysis approach. Two general techniques are applied for this: those based upon finite-difference ideas and those based upon finite-element concepts. General numerical formulations are introduced in other sections of this book. In this section, a special, physical formulation of the finite-difference equations to conduction phenomena is briefly outlined.

Attention is drawn to a one-dimensional slab (very large in two directions compared with the thickness). The slab is divided across the thickness into smaller subslabs, and this is shown in [Figure 4.1.5](#). All subslabs are thickness  $\Delta x$  except for the two boundaries where the thickness is  $\Delta x/2$ . A characteristic temperature for each slab is assumed to be represented by the temperature at the slab center. Of course, this assumption becomes more accurate as the size of the slab becomes smaller. With

**FIGURE 4.1.4.** Three types of bodies that can be analyzed with results given in this section. (a) Large plane wall of  $2L$  thickness; (b) long cylinder with  $2R$  diameter; (c) composite intersection.

**FIGURE 4.1.5.** A one-dimensional finite differencing of a slab with a general interior node and one surface node detailed.

the two boundary-node centers located exactly on the boundary, a total of  $n$  nodes are used ( $n - 2$  full nodes and one half node on each of the two boundaries).

In the analysis, a general interior node  $i$  (this applies to all nodes 2 through  $n - 1$ ) is considered for an overall energy balance. Conduction from node  $i - 1$  and from node  $i + 1$  as well as any heat generation present is assumed to be energy per unit time flowing into the node. This is then equated to the time rate of change of energy within the node. A backward difference on the time derivative is applied here, and the notation  $T'_i \equiv T_i(t + \Delta t)$  is used. The balance gives the following on a per-unit-area basis:

$$\frac{T'_{i-1} - T'_i}{\Delta x/k_-} + \frac{T'_{i+1} - T'_i}{\Delta x/k_+} + \dot{q}_{G,i}\Delta x = \rho\Delta x c_p \frac{T'_i - T_i}{\Delta t} \tag{4.1.32}$$

In this equation different thermal conductivities have been used to allow for possible variations in properties throughout the solid.

The analysis of the boundary nodes will depend upon the nature of the conditions there. For the purposes of illustration, convection will be assumed to be occurring off of the boundary at node 1. A balance similar to Equation (4.1.32) but now for node 1 gives the following:

$$\frac{T'_\infty - T'_1}{1/\bar{h}_c} + \frac{T'_2 - T'_1}{\Delta x/k_+} + \dot{q}_{G,1} \frac{\Delta x}{2} = \rho \frac{\Delta x}{2} c_p \frac{T'_1 - T_1}{\Delta t} \quad (4.1.33)$$

After all  $n$  equations are written, it can be seen that there are  $n$  unknowns represented in these equations: the temperature at all nodes. If one or both of the boundary conditions are in terms of a specified temperature, this will decrease the number of equations and unknowns by one or two, respectively. To determine the temperature as a function of time, the time step is arbitrarily set, and all the temperatures are found by simultaneous solution at  $t = 0 + \Delta t$ . The time is then advanced by  $\Delta t$  and the temperatures are then found again by simultaneous solution.

The finite difference approach just outlined using the backward difference for the time derivative is termed the *implicit* technique, and it results in an  $n \times n$  system of linear simultaneous equations. If the forward difference is used for the time derivative, then only one unknown will exist in each equation. This gives rise to what is called an *explicit* or “marching” solution. While this type of system is more straightforward to solve because it deals with only one equation at a time with one unknown, a *stability criterion* must be considered which limits the time step relative to the distance step.

Two- and three-dimensional problems are handled in conceptually the same manner. One-dimensional heat fluxes between adjoining nodes are again considered. Now there are contributions from each of the dimensions represented. Details are outlined in the book by Jaluria and Torrance (1986).

## Defining Terms

**Biot number:** Ratio of the internal (conductive) resistance to the external (convective) resistance from a solid exchanging heat with a fluid.

**Fin:** Additions of material to a surface to increase area and thus decrease the external thermal resistance from convecting and/or radiating solids.

**Fin effectiveness:** Ratio of the actual heat transfer from a fin to the heat transfer from the same cross-sectional area of the wall without the fin.

**Fin efficiency:** Ratio of the actual heat transfer from a fin to the heat transfer from a fin with the same geometry but completely at the base temperature.

**Fourier’s law:** The fundamental law of heat conduction. Relates the local temperature gradient to the local heat flux, both in the same direction.

**Heat conduction equation:** A partial differential equation in temperature, spatial variables, time, and properties that, when solved with appropriate boundary and initial conditions, describes the variation of temperature in a conducting medium.

**Overall heat transfer coefficient:** The analogous quantity to the heat transfer coefficient found in convection (Newton’s law of cooling) that represents the overall combination of several thermal resistances, both conductive and convective.

**Thermal conductivity:** The property of a material that relates a temperature gradient to a heat flux. Dependent upon temperature.

## 4.2 Convection Heat Transfer

### Natural Convection

*George D. Raithby and K.G. Terry Hollands*

#### Introduction

Natural convection heat transfer occurs when the convective fluid motion is induced by density differences that are themselves caused by the heating. An example is shown in Figure 4.2.1(A), where a body at surface temperature  $T_s$  transfers heat at a rate  $q$  to ambient fluid at temperature  $T_\infty < T_s$ .

**FIGURE 4.2.1** (A) Nomenclature for external heat transfer. (A) General sketch; (B) is for a tilted flat plate, and (C) defines the lengths call for horizontal surfaces.

In this section, correlations for the average Nusselt number are provided from which the heat transfer rate  $q$  from surface area  $A_s$  can be estimated. The Nusselt number is defined as

$$\text{Nu} = \frac{\bar{h}_c L}{k} = \frac{qL}{A_s \Delta T k} \quad (4.2.1)$$

where  $\Delta T = T_s - T_\infty$  is the temperature difference driving the heat transfer. A dimensional analysis leads to the following functional relation:

$$\text{Nu} = f(\text{Ra}, \text{Pr}, \text{geometric shape}, \text{boundary conditions}) \quad (4.2.2)$$

For given thermal boundary conditions (e.g., isothermal wall and uniform  $T_\infty$ ), and for a given geometry (e.g., a cube), Equation (4.2.2) states that Nu depends only on the Rayleigh number, Ra, and Prandtl number, Pr. The length scales that appear in Nu and Ra are defined, for each geometry considered, in a separate figure. The fluid properties are generally evaluated at  $T_f$ , the average of the wall and ambient temperatures. The exception is that  $\beta$ , the temperature coefficient of volume expansion, is evaluated at  $T_\infty$  for external natural convection (Figures 4.2.1 to 4.2.3) in a gaseous medium.

The functional dependence on Pr is approximately independent of the geometry, and the following Pr-dependent function will be useful for laminar heat transfer (Churchill and Usagi, 1972):

$$\bar{C}_\ell = 0.671 / \left( 1 + (0.492/\text{Pr})^{9/16} \right)^{4/9} \quad (4.2.3)$$

$C_t^V$  and  $C_t^H$  are functions that will be useful for turbulent heat transfer:

FIGURE 4.2.2 Nomenclature for heat transfer from planar surfaces of different shapes.

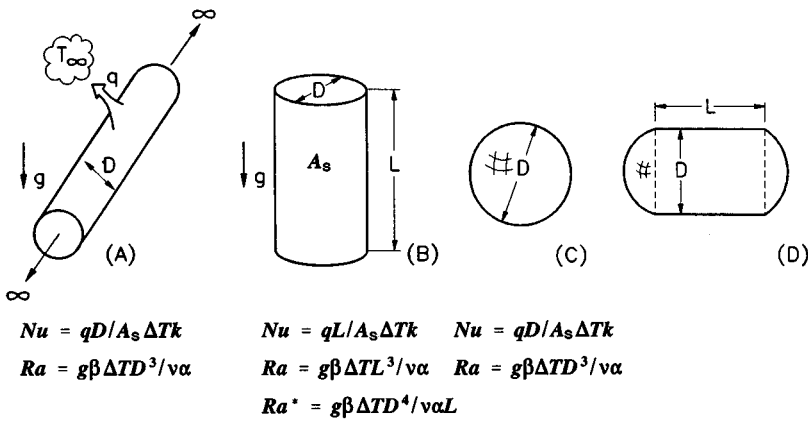

FIGURE 4.2.3 Definitions for computing heat transfer from a long circular cylinder (A), from the lateral surface of a vertical circular cylinder (B), from a sphere (C), and from a compound body (D).

$$C_t^V = 0.13Pr^{0.22} / (1 + 0.61Pr^{0.81})^{0.42} \tag{4.2.4}$$

$$C_t^H = 0.14 \left( \frac{1 + 0.0107Pr}{1 + 0.01Pr} \right) \tag{4.2.5}$$

The superscripts *V* and *H* refer to the vertical and horizontal surface orientation.

The Nusselt numbers for fully laminar and fully turbulent heat transfer are denoted by  $Nu_\ell$  and  $Nu_t$ , respectively. Once obtained, these are blended (Churchill and Usagi, 1972) as follows to obtain the equation for  $Nu$ :

$$Nu = \left( (Nu_\ell)^m + (Nu_t)^m \right)^{1/m} \tag{4.2.6}$$

The blending parameter *m* depends on the body shape and orientation.

The equation for  $Nu_\ell$  in this section is usually expressed in terms of  $Nu^T$ , the Nusselt number that would be valid if the thermal boundary layer were thin. The difference between  $Nu_\ell$  and  $Nu^T$  accounts for the effect of the large boundary layer thicknesses encountered in natural convection.

It is assumed that the wall temperature of a body exceeds the ambient fluid temperature ( $T_s > T_\infty$ ). For  $T_s < T_\infty$  the same correlations apply with  $(T_\infty - T_s)$  replacing  $(T_s - T_\infty)$  for a geometry that is rotated

180° relative to the gravitational vector; for example, the correlations for a horizontal heated upward-facing flat plate applies to a cooled downward-facing flat plate of the same planform.

### Correlations for External Natural Convection

This section deals with problems where the body shapes in [Figures 4.2.1 to 4.2.3](#) are heated while immersed in a quiescent fluid. Different *cases* are enumerated below.

1. *Isothermal Vertical ( $\phi = 0$ ) Flat Plate*, [Figure 4.2.1B](#). For heat transfer from a vertical plate ([Figure 4.2.1B](#)), for  $1 < Ra < 10^{12}$ ,

$$Nu^T = \bar{C}_\ell Ra^{1/4} \quad Nu_\ell = \frac{2.0}{\ln(1 + 2.0/Nu^T)} \quad (4.2.7)$$

$$Nu_t = C_t^V Ra^{1/3} / (1 + 1.4 \times 10^9 Pr/Ra)$$

$\bar{C}_\ell$  and  $C_t^V$  are given by Equations (4.2.3) and (4.2.4). Nu is obtained by substituting Equation (4.2.7) expressions for  $Nu_\ell$  and  $Nu_t$  into Equation (4.2.6) with  $m = 6$ .

2. *Vertical Flat Plate with Uniform Heat Flux*, [Figure 4.2.1B](#). If the plate surface has a constant (known) heat flux,  $\bar{G}_\ell$ , rather than being isothermal, the objective is to calculate the average temperature difference,  $\Delta T$ , between the plate and fluid. For this situation, and for  $15 < Ra^* < 10^5$ ,

$$Nu^T = \bar{G}_\ell (Ra^*)^{1/5} \quad Nu_\ell = \frac{1.83}{\ln(1 + 1.83/Nu^T)} \quad Nu_t = (C_t^V)^{3/4} (Ra^*)^{1/4} \quad (4.2.8a)$$

$$\bar{G}_\ell = \frac{6}{5} \left( \frac{Pr}{4 + 9\sqrt{Pr} + 10Pr} \right)^{1.5} \quad (4.2.8b)$$

$Ra^*$  is defined in [Figure 4.2.1B](#) and  $C_t^V$  is given by Equation (4.2.4). Find Nu by inserting these expressions for  $Nu_\ell$  and  $Nu_t$  into Equation (4.2.6) with  $m = 6$ . The  $\bar{G}_\ell$  expression is due to Fujii and Fujii (1976).

3. *Horizontal Upward-Facing ( $\phi = 90^\circ$ ) Plates*, [Figure 4.2.1C](#). For horizontal isothermal surfaces of various platforms, correlations are given in terms of a lengthscale  $L^*$  (Goldstein et al., 1973), defined in [Figure 4.2.1C](#). For  $Ra \geq 1$ ,

$$Nu^T = 0.835 \bar{C}_\ell Ra^{1/4} \quad Nu_\ell = \frac{2.0}{\ln(1 + 1.4/Nu^T)} \quad Nu_t = C_t^H Ra^{1/3} \quad (4.2.9)$$

Nu is obtained by substituting  $Nu_\ell$  and  $Nu_t$  from Equation 4.2.9 into Equation 4.2.6 with  $m = 10$ . For non-isothermal surfaces, replace  $\Delta T$  by  $\Delta T$ .

4. *Horizontal Downward-Facing ( $\phi = -90^\circ$ ) Plates*, [Figure 4.2.1C](#). For horizontal downward-facing plates of various planforms, the main buoyancy force is into the plate so that only a very weak force drives the fluid along the plate; for this reason, only laminar flows have been measured. For this case, the following equation applies for  $Ra < 10^{10}$ ,  $Pr \geq 0.7$ :

$$Nu^T = H_\ell Ra^{1/5} \quad H_\ell = \frac{0.527}{\left[1 + (1.9/Pr)^{9/10}\right]^{2/9}} \quad Nu = \frac{2.45}{\ln(1 + 2.45/Nu^T)} \quad (4.2.10)$$

$H_\ell$  fits the analysis of Fujii et al. (1973).

5. *Inclined Plates, Downward Facing* ( $-90^\circ \leq \phi \leq 0$ ), *Figure 4.2.1B*. First calculate  $q$  from *Case 1* with  $g$  replaced by  $g \cos \phi$ ; then calculate  $q$  from *Case 4* (horizontal plate) with  $g$  replaced by  $g \sin(-\phi)$ , and use the maximum of these two values of  $q$ .
6. *Inclined Plates, Upward Facing* ( $0 \leq \phi \leq 90$ ), *Figure 4.2.1B*. First calculate  $q$  from *Case 1* with  $g$  replaced by  $g \cos \phi$ ; then calculate  $q$  from *Case 3* with  $g$  replaced by  $g \sin \phi$ , and use the maximum of these two values of  $q$ .
7. *Vertical and Tilted Isothermal Plates of Various Planform*, *Figure 4.2.2*. The line of constant  $\chi$  in *Figure 4.2.2* is the line of steepest ascent on the plate. Provided all such lines intersect the plate edges just twice, as shown in the figure, the thin-layer ( $Nu^T$ ) heat transfer can be found by subdividing the body into strips of width  $\Delta\chi$ , calculating the heat transfer from each strip, and adding. For laminar flow from an isothermal vertical plate, this results in

$$Nu^T = C_1 \bar{C}_\ell Ra^{1/4} \quad C_1 \equiv \left( \frac{L^{1/4}}{A} \int_0^W S^{3/4} d\chi \right) \quad (4.2.11)$$

Symbols are defined in *Figure 4.2.2*, along with  $L$  and calculated  $C_1$  values for some plate shapes. If the plate is vertical, follow the procedure in *Case 1* above (isothermal vertical flat plate) except replace the expression for  $Nu^T$  in Equation (4.2.7) by Equation (4.2.11). If the plate is tilted, follow the procedure described in *Case 5* or *6* (as appropriate) but again use Equation (4.2.11) for  $Nu^T$  in Equation (4.2.7)

8. *Horizontal Cylinders*, *Figure 4.2.3A*. For a long, horizontal circular cylinder use the following expressions for  $Nu_\ell$  and  $Nu_t$ :

$$Nu^T = 0.772 \bar{C}_\ell Ra^{1/4} \quad Nu_\ell = \frac{2f}{(1 + 2f/Nu^T)} \quad Nu_t = \bar{C}_\ell Ra^{1/3} \quad (4.2.12)$$

$\bar{C}_\ell$  is given in the table below. For  $Ra > 10^{-2}$ ,  $f = 0.8$  can be used, but for  $10^{-10} < Ra < 10^{-2}$  use  $f = 1 - 0.13/(Nu^T)^{0.16}$ . To find  $Nu$ , the values of  $Nu_\ell$  and  $Nu_t$  from Equation (4.2.12) are substituted into Equation (4.2.6) with  $m = 15$  (Clemes et al., 1994).

$\bar{C}_\ell$ for Various Shapes and Prandtl Numbers									
Pr→	0.01	0.022	0.10	0.71	2.0	6.0	50	100	2000
Horizontal cylinder	0.077	0.81	0.90	0.103	0.108	0.109	0.100	0.097	0.088
Spheres	0.074	0.078	0.088	0.104	0.110	0.111	0.101	0.97	0.086

9. *Vertical Cylinders* ( $\phi = 90^\circ$ ), *Figure 4.2.3B*. For high  $Ra$  values and large diameter, the heat transfer from a vertical cylinder approaches that for a vertical flat plate. Let the  $Nu^T$  and  $Nu_\ell$  equations for a vertical flat plate of height  $L$ , Equation (4.2.7), be rewritten here as  $Nu_p^T$  and  $Nu_p$ , respectively. At smaller  $Ra$  and diameter, transverse curvature plays a role which is accounted for in the following equations:

$$Nu_\ell = \frac{0.9\xi Nu_p}{\ln(1 + 0.9\xi)} \quad \xi = \frac{2L/D}{Nu_p^T} \quad (4.2.13)$$

These equations are valid for purely laminar flow. To obtain  $Nu$ , blend Equation (4.2.13) for  $Nu_\ell$  with Equation (4.2.7) for  $Nu$ , using Equation (4.2.6) with  $m = 10$ .

10. *Spheres, Figure 4.2.3C.* For spheres use Equation (4.2.6), with  $m = 6$ , and with

$$Nu_\ell = 2 + 0.878\bar{C}_\ell Ra^{1/4} \quad \text{and} \quad Nu_t = \bar{C}_t Ra^{1/3} \quad (4.2.14)$$

The table above contains  $\bar{C}_t$  values.

11. *Combined Shapes, Figure 4.2.3D.* For combined shapes, such as the cylinder in Figure 4.2.3D with spherical end caps, calculate the heat transfer from the cylinder of length  $L$  (Case 8), the heat transfer from a sphere of diameter  $D$  (Case 10) and add to obtain the total transfer. Other shapes can be treated in a similar manner.

**Correlations for Open Cavities**

Examples of this class of problem are shown in Figure 4.2.4. Walls partially enclose a fluid region (cavity) where boundary openings permit fluid to enter and leave. Upstream from its point of entry, the fluid is at the ambient temperature,  $T_\infty$ . Since access of the ambient fluid to the heated surfaces is restricted, some of the heated surface is starved of cool ambient to which heat can be transferred. As the sizes of the boundary openings are increased, the previous class of problems is approached; for example, when the plate spacing in Figure 4.2.4A (Case 12) becomes very large, the heat transfer from each vertical surface is given by Case 1.

FIGURE 4.2.4 Nomenclature for various open-cavity problems.

12. *Isothermal Vertical Channels, Figure 4.2.4A and B.* Figure 4.2.4A shows an open cavity bounded by vertical walls and open at the top and bottom. The large opposing plates are isothermal, at temperatures  $T_1$  and  $T_2$ , respectively, and the spacing between these plates is small.  $\Delta T$  is the average temperature difference between the plates and  $T_\infty$ , as shown in Figure 4.2.4A, but  $T_1$  and  $T_2$  must not straddle  $T_\infty$ . For this case

$$Nu = \left( \left( \frac{Ra}{fRe} \right)^m + \left( C_1 \bar{C}_\ell Ra^{1/4} \right)^m \right)^{1/m} \quad Ra \leq 10^5 \quad (4.2.15)$$

where  $fRe$  is the product of friction factor and Reynolds number for fully developed flow through, and  $C_1$  is a constant that accounts for the augmentation of heat transfer, relative to a vertical flat plate (*Case 1*), due to the chimney effect. The  $fRe$  factor accounts for the cross-sectional shape (Elenbaas, 1942a). Symbols are defined in [Figure 4.2.4A and B](#); in the  $Nu$  equation,  $q$  is the total heat transferred to the ambient fluid from all heated surfaces.

For the parallel plate channel shown in [Figure 4.2.4\(A\)](#), use  $fRe = 24$ ,  $m = -1.9$ , and for gases  $C_1 \approx 1.2$ . It should be noted, however, that  $C_1$  must approach 1.0 as  $Pr$  increases or as the plate spacing increases. For channels of circular cross section ([Figure 4.2.4B](#))  $fRe = 16$ ,  $m = -1.03$ , and for gases  $C_1 \approx 1.17$ . For other cross-sectional shapes like the square ( $fRe = 14.23$ ), hexagonal ( $fRe = 15.05$ ), or equilateral triangle ( $fRe = 13.3$ ), use Equation (4.2.15) with the appropriate  $fRe$ , and with  $m = -1.5$ , and  $C_1 \approx 1.2$  for gases.

The heat transfer per unit cross-sectional area,  $q/A_c$ , for a given channel length  $H$  and temperature difference, passes through a maximum at approximately  $Ra_{max}$ , where

$$Ra_{max} = \left( \frac{fRe C_1 \bar{C}_\ell}{2^{1/m}} \right)^{4/3} \quad (4.2.16)$$

$Ra_{max}$  provides the value of hydraulic radius  $r = 2A_c/P$  at this maximum.

13. *Isothermal Triangular Fins*, [Figure 4.2.4C](#). For a large array of triangular fins (Karagiozis et al., 1994) in air, for  $0.4 < Ra < 5 \times 10^5$

$$Nu = \bar{C}_\ell Ra^{1/4} \left[ 1 + \left( \frac{3.26}{Ra^{0.21}} \right)^3 \right]^{-1/3} \quad 0.4 < Ra < 5 \times 10^5 \quad (4.2.17)$$

In this equation,  $b$  is the average fin spacing ([Figure 4.2.4C](#)), defined such that  $bL$  is the cross-sectional flow area between two adjacent fin surfaces up to the plane of the fin tips. For  $Ra < 0.4$ , Equation (4.2.17) underestimates the convective heat transfer. When such fins are mounted horizontally (vertical baseplate, but the fin tips are horizontal), there is a substantial reduction of the convective heat transfer (Karagiozis et al., 1994).

14. *U-Channel Fins*, [Figure 4.2.4C](#). For the fins most often used as heat sinks, there is uncertainty about the heat transfer at low  $Ra$ . By using a conservative approximation applying for  $Ra < 100$  (that underestimates the real heat transfer), the following equation may be used:

$$Nu = \left[ \left( \frac{Ra}{24} \right)^{-2} + (C_1 \bar{C}_\ell Ra)^{-2} \right]^{-0.5} \quad (4.2.18)$$

For air  $C_1$  depends on aspect ratio of the fin as follows (Karagiozis, 1991):

$$C_1 = \left[ 1 + \left( \frac{H}{b} \right), 1.16 \right]_{\min} \quad (4.2.19)$$

Equation (4.2.18) agrees well with measurements for  $Ra > 200$ , but for smaller  $Ra$  it falls well below data because the leading term does not account for heat transfer from the fin edges and for three-dimensional conduction from the entire array.

15. *Circular Fins on a Horizontal Tube*, [Figure 4.2.4D](#). For heat transfer from an array of circular fins (Edwards and Chaddock, 1963), for  $H/D_i = 1.94$ ,  $5 < Ra < 10^4$ , and for air,

$$Nu = 0.125Ra^{0.55} \left[ 1 - \exp\left(-\frac{137}{Ra}\right) \right]^{0.294} \tag{4.2.20}$$

A more general, but also more complex, relation is reported by Raithby and Hollands (1985).

16. *Square Fins on a Horizontal Tube, Figure 4.2.4D.* Heat transfer (Elenbaas, 1942b) from the square fins (excluding the cylinder that connects them) is correlated for gases by

$$Nu = \left[ (Ra^{0.89}/18)^m + (0.62Ra^{1/4})^m \right]^{1/m} \quad m = -2.7 \tag{4.2.21}$$

**Heat Transfer in Enclosures**

This section deals with cavities where the bounding walls are entirely closed, so that no mass can enter or leave the cavity. The fluid motion inside the cavity is driven by natural convection, which enhances the heat transfer among the interior surfaces that bound the cavity.

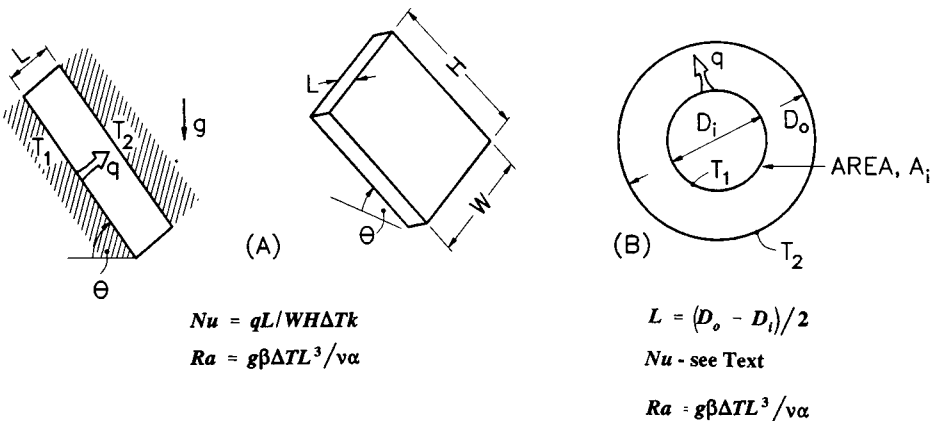

17. *Extensive Horizontal Layers, Figure 4.2.5A with  $\theta = 0^\circ$ .* If the heated plate, in a horizontal parallel-plate cavity, is on the top, heat transfer is by conduction alone, so that  $Nu = 1$ . For heat transfer from below (Hollands, 1984):

$$Nu = 1 + \left[ 1 - \frac{1708}{Ra} \right]^* \left[ k_1 + 2 \left( \frac{Ra^{1/3}}{k_2} \right)^{1 - \ln(Ra^{1/3}/k_2)} \right] + \left[ \left( \frac{Ra}{5830} \right)^{1/3} - 1 \right]^* \tag{4.2.22}$$

where

$$[x]^* = (x, 0)_{\max} \quad k_1 = \frac{1.44}{1 + 0.018/Pr + 0.00136/Pr^2} \quad k_2 = 75 \exp(1.5Pr^{-1/2}) \tag{4.2.23}$$

The equation has been validated for  $Ra < 10^{11}$  for water,  $Ra < 10^8$  for air, and over a smaller  $Ra$  range for other fluids. Equation (4.2.22) applies to extensive layers:  $W/L \geq 5$ . Correlations for nonextensive layers are provided by Raithby and Hollands (1985).

**FIGURE 4.2.5** Nomenclature for enclosure problems.

18. *Vertical Layers, Figure 4.2.5(A), with  $\theta = 90^\circ$ ,  $W/L > 5$ .* For a vertical, gas-filled ( $Pr \approx 0.7$ ) cavity with  $H/L \geq 5$ , the following equation closely fits the data, for example that of Shewen et al. (1996) for  $Ra(H/L)^3 \leq 5 \times 10^{10}$  and  $H/L \geq 40$ .

$$Nu_1 = \left[ 1 + \left( \frac{0.0665Ra^{1/3}}{1 + \left( \frac{9000}{Ra} \right)^{1.4}} \right)^2 \right]^{1/2} \quad Nu_2 = 0.242 \left( Ra \frac{L}{H} \right)^{0.273} \quad Nu = [Nu_1, Nu_2]_{\max} \quad (4.2.24)$$

For  $Pr \geq 4$ , the following equation is recommended (Seki et al., 1978) for  $Ra(H/L)^3 < 4 \times 10^{12}$

$$Nu = \left[ 1, 0.36Pr^{0.051} \left( \frac{L}{H} \right)^{0.36} Ra^{0.25}, 0.084Pr^{0.051} \left( \frac{L}{H} \right)^{0.1} Ra^{0.3} \right]_{\max} \quad (4.2.25a)$$

and for  $Ra(H/L)^3 > 4 \times 10^{12}$

$$Nu = 0.039Ra^{1/3} \quad (4.2.25b)$$

19. *Tilted Layers, Figure 4.2.5A, with  $0 \leq \theta \leq 90^\circ$ ,  $W/L > 8$ .* For gases ( $Pr \approx 0.7$ ),  $0 \leq \theta \leq 60^\circ$  and  $Ra \leq 10^5$  (Hollands et al., 1976), use

$$Nu = 1 + 1.44 \left[ 1 - \frac{1708}{Ra \cos \theta} \right]^* \left[ 1 - \frac{1708(\sin 1.8\theta)^{1.6}}{Ra \cos \theta} \right] + \left[ \left( \frac{Ra \cos \theta}{5830} \right)^{1/3} - 1 \right]^* \quad (4.2.26)$$

See equation (4.2.23) for definition of  $[x]^\circ$ . For  $60^\circ \leq \theta \leq 90^\circ$  linear interpolation is recommended using Equations (4.2.24) for  $\theta = 90^\circ$  and (4.2.26) for  $\theta = 60^\circ$ .

20. *Concentric Cylinders, Figure 4.2.5B.* For heat transfer across the gap between horizontal concentric cylinders, the Nusselt number is defined as  $Nu = q' \ln(D_o/D_i)/2\pi\Delta T$  where  $q'$  is the heat transfer per unit length of cylinder. For  $Ra \leq 8 \times 10^7$ ,  $0.7 \leq Pr \leq 6000$ ,  $1.15 \leq D/D_i \leq 8$  (Raithby and Hollands, 1975)

$$Nu = \left[ 0.603\bar{C}_\ell \frac{\ln(D_o/D_i)Ra^{1/4}}{\left[ (L/D_i)^{3/5} + (L/D_o)^{3/5} \right]^{5/4}}, 1 \right]_{\max} \quad (4.2.27)$$

For eccentric cylinders, see Raithby and Hollands (1985).

21. *Concentric Spheres, Figure 4.2.5B.* The heat transfer between concentric spheres is given by the following equation (Raithby and Hollands, 1975) for  $Ra \leq 6 \times 10^8$ ,  $5 \leq Pr \leq 4000$ ,  $1.25 < D_o/D_i \leq 2.5$ ,

$$Nu = \frac{qL}{D_i D_o k \Delta T} = \left[ 1.16\bar{C}_\ell \left( \frac{L}{D_i} \right)^{1/4} \frac{Ra^{1/4}}{\left[ (D_i/D_o)^{3/5} + (D_o/D_i)^{4/5} \right]^{5/4}}, 1 \right]_{\max} \quad (4.2.28)$$

For eccentric spheres, see Raithby and Hollands (1985).

### Example Calculations

**Problem 1: Heat Transfer from Vertical Plate, Figure 4.2.6A.** For the vertical isothermal surface in Figure 4.2.6A with  $T_s = 40^\circ\text{C}$ ,  $H_1 = 1\text{ m}$ ,  $H_2 = 1\text{ m}$ ,  $W_1 = 1\text{ m}$ ,  $W_2 = 1\text{ m}$  and for an ambient air temperature of  $T_\infty = 20^\circ\text{C}$  (at 1 atm), find the heat transfer from one side of the plate.

**FIGURE 4.2.6** Sketches for example problems.

*Properties:* At  $T_f = (T_w + T_\infty)/2 = 30^\circ\text{C}$  and atmospheric pressure for air:  $\nu = 1.59 \times 10^{-5}\text{ m}^2/\text{sec}$ ,  $\text{Pr} = 0.71$ ,  $k = 0.0263\text{ W/mK}$ . At  $T_\infty$ ,  $\beta \approx 1/T_\infty = 1/(273 + 20) = 0.00341\text{ K}^{-1}$ .

*Solution:* For the geometry shown in Figure 4.2.6A:

$$A_s = (H_1 + H_2)W_1 + \left(H_1 + \frac{H_2}{2}\right)W_2 = 3.5\text{ m}^2 \quad (\text{plate surface area})$$

$$\int_0^{W_1+W_2} S^{3/4} d\chi = (H_1 + H_2)^{3/4} W_1 + \frac{4}{7} \frac{W_2}{H_2} \left[ (H_1 + H_2)^{7/4} - H_1^{7/4} \right] = 3.03\text{ m}^{7/4}$$

$$L^{1/4} = (H_1 + H_2)^{1/4} = 1.19\text{ m}^{1/4} \quad (\text{see comments below})$$

$$C_1 = \frac{L^{1/4} \int_0^{W_1+W_2} S^{3/4} d\chi}{A_s} = \frac{1.19 \times 3.03}{3.5} = 1.03$$

$$\text{Ra} = \frac{g\beta_\infty L^3 (T_w - T_\infty)}{\nu\alpha} = \frac{9.81 \times 0.00341 \times 2^3 \times (40 - 20)}{1.59 \times 10^{-5} \times 2.25 \times 10^{-5}} = 1.50 \times 10^{10}$$

$\bar{C}_\ell = 0.514$  from Equation (4.2.3);  $C_t = C_t^V = 0.103$  from Equation (4.2.4).  $\text{Nu}^T = C_1 \bar{C}_\ell \text{Ra}^{1/4} = 185$  from Equation (4.2.11).

$$\left. \begin{aligned} \text{Nu}_\ell &= \frac{2.0}{\ln(1 + 2.0/\text{Nu}^T)} = 186 \\ \text{Nu}_t &= C_t^V \text{Ra}^{1/3} / (1 + 1.4 \times 10^9 \text{Pr}/\text{Ra}) = 238 \end{aligned} \right\} \quad (\text{from Equation (4.2.7)})$$

$$\text{Nu} = \frac{qL}{A\Delta T k} = (\text{Nu}_\ell^6 + \text{Nu}_t^6)^{1/6} = 246$$

from Equation (4.2.6) with  $m = 6$ .

$$q = \frac{A_s \Delta T k \text{Nu}}{L} = \frac{3.5 \times 20 \times 0.0263 \times 246}{2} = 226 \text{ W}$$

*Comments on Problem 1:* Since  $\text{Nu}_\ell < \text{Nu}_s$ , the heat transfer is primarily turbulent. Do not neglect radiation. Had the surface been specified to be at constant heat flux, rather than isothermal, the equations in this section can be used to find the approximate average temperature difference between the plate and fluid.

*Problem 2: Heat Transfer from Horizontal Strip, Figure 4.2.6B.* Find the rate of heat loss per unit length from a very long strip of width  $W = 0.1$  m with a surface temperature of  $T_s = 70^\circ\text{C}$  in water at  $T_\infty = 30^\circ\text{C}$ .

*Properties:* At  $T_f = (T_s + T_\infty)/2 = 50^\circ\text{C}$

$$\begin{aligned} \nu &= 5.35 \times 10^{-7} \text{ m}^2/\text{sec} & \alpha &= 1.56 \times 10^{-7} \text{ m}^2/\text{sec} & \text{Pr} &= 3.42 \\ k &= 0.645 \text{ W/mK} & \beta &= 2.76 \times 10^{-4} \text{ K}^{-1} \end{aligned}$$

*Solution:* This problem corresponds to *Case 3* and [Figure 4.2.1C](#).

$$C_t^H = 0.14$$

from Equation 4.2.5 and  $\bar{C}_t = 0.563$  from Equation (4.2.3).

$$L^* = \lim_{H \rightarrow \infty} \left( \frac{WH}{2W + 2H} \right) = \frac{W}{2} = 0.05 \text{ m}$$

from [Figure 4.2.1C](#).

$$\text{Ra} = \frac{g\beta\Delta TL^*{}^3}{\nu\alpha} = 1.62 \times 10^8 \quad \text{Nu}^T = 0.835\bar{C}_t \text{Ra}^{1/4} = 53.5$$

$$\text{Nu}_\ell = \frac{1.4}{\ln(1 + 1.4/\text{Nu}^T)} = 54.2 \quad \text{Nu}_t = C_t^H \text{Ra}^{1/3} = 76.3$$

$$\text{Nu} = \frac{q}{WH\Delta T} \frac{L^*}{k} = (\text{Nu}_\ell^{10} + \text{Nu}_t^{10})^{0.1} = 76.5$$

$$q/H = \frac{W\Delta T k \text{Nu}}{L^*} = 3950 \text{ W/m-length}$$

*Comments:* Turbulent heat transfer is dominant. Radiation can be ignored (since it lies in the far infrared region where it is not transmitted by the water).

*Problem 3: Heat Loss across a Window Cavity, Figure 4.2.6C.* The interior glazing is at temperature  $T_1 = 10^\circ\text{C}$ , the exterior glazing at  $T_2 = -10^\circ\text{C}$ , the window dimensions are  $W = 1$  m,  $H = 1.7$  m, and the air gap between the glazings is  $L = 1$  cm and is at atmospheric pressure. Find the heat flux loss across the window.

Properties: At  $\bar{T} = T_1 + T_2/2 = 0^\circ\text{C} = 273\text{K}$

$$\nu = 1.35 \times 10^{-5} \text{ m}^2/\text{sec} \quad \alpha = 1.89 \times 10^{-5} \text{ m}^2/\text{sec} \quad \text{Pr} = 0.71$$

$$k = 0.024 \text{ W/mK} \quad \beta = 1/273 = 3.66 \times 10^{-3} \text{ K}^{-1}$$

Solution: The appropriate correlations are given in Case 18 and by Equation (4.2.24).

$$\text{Ra} = \frac{g\beta(T_1 - T_2)L^3}{\nu\alpha} = \frac{9.81 \times 3.66 \times 10^{-3} \times 20 \times (0.01)^3}{1.35 \times 10^{-5} \times 1.89 \times 10^{-5}} = 2.81 \times 10^3$$

$$\text{Nu}_1 = \left[ 1 + \left\{ \frac{0.0665\text{Ra}^{1/3}}{1 + \left(\frac{9000}{\text{Ra}}\right)^{1.4}} \right\}^2 \right]^{1/2} = 1.01$$

$$\text{Nu}_2 = 0.242 \left( \text{Ra} \frac{L}{H} \right)^{0.273} = 0.242 \left( 2.81 \times 10^3 \times \frac{0.01}{1.7} \right)^{0.273} = 0.520$$

$$\text{Nu} = \frac{qL}{WH(T_1 - T_2)k} = (\text{Nu}_1, \text{Nu}_2)_{\max} = 1.01$$

$$q/WH = \frac{N(T_1 - T_2)k}{L} = \frac{1.01 \times 20 \times 0.24}{0.01} = 48.5 \text{ W/m}^2$$

Comments: For pure conduction across the air layer,  $\text{Nu} = 1.0$ . For the calculated value of  $\text{Nu} = 1.01$ , convection must play little role. For standard glass, the heat loss by radiation would be roughly double the natural convection value just calculated.

## Special Nomenclature

Note that nomenclature for each geometry considered is provided in the figures that are referred to in the text.

$\bar{C}_\ell$  = function of Prandtl number, Equation (4.2.3)

$C_t^V$  = function of Prandtl number, Equation (4.2.4)

$C_t^H$  = function of Prandtl number, Equation (4.2.5)

$\bar{C}_t$  = surface averaged value of  $C_t$ , page 4–38

$\Delta T$  = surface averaged value of  $T_w - T_\infty$

## Further Information

There are several excellent heat transfer textbooks that provide fundamental information and correlations for natural convection heat transfer (e.g., Kreith and Bohn, 1993; Incropera and DeWitt, 1990). The correlations in this section closely follow the recommendations of Raithby and Hollands (1985), but that reference considers many more problems. Alternative equations are provided by Churchill (1983).

## Forced Convection — External Flows

*N.V. Suryanarayana*

### Introduction

In this section we consider heat transfer between a solid surface and an adjacent fluid which is in motion relative to the solid surface. If the surface temperature is different from that of the fluid, heat is transferred as forced convection. If the bulk motion of the fluid results solely from the difference in temperature of the solid surface and the fluid, the mechanism is natural convection. The velocity and temperature of the fluid far away from the solid surface are the free-stream velocity and free-stream temperature. Both

are usually known or specified. We are then required to find the heat flux from or to the surface with specified surface temperature or the surface temperature if the heat flux is specified. The specified temperature or heat flux either may be uniform or may vary. The convective heat transfer coefficient  $h$  is defined by

$$q'' = h(T_s - T_\infty) \quad (4.2.29)$$

In Equation (4.2.29) with the local heat flux, we obtain the local heat transfer coefficient, and with the average heat flux with a uniform surface temperature we get the average heat transfer coefficient. For a specified heat flux the local surface temperature is obtained by employing the local convective heat transfer coefficient.

Many correlations for finding the convective heat transfer coefficient are based on experimental data which have some uncertainty, although the experiments are performed under carefully controlled conditions. The causes of the uncertainty are many. Actual situations rarely conform completely to the experimental situations for which the correlations are applicable. Hence, one should not expect the actual value of the heat transfer coefficient to be within better than  $\pm 10\%$  of the predicted value.

Many different correlations to determine the convective heat transfer coefficient have been developed. In this section only one or two correlations are given. For other correlations and more details, refer to the books given in the bibliography at the end of this section.

### Flat Plate

With a fluid flowing parallel to a flat plate, changes in velocity and temperature of the fluid are confined to a thin region adjacent to the solid boundary — the boundary layer. Several cases arise:

1. Flows without or with pressure gradient
2. Laminar or turbulent boundary layer
3. Negligible or significant viscous dissipation (effect of frictional heating)
4.  $Pr \geq 0.7$  or  $Pr \ll 1$

### Flows with Zero Pressure Gradient and Negligible Viscous Dissipation

When the free-stream pressure is uniform, the free-stream velocity is also uniform. Whether the boundary layer is laminar or turbulent depends on the Reynolds number  $Re_x$  ( $\rho U_\infty x / \mu$ ) and the shape of the solid at entrance. With a sharp edge at the leading edge (Figure 4.2.7) the boundary layer is initially laminar but at some distance downstream there is a transition region where the boundary layer is neither totally laminar nor totally turbulent. Farther downstream of the transition region the boundary layer becomes turbulent. For engineering applications the existence of the transition region is usually neglected and it is assumed that the boundary layer becomes turbulent if the Reynolds number,  $Re_x$ , is greater than the critical Reynolds number,  $Re_{cr}$ . A typical value of  $5 \times 10^5$  for the critical Reynolds number is generally accepted, but it can be greater if the free-stream turbulence is low and lower if the free-stream turbulence is high, the surface is rough, or the surface does not have a sharp edge at entrance. If the entrance is blunt, the boundary layer may be turbulent from the leading edge.

FIGURE 4.2.7 Flow of a fluid over a flat plate with laminar, transition, and turbulent boundary layers.

**Temperature Boundary Layer**

Analogous to the velocity boundary layer there is a temperature boundary layer adjacent to a heated (or cooled) plate. The temperature of the fluid changes from the surface temperature at the surface to the free-stream temperature at the edge of the temperature boundary layer (Figure 4.2.8).

**FIGURE 4.2.8** Temperature boundary layer thickness relative to velocity boundary layer thickness.

The velocity boundary layer thickness \$\delta\$ depends on the Reynolds number \$Re\_x\$. The thermal boundary layer thickness \$\delta\_T\$ depends both on \$Re\_x\$ and \$Pr\$

\$Re\_x < Re\_{cr}\$:

$$\frac{\delta}{x} = \frac{5}{\sqrt{Re_x}} \quad Pr > 0.7 \quad \frac{\delta}{\delta_T} = Pr^{1/3}$$

$$Pr \ll 1 \quad \frac{\delta}{\delta_T} = Pr^{1/2}$$

(4.2.30)

\$Re\_{cr} < Re\_x\$:

$$\frac{\delta}{x} = \frac{0.37}{Re_x^{0.2}} \quad \delta \approx \delta_T$$

(4.2.31)

Viscous dissipation and high-speed effects can be neglected if \$Pr^{1/2} Ec/2 \ll 1\$. For heat transfer with significant viscous dissipation see the section on flow over flat plate with zero pressure gradient: Effect of High Speed and Viscous Dissipation. The Eckert number \$Ec\$ is defined as \$Ec = U\_\infty^2 / C\_p (T\_s - T\_\infty)\$.

With a rectangular plate of length \$L\$ in the direction of the fluid flow the average heat transfer coefficient \$h\_L\$ with uniform surface temperature is given by

$$h_L = \frac{1}{L} \int_0^L h_x dx$$

**Laminar Boundary Layer** (\$Re\_x < Re\_{cr}\$, \$Re\_L < Re\_{cr}\$): With heating or cooling starting from the leading edge the following correlations are recommended. Note: in all equations evaluate fluid properties at the film temperature defined as the arithmetic mean of the surface and free-stream temperatures unless otherwise stated (Figure 4.2.9).

**FIGURE 4.2.9** Heated flat plate with heating from the leading edge.

Local Heat Transfer Coefficient (Uniform Surface Temperature)

The Nusselt number based on the local convective heat transfer coefficient is expressed as

$$\text{Nu}_x = f_{\text{Pr}} \text{Re}_x^{1/2} \quad (4.2.32)$$

The classical expression for  $f_{\text{Pr}}$  is  $0.564 \text{Pr}^{1/2}$  for liquid metals with very low Prandtl numbers,  $0.332\text{Pr}^{1/3}$  for  $0.7 < \text{Pr} < 50$  and  $0.339\text{Pr}^{1/3}$  for very large Prandtl numbers. Correlations valid for all Prandtl numbers developed by Churchill (1976) and Rose (1979) are given below.

$$\text{Nu}_x = \frac{0.3387\text{Re}_x^{1/2} \text{Pr}^{1/3}}{\left[1 + \left(\frac{0.0468}{\text{Pr}}\right)^{2/3}\right]^{1/4}} \quad (4.2.33)$$

$$\text{Nu}_x = \frac{\text{Re}_x^{1/2} \text{Pr}^{1/2}}{(27.8 + 75.9\text{Pr}^{0.306} + 657\text{Pr})^{1/6}} \quad (4.2.34)$$

In the range  $0.001 < \text{Pr} < 2000$ , Equation (4.2.33) is within 1.4% and Equation (4.2.34) is within 0.4% of the exact numerical solution to the boundary layer energy equation.

Average Heat Transfer Coefficient

The average heat transfer coefficient is given by

$$\text{Nu}_L = 2\text{Nu}_{x=L} \quad (4.2.35)$$

From Equation 4.2.35 it is clear that the average heat transfer coefficient over a length  $L$  is twice the local heat transfer coefficient at  $x = L$ .

**Uniform Heat Flux**Local Heat Transfer Coefficient

Churchill and Ozoe (1973) recommend the following single correlation for all Prandtl numbers.

$$\text{Nu}_x = \frac{0.886\text{Re}_x^{1/2} \text{Pr}^{1/2}}{\left[1 + \left(\frac{\text{Pr}}{0.0207}\right)^{2/3}\right]^{1/4}} \quad (4.2.36)$$

Note that for surfaces with uniform heat flux the local convective heat transfer coefficient is used to determine the local surface temperature. The total heat transfer rate being known, an average heat transfer coefficient is not needed and not defined.

**Turbulent Boundary Layer** ( $\text{Re}_x > \text{Re}_{cr}$ ,  $\text{Re}_L > \text{Re}_{cr}$ ): For turbulent boundary layers with heating or cooling starting from the leading edge use the following correlations:

Local Heat Transfer Coefficient

$\text{Re}_{cr} < \text{Re}_x < 10^7$ :

$$\text{Nu}_x = 0.0296\text{Re}_x^{4/5} \text{Pr}^{1/3} \quad (4.2.37)$$

$10^7 < \text{Re}_x$ :

$$\text{Nu}_x = 1.596\text{Re}_x (\ln \text{Re}_x)^{-2.584} \text{Pr}^{1/3} \quad (4.2.38)$$

Equation (4.2.38) is obtained by applying Colburn's  $j$  factor in conjunction with the friction factor suggested by Schlichting (1979).

In laminar boundary layers, the convective heat transfer coefficient with uniform heat flux is approximately 36% higher than with uniform surface temperature. With turbulent boundary layers, the difference is very small and *the correlations for the local convective heat transfer coefficient can be used for both uniform surface temperature and uniform heat flux.*

#### Average Heat Transfer Coefficient

If the boundary layer is initially laminar followed by a turbulent boundary layer at  $Re_x = Re_{cr}$ , the following correlations for  $0.7 < Pr < 60$  are suggested:

$$Re_{cr} < Re_L < 10^7:$$

$$Nu_L = \left[ 0.664 Re_L^{1/2} + 0.037 \left( Re_L^{4/5} - Re_{cr}^{4/5} \right) \right] Pr^{1/3} \quad (4.2.39)$$

If  $Re_{cr} < Re_L < 10^7$  and  $Re_{cr} = 10^5$ , Equation 4.2.39 simplifies to

$$Nu_L = \left( 0.037 Re_L^{4/5} - 871 \right) Pr^{1/3} \quad (4.2.40)$$

$$10^7 < Re_L \text{ and } Re_{cr} = 5 \times 10^5:$$

$$Nu_L = \left[ 1.963 Re_L (\ln Re_L)^{-2.584} - 871 \right] Pr^{1/3} \quad (4.2.41)$$

#### **Uniform Surface Temperature — $Pr > 0.7$ : Unheated Starting Length**

If heating does not start from the leading edge as shown in Figure 4.2.10, the correlations have to be modified. Correlation for the local convective heat transfer coefficient for laminar and turbulent boundary layers are given by Equations (4.2.42) and (4.2.43) (Kays and Crawford, 1993) — the constants in Equations (4.2.42) and (4.2.43) have been modified to be consistent with the friction factors. These correlations are also useful as building blocks for finding the heat transfer rates when the surface temperature varies in a predefined manner. Equations (4.2.44) and (4.2.45), developed by Thomas (1977), provide the average heat transfer coefficients based on Equations (4.2.42) and (4.2.43).

FIGURE 4.2.10 Heated flat plate with unheated starting length.

#### Local Convective Heat Transfer Coefficient

$$Re_x < Re_{cr}:$$

$$Nu_x = \frac{0.332 Re_x^{1/2} Pr^{1/3}}{\left[ 1 - \left( \frac{x_0}{x} \right)^{3/4} \right]^{1/3}} \quad (4.2.42)$$

$$Re_x > Re_{cr}:$$

$$Nu_x = \frac{0.0296 Re_x^{4/5} Pr^{3/5}}{\left[ 1 - \left( \frac{x_0}{x} \right)^{9/10} \right]^{1/9}} \quad (4.2.43)$$

Average Heat Transfer Coefficient over the Length ( $L - x_o$ )

$Re_L < Re_{cr}$ :

$$h_{L-x_o} = \frac{0.664 Re_L^{1/2} Pr^{1/3} \left[ 1 - \left( \frac{x_o}{L} \right)^{3/4} \right]^{2/3} k}{L - x_o} \quad (4.2.44)$$

$$= 2 \frac{1 - \left( \frac{x_o}{L} \right)^{3/4}}{1 - x_o/L} h_{x=L}$$

In Equation (4.2.44) evaluate  $h_{x=L}$  from Equation (4.2.42).

$Re_{cr} = 0$ :

$$h_{L-x_o} = \frac{0.037 Re_L^{4/5} Pr^{3/5} \left[ 1 - \left( \frac{x_o}{L} \right)^{9/10} \right]^{8/9} k}{L - x_o} \quad (4.2.45)$$

$$= 1.25 \frac{1 - \left( x_o/L \right)^{9/10}}{1 - x_o/L} h_{x=L}$$

In Equation (4.2.45) evaluate  $h_{x=L}$  from Equation (4.2.43).

**Flat Plate with Prescribed Nonuniform Surface Temperature**

The linearity of the energy equation permits the use of Equations (4.2.42) through (4.2.45) for uniform surface temperature with unheated starting length to find the local heat flux and the total heat transfer rate by the principle of superposition when the surface temperature is not uniform. Figure 4.2.11 shows the arbitrarily prescribed surface temperature with a uniform free-stream temperature of the fluid. If the surface temperature is a differentiable function of the coordinate  $x$ , the local heat flux can be determined by an expression that involves integration (refer to Kays and Crawford, 1993). If the surface temperature can be approximated as a series of step changes in the surface temperature, the resulting expression for the local heat flux and the total heat transfer rate is the summation of simple algebraic expressions. Here the method using such an algebraic simplification is presented.

**FIGURE 4.2.11** Arbitrary surface temperature approximated as a finite number of step changes.

The local convective heat flux at a distance  $x$  from the leading edge is given by

$$q_x'' = \sum_1^n h_{x_i} \Delta T_{si} \quad (4.2.46)$$

where  $h_{x_i}$  denotes the local convective heat transfer coefficient at  $x$  due to a single step change in the surface temperature  $\Delta T_{si}$  at location  $x_i (x_i < x)$ . Referring to [Figure 4.2.11](#), the local convective heat flux at  $x (x_3 < x < x_4)$  is given by

$$q_x'' = h_x(x, 0) \Delta T_o + h_x(x, x_1) \Delta T_1 + h_x(x, x_2) \Delta T_2 + h_x(x, x_3) \Delta T_3$$

where  $h_x(x, x_1)$  is the local convective heat transfer coefficient at  $x$  with heating starting from  $x_1$ ; the local convective heat transfer is determined from Equation (4.2.42) if the boundary layer is laminar and Equation (4.2.43) if the boundary layer is turbulent from the leading edge. For example,  $h_x(x, x_2)$  in the third term is given by

$$\text{Re}_x < \text{Re}_{cr} \quad h_x(x, x_2) = \frac{0.332 \left( \frac{\rho U_\infty x}{\mu} \right)^{1/2} \text{Pr}^{1/3} \frac{k}{x}}{\left[ 1 - \left( \frac{x_2}{x} \right)^{3/4} \right]^{1/3}}$$

$$\text{Re}_{cr} = 0 \quad h_x(x, x_2) = \frac{0.0296 \left( \frac{\rho U_\infty x}{\mu} \right)^{4/5} \text{Pr}^{3/5} \frac{k}{x}}{\left[ 1 - \left( \frac{x_2}{x} \right)^{9/10} \right]^{1/9}}$$

The procedure for finding the total heat transfer rate from  $x = 0$  to  $x = L$  is somewhat similar. Denoting the width of the plate by  $W$ ,

$$\frac{q}{W} = \sum h_{L-x_i} \Delta T_i (L - x_i) \quad (4.2.47)$$

where  $h_{L-x_i}$  is the average heat transfer coefficient over the length  $L - x_i$  due to a step change  $\Delta T_i$  in the surface temperature at  $x_i$ . For example, the heat transfer coefficient in the third term in Equation (4.2.47) obtained by replacing  $x_o$  by  $x_2$  in Equation (4.2.44) or (4.2.45) depending on whether  $\text{Re}_L < \text{Re}_{cr}$  or  $\text{Re}_{cr} = 0$ .

### Flows with Pressure Gradient and Negligible Viscous Dissipation

Although correlations for flat plates are for a semi-infinite fluid medium adjacent to the plate, most applications of practical interest deal with fluid flowing between two plates. If the spacing between the plates is significantly greater than the maximum boundary layer thickness, the medium can be assumed to approach a semi-infinite medium. In such a case if the plates are parallel to each other and if the pressure drop is negligible compared with the absolute pressure, the pressure gradient can be assumed to be negligible. If the plates are nonparallel and if the boundary layer thickness is very much smaller than the spacing between the plates at that location, the medium can still be considered as approaching a semi-infinite medium with a non-negligible pressure gradient. In such flows the free-stream velocity (core velocity outside the boundary layer) is related to the pressure variation by the Bernoulli equation:

$$\frac{p}{\rho} + \frac{U_\infty^2}{2} + zg = \text{constant}$$

**FIGURE 4.2.12** Flow over a wedge.  $\beta\pi$  is the wedge angle.

Another situation where the free-stream velocity varies in the direction of flow giving rise to a pressure gradient is flow over a wedge. For the family of flows for which the solutions are applicable, the free-stream velocity at the edge of the boundary layer is related to the  $x$ -coordinate by a power law,  $U_\infty = cx^m$ . Flows over semi-infinite wedges (Figure 4.2.12) satisfy that condition. The exponent  $m$  is related to the wedge angle  $\beta\pi$

$$\beta = \frac{2m}{1+m} \quad m = \frac{\beta}{2-\beta}$$

With laminar boundary layers, the boundary layer thickness, friction factor, and Nusselt numbers are defined by

$$\frac{\delta}{x} = \frac{c_1}{\sqrt{\text{Re}_x}} \quad \frac{C_{fx}}{2} = \frac{\tau_w}{\rho U_\infty^2} = \frac{c_2}{\sqrt{\text{Re}_x}} \quad \text{Nu}_x = c_3 \text{Re}_x^{1/2}$$

The values of  $c_1$ ,  $c_2$ , and  $c_3$  are available in Burmeister (1993). For example, for  $\beta = 0.5$  (wedge angle =  $90^\circ$ ),  $m = 1/3$ ,  $c_1 = 3.4$ ,  $c_2 = 0.7575$ , and  $c_3 = 0.384$  for  $\text{Pr} = 0.7$ , and  $c_3 = 0.792$  for  $\text{Pr} = 5$ .  $\text{Re}_x$  is based on  $U_\infty = cx^m$ ; the free-stream velocity is not uniform.

**Uniform Temperature: Flat Plate with Injection or Suction with External Flows of a Fluid Parallel to the Surface**

Injection or suction has engineering applications. When the free-stream temperature of the fluid is high, as in gas turbines, a cooling fluid is introduced into the mainstream to cool the surface. If the cooling fluid is introduced at discrete locations (either perpendicular to the surface or at an angle), it is known as film cooling. If a fluid is introduced or withdrawn through a porous medium, it is known as transpiration (Figure 4.2.13). An application of suction is to prevent boundary layer separation (Figure 4.2.13).

Analytical solutions for a laminar boundary layer with transpiration suction or blowing are available if the velocity perpendicular to the surface varies in the following manner:

$$v_o = \text{constant } x^{(m-1)/2}$$

**FIGURE 4.2.13** Flat plate with transpiration injection.

Solutions are limited to the cases of the injected fluid being at the same temperature as the surface and the injected fluid being the same as the free-stream fluid. Positive values of  $v_o$  indicate blowing and negative values indicate suction. Values of  $Nu_x/Re_x^{1/2}$  for different values of Pr and for different values of blowing or suction parameter are given in Kays and Crawford (1993).

For example, for a laminar boundary layer over a flat plate with a fluid (Pr = 0.7) the value of  $Nu_x/Re_x^{1/2}$  is 0.722 for  $(v_o/U_\infty) \sqrt{\rho U_\infty x/\mu} = -0.75$  (suction) and 0.166 for  $(v_o/U_\infty) \sqrt{\rho U_\infty x/\mu} = 0.25$  (blowing). Heat transfer coefficient increases with suction which leads to a thinning of the boundary layer. Blowing increases the boundary layer thickness and decreases the heat transfer coefficient.

For *turbulent boundary layers* Kays and Crawford (1993) suggest the following procedure for finding the friction factor and convective heat transfer coefficient. Define friction blowing parameter  $B_f$  and heat transfer blowing parameter  $B_h$  as

$$B_f = \frac{v_o/U_\infty}{C_f/2} \quad (4.2.48)$$

$$B_h = \frac{v_o/U_\infty}{St} = \frac{\dot{m}''/G_\infty}{St} \quad (4.2.49)$$

where

- $v_o$  = velocity normal to the plate
- $U_\infty$  = free-stream velocity
- $\dot{m}''$  = mass flux of the injected fluid at the surface ( $\rho v_o$ )
- $G_\infty$  = mass flux in the free stream ( $\rho U_\infty$ )
- St = Stanton number =  $Nu_x/Re_x Pr = h/\rho U_\infty c_p$

The friction factors and Stanton number with and without blowing or suction are related by

$$\frac{C_f}{C_{fo}} = \frac{\ln(1+B_f)}{B_f} \quad (4.2.50)$$

$$\frac{St}{St_o} = \frac{\ln(1+B_h)}{B_h} \quad (4.2.51)$$

In Equations (4.2.50) and (4.2.51)  $C_{fo}$  and  $St_o$  are the friction factor and Stanton number with  $v_o = 0$  (no blowing or suction), and  $C_f$  and  $St$  are the corresponding quantities with blowing or suction at the same  $Re_x(\rho U_\infty x/\mu)$ .

For the more general case of variable free-stream velocity, temperature difference, and transpiration rate, refer to Kays and Crawford (1993).

### Flow over Flat Plate with Zero Pressure Gradient: Effect of High-Speed and Viscous Dissipation

In the boundary layer the velocity of the fluid is reduced from  $U_\infty$  to zero at the plate leading to a reduction in the kinetic energy of the fluid. Within the boundary layer there is also the work done by viscous forces; the magnitude of the such viscous work is related to the velocity of the fluid, the velocity gradient, and the viscosity of the fluid. The effect of such a reduction in the kinetic energy and the viscous work is to increase the internal energy of the fluid in the boundary layer. The increase in the internal energy may be expected to lead to an increase in the temperature; but because of the heat transfer to the adjacent fluid the actual increase in the internal energy (and the temperature) will be less than the sum of the decrease in the kinetic energy and viscous work transfer; the actual temperature

increase depends on the decrease in the kinetic energy, the viscous work transfer, and the heat transfer from the fluid. The maximum temperature in the fluid with an adiabatic plate is known as the adiabatic wall temperature (which occurs at the wall) and is given by

$$T_{aw} = T_{\infty} + r \frac{U_{\infty}^2}{2C_p} \quad (4.2.52)$$

In Equation (4.2.52)  $r$  is the recovery factor and is given by Eckert and Drake (1972).

$$\text{Laminar boundary layer} \quad 0.6 < \text{Pr} < 15 \quad r = \text{Pr}^{1/2}$$

$$\text{Turbulent boundary layer} \quad r = \text{Pr}^{1/3}$$

Equation (4.2.52) can be recast as

$$\frac{T_{aw} - T_{\infty}}{T_s - T_{\infty}} = \frac{r}{2} \frac{U_{\infty}^2}{C_p (T_s - T_{\infty})} \quad (4.2.53)$$

From Equation (4.2.53) the maximum increase in the fluid temperature as a fraction of the difference between the plate and free-stream temperatures is given by  $r Ec/2$ . With air flowing over a plate at 500 m/sec, the increase in the temperature of the air can be as high as 105°C. With  $T_s = 40^\circ\text{C}$  and  $T_{\infty} = 20^\circ\text{C}$ , the temperature of the air close to the plate can be higher than the plate temperature. It is thus possible that although the plate temperature is higher than the free-stream temperature, the heat transfer is from the air to the plate. At a Mach number greater than 0.1 for gases, viscous dissipation becomes significant.

The temperature profiles for high-speed flows for different values of  $T_s$  are shown in Figure 4.2.14. In high-speed flows, as heat transfer can be to the plate even if the plate temperature is greater than the fluid temperature, the definition of the convective heat transfer coefficient given in Equation (4.2.29) is not adequate. On the other hand, as the heat transfer is always from the plate if  $T_s > T_{aw}$ , the adiabatic wall temperature is more appropriate as the reference temperature. Thus, in high-speed flows the definition of the convective heat transfer coefficient is given by

$$q'' = h(T_s - T_{aw}) \quad (4.2.54)$$

**FIGURE 4.2.14** Temperature profiles for high-speed flows: (a)  $T_{\infty} < T_s < T_{aw}$ ; (b)  $T_s = T_{\infty}$ ; (c)  $T_s \ll T_{\infty}$ ; (d)  $T_s > T_{aw}$ .

Equation (4.2.54) is consistent with Equation (4.2.29) as the adiabatic wall temperature equals the free-stream temperature if the effects of viscous dissipation and reduced kinetic energy in the boundary layer are neglected. With the adiabatic wall temperature as the fluid reference temperature for the definition

of the convective heat transfer coefficient, equations for low speeds can also be used for high-speed flows. Because of the greater variation in the fluid temperature in the boundary layer, the variation of properties due to temperature variation becomes important. It is found that the correlations are best approximated if the properties are evaluated at the reference temperature  $T^*$  defined by Eckert (1956):

$$T^* = 0.5(T_s + T_\infty) + 0.22(T_{aw} - T_\infty) \quad (4.2.55)$$

With properties evaluated at the reference temperature given by Equation (4.2.55), Equation (4.2.56) through (4.2.61) are applicable to high-speed flows with Prandtl numbers less than 15. It should be noted that the adiabatic wall temperatures in the laminar and turbulent regions are different affecting both the temperature at which the properties are evaluated and the temperature difference for determining the local heat flux. Therefore, when the boundary layer is partly laminar and partly turbulent, an average value of the heat transfer coefficient is not defined as the adiabatic wall temperatures in the two regions are different. In such cases the heat transfer rate in each region is determined separately to find the total heat transfer rate.

Evaluate properties at reference temperature given by Equation (4.2.55):

Laminar	Local: $Re_x < Re_{cr}$	$Nu_x = 0.332Re_x^{1/2} Pr^{1/3}$	(4.2.56)
---------	-------------------------	-----------------------------------	----------

	Average: $Re_L < Re_{cr}$	$Nu_L = 0.664Re_L^{1/2} Pr^{1/3}$	(4.2.57)
--	---------------------------	-----------------------------------	----------

Turbulent	Local: $10^7 > Re_x > Re_{cr}$	$Nu_x = 0.0296Re_x^{4/5} Pr^{1/3}$	(4.2.58)
-----------	--------------------------------	------------------------------------	----------

	Local: $10^7 < Re_x < 10^9$	$Nu_x = 1.596Re_x (\ln Re_x)^{-2.584} Pr^{1/3}$	(4.2.59)
--	-----------------------------	---	----------

	Average: $Re_{cr} = 0, Re_L < 10^7$	$Nu_L = 0.037Re_L^{4/5} Pr^{1/3}$	(4.2.60)
--	-------------------------------------	-----------------------------------	----------

	Average: $Re_{cr} = 0, 10^7 < Re_L < 10^9$	$Nu_L = 1.967Re_L (\ln Re_L)^{-2.584} Pr^{1/3}$	(4.2.61)
--	--	---	----------

When the temperature variation in the boundary layer is large, such that the assumption of constant specific heat is not justified, Eckert (1956) suggests that the properties be evaluated at a reference temperature corresponding to the specific enthalpy  $i^*$  given by

$$i^* = 0.5(i_s + i_\infty) + 0.22(i_s - i_\infty) \quad (4.2.62)$$

where  $i$  is the specific enthalpy of the fluid evaluated at the temperature corresponding to the subscript. Equation (4.2.62) gives the same values as Equation (4.2.55) if  $C_p$  is constant or varies linearly with temperature.

At very high speeds the gas temperature may reach levels of temperatures that are sufficient to cause disassociation and chemical reaction; these and other effects need to be taken into account in those cases.

### Flow over Cylinders, Spheres, and Other Geometries

Flows over a flat plate and wedges were classified as laminar or turbulent, depending on the Reynolds number, and correlations for the local and average convective heat transfer coefficients were developed. But flows over cylinders (perpendicular to the axis) and spheres are more complex. In general, the flow over cylinders and spheres may have a laminar boundary layer followed by a turbulent boundary layer

**FIGURE 4.2.15** A fluid stream in cross flow over a cylinder.

and a wake region depending on the Reynolds number with the diameter as the characteristic length. Because of the complexity of the flow patterns, only correlations for the average heat transfer coefficients have been developed (Figure 4.2.15).

*Cylinders:* Use the following correlation proposed by Churchill and Bernstein (1977):  $Re_d Pr > 0.2$ . Evaluate properties at  $(T_s + T_\infty)/2$ :

$$Re_d > 400,000: \quad Nu_d = 0.3 + \frac{0.62Re_d^{1/2} Pr^{1/3}}{\left[1 + (0.4/Pr)^{2/3}\right]^{1/4}} \left[1 + \left(\frac{Re_d}{282,000}\right)^{5/8}\right]^{4/5} \quad (4.2.63)$$

$$10,000 < Re_d < 400,000: \quad Nu_d = 0.3 + \frac{0.62Re_d^{1/2} Pr^{1/3}}{\left[1 + (0.4/Pr)^{2/3}\right]^{1/4}} \left[1 + \left(\frac{Re_d}{282,000}\right)^{1/2}\right] \quad (4.2.64)$$

$$Re_d < 10,000: \quad Nu_d = 0.3 + \frac{0.62Re_d^{1/2} Pr^{1/3}}{\left[1 + (0.4/Pr)^{2/3}\right]^{1/4}} \quad (4.2.65)$$

For flow of liquid metals, use the following correlation suggested by Ishiguro et al. (1979):

$$1 < Re_d Pr < 100 \quad Nu_d = 1.125(Re_d Pr)^{0.413} \quad (4.2.66)$$

For more information on heat transfer with flow over cylinders, refer to Morgan (1975) and Zukauskas (1987).

*Spheres:* For flows over spheres (Figure 4.2.16) use one of the following two correlations.

**FIGURE 4.2.16** A fluid flowing over a sphere.

1. Whitaker (1972): Evaluate properties at  $T_\infty$  except  $\mu_s$  at  $T_s$ .

$$3.5 < Re_d < 76,000 \quad 0.71 < Pr < 380 \quad 1 < \mu/\mu_s < 3.2$$

$$\text{Nu}_d = 2.0 + \left(0.4\text{Re}_d^{1/2} + 0.06\text{Re}_d^{2/3}\right) \text{Pr}^{2/5} \left(\frac{\mu}{\mu_s}\right)^{1/4} \quad (4.2.67)$$

2. Achenbach (1978): Evaluate properties at  $(T_s + T_\infty)/2$ :

$$100 < \text{Re}_d < 2 \times 10^5 \quad \text{Pr} = 0.71$$

$$\text{Nu}_d = 2 + \left(0.25\text{Re}_d + 3 \times 10^{-4} \text{Re}_d^{1.6}\right)^{1/2} \quad (4.2.68)$$

$$4 \times 10^5 < \text{Re}_d < 5 \times 10^6 \quad \text{Pr} = 0.71$$

$$\text{Nu}_d = 430 + 5 \times 10^{-3} \text{Re}_d + 0.25 \times 10^{-9} \text{Re}_d^2 - 3.1 \times 10^{-17} \text{Re}_d^3 \quad (4.2.69)$$

3. Liquid Metals: From experimental results with liquid sodium, Witte (1968) proposed

$$3.6 \times 10^4 < \text{Re}_d < 1.5 \times 10^5 \quad \text{Nu}_d = 2 + 0.386(\text{Re}_d \text{Pr})^{1/2} \quad (4.2.70)$$

*Other Geometries:* For geometries other than cylinders and spheres, use Equation (4.2.71) with the characteristic dimensions and values of the constants given in the [Table 4.2.1](#).

$$\text{Nu}_D = c \text{Re}_D^m \quad (4.2.71)$$

Although Equation (4.2.71) is based on experimental data with gases, its use can be extended to fluids with moderate Prandtl numbers by multiplying Equation (4.2.71) by  $(\text{Pr}/0.7)^{1/3}$ .

### Heat Transfer across Tube Banks

When tube banks are used in heat exchangers, the flow over the tubes in the second subsequent rows of tubes is different from the flow over a single tube. Even in the first row the flow is modified by the presence of the neighboring tubes. The extent of modification depends on the spacing between the tubes. If the spacing is very much greater than the diameter of the tubes, correlations for single tubes can be used. Correlations for flow over tube banks when the spacing between tubes in a row and a column is not much greater than the diameter of the tubes have been developed for use in heat-exchanger applications. Two arrangements of the tubes are considered — aligned and staggered as shown in [Figure 4.2.17](#). The nomenclature used in this section is shown in the figure.

For the average convective heat transfer coefficient with tubes at uniform surface temperature, from experimental results, Zukauskas (1987) recommends correlations of the form:

$$\text{Nu}_d = c \left(\frac{a}{b}\right)^p \text{Re}_d^m \text{Pr}^n \left(\frac{\text{Pr}}{\text{Pr}_s}\right)^{0.25} \quad (4.2.72)$$

In Equation (4.2.72) all properties are evaluated at the arithmetic mean of the inlet and exit temperatures of the fluid, except  $\text{Pr}_s$  which is evaluated at the surface temperature  $T_s$ . The values of the constants  $c$ ,  $p$ ,  $m$ , and  $n$  are given in [Table 4.2.2](#) for in-line arrangement and in [Table 4.2.3](#) for staggered arrangement.

TABLE 4.2.1 Values of  $c$  and  $m$  in Equation (4.2.71)

Geometry	$Re_D$	$c$	$m$
	5000-100 000	0.092	0.675
	2500-8000	0.160	0.699
	5000-100 000	0.222	0.588
	2500-7500	0.261	0.624
	5000-19500	0.144	0.638
	19 500-100 000	0.035	0.782
	5000-100 000	0.138	0.638
	2500-15 000	0.224	0.612
	3000-15 000	0.085	0.804
	4000-15 000	0.205	0.731

Characteristic dimension is the equivalent circular diameter = Perimeter/ $\pi$   
 For example, for a square rod with each side  $a$ ,  $D = 4a/\pi$

From Jakob, 1949. With permission.

FIGURE 4.2.17 Two arrangements of tube banks. In-line or aligned arrangement on the left and staggered arrangement on the right. ( $a = S_T/d$ ;  $b = S_L/d$ .)

**TABLE 4.2.2 In-Line Arrangement — Values of Constants in Equation (4.2.72) ( $p = 0$  in all cases)**

$Re_d$	$c$	$m$	$n$
1–100	0.9	0.4	0.36
100–1000	0.52	0.5	0.36
$10^3$ – $2 \times 10^5$	0.27	0.63	0.36
$2 \times 10^5$ – $2 \times 10^6$	0.033	0.8	0.4

**TABLE 4.2.3 Staggered Arrangement — Values of Constants in Equation (4.2.72)**

$Re_d$	$c$	$p$	$m$	$n$
1–500	1.04	0	0.4	0.36
500–1000	0.71	0	0.5	0.36
$10^3$ – $2 \times 10^5$	0.35	0.2	0.6	0.36
$2 \times 10^5$ – $2 \times 10^6$	0.031	0.2	0.8	0.36

In computing  $Re_d$ , the maximum average velocity between tubes is used. The maximum velocities for the in-line and staggered arrangements are given by

$$\text{In-line:} \quad U_{\max} = \frac{U_{\infty} S_T}{S_T - d} \quad (4.2.73)$$

$$\text{Staggered:} \quad S_d > \frac{S_T + d}{2} \quad U_{\max} = \frac{U_{\infty} S_T}{S_T - d} \quad (4.2.74)$$

$$\text{Staggered:} \quad S_d < \frac{S_T + d}{2} \quad U_{\max} = \frac{U_{\infty} S_T}{2(S_d - d)} \quad (4.2.75)$$

$$S_d = \left[ S_L^2 + \left( \frac{S_T}{2} \right)^2 \right]^{1/2}$$

Equation (4.2.72) is for tube banks with 16 or more rows. When there are fewer than 16 rows, the heat transfer coefficient given by Equation (4.2.72) is multiplied by the correction factor  $c_1$  defined by Equation (4.2.76) and given in Table 4.2.4.

$$\frac{h_N}{h_{16}} = c_1 \quad (4.2.76)$$

where

$h_N$  = heat transfer coefficient with  $N$  rows (fewer than 16)

$h_{16}$  = heat transfer coefficient with 16 or more rows

**TABLE 4.2.4 Correction Factor  $c_1$  to Be Used with Equation (4.2.76)**

Tube Arrangement	Number of Rows (N)							
	1	2	3	4	5	7	10	13
In-line	0.70	0.80	0.86	0.90	0.93	0.96	0.98	0.99
Staggered	0.64	0.76	0.84	0.89	0.93	0.96	0.98	0.99

**Pressure Drop:** With tube banks, pressure drop is a significant factor, as it determines the fan power required to maintain the fluid flow. Zukauskas (1987) recommends that the pressure drop be computed from the relation

$$\Delta p = p_i - p_e = N\chi \frac{\rho U_{\max}^2}{2} f \quad (4.2.77)$$

where  $p_i$  and  $p_e$  are the fluid pressures at inlet and exit of the tube banks. The values of  $\chi$  and  $f$  are presented in Figure 4.2.18A. In Figure 4.2.18A the friction factor  $f$  for in-line arrangement is presented for different values of  $b$  ( $S_L/d$ ) for  $S_L = S_T$ . For values of  $S_L/S_T$  other than 1, the correction factor  $\chi$  is given in the inset for different values of  $(a - 1)/(b - 1)$ . Similarly, the friction factor for staggered arrangement (for equilateral triangle arrangement) and a correction factor for different values of  $a/b$  are also given in Figure 4.2.18b. The value of  $f$  is for one row of tubes; the total pressure drop is obtained by multiplying the pressure drop for one row by the number of rows,  $N$ .

The temperature of the fluid varies in the direction of flow, and, therefore, the value of the convective heat transfer coefficient (which depends on the temperature-dependent properties of the fluid) also varies in the direction of flow. However, it is common practice to compute the total heat transfer rate with the assumption of uniform convective heat transfer coefficient evaluated at the arithmetic mean of the inlet and exit temperatures of the fluid. With such an assumption of uniform convective heat transfer coefficient, uniform surface temperature and constant specific heat (evaluated at the mean fluid temperature), the inlet and exit fluid temperatures are related by

$$\ln\left(\frac{T_s - T_e}{T_s - T_i}\right) = -\frac{hA_s}{\dot{m}c_p} \quad (4.2.78)$$

The heat transfer rate to the fluid is related by the equation

$$q = \dot{m}c_p(T_i - T_e) \quad (4.2.79)$$

### Example

A heat exchanger with aligned tubes is used to heat 40 kg/sec of atmospheric air from 10 to 50°C with the tube surfaces maintained at 100°C. Details of the heat exchanger are

Diameter of tubes	25 mm
Number of columns	20
Length of each tube	3 m
$S_L = S_T$	75 mm

Determine the number of rows required.

**Solution:** Average air temperature =  $(T_i + T_e)/2 = 30^\circ\text{C}$ . Properties of atmospheric air (from Suryanarayana, 1995):

$$\begin{aligned} \rho &= 1.165 \text{ kg/m}^3 & c_p &= 1007 \text{ J/kg K} \\ \mu &= 1.865 \times 10^{-5} \text{ Nsec/m}^2 & k &= 0.0264 \text{ W/mK} \\ \text{Pr} &= 0.712 & \text{Pr}_s(\text{at } 100^\circ\text{C}) &= 0.705 \end{aligned}$$

**FIGURE 4.2.18** Friction factors for tube banks. (a) In-line arrangement; (b) Staggered arrangement.

To find  $U_{max}$  we need the minimum area of cross section for fluid flow (Figure 4.2.19).

$$H = 20 \times 0.075 = 1.5 \text{ m}$$

$$A_{min} = 20(0.075 - 0.025) \times 3 = 3 \text{ m}^2$$

$$U_{max} = \frac{\dot{m}}{\rho A_{min}} = \frac{40}{1.165 \times 3} = 11.44 \text{ m/sec}$$

**FIGURE 4.2.19** Aligned tube heat exchanger (only a few of the 20 columns and rows are shown).

$$\text{Re}_d = \frac{\rho U_{\max} d}{\mu} = \frac{1.165 \times 11.44 \times 0.025}{1.865 \times 10^{-5}} = 17,865$$

With values from [Table 4.2.2](#),

$$\text{Nu}_d = 0.27 \times 17,865^{0.63} \times 0.712^{0.36} \left( \frac{0.712}{0.705} \right)^{0.25} = 114.3$$

$$h = \frac{114.3 \times 0.0264}{0.025} = 120.7 \text{ W/m}^2 \text{ K}$$

From Equation 4.2.78,

$$\ln\left(\frac{100 - 50}{100 - 10}\right) = -\frac{120.7 \times A_s}{40 \times 1007} \quad A_s = \pi \times 0.025 \times 3 \times 20 \times N$$

$$N = \text{number of rows} = 42$$

*Fan Power:* From the first law of thermodynamics (see Chapter 2), the fan power is

$$\dot{W}_F = \dot{m} \left( \frac{p_i}{\rho_i} + \frac{p_e}{\rho_e} + \frac{\mathbf{v}_e^2}{2} \right)$$

$p_i$  and  $p_e$  are the pressures at inlet and exit of the heat exchanger and  $\mathbf{v}_e$  is the fluid velocity at exit. Assuming constant density evaluated at  $(T_i + T_e)/2$  the pressure drop is found from [Figure 4.2.18a](#).

$$\text{Re}_p = 17,865:$$

$$a = b = S_T/d = 75/25 = 3$$

In [Figure 4.2.18](#), although the friction factor is available for values of  $b$  up to 2.5, we will estimate the value of  $f$  for  $b = 3$ . From [Figure 4.2.18](#),  $f \approx 0.11$ . The correction factor  $c = 1$ .

$$p_i - p_e = N\chi \frac{\rho U_{\max}^2}{2} f = 42 \times 1 \frac{1.165 \times 11.44^2}{2} \times 0.11 = 352.2 \text{ kPa}$$

$$\mathbf{v}_e = \frac{11.44 \times 50}{75} = 7.63 \text{ m/sec}$$

$$\dot{W}_F = 40 \left( 352.2 + \frac{7.63^2}{2} \right) = \underline{15,250 \text{ W}}$$

### Heat Transfer with Jet Impingement

Jet impingement (Figure 4.2.20) on a heated (or cooled) surface results in high heat transfer rates, and is used in annealing of metals, tempering of glass, cooling of electronic equipment, internal combustion engines, and in a wide variety of industries — textiles, paper, wood, and so on. Usually, the jets are circular, issuing from a round nozzle of diameter  $d$ , or rectangular, issuing from a slot of width  $w$ . They may be used singly or in an array. The jets may impinge normally to the heated surface or at an angle. If there is no parallel solid surface close to the heated surface, the jet is said to be free; in the presence of a parallel surface close to the heated surface, the jet is termed confined. In this section only single, free jets (round or rectangular) impinging normally to the heated surface are considered.

**FIGURE 4.2.20** Circular jet of diameter  $d$  or a rectangular jet of width  $w$ .

Jets may be submerged with the fluid from the nozzle exiting into a body of a fluid (usually the same fluid), for example, air impinging on a surface surrounded by atmospheric air. In submerged jets entrained fluid (the part of the surrounding fluid dragged by the jet) has a significant effect on the flow and heat transfer characteristics of the jet, but the effect of gravity is usually negligible. In free-surface jets — a liquid jet in an atmosphere of air is a good approximation to a free-surface jet — the entrainment effect is usually negligible, but the effect of gravity may be significant.

A jet is usually divided into three regions, a free-jet region, a stagnation region, and a wall-jet region. In the free-jet region the effect of the target surface on the flow is negligible. In the stagnation region the target surface affects the flow field, and the velocity parallel to the surface increases while the velocity component normal to the surface decreases. At the beginning of the stagnation region, the axial velocity of the fluid is very much greater than the radial component (or the  $x$ -component) of the velocity. The stagnation region is followed by the wall-jet region where the radial component (or the  $x$ -component) of the velocity is much greater than the axial velocity.

The heat transfer coefficient is a function of  $H/d$  (or  $H/w$ ),  $Re_d(\rho v_j d/\mu)$  or  $(\rho v_j 2w/\mu)$ , and  $Pr$  and depends on the region (stagnation or wall jet), whether it is submerged or nonsubmerged and whether the flow adjacent to the plate is laminar or turbulent. Some of the heat transfer correlations suggested by different researchers are given below. All the correlations are for single jets.

#### Submerged Jets: Single Circular Jets

$$Re_d = \frac{4\dot{m}}{\pi d\mu} \quad Nu_d = \frac{hd}{k} \quad \dot{m} = \text{mass rate of flow of fluid}$$

Average heat transfer coefficients up to radius  $r$  (Martin, 1990):

$$\text{Nu}_d = 2 \frac{d}{r} \frac{1 - 1.1d/r}{1 + 0.1(H/d - 6)d/r} \left[ \text{Re}_d \left( 1 + \frac{\text{Re}_d^{0.55}}{200} \right) \right]^{1/2} \text{Pr}^{0.42} \quad (4.2.80)$$

Range of validity:

$$2000 \leq \text{Re}_d \leq 400,000 \quad 2.5 \leq r/d \leq 7.5 \quad 2 \leq H/d \leq 12$$

Local convective heat transfer coefficient at radius  $r$  (Webb and Ma, 1995):

$$\text{Nu}_d = 1.29 \text{Re}_d^{1/2} \text{Pr}^{0.4} \left\{ \left[ \frac{\tanh(0.88r/d)}{r/d} \right]^{-8.5} + \left[ 1.69 \left( \frac{r}{d} \right)^{-1.07} \right]^{-17} \right\} \quad (4.2.81)$$

*Submerged Jets: Single Rectangular Jet*

$$\text{Re}_w = \frac{\rho \mathbf{v}_j 2w}{\mu} = \frac{2\dot{m}}{\mu} \quad \dot{m} = \text{mass rate of flow per unit length of jet}$$

$$\text{Nu}_w = \frac{h2w}{k}$$

Average heat transfer coefficient (Martin, 1990):

$$\text{Nu}_w = \frac{1.53 \text{Pr}^{0.42} \text{Re}_w^m}{\frac{x}{2w} + \frac{H}{2w} + 1.39} \quad (4.2.82)$$

$$m = 0.695 - \left[ \frac{x}{2w} + \left( \frac{H}{2w} \right)^{1.33} + 3.06 \right]^{-1}$$

*Free-Surface Jets: Single Circular Jet.* Correlations are given in [Table 4.2.5](#) (Liu et al., 1991 and Webb and Ma, 1995).

For more information on jet impingement heat transfer, refer to Martin (1977) and Webb and Ma (1995) and the references in the two papers.

## Forced Convection — Internal Flows

*N.V. Suryanarayana*

### Introduction

Heat transfer to (or from) a fluid flowing inside a tube or duct is termed *internal forced convection*. The fluid flow may be laminar or turbulent. If the Reynolds number based on the average velocity of the fluid and diameter of the tube ( $\rho v d / \mu$ ) is less than 2100 (Reynolds numbers in the range of 2000 to 2300 are cited in different sources), the flow is laminar. If the Reynolds number is greater than 10,000, the flow is turbulent. The flow with a Reynolds number in the range 2100 to 10,000 is considered to be in the transitional regime. With heating or cooling of the fluid, there may or may not be a change in the phase of the fluid. Here, only heat transfer to or from a single-phase fluid is considered.

*Fully Developed Velocity and Temperature Profiles.* When a fluid enters a tube from a large reservoir, the velocity profile at the entrance is almost uniform as shown in [Figure 4.2.21](#). The fluid in the immediate vicinity of the tube surface is decelerated and the velocity increases from zero at the surface to  $u_c$  at a distance  $\delta$  from the surface; in the region  $r = 0$  to  $(R - \delta)$  the velocity is uniform. The value of  $\delta$  increases in the direction of flow and with constant fluid density the value of the uniform velocity  $u_c$  increases. At some location downstream,  $\delta$  reaches its maximum possible value, equal to the radius of the tube, and from that point onward the velocity profile does not change.

The region where  $\delta$  increases, i.e., where the velocity profile changes, is known as the entrance region or hydrodynamically developing region. The region downstream from the axial location where  $\delta$  reaches its maximum value and where the velocity profile does not change is the fully developed velocity profile or hydrodynamically fully developed region. Similarly, downstream of the location where heating or cooling of the fluid starts, the temperature profile changes in the direction of flow. But beyond a certain distance the dimensionless temperature profile does not change in the direction of flow. The region where the dimensionless temperature profile changes is the thermally developing region or the thermal entrance region, and the region where the dimensionless temperature profile does not change is the thermally

**FIGURE 4.2.21** Developing and fully developed velocity profiles.

fully developed region. For simultaneously developing velocity and temperature profiles in laminar flows, the hydrodynamic and thermal entrance lengths are given by

$$\frac{L_e}{d} = 0.0565\text{Re}_d \quad (4.2.88)$$

$$\frac{L_{e,th}}{d} = 0.053\text{Re}_d\text{Pr} \quad \text{Uniform heat flux} \quad (4.2.89)$$

$$\frac{L_{e,th}}{d} = 0.037\text{RePr} \quad \text{Uniform surface temperature} \quad (4.2.90)$$

In most engineering applications, with turbulent flows, correlations for fully developed conditions can be used after about 10 diameters from where the heating starts.

*Convective Heat Transfer Coefficient and Bulk Temperature.* The reference temperature for defining the convective heat transfer coefficient is the bulk temperature  $T_b$  and the convective heat flux is given by

$$q'' = h(T_s - T_b) \quad (4.2.91)$$

The bulk temperature  $T_b$  is determined from the relation

$$T_b = \frac{\int_{A_c} \rho v C_p T dA_c}{\int_{A_c} \rho v C_p dA_c} \quad (4.2.92)$$

where  $A_c$  is the cross-sectional area perpendicular to the axis of the tube.

If the fluid is drained from the tube at a particular axial location and mixed, the temperature of the mixed fluid is the bulk temperature. It is also known as the mixing cup temperature. With heating or cooling of the fluid the bulk temperature varies in the direction of flow. In some cases we use the term *mean fluid temperature*,  $T_m$ , to represent the arithmetic mean of the fluid bulk temperatures at inlet and exit of the tube.

### Heat Transfer Correlations

*Laminar Flows — Entrance Region.* For laminar flows in a tube with uniform surface temperature, in the entrance region the correlation of Sieder and Tate (1936) is

$$\overline{\text{Nu}}_d = 1.86 \left( \frac{\text{Re}_d \text{Pr}}{L/d} \right)^{1/3} \left( \frac{\mu}{\mu_s} \right)^{0.14} \quad (4.2.93)$$

valid for

$$\frac{L}{d} < \frac{\text{Re}_d \text{Pr}}{8} \left( \frac{\mu}{\mu_s} \right)^{0.42} \quad 0.48 < \text{Pr} < 16,700 \quad 0.0044 < \frac{\mu}{\mu_s} < 9.75$$

The overbar in the Nusselt number indicates that it is formed with the average heat transfer coefficient over the entire length of the tube. Properties of the fluid are evaluated at the arithmetic mean of the inlet and exit bulk temperatures. In Equation (4.2.93) the heat transfer coefficient was determined from

$$q = \bar{h} \pi d L \left( T_s - \frac{T_{bi} + T_{be}}{2} \right) \quad (4.2.94)$$

Therefore, to find the total heat transfer rate with  $\bar{h}$  from Equation (4.2.93) employ Equation (4.2.94).

*Laminar Flows — Fully Developed Velocity and Temperature Profiles.* Evaluate properties at the bulk temperature

$$\text{Uniform Surface Temperature} \quad \text{Nu}_d = 3.66 \quad (4.2.95)$$

$$\text{Uniform Surface Heat Flux} \quad \text{Nu}_d = 4.36 \quad (4.2.96)$$

*Turbulent Flows.* If the flow is turbulent, the difference between the correlations with uniform surface temperature and uniform surface heat flux is not significant and the correlations can be used for both cases. For turbulent flows, Gnielinsky (1976, 1990) recommends:

Evaluate properties at the bulk temperature.

$$0.6 < \text{Pr} < 2000 \quad 2300 < \text{Re}_d < 10^6 \quad 0 < d/L < 1$$

$$\text{Nu}_d = \frac{(f/2)(\text{Re}_d - 1000)\text{Pr}}{1 + 12.7(f/2)^{1/2}(\text{Pr}^{2/3} - 1)} \left[ 1 + \left( \frac{d}{L} \right)^{2/3} \right] \quad (4.2.97)$$

$$f = [1.58 \ln(\text{Re}_d) - 3.28]^{-2} \quad (4.2.98)$$

$f$  = friction factor =  $2\tau_w/\rho v^2$ .

To reflect the effect of variation of fluid properties with temperature, multiply the Nusselt numbers in Equation (4.2.97) by  $(T_b/T_s)^{0.45}$  for gases and  $(\text{Pr}/\text{Pr}_s)^{0.11}$  for liquids where the temperatures are absolute, and  $T$  and  $\text{Pr}$  with a subscript  $s$  are to be evaluated at the surface temperature. The equations can be used to evaluate the heat transfer coefficient in the developing profile region. To determine the heat

transfer coefficient in the fully developed region set  $d/L = 0$ . A simpler correlation (fully developed region) is the Dittus–Boelter (1930) equation. Evaluate properties at  $T_b$ .

$$0.7 \leq \text{Pr} \leq 160 \quad \text{Re}_d > 10,000 \quad d/L > 10$$

$$\text{Nu}_d = 0.023 \text{Re}_d^{4/5} \text{Pr}^n \quad (4.2.99)$$

where  $n = 0.4$  for heating ( $T_s > T_b$ ) and  $n = 0.3$  for cooling ( $T_s < T_b$ ).

For liquid metals with  $\text{Pr} \ll 1$  the correlations due to Sleicher and Rouse (1976) are Uniform surface temperature:

$$\text{Nu}_{d,b} = 4.8 + 0.0156 \text{Re}_{d,f}^{0.85} \text{Pr}_s^{0.93} \quad (4.2.100)$$

Uniform heat flux:

$$\text{Nu}_{d,b} = 6.3 + 0.0167 \text{Re}_{d,f}^{0.85} \text{Pr}_s^{0.93} \quad (4.2.101)$$

Subscripts  $b$ ,  $f$ , and  $s$  indicate that the variables are to be evaluated at the bulk temperature, film temperature (arithmetic mean of the bulk and surface temperatures), and surface temperature, respectively.

In the computations of the Nusselt number the properties (evaluated at the bulk temperature) vary in the direction of flow and hence give different values of  $h$  at different locations. In many cases a representative average value of the convective heat transfer coefficient is needed. Such an average value can be obtained either by taking the arithmetic average of the convective heat transfer coefficients evaluated at the inlet and exit bulk temperatures or the convective heat transfer coefficient evaluated at the arithmetic mean of the inlet and exit bulk temperatures. If the variation of the convective heat transfer coefficient is large, it may be appropriate to divide the tube into shorter lengths with smaller variation in the bulk temperatures and evaluating the average heat transfer coefficient in each section.

Uniform Surface Temperature — Relation between the Convective Heat Transfer Coefficient and the Total Heat Transfer Rate: With a uniform surface temperature, employing an average value of the convective heat transfer coefficient the local convective heat flux varies in the direction of flow. To relate the convective heat transfer coefficient to the temperatures and the surface area, we have, for the elemental length  $\Delta z$  (Figure 4.2.22).

$$\dot{m} C_p \frac{dT_b}{dz} = h \frac{dA_s}{dz} (T_s - T_b) \quad (4.2.102)$$

**FIGURE 4.2.22** Elemental length of a tube for determining heat transfer rate.

Assuming a suitable average convective heat transfer coefficient over the entire length of the tube, separating the variables, and integrating the equation from  $z = 0$  to  $z = L$ , we obtain

$$\ln \frac{T_s - T_{be}}{T_s - T_{bi}} = - \frac{hA_s}{\dot{m}C_p} \quad (4.2.103)$$

Equation (4.2.103) gives the exit temperature. For a constant-density fluid or an ideal gas, the heat transfer rate is determined from

$$q = \dot{m}C_p(T_{be} - T_{bi}) \quad (4.2.104)$$

Equation (4.2.103) was derived on the basis of uniform convective heat transfer coefficient. However, if the functional relationship between  $h$  and  $T_b$  is known, Equation (4.2.102) can be integrated by substituting the relationship. The convective heat transfer coefficient variation with  $T_b$  for water in two tubes of different diameters for two different flow rates is shown in [Figure 4.2.23](#). From the figure it is clear that  $h$  can be very well approximated as a linear function of  $T$ . By substituting such a linear function relationship into Equation (4.2.102), it can be shown that

$$\ln \frac{h_i}{h_e} \frac{T_s - T_{be}}{T_s - T_{bi}} = - \frac{h_s A_s}{\dot{m}C_p} \quad (4.2.105)$$

where  $h_i$ ,  $h_e$ , and  $h_s$  are the values of the convective heat transfer coefficient evaluated at bulk temperatures of  $T_{bi}$ ,  $T_{be}$ , and  $T_s$ , respectively. Although it has been demonstrated that  $h$  varies approximately linearly with the bulk temperature with water as the fluid, the variation of  $h$  with air and oil as the fluid is much smaller and is very well approximated by a linear relationship. For other fluids it is suggested that the relationship be verified before employing Equation (4.2.105). [**Note:** It is tempting to determine the heat transfer rate from the relation

$$q = hA_s \frac{(T_s - T_{be}) + (T_s - T_{bi})}{2}$$

Replacing  $q$  by Equation (4.2.104) and solving for  $T_{be}$  for defined values of the mass flow rate and tube surface area, the second law of thermodynamics will be violated if  $hA_s/\dot{m}C_p > 2$ . Use of Equation (4.2.103) or (4.2.105) ensures that no violation of the second law occurs however large  $A_s$  is.]

**Uniform Surface Heat Flux:** If the imposed heat flux is known, the total heat transfer rate for a defined length of the tube is also known. From Equation (4.2.104) the exit temperature of the fluid is determined. The fluid temperature at any location in the pipe is known from the heat transfer rate up to that location ( $q = q''A_s$ ) and Equation (4.2.104). The convective heat transfer coefficient is used to find the surface temperature of the tube.

**Temperature Variation of the Fluid with Uniform Surface Temperature and Uniform Heat Flux:** The fluid temperature variations in the two cases are different. With the assumption of uniform heat transfer coefficient, with a uniform surface temperature the heat flux decreases in the direction of flow leading to a progressively decreasing rate of temperature change in the fluid with axial distance. With uniform heat flux, the surface and fluid temperatures vary linearly except in the entrance region where the higher heat transfer coefficient leads to a smaller difference between the surface and fluid temperatures. The variation of the fluid temperature in the two cases is shown in [Figure 4.2.24](#).

#### Convective Heat Transfer in Noncircular Tubes

**Laminar Flows:** The Nusselt numbers for laminar flows have been analytically determined for different noncircular ducts. Some of them can be found in Kakac et al. (1987), Kays and Crawford (1993), and

**FIGURE 4.2.23** Variation of  $h$  with  $T_b$  in 1-, 2-, and 4-cm-diameter tubes with water flow rates of 0.2 kg/sec and 0.4 kg/sec with uniform surface temperature.

**FIGURE 4.2.24** Variation of fluid temperature in a tube with (a) uniform surface temperature and (b) uniform heat flux.

Burmeister (1993). A few of the results are given below. The characteristic length for forming the Reynolds number and Nusselt number is the hydraulic mean diameter defined as

$$d_h = \frac{4 \text{ cross-sectional area}}{\text{wetted perimeter}}$$

*Infinite parallel plates:*  $a$  = spacing between plates,  $d_h = 2a$

Both plates maintained at uniform and equal temperatures:  $Nu = 7.54$

Both plates with imposed uniform and equal heat fluxes:  $Nu = 8.24$

*Rectangular ducts:*  $a$  = longer side,  $b$  = shorter side,  $d_h = 2ab/(a + b)$

$b/a$	1	0.7	0.5	0.25	0.125
Uniform surface temperature	2.98	3.08	3.39	4.44	5.6
Uniform heat flux*	3.61	3.73	4.12	5.33	6.49

*Equilateral triangle:*  $d_h = a/3^{1/2}$ ,  $a$  = length of each side

Uniform surface temperature:  $Nu = 2.35$

Uniform surface heat flux:\*  $Nu = 3.0$

*Coaxial tubes:* With coaxial tubes many different cases arise — each tube maintained at uniform but different temperatures, each tube subjected to uniform but different heat fluxes (an insulated

\* Uniform axial heat flux but circumferentially uniform surface temperature.

surface is a special case of imposed heat flux being zero), or a combinations of uniform surface temperature of one tube and heat flux on the other. The manner in which the heat transfer coefficient is determined for uniform but different heat fluxes on the two tubes is described below. Define:

$$d_h = 2(r_o - r_i) \quad r^* = r_i/r_o$$

$$q_i'' = h_i(T_i - T_b) \quad Nu_i = \frac{h_i d_h}{k} \quad q_o'' = h_o(T_o - T_b) \quad Nu_o = \frac{h_o d_h}{k}$$

$$q_o'' = 0 \quad Nu_{ii} = \frac{h_i d_h}{k} \quad \text{and} \quad q_i'' = 0 \quad Nu_{oo} = \frac{h_o d_h}{k}$$

Then

$$Nu_i = \frac{Nu_{ii}}{1 - \frac{q_o''}{q_i''} \theta_i^*} \quad \text{and} \quad Nu_o = \frac{Nu_{oo}}{1 - \frac{q_i''}{q_o''} \theta_o^*} \tag{4.2.106}$$

**TABLE 4.2.6 Values for Use with Equation (4.2.106)**

$r^*$	$Nu_{ii}$	$Nu_{oo}$	$\theta_i^*$	$\theta_o^*$
0.05	17.81	4.792	2.18	0.0294
0.1	11.91	4.834	1.383	0.0562
0.2	8.499	4.883	0.905	0.1041
0.4	6.583	4.979	0.603	0.1823
0.6	5.912	5.099	0.473	0.2455
0.8	5.58	5.24	0.401	0.299
1.0	5.385	5.385	0.346	0.346

Some of the values needed for the computations of  $Nu_i$  and  $Nu_o$  (taken from Kays and Crawford, 1993) are given in the [Table 4.2.6](#).

For a more detailed information on heat transfer and friction factors for laminar flows in noncircular tubes refer to Kakac et al. (1987).

*Turbulent Flows:* For noncircular tubes, estimates of the convective heat transfer coefficient can be obtained by employing equations for circular tubes with  $d_h$  replacing  $d$  in the computations of the Reynolds and Nusselt numbers. To determine the heat transfer coefficients in developing regions and for more-accurate values with turbulent flows in noncircular tubes refer to Kakac et al. (1987) and the references in that book.

**Mixed Convection**

If the fluid velocity is low, the effect of natural convection becomes significant and the heat transfer rate may be increased or decreased by natural convection. From a review of experimental results, Metals and Eckert (1964) developed maps to delineate the different regimes where one or the other mode is dominant and where both are significant. [Figures 4.2.25 and 4.2.26](#) show the relative significance of natural and forced convection in vertical and horizontal tubes. The maps are applicable for  $10^{-2} < Pr(d/L) < 1$  where  $d$  and  $L$  are the diameter and the axial length of the tube. The maps show the limits of forced and natural convection regimes. The limits are delineated “in such a way that the actual heat flux under the combined influence of the forces does not deviate by more than 10 percent from the heat flux that

FIGURE 4.2.25 Map delineating forced, mixed, and natural convection — vertical tubes.

FIGURE 4.2.26 Map delineating forced, mixed, and natural convection — horizontal tubes.

would be caused by the external forces alone or by the body forces alone.” The Grashof number is based on the diameter of the tube.

For flows in horizontal tubes, correlations were developed for the mixed convection regime in isothermal tubes by Depew and August (1971) and for uniform heat flux by Morcos and Bergles (1975).

*Uniform Surface Temperature.* Fully developed velocity profile, developing temperature profile:

$$L/d < 28.4 \quad 25 < Gz < 712 \quad 0.7 \times 10^5 < Gr < 9.9 \times 10^5$$

$\mu_s$  = dynamic viscosity, evaluated at the wall temperature

All other properties at the average bulk temperature of the fluid

$$\text{Gz} = \frac{\dot{m}C_p}{kL} \quad \text{Gr} = g\beta\Delta T d^3/\nu^2$$

$$\text{Nu}_d = 1.75 \left[ \text{Gz} + 0.12 \left( \text{GzGr}^{1/3} \text{Pr}^{0.36} \right)^{0.88} \right]^{1/3} \left( \mu_b/\mu_s \right)^{0.14} \quad (4.2.107)$$

*Uniform Heat Flux.* Properties at  $(T_s + T_b)/2$ :  $3 \times 10^4 < \text{Ra} < 10^6$ ,  $4 < \text{Pr} < 175$ ,  $2 < hd^2/(k_w t) < 66$ ,  $k_w$  = tube wall thermal conductivity,  $t$  = tube wall thickness.

$$\text{Gr}_d^* = g\beta d^4 q_w'' / (\nu^2 k) \quad P_w = kd / (k_w t) \quad \text{Ra}_d = g\beta\Delta T d^3 \text{Pr} / \nu^2$$

$$\text{Nu}_d = \left\{ 4.36^2 + \left[ 0.145 \left( \frac{\text{Gr}_d^* \text{Pr}^{1.35}}{P_w^{0.25}} \right)^{0.265} \right]^2 \right\}^{0.5} \quad (4.2.108)$$

In Equation (4.2.107) and (4.2.108) evaluate fluid properties at the arithmetic mean of the bulk and wall temperatures.

## Nomenclature

- $A_s$  — surface area
- $d$  — diameter
- $d_h$  — hydraulic mean diameter
- $f$  — friction factor
- $h$  — convective heat transfer coefficient
- $k$  — fluid thermal conductivity
- $L_e$  — hydrodynamic entrance length
- $L_{e,\text{th}}$  — thermal entrance length
- $\text{Nu}_d$  — Nusselt number
- $\text{Nu}_{ii}$  — Nusselt number with only inner tube heated
- $\text{Nu}_{oo}$  — Nusselt number with only outer tube heated
- $\text{Pr}$  — Prandtl number
- $q''$  — heat flux
- $q_i''$  — heat flux on the inner tube surface
- $q_o''$  — heat flux on the outer tube surface
- $\text{Re}_d$  — Reynolds number ( $\rho\nu d/\mu$ )
- $T_b$  — bulk temperature
- $T_s$  — surface temperature
- $\nu$  — average fluid velocity
- $\mu$  — dynamic viscosity
- $\mu_s$  — dynamic viscosity at surface temperature
- $\rho$  — fluid density

## 4.3 Radiation\*

*Michael F. Modest*

### Nature of Thermal Radiation

All materials continuously emit and absorb radiative energy by lowering or raising their molecular energy levels. This thermal radiative energy may be viewed as consisting of electromagnetic waves or of massless energy parcels, called **photons**. Electromagnetic waves travel through any medium at the speed of light  $c$ , which is  $c_0 = 2.998 \times 10^8$  m/sec in vacuum and approximately the same in most gases such as air and combustion products. These are characterized by their wavelength  $\lambda$  or frequency  $\nu$ , which are related by

$$\nu = c/\lambda \quad (4.3.1)$$

The strength and wavelengths of **emission** and **absorption** depend on the temperature and nature of the material.

The ability of photons to travel unimpeded through vacuum and gases makes thermal radiation the dominant mode of heat transfer in vacuum, low-pressure environments, and outer space applications (due to the near absence of conduction and convection). Its temperature dependence [as given by Equation (4.3.3) below] on the other hand, guarantees that radiative heat transfer is of utmost importance in high-temperature applications (including solar radiation: with the sun being a high-temperature heat source at an effective temperature of  $T_{\text{sun}} = 5762$  K).

When an electromagnetic wave traveling through a gas (or vacuum) strikes the surface of a medium, the wave may be partly or totally reflected, and any nonreflected part will penetrate into the medium. If a wave passes through a medium without any attenuation, the material is called **transparent**. A body with partial attenuation is known as **semitransparent**, and a body through which none of the incoming radiation penetrates is called **opaque**. Most gases are rather transparent to radiation (except for narrow spectral regions, called *absorption bands*), while most solids tend to be strong absorbers for most wavelengths, making them opaque over a distance of a few nanometers (electrical conductors, i.e., metals) to a few micrometers (ceramics, semiconductors), or more (dielectrics).

### Blackbody Radiation

The total amount of radiative energy emitted from a surface into all directions above it is termed **emissive power**; we distinguish between **spectral** (at a given wavelength  $\lambda$ , per unit wavelength) and total (encompassing all wavelengths) emissive power. The magnitude of emissive power depends on wavelength  $\lambda$ , temperature  $T$ , and a surface property, called **emissivity**  $\epsilon$ , which relates the ability of a surface to emit radiative energy to that of an ideal surface, which emits the maximum possible energy (at a given wavelength and temperature). Such an ideal surface is known as a “**blackbody**” or “black surface,” since it absorbs all incoming radiation; i.e., it reflects no radiation and is, therefore, invisible (“black”) to the human eye. The spectral distribution of the emissive power of a black surface is given by **Planck’s law**.

$$E_{b\lambda} = \frac{C_1}{\lambda^5 [e^{C_2/\lambda T} - 1]}, \quad C_1 = 3.7419 \times 10^{-16} \text{ Wm}^2, \quad C_2 = 14,388 \text{ } \mu\text{mK} \quad (4.3.2)$$

where  $C_1$  and  $C_2$  are sometimes called Planck function constants. The total emissive power of a blackbody is given by

\*From Modest, M., Radiative Heat Transfer, 1993; reproduced with permission of MacGraw-Hill, Inc.

$$E_b = \int_0^\infty E_{b\lambda} d\lambda = \sigma T^4, \quad \sigma = 5.670 \times 10^{-8} \text{ W/m}^2\text{K}^4 \tag{4.3.3}$$

with  $\sigma$  known as the Stefan–Boltzmann constant. Figure 4.3.1 shows the spectral solar irradiation that impinges on Earth, which closely resembles the spectrum of a blackbody at 5762 K. The general behavior of Planck’s law is depicted in Figure 4.3.2, together with the fractional emissive power,  $f(\lambda T)$ , defined as

$$f(\lambda T) = \frac{1}{E_b} \int_0^\lambda E_{b\lambda}(\lambda, T) d\lambda \tag{4.3.4}$$

FIGURE 4.3.1 Solar irradiation onto Earth.

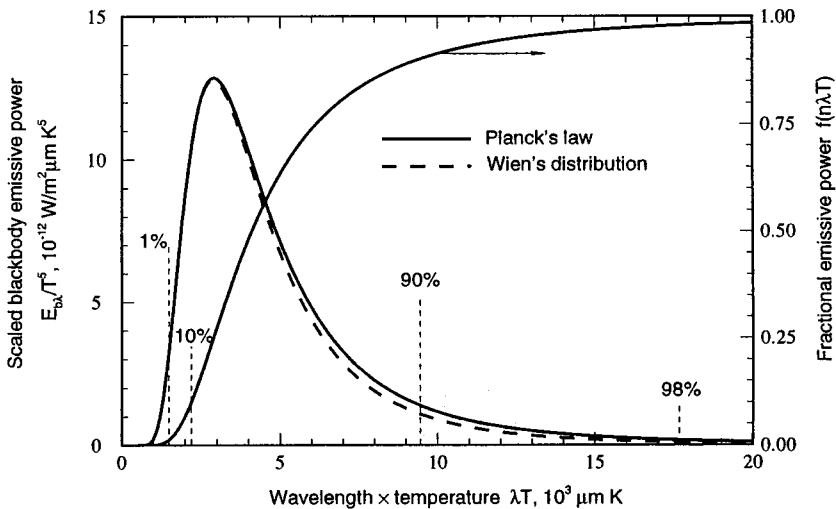

FIGURE 4.3.2 Normalized blackbody emissive power spectrum.

Note that 90% of all blackbody emission takes place at wavelengths of  $\lambda T > 2200 \mu\text{mK}$  and at all wavelengths  $\lambda T < 9400 \mu\text{mK}$ . This implies that — for typical high-temperature heat transfer applications in the range between 1000 and 2000 K — infrared wavelengths in the range  $1 \mu\text{m} < \lambda < 10 \mu\text{m}$  govern the heat transfer rates. For solar applications shorter wavelengths, down to  $\lambda \cong 0.4 \mu\text{m}$  are also important. Also shown in Figure 4.3.2 is Wien’s law:

$$E_{b\lambda} = \frac{C_1}{\lambda^5} e^{-C_2/\lambda T} \quad (4.3.5)$$

which approximates Planck’s law accurately over the part of the spectrum that is important to heat transfer, and that is easier to manipulate mathematically.

### Example 4.3.1

What fraction of total solar emission falls into the visible spectrum (0.4 to 0.7  $\mu\text{m}$ )?

*Solution:* With a solar temperature of 5762 K it follows that for

$$\lambda_1 = 0.4 \mu\text{m}, \quad \lambda_1 T_{\text{sun}} = 0.4 \times 5762 = 2304 \mu\text{mK}$$

and for

$$\lambda_2 = 0.7 \mu\text{m}, \quad \lambda_2 T_{\text{sun}} = 0.7 \times 5762 = 4033 \mu\text{mK}$$

From Figure 4.3.2 we can estimate  $f(\lambda_1 T_{\text{sun}}) \cong 12\%$  and  $f(\lambda_2 T_{\text{sun}}) \cong 48\%$ . Thus, the visible fraction of sunlight is  $48 - 12 \cong 36\%$ : with a bandwidth of only 0.3  $\mu\text{m}$  the human eye responds to approximately 36% of all emitted sunlight!

## Radiative Exchange between Opaque Surfaces

### Radiative Properties of Surfaces

Strictly speaking, the surface of an enclosure wall can only reflect radiative energy and allow a part of it to penetrate into the substrate. A surface cannot absorb or emit photons: attenuation takes place inside the solid, as does emission of radiative energy (with some of the emitted energy escaping through the surface into the enclosure). In practical systems, the thickness of the surface layer over which absorption of **irradiation** from inside the enclosure occurs is very small compared with the overall dimension of an enclosure — usually a few nanometers for metals and a few micrometers for most nonmetals. The same may be said about emission from within the walls that escapes into the enclosure. Thus, in the case of opaque walls it is customary to speak of absorption by and emission from a “surface,” although a thin surface layer is implied. Four fundamental radiative properties are defined:

$$\text{Reflectivity,} \quad \rho \equiv \frac{\text{reflected part of incoming radiation}}{\text{total incoming radiation}} \quad (4.3.6a)$$

$$\text{Absorptivity,} \quad \rho \equiv \frac{\text{absorbed part of incoming radiation}}{\text{total incoming radiation}} \quad (4.3.6b)$$

$$\text{Transmissivity,} \quad \tau \equiv \frac{\text{transmitted part of incoming radiation}}{\text{total incoming radiation}} \quad (4.3.6c)$$

$$\text{Emissivity, } \varepsilon \equiv \frac{\text{energy emitted from a surface}}{\text{energy emitted by a black surface at same temperature}} \quad (4.3.6d)$$

Since all incoming radiation must be reflected, absorbed, or transmitted, it follows that

$$\rho + \alpha + \tau = 1 \quad (4.37)$$

In most practical applications surface layers are thick enough to be opaque ( $\tau = 0$ , leading to  $\rho + \alpha = 1$ ). All four properties may be functions of wavelength, temperature, incoming direction (except emissivity), and outgoing direction (except absorptivity).

*Directional Behavior.* For heat transfer applications, the dependence on incoming direction for absorptivity (as well as  $\rho$  and  $\tau$ ) and outgoing direction for emissivity is generally weak and is commonly neglected; i.e., it is assumed that the surface absorbs and emits **diffusely**. Then, for an opaque surface, for any given wavelength

$$\varepsilon_\lambda = \alpha_\lambda = 1 - \rho_\lambda \quad (4.38)$$

Published values of emissivities are generally either “normal emissivities” (the directional value of  $\varepsilon_\lambda$  in the direction perpendicular to the surface) or “hemispherical emissivities” (an average value over all outgoing directions). The difference between these two values is often smaller than experimental accuracy and/or repeatability.

Reflected energy (due to a single, distinct incoming direction) may leave the surface into a single direction (“specular” reflection, similar to reflection from a mirror for visible light), or the reflection may spread out over all possible outgoing directions. In the extreme case of equal amounts going into all directions, we talk about “diffuse” reflection. Smooth surfaces (as compared with the wavelength of radiation) tend to be specular reflectors, while rough surfaces tend to be more or less diffusely reflecting. Analysis is vastly simplified if diffuse reflections are assumed. Research has shown that — except for some extreme geometries and irradiation conditions susceptible to beam channeling (irradiated open cavities, channels with large aspect ratios) — radiative heat transfer rates are only weakly affected by the directional distribution of reflections. Therefore, it is common practice to carry out radiative heat transfer calculations assuming only diffuse reflections.

*Spectral Dependence.* The emissivity of a surface generally varies strongly and in complex ways with wavelength, depending on the material, surface layer composition, and surface structure (roughness). Therefore, unlike bulk material properties (such as thermal conductivity) the surface emissivity may display significant differences between two ostensibly identical samples, and even for one and the same sample measured at different times (due to surface roughness and contamination). Despite these difficulties, surfaces may be loosely grouped into two categories — metals and nonconductors (dielectrics), and some generalizations can be made.

*Polished Metals.* Smooth, purely metallic surfaces (i.e., without any nonmetallic surface contamination, such as metal oxides) tend to have very low emissivities in the infrared. For many clean metals  $\varepsilon_\lambda < 0.1$  for  $\lambda > 2 \mu\text{m}$ , and spectral as well as temperature dependence are generally well approximated by the proportionality  $\varepsilon_\lambda \propto \sqrt{T/\lambda}$  in the infrared. However, for shorter wavelengths ( $\lambda < 1 \mu\text{m}$ ), emissivity values may become quite substantial, and temperature dependence is usually reversed (decreasing, rather than increasing, with temperature). Typical room temperature behavior of several metals is shown in [Figure 4.3.3](#). Caution needs to be exercised when choosing an emissivity value for a metal surface: unless extraordinary care is taken to keep a polished metal clean (i.e., free from oxidation and/or surface contamination), its emissivity may soon become several times the value of the original, polished specimen (for example, consider the formation of aluminum oxide on top of aluminum, [Figure 4.3.3](#)).

FIGURE 4.3.3 Normal, spectral emissivities for selected materials.

*Ceramics and Refractories.* Smooth ceramics tend to have fairly constant and intermediate emissivity over the near- to mid-infrared, followed by a sharp increase somewhere between 4 and 10  $\mu\text{m}$ . At short wavelengths these materials display strong decreases in emissivity, so that a number of them may appear white to the human eye even though they are fairly black in the infrared. The temperature dependence of the emissivity of ceramics is rather weak; generally a slight increase with temperature is observed in the infrared. The spectral emissivity of a few ceramics is also shown in Figure 4.3.3.

*Other Nonconductors.* The behavior of most electrically nonconducting materials is governed by surface structure, nonhomogeneity, dopants, porosity, flaws, surface films, etc. The emissivity may vary irregularly across the spectrum because of various emission bands, influence of flaws, etc., making any generalization impossible. This irregularity may be exploited to obtain surfaces of desired spectral behavior, so-called selective surfaces. Some selective surfaces (as compared with a common steel) are depicted in Figure 4.3.4. For a solar collector it is desirable to have a high spectral emissivity for short wavelengths  $\lambda < 2.5 \mu\text{m}$  (strong absorption of solar irradiation), and a low value for  $\lambda > 2.5 \mu\text{m}$  (to minimize re-emission from the collector). The opposite is true for a spacecraft radiator panel used to reject heat into space.

It is clear that (1) values of spectral surface emissivity are subject to great uncertainty and (2) only a relatively small range of infrared wavelengths are of importance. Therefore, it is often assumed that the surfaces are “gray”, i.e., the emissivity is constant across (the important fraction of) the spectrum,  $\epsilon_\lambda \neq \epsilon_\lambda(\lambda)$ , since this assumption also vastly simplifies analysis. Table 4.3.1 gives a fairly detailed listing of total emissivities of various materials, defined as

$$\epsilon(T) = \frac{1}{E_b(T)} \int_0^\infty \epsilon_\lambda(\lambda, T) E_{b\lambda}(T) d\lambda \quad (4.3.9)$$

which may be enlisted for a gray analysis.

### View Factors

In many engineering applications the exchange of radiative energy between surfaces is virtually unaffected by the medium that separates them. Such (radiatively) *nonparticipating media* include vacuum as well as monatomic and most diatomic gases (including air) at low to moderate temperature levels (i.e., before ionization and dissociation occurs). Examples include spacecraft heat rejection systems, solar collector systems, radiative space heaters, illumination problems, and so on. It is common practice

FIGURE 4.3.4 Spectral, hemispherical reflectivities of several spectrally selective surfaces.

to simplify the analysis by making the assumption of an *idealized enclosure* and/or of *ideal surface properties*. The greatest simplification arises if all surfaces are black: for such a situation no reflected radiation needs to be accounted for, and all emitted radiation is diffuse (i.e., the radiative energy leaving a surface does not depend on direction). The next level of difficulty arises if surfaces are assumed to be gray, diffuse emitters (and, thus, absorbers) as well as gray, diffuse reflectors. The vast majority of engineering calculations are limited to such ideal surfaces, since, particularly, the effects of nondiffuse reflections are usually weak (see discussion in previous section).

Thermal radiation is generally a long-range phenomenon. This is *always* the case in the absence of a participating medium, since photons will travel unimpeded from surface to surface. Therefore, performing a thermal radiation analysis for one surface implies that all surfaces, no matter how far removed, that can exchange radiative energy with one another must be considered simultaneously. How much energy any two surfaces exchange depends in part on their size, separation, distance, and orientation, leading to geometric functions known as **view factors**, defined as

$$F_{i-j} = \frac{\text{diffuse energy leaving } A_i \text{ directly toward and intercepted by } A_j}{\text{total diffuse energy leaving } A_i} \quad (4.3.10)$$

In order to make a radiative energy balance we always need to consider an entire *enclosure* rather than an infinitesimal control volume (as is normally done for other modes of heat transfer, i.e., conduction or convection). The enclosure must be closed so that irradiation from all possible directions can be accounted for, and the enclosure surfaces must be *opaque* so that all irradiation is accounted for, for each direction. In practice, an incomplete enclosure may be closed by introducing artificial surfaces. An enclosure may be idealized in two ways, as indicated in Figure 4.3.5: by replacing a complex geometric shape with a few simple surfaces, and by assuming surfaces to be isothermal with constant (i.e., average) heat flux values across them. Obviously, the idealized enclosure approaches the real enclosure for sufficiently small isothermal subsurfaces.

Mathematically, the view factor needs to be determined from a double integral, i.e.,

$$F_{i-j} = \frac{1}{A_i} \int_{A_i} \int_{A_j} \frac{\cos\theta_i \cos\theta_j}{\pi S_{ij}^2} dA_j dA_i \quad (4.3.11)$$

where  $\theta_i$  and  $\theta_j$  are the angles between the surface normals on  $A_i$  and  $A_j$ , respectively, and the line (of length  $S_{ij}$ ) connecting two points on the two surfaces. Analytical solutions to Equation (4.3.11) may be found for relatively simple geometries. A few graphical results for important geometries are shown in Figures 4.3.6 to 4.3.8. More-extensive tabulations as well as analytical expressions may be found in textbooks on the subject area (Modest, 1993; Siegel and Howell, 1992) as well as view factor catalogs (Howell, 1982). For nontrivial geometries view factors must be calculated numerically, either (1) by numerical quadrature of the double integral in Equation (4.3.11), or (2) by converting Equation (4.3.11) into a double-line integral, followed by numerical quadrature, or (3) by a Monte Carlo method (statistical sampling and tracing of selected light rays).

*View Factor Algebra.* For simple geometries analytical values can often be found by expressing the desired view factor in terms of other, known ones. This method is known as *view factor algebra*, by manipulating the two relations,

$$\text{Reciprocity rule:} \quad A_i F_{i-j} = A_j F_{j-i} \quad (4.3.12)$$

FIGURE 4.3.6 View factor between parallel, coaxial disks of unequal radius.

FIGURE 4.3.7 View factor between identical, parallel, directly opposed rectangles.

FIGURE 4.3.8 View factor between perpendicular rectangles with common edge.

Summation rule: 
$$\sum_{j=1}^N F_{i-j} = 1, \quad i = 1, N \tag{4.3.13}$$

assuming that the (closed) configuration consists of  $N$  surfaces. The reciprocity rule follows immediately from Equation (4.3.11), while the summation rule simply states that the fractional energies leaving surface  $A_i$  must add up to a whole.

**Example 4.3.2**

Assuming the view factor for a finite corner, as shown in Figure 4.3.8 is known, determine the view factor  $F_{3-4}$ , between the two perpendicular strips as shown in Figure 4.3.9.

FIGURE 4.3.9 Configuration for Example 4.3.2 (strips on a corner piece).

*Solution.* From the definition of the view factor, and since the energy traveling to  $A_4$  is the energy going to  $A_2$  and  $A_4$  minus the one going to  $A_2$ , it follows that

$$F_{3-4} = F_{3-(2+4)} - F_{3-2}$$

and, using reciprocity,

$$F_{3-4} = \frac{1}{A_3} \left[ (A_2 + A_4) F_{(2+4)-3} - A_2 F_{2-3} \right]$$

Similarly, we find

$$F_{3-4} = \frac{A_2 + A_4}{A_3} \left( F_{(2+4)-(1+3)} - F_{(2+4)-1} \right) - \frac{A_2}{A_3} \left( F_{2-(1+3)} - F_{2-1} \right)$$

All view factors on the right-hand side are corner pieces and, thus, are known from [Figure 4.3.8](#).

*Crossed-Strings Method.* A special type of view factor algebra may be used to determine all the view factors in long enclosures with constant cross section. The method is called the crossed-strings method since the view factors can be determined experimentally with four pins, a roll of string, and a yardstick. Consider the configuration in [Figure 4.3.10](#), which shows the cross section of an infinitely long enclosure, continuing into and out of the plane of the figure. Repeatedly applying reciprocity and summation rules allows the evaluation of  $F_{1-2}$  as

$$F_{1-2} = \frac{(A_{bc} + A_{ad}) - (A_{ac} + A_{bd})}{2A_1} \tag{4.3.14}$$

**FIGURE 4.3.10** The crossed-strings method for arbitrary two-dimensional configurations.

where  $A_{ab}$  is the area (per unit depth) defined by the length of the string between points  $a$  and  $b$ , etc. This formula is easily memorized by looking at the configuration between any two surfaces as a generalized "rectangle," consisting of  $A_1$ ,  $A_2$ , and the two sides  $A_{ac}$  and  $A_{bd}$ . Then

$$F_{1-2} = \frac{\text{diagonals} - \text{sides}}{2 \times \text{originating area}} \tag{4.3.15}$$

**Example 4.3.3**

Calculate  $F_{1-2}$  for the configuration shown in [Figure 4.3.11](#).

*Solution.* From the figure it is obvious that

$$s_1^2 = (c - d \cos \alpha)^2 + d^2 \sin^2 \alpha = c^2 + d^2 - 2cd \cos \alpha$$

**FIGURE 4.3.11** Infinitely long wedge-shaped groove for Example 4.3.3.

Similarly, we have

$$s_2^2 = (a + c)^2 + (b + d)^2 - 2(a + c)(b + d)\cos\alpha$$

$$d_1^2 = (a + c)^2 + d^2 - 2(a + c)d\cos\alpha$$

$$d_2^2 = c^2 + (b + d)^2 - 2c(b + d)\cos\alpha$$

and

$$F_{1-2} = \frac{d_1 + d_2 - (s_1 + s_2)}{2a}$$

### Radiative Exchange between Opaque Surfaces (Net Radiation Method)

Consider an enclosure consisting of  $N$  opaque surfaces. The enclosure is closed, or, if not, no surface external to the surface reflects or emits radiation into the enclosure (i.e., the open configuration may be artificially closed by replacing openings with cold, black surfaces); any external radiation entering the enclosure is dealt with individually for each surface [see Equation (4.3.17) below]. All surfaces are assumed to be gray, and emit and reflect diffusely. Traditionally, the **radiosity**  $J$  of the surfaces is determined, defined as the total diffuse radiative energy leaving a surface (by emission and reflection),

$$J_i = \varepsilon_i E_{bi} + \rho_i H_i, \quad i = 1, N \quad (4.3.16)$$

where  $H_i$  is the incoming radiative flux (irradiation) onto surface  $A_i$ . This leads to  $N$  simultaneous equations for the unknown radiosities, specifically,

$$J_i = \varepsilon_i E_{bi} + (1 - \varepsilon_i) \left[ \sum_{j=1}^N J_j F_{i-j} + H_{oi} \right] \quad (4.3.17a)$$

or

$$J_i = q_i + \sum_{j=1}^N J_j F_{i-j} + H_{oi} \quad (4.3.17b)$$

depending on whether surface temperature or surface flux are known on surface  $A_i$ . In Equation (4.3.17)  $H_{oi}$  is irradiation on surface  $A_i$  from outside the enclosure, if any;  $H_{oi}$  is always zero for closed configurations, but is useful in the presence of external light sources (such as solar energy, lasers, etc.). The

radiosity neither is a useful quantity to determine, nor is there a need to determine it. Eliminating the radiosities from Equations (4.3.17a) and (4.3.17b) leads to  $N$  simultaneous equations in temperature ( $E_{bi}$ ) and heat flux ( $q_i$ ):

$$\frac{q_i}{\epsilon_i} - \sum_{j=1}^N \left( \frac{1}{\epsilon_j} - 1 \right) F_{i-j} q_j + H_{oi} = E_{bi} - \sum_{j=1}^N F_{i-j} E_{bj} \quad (4.3.18)$$

Note that no artificial closing surfaces ( $j > N$ ) appear in Equation (4.3.18), since for these surfaces  $\epsilon_j = 1$  and  $E_{bj} = 0$ . Thus, such closing surfaces may simply be ignored in the analysis.

Since Equation (4.3.18) is a set of  $N$  equations, this requires that  $N$  values of emissive power  $E_{bi}$  and/or flux  $q_i$  must be given as boundary conditions, in order to solve for the remaining  $N$  unknowns. For computer calculations Equation (4.3.18) may be recast in matrix form

$$\mathbf{C} \cdot \mathbf{q} = \mathbf{A} \cdot \mathbf{e}_b - \mathbf{h}_o \quad (4.3.19a)$$

where

$$C_{ij} = \frac{\delta_{ij}}{\epsilon_j} - \left( \frac{1}{\epsilon_j} - 1 \right) F_{i-j} \quad (4.3.19b)$$

$$A_{ij} = \delta_{ij} - F_{i-j} \quad (4.3.19c)$$

$\delta_{ij}$  is Kronecker's delta, i.e.,

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases} \quad (4.3.20)$$

and  $\mathbf{q}$ ,  $\mathbf{e}_b$ , and  $\mathbf{h}_o$  are vectors of the surface heat fluxes  $q_i$ , emissive powers  $E_{bi}$ , and external irradiations  $H_{oi}$  (if any). For example, if the temperatures are given for all the surfaces, and the heat fluxes are to be determined, Equation (4.3.19) is solved by matrix inversion, and

$$\mathbf{q} = (\mathbf{C}^{-1} \cdot \mathbf{A}) \cdot \mathbf{e}_b - (\mathbf{C}^{-1} \cdot \mathbf{h}_o) \quad (4.3.21)$$

#### Example 4.3.4

A right-angled groove, consisting of two long black surfaces of width  $a$ , is exposed to solar radiation  $q_{\text{sol}}$  (Figure 4.3.12). The entire groove surface is kept isothermal at temperature  $T$ . Determine the net radiative heat transfer rate from the groove.

*Solution.* We may employ Equation (4.3.19). However, the enclosure is not closed, and we must close it artificially. We note that any radiation leaving the cavity will not come back (barring any reflection from other surfaces nearby). Thus, our artificial surface should be black. We also assume that, with the exception of the (parallel) solar irradiation, no external radiation enters the cavity. Since the solar irradiation is best treated separately through the external irradiation term  $H_o$ , our artificial surface is nonemitting. Both criteria are satisfied by covering the groove with a black surface at 0 K ( $A_3$ ). Even though we now have three surfaces, the last one does not really appear in Equation (4.3.18) (since  $E_{b3} = 0$  and  $1/\epsilon_3 - 1 = 0$ ):

FIGURE 4.3.12 Right-angled groove exposed to solar irradiation, Example 4.3.4.

$$q_1 = E_{b1} - F_{1-2}E_{b2} - H_{o1} = \sigma T^4(1 - F_{1-2}) - q_{sol} \cos \alpha$$

$$q_2 = E_{b2} - F_{2-1}E_{b1} - H_{o2} = \sigma T^4(1 - F_{2-1}) - q_{sol} \sin \alpha$$

From the crossed-strings method, Equation (4.3.15), we find

$$F_{1-2} = \frac{a + a - (\sqrt{2}a + 0)}{2a} = \frac{1}{2}(2 - \sqrt{2}) = 0.293 = F_{2-1}$$

and

$$Q' = a(q_1 + q_2) = a[\sqrt{2}\sigma T^4 - q_{sol}(\cos \alpha + \sin \alpha)]$$

**Example 4.3.5**

Consider a very long duct as shown in Figure 4.3.13. The duct is 30 × 40 cm in cross section, and all surfaces are covered with gray, diffuse surface material. Top and bottom walls are at  $T_1 = T_3 = 1000$  K with  $\epsilon_1 = \epsilon_3 = 0.3$ , while the side walls are at  $T_2 = T_4 = 600$  K with  $\epsilon_2 = \epsilon_4 = 0.8$  as shown. Determine the net radiative heat transfer rates for each surface.

FIGURE 4.3.13 Two-dimensional gray, diffuse duct for Example 4.3.5.

*Solution.* Using Equation (4.3.18) for  $i = 1$  and  $i = 2$  and noting that  $F_{1-2} = F_{1-4}$  and  $F_{2-1} = F_{2-3}$ ,

$$i = 1: \quad \frac{q_1}{\varepsilon_1} - 2 \left( \frac{1}{\varepsilon_2} - 1 \right) F_{1-2} q_2 - \left( \frac{1}{\varepsilon_1} - 1 \right) F_{1-3} q_1 = 2 F_{1-2} (E_{b1} - E_{b2})$$

$$i = 2: \quad \frac{q_2}{\varepsilon_2} - 2 \left( \frac{1}{\varepsilon_1} - 1 \right) F_{2-1} q_1 - \left( \frac{1}{\varepsilon_2} - 1 \right) F_{2-4} q_2 = 2 F_{2-1} (E_{b2} - E_{b1})$$

The view factors are readily evaluated from the crossed-strings method as  $F_{1-2} = 1/4$ ,  $F_{1-3} = 1 - 2F_{1-2} = 1/2$ ,  $F_{2-1} = 4/3$ ,  $F_{1-2} = 1/3$  and  $F_{2-4} = 1 - 2F_{2-1} = 1/3$ . Substituting these, as well as emissivity values, into the relations reduces them to the simpler form of

$$\left[ \frac{1}{0.3} - \left( \frac{1}{0.3} - 1 \right) \frac{1}{2} \right] q_1 - 2 \left( \frac{1}{0.8} - 1 \right) \frac{1}{4} q_2 = 2 \times \frac{1}{4} (E_{b1} - E_{b2})$$

$$-2 \left( \frac{1}{0.3} - 1 \right) \frac{1}{3} q_1 + \left[ \frac{1}{0.8} - \left( \frac{1}{0.8} - 1 \right) \right] \frac{1}{3} q_2 = 2 \times \frac{1}{3} (E_{b2} - E_{b1})$$

or

$$\frac{13}{6} q_1 - \frac{1}{8} q_2 = \frac{1}{2} (E_{b1} - E_{b2})$$

$$-\frac{14}{9} q_1 + \frac{7}{6} q_2 = -\frac{2}{3} (E_{b1} - E_{b2})$$

Thus,

$$\left( \frac{13}{6} \times \frac{7}{6} - \frac{14}{9} \times \frac{1}{8} \right) q_1 = \left( \frac{1}{2} \times \frac{7}{6} - \frac{2}{3} \times \frac{1}{8} \right) (E_{b1} - E_{b2})$$

$$q_1 = \frac{3}{7} \times \frac{1}{2} (E_{b1} - E_{b2}) = \frac{3}{14} \sigma (T_1^4 - T_2^4)$$

and

$$\left( -\frac{1}{8} \times \frac{14}{9} + \frac{7}{6} \times \frac{13}{6} \right) q_2 = \left( \frac{1}{2} \times \frac{14}{9} - \frac{2}{3} \times \frac{13}{6} \right) (E_{b1} - E_{b2})$$

$$q_2 = \frac{3}{7} \times \frac{2}{3} (E_{b1} - E_{b2}) = -\frac{2}{7} \sigma (T_1^4 - T_2^4)$$

Finally, substituting values for temperatures,

$$Q'_1 = 0.4 \text{ m} \times \frac{3}{14} \times 5.670 \times 10^{-8} \frac{\text{W}}{\text{m}^2 \text{K}^4} (1000^4 - 600^4) \text{ K}^4 = 4230 \text{ W/m}$$

$$Q'_2 = -0.3 \text{ m} \times \frac{2}{7} \times 5.670 \times 10^{-8} \frac{\text{W}}{\text{m}^2\text{K}^4} (1000^4 - 600^4) \text{ K}^4 = -4230 \text{ W/m}$$

Note that, for conservation of energy, both heat transfer rates must add up to zero.

*Small Body Inside Isothermal Enclosure.* An especially simple — but important — case occurs if a small, convex body  $A_1$  (i.e., a surface that cannot “see” itself, or  $F_{1-1} = 0$ ) is totally enclosed by an isothermal enclosure  $A_2$ . Then, with  $N = 2$  and  $F_{1-2} = 1$ , Equation (4.3.18) reduces to

$$q_1 = \frac{E_{b1} - E_{b2}}{\frac{1}{\epsilon_1} + \frac{A_1}{A_2} \left( \frac{1}{\epsilon_2} - 1 \right)} = \frac{\sigma(T_1^4 - T_2^4)}{\frac{1}{\epsilon_1} + \frac{A_1}{A_2} \left( \frac{1}{\epsilon_2} - 1 \right)} \tag{4.3.22}$$

If the enclosure is large, i.e.,  $A_1 \ll A_2$ , then Equation (4.3.22) simplifies further to

$$q_1 = \epsilon_1 \sigma(T_1^4 - T_2^4) \tag{4.3.23}$$

*Radiation Shields.* If it is desired to minimize radiative heat transfer between two surfaces, it is common practice to place one or more radiation shields between them (usually thin metallic sheets of low emissivity). If two surfaces  $A_i$  and  $A_j$  are close together, so that  $A_i \cong A_j$  and  $F_{i-j} \cong 1$ , then the radiative exchange between them is, from Equation (4.3.22),

$$q = \frac{E_{bi} - E_{bj}}{R_{ij}}, \quad R_{ij} = \frac{1}{\epsilon_i} + \frac{1}{\epsilon_j} - 1 \tag{4.3.24}$$

**FIGURE 4.3.14** Placement of radiation shields between two large, parallel plates.

where  $R_{ij}$  is termed the *radiative resistance*. Equation (4.3.24) is seen to be analogous to an electrical circuit with “current”  $q$  and “voltage potential”  $E_{bi} - E_{bj}$ . Therefore, expressing radiative fluxes in terms of radiative resistances is commonly known as **network analogy**. The network analogy is a very powerful method of solving one-dimensional problems (i.e., whenever only two isothermal surfaces see each other, such as infinite parallel plates, or when one surface totally encloses another). Consider, for example, two large parallel plates,  $A_1$  and  $A_N$ , separated by  $N - 2$  radiation shields, as shown in [Figure 4.3.14](#). Let each shield have an emissivity  $\epsilon_s$  on both sides. Then, by applying Equation (4.3.24) to any two consecutive surfaces and using the fact that  $q$  remains constant throughout the gap,

$$q = \frac{E_{b1} - E_{b2}}{R_{12}} = \dots = \frac{E_{bk-1} - E_{bk}}{R_{k-1,k}} = \dots = \frac{E_{bN-1} - E_{bN}}{R_{N-1,N}} = \frac{E_{b1} - E_{bN}}{\sum_{j=2}^N R_{j-1,j}} \quad (4.3.25)$$

where

$$R_{j-1,j} = \frac{1}{\epsilon_{j-1}} + \frac{1}{\epsilon_j} - 1 \quad (4.3.26)$$

and, if  $\epsilon_2 = \epsilon_3 = \dots = \epsilon_{N-1} = \epsilon_s$ ,

$$\sum_{j=2}^N R_{j-1,j} = \frac{1}{\epsilon_1} + \frac{1}{\epsilon_N} - 1 + (N-2) \left( \frac{2}{\epsilon_s} - 1 \right) \quad (4.3.27)$$

Equations (4.3.24) to (4.3.27) are also valid for concentric cylinders, concentric spheres, and similar configurations, as long as  $r_N - r_1 \ll r_1$ . Also, the relations are readily extended to shields with nonidentical emissivities.

While the network analogy can (and has been) applied to configurations with more than two surfaces seeing each other, this leads to very complicated circuits (since there is one resistance between any two surfaces). For such problems the network analogy is not recommended, and the net radiation method, Equation (4.3.18), should be employed.

## Radiative Exchange within Participating Media

In many high-temperature applications, when radiative heat transfer is important, the medium between surfaces is not transparent, but is “participating,” i.e., it absorbs, emits, and (possibly) scatters radiation. In a typical combustion process this interaction results in (1) continuum radiation due to tiny, burning soot particles (of dimension  $<1 \mu\text{m}$ ) and also due to larger suspended particles, such as coal particles, oil droplets, fly ash; (2) banded radiation in the infrared due to emission and absorption by molecular gaseous combustion products, mostly water vapor and carbon dioxide; and (3) chemiluminescence due to the combustion reaction itself. While chemiluminescence may normally be neglected, particulates as well as gas radiation generally must be accounted for.

### Radiative Properties of Molecular Gases

When a photon (or an electromagnetic wave) interacts with a gas molecule, it may be absorbed, raising the energy level of the molecule. Conversely, a gas molecule may spontaneously lower its energy level by the emission of an appropriate photon. This leads to large numbers of narrow spectral lines, which partially overlap and together form so-called vibration-rotation bands. As such, gases tend to be transparent over most of the spectrum, but may be almost opaque over the spectral range of a band. The **absorption coefficient**  $\kappa_\lambda$  is defined as a measure of how strongly radiation is absorbed or emitted along a path of length,  $L$ , leading to the spectral absorptivity and emissivity for this path, or

$$\alpha_\lambda = \epsilon_\lambda = 1 - e^{-\kappa_\lambda L} \quad (4.3.28)$$

Although gases are distinctly nongray, for simple heat transfer calculations we often need to determine the total emissivity for an isothermal path (compare Equation (4.3.9))

$$\epsilon = \frac{1}{E_b} \int_0^\infty (1 - e^{-\kappa_\lambda L}) E_{b\lambda}(T_g) d\lambda \quad (4.3.29)$$

For a mixture of gases the total emissivity is a function of path length  $L$ , gas temperature  $T_g$ , partial pressure(s) of the absorbing gas(es)  $p_a$ , and total pressure  $p$ . For the — in combustion applications most important — mixture of nitrogen with water vapor and/or carbon dioxide, the total emissivity may be calculated from Leckner.<sup>8</sup> First, the individual emissivities for water vapor and carbon dioxide, respectively, are calculated separately from

$$\epsilon(p_a L, p, T_g) = \epsilon_0(p_a L, T_g) \left( \frac{\epsilon}{\epsilon_0} \right) (p_a L, p, T_g) \tag{4.3.30a}$$

$$\left( \frac{\epsilon}{\epsilon_0} \right) (p_a L, p, T_g) = \left[ 1 - \frac{(a-1)(1-P_E)}{a+b-1+P_E} \exp \left( -c \left[ \log_{10} \left( \frac{(p_a L)_m}{p_a L} \right) \right]^2 \right) \right] \tag{4.3.30b}$$

$$\epsilon_0(p_a L, T_g) = \exp \left[ \sum_{i=0}^N \sum_{j=0}^N c_{ji} \left( \frac{T_g}{T_0} \right)^j \left( \log_{10} \frac{p_a L}{(p_a L)_0} \right)^i \right] \tag{4.3.30c}$$

Here  $\epsilon_0$  is the total emissivity of a reference state, i.e., for the case of  $p = 1$  bar and  $p_a \rightarrow 0$  (but  $p_a L > 0$ ), and the correlation constants  $a, b, c, c_{ji}, P_E, (p_a L)_0, (p_a L)_m$ , and  $T_0$  are given in Table 4.3.2 for water vapor and carbon dioxide. (For convenience, plots of  $\epsilon_0$  are given in Figures 4.3.15 for CO<sub>2</sub> and 4.3.16 for H<sub>2</sub>O.) The total emissivity of a mixture of nitrogen with both water vapor and carbon dioxide is calculated from

$$\epsilon_{\text{CO}_2+\text{H}_2\text{O}} = \epsilon_{\text{CO}_2} + \epsilon_{\text{H}_2\text{O}} - \Delta\epsilon \tag{4.3.31}$$

**TABLE 4.3.2 Correlation Constants for the Determination of the Total Emissivity for Water Vapor and Carbon Dioxide**

Gas	Water Vapor			Carbon Dioxide			
$M, N$	2,2			2,3			
$c_{00} \dots c_{N1}$	-2.2118	-1.1987	0.035596	-3.9893	2.7669	-2.1081	0.39163
$\vdots \dots \vdots$	0.85667	0.93048	-0.14391	1.2710	-1.1090	1.0195	-0.21897
$c_{0M} \dots c_{NM}$	-0.10838	-0.17156	0.045915	-0.23678	0.19731	-0.19544	0.044644
$P_E$	$(p + 2.56 p_a / \sqrt{t}) / p_0$			$(p + 0.28 p_a) / p_0$			
$(p_a L)_m / (p_a L)_0$	13.2 $t^2$			0.054/ $t^2$ , $t < 0.7$ 0.225/ $t^2$ , $t > 0.7$			
$a$	2.144, $t < 0.75$ 1.88 - 2.053 $\log_{10} t$ , $t > 0.75$			1 + 0.1/ $t^{1.45}$			
$b$	1.10/ $t^{1.4}$			0.23			
$c$	0.5			1.47			

Note:  $T_0 = 1000$  K,  $p_0 = 1$  bar,  $t = T/T_0$ ,  $(p_a L)_0 = 1$  bar cm.

$$\Delta\varepsilon = \left( \frac{\zeta}{10.7 + 101\zeta} - 0.0089\zeta^{10.4} \right) \left( \log_{10} \frac{(p_{H_2O} + p_{CO_2})L}{(p_a L)_0} \right)^{2.76} \tag{4.3.32}$$

$$\zeta = \frac{p_{H_2O}}{p_{H_2O} + p_{CO_2}}$$

**FIGURE 4.3.15** Total emissivity of water vapor at reference state (total gas pressure  $p = 1$  bar, partial pressure of  $H_2O$   $p_a \rightarrow 0$ ).

where the  $\Delta\varepsilon$  compensates for overlap effects between  $H_2O$  and  $CO_2$  bands, and the  $\varepsilon_{CO_2}$  and  $\varepsilon_{H_2O}$  are calculated from Equation (4.3.30).

If radiation emitted externally to the gas (for example, by emission from an adjacent wall at temperature  $T_s$ ) travels through the gas, the total amount absorbed by the gas is of interest. This leads to the absorptivity of a gas path at  $T_g$  with a source at  $T_s$ :

$$\alpha(p_a L, p, T_g, T_s) = \frac{1}{E_b(T_s)} \int_0^\infty \left( 1 - e^{-\kappa_\lambda(T_g)L} \right) E_{b\lambda}(T_s) d\lambda \tag{4.3.33}$$

which for water vapor or carbon dioxide may be estimated from

$$\alpha(p_a L, p, T_g, T_s) = \left( \frac{T_g}{T_s} \right)^{1/2} \varepsilon \left( p_a L \frac{T_s}{T_g}, p, T_s \right) \tag{4.3.34}$$

**FIGURE 4.3.16** Total emissivity of carbon dioxide at reference state (total gas pressure  $p = 1$  bar, partial pressure of  $\text{CO}_2$   $p_a \rightarrow 0$ ).

where  $\epsilon$  is the emissivity calculated from Equation (4.3.30) evaluated at the temperature of the surface  $T_s$ , and using an adjusted pressure path length,  $p_a L T_s / T_g$ . For mixtures of water vapor and carbon dioxide band overlap is again accounted for by taking

$$\alpha_{\text{CO}_2+\text{H}_2\text{O}} = \alpha_{\text{CO}_2} + \alpha_{\text{H}_2\text{O}} - \Delta\epsilon \tag{4.3.35}$$

with  $\Delta\epsilon$  evaluated for a pressure path length of  $p_a L T_s / T_g$ .

**Example 4.3.6**

Consider a layer of a gas mixture at 1000 K and 5 bar that consists of 10% carbon dioxide and 70% nitrogen. What is its emissivity for a path length of 1.76 m, and its absorptivity (for the same path) if the layer is irradiated by a source at 1500 K?

*Solution.* First we calculate the total emissivity of the  $\text{CO}_2$  at the reference state ( $p = 1$  bar,  $p_a \rightarrow 0$ ) for a length of 1.76 m from Equation (4.3.30c) or Figure 4.3.15. With

$$T_g = 1000 \text{ K} = 727^\circ\text{C} \quad \text{and} \quad p_a L = 0.1 \times 5 \text{ bar} \times 1.76 \text{ m} = 88 \text{ bar cm}$$

one gets, interpolating Figure 4.3.15,  $\epsilon_0 \cong 0.15$ . The correction factor in Equation (4.3.30b) is calculated from Table 4.3.2 with  $P_E = 5 + 0.28 \times 0.5 = 5.14$ ,  $a = 1.1$ ,  $b = 0.23$ ,  $c = 1.47$ , and  $(p_a L)_m = 0.225$  bar cm. Thus,

$$\frac{\epsilon}{\epsilon_0} = 1 - \frac{0.1 \times (-4.14)}{0.33 + 5.14} \exp\left(-1.47 \left(\log_{10} \frac{0.225}{88}\right)^2\right) \cong 1$$

and

$$\varepsilon \cong 0.15$$

To calculate the absorptivity  $\varepsilon_0$  must be found for a temperature of

$$T_s = 1500 \text{ K} = 1227^\circ\text{C} \quad \text{and} \quad p_a L \frac{T_s}{T_g} = 88 \times 1500/1000 = 132 \text{ bar cm}$$

From Figure 4.3.15 it follows that  $\varepsilon_0 \cong 0.15$  again and, with  $\varepsilon/\varepsilon_0$  pretty much unchanged, from Equation (4.3.34),

$$\alpha \cong \left( \frac{1000}{1500} \right)^{1/2} \times 0.15 \times 1.00 = 0.122$$

### Radiative Properties of Particle Clouds

Nearly all flames are visible to the human eye and are, therefore, called *luminous* (sending out light). Apparently, there is some radiative emission from within the flame at wavelengths where there are no vibration-rotation bands for any combustion gases. This luminous emission is known today to come from tiny *char* (almost pure carbon) particles, call *soot*, which are generated during the combustion process. The “dirtier” the flame is (i.e., the higher the soot content), the more luminous it is.

*Radiative Properties of Soot.* Soot particles are produced in fuel-rich flames, or fuel-rich parts of flames, as a result of incomplete combustion of hydrocarbon fuels. As shown by electron microscopy, soot particles are generally small and spherical, ranging in size between approximately 50 and 800 Å (0.005 to 0.08 μm), and up to about 3000 Å in extreme cases. While mostly spherical in shape, soot particles may also appear in agglomerated chunks and even as long agglomerated filaments. It has been determined experimentally in typical diffusion flames of hydrocarbon fuels that the volume percentage of soot generally lies in the range between 10<sup>-4</sup> to 10<sup>-6</sup>%.

Since soot particles are very small, they are generally at the same temperature as the flame and, therefore, strongly emit thermal radiation in a continuous spectrum over the infrared region. Experiments have shown that soot emission often is considerably stronger than the emission from the combustion gases.

For a simplified heat transfer analysis it is desirable to use suitably defined mean absorption coefficients and emissivities. If the soot volume fraction  $f_v$  is known as well as an appropriate spectral average of the complex index of refraction of the soot,  $m = n - ik$ , one may approximate the spectral absorption coefficient by (Felske and Tien, 1977).

$$\kappa_\lambda = C_0 \frac{f_v}{\lambda} \quad C_0 = \frac{36\pi nk}{(n^2 - k^2 + 2)^2 + 4n^2 k^2} \quad (4.3.36)$$

and a total, or spectral-average value may be taken as

$$\kappa_m = 3.72 f_v C_0 T / C_2 \quad (4.3.37)$$

where  $C_2 = 1.4388 \text{ mK}$  is the second Planck function constant. Substituting Equation (4.3.37) into Equation (4.3.29) gives a total soot cloud emissivity of

$$\varepsilon(f_v TL) = 1 - e^{-\kappa_m L} = 1 - e^{-3.72 C_0 f_v TL / C_2} \quad (4.3.38)$$

*Pulverized Coal and Fly Ash Dispersions.* To calculate the radiative properties of arbitrary size distributions of coal and ash particles, one must have knowledge of their complex index of refraction as a function of wavelength and temperature. Data for carbon and different types of coal indicate that its real part,  $n$ , varies little over the infrared and is relatively insensitive to the type of coal (e.g., anthracite, lignite, bituminous), while the absorptive index,  $k$ , may vary strongly over the spectrum and from coal to coal. If the number and sizes of particles are known and if a suitable average value for the complex index of refraction can be found, then the spectral absorption coefficient of the dispersion may be estimated by a correlation given by Buckius and Hwang, 1980. Substitution into Equation (4.3.29) can then provide an estimate of the total emissivity. If both soot as well as larger particles are present in the dispersion, the absorption coefficients of all constituents must be added before applying Equation (4.3.29).

*Mixtures of Molecular Gases and Particulates.* To determine the total emissivity of a mixture it is generally necessary to find the spectral absorption coefficient  $\kappa_\lambda$  of the mixture (i.e., the sum of the absorption coefficient of all contributors), followed by numerical integration of Equation (4.3.29). However, since the molecular gases tend to absorb only over a small part of the spectrum, to some degree of accuracy

$$\epsilon_{\text{mix}} \cong \epsilon_{\text{gas}} + \epsilon_{\text{particulates}} \quad (4.3.39)$$

Equation (4.3.39) gives an upper estimate since overlap effects result in lower emissivity (compare Equation (4.3.31) for gas mixtures).

### Heat Exchange in the Presence of a Participating Medium

The calculation of radiative heat transfer rates through an enclosure filled with a participating medium is a challenging task, to say the least. High-accuracy calculations are rare and a topic of ongoing research. There are, however, several simplistic models available that allow the estimation of radiative heat transfer rates, and relatively accurate calculations for some simple cases.

*Diffusion Approximation.* A medium through which a photon can only travel a short distance without being absorbed is known as *optically thick*. Mathematically, this implies that  $\kappa_\lambda L \gg 1$  for a characteristic dimension  $L$  across which the temperature does not vary substantially. For such an optically thick, nonscattering medium the spectral radiative flux may be calculated from

$$\mathbf{q}_\lambda = -\frac{4}{3\kappa_\lambda} \nabla E_{b\lambda} \quad (4.3.40)$$

similar to Fourier's diffusion law for heat conduction. Note that a medium may be optically thick at some wavelengths, but thin ( $\kappa_\lambda L \ll 1$ ) at others (e.g., molecular gases!). For a medium that is optically thick for all wavelengths, Equation (4.3.40) may be integrated over the spectrum, yielding the total radiative flux

$$\mathbf{q} = -\frac{4}{3\kappa_R} \nabla E_b = -\frac{4}{3\kappa_R} \nabla(\sigma T^4) = -\frac{16\sigma T^3}{3\kappa_R} \nabla T \quad (4.3.41)$$

where  $\kappa_R$  is the suitably averaged absorption coefficient, termed the *Rosseland-mean absorption coefficient*. For a cloud of soot particles,  $\kappa_R \cong \kappa_m$  from Equation (4.3.37) is a reasonable approximation. Equation (4.3.41) may be rewritten by defining a "radiative conductivity"  $k_R$ ,

$$\mathbf{q} = -k_R \nabla T \quad k_R = \frac{16\sigma T^3}{3\kappa_R} \quad (4.3.42)$$

This form shows that the diffusion approximation is mathematically equivalent to conductive heat transfer with a (strongly) temperature-dependent conductivity.

*Note:* More accurate calculations show that, in the absence of other modes of heat transfer (conduction, convection), there is generally a temperature discontinuity near the boundaries ( $T_{\text{surface}} \neq T_{\text{adjacent medium}}$ ), and, unless boundary conditions that allow such temperature discontinuities are chosen, the diffusion approximation will do very poorly in the vicinity of bounding surfaces.

### Example 4.3.7

A soot cloud is contained between two walls at  $T_1 = 1000$  K and  $T_2 = 2000$  K, spaced 1 m apart. The effective absorption coefficient of the medium is  $\kappa_R = 10$  m<sup>-1</sup> and the effective thermal conductivity is  $k_c = 0.1$  W/mK. Estimate the total heat flux between the plates (ignoring convection effects).

*Solution.* For simplicity we may want to assume a constant total conductivity  $k = k_c + k_R$ , leading to

$$q = -k \frac{dT}{dx} = k \frac{T_2 - T_1}{L}$$

where  $k_R$  must be evaluated at some effective temperature. Choosing, based on its temperature dependence,

$$k_R \equiv \frac{8\sigma}{3\kappa_R} (T_1^3 + T_2^3) = \frac{8 \times 5.670 \times 10^{-8} \text{ W/m}^2\text{K}^4}{3 \times 10/\text{m}} (1000^3 + 2000^3) \text{ K}^3 = 136 \frac{\text{W}}{\text{mK}}$$

gives

$$q = (0.1 + 136) \frac{2000 - 1000}{1} \frac{\text{W}}{\text{m}^2} = 136 \frac{\text{kW}}{\text{m}^2\text{K}}$$

Note that (1) conduction is negligible in this example and (2) the surface emissivities do not enter the diffusion approximation. While a more accurate answer can be obtained by taking the temperature dependence of  $k_R$  into account, the method itself should be understood as a relatively crude approximation.

*Mean Beam Length Method.* Relatively accurate yet simple heat transfer calculations can be carried out if an isothermal, absorbing–emitting, but not scattering medium is contained in an isothermal, black-walled enclosure. While these conditions are, of course, very restrictive, they are met to some degree by conditions inside furnaces. For such cases the local heat flux on a point of the surface may be calculated from

$$q = [1 - \alpha(L_m)] E_{bw} - \epsilon(L_m) E_{bg} \quad (4.3.43)$$

where  $E_{bw}$  and  $E_{bg}$  are blackbody emissive powers for the walls and medium (gas and/or particulates), respectively, and  $\alpha(L_m)$  and  $\epsilon(L_m)$  are the total absorptivity and emissivity of the medium for a path length  $L_m$  through the medium. The length  $L_m$ , known as the average *mean beam length*, is a directional average of the thickness of the medium as seen from the point on the surface. On a spectral basis Equation (4.3.43) is exact, provided the above conditions are met and provided an accurate value of the (spectral) mean beam length is known. It has been shown that spectral dependence of the mean beam length is weak (generally less than  $\pm 5\%$  from the mean). Consequently, total radiative heat flux at the

surface may be calculated very accurately from Equation (4.3.43), provided the emissivity and absorptivity of the medium are also known accurately. The mean beam lengths for many important geometries have been calculated and are collected in Table 4.3.3. In this table  $L_o$  is known as the geometric mean beam length, which is the mean beam length for the optically thin limit ( $\kappa_\lambda \rightarrow 0$ ), and  $L_m$  is a spectral average of the mean beam length. For geometries not listed in Table 4.3.3, the mean beam length may be estimated from

$$L_o \cong 4 \frac{V}{A} \quad L_m \cong 0.9L_o \cong 3.6 \frac{V}{A} \quad (4.3.44)$$

**TABLE 4.3.3 Mean Beam Lengths for Radiation from a Gas Volume to a Surface on Its Boundary**

Geometry of Gas Volume	Characterizing Dimension L	Geometric Mean Beam Length $L_o/L$	Average Mean Beam Length $L_m/L$	$L_m/L_o$
Sphere radiating to its surface	Diameter, $L = D$	0.67	0.65	0.97
Infinite circular cylinder to bounding surface	Diameter, $L = D$	1.00	0.94	0.94
Semi-infinite circular cylinder to:	Diameter, $L = D$			
Element at center of base		1.00	0.90	0.90
Entire base		0.81	0.65	0.80
Circular cylinder (height/diameter = 1) to:	Diameter, $L = D$			
Element at center of base		0.76	0.71	0.92
Entire surface		0.67	0.60	0.90
Circular cylinder (height/diameter = 2) to:	Diameter, $L = D$			
Plane base		0.73	0.60	0.82
Concave surface		0.82	0.76	0.93
Entire surface		0.80	0.73	0.91
Circular cylinder (height/diameter = 0.5) to:	Diameter, $L = D$			
Plane base		0.48	0.43	0.90
Concave surface		0.53	0.46	0.88
Entire surface		0.50	0.45	0.90
Infinite semicircular cylinder to center of plane rectangular face	Radius, $L = R$	—	1.26	—
Infinite slab to its surface	Slab thickness, L	2.00	1.76	0.88
Cube to a face	Edge L	0.67	0.6	0.90
Rectangular $1 \times 1 \times 4$ parallelepipeds:	Shortest edge, L			
To $1 \times 4$ face		0.90	0.82	0.91
To $1 \times 1$ face		0.86	0.71	0.83
To all faces		0.89	0.81	0.91

where  $V$  is the volume of the participating medium and  $A$  is its entire bounding surface area.

### Example 4.3.8

An isothermal mixture of 10% CO<sub>2</sub> and 90% nitrogen at 1000 K and 5 bar is contained between two large, parallel, black plates, which are both isothermal at 1500 K. Estimate the net radiative heat loss from the surfaces.

*Solution.* The heat loss may be calculated from Equation (4.3.43), after determining the mean beam length, followed by evaluation of  $\epsilon(L_m)$  and  $\alpha(L_m)$ . From Table 4.3.3 it is clear that  $L_m = 1.76 \times$  thickness of slab = 1.76 m. It turns out that the necessary  $\epsilon(L_m) = 0.15$  and  $\alpha(L_m) = 0.122$  have already been calculated in Example 4.3.6. Thus, the heat flux is immediately calculated from Equation (4.3.43) as

$$\begin{aligned}
 q &= (1 - 0.122)5.670 \times 10^{-8} \times 1500^4 - 0.15 \times 5.670 \times 10^{-8} \times 1000^4 \\
 &= 2.44 \times 10^5 \frac{\text{W}}{\text{m}^2} = 244 \text{ kW/m}^2
 \end{aligned}$$

## Defining Terms

**Absorptivity:** The ability of a medium to absorb (i.e., trap and convert to other forms of energy) incoming radiation; gives the fraction of incoming radiation that is absorbed by the medium.

**Absorption coefficient:** The ability of a medium to absorb (i.e., trap and convert to other forms of energy) over a unit path length; the reciprocal of the mean distance a photon travels before being absorbed.

**Blackbody:** Any material or configuration that absorbs all incoming radiation completely. A blackbody also emits the maximum possible amount of radiation as described by Planck's law.

**Diffuse surface:** A surface that emits and/or reflects equal amounts of radiative energy (photons) into all directions. Or a surface that absorbs and/or reflects equal amounts of radiation independent of incoming direction.

**Emissive power:** The rate of radiative energy leaving a surface through emission. The maximum amount of emissive power is emitted by a blackbody with a spectral strength described by Planck's law.

**Emissivity:** The ability of a medium to emit (i.e., convert internal energy into electromagnetic waves or photons) thermal radiation; gives the fraction of emission as compared with a blackbody.

**Gray:** A medium whose radiative properties (such as absorptivity, emissivity, reflectivity, absorption coefficient) do not vary with wavelength.

**Irradiation:** Incoming radiative flux onto a surface from outside it.

**Network analogy:** Expressing radiative heat exchange between surfaces in terms of an electrical network, with heat flux as "current," differences in emissive power as "potentials," and defining radiative resistances.

**Opaque medium:** A medium of sufficient thickness that absorbs all nonreflected irradiation; no radiation is transmitted through the medium.

**Photon:** A massless particle carrying energy in the amount of  $h\nu$ ; the quantum mechanical alternative view of an electromagnetic wave carrying radiative energy.

**Planck's law:** The law describing the spectral distribution of the radiative energy emitted (emissive power) of a blackbody.

**Radiosity:** Total radiative flux leaving a surface (diffusely), consisting of emitted as well as reflected radiation.

**Reflectivity:** The ability of an interface, or of a medium or of a composite with a number of interfaces, to reflect incoming radiation back into the irradiating medium.

**Semitransparent:** See **transparent**.

**Spectral value:** The value of a quantity that varies with wavelength at a given wavelength; for dimensional quantities the amount per unit wavelength.

**Transmissivity:** The ability of a medium to let incoming radiation pass through it; gives the fraction of incoming radiation that is transmitted through the medium.

**Transparent:** The ability of a medium to let incoming radiation pass through it. A medium that lets all radiation pass through it is called transparent, a medium that only allows a part to pass through it is called **semitransparent**.

**View factor:** The fraction of diffuse radiant energy leaving one surface that is intercepted by another surface.

## 4.4 Phase-Change

### Boiling and Condensation

*Van P. Carey*

#### Introduction

Liquid-vapor phase-change processes play an important role in many technological applications. The virtually isothermal heat transfer associated with boiling and condensation processes makes their inclusion in power and refrigeration processes highly advantageous from a thermodynamic efficiency standpoint. In addition, the high heat transfer coefficients associated with boiling and condensation have made the use of these processes increasingly attractive in the thermal control of compact devices that have high heat dissipation rates. Applications of this type include the use of boiling heat transfer to cool electronic components in computers and the use of compact evaporators and condensers for thermal control of aircraft avionics and spacecraft environments. Liquid-vapor phase-change processes are also of critical importance to nuclear power plant design, both because they are important in normal operating circumstances and because they dominate many of the accident scenarios that are studied as part of design evaluation.

The heat transfer and fluid flow associated with liquid-vapor phase-change processes are typically among the more complex transport circumstances encountered in engineering applications. These processes have all the complexity of single-phase convective transport, plus additional elements resulting from motion of the interface, nonequilibrium effects, and dynamic interactions between the phases. Due to the highly complex nature of these processes, development of methods to accurately predict the associated heat and mass transfer is often a formidable task.

In this section, commonly used variables not defined in the nomenclature are as follows:  $q''$  = surface heat flux,  $\mu_l$  = liquid viscosity,  $\mu_v$  = vapor viscosity,  $Pr_l$  = liquid Prandtl number,  $T_w$  = wall surface temperature,  $T_{\text{sat}}$  = saturation temperature,  $c_{pl}$  = liquid specific heat,  $k_v$  = vapor thermal conductivity,  $g$  = gravitational acceleration, and  $x$  = mass quality.

#### Boiling

Three mechanisms that play important roles in boiling processes are (1) surface tension effects, (2) surface wetting characteristics of the liquid, and (3) metastable phase stability.

Anyone who has watched small bubbles rise in a carbonated beverage or a pot of boiling water has undoubtedly noticed that the bubbles are almost perfectly spherical, as if an elastic membrane were present at the interface to pull the vapor into a spherical shape. This apparent interfacial tension or *surface tension*  $\sigma$  is equivalent to an energy stored in the interface region per unit area. The energy excess in this region is due to the slightly larger separation of the liquid phase molecules adjacent to the gas phase.

The magnitude of the surface tension for a substance is directly linked to the strength of intermolecular forces in the material. Nonpolar liquids typically have the lowest surface tension. Water and other **polar molecules** have somewhat higher surface tension, and liquid metals, which exhibit metallic bond attraction, have very high surface tension. The surface tension of water at 20°C is 0.0728 N/m, whereas liquid mercury has a surface tension of 0.484 N/m at the same temperature. The surface tension for any pure liquid varies with temperature. It decreases almost linearly with increasing temperature, vanishing altogether at the critical point where the distinction between the phases disappears.

As a result of the surface tension at the interface, the pressure inside a spherical bubble of radius  $r$  must exceed that in the surrounding liquid by  $2\sigma/r$ :

$$P_v = P_l + \frac{2\sigma}{r} \quad (4.4.1)$$

By using the relation (1) between the pressure in the two phases it can be shown that for the bubble to be in equilibrium with the surrounding liquid, the liquid must actually be superheated above the saturation temperature for the ambient liquid pressure. The amount of required superheating increases as the radius of curvature of the bubble interface decreases.

The wetting characteristics of the liquid are generally quantified in terms of a *contact angle* between the solid surface and the tangent to the interface at the point where it contacts the solid. This angle is measured through the liquid phase, as shown in Figure 4.4.1. In some systems, the wetting angle established at equilibrium may depend on the fluid motion history. For some systems the contact angle established by liquid advancing over a solid surface is larger than that established when a liquid front recedes over the surface. This behavior is referred to as *contact angle hysteresis*. Contact angle hysteresis can have an important effect on boiling and condensation processes, particularly those involving water.

FIGURE 4.4.1 Definition of the contact angle  $\theta$ .

For a bubble with a specified vapor volume, the contact angle will dictate the radius of curvature of the bubble interface. The wetting behavior in combination with the surface tension effect, thus, determines the level of superheat required for the bubble to be in equilibrium with the surrounding liquid. The liquid must be heated above this superheat level for the bubble to grow. A steady boiling process can be sustained only if the liquid is heated above this threshold superheat level.

It can be shown from basic thermodynamic analysis that a necessary and sufficient condition for phase stability is that

$$\left(\frac{\partial P}{\partial v}\right)_T < 0 \quad (4.4.2)$$

where  $v$  is the specific volume. Below the critical temperature, extrapolation of the isotherms for the liquid and vapor phases consistent with an equation of state like the van de Waals equation results in an isotherm shape similar to that shown in Figure 4.4.2.

The locus of points where  $(\partial P/\partial v)_T = 0$  are termed *spinodal curves*. Regions of metastable vapor and liquid exist between the saturation curve and the spinodal curves. The effects of surface tension discussed above require that fluid surrounding a vapor bubble be in the metastable superheated liquid region. Predictions of statistical thermodynamics imply that as  $(\partial P/\partial v)_T$  approaches zero, the level of fluctuations in a fluid system increases. This, in turn, increases the probability that an embryonic new phase will form as a result of density fluctuations. Initiation of a phase change in this manner is termed *homogeneous nucleation*. Generally, a pure liquid must be heated to nearly 90% of its absolute critical temperature before homogeneous nucleation of vapor bubbles occurs.

In most physical systems of engineering interest, the bulk phase is in contact with solid walls of the containing structures, or solid particulate contaminants. These solid phases may provide nucleation sites where phase change may occur if the system state is driven into the metastable range. Nucleation of vapor bubbles may preferentially occur at low liquid superheat levels in crevices in the solid surface where gas is trapped. This type of nucleation at the solid surface of a containment wall is categorized as *heterogeneous nucleation*. Because solid containment walls usually contain microscopic crevice-type

**FIGURE 4.4.2** Spinodal lines and metastable regions on a  $P$ - $v$  diagram.

imperfections, heterogeneous nucleation is more common than homogeneous nucleation in systems where boiling occurs.

Vapor entrapment in crevices of the heated walls of evaporator heat exchangers usually makes it easier to initiate the vaporization process. Vapor bubbles grow from these crevices until buoyancy or drag on the bubbles exceeds the surface tension force holding the droplet to the solid surface. The bubble then releases into the bulk liquid. A small remnant of vapor remains in the crevice after a bubble releases, and this remnant grows in size as further vaporization occurs until the bubble grows out of the crevice again. The result is a cyclic process of bubble growth and release known as the *ebullition cycle*. Crevices at which the ebullition cycle is sustained are said to be active nucleation sites. When the ebullition process occurs at many sites over a heated surface, the overall process is referred to as **nucleate boiling**, which is one possible mode of **pool boiling**.

### Pool Boiling

Vaporization of liquid at the surface of a body immersed in an extensive pool of motionless liquid is generally referred to as pool boiling. The nature of the pool boiling process varies considerably depending on the conditions at which boiling occurs. The level of heat flux, the thermophysical properties of the liquid and vapor, the surface material and finish, and the physical size of the heated surface all may have an effect on the boiling process.

The regimes of pool boiling are most easily understood in terms of the so-called boiling curve: a plot of heat flux  $q''$  vs. wall superheat  $T_w - T_{\text{sat}}$  for the circumstances of interest. Many of the features of the classic pool boiling curve were determined in the early investigations of pool boiling conducted by Nukiyama (1934). Strictly speaking, the classic pool boiling curve defined by the work of this investigator and others applies to well-wetted surfaces for which the characteristic physical dimension  $L$  is large compared to the bubble or capillary length scale  $L_b$  defined as

$$L_b = \sqrt{\frac{\sigma}{g(\rho_l - \rho_v)}} \quad (4.4.3)$$

The discussion in this section is limited to pool boiling of wetting liquids on surfaces with dimensions large compared with  $L_b$ . Additional information on features of the boiling curve when the liquid poorly wets the surface or when  $L/L_b$  is small can be found in Carey (1992). To make this discussion concrete, we will assume that the ambient liquid surrounding the immersed body is at the saturation temperature for the ambient pressure. If the surface temperature of the immersed body is controlled and slowly

**FIGURE 4.4.3** Pool boiling regimes for an independently controlled surface temperature.

increased, the boiling curve will look similar to that shown in Figure 4.4.3. The axes in this plot are logarithmic scales. The regimes of pool boiling encountered for an upward-facing horizontal flat surface as its temperature is increased are also indicated in Figure 4.4.3. The lateral extent of the surface is presumed to be much larger than  $L_b$ . At very low wall superheat levels, no nucleation sites may be active and heat may be transferred from the surface to the ambient liquid by natural convection alone and  $q''$  increases slowly with  $T_w - T_{\text{sat}}$ .

Eventually, the superheat becomes large enough to initiate nucleation at some of the cavities on the surface. This *onset of nucleate boiling* (ONB) condition occurs at point *c* in Figure 4.4.3. Once nucleate boiling is initiated, any further increase in wall temperature causes the system operating point to move upward along section *d-f* of the curve in Figure 4.4.3. This portion of the curve corresponds to the nucleate boiling regime. The active sites are few and widely separated at low wall superheat levels. This range of conditions, corresponding to segment *d-e* of the curve, is sometimes referred to as the *isolated bubble regime*.

With increasing surface superheat, more sites become active, and the bubble frequency at each site generally increases. Eventually, the active sites are spaced so closely that bubbles from adjacent sites merge together during the final stages of growth and release. Vapor is being produced so rapidly that bubbles merging together form columns of vapor slugs that rise upward in the liquid pool toward its free surface. This higher range of wall superheat, corresponding to segment *e-f* of the boiling curve in Figure 4.4.3, is referred to as the *regime of slugs and columns*.

Increasing the wall superheat and heat flux within the regime of slugs and columns produces an increase in the flow rate of vapor away from the surface. Eventually, the resulting vapor drag on the liquid moving toward the surface becomes so severe that liquid is unable to reach the surface fast enough to keep the surface completely wetted with liquid. Vapor patches accumulate at some locations and evaporation of the liquid between the surface and some of these patches dries out portions of the surface.

If the surface temperature is held constant and uniform, dry portions of the surface covered with a vapor film will locally transfer a much lower heat flux than wetted portions of the surface where nucleate boiling is occurring. Because of the reduction in heat flux from intermittently dry portions of the surface, the mean overall heat flux from the surface is reduced. Thus, increasing the wall temperature within the

slugs and columns region ultimately results in a peaking and rollover of the heat flux. The peak value of heat flux is called the **critical heat flux** (CHF), designated as point *f* in Figure 4.4.3

If the wall temperature is increased beyond the critical heat flux condition, a regime is encountered in which the mean overall heat flux decreases as the wall superheat increases. This regime, which is usually referred to as the **transition boiling** regime, corresponds to segment *f-g* on the boiling curve shown in Figure 4.4.3. The transition boiling regime is typically characterized by rapid and severe fluctuations in the local surface heat flux and/or temperature values (depending on the imposed boundary condition). These fluctuations occur because the dry regions are generally unstable, existing momentarily at a given location before collapsing and allowing the surface to be rewetted.

The vapor film generated during transition boiling can be sustained for longer intervals at higher wall temperatures. Because the intermittent insulating effect of the vapor blanketing is maintained longer, the time-averaged contributions of the blanketed locations to the overall mean heat flux are reduced. The mean heat flux from the surface thus decreases as the wall superheat is increased in the transition regime. As this trend continues, eventually a point is reached at which the surface is hot enough to sustain a stable vapor film on the surface for an indefinite period of time. The entire surface then becomes blanketed with a vapor film, thus making the transition to the **film boiling** regime. This transition occurs at point *g* in Figure 4.4.3.

Within the film boiling regime, the heat flux monotonically increases as the superheat increases. This trend is a consequence of the increased conduction and/or convection transport due to the increased driving temperature difference across the vapor film. Radiative transport across the vapor layer may also become important at higher wall temperatures.

Once a surface is heated to a superheat level in the film boiling regime, if the surface temperature is slowly decreased, in general the system will progress through each of the regimes described above in reverse order. However, the path of the boiling curve may differ significantly from that observed for increasing wall superheat, depending on whether the surface heat flux or temperature is controlled.

Experimental evidence summarized by Witte and Lienhard (1982) implies that the path of the transition boiling curve is determined, to a large degree, by the wetting characteristics of the liquid on the solid surface. For a given wall superheat level in the transition boiling regime, a higher heat flux is generally obtained if the liquid wets the surface than if it poorly wets the surface. For systems that exhibit contact angle hysteresis, the transition boiling curves obtained for decreasing and increasing wall superheat may therefore be somewhat different. The transition boiling curve for decreasing wall superheat may be significantly below that for increasing superheat for such circumstances, as indicated in Figure 4.4.4.

For an electrically heated surface, the rise in temperature associated with the jump from nucleate to film boiling at the critical heat flux is very often large enough to melt component materials and burn out the component. As a result, the critical heat flux is often referred to as the *burnout heat flux* to acknowledge the potentially damaging effects of applying this heat flux level to components cooled by nucleate boiling. Once the jump to film boiling has been made, any further increase in applied heat flux increases the wall superheat, and the system follows basically the same film boiling curve as in the temperature-controlled case.

Correlations of nucleate pool boiling heat transfer data have typically been used as tools to predict nucleate boiling heat transfer in engineering systems and heat exchangers. Many investigators have proposed methods of correlating data of this type; so many, in fact, that a complete discussion of them all could easily fill a major portion of this section. In this section, three of the more commonly used correlation methods will be mentioned. However, before proceeding, two aspects of the interpretation of such correlations are worth noting. First, experimental data indicate that the subcooling of the liquid pool has a negligible effect on the nucleate boiling heat transfer rate. Consequently, the pool boiling correlations are generally regarded as being valid for both subcooled and saturated nucleate boiling. Second, it has also been observed that at moderate to high heat flux levels, a pool boiling heat transfer correlation developed for one heated surface geometry in one specific orientation often works reasonably well for other geometries and/or other orientations. Hence, although a correlation was developed for a

**FIGURE 4.4.4** Relative locations of the nucleate transition and film transition portions of the pool boiling curve.

specific geometry and orientation, it may often be used for other geometries, at least at moderate to high heat flux levels.

Having taken note of the above points, a commonly used correlation for nucleate boiling heat transfer developed by Rohsenow (1962) is

$$\frac{q''}{\mu_l h_{fg}} \left[ \frac{\sigma}{g(\rho_l - \rho_v)} \right]^{1/2} = \left( \frac{1}{C_{sf}} \right)^{1/r} Pr_l^{-s/r} \left[ \frac{c_{pl} [T_w - T_{sat}(P_l)]}{h_{fg}} \right]^{1/r} \quad (4.4.4)$$

Values of  $r = 0.33$  and  $s = 1.7$  are recommended for this correlation, but for water  $s$  should be changed to 1.0. The values of  $C_{sf}$  in this correlation vary with the type of solid surface and the type of fluid in the system. This empirically accounts for material property and/or wetting angle effects. Recommended values of  $C_{sf}$  for specific liquid–solid combinations are given by Rohsenow (1962), but whenever possible, an experiment should be conducted to determine the appropriate value of  $C_{sf}$  for the particular solid–liquid combination of interest. If this is not possible, a value of  $C_{sf} = 0.013$  is recommended as a first approximation.

As noted previously, the pool boiling curve generally exhibits a maximum heat flux or CHF at the transition between nucleate and transition boiling. This peak value is the maximum level of heat flux from the surface which the system can provide in a nonfilm-boiling mode at a given pressure. The mechanism responsible for the CHF has been the subject of considerable investigation and debate over the past five decades. As the heat flux increases, bubbles generated at the surface coalesce to form vapor columns or jets. Perhaps the most widely cited CHF model postulates that the CHF condition occurs when Helmholtz instability of the large vapor jets leaving the surface distorts the jets, blocking liquid flow to portions of the heated surface. Continued vaporization of liquid at locations on the surface which are starved of replacement liquid than leads to formation of a vapor blanket over part or all of the surface. According to Zuber (1959) for a flat horizontal surface, the predicted maximum heat flux  $q''_{max}$  is

$$q''_{\max} = 0.131\rho_v h_{fg} \left[ \frac{\sigma_g (\rho_l - \rho_v)}{\rho_v^2} \right]^{1/4} \quad (4.4.5)$$

but Lienhard and Dhir (1973) recommend that the constant 0.131 in the above relation be replaced with 0.141. Other geometries are treated by Lienhard et al. (1973) and Lienhard and Dhir (1973b). An alternative model has been proposed by Haramura and Katto (1983).

Lienhard and Witte (1985) discuss the development and limitations of hydrodynamic CHF theories.

As shown in the [Figure 4.4.3](#), the boundary between the transition boiling regime and the film boiling regime corresponds to a minimum in the heat flux vs. superheat curve. This condition is referred to as the **minimum heat flux** condition, referred to as the *Leidenfront point*. The minimum heat flux corresponds approximately to the lowest heat flux which will sustain stable film boiling.

For an infinite flat (upward-facing) heated surface, vapor generated at the interface during stable film boiling is released as bubbles at the nodes of a standing two-dimensional Taylor wave pattern. The following relation for the minimum heat flux  $q''_{\min}$  derived by Zuber (1959) and Berenson (1961).

$$q''_{\min} = 0.09\rho_v h_{fg} \left[ \frac{\sigma_g (\rho_l - \rho_v)}{(\rho_l + \rho_v)^2} \right]^{1/4} \quad (4.4.6)$$

$q''_{\min}$  correlations have been developed by Lienhard and Wong (1964) for horizontal cylinders and Gunnerson and Cronenberg (1980) for spheres.

In film boiling, transport of heat across the vapor film from the wall to the interface may occur by convection, conduction, and radiation. The radiation contribution depends on the nature of the solid surface, but when the radiation effect is small, the heat transfer for film boiling is independent of the material properties and finish of the surface. For buoyancy-driven laminar film boiling over a vertical flat isothermal surface in a pool of saturated liquid, the local heat transfer coefficient from the surface can be obtained from the following relation:

$$h = \left[ \frac{k_v^3 g \rho_v (\rho_l - \rho_v) h_{fg}}{4\mu_v (T_w - T_{\text{sat}}) x} \right]^{1/4} \quad (4.4.7)$$

At low surface temperatures, radiation effects are negligible and consideration of convective transport alone is sufficient to predict the heat transfer. At higher temperatures radiation effects must also be included. If the vapor in the film absorbs and emits radiation at infrared wavelengths, a detailed treatment of the radiation interaction with the vapor may be necessary to accurately predict the film boiling heat transfer.

Additional information mechanisms such as interfacial waves, turbulence, and variable properties is summarized in Carey (1992).

Transition pool boiling has traditionally been interpreted as a combination of nucleate and film boiling alternately occurring over the heated surface, and a model of transition boiling that accounts for contact angle effects has been proposed by Ramilison and Lienhard (1987).

### Internal Convective Boiling

Flow boiling in tubes is perhaps the most complex convective process encountered in applications. In most evaporator and boiler applications, the flow is either horizontal or vertically upward. [Figure 4.4.5](#) schematically depicts a typical low-flux vaporization process in a horizontal round tube. In this example liquid enters as subcooled liquid and leaves as superheated vapor. As indicated in [Figure 4.4.5](#), the flow undergoes transitions in the boiling regime and the two-phase flow regime as it proceeds down the tubes. The regimes encountered depend on the entrance conditions and the thermal boundary conditions at the

**FIGURE 4.4.5** Qualitative variation of the heat transfer coefficient  $h$  and flow regime with quality for internal convective boiling in a horizontal tube at moderate wall superheat.

tube wall. At low quality the vaporization process is dominated by nucleate boiling, with convective effects being relatively weak. As the quality increases, the flow quickly enters the annular film flow regime in which convective evaporation of the annular liquid film is the dominant heat transfer mechanism. Often the conditions are such that liquid droplets are often entrained in the core vapor flow during annular flow evaporation. Eventually, the annular film evaporates away, leaving the wall dry. Mist-flow evaporation of entrained liquid droplets continues in the post-dryout regime until only vapor remains. Similar, sequences of flow and boiling regimes occurring in vertical upward flow, as indicated in [Figure 4.4.6](#).

The boiling regime trends shown in [Figures 4.4.5 and 4.4.6](#) are typical for low heat flux vaporization processes. At high wall superheat levels, transition boiling or film boiling can also occur. The transition from nucleate boiling to one of these regimes is termed a *departure from nucleate boiling* (DNB) or the CHF condition. However, the heat transfer performance of an evaporator under transition or film boiling conditions is so poor that equipment is not usually designed to operate under such conditions.

Because low-quality or subcooled flow boiling are nucleate boiling dominated, the heat transfer coefficient in these regimes is often predicted using a nucleate boiling correlation developed as a fit to pool boiling data. The usefulness of such an approach is a consequence of the fact that for most conditions of practical interest, nucleate boiling heat transfer is only weakly affected by liquid subcooling or liquid bulk convection.

For saturated convective boiling prior to dryout, relations to predict the heat transfer coefficient have typically been formulated to impose a gradual suppression of nucleate boiling and gradual increase in liquid film evaporation heat transfer as the quality increases. A number of correlations based on such an approach have been developed. An early correlation of this type developed by Chen (1966) has been widely used. One of the better methods of this type is the recently developed correlation of Kandlikar

**FIGURE 4.4.6** Flow regimes and boiling mechanisms for upflow convective boiling in a vertical tube at moderate wall superheat.

(1989) which has been fit to a broad spectrum of data for both horizontal and vertical tubes. For this method the heat transfer coefficient for a tube of diameter  $D$  is given by

$$h = h_l \left[ C_1 C_o^{C_2} (25 Fr_{le})^{C_3} + C_3 Bo^{C_4} F_K \right] \quad (4.4.8)$$

where

$$C_o = \left( \frac{1-x}{x} \right)^{0.8} \left( \frac{\rho_v}{\rho_l} \right)^{0.5} \quad (4.4.9)$$

$$Bo = q'' / Gh_{fg} \quad (4.4.10)$$

$$Fr_{le} = G^2 / \rho_l^2 gD \quad (4.4.11)$$

and  $h_l$  is the single-phase heat transfer coefficient for the liquid phase flowing alone in the tube computed as

$$h_l = 0.023 \left( \frac{k_l}{D} \right) \left( \frac{G(1-x)D}{\mu_l} \right)^{0.8} \text{Pr}_l^{0.4} \quad (4.4.12)$$

The constants  $C_1 - C_5$  are given in Table 4.4.1. The factor  $F_K$  is a fluid-dependent parameter. For water,  $F_K = 1$ . For R-12 and nitrogen, recommended values of  $F_K$  are 1.50 and 4.70, respectively. Values of  $F_K$  for a variety of other fluids can be obtained from Kandlikar (1989).

**TABLE 4.4.1 Constants for the Correlation of Kandlikar (1987)**

	$Co < 0.65$ (Convective Region)	$Co \geq 0.65$ (Nucleate Boiling Region)
$C_1$	1.1360	0.6683
$C_2$	-0.9	-0.2
$C_3$	667.2	1058.0
$C_4$	0.7	0.7
$C_5^a$	0.3	0.3

<sup>a</sup>  $C_5 = 0$  for vertical tubes and horizontal tubes with  $\text{Fr}_{lc} > 0.04$ .

Methods for predicting the conditions at which dryout or a DNB transition occurs have typically been empirical in nature. Based on fits to extensive data, Levitan and Lantsman (1975) recommended the following relations for the DNB heat flux and the quality at which dryout occurs during flow boiling of water in a tube with an 8-mm diameter.

$$q''_{\text{crit}} = \left[ 10.3 - 7.8 \left( \frac{P}{98} \right) + 1.6 \left( \frac{P}{98} \right)^2 \right] \left( \frac{G}{1000} \right)^{1.2 \left\{ \left[ \frac{0.25(P-98)}{98} \right] - x \right\}} e^{-1.5x} \quad (4.4.13)$$

$$x_{\text{crit}} = \left[ 0.39 + 1.57 \left( \frac{P}{98} \right) - 2.04 \left( \frac{P}{98} \right)^2 + 0.68 \left( \frac{P}{98} \right)^3 \right] \left( \frac{G}{1000} \right)^{-0.5} \quad (4.4.14)$$

In the above relations,  $q''_{\text{crit}}$  is in  $\text{MW/m}^2$ ,  $P$  is the pressure in bar, and  $G$  is in  $\text{kg/m}^2\text{sec}$ . To obtain values of  $q''_{\text{crit}}$  and  $x_{\text{crit}}$  for diameters other than 8 mm, Levitan and Lantsman (1975) recommended that the 8-mm values from the above relations be corrected as follows:

$$q''_{\text{crit}} = (q''_{\text{crit}})_{8\text{mm}} \left( \frac{8}{D} \right)^{1/2} \quad (4.4.15)$$

$$x_{\text{crit}} = (x_{\text{crit}})_{8\text{mm}} \left( \frac{8}{D} \right)^{0.15} \quad (4.4.16)$$

where  $D$  is the diameter in millimeters. A good generalized empirical correlation for predicting dryout or CHF conditions in vertical uniformly heated tubes is that recently proposed by Katto and Ohno (1984).

In many cases, post-dryout mist flow evaporation is driven primarily by convective transport from the tube wall to the gas and then to the entrained droplets. In some circumstances, impingement of droplets onto the heat surface and radiation interactions may also be important. In cases where convection is dominant, predictions of the heat transfer coefficient have been developed by modifying a single-phase correlation for the entire flow as vapor with a correction factor which accounts for the presence of the entrained droplets. Often this correction factor has been presumed to be a function of property ratios. An example of such an approach is the correlation of Dougall and Rohsenow (1963) for which the heat transfer coefficient  $h$  is given by

$$\frac{hD}{k_v} = 0.023 \left[ \left( \frac{GD}{\mu_v} \right) \left( x + \frac{\rho_v}{\rho_l} (1-x) \right) \right]^{0.8} \text{Pr}_{v,\text{sat}}^{0.4} \quad (4.4.17)$$

For further information on mechanisms of convective boiling, see the texts of Collier (1981), Stephan (1992), and Carey (1992).

### Condensation

As in the case of boiling, surface tension effects, surface wetting characteristics, and metastable phase stability also can play important roles in condensation processes. As a result of interfacial tension, the pressure inside a spherical liquid droplet of radius  $r$  must exceed that in the surrounding liquid by  $2\sigma/r$ . A consequence of this and basic thermodynamics is that at equilibrium the surrounding vapor must actually be slightly supersaturated. The amount of supersaturation required at equilibrium increases as the radius of curvature of the bubble interface decreases.

For a liquid droplet on a solid surface with a specified volume, the wetting contact angle dictates the radius of curvature of the droplet interface. Because of the linkage between the interface curvature and the required equilibrium supersaturation, the wetting behavior thus determines the level above which the vapor supersaturation must be raised for the droplet to grow. Steady condensation on the droplet interface can be sustained only if the vapor is driven beyond this supersaturation level by cooling or depressurization. For such conditions, the vapor is in the metastable supersaturated range indicated in Figure 4.4.2.

Condensation on external surfaces of a body immersed in a gas phase generally falls into one or two categories: **dropwise condensation** or **film condensation**. In dropwise condensation, the liquid-phase condensate collects as individual droplets which grow in size with time on the cold surface. This mode of condensation is most likely when the liquid poorly wets the solid surface. When the condensation rate is high or the liquid readily wets the surface, a film of liquid condensate covers the solid surface, and the process is referred to as film condensation.

*Dropwise Condensation.* Dropwise condensation may occur on a solid surface cooled below the saturation temperature of a surrounding vapor when the surface is poorly wetted except at locations where well-wetted contaminant nuclei exist. The poorly wetted surface condition can result from contamination or coating of the surface with a substance which is poorly wetted by the liquid phase of the surrounding vapor. In practice, this can be achieved for steam condensation by (1) injecting a nonwetting chemical into the vapor which subsequently deposits on the surface, (2) introducing a substance such as a fatty (i.e., oleic) acid or wax onto the solid surface, or (3) by permanently coating the surface with a low-surface-energy polymer or a noble metal. The effects of the first two methods are generally temporary, since the resulting surface films eventually are dissolved or eroded away.

During dropwise condensation, the condensate is usually observed to appear in the form of droplets which grow on the surface and coalesce with adjacent droplets. When droplets become large enough, they are generally removed from the surface by the action of gravity or drag forces resulting from the motion of the surrounding gas. As the drops roll or fall from the surface they merge with droplets in their path, effectively sweeping the surface clean of droplets. Droplets then begin to grow anew on the freshly-exposed solid surface. This sweeping and renewal of the droplet growth process is responsible for the high heat transfer coefficients associated with dropwise condensation. Theoretical aspects of dropwise condensation are described in two publications by Tanaka (1975, 1979). A discussion of correlations for the heat transfer coefficient associated with dropwise condensation is provided in the review article by Merte (1973).

*External Film Condensation.* If the liquid phase fully wets a cold surface in contact with a vapor near saturation conditions, the conversion of vapor to liquid will take the form of film condensation. As the name implies, the condensation takes place at the interface of a liquid film covering the solid surface. Because the latent heat of vaporization must be removed at the interface to sustain the process, the rate

of condensation is directly linked to the rate at which heat is transported across the liquid film from the interface to the surface.

The classic integral analysis of Nusselt (1916) for laminar falling-film condensation on a vertical surface considers the physical circumstances shown in Figure 4.4.7. The surface exposed to a motionless ambient of saturated vapor is taken to be isothermal with a temperature below the saturation temperature. Note that although a vertical surface is considered here, the analysis is identical for an inclined surface, except that the gravitational acceleration  $g$  is replaced by  $g \sin \Omega$ , with  $\Omega$  being the angle between the surface and the horizontal. Because the liquid film flows down the surface because of gravity, this situation is sometimes referred to as *falling-film condensation*.

**FIGURE 4.4.7** System model for the Nusselt analysis of falling-film condensation.

In its simplest form, the classic Nusselt analysis incorporates the following idealizations: (1) laminar flow, (2) constant properties, (3) that subcooling of liquid is negligible in the energy balance, (4) that inertia effects are negligible in the momentum balance, (5) that the vapor is stationary and exerts no drag, (6) that the liquid-vapor interface is smooth, and (7) that heat transfer across film is only by conduction (convection is neglected). With these idealizations, the following relation for the local heat transfer coefficient  $h$  can be obtained

$$\frac{hz}{k_l} = \left[ \frac{\rho_l(\rho_l - \rho_v)gh_{fg}z^3}{4k_l\mu_\ell(T_{\text{sat}} - T_w)} \right]^{1/4} \quad (4.4.18)$$

Modified versions of this analysis have been subsequently developed which relax many of these assumptions. Laminar film condensation on a vertical surface can also be analyzed with a full boundary layer formulation. An example of this type of approach is the analysis presented by Sparrow and Gregg (1959).

The analyses described above do not include two physical mechanisms which can significantly affect the transport: (1) the effects of waves on the liquid-vapor interface and (2) interfacial vapor shear drag on the interface. The effects of interfacial shear have been studied analytically by numerous investigators. The effects of surface waves on laminar film condensation are more difficult to incorporate into theoretical analyses. In general, interfacial waves are expected to enhance convective heat transport in the film since it intermittently thins the film, increases the interfacial area, and induces mixing. Because of these effects, laminar film condensation heat transfer data are often significantly higher than the values predicted by simple boundary layer models.

As for any boundary layer flow, when the film Reynolds number becomes large enough, it is expected that a transition to turbulent flow will occur. Eddy diffusivity models of the resulting turbulent transport have been developed by Seban (1954), Dukler (1960), and others. This methodology was later extended to evaporation of a falling liquid film (see, for example, Mills and Chung, 1973).

Subsequent studies (see, for example, Mills and Chung, 1973) have suggested that the presence of the interface tends to damp larger turbulent eddies near the interface in the liquid film. This implies that a viscous sublayer exists at the interface as well as at the wall. Recent efforts to model turbulent falling-film evaporation and condensation processes have therefore included a variation of the eddy viscosity in which it goes to zero at both the wall and the interface. The analysis tools and correlations described above work reasonably well for values of liquid Prandtl number above 1. However, deviation of the predictions using these methods from heat transfer data for liquid metals can be quite significant.

Because of its importance to the design of tube-and-shell condensers, condensation on the outside of horizontal tubes has been the subject of numerous studies. The length of the tube perimeter over which the condensate flows is usually small for commonly used tubes. Consequently, the film Reynolds number is usually low and the flow in the liquid film is laminar.

With slight modification, the Nusselt (1916) analysis of laminar falling-film condensation over a flat plate can be adapted to film condensation on an isothermal horizontal cylinder. Doing so yields the following relation for the mean heat transfer coefficient:

$$\frac{\bar{h}D}{k_l} = 0.728 \left[ \frac{(\rho_l - \rho_v) g h_{fg} D^3 \text{Pr}_l}{\rho_l \nu_l^2 c_{pl} (T_{\text{sat}} - T_w)} \right]^{1/4} \quad (4.4.19)$$

Selin (1961) found that better agreement with film condensation data for horizontal tubes was obtained by replacing the constant factor in Equation (4.4.19) by 0.61. Correlations similar to the single-tube relation above have also been developed for the average condensation heat transfer coefficient for banks of round tubes.

Analytical treatment of laminar film condensation on a sphere is virtually the same as that for a horizontal cylinder. The only differences result from the angular variation of the body perimeter because of the spherical geometry. A general analytical prediction of the local heat transfer coefficient for laminar film condensation on arbitrary axisymmetric bodies has been developed by Dhira and Lienhard (1971).

*Condensation in the Presence of a Noncondensable Gas.* In nature and in a number of technological applications, condensation of one component vapor in a mixture may occur in the presence of other noncondensable components. The most common example is the condensation of water vapor in the air on a cold solid surface. If the component gases are considered to be a mixture of independent substances, condensation of one component vapor will occur if the temperature of the surface is below the saturation temperature of the pure vapor at its partial pressure in the mixture. This temperature threshold is referred to as the *dew point* of the mixture.

Because only the vapor is condensed, the concentration of the noncondensable gas at the interface is higher than its value in the far ambient. This, in turn, decreases the partial pressure of the vapor at the interface below its ambient value. The corresponding saturation temperature at the interface is therefore lower than the bulk temperature. The resulting depression of the interface temperature generally reduces the condensation heat transfer rate below that which would result for pure vapor alone under the same conditions. Space limitations here preclude a detailed discussion of the effects of noncondensable gases. The interested reader may find more-extensive discussions of this topic in the references by Collier (1981) and Carey (1992).

*Internal Convective Condensation.* In most power and refrigeration systems, the flow in the condenser is either horizontal or vertically downward. Figure 4.4.8 schematically depicts a typical condensation process in a horizontal round tube. Superheated vapor enters the tube and at the exit end the liquid is subcooled. At a point some distance downstream of the entrance, vapor begins to condense on the walls of the tube. The location at which this occurs is at or slightly before the bulk flow reaches the equilibrium saturation condition. In most condensers, the liquid readily wets the interior of the tube and at high vapor volume fractions the liquid forms a thin liquid film on the interior wall of the tube.

**FIGURE 4.4.8** Flow regimes during horizontal cocurrent flow with condensation.

The vapor velocity is generally high at the inlet end of the condenser tube, and the liquid film is driven along the tube by strong vapor shear on the film. At low vapor flow rates, some stratification may occur and the film may be thicker on the bottom of the horizontal tube. At high vapor flow rates, turbulent stresses acting on the liquid may tend to keep the thickness of the liquid film nominally uniform over the perimeter of the tube.

In most condenser applications, shear-dominated annular flow persists to very low qualities and the overwhelming majority of the heat transfer occurs in this regime. The very last stage of the condensation process, corresponding to qualities less than a few percent, may occur in slug, plug, or bubbly two-phase flow. Generally these regimes represent such a small portion of the overall heat transfer in the condenser that some inaccuracy in estimating the heat transfer coefficient for them is tolerated. As a first estimate, the heat transfer coefficient may be predicted using a correlation for pure single-phase liquid flow in the tube at the same total flow rate, or a correlation for annular flow condensation may simply be extrapolated to zero quality.

Because most of the heat duty occurs in the annular flow regime, accurate prediction of the overall heat transfer performance of the condenser requires a predictive methodology that accurately treats the transport in this regime. For this reason, the form of most correlation methods for predicting local convective condensation heat transfer coefficients are optimized to match data in the annular flow regime. One example of such a correlation is the following relation for the local heat transfer coefficient for annular flow condensation proposed by Travis et al. (1973):

$$\frac{hD}{k_l} = \frac{0.15Pr_l Re_l^{0.9}}{F_T} \left[ \frac{1}{X_{tt}} + \frac{2.85}{X_{tt}^{0.476}} \right] \quad (4.4.20)$$

where

$$Re_l = \frac{G(1-x)D}{\mu_l}, \quad X_{tt} = \left( \frac{1-x}{x} \right)^{0.9} \left( \frac{\rho_v}{\rho_l} \right)^{0.5} \left( \frac{\mu_l}{\mu_v} \right)^{0.1}$$

and  $F_T$  is given by

$$\begin{aligned}
 F_T &= 5Pr_i + 5\ln\{1 + 5Pr_i\} + 2.5\ln\{0.0031Re_i^{0.812}\} & \text{for } Re_i > 1125 \\
 &= 5Pr_i + 5\ln\{1 + Pr_i(0.0964Re_i^{0.585} - 1)\} & \text{for } 50 < Re_i < 1125 \\
 &= 0.707Pr_iRe_i^{0.5} & \text{for } Re_i < 50
 \end{aligned}$$

Carey (1992) has shown that the generic form of this correlation can be derived from a theoretical model of annular flow condensation in a round tube. Several correlations of this general type have been developed as fits to experimental data; see Carey (1992) for a summary. The predictions of these correlations may vary significantly for a given set of conditions. When possible, a correlation should be selected which has been tested against data for conditions close to those for the application of interest.

A correlation methodology that can be used to predict internal convective condensation heat transfer for slug, plug, or wavy stratified flow has also been proposed by Rossen and Meyers (1965). To predict the overall heat transfer performance of a condenser, methods to predict the local heat transfer coefficient must be combined with a scheme to numerically integrate finite-difference forms of the energy, mass, and momentum balances in the tube. For further information on such schemes see the references by Collier (1981) and Carey (1992) (Figure 4.4.9).

**FIGURE 4.4.9** Comparison of the variation of  $h$  with  $x$  predicted by four correlation methods for internal convective condensation. References cited in this figure are listed in chapter 11 of Carey (1992).

## Defining Terms

**Critical heat flux (CHF):** A maximum heat flux condition that characterizes the transition between nucleate boiling and transition boiling or film boiling.

**Dropwise condensation:** Condensation of vapor into liquid in discrete droplets, usually attained when a cold surface is poorly wetted by the liquid phase.

**Film boiling:** Generation of vapor at the interface of a vapor film which entirely covers the hot surface.

**Film condensation:** Condensation of vapor onto the interface of a liquid film that completely covers a cold surface.

**Minimum heat flux:** A minimum heat flux condition on the classic boiling curve that characterizes the transition between film boiling and transition boiling. Also, sometimes referred to as the Leidenfrost point, it is a lower bound for heat flux values at which stable film boiling may occur.

- Nucleate boiling:** Generation of vapor at a hot surface by formation of bubbles at discrete nucleation sites with full liquid wetting of the surface.
- Polar molecules:** Molecules which have a permanent electric dipole moment. Examples include water and ammonia.
- Pool boiling:** Generation of vapor at the surface of a hot body immersed in an extensive liquid pool.
- Transition boiling:** Generation of vapor at a hot surface with intermittent or partial liquid wetting of the surface.

## Further Information

The texts *Heat Transfer in Condensation and Boiling* by K. Stephan (Springer-Verlag, New York, 1992) and *Liquid-Vapor Phase Change Phenomena* by V.P. Carey (Taylor and Francis, Washington, D.C., 1992) provide an introduction to the physics of boiling and condensation processes. The text by J.G. Collier, *Convective Boiling and Condensation* (2nd ed., McGraw-Hill, New York, 1981), summarizes more-advanced elements of convective boiling and condensation processes. The *ASHRAE Handbook of Fundamentals* (American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Atlanta, GA, 1993) provides some information on boiling and condensation heat transfer and is a good source of thermophysical property data needed to analyze boiling and condensation processes.

## Particle Gas Convection

*John C. Chen*

### Introduction

Heat transfer in two-phase systems involving gas and solid particles are encountered in several types of operations important in chemical, power, and environmental technologies. Chief among these are gas fluidized beds which are widely used to achieve either physical processing or chemical reactions that require interfacial contact between gas and solid particles. Currently, fluidized beds operate in either the *bubbling regime* or the *fast-circulating regime*. In the first case, particles are retained in the fluidized bed while the gas passes upward past the particles, partially as rising bubbles. In the second case, gas velocities exceed terminal velocity for the individual particles and the two phases flow through the fluidized bed in cocurrent upward flow. For those applications which require thermal control, convective heat transfer between the fluidized medium and heat transfer surfaces (either immersed tubes or the vessel walls) is an essential element of the process design.

### Bubbling Fluidized Beds

Bubbling fluidization occurs when the superficial gas velocity exceeds a critical value wherein the gravitational body force on the solid particles is balanced by the shear force between particles and flowing gas. The superficial gas velocity at this condition, commonly called the minimum fluidization velocity ( $U_{mf}$ ), marks the boundary between gas flow through packed beds and gas flow in fluidized beds. Wen and Yu (1966) derived the following general equation to estimate  $U_{mf}$  for spherical particles:

$$\text{Re}_{mf} = \left[ (33.7)^2 + 0.0408 \text{Ar} \right]^{1/2} - 33.7 \quad (4.4.21)$$

where

$$\text{Re}_{mf} = \text{particle Reynolds number at } U_{mf} = \frac{U_{mf} d_p \rho_g}{\mu_g}$$

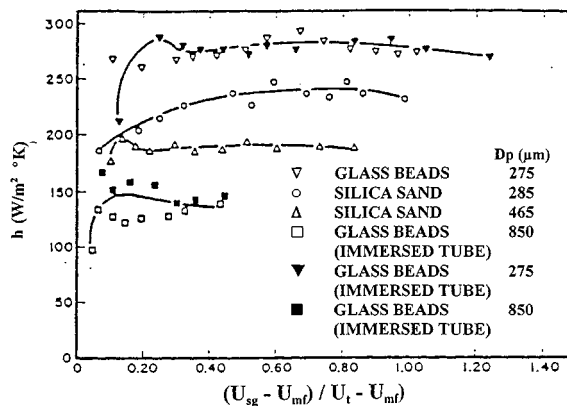

$$\text{Ar} = \text{Archimedes number} = \frac{d_p^3 \rho_g (\rho_s - \rho_g) g}{\mu_g^2}$$

Increasing gas velocity beyond minimum fluidization causes the excess gas to collect into discrete bubbles that grow and rise through the fluidized matrix of solid particles. In this bubbling fluidization regime, the total pressure drop over the height of the fluidized bed,  $H$ , is equal to the hydrostatic pressure of the solid mass,

$$\Delta P = g \rho_s (1 - \epsilon) H \quad (4.4.22)$$

where  $\epsilon$  = volume fraction of gas (void fraction).

Tubes carrying cooling or heating fluids are often immersed in bubbling fluidized beds to extract or add thermal energy. The effective heat transfer coefficient at the surface of such tubes has been the objective of numerous experimental and analytical investigations. Data for the circumferentially averaged heat transfer coefficient for horizontal tubes are shown in Figure 4.4.10 for various types of solid particles. Characteristics representative of such systems are

**FIGURE 4.4.10** Average heat transfer coefficients for horizontal tubes immersed in bubbling fluidized beds. (From Biyikli, Tuzla and Chen, 1983.)

- The heat transfer coefficient increases sharply as the gas velocity exceeds minimum fluidization velocity,
- After the initial increase, the heat transfer coefficient remains fairly constant over a significant range of the gas velocity beyond minimum fluidization velocity,
- The absolute magnitude of the heat transfer coefficient is severalfold greater than single-phase gas convection at the same superficial velocity,
- The heat transfer coefficient increases as particle size decreases.

Kunii and Levenspiel (1991) have shown that increasing gas pressure and density significantly increases the magnitude of the heat transfer coefficient as well as promoting the occurrence of minimum fluidization at a lower value of superficial gas velocity. The effect of bundle spacing is insignificant at 1-atm pressure but becomes increasingly more important as gas pressure and density increase. The data

of Jacob and Osberg (1957) indicate that the convective heat transfer coefficient in fluidized beds increases with increasing thermal conductivity of the gas phase, for any given particle size.

Several different types of correlations have been suggested for predicting convective heat transfer coefficients at submerged surfaces in bubbling fluidized beds. The first type attributes the enhancement of heat transfer to the scouring action of solid particles on the gas boundary layer, thus decreasing the effective film thickness. These models generally correlate a heat transfer Nusselt number in terms of the fluid Prandtl number and a modified Reynolds number with either the particle diameter or the tube diameter as the characteristic length scale. Examples are

Leva's correlation for vertical surfaces and larger particles (Leva and Gummer, 1952);

$$\text{Nu}_{d_p} = \frac{h_c d_p}{k_g} = 0.525 (\text{Re}_p)^{0.75} \quad (4.4.23)$$

where

$$\text{Re}_p = \frac{d_p \rho_g U}{\mu_g}$$

Vreedenberg's (1958) correlation for horizontal tubes refers to the particle of diameter  $D_t$ .

$$\text{Nu}_{D_t} = \frac{h_c D_t}{k_g} = 420 \left( \frac{\rho_s}{\rho_g} \text{Re}_t \right)^{0.3} \left( \frac{\mu_g^2}{g \rho_s^2 d_p^3} \right)^{0.3} (\text{Pr}_g)^{0.3} \quad (4.4.24)$$

for

$$\left( \frac{\rho_s}{\rho_g} \text{Re}_t \right) > 2250$$

where

$$\text{Re}_t = \frac{D_t \rho_g U}{\mu_g}$$

Molerus and Schweinzer (1989) developed an alternative type of correlation based on the supposition that the heat transfer is dominated by gas convection through the matrix of particles in the vicinity of the heat transfer surface. Their correlation takes the form:

$$\text{Nu} = \frac{h_c d_p}{k_g} = 0.0247 (\text{Ar})^{0.4304} (\text{Pr})^{0.33} \quad (4.4.25)$$

Figure 4.4.11 shows comparison of this model with experimental data obtained at three different pressures. The solid curve represents the relationship for fixed beds, while the dashed lines represent the behavior for fluidized beds (i.e., Equation 4.4.25) upon exceeding minimum fluidization.

A third type of model considers the heat transfer surface to be contacted alternately by gas bubbles and packets of packed particles, leading to a surface renewal process for heat transfer. Mickley and Fairbanks (1955) provided the first analysis of this renewal mechanism. Ozkaynak and Chen (1980)

FIGURE 4.4.11 Correlation of Molerus and Schweinzer compared with experimental data (1989).

showed that if experimentally measured values of the packet contact time and residence times are used in the packet model analysis, excellent agreement is obtained.

### Fast-Circulating Fluidized Beds

Fast fluidization occurs when the superficial gas velocity exceeds the terminal velocity of the solid particles, causing the particles to be suspended in cocurrent upward flow with the gas. This upward flow occurs in “rise reactors” wherein desired physical or chemical reactions occur. In most applications, the two-phase flow exits the top of the riser into a cyclone where the gas phase is separated and exhausted while the solid particles are captured and returned for reinjection at the bottom of the riser. The volumetric concentration of solid particles in these fast fluidized beds (FFBs) tend to be fairly dilute, often with average concentrations of less than 2%. Heat exchange with the particle/gas suspension is usually accomplished through the vertical wall surfaces or through vertical tubes immersed in the duct.

The heat transfer coefficient at vertical surfaces FFBs has been found to increase with increasing solid concentration, aside from other second-order parametric effects. Figure 4.4.12 shows heat transfer coefficients experimentally measured by Dou et al. (1994) for an FFB operating with sand particles of 124  $\mu\text{m}$  mean diameter. Figure 4.4.12b shows that the heat transfer coefficient increased with solid mass flux, for a constant superficial gas velocity. Figure 4.4.12a shows that the heat transfer coefficient decreased parametrically with superficial gas velocity for a constant solid mass flux. Both figures indicate that heat transfer coefficients decrease with increasing elevation in the riser duct. These three parametric trends are all consistent with the hypothesis that heat transfer in FFBs increases with increasing concentration of the solid phase.

It is generally accepted that the effective heat transfer coefficient for surfaces in FFBs have contributions for gas-phase convection, particle-induced convection, and radiation:

$$h = h_g + h_p + h_r \quad (4.4.26)$$

**FIGURE 4.4.12** Heat transfer coefficients in fast fluidized beds;  $V_g$  is superficial gas velocity,  $G_s$  is mass flux of particles, and  $Z$  is elevation in FFB. (From Dou, Tuzla and Chen, 1992.)

In contrast to the situation in dense-bubbling fluidized beds, the relatively dilute concentration of solid particles in FFBS often results in significant contributions from all three heat transfer mechanisms. The radiation coefficient can be obtained by a gray body model suggested by Grace (1985). The contribution of the gas phase convection ( $h_g$ ) is commonly estimated based on correlations for gas flow alone at the same superficial gas velocity. Although the presence of particles may alter the turbulence characteristic of this gas flow, any errors caused by this procedure are usually small since  $h_g$  is generally smaller than the particle-phase convective coefficient  $h_p$ .

For most FFBS, the particle convective contribution to heat transfer is most important and the prediction of  $h_p$  is the major concern in thermal design. Unfortunately, mechanistically based models are still lacking and most design methods rely on empirical correlations which often combine the contributions of gas and particle phases into a single convective heat transfer coefficient ( $h_c$ ). One such correlation proposed by Wen and Miller (1961) is

$$\text{Nu}_{d_p} = \frac{h_c d_p}{k_g} = \left( \frac{C_{pp}}{C_{pg}} \right) \left( \frac{\rho_{\text{susp}}}{\rho_p} \right)^{0.3} \left( \frac{V_t}{g d_p} \right)^{0.21} \text{Pr}_g \quad (4.4.27)$$

where  $V_t$  = terminal velocity of particle.

Other correlations have been proposed by Fraley (1992) and Martin (1984). These correlations are useful as a starting point but have not yet been verified over wide parametric ranges. Large deviations can occur when compared with measurements obtained outside of the experimental parametric ranges.

## Melting and Freezing

*Noam Lior*

### Introduction and Overview

Melting and freezing occur naturally (Lunardini, 1981) as with environmental ice in the atmosphere (hail, icing on aircraft), on water bodies and ground regions at the Earth surface, and in the molten Earth core (Figure 4.4.13). They are also a part of many technological processes, such as preservation of foodstuffs (ASHRAE, 1990, 1993), refrigeration and air-conditioning (ASHRAE, 1990, 1993), snow and ice making for skiing and skating (ASHRAE, 1990), organ preservation and cryosurgery (Rubinsky and Eto, 1990), manufacturing (such as casting, molding of plastics, coating, welding, high-energy beam cutting and forming, crystal growth, electrodischarge machining, electrodeposition) (Flemings, 1974; Cheng and Seki, 1991; Tanasawa and Lior, 1992), and thermal energy storage using solid–liquid phase-changing materials (deWinter, 1990).

**FIGURE 4.4.13** Melting and freezing in nature. (a) A melting icicle. (b) Frozen lava in Hawaii.

In simple thermodynamic systems (i.e., without external fields, surface tension, etc.) of a pure material, melting or freezing occurs at certain combinations of temperature and pressure. Since pressure typically has a relatively smaller influence, only the fusion (freezing or melting) temperature is often used to identify this phase transition. Fusion becomes strongly dependent on the concentration when the material contains more than a single species. Furthermore, melting and freezing are also sensitive to external effects, such as electric and magnetic fields, in more-complex thermodynamic systems.

The equilibrium thermodynamic system parameters during phase transition can be calculated from the knowledge that the partial molar Gibbs free energies or chemical potentials of each component in the two phases must be equal. One important result of using this principle for simple single-component systems is the Clapeyron equation relating the temperature ( $T$ ) and pressure ( $P$ ) during the phase transition, such that

$$\frac{dP}{dT} = \frac{h_{s\ell}}{T\Delta v} \quad (4.4.28)$$

where  $h_{s\ell}$  is the enthalpy change from phase A to phase B ( $=h_B - h_A$ , the latent heat of fusion with appropriate sign) and  $\Delta v$  is the specific volume difference between phases A and B ( $=v_B - v_A$ ). Considering for example that phase A is a solid and B a liquid ( $h_{s\ell}$  is then positive), examination of Equation (4.4.28) shows that increasing the pressure will result in an increase in the melting temperature if  $\Delta v > 0$  (i.e., when the specific volume of the liquid is higher than that of the solid, which is a property of tin, for example), but will result in a decrease of the melting temperature when  $\Delta v < 0$  (for water, for example).

In some materials, called glassy, the phase change between the liquid and solid occurs with a gradual transition of the physical properties, from those of one phase to those of the other. When the liquid phase flows during the process, the flow is strongly affected because the viscosity increases greatly as the liquid changes to solid. Other materials, such as pure metals and ice, and eutectic alloys, have a definite line of demarcation between the liquid and the solid, the transition being abrupt. This situation is easier to analyze and is therefore more thoroughly addressed in the literature.

Gradual transition is most distinctly observed in mixtures. Consider the equilibrium phase diagram for a binary mixture (or alloy) composed of species  $a$  and  $b$ , shown in Figure 4.4.14.  $\chi$  is the concentration of species  $b$  in the mixture,  $\ell$  denotes the liquid,  $s$  the solid,  $s_a$  a solid with a lattice structure of species  $a$  in its solid phase but containing some molecules of species  $b$  in that lattice, and  $s_b$  a solid with a lattice structure of species  $b$  in its solid phase but containing some molecules of species  $a$  in that lattice. “Liquidus” denotes the boundary above which the mixture is just liquid, and “solidus” is the boundary separating the final solid mixture of species  $a$  and  $b$  from the solid–liquid mixture zones and from the other zones of solid  $s_a$  and solid  $s_b$ .

For illustration, assume that a liquid mixture is at point 1, characterized by concentration  $\chi_1$  and temperature  $T_1$  (Figure 4.4.14), and is cooled (descending along the dashed line) while maintaining the concentration constant. When the temperature drops below the liquidus line, solidification starts, creating a mixture of liquid and of solid  $s_a$ . Such a two-phase mixture is called the **mushy zone**. At point 2 in that zone, the solid phase ( $s_a$ ) portion contains a concentration  $\chi_{2,s_a}$  of component  $b$ , and the liquid phase portion contains a concentration  $\chi_{2,\ell}$  of component  $b$ . The ratio of the mass of the solid  $s_a$  to that of the liquid is determined by the lever rule, and is  $(\chi_{2,\ell} - \chi_2)/(\chi_2 - \chi_{2,s_a})$  at point 2. Further cooling to below the solidus line, say to point 3, results in a solid mixture (or alloy) of  $s_a$  and  $s_b$ , containing concentrations  $\chi_{3,s_a}$  and  $\chi_{3,s_b}$  of species  $b$ , respectively. The ratio of the mass of the solid  $s_a$  to that of  $s_b$  is again determined by the lever rule, and is  $(\chi_{3,s_b} - \chi_3)/(\chi_3 - \chi_{3,s_a})$  at point 3.

A unique situation occurs if the initial concentration of the liquid is  $\chi_e$ : upon constant-concentration cooling, the liquid forms the solid mixture  $s_a + s_b$  having the same concentration and without the formation of a two-phase zone.  $\chi_e$  is called the **eutectic concentration**, and the resulting solid mixture (or alloy) is called a *eutectic*.

**FIGURE 4.4.15** Freezing of semi-infinite liquid with heat conduction in both phases.

at the position  $x = X(t)$  moves gradually to the right (in the positive  $x$  direction). We note that in this problem heat is conducted in both phases.

Assuming for simplification that heat transfer is by conduction only — although at least natural convection (Incropera and Viskanta, 1992) and sometimes forced convection and radiation also take place — the governing equations are

*In the liquid:* The transient heat conduction equation is

$$\frac{\partial T_\ell(x,t)}{\partial t} = \alpha_\ell \frac{\partial^2 T_\ell(x,t)}{\partial x^2} \quad \text{in } X(t) < x < \infty \quad \text{for } t > 0 \quad (4.4.29)$$

$$T_\ell(x,t) = T_i \quad \text{in } x > 0, \quad \text{at } t = 0 \quad (4.4.30)$$

where  $\alpha_\ell$  is the thermal diffusivity of the liquid, with the initial condition and the boundary condition

$$T_\ell(x \rightarrow \infty, t) \rightarrow T_i \quad \text{for } t > 0 \quad (4.4.31)$$

*In the solid:* The transient heat conduction equation is

$$\frac{\partial T_s(x,t)}{\partial t} = \alpha_s \frac{\partial^2 T_s(x,t)}{\partial x^2} \quad \text{in } 0 < x < X(t) \quad \text{for } t > 0 \quad (4.4.32)$$

where  $\alpha_s$  is the thermal diffusivity of the solid, with the boundary condition

$$T_s(0,t) = T_0 \quad \text{for } t > 0 \quad (4.4.33)$$

The remaining boundary conditions are those of temperature continuity and heat balance at the solid–liquid phase-change interface  $X(t)$ ,

$$T_\ell[X(t)] = T_s[X(t)] = T_f \quad \text{for } t > 0 \quad (4.4.34)$$

$$k_s \left( \frac{\partial T_s}{\partial x} \right)_{[X(t)]} - k_\ell \left( \frac{\partial T_\ell}{\partial x} \right)_{[X(t)]} = \rho h_{s\ell} \frac{dX(t)}{dt} \quad \text{for } t > 0 \quad (4.4.35)$$

where  $k_s$  and  $k_\ell$  are the thermal conductivities of the solid and liquid, respectively,  $\rho$  is the density (here it is assumed for simplicity to be the same for the liquid and solid), and  $h_{s\ell}$  is the latent heat of fusion. The two terms on the left-hand side of Equation (4.4.35) thus represent the conductive heat flux away from the phase-change interface, into the solid at left and the liquid at right, respectively. Energy conservation at the interface requires that the sum of these fluxes leaving the interface be equal to the amount of heat generated due to the latent heat released there, represented by the term on the right-hand side of the equation.

The analytical solution of Equations (4.4.29) to (4.4.35) yields the temperature distributions in the liquid and solid phases,

$$T_\ell(x,t) = T_i - (T_i - T_f) \frac{\operatorname{erfc}\left(\frac{x}{2\sqrt{\alpha_\ell t}}\right)}{\operatorname{erfc}\left(\lambda\sqrt{\alpha_s/\alpha_\ell}\right)} \quad (4.4.36)$$

$$T_s(x,t) = T_0 + (T_f - T_0) \frac{\operatorname{erfc}\left(\frac{x}{2\sqrt{\alpha_s t}}\right)}{\operatorname{erfc}\lambda} \quad (4.4.37)$$

where erf and erfc are the *error function* and the *complementary error function*, respectively, and  $\lambda$  is a constant, obtained from the solution of the equation

$$\frac{e^{\lambda^2}}{\operatorname{erf}\lambda} - \frac{k_\ell}{k_s} \sqrt{\frac{\alpha_s}{\alpha_\ell}} \frac{T_i - T_f}{T_f - T_0} \frac{e^{(\alpha_s/\alpha_\ell)\lambda^2}}{\operatorname{erfc}\left(\lambda\sqrt{\alpha_s/\alpha_\ell}\right)} = \frac{\lambda\sqrt{\pi}}{\operatorname{Ste}_s} \quad (4.4.38)$$

where  $\operatorname{Ste}_s$  is the Stefan number (dimensionless), here defined for the solid as

$$\operatorname{Ste}_s \equiv \frac{c_s(T_f - T_0)}{h_{s\ell}} \quad (4.4.39)$$

and  $c_s$  is the specific heat of the solid. Solutions of Equation (4.4.38) are available for some specific cases in several of the references, and can be obtained relatively easily by a variety of commonly used software packages.

The solution of Equations (4.4.29) to (4.4.35) also gives an expression for the transient position of the freezing interface,

$$X(t) = 2\lambda(\alpha_s t)^{1/2} \quad (4.4.40)$$

where  $\lambda$  is the solution of Equation 4.4.38, and thus the expression for the rate of freezing, i.e., the velocity of the motion of the solid liquid interface, is

$$\frac{dX(t)}{dt} = \lambda \alpha_s^{1/2} t^{1/2} \quad (4.4.41)$$

**FIGURE 4.4.16** Melting of semi-infinite solid with conduction in the liquid phase only.

For a simple one-dimensional melting example of an analytical solution for melting, consider the semi-infinite solid described in Figure 4.4.16, initially at the fusion temperature  $T_f$ . For time  $t > 0$  the temperature of the surface (at  $x = 0$ ) is raised to  $T_0 > T_f$ , and the solid consequently starts to melt there. In this case the temperature in the solid remains constant,  $T_s = T_f$ , so the temperature distribution needs to be calculated only in the liquid phase. It is assumed that the liquid formed by melting remains motionless and in place. Very similarly to the above-described freezing case, the equations describing this problem are the heat conduction equation

$$\frac{\partial T_\ell(x,t)}{\partial t} = \alpha_\ell \frac{\partial^2 T_\ell(x,t)}{\partial x^2} \quad \text{in } 0 < x < X(t) \quad \text{for } t > 0 \quad (4.4.42)$$

with the initial condition

$$T_\ell(x,t) = T_f \quad \text{in } x > 0, \quad \text{at } t = 0 \quad (4.4.43)$$

the boundary condition

$$T_\ell(0,t) = T_0 \quad \text{for } t > 0 \quad (4.4.44)$$

and the liquid–solid interfacial temperature and heat flux continuity conditions

$$T_\ell[X(t)] = T_f \quad \text{for } t > 0 \quad (4.4.45)$$

$$-k_\ell \left( \frac{\partial T_\ell}{\partial x} \right)_{[X(t)]} = \rho h_{fs} \frac{dX(t)}{dt} \quad \text{for } t > 0 \quad (4.4.46)$$

The analytical solution of this problem yields the temperature distribution in the liquid,

$$T_\ell(x,t) = T_0 - (T_0 - T_f) \frac{\operatorname{erf}\left(\frac{x}{2\sqrt{\alpha_\ell t}}\right)}{\operatorname{erf}\lambda'} \quad \text{for } t > 0 \quad (4.4.47)$$

where  $\lambda'$  is the solution of the equation

$$\lambda' e^{\lambda'^2} \operatorname{erf}(\lambda') = \frac{\operatorname{Ste}_\ell}{\sqrt{\pi}} \quad (4.4.48)$$

with  $\operatorname{Ste}_\ell$  here defined for the liquid as

$$\operatorname{Ste}_\ell \equiv \frac{c_\ell(T_0 - T_f)}{h_{s\ell}} \quad (4.4.49)$$

$\lambda'$  as a function of  $\operatorname{Ste}$ , for  $0 \leq \operatorname{Ste} \leq 5$ , is given in [Figure 4.4.17](#). The interface position is

$$X(t) = 2\lambda'(\alpha_\ell t)^{1/2} \quad (4.4.50)$$

**FIGURE 4.4.17** The root  $\lambda'$  of Equation 4.4.48.

The solution of the *freezing* problem under similar conditions, i.e., of a semi-infinite liquid initially at temperature  $T_f$  where  $T(0,t)$  is abruptly reduced to  $T_0 < T_f$  for  $t > 0$ , is identical to the above if every subscript  $\ell$  is replaced by  $s$  and the latent heat  $h_{s\ell}$  is replaced by  $-h_{s\ell}$ .

*Example:* The temperature of the vertical surface of a large volume of solid paraffin wax used for heat storage, initially at the fusion temperature,  $T_i = T_f = 28^\circ\text{C}$ , is suddenly raised to  $58^\circ\text{C}$ . Any motion in the melt may be neglected. How long would it take for the paraffin to solidify to a depth of 0.1 m? Given properties:  $\alpha_\ell = (1.09) 10^{-7} \text{ m}^2/\text{sec}$ ,  $\rho_s = \rho_\ell = 814 \text{ kg/m}^3$ ,  $h_{s\ell} = 241 \text{ kJ/kg}$ ,  $c_\ell = 2.14 \text{ kJ/kg}^\circ\text{C}$ . To find the required time we use Equation (4.4.50), in which the value of  $\lambda'$  needs to be determined.  $\lambda'$  is calculated from Equation (4.4.48), which requires the knowledge of  $\operatorname{Ste}_\ell$ . From Equation (4.4.49)

$$\text{Ste}_\ell = \frac{(2.14 \text{ kJ/kg}^\circ\text{C})(58^\circ\text{C} - 28^\circ\text{C})}{241.2 \text{ kJ/kg}} = 0.266$$

The solution of Equation (4.4.48) as a function of  $\text{Ste}_\ell$  is given in Figure 4.4.17, yielding  $\lambda \approx 0.4$ . By using Equation (4.4.50), the time of interest is calculated by

$$t = \frac{[X(t)]^2}{4\lambda^2\alpha_\ell} = \frac{(0.1 \text{ m})^2}{4(0.4)^2 [(1.09)10^7 \text{ m}^2/\text{sec}]} = (1.43)10^5 \text{ sec} = 39.8 \text{ hr}$$

The axisymmetric energy equation in *cylindrical coordinates*, applicable to both the solid phase and immobile liquid phase (with appropriate assignment of the properties) is

$$\frac{\partial T(r,t)}{\partial t} = \frac{1}{\rho c} \frac{\partial}{\partial r} \left( \frac{k}{r} \frac{\partial T(r,t)}{\partial r} \right) \quad \text{for } t > 0 \quad (4.4.51)$$

and the temperature and heat balance conditions at the solid–liquid phase-change interface  $r = R(t)$  are

$$T_\ell[R(t)] = T_s[R(t)] \quad \text{for } t > 0 \quad (4.4.52)$$

$$k_s \left( \frac{\partial T_s}{\partial r} \right)_{R(t)} - k_\ell \left( \frac{\partial T_\ell}{\partial r} \right)_{R(t)} = h_{s\ell} \frac{dR(t)}{dt} \quad (4.4.53)$$

Because of the nature of the differential equations describing nonplanar and multidimensional geometries, analytical solutions are available for only a few cases, such as line heat sources in cylindrical coordinate systems or point heat sources in spherical ones, which have very limited practical application. Other phase-change problems in nonplanar geometries, and in cases when the melt flows during phase change, are solved by approximate and numerical methods (Yao and Prusa, 1989; Alexiades and Solomon, 1993).

### Some Approximate Solutions

Two prominent approximate methods used for the solution of melting and freezing problems are the integral method and the *quasi-static* approximation. The integral method is described in Goodman (1964), and only the quasi-static approximation is described here.

To obtain rough estimates of melting and freezing processes quickly, in cases where heat transfer takes place in only one phase, it is assumed in this approximation that effects of sensible heat are negligible relative to those of latent heat ( $\text{Ste} \rightarrow 0$ ), thus eliminating the sensible-heat left-hand side of the energy equations (such as (4.4.29), (4.4.32), and (4.4.51)). This is a significant simplification, since the energy equation then becomes independent of time, and solutions to the steady-state heat conduction problem are much easier to obtain. At the same time, the transient phase-change interface condition (such as Equations (4.4.35) and (4.4.53)) is retained, allowing the estimation of the transient interface position and velocity. This is hence a quasi-static approximation, and its use is shown below.

We emphasize that these are just approximations, without full information on the effect of specific problem conditions on the magnitude of the error incurred when using them. In fact, in some cases, especially with a convective boundary condition, they may produce incorrect results. It is thus necessary to examine the physical viability of the results, such as overall energy balances, when using these approximations.

All of the examples are for melting, but freezing problems have the same solutions when the properties are taken to be those of the solid and  $h_{st}$  is replaced everywhere by  $-h_{st}$ . It is assumed here that the problems are one-dimensional, and that the material is initially at the fusion temperature  $T_f$ .

*Examples of the Quasi-Static Approximation for Cartesian Coordinate Geometries.* Given a semi-infinite solid (Figure 4.4.16), on which a *time-dependent temperature*  $T_0(t) > T_f$  is imposed at  $x = 0$ , the above-described quasi-static approximation of Equations (4.4.42) to (4.4.46) easily yields the solution

$$X(t) = \left[ 2 \frac{k_\ell}{\rho h_{st}} \int_0^t [T_0(t) - T_f] dt \right]^{1/2} \quad \text{for } t \geq 0 \quad (4.4.54)$$

$$T_\ell(x, t) = T_0(t) - [T_0(t) - T_f] \frac{x}{X(t)} \quad \text{in } 0 \leq x \leq X(t) \quad \text{for } t \geq 0 \quad (4.4.55)$$

The heat flux needed for melting,  $q(x, t)$ , can easily be determined from the temperature distribution in the liquid (Equation 4.4.55), which is linear because of the steady-state form of the heat conduction equation in this quasi-static approximation, so that

$$q(x, t) = -k_\ell \frac{dT_\ell(x, t)}{dx} = k_\ell \frac{T_0(t) - T_f}{X(t)} \quad (4.4.56)$$

For comparison of this approximate solution to the exact one (Equations (4.4.47) and (4.4.50)), consider the case where  $T_0(t) = T_0 = \text{constant}$ . Rearranging to use the Stefan number, Equations (4.4.54) and (4.4.55) become

$$X(t) = 2(\text{Ste}_\ell/2)^{1/2} (\alpha_\ell t)^{1/2} \quad \text{for } t > 0 \quad (4.4.57)$$

$$T(x, t) = T_0 - [T_0 - T_f] \frac{x / [2(\alpha_\ell t)^{1/2}]}{(\text{Ste}_\ell/2)^{1/2}} \quad \text{in } 0 \leq x \leq X(t) \quad \text{for } t \geq 0 \quad (4.4.58)$$

It is easy to show that  $\lambda'$  in the exact solution (Equation 4.4.48) approaches the value  $(\text{Ste}_\ell/2)^{1/2}$  when  $\text{Ste}_\ell \rightarrow 0$ , and that otherwise  $\lambda' < (\text{Ste}_\ell/2)^{1/2}$ . The approximate solution is therefore indeed equal to the exact one when  $\text{Ste}_\ell \rightarrow 0$ , and it otherwise overestimates the values of both  $X(t)$  and  $T(x, t)$ . While the errors depend on the specific problem, they are confined to about 10% in the above-described case (Alexiades and Solomon, 1993).

For the same melting problem but with the *boundary condition of an imposed time-dependent heat flux*  $q_0(t)$ ,

$$-k_\ell \left( \frac{dT_\ell}{dx} \right)_{0,t} = q_0(t) \quad \text{for } t > 0 \quad (4.4.59)$$

the quasi-static approximate solution is

$$X(t) \equiv \frac{1}{\rho h_{st}} \int_0^t q_0(t) dt \quad \text{for } t > 0 \quad (4.4.60)$$

$$T_\ell(x,t) = T_f + \frac{q_0}{k_\ell} \left[ \frac{q_0}{\rho h_{s\ell}} t - x \right] \quad \text{in } 0 \leq x \leq X(t) \quad \text{for } t > 0 \quad (4.4.61)$$

For the same case if the *boundary condition is a convective heat flux* from an ambient fluid at the transient temperature  $T_a(t)$ , characterized by a heat transfer coefficient  $\bar{h}$ ,

$$-k_\ell \left( \frac{dT_\ell}{dx} \right)_{0,x} = \bar{h} [T_a(t) - T_\ell(0,t)] \quad \text{for } t \geq 0 \quad (4.4.62)$$

the quasi-static approximate solution is

$$X(t) = -\frac{k_\ell}{\bar{h}} + \left\{ \left( \frac{k_\ell}{\bar{h}} \right)^2 + 2 \frac{k_\ell}{\rho h_{s\ell}} \int_0^t [T_a(t) - T_f] dt \right\}^{1/2} \quad \text{for } t \geq 0 \quad (4.4.63)$$

$$T_\ell(x,t) = T_f(t) \left[ T_a(t) - T_f \right] \frac{\bar{h} [X(t) - x]}{\bar{h} X(t) + k_\ell} \quad \text{in } 0 \leq x \leq X(t) \quad \text{for } t > 0 \quad (4.4.64)$$

*Examples of the Quasi-Static Approximation for Cylindrical Coordinate Geometries.* It is assumed in these examples that the cylinders are very long and that the problems are axisymmetric. Just as in the Cartesian coordinate case, the energy equation (4.4.51) is reduced by the approximation to its steady-state form. Here

$$T_\ell(r_i,t) = T_0(t) > T_f \quad \text{for } t > 0 \quad (4.4.65)$$

Consider the *outward-directed melting* of a hollow cylinder due to a temperature imposed at the internal radius  $r_i$ . The solution is

$$T_\ell(r,t) = T_f + [T_0(t) - T_f] \frac{\ln[r/R(t)]}{\ln[r_i/R(t)]} \quad \text{in } r_i \leq r \leq R(t) \quad \text{for } t > 0 \quad (4.4.66)$$

and the transient position of the phase front,  $R(t)$ , can be calculated from the transcendental equation

$$2R(t)^2 \ln \frac{R(t)}{r_i} = R(t)^2 - r_i^2 + \frac{4k_\ell}{\rho h_{s\ell}} \int_0^t [T_0(t) - T_f] dt \quad (4.4.67)$$

If the melting for the same case occurs due to the imposition of a *heat flux*  $q_0$  at  $r_p$

$$-k_\ell \left( \frac{dT_\ell}{dx} \right)_{r_i,t} = q_0(t) > 0 \quad \text{for } t > 0 \quad (4.4.68)$$

the solution is

$$T_\ell(r,t) = T_f - \frac{q_0(t)r_i}{k_\ell} \ln \frac{r}{R(t)} \quad \text{in } r_i \leq r \leq R(t) \quad \text{for } t > 0 \quad (4.4.69)$$

$$R(t) = \left( r_i^2 + 2 \frac{r_i}{\rho h_{s\ell}} \int_0^t q_0(t) dt \right)^{1/2} \quad \text{for } t > 0 \quad (4.4.70)$$

If the melting for the same case occurs due to the imposition of a *convective heat flux from a fluid at the transient temperature*  $T_a(t)$ , with a heat transfer coefficient  $\bar{h}$ , at  $r_i$

$$-k_\ell \left( \frac{dT_\ell}{dr} \right)_{r_i,t} = \bar{h} [T_a(t) - T_f(r_i,t)] > 0 \quad \text{for } t > 0 \quad (4.4.71)$$

The solution is

$$T_\ell(r,t) = T_f + [T_a(t) - T_f] \frac{\ln[r/R(t)]}{\ln[r_i/R(t)] - k_\ell/\bar{h}r_i} \quad \text{in } r_i \leq r \leq R(t) \quad \text{at } t > 0 \quad (4.4.72)$$

with  $R(t)$  calculated from the transcendental equation

$$2R(t)^2 \ln \frac{R(t)}{r_i} = \left( 1 - \frac{2k_\ell}{\bar{h}r_i} \right) [R(t)^2 - r_i^2] + \frac{4k_\ell}{\rho h_{s\ell}} \int_0^t [T_a(t) - T_f] dt \quad (4.4.73)$$

The solutions for *inward melting* of a cylinder, where heating is applied at the outer radius  $r_o$ , are the same as the above-described ones for the outward-melting cylinder, if the replacements  $r_i \rightarrow r_o$ ,  $q_0 \rightarrow -q_0$ , and  $\bar{h} \rightarrow -\bar{h}$  are made. If such a cylinder is not hollow, then  $r_i = 0$  is used.

### Estimation of Freezing and Melting Time

There are a number of approximate formulas for estimating the freezing and melting times of different materials having a variety of shapes. The American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) provides a number of such approximations for estimating the freezing and thawing times of foods (ASHRAE, 1993). For example, if it can be assumed that the freezing or thawing occurs at a single temperature, the time to freeze or thaw,  $t_f$ , for a body that has shape parameters  $P$  and  $R$  (described below) and thermal conductivity  $k$ , initially at the fusion temperature  $T_f$ , and which is exchanging heat via heat transfer coefficient  $\bar{h}$  with an ambient at the constant  $T_a$ , can be approximated by Plank's equation

$$t_f = \frac{h_{s\ell} \rho}{|T_f - T_a|} \left( \frac{Pd}{\bar{h}} + \frac{Rd^2}{k} \right) \quad (4.4.74)$$

where  $d$  is the diameter of the body if it is a cylinder or a sphere, or the thickness when it is an infinite slab, and where the shape coefficients  $P$  and  $R$  for a number of body forms are given in [Table 4.4.2](#). Shape coefficients for other body forms are also available. To use Equation 4.4.74 for freezing,  $k$  and  $\rho$  should be the values for the food in its frozen state. In thawing, they should be for the unfrozen food. Other simple approximations for melting and thawing times can be found in Cleland et al. (1987).

*Example of Using Plank's Equation (4.4.74) for Estimating Freezing Time.* Estimate the time needed to freeze a fish, the shape of which can be approximated by a cylinder 0.5 m long having a diameter of 0.1 m. The fish is initially at its freezing temperature, and during the freezing process it is surrounded by air at  $T_a = -25^\circ\text{C}$ , with the cooling performed with a convective heat transfer coefficient  $\bar{h} = 68 \text{ W/m}^2 \text{ K}$ . For the fish,  $T_f = -1^\circ\text{C}$ ,  $h_{s\ell} = 200 \text{ kJ/kg}$ ,  $\rho_s = 992 \text{ kg/m}^3$ , and  $k_s = 1.35 \text{ W/m K}$ .

**TABLE 4.4.2 Shape Factors for Equation (4.4.74)**

Forms	$P$	$R$
Slab	1/2	1/8
Cylinder	1/4	1/16
Sphere	1/6	1/24

From ASHRAE, in *Fundamentals*, ASHRAE, Atlanta, 1993, chap. 29. With permission.

By using Table 4.4.2, the geometric coefficients for the cylindrical shape of the fish are  $P = 1/2$  and  $R = 1/16$ , while  $d$  is the cylinder diameter,  $= 0.1$  m. Substituting these values into Equation (4.4.74) gives

$$t_f = \frac{200,000 \cdot 992}{-1 - (-25)} \left( \frac{1/4(0.1)}{68} + \frac{1/16(0.1)^2}{1.35} \right) = 6866 \text{ sec} = 1.9 \text{ hr}$$

In fact, freezing or melting of food typically takes place over a range of temperatures, and approximate Plank-type formulas have been developed for various specific foodstuffs and shapes to represent reality more closely than Equation (4.4.74) (ASHRAE, 1993).

Alexiades and Solomon (1993) provide several easily computable approximate equations for estimating the time needed to melt a simple solid body initially at the fusion temperature  $T_f$ . It is assumed that conduction occurs in one phase (the liquid) only, that the problems are axi- and spherically symmetric for cylindrical and spherical bodies, respectively, and that the melting process for differently shaped bodies can be characterized by a single geometric parameter,  $r$ , in the body domain  $0 \leq r \leq L$ , using a shape factor,  $\omega$ , defined by

$$\omega = \frac{LA}{V} - 1 \quad (4.4.75)$$

where  $A$  is the surface area across which the heat is transferred into the body and  $V$  is the body volume, to account for the specific body shape:

$$\begin{aligned} \omega &= 0 && \text{for a slab insulated at one end} \\ \omega &= 1 && \text{for a cylinder} \\ \omega &= 2 && \text{for a sphere} \end{aligned} \quad (4.4.76)$$

$0 \leq \omega \leq 2$  always, and  $\omega$  may be assigned appropriate values for shapes intermediate between the slab, cylinder, and sphere. For example, a football-shaped body, somewhere between a cylinder and sphere, may be assigned  $\omega = 1.5$ , and a short cylinder with a large diameter-to-height ratio may have  $\omega = 0.5$ .

For the case where the temperature  $T_0 > T_f$  is imposed on the boundary at  $t = 0$ , the melt time,  $t_m$  can be estimated by

$$t_m = \frac{L^2}{2\alpha_\ell(1+\omega)\text{Ste}_\ell} \left[ 1 + (0.25 + 0.17\omega^{0.7})\text{Ste}_\ell \right] \quad (4.4.77)$$

valid for  $0 \leq \text{Ste}_\ell \leq 4$ .

If the *heat input is convective*, with a heat transfer coefficient  $\bar{h}$  from a fluid at temperature  $T_a$ , the approximate melt time is

$$t_m = \frac{L^2}{2\alpha_\ell(1+\omega)\text{Ste}_\ell} \left[ 1 + \frac{2k_\ell}{\bar{h}L} + (0.25 + 0.17\omega^{0.7})\text{Ste}_\ell \right] \quad (4.4.78)$$

valid for  $0 \leq \text{Ste}_\ell \leq 4$  and  $\bar{h}L/k_\ell \geq 0.1$ , and the temperature,  $T(0,t)$ , of the surface across which the heat is supplied can be estimated from the implicit time-temperature relationship:

$$t = \frac{\rho c_\ell k_\ell}{2\bar{h}^2 \text{Ste}_\ell} \left[ 1.18 \text{Ste}_\ell \left( \frac{T(0,t) - T_f}{T_a - T(0,t)} \right)^{1.83} + \left( \frac{T_a - T_f}{T_a - T(0,t)} \right)^2 - 1 \right] \quad (4.4.79)$$

Both equations (4.4.78) and (4.4.79) are claimed to be accurate within 10%.

The suitability of using several simplified analytical solutions for the estimation of freezing and melting times for more-realistic problems was assessed by Dilley and Lior (1986).

## Defining Terms

**Eutectic concentration:** A concentration of a component of a multicomponent liquid at which the liquid would upon freezing form a solid containing the same concentration, and at which the freezing process is completed at a single temperature.

**Mushy zone:** The zone composed of both liquid and solid, bounded by the liquidus and solidus curves, in a freezing or melting process.

**Medical:** *Cryobiology*, *ASME Journal of Biomechanical Engineering*, *Journal of General Physiology*

## 4.5 Heat Exchangers

*Ramesh K. Shah and Kenneth J. Bell*

The two major categories of heat exchangers are shell-and-tube exchangers and compact exchangers. Basic constructions of gas-to-gas compact heat exchangers are plate-fin, tube-fin and all prime surface recuperators (including polymer film and laminar flow exchangers), and compact regenerators. Basic constructions of liquid-to-liquid and liquid-to-phase-change compact heat exchangers are gasketed and welded plate-and-frame, welded stacked plate (without frames), spiral plate, printed circuit, and dimple plate heat exchangers.

Shell-and-tube exchangers are custom designed for virtually any capacity and operating condition, from high vacuums to ultrahigh pressures, from cryogenics to high temperatures, and for any temperature and pressure differences between the fluids, limited only by the materials of construction. They can be designed for special operating conditions: vibration, heavy fouling, highly viscous fluids, erosion, corrosion, toxicity, radioactivity, multicomponent mixtures, etc. They are made from a variety of metal and nonmetal materials, and in surface areas from less than 0.1 to 100,000 m<sup>2</sup> (1 to over 1,000,000 ft<sup>2</sup>). They have generally an order of magnitude less surface area per unit volume than the compact exchangers, and require considerable space, weight, support structure, and footprint.

Compact heat exchangers have a large heat transfer surface area per unit volume of the exchanger, resulting in reduced space, weight, support structure and footprint, energy requirement and cost, as well as improved process design, plant layout and processing conditions, together with low fluid inventory compared with shell-and-tube exchangers. From the operating condition and maintenance point of view, compact heat exchangers of different constructions are used for specific applications, such as for high-temperature applications (up to about 850°C or 1550°F), high pressure applications (over 200 bars), and moderate fouling applications. However, applications do not involve both high temperature and pressure simultaneously. Plate-fin exchangers are generally brazed, and the largest size currently manufactured is 1.2 × 1.2 × 6 m (4 × 4 × 20 ft). Fouling is one of the major potential problems in many compact exchangers except for the plate heat exchangers. With a large frontal area exchanger, flow maldistribution could be another problem. Because of short transient times, a careful design of controls is required for startup of some compact heat exchangers compared with shell-and-tube exchangers. No industry standards or recognized practice for compact heat exchangers is yet available.

This section is divided into two parts: Compact Heat Exchangers and Shell-and-Tube Exchangers, written by R. K. Shah and K. J. Bell, respectively. In the compact heat exchangers section, the following topics are covered: definition and description of exchangers, heat transfer and pressure drop analyses, heat transfer and flow friction correlations, exchanger design (rating and sizing) methodology, flow maldistribution, and fouling. In the shell-and-tube heat exchangers section, the following topics are covered: construction features, principles of design, and an approximate design method with an example.

### Compact Heat Exchangers

*Ramesh K. Shah*

#### Introduction

A heat exchanger is a device to provide for transfer of internal thermal energy (enthalpy) between two or more fluids, between a solid surface and a fluid, or between solid particulates and a fluid, in thermal contact without external heat and work interactions. The fluids may be single compounds or mixtures. Typical applications involve heating or cooling of a fluid stream of concern, evaporation or condensation of single or multicomponent fluid stream, and heat recovery or heat rejection from a system. In other applications, the objective may be to sterilize, pasteurize, fractionate, distill, concentrate, crystallize, or control process fluid. In some heat exchangers, the fluids transferring heat are in direct contact. In other heat exchangers, heat transfer between fluids takes place through a separating wall or into and out of a

wall in a transient manner. In most heat exchangers, the fluids are separated by a heat transfer surface and do not mix. Such exchangers are referred to as *direct transfer type*, or simply *recuperators*. Exchangers in which there is an intermittent flow of heat from the hot to cold fluid (via heat storage and heat rejection through the exchanger surface or matrix) are referred to as *indirect transfer type* or simply *regenerators*.

The heat transfer surface is a surface of the exchanger core which is in direct contact with fluids and through which heat is transferred by conduction in a recuperator. The portion of the surface which also separates the fluids is referred to as a *primary or direct surface*. To increase heat transfer area, appendages known as fins may be intimately connected to the primary surface to provide an *extended, secondary, or indirect surface*. Thus, the addition of fins reduces the thermal resistance on that side and thereby increases the net heat transfer from the surface for the same temperature difference.

Heat exchangers may be classified according to transfer process, construction, flow arrangement, surface compactness, number of fluids, and heat transfer mechanisms as shown in Figure 4.5.1.

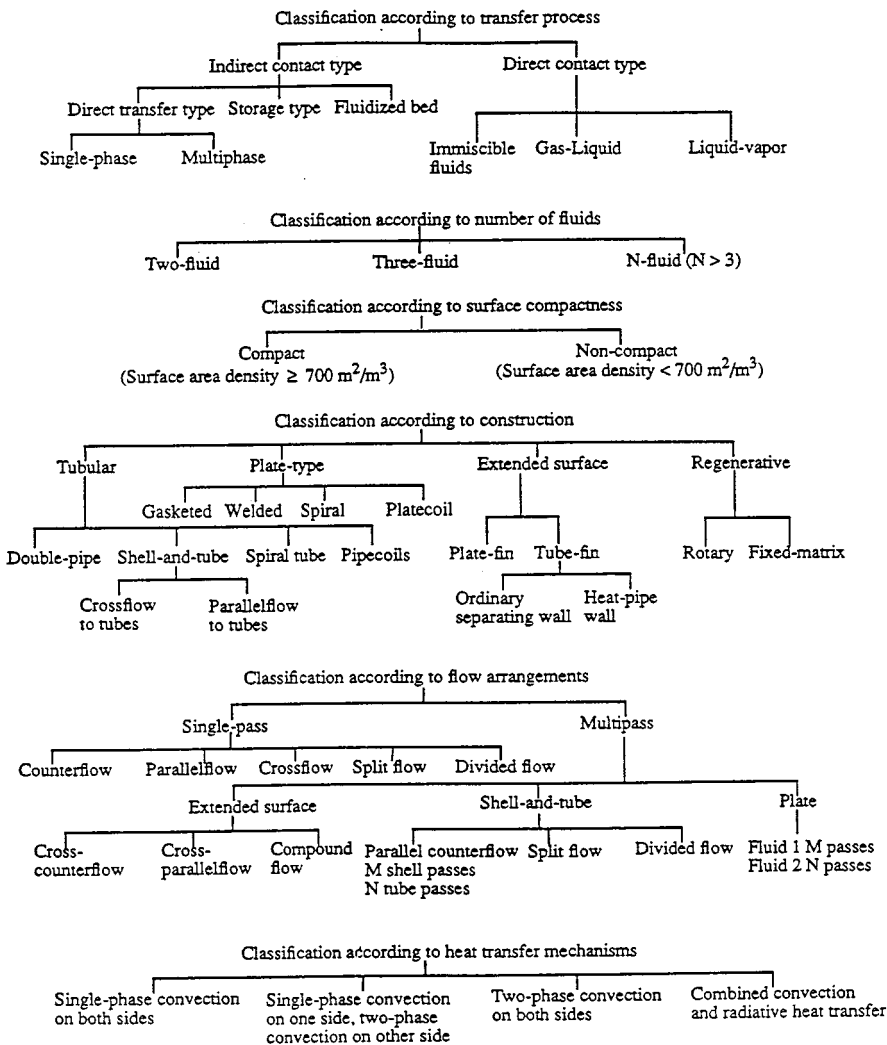

FIGURE 4.5.1 Classification of heat exchangers.

A gas-to-fluid heat exchanger is referred to as a compact heat exchanger if it incorporates a heat transfer surface having a surface area density above about  $700 \text{ m}^2/\text{m}^3$  ( $213 \text{ ft}^2/\text{ft}^3$ ) on at least one of the fluid sides which usually has gas flow. It is referred to as a laminar flow heat exchanger if the surface area density is above about  $3000 \text{ m}^2/\text{m}^3$  ( $914 \text{ ft}^2/\text{ft}^3$ ), and as a micro heat exchanger if the surface area density is above about  $10,000 \text{ m}^2/\text{m}^3$  ( $3050 \text{ ft}^2/\text{ft}^3$ ). A liquid/two-phase heat exchanger is referred to as a compact heat exchanger if the surface area density on any one fluid side is above about  $400 \text{ m}^2/\text{m}^3$  ( $122 \text{ ft}^2/\text{ft}^3$ ). A typical process industry shell-and-tube exchanger has a surface area density of less than  $100 \text{ m}^2/\text{m}^3$  on one fluid side with plain tubes, and two to three times that with the high-fin-density low-finned tubing. Plate-fin, tube-fin, and rotary regenerators are examples of compact heat exchangers for gas flows on one or both fluid sides, and gasketed and welded plate heat exchangers are examples of compact heat exchangers for liquid flows.

## Types and Description

### *Gas-to-Fluid Exchangers.*

The important design and operating considerations for compact extended surface exchangers are (1) usually at least one of the fluids is a gas or specific liquid that has low  $h$ ; (2) fluids must be clean and relatively noncorrosive because of small hydraulic diameter ( $D_h$ ) flow passages and no easy techniques for mechanically cleaning them; (3) the fluid pumping power (i.e., pressure drop) design constraint is often equally as important as the heat transfer rate; (4) operating pressures and temperatures are somewhat limited compared with shell-and-tube exchangers as a result of the joining of the fins to plates or tubes such as brazing, mechanical expansion, etc.; (5) with the use of highly compact surfaces, the resultant shape of a gas-to-fluid exchanger is one having a large frontal area and a short flow length (the header design of a compact heat exchanger is thus important for a uniform flow distribution among the very large number of small flow passages); (6) the market potential must be large enough to warrant the sizable manufacturing research and tooling costs for new forms to be developed.

Some advantages of plate-fin exchangers over conventional shell-and-tube exchangers are as follows. Compact heat exchangers, generally fabricated from thin metallic plates, yield large heat transfer surface area per unit volume ( $\beta$ ), typically up to ten times greater than the 50 to  $100 \text{ m}^2/\text{m}^3$  provided by a shell-and-tube exchanger for general process application and from 1000 to  $6000 \text{ m}^2/\text{m}^3$  for highly compact gas side surfaces. Compact liquid or two-phase side surfaces have a  $\beta$  ratio ranging from 500 to 600  $\text{m}^2/\text{m}^3$ . A compact exchanger provides a tighter temperature control; thus it is useful for heat-sensitive materials, improves the product (e.g., refining fats from edible oil) and its quality (such as a catalyst bed). Also, a compact exchanger could provide rapid heating or cooling of a process stream, thus improving the product quality. The plate-fin exchangers can accommodate multiple (up to 12 or more) fluid streams in one exchanger unit with proper manifolding, thus allowing process integration and cost-effective compact solutions.

Fouling is one of the potential major problems in compact heat exchangers (except for plate-and-frame heat exchangers), particularly those having a variety of fin geometries or very fine circular or noncircular flow passages that cannot be cleaned mechanically. Chemical cleaning may be possible; thermal baking and subsequent rinsing is possible for small-size units. Hence, extended surface compact heat exchangers may not be used in heavy fouling applications.

### *Liquid-to-Liquid Exchangers.*

Liquid-to-liquid and phase-change exchangers are plate-and-frame and welded plate heat exchangers (PHE), spiral plate, and printed circuit exchangers; some of them are described next in some detail along with other compact heat exchangers and their applications.

### *Plate-Fin Heat Exchangers.*

This type of exchanger has “corrugated” fins or spacers sandwiched between parallel plates (referred to as plates or parting sheets) as shown in [Figure 4.5.2](#). Sometimes fins are incorporated in a flat tube with rounded corners (referred to as a formed tube), thus eliminating a need for the side bars. If liquid or

**FIGURE 4.5.2** Typical components of a plate-fin exchanger.

phase-change fluid flows on the other side, the parting sheet is usually replaced by a flat tube with or without inserts/webs. Other plate-fin constructions include drawn-cup (see [Figure 4.5.3](#)) or tube-and-

**FIGURE 4.5.3** U-channel ribbed plates and multilouver fin automotive evaporator. (Courtesy of Delphi Harrison Thermal Systems, Lockport, NY.)

center configurations. Fins are die- or roll-formed and are attached to the plates by brazing, soldering, adhesive bonding, welding, mechanical fit, or extrusion. Fins may be used on both sides in gas-to-gas heat exchangers. In gas-to-liquid applications, fins are usually used only on the gas side; if employed on the liquid side, they are used primarily for structural strength and flow-mixing purposes. Fins are also sometimes used for pressure containment and rigidity.

**FIGURE 4.5.4** Fin geometries for plate-fin heat exchangers: (a) plain triangular fin, (b) plain rectangular fin, (c) wavy fin, (d) offset strip fin, (e) multilouver fin, and (f) perforated fin.

Plate fins are categorized as (1) plain (i.e., uncut) and straight fins, such as plain triangular and rectangular fins; (2) plain but wavy fins (wavy in the main fluid flow direction); and (3) interrupted fins such as offset strip, louver, and perforated. Examples of commonly used fins are shown in Figure 4.5.4.

Plate-fin exchangers have been built with a surface area density of up to about  $5900 \text{ m}^2/\text{m}^3$  ( $1800 \text{ ft}^2/\text{ft}^3$ ). There is a total freedom of selecting fin surface area on each fluid side, as required by the design, by varying fin height and fin density. Although typical fin densities are 120 to 700 fins/m (3 to 18 fins/in.), applications exist for as many as 2100 fins/m (53 fins/in.). Common fin thicknesses range from 0.05 to 0.25 mm (0.002 to 0.010 in.). Fin heights range from 2 to 25 mm (0.08 to 1.0 in.). A plate-fin exchanger with 600 fins/m (15.2 fins/in.) provides about  $1300 \text{ m}^2$  ( $400 \text{ ft}^2/\text{ft}^3$ ) of heat transfer surface area per cubic meter volume occupied by the fins. Plate-fin exchangers are manufactured in virtually all shapes and sizes, and made from a variety of materials.

#### ***Tube-Fin Heat Exchangers.***

In this type of exchanger, round and rectangular tubes are the most common, although elliptical tubes are also used. Fins are generally used on the outside, but they may be used on the inside of the tubes in some applications. They are attached to the tubes by a tight mechanical fit, tension winding, adhesive bonding, soldering, brazing, welding, or extrusion. Fins on the outside of the tubes may be categorized as follows: (1) normal fins on individual tubes, referred to as individually finned tubes or simply as *finned tubes*, as shown in Figures 4.5.6 and 4.5.5a; (2) flat or continuous (plain, wavy, or interrupted) external fins on an array of tubes, as shown in Figures 4.5.7 and 4.5.5b; (3) longitudinal fins on individual tubes. The exchanger having flat (continuous) fins on tubes has also been referred to as a *plate-fin and tube* exchanger in the literature. In order to avoid confusion with plate-fin surfaces, we will refer to it as a tube-fin exchanger having flat (plain, wavy, or interrupted) fins. Individually finned tubes are probably more rugged and practical in large tube-fin exchangers. Shell-and-tube exchangers sometimes employ low-finned tubes to increase the surface area on the shell side when the shell-side heat transfer coefficient is low compared with the tube side coefficient. The exchanger with flat fins is usually less expensive on a unit heat transfer surface area basis because of its simple and mass-production-type construction

**FIGURE 4.5.5** (a) Individually finned tubes, (b) flat or continuous fins on an array of tubes.

**FIGURE 4.5.6** Individually finned tubes: (a) helical, (b) annular disk, (c) segmented, (d) studded, (e) wire loop, and (f) slotted helical.

features. Longitudinal fins are generally used in condensing applications and for viscous fluids in double-pipe heat exchangers.

Tube-fin exchangers can withstand high pressures on the tube side. The highest temperature is again limited by the type of bonding, the materials employed, and the material thickness. Tube-fin exchangers with an area density of about  $3300 \text{ m}^2/\text{m}^3$  ( $1000 \text{ ft}^2/\text{ft}^3$ ) are commercially available. On the fin side, the desired surface area can be employed by using the proper fin density and fin geometry. The typical fin densities for flat fins vary from 250 to 800 fins/m (6 to 20 fins/in.), fin thicknesses vary from 0.08 to 0.25 mm (0.003 to 0.010 in.), and fin flow lengths from 25 to 250 mm (1 to 10 in.). A tube-fin exchanger having flat fins with 400 fins/m (10 fins/in.) has a surface area density of about  $720 \text{ m}^2/\text{m}^3$  ( $220 \text{ ft}^2/\text{ft}^3$ ). These exchangers are extensively used as condensers and evaporators in air-conditioning and refrigeration applications, as condensers in electric power plants, as oil coolers in propulsive power plants, and as air-cooled exchangers (also referred to as a fin-fan exchanger) in process and power industries.

**FIGURE 4.5.7** Flat or continuous fins on an array of tubes: On round tubes: (a) wavy fin, (b) multilouver fin, (c) fin with structured surface roughness (dimples), (d) parallel louver fin; (e) louver fin on flat tubes; (f) multilouver fin on elliptical tubes.

### **Regenerators.**

The regenerator is a storage-type exchanger. The heat transfer surface or elements are usually referred to as a matrix in the regenerator. In order to have continuous operation, either the matrix must be moved periodically into and out of the fixed streams of gases, as in a *rotary* regenerator (Figure 4.5.8a), or the gas flows must be diverted through valves to and from the fixed matrices as in a *fixed-matrix* regenerator (Figure 4.5.8b). The latter is also sometimes referred to as a *periodic-flow regenerator* or a *reversible heat accumulator*. A third type of regenerator has a fixed matrix (in the disk form) and the fixed stream of gases, but the gases are ducted through rotating hoods (headers) to the matrix as shown in Figure 4.5.8c. This Rothemuhle regenerator is used as an air preheater in some power-generating plants. The thermodynamically superior counterflow arrangement is usually employed in regenerators.

The **rotary regenerator** is usually a disk type in which the matrix (heat transfer surface) is in a disk form and fluids flow axially. It is rotated by a hub shaft or a peripheral ring gear drive. For a rotary regenerator, the design of seals to prevent leakage of hot to cold fluids and vice versa becomes a difficult task, especially if the two fluids are at significantly differing pressures. Rotating drives also pose a challenging mechanical design problem.

Major advantages of rotary regenerators are the following. For a highly compact regenerator, the cost of the regenerator surface per unit of heat transfer area is usually substantially lower than that for the equivalent recuperator. A major disadvantage of a regenerator is an unavoidable carryover of a small fraction of the fluid trapped in the passage to the other fluid stream just after the periodic flow switching. Since fluid contamination (small mixing) is prohibited with liquids, the regenerators are used exclusively for gas-to-gas heat or energy recovery applications. Cross contamination can be minimized significantly by providing a purge section in the disk and using double-labyrinth seals.

Rotary regenerators have been designed for a surface area density of up to about  $6600 \text{ m}^2/\text{m}^3$  ( $2000 \text{ ft}^2/\text{ft}^3$ ), and exchanger effectivenesses exceeding 85% for a number of applications. They can employ thinner stock material, resulting in the lowest amount of material for a given effectiveness and pressure

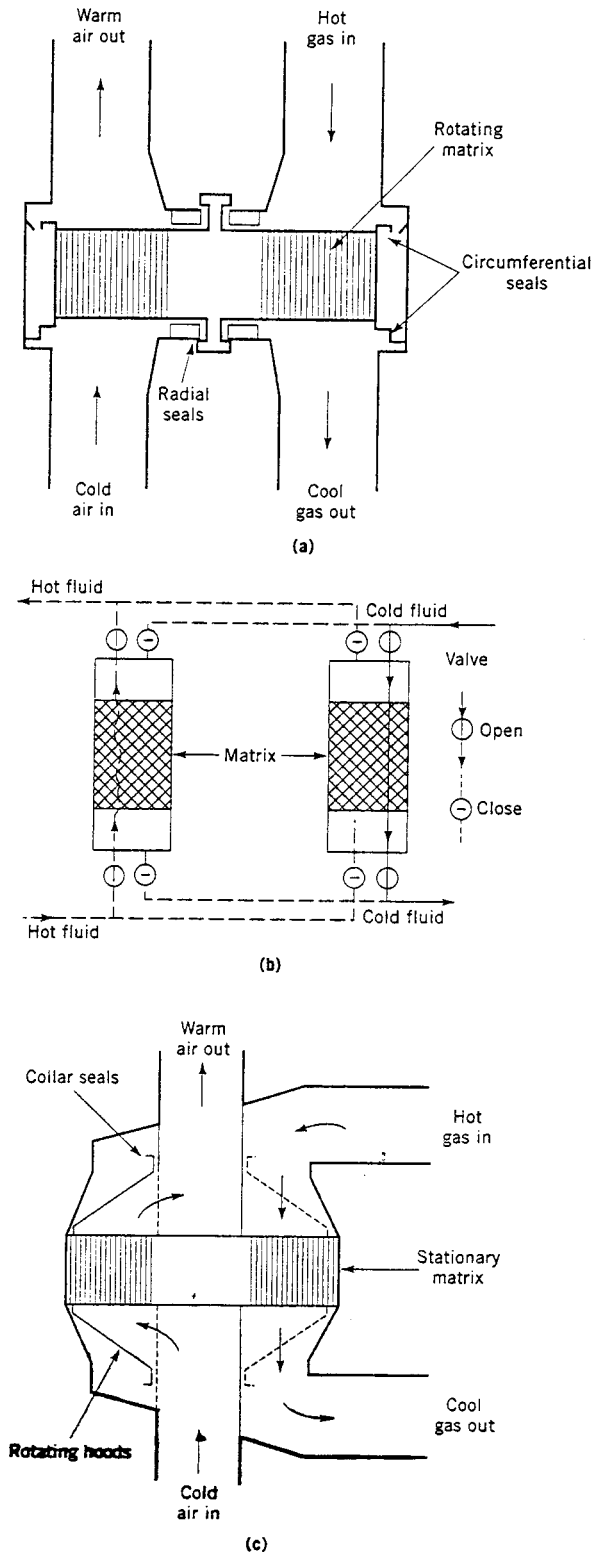

FIGURE 4.5.8 Regenerators: (a) rotary, (b) fixed-matrix, and (c) Rothemuhle.

drop of any heat exchanger known today. The metal rotary regenerators have been designed for continuous inlet temperatures up to about 790°C (1450°F) and ceramic matrices for higher-temperature applications; these regenerators are designed up to 400 kPa or 60 psi pressure differences between hot and cold gases. Plastic, paper, and wool are used for regenerators operating below 65°C (150°F) inlet temperature of the hot gas and 1 atm pressure. Typical regenerator rotor diameters and rotational speeds are as follows: up to 10 m (33 ft) and 0.5 to 3 rpm for power plant regenerators, 0.25 to 3 m (0.8 to 9.8 ft) and up to 10 rpm for air-ventilating regenerators, and up to 0.6 m (24 in.) and up to 18 rpm for vehicular regenerators. Refer to Shah (1994) for the description of **fixed-matrix regenerator**, also referred to as a *periodic-flow, fixed bed, valved, or stationary* regenerator.

#### **Plate-Type Heat Exchangers.**

These exchangers are usually built of thin plates (all prime surface). The plates are either smooth or have some form of corrugations, and they are either flat or wound in an exchanger. Generally, these exchangers cannot accommodate very high pressures, temperatures, and pressure and temperature differentials. These exchangers may be further classified as plate, spiral plate, lamella, and plate-coil exchangers as classified in Figure 4.5.1. The plate heat exchanger, being the most important of these, is described next.

The **plate-and-frame** or **gasketed PHE** consists of a number of thin rectangular corrugated or embossed metal plates sealed around the edges by gaskets and held together in a frame as shown in Figure 4.5.9. The plate pack with fixed and movable end covers is clamped together by long bolts, thus compressing the gaskets and forming a seal. Sealing between the two fluids is accomplished by elastomeric molded gaskets (typically 5 mm or 0.2 in. thick) that are fitted in peripheral grooves mentioned earlier. The most conventional flow arrangement is one pass to one pass counterflow with all inlet and outlet connections on the fixed end cover. By blocking flow through some ports with proper gasketing, either one or both fluids could have more than one pass. Also more than one exchanger can be accommodated in a single frame with the use of intermediate connector plates such as up to five “exchangers” or sections to heat, cool, and regenerate heat between raw milk and pasteurized milk in a milk pasteurization application.

**FIGURE 4.5.9** A plate-and-frame or gasketed PHE.

**TABLE 4.5.1** Some Geometric and Operating Condition Characteristics of Plate-and-Frame Heat Exchangers

Unit		Operation	
Maximum surface area	2500 m <sup>2</sup>	Pressure	0.1 to 2.5 MPa
Number of plates	3–700	Temperature	–40 to 260°C
Port size	Up to 400 mm	Maximum port velocity	6 m/sec
<b>Plates</b>		Channel flow rates	0.05 to 12.5 m <sup>3</sup> /hr
Thickness	0.5–1.2 mm	Max unit flow rate	2500 m <sup>3</sup> /hr
Size	0.03–3.6 m <sup>2</sup>	<b>Performance</b>	
Spacing	1.5–5 mm	Temperature approach	As low as 1°C
Width	70–1200 mm	Heat exchanger efficiency	Up to 93%
Length	0.6–5 m	Heat transfer coefficients	3000 to 7000 W/m <sup>2</sup> K
		for water-water duties	

Source: From Shah, R.K., in *Encyclopedia of Energy Technology and the Environment*, A. Bision and S.G. Boots, Eds., John Wiley & Sons, New York, 1994, 1651–1670. With permission.

Typical PHE dimensions and performance parameters are given in Table 4.5.1 (Shah, 1994). Any metal which can be cold-worked is suitable for PHE applications. The most common plate materials are stainless steel (AISI 304 or 316) and titanium. Plates made from Incoloy 825, Inconel 625, Hastelloy C-276 are also available. Nickel, cupronickel, and monel are rarely used. Carbon steel is not used because of low corrosion resistance for thin plates. The heat transfer surface area per unit volume for plate exchangers ranges from 120 to 660 m<sup>2</sup>/m<sup>3</sup> (37 to 200 ft<sup>2</sup>/ft<sup>3</sup>).

In PHEs, the high turbulence due to plates reduces fouling from about 10 to 25% of that of a shell-and-tube exchanger. High thermal performance can be achieved in plate exchangers because the high degree of counterflow in PHEs makes temperature approaches of up to 1°C (2°F) possible. The high thermal effectiveness (up to about 93%) makes low-grade heat recovery economical. PHEs are most suitable for liquid-liquid heat transfer duties.

**Welded PHEs.** One of the limitations of gasketed PHE is the presence of the gaskets which restricts the use to compatible fluids and which limits operating temperatures and pressures. In order to overcome this limitation, a number of welded PHE designs have surfaced with a welded pair of plates for one or both fluid sides. However, the disadvantage of such design is the loss of disassembling flexibility on the fluid side where the welding is done. Essentially, welding is done around the complete circumference where the gasket is normally placed. A *stacked plate heat exchanger* is another welded PHE design from Pacinox in which rectangular plates are stacked and welded at the edges. The physical size limitations of PHEs (1.2 m wide × 4 m long max, 4 × 13 ft) are considerably extended to 1.5 m wide × 20 m long (5 × 66 ft) in this exchanger. A maximum surface area of (10,000 m<sup>2</sup> or over 100,000 ft<sup>2</sup>) can be accommodated in one unit. The potential maximum operating temperature is 815°C (1500°F) with an operating pressure of up to 20 MPa (3000 psig) when the stacked plate assembly is placed in a cylindrical pressure vessel. For operating pressures below 2 MPa (300 psig) and operating temperatures below 200°C (400°F), the plate bundle is not contained in a pressure vessel, but is bolted between two heavy plates. Some of the applications of this exchanger are catalytic reforming, hydrosulfurization, crude distillation, synthesis converter feed effluent exchanger for methanol, propane condenser, etc.

A number of other PHE constructions have been developed to address some of the limitations of the conventional PHEs. A double-wall PHE is used to avoid mixing of the two fluids. A wide-gap PHE is used for fluids having high fiber content or coarse particles. A graphite PHE is used for highly corrosive fluids. A flow-flex exchanger has plain fins on one side between plates and the other side has conventional plate channels, and is used to handle asymmetric duties (flow rate ratio of 2 to 1 and higher).

A vacuum **brazed PHE** is a compact PHE for high-temperature and high-pressure duties, and it does not have gaskets, tightening bolts, frame, or carrying and guide bars. It simply consists of stainless steel plates and two end plates. The brazed unit can be mounted directly on piping without brackets and foundations.

**Printed Circuit Heat Exchangers.** This exchanger, as shown in [Figure 4.5.10](#), has only primary heat transfer surfaces as PHEs. Fine grooves are made in the plate by using the same techniques as those employed for making printed electrical circuits. High surface area densities (650 to 1350 m<sup>2</sup>/m<sup>3</sup> or 200 to 400 ft<sup>2</sup>/ft<sup>3</sup> for operating pressures of 500 to 100 bar respectively) are achievable. A variety of materials including stainless steel, nickel, and titanium alloys can be used. It has been successfully used with relatively clean gases, liquids and phase-change fluids in chemical processing, fuel processing, waste heat recovery, and refrigeration industries. Again, this exchanger is a new construction with limited special applications currently.

### Exchanger Heat Transfer and Pressure Drop Analysis

In this subsection, starting with the thermal circuit associated with a two-fluid exchanger,  $\epsilon$ -NTU, P-NTU, and mean temperature difference (MTD) methods used for an exchanger analysis are presented, followed by the fin efficiency concept and various expressions. Finally, pressure drop expressions are outlined for various single-phase exchangers.

Two energy conservation differential equations for a two-fluid exchanger with any flow arrangement are (see [Figure 4.5.11](#) for counterflow)

$$dq = q'' dA = -C_h dT_h = \pm C_c dT_c \quad (4.5.1)$$

where the  $\pm$  sign depends upon whether  $dT_c$  is increasing or decreasing with increasing  $dA$  or  $dx$ . The local overall rate equation is

$$dq = q'' dA = U(T_h - T_c)_{\text{local}} dA = U \Delta T dA \quad (4.5.2)$$

Integration of Equations (4.5.1) and (4.5.2) across the exchanger surface area results in

$$q = C_h(T_{h,i} - T_{h,o}) = C_c(T_{c,o} - T_{c,i}) \quad (4.5.3)$$

and

$$q = UA \Delta T_m = \Delta T_m / R_o \quad (4.5.4)$$

where  $\Delta T_m$  is the true mean temperature difference (or MTD) that depends upon the exchanger flow arrangement and degree of fluid mixing within each fluid stream. The inverse of the overall thermal conductance  $UA$  is referred to as the overall thermal resistance  $R_o$ , as follows (see [Figure 4.5.12](#)).

FIGURE 4.5.11 Nomenclature for heat exchanger variables.

FIGURE 4.5.12 Thermal circuit for heat transfer in an exchanger.

$$R_o = R_h + R_{s,h} + R_w + R_{s,c} + R_c \tag{4.5.5}$$

where the subscripts  $h$ ,  $c$ ,  $s$ , and  $w$  denote hot, cold, fouling (or scale), and wall, respectively. In terms of the overall and individual heat transfer coefficients, Equation (4.5.5) is represented as

$$\frac{1}{UA} = \frac{1}{(\eta_o hA)_h} + \frac{1}{(\eta_o h_s A)_h} + R_w + \frac{1}{(\eta_o h_s A)_c} + \frac{1}{(\eta_o hA)_c} \tag{4.5.6}$$

where  $\eta_o$  = the overall surface efficiency of an extended (fin) surface and is related to the fin efficiency  $\eta_f$ , fin surface area  $A_f$ , and the total surface area  $A$  as follows:

$$\eta_o = 1 - \frac{A_f}{A} (1 - \eta_f) \tag{4.5.7}$$

The wall thermal resistance  $R_w$  of Equation (4.5.5) is given by

$$R_w = \begin{cases} \delta/A_w k_w & \text{for a flat wall} \\ \frac{\ln(d_o/d_i)}{2\pi k_w L N_t} & \text{for a circular tube with a single-layer wall} \\ \frac{1}{2\pi L N_t} \left[ \sum_j \frac{\ln(d_{j+1}/d_j)}{k_{w,j}} \right] & \text{for a circular tube with a multiple-layer wall} \end{cases} \quad (4.5.8)$$

If one of the resistances on the right-hand side of Equation (4.5.5) or (4.5.6) is significantly higher than the other resistances, it is referred to as the *controlling thermal resistance*. A reduction in the controlling thermal resistance will have much more impact in reducing the exchanger surface area ( $A$ ) requirement compared with the reduction in  $A$  as a result of the reduction in other thermal resistances.

$UA$  of Equation (4.5.6) may be defined in terms of hot or cold fluid side surface area or wall conduction area as

$$UA = U_h A_h = U_c A_c = U_w A_w \quad (4.5.9)$$

When  $R_w$  is negligible,  $T_{w,h} = T_{w,c} = T_w$  of Figure 4.5.12 is computed from

$$T_w = \frac{T_h + \left[ (R_h + R_{s,h}) / (R_c + R_{s,c}) \right] T_c}{1 + \left[ (R_h + R_{s,h}) / (R_c + R_{s,c}) \right]} \quad (4.5.10)$$

When  $R_{s,h} = R_{s,c} = 0$ , Equation (4.5.10) reduces to

$$T_w = \frac{T_h/R_h + T_c/R_c}{1/R_h + 1/R_c} = \frac{(\eta_o hA)_h T_h + (\eta_o hA)_c T_c}{(\eta_o hA)_h + (\eta_o hA)_c} \quad (4.5.11)$$

*$\varepsilon$ -NTU,  $P$ -NTU, and MTD Methods.* If we consider the fluid outlet temperatures or heat transfer rate as dependent variables, they are related to independent variable/parameters of Figure 4.5.11 as follows.

$$T_{h,o}, T_{c,o}, \text{ or } q = \phi \left\{ T_{h,i}, T_{c,i}, C_c, C_h, U, A, \text{ flow arrangement} \right\} \quad (4.5.12)$$

Six independent and three dependent variables of Equation (4.5.12) for a given flow arrangement can be transferred into two independent and one dependent dimensionless groups; three different methods are presented in Table 4.5.2 based on the choice of three dimensionless groups. The relationship among three dimensionless groups is derived by integrating Equations (4.5.1) and (4.5.2) across the surface area for a specified exchanger flow arrangement. Such expressions are presented later in Table 4.5.4 for the industrially most important flow arrangements. Now we briefly describe the three methods.

In the  *$\varepsilon$ -NTU method*, the heat transfer rate from the hot fluid to the cold fluid in the exchanger is expressed as

$$q = \varepsilon C_{\min} (T_{h,i} - T_{c,i}) \quad (4.5.13)$$

**TABLE 4.5.2 General Functional Relationships and Dimensionless Groups for  $\epsilon$ -NTU, P-NTU, and MTD Methods**

$\epsilon$ -NTU Method	P-NTU Method <sup>a</sup>	MTD Method <sup>a</sup>
$q = \epsilon C_{\min}(T_{h,i} - T_{c,i})$	$q = P_1 C_1  T_{1,i} - T_{2,i} $	$q = UAF\Delta T_m$
$\epsilon = \phi(\text{NTU}, C^*, \text{flow arrangement})$	$P_1 = \phi(\text{NTU}_1, R_1, \text{flow arrangement})$	$F = \phi(P, R, \text{flow arrangement})^b$
$\epsilon = \frac{C_h(T_{h,i} - T_{h,o})}{C_{\min}(T_{h,i} - T_{c,i})} = \frac{C_c(T_{c,o} - T_{c,i})}{C_{\min}(T_{h,i} - T_{c,i})}$	$P_1 = \frac{T_{1,o} - T_{1,i}}{T_{2,i} - T_{1,i}}$	$F = \frac{\Delta T_m}{\Delta T_{\text{lm}}}$
$\text{NTU} = \frac{UA}{C_{\min}} = \frac{1}{C_{\min}} \int_A U dA$	$\text{NTU}_1 = \frac{UA}{C_1} = \frac{ T_{1,o} - T_{1,i} }{\Delta T_m}$	$\text{LMTD} = \Delta T_{\text{lm}} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)}$
$C^* = \frac{C_{\min}}{C_{\max}} = \frac{(\dot{m}c_p)_{\min}}{(\dot{m}c_p)_{\max}}$	$R_1 = \frac{C_1}{C_2} = \frac{T_{2,i} - T_{2,o}}{T_{1,o} - T_{1,i}}$	$\Delta T_1 = T_{h,i} - T_{c,o} \quad \Delta T_2 = T_{h,o} - T_{c,i}$

<sup>a</sup> Although P, R, and  $\text{NTU}_1$  are defined on fluid side 1, it must be emphasized that all the results of the P-NTU and MTD methods are valid if the definitions of P, NTU, and R are consistently based on  $C_c$ ,  $C_s$ ,  $C_h$ , or C.

<sup>b</sup> P and R are defined in the P-NTU method.

Here the exchanger effectiveness  $\epsilon$  is an efficiency factor. It is a ratio of the actual heat transfer rate from the hot fluid to the cold fluid in a given heat exchanger of any flow arrangement to the maximum possible heat transfer rate  $q_{\max}$  thermodynamically permitted. The  $q_{\max}$  is obtained in a *counterflow* heat exchanger (recuperator) of *infinite surface area* operating with the fluid flow rates (heat capacity rates) and fluid inlet temperatures equal to those of an actual exchanger (constant fluid properties are idealized). As noted in Table 4.5.1, the exchanger effectiveness  $\epsilon$  is a function of NTU and  $C^*$  in this method. The number of transfer units NTU is a ratio of the overall conductance  $UA$  to the smaller heat capacity rate  $C_{\min}$ . NTU designates the dimensionless “heat transfer size” or “thermal size” of the exchanger. Other interpretations of NTU are given by Shah (1983). The heat capacity rate ratio  $C^*$  is simply a ratio of the smaller to the larger heat capacity rate for the two fluid streams. Note that  $0 \leq \epsilon \leq 1$ ,  $0 \leq \text{NTU} \leq \infty$  and  $0 \leq C^* \leq 1$ .

The P-NTU method represents a variant of the  $\epsilon$ -NTU method. The  $\epsilon$ -NTU relationship is different depending upon whether the shell fluid is the  $C_{\min}$  or  $C_{\max}$  fluid in the (stream unsymmetric) flow arrangements commonly used for shell-and-tube exchangers. In order to avoid possible errors and to avoid keeping track of the  $C_{\min}$  fluid side, an alternative is to present the temperature effectiveness  $P$  as a function of NTU and  $R$ , where  $P$ , NTU, and  $R$  are defined consistently either for Fluid 1 side or Fluid 2 side; in Table 4.5.2, they are defined for Fluid 1 side (regardless of whether that side is the hot or cold fluid side), and Fluid 1 side is clearly identified for each flow arrangement in Table 4.5.4; it is the shell side in a shell-and-tube exchanger. Note that

$$q = P_1 C_1 |T_{1,i} - T_{2,i}| = P_2 C_2 |T_{2,i} - T_{1,i}| \quad (4.5.14)$$

$$P_1 = P_2 R_2 \quad P_2 = P_1 R_1 \quad (4.5.15)$$

$$\text{NTU}_1 = \text{NTU}_2 R_2 \quad \text{NTU}_2 = \text{NTU}_1 R_1 \quad (4.5.16)$$

and

$$R_1 = 1/R_2 \quad (4.5.17)$$

In the MTD method, the heat transfer rate from the hot fluid to the cold fluid in the exchanger is given by

$$q = UA\Delta T_m = UAF\Delta T_{lm} \quad (4.5.18)$$

where  $\Delta T_m$  the log-mean temperature difference (LMTD), and  $F$  the LMTD correction factor, a ratio of true (actual) MTD to the LMTD, where

$$\text{LMTD} = \Delta T_{lm} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)} \quad (4.5.19)$$

Here  $\Delta T_1$  and  $\Delta T_2$  are defined as

$$\begin{aligned} \Delta T_1 = T_{h,i} - T_{c,o} \quad \Delta T_2 = T_{h,o} - T_{c,i} & \quad \text{for all flow arrangements} \\ & \quad \text{except for parallel flow} \end{aligned} \quad (4.5.20)$$

$$\begin{aligned} \Delta T_1 = T_{h,i} - T_{c,i} \quad T_2 = T_{h,o} - T_{c,o} & \quad \text{for parallel flow} \end{aligned} \quad (4.5.21)$$

The LMTD represents a true MTD for a counterflow arrangement under the idealizations listed below. Thus, the LMTD correction factor  $F$  represents a degree of departure for the MTD from the counterflow LMTD; it does not represent the effectiveness of a heat exchanger. It depends on two dimensionless group  $P_1$  and  $R_1$  or  $P_2$  and  $R_2$  for a given flow arrangement.

**TABLE 4.5.3 Relationships between Dimensionless Groups of the P-NTU and LMTD Methods and Those of the  $\epsilon$ -NTU Method**

---

$$P_1 = \frac{C_{\min}}{C_1} \epsilon = \begin{cases} \epsilon & \text{for } C_1 = C_{\min} \\ \epsilon C^* & \text{for } C_1 = C_{\max} \end{cases}$$

$$R_1 = \frac{C_1}{C_2} = \begin{cases} C^* & \text{for } C_1 = C_{\min} \\ 1/C^* & \text{for } C_1 = C_{\max} \end{cases}$$

$$\text{NTU}_1 = \text{NTU} \frac{C_{\min}}{C_1} = \begin{cases} \text{NTU} & \text{for } C_1 = C_{\min} \\ \text{NTU} C^* & \text{for } C_1 = C_{\max} \end{cases}$$

$$F = \frac{\text{NTU}_{cf}}{\text{NTU}} = \frac{1}{\text{NTU}(1-C^*)} \ln \left[ \frac{1-C^*\epsilon}{1-\epsilon} \right] \xrightarrow{C^*=1} \frac{\epsilon}{\text{NTU}(1-\epsilon)}$$

$$F = \frac{1}{\text{NTU}_1(1-R_1)} \ln \left[ \frac{1-RP_1}{1-P_1} \right] \xrightarrow{R_1=1} \frac{P_1}{\text{NTU}_1(1-P_1)}$$

---

The relationship among the dimensionless groups of the  $\epsilon$ -NTU, P-NTU, and MTD methods are presented in Table 4.5.3. The closed-form formulas for industrially important exchangers are presented in terms of  $P_1$ ,  $\text{NTU}_1$ , and  $R_1$  in Table 4.5.4. These formulas are valid under idealizations which include: (1) steady-state conditions; (2) negligible heat losses to the surrounding; (3) no phase changes in the fluid streams flowing through the exchanger, or phase changes (condensation or boiling) occurring at constant temperature and constant effective specific heat; (4) uniform velocity and temperature at the entrance of the heat exchanger on each fluid side; (5) the overall extended surface efficiency  $\eta_o$  is uniform and constant; (6) constant individual and overall heat transfer coefficients; (7) uniformly distributed heat transfer area on each fluid side; (7) the number of baffles as large in shell-and-tube exchangers; (8) no flow maldistribution; and (9) negligible longitudinal heat conduction in the fluid and exchanger wall.

The overall heat transfer coefficient can vary as a result of variations in local heat transfer coefficients due to two effects: (1) change in heat transfer coefficients in the exchanger as a result of changes in the fluid properties or radiation due to rise or drop of fluid temperatures and (2) change in heat transfer coefficients in the exchanger due to developing thermal boundary layers; it is referred to as the *length effect*. The first effect due to fluid property variations (or radiation) consists of two components: (1) distortion of velocity and temperature profiles at a given flow cross section due to fluid property variations — this effect is usually taken into account by the so-called property ratio method, with the correction scheme of Equations (4.5.55) and (4.5.56) — and (2) variations in the fluid temperature along the axial and transverse directions in the exchanger depending upon the exchanger flow arrangement — this effect is referred to as the *temperature effect*. The resultant axial changes in the overall mean heat transfer coefficient can be significant; the variations in  $U_{\text{local}}$  could be nonlinear, dependent upon the type of the fluid. The effect of varying  $U_{\text{local}}$  can be taken into account by evaluating  $U_{\text{local}}$  at a few points in the exchanger and subsequently integrating  $U_{\text{local}}$  values by the Simpson or Gauss method (Shah, 1993). The temperature effect can increase or decrease mean  $U$  slightly or significantly, depending upon the fluids and applications. The length effect is important for developing laminar flows for which high heat transfer coefficients are obtained in the thermal entrance region. However, in general it will have less impact on the overall heat transfer coefficient because the other thermal resistances in series in an exchanger may be controlling. The length effect reduces the overall heat transfer coefficient compared with the mean value calculated conventionally (assuming uniform mean heat transfer coefficient on each fluid side). It is shown that this reduction is up to about 11% for the worst case (Shah, 1993).

Shah and Pignotti (1997) have shown that the following are the specific number of baffles beyond which the influence of the finite number of baffles on the exchanger effectiveness is not significantly larger than 2%:  $N_b \geq 10$  for 1-1 TEMA E counterflow exchanger;  $N_b \geq 6$  for 1-2 TEMA E exchanger for  $\text{NTU}_s \leq 2$ ,  $R_s \leq 5$ ;  $N_b \geq 9$  for 1-2 TEMA J exchanger for  $\text{NTU}_s \leq 2$ ,  $R_s \leq 5$ ;  $N_b \geq 5$  for 1-2 TEMA G exchanger for  $\text{NTU}_s \leq 3$ , all  $R_s$ ;  $N_b \geq 11$  for 1-2 TEMA H exchanger for  $\text{NTU}_s \leq 3$ , all  $R_s$ . Various shell-and-tube heat exchangers (such as TEMA E, G, H, J, etc.) are classified by the Tubular Exchanger Manufacturers' Association (TEMA, 1988).

If any of the basic idealizations are not valid for a particular exchanger application, the best solution is to work directly with either Equations 4.5.1 and 4.5.2 or their modified form by including a particular effect, and to integrate them over a small exchanger segment numerically in which all of the idealizations are valid.

### ***Fin Efficiency and Extended Surface Efficiency.***

Extended surfaces have fins attached to the primary surface on one or both sides of a two-fluid or a multfluid heat exchanger. Fins can be of a variety of geometries — plain, wavy, or interrupted — and can be attached to the inside, outside, or both sides of circular, flat, or oval tubes, or parting sheets. Fins are primarily used to increase the surface area (when the heat transfer coefficient on that fluid side is relatively low) and consequently to increase the total rate of heat transfer. In addition, enhanced fin geometries also increase the heat transfer coefficient compared to that for a plain fin. Fins may also be used on the high heat transfer coefficient fluid side in a heat exchanger primarily for structural strength purposes (for example, for high-pressure water flow through a flat tube) or to provide a thorough mixing of a highly viscous liquid (such as for laminar oil flow in a flat or a round tube). Fins are attached to the primary surface by brazing, soldering, welding, adhesive bonding, or mechanical expansion, or they are extruded or integrally connected to the tubes. Major categories of extended surface heat exchangers are plate-fin (Figures 4.5.2 to 4.5.4) and tube-fin (Figures 4.5.5 to 4.5.7) exchangers. Note that shell-and-tube exchangers sometimes employ individually finned tubes — low finned tubes (similar to Figure 4.5.5a but with low-height fins) (Shah, 1985).

The concept of fin efficiency accounts for the reduction in temperature potential between the fin and the ambient fluid due to conduction along the fin and convection from or to the fin surface depending upon the fin cooling or heating situation. The fin efficiency is defined as the ratio of the actual heat transfer rate through the fin base divided by the maximum possible heat transfer rate through the fin

TABLE 4.5.4  $P_1 - NTU_1$  Formulas and Limiting Values  $P_1$  and  $R_1 = 1$  and  $NTU_1 \rightarrow \infty$  for Various Exchanger Flow Arrangements<sup>a</sup>

Series coupling of n exchangers, overall counterflow arrangement. Stream symmetric if all  $A_i$  are stream symmetric.

<sup>a</sup> In this table, all variables, except  $P_1$ ,  $R_1$ ,  $NTU_1$  and  $F$ , are local or dummy variables not necessarily related to similar ones defined in the nomenclature and the text. Source: Shah, R.K. and Mueller, A.C., 1988. With permission.

**FIGURE 4.5.13** A flat fin over (a) an in-line and (b) staggered tube arrangement; the smallest representative segment of the fin for (c) an in-line and (d) a staggered tube arrangement.

base which would be obtained if the entire fin were at the base temperature (i.e., its material thermal conductivity were infinite). Since most of the real fins are “thin”, they are treated as one-dimensional (1-D) with standard idealizations used for the analysis (Huang and Shah, 1992). This 1-D fin efficiency is a function of the fin geometry, fin material thermal conductivity, heat transfer coefficient at the fin surface, and the fin tip boundary condition; it is not a function of the fin base or fin tip temperature, ambient temperature, and heat flux at the fin base or fin tip in general. Fin efficiency formulas for some common fins are presented in Table 4.5.5 (Shah, 1985). Huang and Shah (1992) also discuss the influence on  $\eta_f$  if any of the basic idealizations used in the fin analysis are violated.

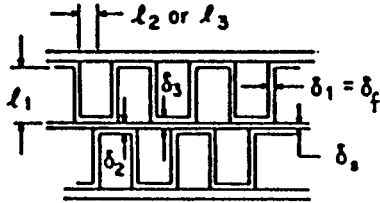

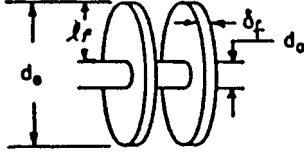

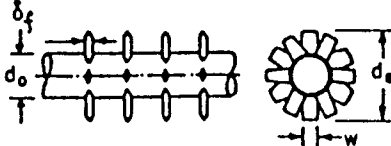

The fin efficiency for flat fins (Figure 4.5.5b) is obtained by a sector method (Shah, 1985). In this method, the rectangular or hexagonal fin around the tube (Figures 4.5.7a and b) or its smallest symmetrical section is divided into  $n$  sectors (Figure 4.5.13). Each sector is then considered as a circular fin with the radius  $r_{e,i}$  equal to the length of the centerline of the sector. The fin efficiency of each sector is subsequently computed using the circular fin formula of Table 4.5.5. The fin efficiency  $\eta_f$  for the whole fin is then the surface area weighted average of  $\eta_{f,i}$  of each sector.

$$\eta_f = \frac{\sum_{i=1}^n \eta_{f,i} A_{f,i}}{\sum_{i=1}^n A_{f,i}} \tag{4.5.22}$$

Since the heat flow seeks the path of least thermal resistance, actual  $\eta_f$  will be equal to or higher than that calculated by Equation (4.5.22); hence, Equation (4.5.22) yields a somewhat conservative value of  $\eta_f$ .

The  $\eta_f$  values of Table 4.5.5 or Equation (4.5.22) are not valid in general when the fin is thick, when it is subject to variable heat transfer coefficients or variable ambient fluid temperature, or when it has a temperature depression at the fin base. See Huang and Shah (1992) for details. For a thin rectangular fin of constant cross section, the fin efficiency as presented in Table 4.5.5 is given by

 <p data-bbox="330 1711 465 1734">Studded fin</p>	$\eta_j = \frac{\tanh(m l_e)}{m l_e}$ $m = \left( \frac{2h}{k_f \delta_f} \right)^{1/2} \quad l_e = l_j + \frac{\delta_f}{2} \quad r^* = \frac{d_e}{d_o}$ $m = \left[ \frac{2h}{k_f \delta_f} \left( 1 + \frac{\delta_f}{w} \right) \right]^{1/2} \quad l_e = l_j + \frac{\delta_f}{2} \quad l_f = \frac{(d_e - d_o)}{2}$

$$\eta_f = \frac{\tanh(m\ell)}{m\ell} \quad (4.5.23)$$

where  $m = [2h(1 + \delta_f \ell_f)/k_f \delta_f]^{1/2}$ . For a thick rectangular fin of constant cross section, the fin efficiency (a counterpart of Equation (4.5.23) is given by (Huang and Shah, 1992)

$$\eta_f = \frac{(\text{Bi}^+)^{1/2}}{K\text{Bi}} \tanh[K(\text{Bi}^+)^{1/2}] \quad (4.5.24)$$

where  $\text{Bi}^+ = \text{Bi}/(1 + \text{Bi}/4)$ ,  $\text{Bi} = (h\delta_f/2k_f)^{1/2}$ ,  $K = 2\ell/\delta_f$ . Equation (4.5.23) is accurate (within 0.3%) for a “thick” rectangular fin having  $\eta_f > 80\%$ ; otherwise, use Equation (4.5.24) for a thick fin.

In an extended-surface heat exchanger, heat transfer takes place from both the fins ( $\eta_f < 100\%$ ) and the primary surface ( $\eta_f = 100\%$ ). In that case, the total heat transfer rate is evaluated through a concept of extended surface efficiency  $\eta_o$  defined as

$$\eta_o = \frac{A_p}{A} + \eta_f \frac{A_f}{A} = 1 - \frac{A_f}{A} (1 - \eta_f) \quad (4.5.25)$$

where  $A_f$  is the fin surface area,  $A_p$  is the primary surface area, and  $A = A_f + A_p$ . In Equation 4.5.25, heat transfer coefficients over the finned and unfinned surfaces are idealized to be equal. Note that  $\eta_o \geq \eta_f$  and  $\eta_o$  is always required for the determination of thermal resistances of Equation (4.5.5) in heat exchanger analysis.

### Pressure Drop Analysis.

Usually a fan, blower, or pump is used to flow fluid through individual sides of a heat exchanger. Due to potential initial and operating high cost, low fluid pumping power requirement is highly desired for gases and viscous liquids. The fluid pumping power  $\wp$  is approximately related to the core pressure drop in the exchanger as (Shah, 1985).

$$\wp = \frac{\dot{m} \Delta p}{\rho} \approx \begin{cases} \frac{1}{2g_c} \frac{\mu}{\rho^2} \frac{4L}{D_h} f \text{Re} & \text{for laminar flow} \\ \frac{0.046}{2g_c} \frac{\mu^{0.2}}{\rho^2} \frac{4L}{D_h} \frac{\dot{m}^{2.8}}{A_0^{1.8} D_h^{0.2}} & \text{for turbulent flow} \end{cases} \quad (4.5.26)$$

$$\wp = \frac{\dot{m} \Delta p}{\rho} \approx \begin{cases} \frac{0.046}{2g_c} \frac{\mu^{0.2}}{\rho^2} \frac{4L}{D_h} \frac{\dot{m}^{2.8}}{A_0^{1.8} D_h^{0.2}} & \text{for turbulent flow} \end{cases} \quad (4.5.27)$$

It is clear from Equations (4.2.26) and (4.2.27) that the fluid pumping power is strongly dependent upon the fluid density ( $\wp \propto 1/\rho^2$ ) particularly for low-density fluids in laminar and turbulent flows, and upon the viscosity in laminar flow. In addition, the pressure drop itself can be an important consideration when blowers and pumps are used for the fluid flow since they are head limited. Also for condensing and evaporating fluids, the pressure drop affects the heat transfer rate. Hence, the pressure drop determination in the exchanger is important.

The pressure drop associated with a heat exchanger consists of (1) core pressure drop, and (2) the pressure drop associated with the fluid distribution devices such as inlet and outlet manifolds, headers, tanks, nozzles, ducting, and so on, which may include bends, valves, and fittings. This second  $\Delta p$  component is determined from Idelchik (1994) and Miller (1990). The core pressure drop may consist of one or more of the following components depending upon the exchanger construction: (1) friction losses associated with fluid flow over heat transfer surface (this usually consists of skin friction, form (profile) drag, and internal contractions and expansions, if any); (2) the momentum effect (pressure drop or rise due to fluid density changes) in the core; (3) pressure drop associated with sudden contraction and expansion at the core inlet and outlet, and (4) the gravity effect due to the change in elevation

between the inlet and outlet of the exchanger. The gravity effect is generally negligible for gases. For vertical flow through the exchanger, the pressure drop or rise (“static head”) due to the elevation change is given by

$$\Delta p = \pm \frac{\rho_m g L}{g_c} \quad (4.5.28)$$

Here the “+” sign denotes vertical upflow (i.e., pressure drop), the “-” sign denotes vertical downflow (i.e., pressure rise). The first three components of the core pressure drop are now presented for plate-fin, tube-fin, plate, and regenerative heat exchangers.

*Plate-fin heat exchangers.* For the plate-fin exchanger (Figure 4.5.2), all three components are considered in the core pressure drop evaluation as follows:

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c} \frac{1}{p_i \rho_i} \left[ (1 - \sigma^2 + K_c) + f \frac{L}{r_h} \rho_i \left( \frac{1}{\rho} \right)_m + 2 \left( \frac{\rho_i}{\rho_o} - 1 \right) - (1 - \sigma^2 - K_e) \frac{\rho_i}{\rho_o} \right] \quad (4.5.29)$$

where  $f$  is the Fanning friction factor,  $K_c$  and  $K_e$  are flow contraction (entrance) and expansion (exit) pressure loss coefficients (see Figure 4.5.14), and  $\sigma$  is a ratio of minimum free flow area to frontal area.  $K_c$  and  $K_e$  for four different entrance flow passage geometries are presented by Kays and London (1984). The entrance and exit losses are important at low values of  $\sigma$  and  $L$  (short cores), high values of  $Re$ , and for gases; they are negligible for liquids. The values of  $K_c$  and  $K_e$  apply to long tubes for which flow is fully developed at the exit. For partially developed flows,  $K_c$  and  $K_e$  is higher than that for fully developed flows. For interrupted surfaces, flow is never a fully developed boundary layer type. For highly interrupted fin geometries, the entrance and exit losses are generally small compared to the core pressure drop and the flow is well mixed; hence,  $K_c$  and  $K_e$  for  $Re \rightarrow \infty$  should represent a good approximation. The mean specific volume  $v_m$  or  $(1/\rho)_m$  in Equation (4.5.29) is given as follows. For liquids with any flow arrangement, or for a perfect gas with  $C^* = 1$  and any flow arrangement (except for parallel flow),

$$\left( \frac{1}{\rho} \right)_m = v_m = \frac{v_i + v_o}{2} = \frac{1}{2} \left( \frac{1}{\rho_i} + \frac{1}{\rho_o} \right) \quad (4.5.30)$$

where  $v$  is the specific volume in  $m^3/kg$ . For a perfect gas with  $C^* = 0$  and any flow arrangement,

$$\left( \frac{1}{\rho} \right)_m = \frac{\tilde{R}}{p_{ave}} T_{lm} \quad (4.5.31)$$

Here  $\tilde{R}$  is the gas constant in  $J/(kg \text{ K})$ ,  $p_{ave} = (p_i + p_o)/2$ , and  $T_{lm} = T_{const} + \Delta T_{lm}$  where  $T_{const}$  is the mean average temperature of the fluid on the other side of the exchanger; the LMTD  $\Delta T_{lm}$  is defined in Table 4.5.2. The core frictional pressure drop in Equation 4.5.29 may be approximated as

$$\Delta p \approx \frac{4fLG^2}{2g_c D_h} \left( \frac{1}{\rho} \right)_m \quad (4.5.32)$$

*Tube-fin heat exchangers.* The pressure drop inside a circular tube is computed using Equation (4.5.29) with proper values of  $f$  factors, and  $K_c$  and  $K_e$  from Figure (4.5.18) for circular tubes.

For flat fins on an array of tubes (see Figure 4.5.5b), the components of the core pressure drop (such as those in Equation 4.5.29) are the same with the following exception: the core friction and momentum effect take place within the core with  $G = \dot{m}/A_o$ , where  $A_o$  is the minimum free-flow area within the

**FIGURE 4.5.14** Entrance and exit pressure loss coefficients: (a) circular tubes, (b) parallel plates, (c) square passages, and (d) triangular passages. (From Kays, W.M. and London, A.L., *Compact Heat Exchangers*, 3rd ed., McGraw-Hill, New York, 1984. With permission.) For each of these flow passages, shown in the inset, the fluid flows perpendicular to the plane of the paper into the flow passages.

core, and the entrance and exit losses occur at the leading and trailing edges of the core with the associated flow area  $A'_0$  such that

$$\dot{m} = GA_0 = G'A'_0 \quad \text{or} \quad G'\sigma' = G\sigma \quad (4.5.33)$$

where  $\sigma'$  is the ratio of free-flow area to frontal area at the fin leading edges. The pressure drop for flow normal to a tube bank with flat fins is then given by

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c} \frac{1}{p_i \rho_i} \left[ f \frac{L}{r_h} \rho_i \left( \frac{1}{\rho} \right)_m + 2 \left( \frac{\rho_i}{\rho_o} - 1 \right) \right] + \frac{G'^2}{2g_c} \frac{1}{p_i \rho_i} \left[ (1 - \sigma'^2 - K_c) - (1 - \sigma'^2 - K_e) \frac{\rho_i}{\rho_o} \right] \quad (4.5.34)$$

For individually finned tubes as shown in Figure 4.5.5a, flow expansion and contraction take place along each tube row, and the magnitude is of the same order as that at the entrance and exit. Hence, the entrance and exit losses are generally lumped into the core friction factor. Equation (4.5.29) then reduces for individually finned tubes to

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c} \frac{1}{p_i \rho_i} \left[ f \frac{L}{r_h} \rho_i \left( \frac{1}{\rho} \right)_m + 2 \left( \frac{\rho_i}{\rho_o} - 1 \right) \right] \quad (4.5.35)$$

*Regenerators.* For regenerator matrices having cylindrical passages, the pressure drop is computed using Equation (4.5.29) with appropriate values of  $f$ ,  $K_c$ , and  $K_e$ . For regenerator matrices made up of any porous material (such as checkerwork, wire, mesh, spheres, copper wools, etc.), the pressure drop is calculated using Equation (4.5.35) in which the entrance and exit losses are included in the friction factor  $f$ .

*Plate heat exchangers.* Pressure drop in a PHE consists of three components: (1) pressure drop associated with the inlet and outlet manifolds and ports, (2) pressure drop within the core (plate passages), and (3) pressure drop due to the elevation change. The pressure drop in the manifolds and ports should be kept as low as possible (generally < 10%, but it is found as high as 25 to 30% of higher in some designs). Empirically, it is calculated as approximately 1.5 times the inlet velocity head per pass. Since the entrance and exit losses in the core (plate passages) cannot be determined experimentally, they are included in the friction factor for the given plate geometry. The pressure drop (rise) caused by the elevation change for liquids is given by Equation (4.5.28). Hence, the pressure drop on one fluid side in a PHE is given by

$$\Delta p = \frac{1.5G^2 N_p}{2g_c \rho_i} + \frac{4fLG^2}{2g_c D_e} \left( \frac{1}{\rho} \right)_m + \left( \frac{1}{\rho_o} - \frac{1}{\rho_i} \right) \frac{G^2}{g_c} \pm \frac{\rho_m g L}{g_c} \quad (4.5.36)$$

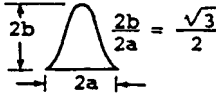

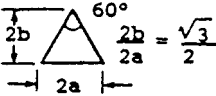

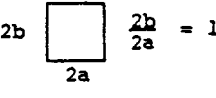

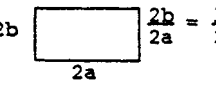

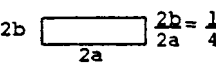

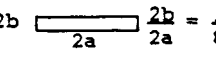

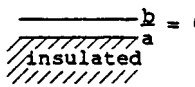

where  $N_p$  is the number of passes on the given fluid side and  $D_e$  is the equivalent diameter of flow passages (usually twice the plate spacing). Note that the third term on the right-hand side of the equality sign of Equation (4.5.36) is for the momentum effect which is generally negligible in liquids.

### Heat Transfer and Flow Friction Correlations

Accurate and reliable surface heat transfer and flow friction characteristics are a key input to the exchanger heat transfer and pressure drop analyses or to the rating and sizing problems (Shah, 1985). Some important analytical solutions and empirical correlations are presented next for selected exchanger geometries.

The heat transfer rate in laminar duct flow is very sensitive to the thermal boundary condition. Hence, it is essential to identify carefully the thermal boundary condition in laminar flow. The heat transfer rate in turbulent duct flow is insensitive to the thermal boundary condition for most common fluids ( $Pr >$

**TABLE 4.5.6 Solutions for Heat Transfer and Friction for Fully Developed Flow-Through Specified Ducts**

<sup>b</sup> Interpolated values.

0.7); the exception is liquid metals ( $Pr < 0.03$ ). Hence, there is generally no need to identify the thermal boundary condition in turbulent flow for all fluids except liquid metals.

Fully developed laminar flow analytical solutions for some duct shapes of interest in compact heat exchangers are presented in Table 4.5.6 for three important thermal boundary conditions denoted by the subscripts  $H1$ ,  $H2$ , and  $T$  (Shah and London, 1978; Shah and Bhatti, 1987). Here,  $H1$  denotes constant axial wall heat flux with constant peripheral wall temperature,  $H2$  denotes constant axial and peripheral wall heat flux, and  $T$  denotes constant wall temperature. The entrance effects, flow maldistribution, free convection, property variation, fouling, and surface roughness all affect fully developed analytical solutions. In order to account for these effects in real plate-fin plain fin geometries having fully developed flows, it is best to reduce the magnitude of the analytical  $Nu$  by at least 10% and to increase the value of the analytical  $fRe$  by 10% for design purposes.

The initiation of transition flow, the lower limit of the critical Reynolds number ( $Re_{crit}$ ), depends upon the type of entrance (e.g., smooth vs. abrupt configuration at the exchanger flow passage entrance). For a sharp square inlet configuration,  $Re_{crit}$  is about 10 to 15% lower than that for a rounded inlet configuration. For most exchangers, the entrance configuration would be sharp. Some information on  $Re_{crit}$  is provided by Ghajar and Tam (1994).

Transition flow and fully developed turbulent flow Fanning friction factors (within  $\pm 2\%$  accuracy) are given by Bhatti and Shah (1987) as

$$f = A + B\text{Re}^{-1/m} \quad (4.5.37)$$

where

$$\begin{aligned} A = 0.0054, \quad B = 2.3 \times 10^{-8}, \quad m = -2/3, \quad & \text{for } 2100 \leq \text{Re} \leq 4000 \\ A = 0.00128, \quad B = 0.1143, \quad m = 3.2154, \quad & \text{for } 4000 \leq \text{Re} \leq 10^7 \end{aligned}$$

The transition flow and fully developed turbulent flow Nusselt number correlation for a circular tube is given by Gnielinski as reported in Bhatti and Shah (1987) as

$$\text{Nu} = \frac{(f/2)(\text{Re} - 1000)\text{Pr}}{1 + 12.7(f/2)^{1/2}(\text{Pr}^{2/3} - 1)} \quad (4.5.38)$$

which is accurate within about  $\pm 10\%$  with experimental data for  $2300 \leq \text{Re} \leq 5 \times 10^6$  and  $0.5 \leq \text{Pr} \leq 2000$ .

A careful observation of accurate experimental friction factors for all noncircular smooth ducts reveals that ducts with laminar  $f\text{Re} < 16$  have turbulent  $f$  factors lower than those for the circular tube; whereas ducts with laminar  $f\text{Re} > 16$  have turbulent  $f$  factors higher than those for the circular tube (Shah and Bhatti, 1988). Similar trends are observed for the Nusselt numbers. Within  $\pm 15\%$  accuracy, Equations (4.5.37) and (4.5.38) for  $f$  and Nu can be used for noncircular passages with the hydraulic diameter as the characteristic length in  $f$ , Nu, and Re; otherwise, refer to Bhatti and Shah (1987) for more accurate results for turbulent flow.

For hydrodynamically and thermally developing flows, the analytical solutions are boundary condition dependent (for laminar flow heat transfer only) and geometry dependent. The hydrodynamic entrance lengths for developing laminar and turbulent flows are given by Shah and Bhatti (1987) and Bhatti and Shah (1987) as

$$\frac{L_{hy}}{D_h} = \begin{cases} 0.0565\text{Re} & \text{for laminar flow } (\text{Re} \leq 2100) \\ 1.359\text{Re}^{1/4} & \text{for turbulent flow } (\text{Re} \geq 10^4) \end{cases} \quad (4.5.39)$$

$$\frac{L_{hy}}{D_h} = \begin{cases} 0.0565\text{Re} & \text{for laminar flow } (\text{Re} \leq 2100) \\ 1.359\text{Re}^{1/4} & \text{for turbulent flow } (\text{Re} \geq 10^4) \end{cases} \quad (4.5.40)$$

Analytical results are useful for well-defined constant-cross-sectional surfaces with essentially unidirectional flows. The flows encountered in heat exchangers are generally very complex having flow separation, reattachment, recirculation, and vortices. Such flows significantly affect Nu and  $f$  for the specific exchanger surfaces. Since no analytical or accurate numerical solutions are available, the information is derived experimentally. Kays and London (1984) and Webb (1994) present most of the experimental results reported in the open literature. In the following, empirical correlations for only some important surfaces are summarized due to space limitations. Refer to section 4.2, subsection External Flow Forced Convection for bare tube banks.

#### **Plate-Fin Extended Surfaces.**

*Offset strip fins.* This is one of the most widely used enhanced fin geometries (Figure 4.5.15) in aircraft, cryogenics, and many other industries that do not require mass production. This surface has one of the highest heat transfer performances relative to the friction factor. The most comprehensive correlations for  $j$  and  $f$  factors for the offset strip fin geometry is provided by Manglik and Bergles (1995) as follows.

FIGURE 4.5.15 An offset strip fin geometry.

$$j = 0.6522 \text{Re}^{-0.5403} \left(\frac{s}{h'}\right)^{-0.1541} \left(\frac{\delta_f}{l_f}\right)^{0.1499} \left(\frac{\delta_f}{s}\right)^{-0.0678} \times \left[1 + 5.269 \times 10^{-5} \text{Re}^{1.340} \left(\frac{s}{h'}\right)^{0.504} \left(\frac{\delta_f}{l_f}\right)^{0.456} \left(\frac{\delta_f}{s}\right)^{-1.055}\right]^{0.1} \quad (4.5.41)$$

$$f = 9.6243 \text{Re}^{-0.7422} \left(\frac{s}{h'}\right)^{-0.1856} \left(\frac{\delta_f}{l_f}\right)^{0.3053} \left(\frac{\delta_f}{s}\right)^{-0.2659} \times \left[1 + 7.669 \times 10^{-8} \text{Re}^{4.429} \left(\frac{s}{h'}\right)^{0.920} \left(\frac{\delta_f}{l_f}\right)^{3.767} \left(\frac{\delta_f}{s}\right)^{0.236}\right]^{0.1} \quad (4.5.42)$$

where

$$D_h = 4A_o / (A/l_f) = 4sh'l_f / [2(sl_f + h'l_f + \delta_f h') + \delta_f s] \quad (4.5.43)$$

Geometric symbols in Equation (4.5.43) are shown in [Figure 4.5.15](#).

These correlations predict the experimental data of 18 test cores within  $\pm 20\%$  for  $120 \leq \text{Re} \leq 10^4$ . Although all the experimental data for these correlations are obtained for air, the  $j$  factor takes into consideration minor variations in the Prandtl number, and the above correlations should be valid for  $0.5 < \text{Pr} < 15$ .

**Lower fins.** Louver or multilouver fins are extensively used in the auto industry because of their mass production manufacturability and hence lower cost. The louver fin has generally higher  $j$  and  $f$  factors than those for the offset strip fin geometry, and also the increase in the friction factors is in general higher than the increase in the  $j$  factors. However, the exchanger can be designed for higher heat transfer and the same pressure drop compared to that with the offset strip fins by a proper selection of exchanger frontal area, core depth, and fin density. Published literature and correlations on the louver fins are summarized by Webb (1994) and Cowell et al. (1995), and the understanding of flow and heat transfer phenomena is summarized by Cowell et al. (1995). Because of the lack of systematic studies reported

in the open literature on modern louver fin geometries, no correlation can be recommended for the design purpose.

### **Tube-Fin Extended Surfaces.**

Two major types of tube-fin extended surfaces as shown in Figure 4.5.5 are (1) individually finned tubes and (2) flat fins (also sometimes referred to as plate fins) with or without enhancements/interruptions on an array of tubes. An extensive coverage of the published literature and correlations for these extended surfaces are provided by Webb (1994), Kays and London (1984), and Rozenman (1976). Empirical correlations for some important geometries are summarized below.

*Individually finned tubes.* This fin geometry, helically wrapped (or extruded) circular fins on a circular tube as shown in Figure 4.5.5a, is commonly used in process and waste heat recovery industries. The following correlation for  $j$  factors is recommended by Briggs and Young (see Webb, 1994) for individually finned tubes on staggered tube banks.

$$j = 0.134 \text{Re}_d^{-0.319} \left( s/l_f \right)^{0.2} \left( s/\delta_f \right)^{0.11} \quad (4.5.44)$$

where  $l_f$  is the radial height of the fin,  $\delta_f$  the fin thickness,  $s = p_f - \delta_f$  is the distance between adjacent fins and  $p_f$  is the fin pitch. Equation (4.5.44) is valid for the following ranges:  $1100 \leq \text{Re}_d \leq 18,000$ ,  $0.13 \leq s/l_f \leq 0.63$ ,  $1.01 \leq s/\delta_f \leq 6.62$ ,  $0.09 \leq l_f/d_o \leq 0.69$ ,  $0.011 \leq \delta_f/d_o \leq 0.15$ ,  $1.54 \leq X_l/d_o \leq 8.23$ , fin root diameter  $d_o$  between 11.1 and 40.9 mm, and fin density  $N_f (= 1/p_f)$  between 246 and 768 fin/m. The standard deviation of Equation (4.5.44) with experimental results was 5.1%.

For friction factors, Robinson and Briggs (see Webb, 1994) recommended the following correlation:

$$f_{ib} = 9.465 \text{Re}_d^{-0.316} \left( X_l/d_o \right)^{-0.927} \left( X_t/X_d \right)^{0.515} \quad (4.5.45)$$

Here  $X_d = (X_t^2 + X_l^2)^{1/2}$  is the diagonal pitch, and  $X_t$  and  $X_l$  are the transverse and longitudinal tube pitches, respectively. The correlation is valid for the following ranges:  $2000 \leq \text{Re}_d \leq 50,000$ ,  $0.15 \leq s/l_f \leq 0.19$ ,  $3.75 \leq s/\delta_f \leq 6.03$ ,  $0.35 \leq l_f/d_o \leq 0.56$ ,  $0.011 \leq \delta_f/d_o \leq 0.025$ ,  $1.86 \leq X_l/d_o \leq 4.60$ ,  $18.6 \leq d_o \leq 40.9$  mm, and  $311 \leq N_f \leq 431$  fin/m. The standard deviation of Equation (4.5.45) with correlated data was 7.8%

For crossflow over low-height finned tubes, a simple but accurate correlation for heat transfer is given by Ganguli and Yilmaz (1987) as

$$j = 0.255 \text{Re}_d^{-0.3} \left( d_e/s \right)^{-0.3} \quad (4.5.46)$$

A more accurate correlation for heat transfer is given by Rabas and Taborek (1987). Chai (1988) provides the best correlation for friction factors:

$$f_{ib} = 1.748 \text{Re}_d^{-0.233} \left( \frac{l_f}{s} \right)^{0.552} \left( \frac{d_o}{X_t} \right)^{0.599} \left( \frac{d_o}{X_l} \right)^{0.1738} \quad (4.5.47)$$

This correlation is valid for  $895 < \text{Re}_d < 713,000$ ,  $20 < \theta < 40^\circ$ ,  $X_l/d_o < 4$ ,  $N \geq 4$ , and  $\theta$  is the tube layout angle. It predicts 89 literature data points within a mean absolute error of 6%; the range of actual error is from -16.7 to 19.9%.

*Flat plain fins on a staggered tubebank.* This geometry, as shown in Figure 4.5.5b, is used in air-conditioning/refrigeration industry as well as where the pressure drop on the fin side prohibits the use of enhanced/interrupted flat fins. An inline tubebank is generally not used unless very low fin side pressure drop is the essential requirement. Heat transfer correlation for Figure 4.5.5b flat plain fins on

staggered tubebanks is provided by Gray and Webb (see Webb, 1994) as follows for four or more tube rows.

$$j_4 = 0.14 \text{Re}_d^{-0.328} (X_t/X_l)^{-0.502} (s/d_o)^{0.031} \quad (4.5.48)$$

For the number of tube rows  $N$  from 1 to 3, the  $j$  factor is lower and is given by

$$\frac{j_N}{j_4} = 0.99 \left[ 2.24 \text{Re}_d^{-0.092} (N/4)^{-0.031} \right]^{0.607(4-N)} \quad (4.5.49)$$

Gray and Webb (see Webb, 1994) hypothesized the friction factor consisting of two components: one associated with the fins and the other associated with the tubes as follows.

$$f = f_f \frac{A_f}{A} + f_t \left( 1 - \frac{A_f}{A} \right) \left( 1 - \frac{\delta_f}{p_f} \right) \quad (4.5.50)$$

where

$$f_f = 0.508 \text{Re}_d^{-0.521} (X_t/d_o)^{1.318} \quad (4.5.51)$$

and  $f_t$  (defined the same way as  $f$ ) is the Fanning friction factor associated with the tube and can be determined from Eu of Figure 19 of Zukauskas (1987) as  $f_t = \text{Eu}N(X_t - d_o)/\pi d_o$ . Equation (4.5.50) correlated 90% of the data for 19 heat exchangers within  $\pm 20\%$ . The range of dimensionless variables of Equations (4.5.50) and (4.5.51) are  $500 \leq \text{Re} \leq 24,700$ ,  $1.97 \leq X_t/d_o \leq 2.55$ ,  $1.7 \leq X_l/d_o \leq 2.58$ , and  $0.08 \leq s/d_o \leq 0.64$ .

### Exchanger Design Methodology

The problem of heat exchanger design is complex and multidisciplinary (Shah, 1991). The major design considerations for a new heat exchanger include process/design specifications, thermal and hydraulic design, mechanical design, manufacturing and cost considerations, and trade-offs and system-based optimization, as shown in Figure 4.5.16 with possible strong interactions among these considerations as indicated by double-sided arrows. The thermal and hydraulic design methods are mainly analytical, and the structural design is analytical to some extent. Most of the other major design considerations involve qualitative and experience-based judgments, trade-offs, and compromises. Therefore, there is no unique solution to designing a heat exchanger for given process specifications. Further details on this design methodology is given by Shah (1991).

Two important heat exchanger design problems are the rating and sizing problems. Determination of heat transfer and pressure drop performance of either an existing exchanger or an already sized exchanger is referred to as the rating problem. The objective here is to verify vendor's specifications or to determine the performance at off-design conditions. The rating problem is also sometimes referred to as the performance problem. In contrast, the design of a new or existing type of exchanger is referred to as the sizing problem. In a broad sense, it means the determination of the exchanger construction type, flow arrangement, heat transfer surface geometries and materials, and the physical size of an exchanger to meet the specified heat transfer and pressure drops. However, from the viewpoint of quantitative thermal-hydraulic analysis, we will consider that the selection of the exchanger construction type, flow arrangement, and materials has already been made. Thus, in the sizing problem, we will determine the physical size (length, width, height) and surface areas on each side of the exchanger. The sizing problem is also sometimes referred to as the design problem.

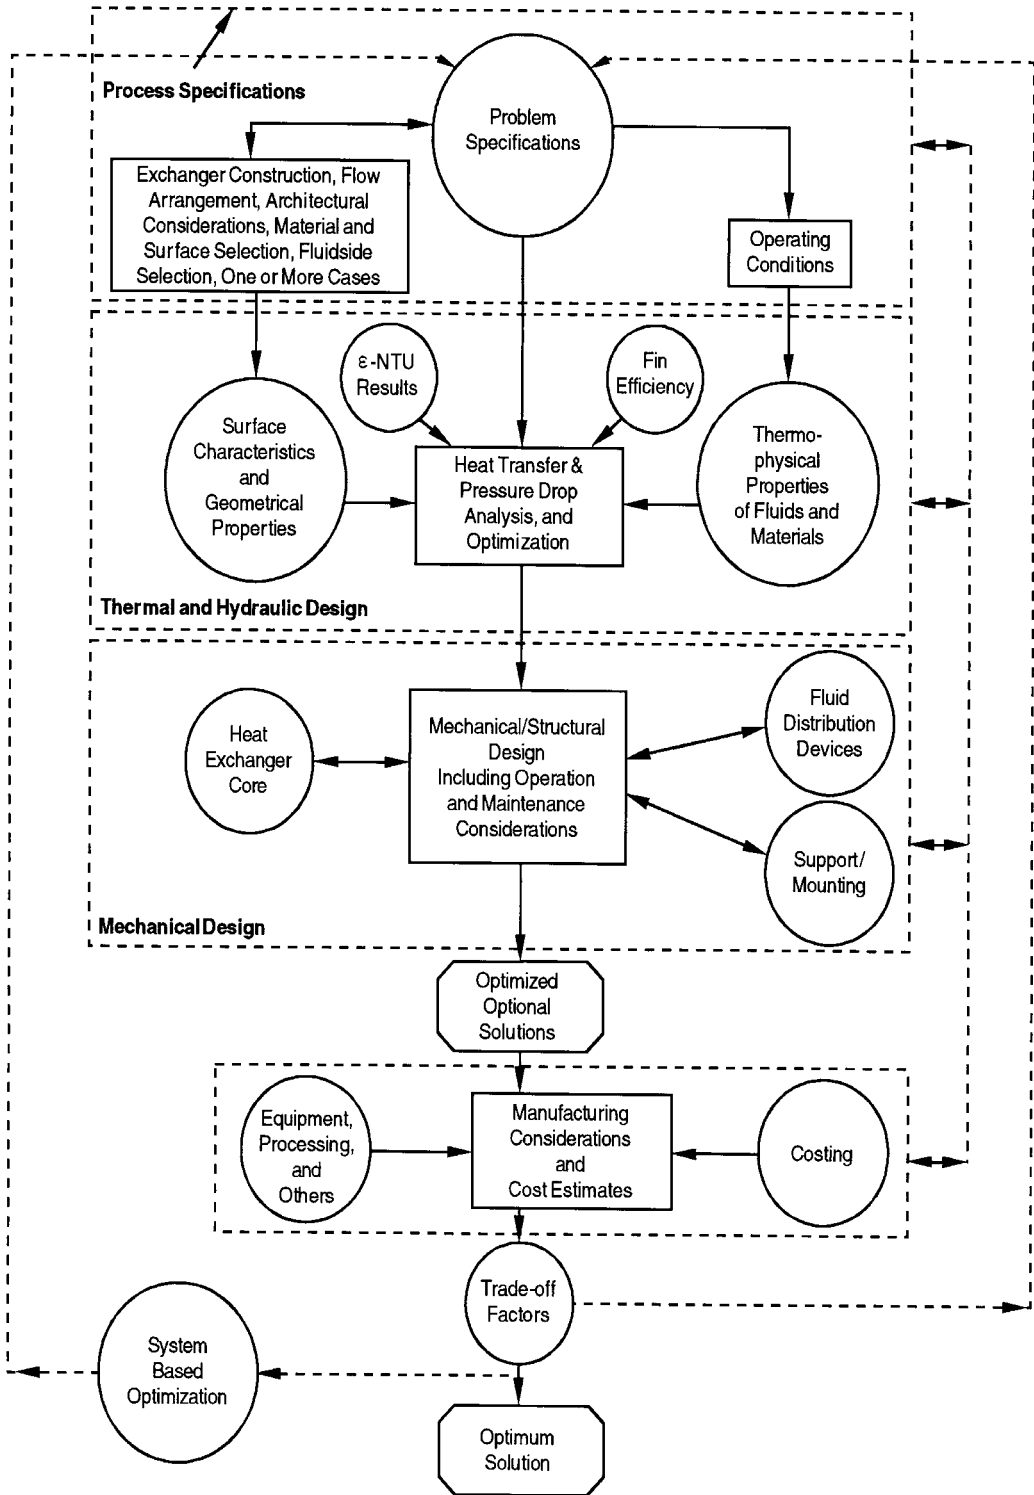

FIGURE 4.5.16 Heat exchanger design methodology.

The step-by-step solution procedures for the rating and sizing problems for counterflow and cross-flow single-pass plate-fin heat exchangers have been presented with a detailed illustrative example by Shah (1981). Shah (1988a) presented further refinements in these procedures as well as step-by-step procedures for two-pass cross-counterflow plate-fin exchangers, and single-pass crossflow and two-pass cross-counterflow tube-fin exchangers. Also, step-by-step solution procedures for the rating and sizing problems for rotary regenerators (Shah, 1988b), heat pipe heat exchangers (Shah and Giovannelli, 1988) and PHEs (Shah and Wanniarachchi, 1991) are available. As an illustration, the step-by-step solution procedures will be covered here for a single-pass crossflow exchanger.

### Rating Problem for a Crossflow Plate-Fin Exchanger.

Following is a step-by-step procedure for rating a crossflow plate-fin exchanger. Inputs to the rating problem for a two-fluid exchanger are the exchanger construction, flow arrangement and overall dimensions, complete details on the materials and surface geometries on both sides including their nondimensional heat transfer and pressure drop characteristics ( $j$  and  $f$  vs.  $Re$ ), fluid flow rates, inlet temperatures, and fouling factors. The fluid outlet temperatures, total heat transfer rate, and pressure drops on each side of the exchanger are then determined as the rating problem solution.

1. Determine the surface geometric properties on each fluid side. This includes the minimum free-flow area  $A_o$ , heat transfer surface area  $A$  (both primary and secondary), flow lengths  $L$ , hydraulic diameter  $D_h$ , heat transfer surface area density  $\beta$ , the ratio of minimum free-flow area to frontal area  $\sigma$ , fin length  $l_f$ , and fin thickness  $\delta$  for fin efficiency determination, and any specialized dimensions used for heat transfer and pressure drop correlations.
2. Compute the fluid bulk mean temperature and fluid thermophysical properties on each fluid side. Since the outlet temperatures are not known for the rating problem, they are estimated initially. Unless it is known from past experience, assume an exchanger effectiveness as 60 to 75% for most single-pass crossflow exchangers, or 80 to 85% for single-pass counterflow exchangers. For the assumed effectiveness, calculate the fluid outlet temperatures.

$$T_{h,o} = T_{h,i} - \epsilon(C_{\min}/C_h)(T_{h,i} - T_{c,i}) \quad (4.5.52)$$

$$T_{c,o} = T_{c,i} - \epsilon(C_{\min}/C_c)(T_{h,i} - T_{c,i}) \quad (4.5.53)$$

Initially, assume  $C_c/C_h = \dot{m}_c/\dot{m}_h$  for a gas-to-gas exchanger, or  $C_c/C_h = \dot{m}_c c_{p,c}/\dot{m}_h c_{p,h}$  for a gas-to-liquid exchanger with very approximate values of  $c_p$  for the fluids in question.

For exchangers with  $C^* > 0.5$  (usually gas-to-gas exchangers), the bulk mean temperatures on each fluid side will be the arithmetic mean of the inlet and outlet temperatures on each fluid side (Shah, 1981). For exchangers with  $C^* < 0.5$  (usually gas-to-gas exchangers), the bulk mean temperature on the  $C_{\max}$  side will be the arithmetic mean of inlet and outlet temperatures; the bulk mean temperature on the  $C_{\min}$  side will be the log-mean average temperature obtained as follows:

$$T_{m,C_{\min}} = T_{m,C_{\max}} \pm \Delta T_{\text{lm}} \quad (4.5.54)$$

where  $\Delta T_{\text{lm}}$  is the LMTD based on the terminal temperatures (see Equation 4.5.19). Use the plus sign if the  $C_{\min}$  side is hot; otherwise, use the negative sign.

Once the bulk mean temperature is obtained on each fluid side, obtain the fluid properties from thermophysical property books or from handbooks. The properties needed for the rating problem are  $\mu$ ,  $c_p$ ,  $k$ ,  $Pr$ , and  $p$ . With this  $c_p$ , one more iteration may be carried out to determine  $T_{h,o}$  or  $T_{c,o}$  from Equation 4.5.52 or 4.5.53 on the  $C_{\max}$  side, and subsequently  $T_m$  on the  $C_{\max}$  side, and refine fluid properties accordingly.

- Calculate the Reynolds number  $Re = GD_h/\mu$  and/or any other pertinent dimensionless groups (from the basic definitions) needed to determine the nondimensional heat transfer and flow friction characteristics (e.g.,  $j$  or  $Nu$  and  $f$ ) of heat transfer surfaces on each side of the exchanger. Subsequently, compute  $j$  or  $Nu$  and  $f$  factors. Correct  $Nu$  (or  $j$ ) for variable fluid property effects (Shah, 1981) in the second and subsequent iterations from the following equations.

$$\text{For gases: } \frac{Nu}{Nu_{cp}} = \left[ \frac{T_w}{T_m} \right]^{n'} \quad \frac{f}{f_{cp}} = \left[ \frac{T_w}{T_m} \right]^{m'} \quad (4.5.55)$$

$$\text{For liquids: } \frac{Nu}{Nu_{cp}} = \left[ \frac{\mu_w}{\mu_m} \right]^{n'} \quad \frac{f}{f_{cp}} = \left[ \frac{\mu_w}{\mu_m} \right]^{m'} \quad (4.5.56)$$

where the subscript cp denotes constant properties, and  $m'$  and  $n'$  are empirical constants provided in Table 4.5.7. Note that  $T_w$  and  $T_m$  in Equations (4.5.55) and (4.5.56) and in Tables 4.5.7a and b and are absolute temperatures.

Fluid	Heating	Cooling
Gases	$Nu = 5 + 0.012 Re^{0.83} (Pr + 0.29) (T_w/T_m)^n$ $n = -[\log_{10}(T_w/T_m)]^{1/4} + 0.3$ for $1 < T_w/T_m < 5, 0.6 < Pr < 0.9,$ $10^4 < Re < 10^6,$ and $L/D_h > 40$	$n' = 0$
	$m' = -0.1$ for $1 < T_w/T_m < 2.4$	$m' = -0.1$ (tentative)
Liquids	$n' = -0.11^a$ for $0.08 < \mu_w/\mu_m < 1$	$n' = -0.25^a$ for $1 < \mu_w/\mu_m < 40$
	$ff_{cp} = (7 - \mu_w/\mu_m)/6^b$ or $m' = 0.25$ for $0.35 < \mu_w/\mu_m < 1$	$m' = 0.24^b$ for $1 < \mu_w/\mu_m < 2$

<sup>a</sup> Valid for  $2 \leq Pr \leq 140, 10^4 \leq Re \leq 1.25 \times 10^5$ .

<sup>b</sup> Valid for  $1.3 \leq Pr \leq 10, 10^4 \leq Re \leq 2.3 \times 10^5$ .

Source: Shah, R.K., in *Heat Exchangers: Thermal-Hydraulic Fundamentals and Design*, S. Kakaç et al., Eds., Hemisphere Publishing, Washington, D.C., 1981. With permission.

- From  $Nu$  or  $j$ , compute the heat transfer coefficients for both fluid streams.

$$h = Nu k / D_h = j G C_p Pr^{-2/3} \quad (4.5.57)$$

Subsequently, determine the fin efficiency  $\eta_f$  and the extended surface efficiency  $\eta_o$

$$\eta_f = \frac{\tanh m\ell}{m\ell} \quad \text{where} \quad m^2 = \frac{h\tilde{P}}{k_f A_k} \quad (4.5.58)$$

where  $\tilde{P}$  is the wetted perimeter of the fin surface.

$$\eta_o = 1 - \frac{A_f}{A} (1 - \eta_f) \quad (4.5.59)$$

Also calculate the wall thermal resistance  $R_w = \delta/A_w k_w$ . Finally, compute the overall thermal conductance  $UA$  from Equation (4.5.6) knowing the individual convective film resistances, wall thermal resistances, and fouling resistances, if any.

5. From the known heat capacity rates on each fluid side, compute  $C^* = C_{\min}/C_{\max}$ . From the known  $UA$ , determine  $NTU = UA/C_{\min}$ . Also calculate the longitudinal conduction parameter  $\lambda$ . With the known  $NTU$ ,  $C^*$ ,  $\lambda$ , and the flow arrangement, determine the exchanger effectiveness  $\epsilon$  from either closed-form equations of Table 4.5.4 or tabular/graphical results from Kays and London (1984).
6. With this  $\epsilon$ , finally compute the outlet temperatures from Equations (4.5.52) and (4.5.53). If these outlet temperatures are significantly different from those assumed in Step 2, use these outlet temperatures in Step 2 and continue iterating Steps 2 to 6, until the assumed and computed outlet temperatures converge within the desired degree of accuracy. For a gas-to-gas exchanger, most probably one or two iterations will be sufficient.
7. Finally, compute the heat duty from

$$q = \epsilon C_{\min} (T_{h,i} - T_{c,i}) \quad (4.5.60)$$

8. For the pressure drop calculations, first we need to determine the fluid densities at the exchanger inlet and outlet ( $\rho_i$  and  $\rho_o$ ) for each fluid. The mean specific volume on each fluid side is then computed from Equation (4.5.30).

Next, the entrance and exit loss coefficients,  $K_c$  and  $K_e$ , are obtained from Figure 4.5.14 for known  $\sigma$ ,  $Re$ , and the flow passage entrance geometry.

The friction factor on each fluid side is corrected for variable fluid properties using Equation (4.5.55) or (4.5.56). Here, the wall temperature  $T_w$  is computed from

$$T_{w,h} = T_{m,h} - (R_h + R_{s,h})q \quad (4.5.61)$$

$$T_{w,c} = T_{m,c} + (R_c + R_{s,c})q \quad (4.5.62)$$

where the various resistance terms are defined by Equation (4.5.6).

The core pressure drops on each fluid side are then calculated from Equation (4.5.29). This then completes the procedure for solving the rating problem.

### Sizing Problem for a Crossflow Plate-Fin Exchanger.

As defined earlier, we will concentrate here to determine the physical size (length, width, and height) of a single-pass crossflow exchanger for specified heat duty and pressure drops. More specifically, inputs to the sizing problem are surface geometries (including their nondimensional heat transfer and pressure drop characteristics), fluid flow rates, inlet and outlet fluid temperatures, fouling factors, and pressure drops on each side.

For the solution to this problem, there are four unknowns — two flow rates or Reynolds numbers (to determine correct heat transfer coefficients and friction factors) and two surface areas — for the two-

fluid crossflow exchanger. The following four equations (Equations (4.5.63), (4.5.65), and (4.5.67) are used to solve iteratively the surface areas on each fluid side:  $UA$  in Equation (4.5.63) is determined from NTU computed from the known heat duty or  $\varepsilon$  and  $C^*$ ;  $G$  in Equation (4.5.65) represents two equations, for Fluids 1 and 2 (Shah, 1988a); and the volume of the exchanger in Equation (4.5.67) is the same based on the surface area density of Fluid 1 or Fluid 2.

$$\frac{1}{UA} \approx \frac{1}{(\eta_o hA)_h} + \frac{1}{(\eta_o hA)_c} \quad (4.5.63)$$

Here we have neglected the wall and fouling thermal resistances. This equation in nondimensional form is given by

$$\frac{1}{NTU} = \frac{1}{ntu_h(C_h/C_{\min})} + \frac{1}{ntu_c(C_c/C_{\min})} \quad (4.5.64)$$

$$G_i = \left[ \frac{2g_c \Delta p}{\text{Deno}_i} \right]^{1/2} \quad i = 1, 2 \quad (4.5.65)$$

where

$$\text{Deno}_i = \left[ \frac{f}{j} \frac{ntu}{\eta_o} \text{Pr}^{2/3} \left( \frac{1}{\rho} \right)_m + 2 \left( \frac{1}{\rho_o} - \frac{1}{\rho_i} \right) + (1 - \sigma^2 + K_c) \frac{1}{\rho_i} - (1 - \sigma^2 - K_e) \frac{1}{\rho_o} \right] \quad (4.5.66)$$

$$V = \frac{A_1}{\alpha_1} = \frac{A_2}{\alpha_2} \quad (4.5.67)$$

In the iterative solutions, the first time one needs  $ntu_h$  and  $ntu_c$  to start the iterations. These can be either determined from the past experience or by estimations. If both fluids are gases or both fluids are liquid, one could consider that the design is “balanced,” i.e., that the thermal resistances are distributed approximately equally on the hot and cold sides. In that case,  $C_h = C_c$ , and

$$ntu_h \approx ntu_c \approx 2NTU \quad (4.5.68)$$

Alternatively, if we have liquid on one side and gas on the other side, consider 10% thermal resistance on the liquid side, i.e.,

$$0.10 \left( \frac{1}{UA} \right) = \frac{1}{(\eta_o hA)_{\text{liq}}} \quad (4.5.69)$$

Then, from Equations (4.5.63) and (4.5.64) with  $C_{\text{gas}} = C_{\min}$ , we can determine the  $ntu$  values on each side as follows:

$$ntu_{\text{gas}} = 1.11NTU, \quad ntu_{\text{liq}} = 10C^*NTU \quad (4.5.70)$$

Also note that initial guesses of  $\eta_o$  and  $j/f$  are needed for the first iteration to solve Equation (4.5.66). For a good design, consider  $\eta_o = 0.80$  and determine an approximate value of  $j/f$  from the plot of  $j/f$  vs.

Re curve for the known  $j$  and  $f$  vs. Re characteristics of each fluid side surface. The specific step-by-step design procedure is as follows:

1. In order to compute the fluid bulk mean temperature and the fluid thermophysical properties on each fluid side, determine the fluid outlet temperatures from the specified heat duty

$$q = (\dot{m}c_p)_h (T_{h,i} - T_{h,o}) = (\dot{m}c_p)_c (T_{c,o} - T_{c,i}) \quad (4.5.71)$$

or from the specified exchanger effectiveness using Equation (4.5.52) and (4.5.53). For the first time, estimate the values of  $c_p$ .

For exchangers with  $C^* \geq 0.5$ , the bulk mean temperature on each fluid side will be the arithmetic mean of inlet and outlet temperatures on each side. For exchangers with  $C^* < 0.5$ , the bulk mean temperature on the  $C_{\max}$  side will be the arithmetic mean of the inlet and outlet temperatures on that side and the bulk mean temperature on the  $C_{\min}$  side will be the log-mean average as given by Equation (4.5.54). With these bulk mean temperatures, determine  $c_p$  and iterate one more time for the outlet temperatures if warranted. Subsequently, determine  $\mu$ ,  $c_p$ ,  $k$ ,  $Pr$ , and  $\rho$  on each fluid side.

2. Calculate  $C^*$  and  $\epsilon$  (if  $q$  is given), and determine NTU from the  $\epsilon$ -NTU expression, tables, or graphical results for the selected flow arrangement (in this case, it is unmixed–unmixed cross-flow, Table 4.5.4). The influence of longitudinal heat conduction, if any, is ignored in the first iteration since we don't know the exchanger size yet.
3. Determine  $ntu$  on each side by the approximations discussed with Equations (4.5.68) and (4.5.70) unless it can be estimated from past experience.
4. For the selected surfaces on each fluid side, plot  $j/f$  vs. Re curve from the given surface characteristics and obtain an approximate value of  $j/f$ . If fins are employed, assume  $\eta_o = 0.80$  unless a better value can be estimated.
5. Evaluate  $G$  from Equation (4.5.65) on each fluid side using the information from Steps 1 to 4 and the input value of  $\Delta p$ .
6. Calculate Reynolds number  $Re$ , and determine  $j$  and  $f$  on each fluid side from the given design data for each surface.
7. Compute  $h$ ,  $\eta_p$ , and  $\eta_o$  using Equations (4.5.57) to (4.5.59). For the first iteration, determine  $U_1$  on Fluid 1 side from the following equation derived from Equations (4.5.6) and (4.5.67).

$$\frac{1}{U_1} = \frac{1}{(\eta_o h)_1} + \frac{1}{(\eta_o h_s)_1} + \frac{\alpha_1/\alpha_2}{(\eta_o h_s)_2} + \frac{\alpha_1/\alpha_2}{(\eta_o h)_2} \quad (4.5.72)$$

where  $\alpha_1/\alpha_2 = A_1/A_2$ ,  $\alpha = A/V$ ,  $V$  is the exchanger total volume, and subscripts 1 and 2 denote Fluid 1 and 2 sides. For a plate-fin exchanger,  $\alpha$  terms are given by Shah (1981) and Kays and London (1984):

$$\alpha_1 = \frac{b_1\beta_1}{b_1 + b_2 + 2a} \quad \alpha_2 = \frac{b_2\beta_2}{b_1 + b_2 + 2a} \quad (4.5.73)$$

Note that the wall thermal resistance in Equation (4.5.72) is ignored in the first iteration. In second and subsequent iterations, compute  $U_1$  from

$$\frac{1}{U_1} = \frac{1}{(\eta_o h)_1} + \frac{1}{(\eta_o h_s)_1} + \frac{\delta A_1}{k_w A_w} + \frac{A_1/A_2}{(\eta_o h_s)_2} + \frac{A_1/A_2}{(\eta_o h)_2} \quad (4.5.74)$$

where the necessary geometry information  $A_1/A_2$  and  $A_1/A_w$  is determined from the geometry calculated in the previous iteration.

8. Now calculate the core dimensions. In the first iteration, use NTU computed in Step 2. For subsequent iterations, calculate longitudinal conduction parameter  $\lambda$  (and other dimensionless groups for a crossflow exchanger). With known  $\varepsilon$ ,  $C^*$ , and  $\lambda$ , determine the correct value of NTU using either a closed-form equation or tabular/graphical results (Kays and London, 1984). Determine  $A_1$  from NTU using  $U_1$  from the previous step and known  $C_{\min}$ .

$$A_1 = \text{NTU} C_{\min} / U_1 \quad (4.5.75)$$

and hence

$$A_2 = (A_2/A_1)A_1 = (\alpha_2/\alpha_1)A_1 \quad (4.5.76)$$

$A_o$  from known  $\dot{m}$  and  $G$  is given by

$$A_{o,1} = (\dot{m}/G)_1 \quad A_{o,2} = (\dot{m}/G)_2 \quad (4.5.77)$$

so that

$$A_{fr,1} = A_{o,1}/\sigma_1 \quad A_{fr,2} = A_{o,2}/\sigma_2 \quad (4.5.78)$$

where  $\sigma_1$  and  $\sigma_2$  are generally specified for the surface or can be computed for plate-fin surfaces from Shah (1981) and Kays and London (1984):

$$\sigma_1 = \frac{b_1\beta_1 D_{h,1}/4}{b_1 + b_2 + 2\delta} \quad \sigma_2 = \frac{b_2\beta_2 D_{h,2}/4}{b_1 + b_2 + 2\delta} \quad (4.5.79)$$

Now compute the fluid flow lengths on each side (see [Figure 4.5.17](#)) from the definition of the hydraulic diameter of the surface employed on each side.

$$L_1 = \left( \frac{D_h A}{4A_o} \right)_1 \quad L_2 = \left( \frac{D_h A}{4A_o} \right)_2 \quad (4.5.80)$$

Since  $A_{fr,1} = L_2 L_3$  and  $A_{fr,2} = L_1 L_3$ , we can obtain

$$L_3 = \frac{A_{fr,1}}{L_2} \quad \text{or} \quad L_3 = \frac{A_{fr,2}}{L_1} \quad (4.5.81)$$

Theoretically,  $L_3$  calculated from both expressions of Equation (4.5.81) should be identical. In reality, they may differ slightly because of the round-off error. In that case, consider an average value for  $L_3$ .

9. Finally, compute the pressure drop on each fluid side, after correcting  $f$  factors for variable property effects, in a manner similar to Step 8 of the rating problem for a Crossflow Plate Fin Exchanger.
10. If the calculated values of  $\Delta p$  are within and close to input specifications, the solution to the sizing problem is completed. Finer refinements in the core dimensions, such as integer numbers of flow passages, etc., may be carried out at this time. Otherwise, compute the new value of  $G$  on each fluid side using Equation (4.5.29) in which  $\Delta p$  is the input-specified value, and  $f$ ,  $K_e$ ,  $K_e$ , and geometric dimensions are from the previous iteration.

**FIGURE 4.5.17** A single-pass crossflow exchanger.

11. Repeat (iterate) Steps 6 to 10 until both transfer and pressure drops are met as specified. It should be emphasized that since we have imposed no constraints on the exchanger dimensions, the above procedure will yield  $L_1$ ,  $L_2$ , and  $L_3$  for the selected surfaces such that the design will meet exactly the heat duty and pressure drops on both fluid sides.

### Flow Maldistribution

In the previously presented heat transfer ( $\epsilon$ -NTU, MTD, etc. methods) and pressure drop analyses, it is presumed that the fluid is uniformly distributed through the core. In practice, flow maldistribution does occur to some extent and often severely, and may result in a significant reduction in exchanger heat transfer performance and an increase in the pressure drop. Hence, it may be necessary for the designer to take into account the effect of flow maldistribution causing undesirable performance deterioration up front while designing a heat exchanger.

Some maldistributions are geometry-induced (i.e., the result of exchanger fabrication conditions, such as header design or manufacturing tolerances, or the duct geometry/structure upstream of the exchanger), and other maldistributions are the result of exchanger operating conditions. Gross, passage-to-passage and manifold-induced flow maldistributions are examples of the former category, while viscosity, natural convection, and density-difference-induced flow maldistributions are of the latter category. Flow maldistributions associated with two-phase and multiphase flow are too complex, with only limited information available in the literature. The analysis methods and results for some of the above flow maldistributions for single-phase flows are given by Shah (1985), Mueller and Chiou (1987), and Putnam and Rohsenow (1985).

### Fouling in Heat Exchangers

#### *Fouling, Its Effect, and Mechanisms.*

Fouling refers to undesired accumulation of solid material (by-products of the heat transfer processes) on heat exchanger surfaces which results in additional thermal resistance to heat transfer, thus reducing exchanger performance. The fouling layer also blocks the flow passage/area and increases surface roughness, thus either reducing the flow rate in the exchanger or increasing the pressure drop or both. The foulant deposits may be loose such as magnetite particles or hard and tenacious such as calcium carbonate scale; other deposits may be sediment, polymers, coking or corrosion products, inorganic salts, biological growth, etc. Depending upon the fluids, operating conditions, and heat exchanger construction, the maximum fouling layer thickness on the heat transfer surface may result in a few hours to a number of years.

Fouling could be very costly depending upon the nature of fouling and the applications. It increases capital costs: (1) oversurfacing heat exchanger, (2) provisions for cleaning, and (3) use of special materials and constructions/surface features. It increases maintenance costs: (1) cleaning techniques, (2) chemical additives, and (3) troubleshooting. It may cause a loss of production: (1) reduced capacity and (2) shutdown. It increases energy losses: (1) reduced heat transfer, (2) increased pressure drop, and (3) dumping dirty streams. Fouling promotes corrosion, severe plugging, and eventual failure of uncleaned

heat exchangers. In a fossil-fired exhaust environment, gas-side fouling produces a potential fire hazard in heat exchangers.

The following are the major fouling mechanisms:

- *Crystallization or precipitation fouling* results from the deposition/formation of crystals of dissolved substances from the liquid onto heat transfer surface due to solubility changes with temperature beyond the saturation point. If the deposited layer is hard and tenacious, it is often referred to as scaling. If it is porous and mushy, it is called sludge.
- *Particulate fouling* results from the accumulation of finely divided substances suspended in the fluid stream onto heat transfer surface. If the settling occurs as a result of gravity, it is referred to as sedimentation fouling.
- *Chemical reaction fouling* is defined as the deposition of material produced by chemical reaction (between reactants contained in the fluid stream) in which the heat transfer surface material does not participate.
- *Corrosion fouling* results from corrosion of the heat transfer surface that produces products fouling the surface and/or roughens the surface, promoting attachment of other foulants.
- *Biological fouling* results from the deposition, attachment, and growth of biological organisms from liquid onto a heat transfer surface. Fouling due to microorganisms refers to microbial fouling and fouling due to macroorganisms refers to macrobial fouling.
- *Freezing fouling* results from the freezing of a single-component liquid or higher-melting-point constituents of a multicomponent liquid onto a subcooled heat transfer surface.

Biological fouling occurs only with liquids since there are no nutrients in gases. Also crystallization fouling is not too common with gases since most gases contain few dissolved salts (mainly in mists) and even fewer inverse-solubility salts. All other types of fouling occur in both liquid and gas. More than one mechanism is usually present in many fouling situations, often with synergetic results. Liquid-side fouling generally occurs on the exchanger side where the liquid is being heated, and gas-side fouling occurs where the gas is being cooled; however, reverse examples can be found.

### **Importance of Fouling.**

Fouling in liquids and two-phase flows has a significant detrimental effect on heat transfer with some increase in pressure drop. In contrast, fouling in gases reduces heat transfer somewhat (5 to 10% in general) in compact heat exchangers, but increases pressure drop significantly up to several hundred percent. For example, consider  $U = 1400 \text{ W/m}^2\text{K}$  as in a process plant liquid-to-liquid heat exchanger. Hence,  $R = 1/U = 0.00072 \text{ m}^2\text{K/W}$ . If the fouling factors ( $r_{s,h} + r_{s,c}$ ) together amount to 0.00036 (considering a typical TEMA value of the fouling factor as 0.00018), 50% of the heat transfer area requirement  $A$  for given  $q$  is chargeable to fouling. However, for gas flows on both sides of an exchanger,  $U \approx 280 \text{ W/m}^2\text{K}$ , and the same fouling factor of 0.00036 would represent only about 10% of the total surface area. Thus, one can see a significant impact on the heat transfer surface area requirement due to fouling in heat exchangers having high  $U$  values (such as having liquids or phase-change flows).

Considering the core frictional pressure drop (Equation (4.5.32)) as the main pressure drop component, the ratio of pressure drops of fouled and cleaned exchangers is given by

$$\frac{\Delta p_F}{\Delta p_C} = \frac{f_F}{f_C} \left( \frac{D_{h,C}}{D_{h,F}} \right) \left( \frac{u_{m,F}}{u_{m,C}} \right)^2 = \frac{f_F}{f_C} \left( \frac{D_{h,C}}{D_{h,F}} \right)^5 \quad (4.5.82)$$

where the term after the second equality sign is for a circular tube and the mass flow rates under fouled and clean conditions remain the same. Generally,  $f_F > f_C$  due to the fouled surface being rough. Thus, although the effect of fouling on the pressure drop is usually neglected, it can be significant, particularly for compact heat exchangers with gas flows. If we consider  $f_F = f_C$ , and the reduction in the tube inside

diameter due to fouling by only 10 and 20%, the resultant pressure drop increase will be 69 and 205%, respectively, according to Equation (4.5.82) regardless of whether the fluid is liquid or gas!

### Accounting of Fouling in Heat Exchangers.

Fouling is an extremely complex phenomenon characterized by a combined heat, mass, and momentum transfer under transient condition. Fouling is affected by a large number of variables related to heat exchanger surfaces, operating conditions, and fluids. Fouling is time dependent, zero at  $\tau = 0$ ; after the induction or delay period  $\tau_d$ , the fouling resistance is either pseudolinear, falling rate, or asymptotic.

Fouling is characterized by all or some of the following sequential events: initiation, transport, attachment, removal, and aging (Epstein, 1983). Research efforts are concentrated on quantifying these events by semitheoretical models (Epstein, 1978) with very limited success on specific fouling situations. Hence, the current heat exchanger design approach is to use a constant (supposedly an asymptotic) value of the fouling factor  $r_s = 1/h_s$ . Equation (4.5.6) presented earlier includes the fouling resistances on the hot and cold sides for a nontubular extended-surface exchanger. Here  $1/h_s = r_s$  is generally referred to as the *fouling factor*. Fouling factors for some common fluids are presented in [Tables 4.5.8 and 4.5.9](#).

The specification of fouling effects in a process heat exchanger is usually represented in the following form, wherein the combined fouling factor  $r_{s,t}$  is the sum of the fouling factors on the hot and cold sides:

$$\text{Combined fouling factor} \quad r_{s,t} = \frac{1}{U_C} - \frac{1}{U_F} \quad (4.5.83)$$

$$\text{Cleanliness factor} \quad \text{CF} = U_F/U_C \quad (4.5.84)$$

$$\text{Percentage oversurface} \quad \% \text{OS} = \left( \frac{A_F}{A_C} - 1 \right) 100 \quad (4.5.85)$$

Here the subscripts  $F$  and  $C$  denote fouled and clean exchanger values. From Equation (4.5.6) with  $A_h = A_c = A$ ,  $\eta_o = 1$ ,  $\Delta T_{m,F} = \Delta T_{m,C}$ , it can be shown that

$$\frac{A_F}{A_C} = \frac{U_C}{U_F} = 1 + U_C r_{s,t} \quad (4.5.86)$$

where  $r_{s,t} = r_{s,h} + r_{s,c}$ . In heat exchanger design, constant (supposedly an asymptotic) values of  $r_{s,h}$  and  $r_{s,c}$  are used. Accordingly, extra heat transfer surface area is provided to take into account the deleterious effect of fouling. Thus, the heat exchanger will be “oversized” for the initial clean condition, “correctly sized” for asymptotic fouling (if it occurs in practice), and “undersized” just before the cleaning operation for nonasymptotic fouling.

### Influence of Operating and Design Variables.

Based on operational experience and research over the last several decades, many variables have been identified that have a significant influence on fouling. The most important variables are summarized next.

**Flow velocity.** Flow velocity is one of the most important variables affecting fouling. Higher velocities increase fluid shear stress at the fouling deposit–fluid interface and increase the heat transfer coefficient; but, at the same time, increased pressure drop and fluid pumping power may erode the surface and may accelerate the corrosion of the surface by removing the protective oxide layer. The fouling buildup in general is inversely proportional to  $u_m^{1.5}$ . For water, the velocity should be kept above 2 m/sec to suppress fouling, and the absolute minimum should be above 1 m/sec to minimize fouling.

**Surface temperature.** Higher surface temperatures promote chemical reaction, corrosion, crystal formation (with inverse solubility salts), and polymerization, but reduce biofouling for temperatures above the optimum growth, avoid potential freezing fouling, and avoid precipitation of normal-solubility salts.

**TABLE 4.5.8 Fouling Factors for Various Fluid Streams Used in Heat Exchangers**

<b>Water Type</b>	<b>Fouling Factors (m<sup>2</sup> · K)/W</b>
Seawater (43°C maximum outlet)	0.000275 to 0.00035

It is highly recommended that the surface temperature be maintained below the reaction temperature; it should be kept below 60°C for cooling tower water.

*Tube material.* The selection of the tube material is important from the corrosion point of view which in turn could increase crystallization and biological fouling. Copper alloys can reduce certain biofouling, but their use is limited by environmental concerns with river, ocean, and lake waters.

There are many other variables that affect fouling. It is beyond the scope here, but the reader may refer to TEMA (1988).

**Fouling Control and Cleaning Techniques.**

Control of fouling should be attempted first before any cleaning method is attempted. For gas-side fouling, one should verify that fouling exists, identify the sequential event that dominates the foulant accumulation, and characterize the deposit. For liquid-side fouling, fouling inhibitors/additives should be employed while the exchanger is in operation; for example, use antidispersant polymers to prevent sedimentation fouling, “stabilizing” compounds to prevent polymerization and chemical reaction fouling, corrosion inhibitors to prevent corrosion fouling, biocide/germicide to prevent biofouling, softeners, acids, and polyphosphates to prevent crystallization fouling.

If the foulant control is not effective, the exchanger must be cleaned either on-line or off-line. On-line cleaning includes flow-driven brushes/sponge balls inside tubes, power-driven rotating brushes inside tubes, acoustic horns/mechanical vibrations for tube banks with gases, soot blowers, and shutting off of the cold gas supply, flowing hot gas, or reversing of the fluids. Off-line cleaning methods, without dismantling the exchanger include chemical cleaning (circulate acid/detergent solutions), circulating of particulate slurry (such as sand and water), and thermal melting of frost layers. Off-line cleaning with a heat exchanger opened includes high-pressure steam or water cleaning, and thermal baking of an exchanger and then rinsing for small heat exchanger modules removed from the container of the modular exchangers.

## Nomenclature

- $A$  total heat transfer area (primary + fin) on one fluid side of a heat exchanger,  $A_p$ : primary surface area,  $A_f$ : fin surface area, m<sup>2</sup>
- $A_{fr}$  frontal area on one side of an exchanger, m<sup>2</sup>
- $A_k$  total wall cross-sectional area for heat conduction in fin or for longitudinal conduction in the exchanger, m<sup>2</sup>
- $A_o$  minimum free-flow area on one fluid side of a heat exchanger, m<sup>2</sup>
- $b$  plate spacing,  $h' + \delta_f$ , m
- $C$  flow stream heat capacity rate with a subscript  $c$  or  $h$ ,  $\dot{m}c_p$ , W/°C
- $C^*$  heat capacity rate ratio,  $C_{\min}/C_{\max}$ , dimensionless
- $c_p$  specific heat of fluid at constant pressure, J/kg K
- $D_h$  hydraulic diameter of flow passages,  $4A_o/L/A$ , m
- $d_e$  fin tip diameter of an individually finned tube, m
- $d_i, d_o$  tube inside and outside diameters, respectively, m
- Eu  $N$ -row average Euler number,  $\Delta p/(\rho u_m^2 N/2g_c)$ ,  $\rho \Delta p g_c / (NG^2/2)$ , dimensionless

$F$	log-mean temperature difference correction factor, dimensionless
$f$	Fanning friction factor, $\rho\Delta p g_c D_h / (2LG^2)$ , dimensionless
$f_{fb}$	Fanning friction factor per tube row for crossflow over a tube bank outside, $\rho\Delta p g_c / (2NG^2)$
$G$	mass velocity based on the minimum free flow area, $\dot{m}/A_o$ , kg/m <sup>2</sup> sec
$g$	gravitational acceleration, m <sup>2</sup> /sec
$g_c$	proportionality constant in Newton's second law of motion, $g_c = 1$ and dimensionless in SI units
$H$	fin length for heat conduction from primary surface to either fin tip or midpoint between plates for symmetric heating, m
$h$	heat transfer coefficient, W/m <sup>2</sup> K
$h'$	height of the offset strip fin (see Figure 4.5.15), m
$j$	Colburn factor, $NuPr^{-1/3}/Re$ , $StPr^{2/3}$ , dimensionless
$k$	fluid thermal conductivity, W/m K
$k_f$	thermal conductivity of the fin material, W/m K
$k_w$	thermal conductivity of the matrix (wall) material, W/m K
$L$	fluid flow (core or tube) length on one side of an exchanger, m
$l$	fin length for heat conduction from primary surface to the midpoint between plates for symmetric heating, see Table 4.5.5 for other definitions of $l$ , m
$l_f$	offset trip fin length or fin height for individually finned tubes, $l_f$ represents the fin length in the fluid flow direction for an uninterrupted fin with $l_f = L$ in most cases, m
$m$	fin parameter, 1/m
$N$	number of tube rows
$N_f$	number of fins per meter, 1/m
$N_t$	total number of tubes in an exchanger
NTU	number of heat transfer units, $UA/C_{\min}$ , it represents the total number of transfer units in a multipass unit, $NTU_s = UA/C_{\text{shell}}$ , dimensionless
Nu	Nusselt number, $hD_h/k$ , dimensionless
$ntu_c$	number of heat transfer units based on the cold side, $(\eta_o hA)_c / C_c$ , dimensionless
$ntu_h$	number of heat transfer units based on the hot side, $(\eta_o hA)_h / C_h$ , dimensionless
$\dot{m}$	mass flow rate, kg/sec
$P$	temperature effectiveness of one fluid, dimensionless
$\wp$	fluid pumping power, W
Pr	fluid Prandtl number, $\mu c_p / k$ , dimensionless
$p$	fluid static pressure, Pa
$\Delta p$	fluid static pressure drop on one side of heat exchanger core, Pa
$p_f$	fin pitch, m
$q$	heat duty, W
$q_e$	heat transfer rate (leakage) at the fin tip, W
$q''$	heat flux, W/m <sup>2</sup>
$R$	heat capacity rate ratio used in the P-NTU method, $R_1 = C_1/C$ , $R_2 = C_2/C_1$ , dimensionless
$R$	thermal resistance based on the surface area $A$ , compare Equations 4.5.5 and 4.5.6 for definitions of specific thermal resistances, K/W
Re	Reynolds number, $GD_h/\mu$ , dimensionless
$Re_d$	Reynolds number, $\rho u_m d_o / \mu$ , dimensionless
$r_h$	hydraulic radius, $D_h/4$ , $A_o L/A$ , m
$r_s$	fouling factor, $1/h_s$ , m <sup>2</sup> K/W
St	Stanton number, $h/Gc_p$ , dimensionless
$s$	distance between adjacent fins, $p_f - \delta_f$ , m
$T$	fluid static temperature to a specified arbitrary datum, °C
$T_a$	ambient temperature, °C
$T_o$	fin base temperature, °C
$T_l$	fin tip temperature, °C
$U$	overall heat transfer coefficient, W/m <sup>2</sup> K
$u_m$	mean axial velocity in the minimum free flow area, m/sec

$V$	heat exchanger total volume, $m^3$
$X_d$	diagonal tube pitch, m
$X_l$	longitudinal tube pitch, m
$X_t$	transverse tube pitch, m
$\alpha$	ratio of total heat transfer area on one side of an exchanger to the total volume of an exchanger, $A/V$ , $m^2/m^3$
$\beta$	heat transfer surface area density, a ratio of total transfer area on one side of a plate-fin heat exchanger to the volume between the plates on that side, $m^2/m^3$
$\varepsilon$	heat exchanger effectiveness, it represents an overall exchanger effectiveness for a multipass unit, dimensionless
$\delta$	wall thickness, m
$\delta_f$	fin thickness, m
$\eta_f$	fin efficiency, dimensionless
$\eta_o$	extended surface efficiency, dimensionless
$\lambda$	longitudinal wall heat conduction parameter based on the total conduction area, $\lambda = k_w A_{k,t}/C_{\min} L$ , $\lambda_c = k_w A_{k,c}/C_c L$ , $\lambda_h = k_w A_{k,h}/C_h L$ , dimensionless
$\mu$	fluid dynamic viscosity, Pa·s
$\rho$	fluid density, $kg/m^3$
$\sigma$	ratio of free flow area to frontal area, $A_o/A_{fr}$ , dimensionless

### Subscripts

$C$	clean surface value
$c$	cold fluid side
$F$	fouled surface value
$f$	fin
$h$	hot fluid side
$i$	inlet to the exchanger
$o$	outlet to the exchanger
$s$	scale or fouling
$w$	wall or properties at the wall temperature
1	one section (inlet or outlet) of the exchanger
2	other section (outlet or inlet) of the exchanger

## Further Information

Heat exchangers play a crucial and dominant role in many developments related to energy conservation, recovery, utilization, economic development of new energy sources, and environmental issues such as air and water pollution control, thermal pollution, waste disposal, etc. Many new and innovative heat exchangers have been developed for these and many other applications worldwide. A broad overview is provided for various heat exchangers and basic design theory for single-phase heat exchangers. For further details and study, the reader may refer to the following references: Kakaç et al. (1981; 1983; 1988), Taylor (1987), Shah et al. (1990), Foumeny and Heggs (1991), Kakaç (1991), Roetzel et al. (1991), Shah and Hashemi (1993), and Shah et al. (1997).

## Shell-and-Tube Heat Exchangers

*Kenneth J. Bell*

### Introduction

A shell-and-tube heat exchanger is essentially a bundle of tubes enclosed in a shell and so arranged that one fluid flows through the tubes and another fluid flows across the outside of the tubes, heat being transferred from one fluid to the other through the tube wall. A number of other mechanical components are required to guide the fluids into, through, and out of the exchanger, to prevent the fluids from mixing, and to ensure the mechanical integrity of the heat exchanger. A typical shell-and-tube heat exchanger is shown in [Figure 4.5.18](#) (TEMA, 1988), but the basic design allows many modifications and special features, some of which are described below.

### Nomenclature of Heat Exchanger Components

For the purpose of establishing standard terminology, [Figure 4.5.18](#) illustrates various types of heat exchangers. Typical parts and connections, for illustrative purposes only, are numbered for identification:

**FIGURE 4.5.18** Longitudinal section of a typical shell-and-tube heat exchanger (TEMA AES) with nomenclature. (Modified from TEMA, *Standards 7th ed.*, Tubular Exchanger Manufacturers Association, Tarrytown, NY, 1988.)

Shell-and-tube heat exchangers have been constructed with heat transfer areas from less than 0.1 m<sup>2</sup> (1 ft<sup>2</sup>) to over 100,000 m<sup>2</sup> (1,000,000 ft<sup>2</sup>), for pressures from deep vacuum to over 1000 bar (15,000 psi), for temperatures from near 0 to over 1400 K (2000°F), and for all fluid services including single-phase heating and cooling and multiphase vaporization and condensation. The key to such flexibility is the wide range of materials of construction, forming and joining methods, and design features that can be built into these exchangers (see Schlünder, Vol. 4, 1983; Saunders, 1988; and Yokell, 1990). Most

shell-and-tube heat exchangers are manufactured in conformity with TEMA *Standards* (1988) and the *ASME Boiler and Pressure Vessel Code* (latest edition), but other codes and standards may apply.

### Construction Features

In the design process, it is important to consider the mechanical integrity under varying operational conditions and the maintainability (especially cleaning) of the exchanger as equally important with the thermal-hydraulic design.

**Tubes.** Tubes used in shell-and-tube exchangers range from 6.35 mm ( $1/4$  in.) to 50.8 mm (2 in.) and above in outside diameter, with the wall thickness usually being specified by the Birmingham wire gauge (BWG). Tubes are generally available in any desired length up to 30 m (100 ft) or more for plain tubes. While plain tubes are widely used, a variety of internally and/or externally enhanced tubes is available to provide special heat transfer characteristics when economically justified (see subsection on enhancement in Section 4.8). Low fin tubes having circumferential fins typically 0.8 to 1.6 mm (0.032 to 0.062 in.) high, spaced 630 to 1260 fins/m (16 to 32 fins/in.) are often employed, especially when the shell-side heat transfer coefficient is substantially smaller than the tube-side coefficient. The outside heat transfer area of a low fin tube is three to six times the inside area, resulting in a smaller heat exchanger shell for the same service, which may offset the higher cost of the tube per unit length.

The tubes are inserted into slightly oversized holes drilled (or, occasionally, punched) through the tubesheets (items 5 and 13, [Figure 4.5.18](#)). The tubes are secured by several means, depending upon the mechanical severity of the application and the need to avoid leakage between the streams. In some low-severity applications, the tubes are roller-expanded into smooth holes in the tubesheet. For a stronger joint, two shallow circumferential grooves are cut into the wall of the hole in the tubesheet and the tube roller-expanded into the grooves; to eliminate the possibility of leakage, a seal weld can be run between the outer end of the tube and the tubesheet. Alternatively, the tubes may be strength-welded into the tubesheet.

**Tube Supports.** It is essential to provide periodic support along the length of the tubes to prevent sagging and destructive vibration caused by the fluid flowing across the tube bank. A secondary role played by the tube supports is to guide the flow back and forth across the tube bank, increasing the velocity and improving the heat transfer on the shell side (but also increasing the pressure drop). The tube support is usually in the form of single segmental baffles (item 18 in [Figure 4.5.18](#)) — circular plates with holes drilled to accommodate the tubes and with a segment sheared off to form a “window” or “turnaround” to allow the shell-side fluid to pass from one cross-flow section to the next. The baffles must overlap at least one full row of tubes to give the bundle the necessary rigidity against vibration. When minimizing shell-side pressure drop is not a priority, a baffle cut of 15 to 25% of the shell inside diameter is customary. Baffle spacing is determined first by the necessity to avoid vibration and secondarily to approximately match the free cross-flow area between adjacent baffles to the flow area in the window; i.e., small baffle cuts correspond to closer baffle spacing.

In situations such as low-pressure gas flows on the shell side where pressure drop is severely limited, double segmental and strip baffle arrays can be used. More recently, a helical baffle arrangement has been introduced (Kral et al., 1996) which causes the shell-side fluid to spiral through the exchanger giving improved heat transfer vs. pressure drop characteristics. Where vibration prevention and/or minimum pressure drop are the main concerns, grids of rods or strips can be used (Gentry et al., 1982).

**Shells.** The shell is the cylinder which confines the shell-side fluid (item 7 in [Figure 4.5.18](#)), fitted with nozzles for fluid inlet and exit. Diameters range from less than 50 mm (2 in.) to 3.05 m (10 ft) commonly, and at least twice that value for special applications. In diameters up to 610 mm (24 in.), shells are usually made from standard pipe or tubular goods by cutting to the desired length; in larger sizes, metal plates are rolled to the desired diameter and welded.

A variety of nozzle arrangements are used for special purposes, and TEMA has a standard code to identify the major types, as well as the various front and rear head configurations on the tube side. Figure 4.5.19 shows these configurations with the corresponding code letters.

FIGURE 4.5.19 TEMA nomenclature for shell and tube configurations. (From TEMA, *Standards*, 7th ed., Tubular Exchanger Manufacturers Association, Tarrytown, NY, 1988. With permission.)

The E shell (center column, top) has the nozzles on opposite ends of the shell and is the most common configuration. It is used for any of the thermal services (single-phase heating or cooling, vaporization, and condensation). The nozzles may be on opposite sides of the shell as shown, or on the same side; the choice is largely determined by plumbing convenience. The E shell allows countercurrent flow (see below) of the two streams if there is one tube-side pass (i.e., the tube-side fluid flows through all of the tubes in parallel).

The F shell has both nozzles at one end of the shell and uses a longitudinal baffle on the shell side (shown dashed in the drawing) to force the shell-side fluid to flow to the far end of the heat exchanger and then back to the exit nozzle on the other side of the longitudinal baffle. Ideally, this allows countercurrent flow of the two streams if there are two tube-side passes (i.e., the tube-side fluid flows through half of the tubes in one direction, is turned around in the rear head, and returns through the other half of the tubes — see discussion of head types below). However, the longitudinal baffle must be carefully sealed to the shell to prevent leakage of the shell-side fluid across it; this is done by welding the longitudinal baffle to the shell and front tubesheet (which limits some design options) or by using mechanical seals. The F shell is mainly used for sensible heat transfer services.

The G shell has both nozzles at the center of the shell, with a centrally located longitudinal baffle to force the fluid to the ends of the shell before returning. While the G shell is used for all services, its main application is as a shellside vaporizer with either forced or natural (thermosiphon) convection of the boiling fluid; in the latter service, limited leakage across the baffle generally does not greatly degrade the thermal performance and the longitudinal baffle does not need to be perfectly sealed against the shell.

The H shell is effectively a double G shell and is employed in the same services. It is considered when the calculated shell-side pressure drop for a G arrangement is too high and threatens to limit the circulation rate.

The J shell, with one nozzle on top of the shell and two on the bottom, or vice versa, is commonly used in vacuum-condensing applications because of its low pressure drop. Two J shells (one inverted) may be mated in series for long-condensing-range mixtures. The nozzles are usually different diameters, with the large diameter accommodating the inlet vapor. The baffles are vertically cut.

The K shell (or kettle reboiler or flooded chiller) is exclusively intended for vaporization of liquid on the shell side, with a condensing vapor (usually steam) or a hot liquid on the tube side as the heating medium. The tubesheet diameter is large enough to accommodate the tube bundle, but the shell transitions to a larger diameter to allow the vapor to disengage from the liquid pool and exit from the top nozzle. A weir or other level control is used to maintain the liquid level, usually just above the top tubes in the bundle.

The X shell is intended to provide a well-distributed cross flow of the shell-side fluid, the fluid usually entering at the top and exiting at the bottom but occasionally used for upflow or horizontal cross flow. To obtain good distribution, multiple nozzles from a properly designed manifold may be required. Alternatively, the upper tubes in the bundle may be omitted to allow internal redistribution, or a large plenum chamber may be welded to the top of the shell (“vapor dome” or “bathtub nozzle”), or a diverging transition section may be placed between the inlet piping and the top of the shell. The tube supports may be complete circles since there is little or no longitudinal shell-side flow. The X shell gives the lowest shell-side pressure drop of any configuration and is often used for low-pressure vapor condensers.

*Front Head.* TEMA recognizes several front head designs as shown in the first column of [Figure 4.5.19](#). Any of these designs will get the tube-side fluid into the tubes, but each has special features which recommend it to meet special needs. In [Figure 4.5.19](#) the dashed lines indicate optional features depending upon need.

The A head, a channel with removable cover, bolts directly to the shell flange as shown in [Figure 4.5.18](#), the tubesheet in that case being held between them and sealed with gaskets. Alternatively, the tubesheet may be integral with the shell (see the L rear head in [Figure 4.5.19](#)). A removable channel cover permits inspection, cleaning, removal, and replacement of tubes without disturbing the piping. The dashed lines at the center and the lower nozzle indicate that a pass partition plate may be welded

in the channel (and gasketed against the tubesheet and channel cover) to provide for two tube-side passes (as shown in [Figure 4.5.18](#) and required by the F shell design). Additional pass partitions may be provided to allow four, six, or any even number of tube-side passes. This permits the designer to utilize the available tube-side pressure drop to increase velocity, improve the heat transfer coefficient, and possibly reduce fouling. A second nozzle is required on the channel for multipass designs.

The B, or bonnet, front head reduces the number of gasketed joints and thus the opportunity for leakage, but it does not permit inspection of the tubes without breaking the piping connection. It is generally less expensive than the A head.

C and N heads retain the removable cover feature of the A head but, respectively, replace the channel-to-tubesheet and the tubesheet-to-shell gasketed connections with welds to minimize leakage possibilities. The N head is particularly used in nuclear services.

The D head is mainly used in feed-water heater applications where tube-side pressures are in the 100 to 400 bar range. The internal partition (optional) need only withstand the 1 to 2 bar pressure drop through the tubes so it can be of lightweight construction. The high-pressure closure against the atmosphere uses a shear key ring to lock the main closure in place.

*Rear Head.* A variety of rear head designs are used in shell-and-tube exchangers, primarily because of the need to accommodate thermally induced stresses. During operation, the tubes and the shell have different temperatures and therefore will expand (or try to) different amounts, even if there were no residual stresses in the exchanger before start-up and even if the entire exchanger is made out of the same material. The thermal stress problem is exacerbated if there are residual stresses, or if the exchanger is made of different materials, or during transient operation (including start-up and shutdown). If the temperature differences are small, the structure may be able to accommodate the thermal stresses safely; usually, however, it is necessary to make specific provision to allow the shell and the tubes to expand or contract independently. Failure to do so can result in buckling, bending, or even rupture of the shell or the tubes, or destruction of the tube-to-tubesheet joint.

A simple solution is to incorporate an expansion joint or a bellows into the shell (or in certain special applications, into the tube-side piping internal to the shell cover). However, this solution cannot cover the entire range of pressures and temperature differences encountered in practice. Further, it is usually possible to incorporate other desirable features, such as removable bundles, with thermal stress relief in the variety of rear head designs available. These are shown in the last column of [Figure 4.5.19](#).

The L and M rear heads correspond to the A and B front heads previously described. As shown, they require a fixed tubesheet design; that is, the tubesheets are rigidly fastened to the shell, and thermal stress relief, if necessary, must be provided by a shell-side expansion joint or bellows. The tube bundle cannot be removed for inspection or mechanical cleaning on the shell side. However, the outer tube limit (OTL) — the diameter of the tube field circumscribing the outermost tubes in the bundle — can be as little as 0.4 in. (10 mm) less than the inside diameter of a pipe shell and 0.5 in. (12.7 mm) for a rolled shell. Therefore, the tube field can be very full, giving more tubes and minimizing bypass flow. Similar comments apply to the N rear head, except that more clearance must be left between the outermost tubes and the shell.

The type P head uses packing between the skirt on the rear tubesheet and the shell extension to seal the shell-side fluid against leakage. The compression on the packing has to be adjusted to prevent excessive leakage on the one hand and to allow limited movement of the tube-side head on the other, so the shell-side fluid must be benign and cheap (not surprisingly, it is often cooling water). On the other hand, leakage between the two fluids can occur only through tube hole leaks. Because of the tubesheet skirt, clearance between the outermost tubes and the shell must increase compared with types L or M; accordingly, fewer tubes are possible in a given shell, and sealing strips to partially block the bundle-to-shell bypass stream are recommended. When the floating head cover and packing gland are removed, the tube bundle can be pulled out of the shell for inspection and cleaning.

The TEMA S split-ring floating head design uses a split backing ring to hold the floating head cover and its gasket to the tubesheet. The split backing ring is bolted to the cover with a bolt circle outside

the diameter of the tubesheet. Therefore, when the split ring is removed, the entire tube bundle may be pulled out of the shell. Tube count is similar to type P design and sealing strips are recommended. Usually, the split-ring floating head is used with an even number of tube passes so that a plain bonnet-type shell cover can be used. However, as shown by the dashed lines in Figure 4.5.19, single tube-side pass design (and countercurrent flow) can be achieved by use of a packing gland on the exit piping through the bonnet; alternatively, a deep bonnet can be used together with an expansion joint or bellows on the tube-side exit piping.

The pull-through floating head, type T, uses a floating head cover that flanges directly to the tubesheet, reducing the possibility of internal leakage compared with type S, but also eliminating more tubes around the periphery. Sealing strips are a virtual necessity. Single tube-side pass design is similar to type S, but is rarely used.

TEMA type U uses a bundle of U tubes and hence requires no rear head at all. The U-tube bundle effectively eliminates the thermal stress problem between shell and tubes, because each tube is free to expand or contract independently. The U bundle is also the cheapest construction because the cost of a second tubesheet is avoided. However, there are a number of drawbacks: designs must have an even number of tube-side passes, mechanical cleaning of the smaller bend radius tubes in the U bend is impossible, individual tubes cannot be replaced except in the outer row, some tube count is lost because of minimum bend limits, and the U bend must be carefully supported against vibration or kept out of the cross-flow stream by placing the shell nozzle upstream of the bend. The tube side in the U bend is susceptible to erosion, especially with two-phase or particulate-containing fluids.

Type W uses two sets of packing, often with a lantern ring in between. This construction is generally limited to benign fluids and low to very moderate pressures and temperatures.

*Other Features.* Numerous other components are necessary or optional to construction of shell-and-tube exchangers. Probably the most complete discussion is given by Yokell (1990).

## Principles of Design

*Design Logic.* The design of a shell-and-tube exchanger involves the following steps:

1. Selection of a set of design features which are required for mechanical integrity and ease of maintenance, and which will likely lead to satisfying the thermal requirements within the allowable pressure drops, and at lowest cost.
2. Selection of a set of dimensions for the actual exchanger.
3. For the dimensions selected in (2), calculation of the thermal performance of the heat exchanger and both tube-side and shell-side pressure drops, using available rating procedures.
4. Comparison of the thermal performance calculated in (3) with that required and examination of the pressure drops calculated in (3) to ensure that the allowed pressure drops are reasonably used but not exceeded.
5. Adjustment of the dimensions selected in (2) and repetition of steps (3) and (4) until the criteria are satisfied.
6. Completion of the mechanical design to satisfy code requirements.
7. Cost estimation.

*Basic Design Equations.* The basic design equation for a shell-and-tube exchanger in steady-state service is

$$A^* = \int_0^{q_T} \frac{dq}{U^*(T_h - T_c)} \quad (4.5.87)$$

where  $A^*$  is the heat transfer area required in the heat exchanger,  $m^2$  ( $ft^2$ );  $q_T$  is the heat transfer rate of the heat exchanger, W (Btu/hr);  $U^*$  is the local overall heat transfer coefficient referenced to area  $A^*$ ,  $W/m^2$  K (Btu/hr  $ft^2$  °F); and  $T_h$  and  $T_c$  are the local hot and cold stream temperatures, K (°F). The \*

superscript on  $A^*$  and  $U^*$  only means that a consistent reference area must be used in defining these terms. For example, for an exchanger with plain tubes, it is customary to use the total outside heat transfer area of all of the tubes in the exchanger,  $A_o$ , as the reference area, and then  $U_o$  is the overall heat transfer coefficient referenced to  $A_o$ . If the exchanger has low-finned tubes,  $A^*$  may refer either to the total outside area including fins or to the inside tube heat transfer area; the choice is optional, but must be spelled out. Since  $T_h$  and  $T_c$  generally vary with the amount of heat transferred (following the first law of thermodynamics, and excepting isobaric phase transition of a pure component) and  $U^*$  may vary with local heat transfer conditions, in principle Equation 4.5.87 must be numerically integrated with  $T_h$ ,  $T_c$ , and  $U^*$  calculated along the path of integration, and this process is performed by the most-advanced computer-based design methods.

For many applications, certain reasonable assumptions can be made allowing the analytical integration of Equation 4.5.87 to give (Schlünder, Vol. 1, 1983; Hewitt et al., 1994)

$$A^* = \frac{q_T U^*}{(\text{MTD})} \quad (4.5.88)$$

where MTD is the mean temperature difference for the particular flow conditions and configuration. The key assumptions are that there is no significant bypassing of fluid around the heat transfer surface, that the overall heat transfer coefficient is constant, and that the specific heats of the two streams are constant over their temperature ranges in the exchanger; isothermal phase transitions, such as vaporizing or condensing a pure component at constant pressure, are also allowed.

If the two streams are in countercurrent flow, i.e., if they flow always in the opposite direction to one another,

$$\text{MTD} = (\text{LMTD})_{\text{countercurrent}} = \frac{(T_{h,i} - T_{c,o}) - (T_{h,o} - T_{c,i})}{\ln\left(\frac{T_{h,i} - T_{c,o}}{T_{h,o} - T_{c,i}}\right)} \quad (4.5.89)$$

where  $(\text{LMTD})_{\text{countercurrent}}$  is the “logarithmic mean temperature difference for countercurrent flow” and the subscripts  $i$  and  $o$  indicate “inlet” and “outlet,” respectively. E shells with a single tube-side pass and F shells with two tube-side passes are almost always designed for countercurrent flow. (While the flow between adjacent baffles is basically cross flow, it can be shown that the total shell-side flow pattern is equivalent to countercurrent flow if there are more than three or four baffles).

Very occasionally, usually when close control of tube wall temperatures is required, cocurrent flow is specified, with the two streams flowing in the same direction through the exchanger. For this case,

$$\text{MTD} = (\text{LMTD})_{\text{cocurrent}} = \frac{(T_{h,i} - T_{c,i}) - (T_{h,o} - T_{c,o})}{\ln\left(\frac{T_{h,i} - T_{c,i}}{T_{h,o} - T_{c,o}}\right)} \quad (4.5.90)$$

where the symbols have the same meaning as before.  $(\text{LMTD})_{\text{countercurrent}}$  is always equal to or greater than  $(\text{LMTD})_{\text{cocurrent}}$ , so wherever possible, countercurrent design and operation is preferred.

However, most shell-and-tube exchangers have nozzle and tube pass configurations which lead to mixed countercurrent and cocurrent flow regions (as well as cross flow in the X shell). For these cases,

$$\text{MTD} = F(\text{LMTD})_{\text{countercurrent}} \quad (4.5.91)$$

where  $(\text{LMTD})_{\text{countercurrent}}$  is calculated from Equation (4.5.89) and  $F$  is the “configuration correction factor” for the flow configuration involved.  $F$  has been found as a function of dimensionless temperature ratios for most flow configurations of interest and is given in analytical and/or graphical form in the earlier part of this section by Shah and in many heat transfer references (e.g., Schlünder, Vol. 1, 1983).  $F$  is equal to unity for pure countercurrent flow and is less than unity for all other cases; practical considerations limit the range of interest to values above 0.7 at the lowest and more comfortably to values above 0.8. Values of zero or below indicate conditions that violate the second law of thermodynamics.

*The Overall Heat Transfer Coefficient.* The overall heat transfer coefficient  $U^*$ , referenced to the heat transfer area  $A^*$ , is related to the individual (film) heat transfer coefficients and the fouling resistances by

$$U^* = \frac{1}{\frac{A^*}{h_i A_i} + R_{fi} \frac{A^*}{A_i} + \frac{A^* \ln(d_o/d_i)}{2\pi N_i L k_w} + R_{fo} \frac{A^*}{A_o} + \frac{A^*}{h_o A_o}} \quad (4.5.92)$$

where  $h_i$  and  $h_o$  are, respectively, the tube-side and shell-side film heat transfer coefficients,  $\text{W/m}^2\text{K}$  ( $\text{Btu/hr ft}^2 \text{ }^\circ\text{F}$ ), each referenced to its corresponding heat transfer area;  $R_{fi}$  and  $R_{fo}$  the corresponding fouling resistances (see below),  $\text{m}^2\text{K/W}$  ( $\text{hr ft}^2 \text{ }^\circ\text{F/Btu}$ );  $N_i$  the total number of tubes in the heat exchanger;  $L$  the effective tube length between the inside surfaces of the tubesheets, m (ft);  $d_o$  and  $d_i$  the outside and inside tube diameters, m (ft); and  $k_w$  the thermal conductivity of the tube wall material,  $\text{W/m K}$  ( $\text{Btu/hr ft}^\circ\text{F}$ ). For the special but important case of plain tubes

$$A^* = A_o = N_i (\pi d_o L) \quad (4.5.93)$$

and Equation (4.5.92) reduces to

$$U_o = \frac{1}{\frac{d_o}{h_i d_i} + R_{fi} \frac{d_o}{d_i} + \frac{d_o \ln(d_o/d_i)}{2k_w} + R_{fo} + \frac{1}{h_o}} \quad (4.5.94)$$

If finned tubes are used, the root diameter  $d_r$  of the fins replaces  $d_o$  in Equation (4.5.92) and  $A_o$  includes the surface area of the fins as well as the bare tube surface between the fins; it is also necessary to include a fin efficiency (typically about 0.8 to 0.95) multiplier in the numerators of the last two terms on the right side of Equation (4.5.92) to account for resistance to conduction in the fins. The treatment of fin efficiency is fully developed in Kern and Kraus (1972). Efficiencies of some of the important geometries are given in the earlier half of this section.

*Film Heat Transfer Coefficients.* Calculation of single-phase tube-side heat transfer coefficients for plain tubes is discussed in Section 4.1; special correlations are required for internally enhanced tubes, see discussion of enhancement in Section 4.8. Intube condensation and vaporization are covered in the subsection on boiling and condensation in Section 4.4.

Shell-side heat transfer calculations are more complex owing to the large number and range of design variables and process conditions that can occur. The most accurate methods are proprietary and computer based. The best known of these methods are those of Heat Transfer Research, Inc. (HTRI), College Station, TX; Heat Transfer and Fluid Flow Services (HTFS), Harwell, U.K.; and B-JAC, Midlothian, VA. For single-phase flow, the Delaware method appears to be the best in the open literature, and it is feasible for both hand and computer use; various presentations of the method appear in many references, including Schlünder, Vol. 3 (1983) and Hewitt et al. (1994). These references also give methods for

shell-side vaporizing and condensing design. An approximate design procedure is given in the next subsection.

**Fouling.** Fouling is the formation of any undesired deposit on the heat transfer surface, and it presents an additional resistance to the flow of heat. Several different types of fouling are recognized:

Sedimentation: deposition of suspended material on the surface.

Crystallization: precipitation of solute from supersaturated solutions.

Corrosion: formation of corrosion products on the surface.

Thermal degradation/polymerization: formation of insoluble products by oxidation, charring, and/or polymerization of a process stream.

Biofouling: growth of large organisms (e.g., barnacles) that interfere with flow to or past a heat transfer surface (“macrobiofouling”) or small organisms (e.g., algae) that form a fouling layer on the surface (“microbiofouling”).

The effect of fouling on design is twofold: Extra surface must be added to the heat exchanger to overcome the additional thermal resistance, and provision must be made to allow cleaning either by chemical or mechanical means. The fouling resistances included in Equation (4.5.92) result in requiring extra surface by reducing  $U^*$  (though they do not properly account for the time-dependent nature of fouling) and should be chosen with care. Table 4.5.8, based on the TEMA *Standards* provides some guidance, but prior experience with a given service is the best source of values. Ranges of typical values for major classes of service are included in Table 4.5.10.

Other things being equal, a fouling stream that requires mechanical cleaning should be put in the tubes because it is easier to clean the tube side. If this is not possible or desirable, then a removable bundle with a rotated square tube layout should be chosen to facilitate cleaning.

**Pressure Drop.** Tube-side pressure drop in plain tubes is discussed in Section 3.4. These calculations are straightforward and quite accurate as long as the tubes are smooth and clean; however, even a small amount of roughening due to corrosion or fouling (sometimes with a significant reduction of flow area) can double or triple tube-side pressure drop. Special correlations are required for internally enhanced tubes.

Calculation of shell-side pressure drop is implicit in the design methods mentioned above for heat transfer. Roughness has less effect on shell-side pressure drop than on tube side, but fouling still may have a very substantial effect if the deposits fill up the clearances between the baffles and the shell and between the tubes and the baffles, or if the deposits are thick enough to narrow the clearances between adjacent tubes. Existing design methods can predict these effects if the thickness of the fouling layer can be estimated.

**Limitations of Design.** It should be recognized that even under the best of conditions — new, clean exchangers with conventional construction features — heat exchanger design is not highly accurate. The best methods, when compared with carefully taken test data, show deviations of  $\pm 20\%$  on overall heat transfer and  $\pm 40\%$  on shell-side pressure drop (Palen and Taborek, 1969). These ranges are considerably worsened in fouling services. In these cases, the thermal *system* should be designed for operational flexibility, including carefully chosen redundancy of key components, and easy maintenance.

### Approximate Design Method

Because of the complexity of rigorous design methods, it is useful to have an estimation procedure that can quickly give approximate dimensions of a heat exchanger for a specified service. Such a method is given here for purposes of preliminary cost estimation, plant layout, or checking the results of computer output. This method is based upon Equation (4.5.88) with  $A^* = A_o$  and  $U^* = U_o$  and depends upon rapidly estimating values for  $q_T$ , MTD, and  $U_o$ . The procedure is as follows:

TABLE 4.5.10 Typical Film Heat Transfer Coefficients for Shell-and-Tube Heat Exchangers

Fluid Conditions		$h$ , W/m <sup>2</sup> K <sup>a,b</sup>	Fouling resistance, m <sup>2</sup> K/W <sup>a</sup>
<b>Sensible heat transfer</b>			
Water <sup>c</sup>	Liquid	5000–7500	$1-2.5 \times 10^{-4}$
Ammonia	Liquid	6000–8000	$0-1 \times 10^{-4}$
Light organics <sup>d</sup>	Liquid	1500–2000	$0-2 \times 10^{-4}$
Medium organics <sup>e</sup>	Liquid	750–1500	$1-4 \times 10^{-4}$
Heavy organics <sup>f</sup>	Liquid		
	Heating	250–750	$2-10 \times 10^{-4}$
	Cooling	150–400	$2-10 \times 10^{-4}$
Very heavy organics <sup>g</sup>	Liquid		
	Heating	100–300	$4-30 \times 10^{-3}$
	Cooling	60–150	$4-30 \times 10^{-3}$
Gas <sup>h</sup>	Pressure 100–200 kN/m <sup>2</sup> abs	80–125	$0-1 \times 10^{-4}$
Gas <sup>h</sup>	Pressure 1 MN/m <sup>2</sup> abs	250–400	$0-1 \times 10^{-4}$
Gas <sup>h</sup>	Pressure 10 MN/m <sup>2</sup> abs	500–800	$0-1 \times 10^{-4}$
<b>Condensing heat transfer</b>			
Steam, ammonia	Pressure 10 kN/m <sup>2</sup> abs, no noncondensables <sup>i,j</sup>	8000–12000	$0-1 \times 10^{-4}$
Steam, ammonia	Pressure 10 kN/m <sup>2</sup> abs, 1% noncondensables <sup>k</sup>	4000–6000	$0-1 \times 10^{-4}$
Steam, ammonia	Pressure 10 kN/m <sup>2</sup> abs, 4% noncondensables <sup>k</sup>	2000–3000	$0-1 \times 10^{-4}$
Steam, ammonia	Pressure 100 kN/m <sup>2</sup> abs, no noncondensables <sup>i,j,k,l</sup>	10000–15000	$0-1 \times 10^{-4}$
Steam, ammonia	Pressure 1 MN/m <sup>2</sup> abs, no noncondensables <sup>i,j,k,l</sup>	15000–25,000	$0-1 \times 10^{-4}$
Light organics <sup>d</sup>	Pure component, pressure 10 kN/m <sup>2</sup> abs, no noncondensables <sup>i</sup>	1500–2000	$0-1 \times 10^{-4}$
Light organics <sup>d</sup>	Pressure 10 kN/m <sup>2</sup> abs, 4% noncondensables <sup>k</sup>	750–1000	$0-1 \times 10^{-4}$
Light organics <sup>d</sup>	Pure component, pressure 100 kN/m <sup>2</sup> abs, no noncondensables	2000–4000	$0-1 \times 10^{-4}$
Light organics <sup>d</sup>	Pure component, pressure 1 MN/m <sup>2</sup> abs	3000–4000	$0-1 \times 10^{-4}$
Medium organics <sup>e</sup>	Pure component or narrow condensing range, pressure 100 kN/m <sup>2</sup> abs <sup>m,n</sup>	1500–4000	$1-3 \times 10^{-4}$
Heavy organics	Narrow condensing range pressure 100 kN/m <sup>2</sup> abs <sup>m,n</sup>	600–2000	$2-5 \times 10^{-4}$
Light multicomponent mixtures, all condensable <sup>d</sup>	Medium condensing range, pressure 100 kN/m <sup>2</sup> abs <sup>k,m,o</sup>	1000–2500	$0-2 \times 10^{-4}$
Medium multicomponent mixtures, all condensable <sup>e</sup>	Medium condensing range, pressure 100 kN/m <sup>2</sup> abs <sup>k,m,o</sup>	600–1500	$1-4 \times 10^{-4}$
Heavy multicomponent mixtures, all condensable <sup>f</sup>	Medium condensing range, pressure 100 kN/m <sup>2</sup> abs <sup>k,m,o</sup>	300–600	$2-8 \times 10^{-4}$
<b>Vaporizing heat transfer<sup>p,q</sup></b>			
Water <sup>r</sup>	Pressure < 0.5 MN/m <sup>2</sup> abs, $\Delta T_{SH,max} = 25$ K	3000–10000	$1-2 \times 10^{-4}$
Water <sup>r</sup>	Pressure < 0.5 MN/m <sup>2</sup> abs, pressure < 10 MN/m <sup>2</sup> abs, $\Delta T_{SH,max} = 20$ K	4000–15000	$1-2 \times 10^{-4}$

- <sup>a</sup> Heat transfer coefficients and fouling resistances are based on area in contact with fluid. Ranges shown are typical, not all encompassing. Temperatures are assumed to be in normal processing range; allowances should be made for very high or low temperatures.
- <sup>b</sup> Allowable pressure drops on each side are assumed to be about 50–100 kN/m<sup>2</sup> except for (1) low-pressure gas and two-phase flows, where the pressure drop is assumed to be about 5% of the absolute pressure; and (2) very viscous organics, where the allowable pressure drop is assumed to be about 150–250 kN/m<sup>2</sup>.
- <sup>c</sup> Aqueous solutions give approximately the same coefficients as water.
- <sup>d</sup> Light organics include fluids with liquid viscosities less than about  $0.5 \times 10^{-3}$  Nsec/m<sup>2</sup>, such as hydrocarbons through C<sub>8</sub>, gasoline, light alcohols and ketones, etc.
- <sup>e</sup> Medium organics include fluids with liquid viscosities between about  $0.5 \times 10^{-3}$  and  $2.5 \times 10^{-3}$  Nsec/m<sup>2</sup>, such as kerosene, straw oil, hot gas oil, and light crudes.
- <sup>f</sup> Heavy organics include fluids with liquid viscosities greater than  $2.5 \times 10^{-3}$  Nsec/m<sup>2</sup>, but not more than  $50 \times 10^{-3}$  Nsec/m<sup>2</sup>, such as cold gas oil, lube oils, fuel oils, and heavy and reduced crudes.
- <sup>g</sup> Very heavy organics include tars, asphalts, polymer melts, greases, etc., having liquid viscosities greater than about  $50 \times 10^{-3}$  Nsec/m<sup>2</sup>. Estimation of coefficients for these materials is very uncertain and depends strongly on the temperature difference, because natural convection is often a significant contribution to heat transfer in heating, whereas congelation on the surface and particularly between fins can occur in cooling. Since many of these materials are thermally unstable, high surface temperatures can lead to extremely severe fouling.
- <sup>h</sup> Values given for gases apply to such substances as air, nitrogen, carbon dioxide, light hydrocarbon mixtures (no condensation), etc. Because of the very high thermal conductivities and specific heats of hydrogen and helium, gas mixtures containing appreciable fractions of these components will generally have substantially higher heat transfer coefficients.
- <sup>i</sup> Superheat of a pure vapor is removed at the same coefficient as for condensation of the saturated vapor if the exit coolant temperature is less than the saturation temperature (at the pressure existing in the vapor phase) and if the (constant) saturation temperature is used in calculating the MTD. But see note k for vapor mixtures with or without noncondensable gas.
- <sup>j</sup> Steam is not usually condensed on conventional low-finned tubes; its high surface tension causes bridging and retention of the condensate and a severe reduction of the coefficient below that of the plain tube.

**TABLE 4.5.10 (continued) Typical Film Heat Transfer Coefficients for Shell-and-Tube Heat Exchangers**

Fluid Conditions	$h$ , W/m <sup>2</sup> K <sup>a,b</sup>	Fouling resistance, m <sup>2</sup> K/W <sup>a</sup>
<p><sup>k</sup> The coefficients cited for condensation in the presence of noncondensable gases or for multicomponent mixtures are only for very rough estimation purposes because of the presence of mass transfer resistances in the vapor (and to some extent, in the liquid) phase. Also, for these cases, the vapor-phase temperature is not constant, and the coefficient given is to be used with the MTD estimated using vapor-phase inlet and exit temperatures, together with the coolant temperatures.</p> <p><sup>l</sup> As a rough approximation, the same relative reduction in low-pressure condensing coefficients due to noncondensable gases can also be applied to higher pressures.</p> <p><sup>m</sup> Absolute pressure and noncondensables have about the same effect on condensing coefficients for medium and heavy organics as for light organics. For large fractions of noncondensable gas, interpolate between pure component condensation and gas cooling coefficients.</p> <p><sup>n</sup> Narrow condensing range implies that the temperature difference between dew point and bubble point is less than the smallest temperature difference between vapor and coolant at any place in the condenser.</p> <p><sup>o</sup> Medium condensing range implies that the temperature difference between dew point and bubble point is greater than the smallest temperature difference between vapor and coolant, but less than the temperature difference between inlet vapor and outlet coolant.</p> <p><sup>p</sup> Boiling and vaporizing heat transfer coefficients depend very strongly on the nature of the surface and the structure of the two-phase flow past the surface in addition to all of the other variables that are significant for convective heat transfer in other modes. The flow velocity and structure are very much governed by the geometry of the equipment and its connecting piping. Also, there is a maximum heat flux from the surface that can be achieved with reasonable temperature differences between surface and saturation temperatures of the boiling fluid; any attempt to exceed this maximum heat flux by increasing the surface temperature leads to partial or total coverage of the surface by a film of vapor and a sharp decrease in the heat flux.</p> <p>Therefore, the vaporizing heat transfer coefficients given in this table are only for very rough estimating purposes and assume the use of plain or low-finned tubes without special nucleation enhancement.</p> <p><math>\Delta T_{SH,max}</math> is the maximum allowable temperature difference between surface and saturation temperature of the boiling liquid. No attempt is made in this table to distinguish among the various types of vapor-generation equipment, since the major heat transfer distinction to be made is the propensity of the process stream to foul. Severely fouling streams will usually call for a vertical thermosiphon or a forced-convection (tube-side) reboiler for ease of cleaning.</p> <p><sup>q</sup> Subcooling heat load is transferred at the same coefficient as latent heat load in kettle reboilers, using the saturation temperature in the MTD. For horizontal and vertical thermosiphons and forced-circulation reboilers, a separate calculation is required for the sensible heat transfer area, using appropriate sensible heat transfer coefficients and the liquid temperature profile for the MTD.</p> <p><sup>r</sup> Aqueous solutions vaporize with nearly the same coefficient as pure water if attention is given to boiling-point elevation, if the solution does not become saturated, and if care is taken to avoid dry wall conditions.</p> <p><sup>s</sup> For boiling of mixtures, the saturation temperature (bubble point) of the final liquid phase (after the desired vaporization has taken place) is to be used to calculate the MTD. A narrow-boiling-range mixture is defined as one for which the difference between the bubble point of the incoming liquid and the bubble point of the exit liquid is less than the temperature difference between the exit hot stream and the bubble point of the exit boiling liquid. Wide-boiling-range mixtures require a case-by-case analysis and cannot be reliably estimated by these simple procedures.</p>		

*Estimation of  $q_T$*  For sensible heat transfer,

$$q_T = \dot{m}_h c_{p,h} (T_{h,i} - T_{h,o}) = \dot{m}_c c_{p,c} (T_{c,o} - T_{c,i}) \quad (4.5.95)$$

where  $\dot{m}$  is the mass flow rate,  $c_p$  the specific heat, and  $T$  the stream temperature, with subscripts  $h$  and  $c$  denoting the hot and cold streams, respectively, and  $i$  and  $o$  inlet and outlet, respectively.

For isothermal phase change,

$$q_T = \dot{m} h_{fg} \quad (4.5.96)$$

where  $\dot{m}$  is the mass rate of condensation or vaporization and  $h_{fg}$  is the latent heat of phase transformation.

For more complex cases, such as partial or multicomponent condensation, more elaborate analyses are required, although this method can still be used with care to give rough estimates.

*Estimation of MTD.* The first step is to calculate or estimate  $LMTD_{\text{countercurrent}}$  from Equation (4.5.89) and then estimate  $F$  as follows:

1. If the two streams are in countercurrent flow,  $F = 1$ .
2. If the two streams are in a combination of countercurrent and cocurrent flows (i.e., multiple tube passes) and the outlet temperatures of the two streams are equal,  $F = 0.8$ .
3. If the exchanger has multiple passes and  $T_{h,o} > T_{c,o}$ , then  $0.8 < F < 1.0$ , with the actual value depending upon the temperature ranges of the two streams and  $(T_{h,o} - T_{c,o})$ . It is usually sufficiently accurate to take  $F = 0.9$  in this case, but a more accurate value can be obtained from the earlier half of this section by Shah.
4. Design of a multiple tube pass exchanger with  $T_{h,o} < T_{c,o}$  (i.e., a temperature cross) leads to  $F < 0.8$ , which is inefficient, of uncertain inaccuracy, and perhaps even thermodynamically impossible. The problem can be handled with multiple shells in series. Consult Shah's discussion.
5. Then,  $MTD = F(LMTD)_{\text{countercurrent}}$ , (Equation 4.5.91).

*Estimation of  $U_o$ .* The best way to estimate  $U_o$  is to use Equation (4.5.94), together with values of  $h_o$ ,  $h_i$ ,  $R_{f,o}$ , and  $R_{f,i}$ , chosen from Table 4.5.10. This table includes ranges of values that are typical of the fluids and services indicated assuming normally allowable pressure drops, exchanger construction, and fouling. However, care should be taken in selecting values to consider possible unusual conditions, e.g., especially high or low velocities (implying correspondingly high or low allowable pressure drops), and especially fouling. In selecting values from the table, the user should carefully read the footnotes for each entry.

*Calculation of  $A_o$ .* The total outside tube heat transfer area required in the heat exchanger is now found from Equation (4.5.88).

*Estimation of Exchanger Dimensions.* Figure 4.5.20 shows the relationship among  $A_o$ , effective tube length  $L$ , and inside shell diameter for a fully tubed, fixed tubesheet heat exchanger with one tube-side pass, with  $3/4$  in. (19.05 mm) plain tubes on a  $15/16$  in. (23.8 mm) pitch equilateral triangular tube layout. These curves are constructed using tube count tables (e.g., Saunders, 1988). The dashed lines marked 3:1, 6:1, 8:1, 10:1, and 15:1 indicate ratios of tube length to shell inside diameter for guidance in selection. Exchangers of less than 3:1 ratio are expensive because of the large-diameter shell and tubesheet, with more holes to be drilled and tubes rolled and/or welded, and shell-side flow distribution is likely to be poor and lead to excessive fouling. Exchangers greater than 15:1 ratio are probably beyond the point of saving money by reducing shell diameter and number of tubes and may require excessive clear way for pulling the bundle; the bundles may be springy and difficult to handle during maintenance. Most heat exchangers fall into the 6:1 to 10:1 range.

Figure 4.5.20 is a very specific case which is used as a reference. In order to extend its usefulness to other tube diameters, layouts, bundle constructions, etc., Equation (4.5.97) is used:

$$A'_o = A_o F_1 F_2 F_3 \quad (4.5.97)$$

where  $A'_o$  is the value to be used with Figure 4.5.20,  $A_o$  is the required area calculated from Equation (4.5.88), and

$F_1$  is the correction factor for the tube layout.  $F_1 = 1.00$  for  $3/4$  in. (19.05 mm) outside diameter tubes on a  $15/16$  in. (23.8 mm) triangular pitch. Values of  $F_1$  for other tube diameters and pitches are given in Table 4.5.11.

$F_2$  is the correction factor for the number of tube-side passes.  $F_2 = 1.00$  for one tube-side pass, and Table 4.5.12 gives values of  $F_2$  for more passes.

**FIGURE 4.5.20** Heat transfer area as a function of shell inside diameter and effective tube length for 19.05 mm (3/4 in.) tubes on a 23.8 mm (15/16 in.) equilateral triangular tube layout, fixed tubesheet, one tube-side pass, fully tubed shell. (From Schlünder, E. U., Ed. *Heat Exchanger Design Handbook*, Begell House, New York, 1983. With permission.)

$F_3$  is the correction factor for shell construction/tube bundle configuration.  $F_3 = 1.00$  for fixed tubesheet, fully tubed shells, and Table 4.5.13 gives values of  $F_3$  for the standard TEMA types.

Once a value of  $A'_o$  has been calculated from Equation (4.5.97), enter the ordinate of Figure 4.5.20 at that value and move horizontally, picking off the combinations of shell inside diameter and tube length that meet that requirement. The final choice can then be made from among those possibilities.

**Example of the Approximate Design Method**

*Problem Statement.* Estimate the dimensions of a shell-and-tube heat exchanger to cool 100,000 lb<sub>m</sub>/hr (12.6 kg/sec) of liquid toluene from 250 to 110°F (121.1 to 43.3°C) using cooling tower water available at 80°F (26.7°C). Use split-ring floating head construction (TEMA S) with 3/4 in. (19.05 mm) outside diameter × 14 BWG (0.083 in. = 2.11 mm wall) low-carbon steel tubes on 15/16 in. (23.8 mm) equilateral triangular pitch. This construction implies one shell-side pass and an even number of tube-side passes — assume two for the present. Choose cooling water exit temperature of 100°F (37.8°C). Specific heat of toluene is 0.52 Btu/lb<sub>m</sub>°F (2177 J/kgK) and viscosity at 180°F (82.2°C) is 0.82 lb<sub>m</sub>/ft hr (0.34 × 10<sup>-3</sup> Nsec/m<sup>2</sup> or 0.34 cP).

**TABLE 4.5.11 Values of  $F_1$  for Various Tube Diameters and Layouts**

Tube Outside Diameter, in. (mm)	Tube Pitch, in. (mm)	Layout	$F_1$
5/8 (15.88)	13/16 (20.6)		0.90
5/8 (15.88)	13/16 (20.6)		1.04
3/4 (19.05)	15/16 (23.8)		1.00
3/4 (19.05)	15/16 (23.8)		1.16
3/4 (19.05)	1 (25.4)		1.14
3/4 (19.05)	1 (25.4)		1.31
1 (25.4)	1 1/4 (31.8)		1.34
1 (25.4)	1 1/4 (31.8)		1.54

$$F_1 = \frac{\text{(Heat transfer area / cross-sectional area of unit cell)}_{\text{Reference}}}{\text{(Heat transfer area / cross-sectional area of unit cell)}_{\text{New Case}}}$$

This table may also be used for low-finned tubing in the following way. The value estimated for  $h_o$  from Table 4.5.10 should be multiplied by the fin efficiency (usually between 0.75 and 1 for a good application; 0.85 is a good estimate) and used in Equation 4.5.92 with  $A^* = A_o$ , the total outside heat transfer area including fins. Then this value of  $A_o$  is divided by the ratio of the finned tube heat transfer area to the plain tube area (per unit length). The result of this calculation is used as  $A_o$  in Equation 4.5.96 to find  $A'_o$  to enter Figure 4.5.20.

*Solution.*

$$\begin{aligned}
 q_T &= (100,000 \text{ lb}_m/\text{hr})(0.52 \text{ Btu}/\text{lb}_m \text{ }^\circ\text{F})(250 - 110)^\circ\text{F} \\
 &= 7.28 \times 10^6 \text{ Btu}/\text{hr} = 2.14 \times 10^6 \text{ W}
 \end{aligned}$$

TABLE 4.5.13  $F_3$  for Various Tube Bundle Constructions

Type of Tube Bundle Construction	$F_3$ Inside Shell Diameter, in. (mm)				
	Up to 12 (305)	13–22 (330–559)	23–36 (584–914)	37–48 (940–1219)	Above 48 (1219)
Split backing ring (TEMA S)	1.30	1.15	1.09	1.06	1.04
Outside packed floating heat (TEMA P)	1.30	1.15	1.09	1.06	1.04
U-Tube* (TEMA U)	1.12	1.08	1.03	1.01	1.01
Pull-through floating head (TEMA T)	—	1.40	1.25	1.18	1.15

<sup>a</sup> Since U-tube bundles must always have at least two tube-side passes, it is essential to use Table 4.5.12 also for this configuration.

Source: Schlünder, E.U., Ed., *Heat Exchanger Design Handbook*, Begell House, New York, 1983. With permission.

$$\text{LMTD}_{\text{countercurrent}} = \frac{(250 - 100) - (110 - 80)}{\ln \frac{250 - 100}{110 - 80}} = 74.6^\circ\text{F} = 41.4^\circ\text{C}$$

Since there are at least two tube-side passes, flow is not countercurrent, and  $T_{h_o} > T_{c_o}$ , estimate  $F \approx 0.9$ . Therefore,  $\text{MTD} = 0.9 (74.6^\circ\text{F}) = 67.1^\circ\text{F} = 37.3^\circ\text{C}$ .

Estimation of  $U_o$ . Light organic liquid cooled by liquid water. (Note that  $1 \text{ Btu/hr ft}^2 \text{ }^\circ\text{F} = 5.678 \text{ W/m}^2\text{K}$ ).

Water (in tubes) $h_i$	1000 Btu/hr ft <sup>2</sup> °F	5700 W/m <sup>2</sup> K
Toluene (in shell) $h_o$	300 Btu/hr ft <sup>2</sup> °F	1700 W/m <sup>2</sup> K
Tube-side fouling $R_{f_i}$	0.001 hr ft <sup>2</sup> °F/Btu	$1.8 \times 10^{-4} \text{ m}^2\text{K/W}$
Shell-side fouling $R_{f_o}$	0.0005 hr ft <sup>2</sup> °F/Btu	$8.8 \times 10^{-5} \text{ m}^2\text{K/W}$
Tube wall resistance (for estimation purposes, this term can be approximated by $x_w/k_w$ , where $x_w$ is the wall thickness):		

$$\frac{x_w}{k_w} = \frac{0.083 \text{ in.}}{(12 \text{ in./ft})(26 \text{ Btu/hr ft}^2 \text{ }^\circ\text{F})} = 2.7 \times 10^{-4} \frac{\text{hr ft}^2 \text{ }^\circ\text{F}}{\text{Btu}} = 4.6 \times 10^{-5} \frac{\text{m}^2\text{K}}{\text{W}}$$

Then,

$$U_o = \frac{1}{\frac{0.750}{1000(0.584)} + \frac{0.001(0.750)}{0.584} + 2.7 \times 10^{-4} + 0.0005 + \frac{1}{300}}$$

$$= 150 \text{ Btu/hr ft}^2 \text{ }^\circ\text{F} = 848 \text{ W/m}^2\text{K}$$

$$A_o = \frac{7.28 \times 10^6 \text{ Btu/hr}}{(150 \text{ Btu/hr ft}^2 \text{ }^\circ\text{F})(67.1^\circ\text{F})} = 723 \text{ ft}^2 = 67.7 \text{ m}^2$$

Correct for changes in construction features (preliminary examination of Figure 4.5.20 indicates shell inside diameter will be in the range of 500 mm, or 20 in.):

$F_1: F_1 = 1.00$  since the same tube size and layout is used;

$F_2: F_2 = 1.04$ , assuming two passes;

$F_3: F_3 = 1.15$ , TEMA S construction;

$$A'_o = (723 \text{ ft}^2) (1.00)(1.04)(1.15) = 865 \text{ ft}^2 = 81 \text{ m}^2.$$

From Figure 4.5.20, entering at  $A'_o$ , pick off the following combinations of shell inside diameter and tube length:

Shell Inside Diameter		Effective Tube Length		L/D <sub>s</sub>
in.	mm	ft	m	
27	686	6.6	2.0	2.9
25	635	7.5	2.3	3.6
23 <sup>1</sup> / <sub>4</sub>	591	9.2	2.8	4.7
21 <sup>1</sup> / <sub>4</sub>	540	10.8	3.3	6.1
19 <sup>1</sup> / <sub>4</sub>	489	13.1	4.0	8.2
17 <sup>1</sup> / <sub>4</sub>	438	16.7	5.1	11.6

Any of these combinations would supply the desired area; the 21<sup>1</sup>/<sub>4</sub> in. (540 mm) and 19<sup>1</sup>/<sub>4</sub> in. (489 mm) would appear to be likely choices.

## 4.6 Temperature and Heat Transfer Measurements

---

*Robert J. Moffat*

There are two different kinds of material to consider with respect to experimental methods: the unit operations of measurement (transducers and their environmental errors) and the strategy of experimentation. This section deals only with the unit operations: transducers, their calibrations, and corrections for environmental errors.

### Temperature Measurement

An International Practical Temperature Scale (IPTS) has been defined in terms of a set of fixed points (melting points of pure substances) along with a method for interpolating between the fixed points. The IPTS agrees with the thermodynamic temperature scale within a few degrees Kelvin over most of its range. The IPTS is the basis for all commerce and science, and all calibrations are made with respect to the IPTS temperature. The scale is revised periodically.

Accurate calibrations are not enough to ensure accurate data, however. If a sensor has been installed to measure a gas temperature or a surface temperature, any difference between the sensor temperature and the measurement objective due to heat transfer with the environment of the sensor is an “error.” In most temperature-measuring applications, the environmental errors are far larger than the calibration tolerance on the sensor and must be dealt with just as carefully as the calibration.

### Thermocouples

Any pair of thermoelectrically dissimilar materials can be used as a thermocouple. The pair need only be joined together at one end and connected to a voltage-measuring instrument at the other to form a usable system. A thermocouple develops its signal in response to the temperature difference from one end of the pair to the other. The temperature at one end, known as the *reference junction* end, must be known accurately before the temperature at the other end can be deduced from the voltage.

Thermocouples are the most commonly used electrical output sensors for temperature measurement. With different materials for different ranges, thermocouples have been used from cryogenic temperatures (a few Kelvin) to over 3000 K. In the moderate temperature range, ambient to 1200°C, manufacturer’s quoted calibration accuracy can be as good as  $\pm 3/8\%$  of reading (referred to 0°C) for precision-grade base metal thermocouples. Broader tolerances apply at very high temperature and very low temperatures. Thermocouple signals are DC voltages in the range from a few microvolts to a few tens of microvolts per degree C. Because of their low signal levels, thermocouple circuits must be protected from ground loops, galvanic effects, and from pickup due to electrostatic or electromagnetic interactions with their surroundings. Thermocouples are low-impedance devices. Multiple channels of thermocouples can be fed to a single voltage reader using low-noise-level scanners or preamplifiers and electronic multiplexers.

The alloys most frequently used for temperature measurement are listed in [Table 4.6.1](#). These alloys have been developed, over the years, for the linearity, stability, and reproducibility of their EMF vs. temperature characteristics and for their high-temperature capability.

Calibration data for thermocouples are periodically reviewed by the National Institutes of Science and Technology based on the then-current IPTS. Values in [Table 4.6.1](#) illustrate the approximate levels which can be expected, and are from the National Bureau of Standards Monograph 125. Maximum temperatures listed in this table are estimates consistent with a reasonable service lifetime. Allowable atmosphere refers to the composition in contact with the thermoelements themselves. Accuracy estimates are provided for two levels of precision: standard grade and precision grade where these data are available.

Noble metal and refractory metal thermocouples are often used with substitute lead wires, as a cost-saving measure. These lead wires, described in [Table 4.6.2](#) are cheaper and easier to handle than the high temperature thermocouples. They have the same temperature–EMF characteristics as their primary thermoelements, but only over the range of temperatures the lead wires will usually encounter (up to a few hundred degrees C). Except for the substitute alloys, thermocouple extension wires have the same

composition as thermocouple wires, differing only in the type of insulation and the accuracy of calibration, which is not held as closely for extension wire as for thermocouple-grade wire.

Any instrument capable of reading low DC voltages (on the order of millivolts) with 5 to 10  $\mu\text{V}$  resolution will suffice for temperature measurements. *Galvanometric measuring instruments* can be used, but, since they draw current, the voltage available at the terminals of the instrument depends not only on the voltage output of the thermocouple loop but also on the resistance of the instrument and the loop together. Such instruments are normally marked to indicate the external resistance for which they have been calibrated. *Potentiometric instruments*, either manually balanced or automatically balanced, draw no current when in balance, hence can be used with thermocouple loops of any arbitrary resistance without error. High-input impedance *voltmeters* draw very low currents and, except for very high resistance circuits, are not affected by the loop resistance.

*Thermocouple Theory.* Equation (4.6.1) is the general form describing the EMF generated in a two-wire thermocouple (Moffat, 1962). The same form can be derived from either the free-electron theory of metals or from thermodynamic arguments alone: the output of a thermocouple can be described as the sum of a set of terms, one arising in each wire in the circuit.

The junctions do not generate the EMF: they are merely electrical connections between the wires. For a two-wire circuit,

$$\text{EMF} = \int_0^L \epsilon_1 \frac{dT}{dx} dx + \int_L^0 \epsilon_2 \frac{dT}{dx} dx \quad (4.6.1)$$

where

$\epsilon_1$  and  $\epsilon_2$  = the total thermoelectric power of materials 1 and 2, respectively, mV/C. The value of  $\epsilon$  is equal to the sum of the Thomson coefficient and the temperature derivative of the Peltier coefficient for the material.

$T$  = temperature, C

$x$  = distance along the wire, m

$L$  = length of the wire, m

This form for expressing the output of a two-wire circuit applies regardless of whether the wires are uniform in composition or not. If a circuit contained four wires (two thermocouple wires and two extension wires), then Equation (4.6.1) would be written with four terms, one for each length of wire.

When the wire is uniform in composition and both wires begin at ( $T_o$ ) and both end at ( $T_L$ ) the two terms can be collected into one integral:

$$EMF = \int_{T_o}^{T_L} (\epsilon_1 - \epsilon_2) dT \tag{4.6.2}$$

The EMF–temperature (E–T) tables produced by NIST and others are “solutions” to Equation (4.6.2) and can be used only when the following three conditions are met:

1. The thermoelectric power,  $\epsilon$ , is not a function of position; i.e., the wires are homogeneous;
2. There are only two wires in the circuit;
3. Each wire begins at  $T_o$  and ends at  $T_L$

When the circuit consists entirely of pairs of materials, Equation 4.6.2 can be used directly as the basis for understanding the source of the EMF. As an example, consider the three-pair system shown in Figure 4.6.1. For that circuit, Equation (4.6.2) would have three terms: one for each pair. The total EMF generated by the circuit would be the sum of the EMFs generated in the thermocouple pair and in the extension wire pair. The pair of copper wires would not contribute to the net EMF, assuming the two copper wires were perfectly matched. The EMF contributed by each pair would be proportional to the temperature difference from end to end of that pair, as shown in Equation (4.6.3) and (4.6.4).

$$EMF = \int_{T_1}^{T_2} (\epsilon_{cu} - \epsilon_{cu}) dT + \int_{T_2}^{T_3} (\epsilon_+ - \epsilon_-)_{LEADS} dT + \int_{T_3}^{T_4} (\epsilon_+ - \epsilon_-)_{TC} dT \tag{4.6.3}$$

$$EMF = 0 + (T3 - T2)(\epsilon_+ - \epsilon_-)_{LEADS} + (T4 - T3)(\epsilon_+ - \epsilon_-)_{TC} \tag{4.6.4}$$

FIGURE 4.6.1 A three-pair circuit.

Most thermocouple circuits consist only of pairs of wires and can be understood in terms of these two equations, but some require a more detailed treatment. A graphical method of analysis is available, based on Equation (4.6.1).

The temperature–EMF calibrations of the more common materials are shown in Figure 4.6.2 derived from NBS Monograph 125 and other sources. This figure provides the input data for a simple graphical technique for describing the EMF generation in a circuit. Each curve in Figure 4.6.2 represents the output which would be derived from a thermocouple made of material X used with platinum when the cold end is held at 0°C and the hot end is held at  $T$ .

Those elements commonly used as “first names” for thermocouple pairs, i.e., Chromel (Chromel–Alumel), iron (-constantan), copper (-constantan), have positive slopes in Figure 4.6.2.

The simplest thermocouple circuit for temperature measurement consists of two wires joined together at one end (forming the “measuring junction”) with their other ends connected directly to a measuring instrument, as shown in the upper portion of Figure 4.6.3. The EMF generation in this circuit is graphically represented in the lower portion, an E–T diagram, using the data in Figure 4.6.2. The E–T

FIGURE 4.6.2 E-T calibrations for several common thermocouple materials.

FIGURE 4.6.3 E-T diagram of a thermocouple using an ambient reference.

diagram is used for examining the EMF generated in the circuit, to be certain that it arises only from the desired thermocouple materials, and that all segments of the circuit are properly connected. The E-T diagram is not used for evaluating the output — that is done using the tables after the circuit has been shown to be correctly wired.

To construct an E-T diagram, first sketch the physical system considered and assign a number to each “point of interest” on that sketch and a temperature. On E-T coordinates, locate point 1 at 0/mV and at its assigned temperature. Then start a line from point 1, moving toward the temperature of point 2, and copying the shape of the calibration curve of the iron wire (see Figure 4.6.2). From 2 to 3, use the constantan calibration curve. The difference in elevation of points 1 and 3 describes the net EMF

generated in the circuit between points 1 and 3, and describes the polarity. When point 3 lies physically above point 1 in the E–T diagram, it is, by convention, electrically negative with respect to point 1.

The simple triangular shape shown in Figure 4.6.3 identifies a proper circuit. Any thermocouple circuit whose E–T diagram is equivalent to that is appropriate for temperature measurement and its EMF may be interpreted using the conventional tables. Any circuit whose E–T diagram is not equivalent to the pattern circuit should be rewired.

Thermocouples generate their signal in response to the temperature difference between the two ends of the loop. For accurate measurements, the temperature of the “reference junction” must be known. Laboratory users often use an ice bath made from a good-quality Dewar flask or vacuum-insulated bottle of at least 1 pt capacity, as shown in Figure 4.6.4. The flask should be filled with finely crushed ice and then flooded with water to fill the interstices between the ice particles. The reference thermocouple is inserted into a thin-walled glass tube containing a small amount of silicone oil and submerged six or eight diameters into the ice pack. The oil assures good thermal contact between the thermocouple junction and the ice/water mixture. The tube should be sealed at the top to prevent atmospheric moisture from condensing inside it, which would cause corrosion when using iron-constantan thermocouples. Figure 4.6.5 shows an iron-constantan thermocouple circuit with an ice bath. The individual thermocouple wires are connected to copper wires in the ice bath, and the two copper wires taken to the voltmeter. The lower portion of this figure shows the E–T diagram for this circuit, and proves that the output of this circuit is entirely due to the temperature difference from end to end of the iron-constantan loop: the two copper wires do not contribute to the output.

**FIGURE 4.6.4** Characteristics of a good ice bath.

*Calibration.* Thermocouple calibrations are provided by the wire manufacturers to tolerances agreed upon industry-wide, as summarized in Table 4.6.1. These tolerances include two components: the uncertainty in the average slope of the calibration curve of the wire, and the effects of local inhomogeneities in the wire. It is difficult to improve the accuracy of a thermocouple by calibrating it. For a truly significant calibration, the thermocouple would have to be exposed to the same temperature during calibration, at every point along it, that it would encounter in service. In an oven calibration, most of the signal is generated in the material at the mouth of the oven, as could be recognized by considering the temperature gradient distribution along the wire. The material inside the oven contributes little or nothing to the signal.

### Thermistors

Thermistors are electrical resistance temperature transducers whose resistance varies inversely, and exponentially, with temperature. The resistance of a 5000  $\Omega$  thermistor may go down by 200  $\Omega$  for each degree C increase in temperature in the vicinity of the initial temperature. Interrogated by a 1.0 mA current source, this yields a signal of 200 mV/°C. As a consequence of this large signal, thermistors are frequently used in systems where high sensitivity is required. It is not uncommon to find thermistor data logged to the nearest 0.001°C. This does not mean that the data are accurate to 0.001°C, simply

FIGURE 4.6.5 A thermocouple circuit using an ice bath reference, and its E-T diagram.

that the data are readable to that precision. A thermistor probe is sensitive to the same environmental errors which afflict any immersion sensor: its accuracy depends on its environment.

Thermistor probes can be used between  $-183^{\circ}\text{C}$  (the oxygen point) and  $+327^{\circ}\text{C}$  (the lead point) but most applications are between  $-80$  and  $+150^{\circ}\text{C}$ . The sensitivity of a thermistor (i.e., the percent change in resistance per degree C change in thermistor temperature) varies markedly with temperature, being highest at cryogenic temperatures.

Thermistor probes range in size from 0.25-mm spherical beads (glass covered) to 6-mm-diameter steel-jacketed cylinders. Lead wires are proportionately sized. Disks and pad-mounted sensors are available in a wide range of shapes, usually representing a custom design “gone commercial.” Aside from the unmounted spherical probes and the cylindrical probes, there is nothing standard about the probe shapes.

*Calibration.* Thermistor probes vary in resistance from a few hundred ohms to megohms. Probe resistance is frequently quoted at  $25^{\circ}\text{C}$ , with no power dissipation in the thermistor. The commercial range is from about 2000 to 30,000  $\Omega$ . Representative values of the sensitivity coefficient (% change in resistance per degree C) is given in Table 4.6.3 and resistance values themselves, in Table 4.6.4.

TABLE 4.6.3 Thermistor Temperature Coefficient Variations with Temperature

Temp. $^{\circ}\text{C}$	Condition	$\Delta R/R$ , %
-183	Liquid oxygen	-61.8
-80	Dry ice	-13.4
-40	Frozen mercury	-9.2
0	Ice point	-6.7
25	Room temperature	-5.2
100	Boiling water	-3.6
327	Melting lead	-1.4

**TABLE 4.6.4 Thermistor Resistance Variation with Temperature**

Temp., °C	Res., Ω	Temp., °C	Res., Ω
-80	1.66 M	0	7355
-40	75.79 K	25	2252
-30	39.86 K	100	152.8
-20	21.87 K	120	87.7
-10	12.46 K	150	41.9

Proprietary probes are available which “linearize” thermistors by placing them in combination with other resistors to form a circuit whose overall resistance varies linearly with temperature over some range. These compound probes can be summed, differenced, and averaged as can any linear sensor. Modern manufacturing practices allow matched sets to be made, interchangeable within  $\pm 0.1^\circ\text{C}$ .

*Thermal Characteristics.* Thermistor probes are generally interrogated using a low current, either AC or DC. A level of about  $10\ \mu\text{A}$  would be typical. With a probe resistance of  $10\ \text{K}\ \Omega$ ,  $0.01\ \text{W}$  must be dissipated into its surrounding material. This current results in the probe running slightly above the temperature of the medium into which it is installed: the “self-heating” effect. Since thermistors are often used where very small changes in temperature are important, even small amounts of self-heating may be important.

The self-heating response is discussed in terms of the “dissipation constant” of the probe, in milliwatts per degree C. The dissipation constant depends on the thermal resistance between the thermistor and its surroundings. For fluid-sensing probes, the self-heating varies with velocity and thermal conductivity, while for solid immersion probes, it varies with the method of attachment and type of substrate.

Dissipation constants for representative probes are given in Table 4.6.5. The self-heating effect must be considered in calibration as well as in use.

The transient response of a thermistor is more complex than that of a thermocouple and, size for size, they are not as well suited to transient measurements.

**TABLE 4.6.5 Representative Thermal Dissipation Constants for Two Thermistor Probe Designs**

Environment	1.0-cm Disk	5.0-cm Cylinder
Still air	8 mW/C	1 mW/C
Still oil	55	—
Still water	—	3.5
Oil at 1 m/sec	250	—

Thermistor probes are sold with calibration tables of resistance vs. temperature at some specified accuracy, on the order of  $\pm 0.1$  or  $0.2\ \text{K}$ , depending on the grade of probe purchased. These tables are typically in increments of  $1\ \text{K}$ . For computer interpretation, they should be fit to the Steinhart-Hart form<sup>2</sup> and the coefficients determined for least error.

$$\frac{1}{T} = A_0 + A_1 \ln(R) + A_3 \ln(R^3) \quad (4.6.5)$$

### Resistance Temperature Detectors

The terms *resistance temperature detector* (RTD) and *resistance thermometer* are used interchangeably to describe temperature sensors containing either a fine wire or a thin film metallic element whose resistance increases with temperature. In use, a small current (AC or DC) is passed through the element, and its resistance measured. The temperature of the element is then deduced from the measured resistance using a calibration equation or table lookup.

RTDs are used both for standards and calibration laboratories and for field service. Field-service probes are generally encased in stainless steel protective tubes with either wire or film elements bonded to sturdy support structures. They are made to take considerable physical abuse. Laboratory standard-grade probes are often enclosed in quartz tubes, with the resistance wire mounted in a strain-free manner on a delicate mandrel.

High-quality resistance thermometers have been used as defining instruments over part of the range of the IPTS. Because of this association with high-precision thermometry, resistance thermometers in general have acquired a reputation for high precision and stability. Commercial probes, however, are far different in design from the standards-grade probes, and their stability and precision depend on their design and manufacture.

RTDs are often recommended for single-point measurements in steady-state service at temperatures below 1000°C where longtime stability and traceable accuracy are required and where reasonably good heat transfer conditions exist between the probe and its environment.

They are not recommended for use in still air, or in low-conductivity environments. RTDs self-heat, which causes an error when the probes are used in a situation with poor heat transfer. They are not recommended for transient service or dynamic temperature measurements unless specifically designed for such service. The probes tend to have complex transient characteristics and are not amenable to simple time-constant compensation.

*Physical Characteristics.* The physical characteristics of any given resistance thermometer represent a compromise between two opposing sets of requirements. For accuracy, repeatability, and speed of response, a delicate, low-mass sensing element is desired, supported in a strain-free manner in good thermal contact with its surroundings. For durability, a rugged sensor is indicated, mounted firmly to a sturdy structure inside a robust, sealed protection tube.

Both the short-term calibration (resistance vs. specimen temperature) and the long-term stability (drift) are directly affected by the mechanical configuration of the probe. The electrical resistance of the sensing element is a function of its temperature and state of mechanical strain (Figure 4.6.6).

**FIGURE 4.6.6** Slack-wire platinum resistance thermometer.

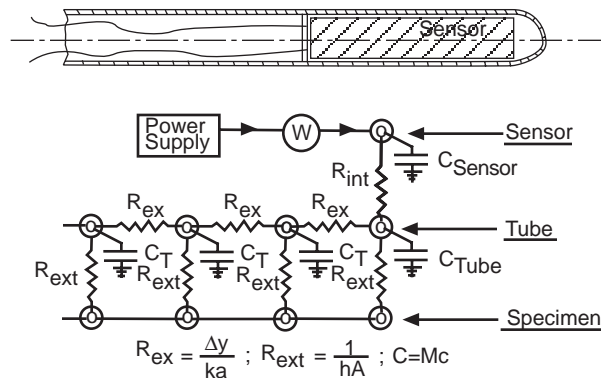

The sensing elements used in field-service RTD probes range from thin metallic films deposited on rectangular ceramic wafers ( $0.5 \times 1.0 \times 2.0$  mm) with pigtail leads (0.25 mm diameter and 2.5 cm long) to glass-encapsulated, wire-wound mandrels (4 mm in diameter and 2.0 cm long), again with pigtail leads. Bonding the sensor to its support provides good mechanical protection to the element, but subjects the element to strain due to thermal expansion. As long as this process is repeatable, the calibration is stable.

*Electrical Characteristics.* RTDs are available commercially with resistances from 20 to 20,000  $\Omega$  with 100  $\Omega$  being common. Bifilar windings are frequently used in wire-wound elements, to reduce the

electrical noise pickup. This is more important in the quartz-jacketed probes than in those with stainless steel protection tubes. Twisted pair lead wires are recommended.

**Thermal Characteristics.** Figure 4.6.7 shows a simplified cross section of a typical resistance thermometer and a thermal circuit which can be used to discuss its behavior. In forming such a thermal circuit model, each element of the probe is described by its resistive and capacitive attributes following conventional heat transfer practice. The principal components are

- The external thermal resistance per unit length;
- The thermal capacitance of the protective tube per unit length,  $C_T$ ;
- The radial internal thermal resistance between the sensor and the protective tube,  $R_{int}$ ;
- The capacitance of the sensor element and its support,  $C_{sensor}$ ;
- The axial internal thermal resistance of the stem, per unit length,  $R_T$ .

**FIGURE 4.6.7** Thermal circuit representation of a typical resistance thermometer.

This circuit can be used to predict the temperature distribution within the probe both at steady state and during transients and can be refined, if needed, by subdividing the resistance and capacitance entities.

**Steady-State Self-Heating.** Interrogating an RTD by passing a current through it dissipates power in the element, shown in Figure 4.6.7 as  $W$ , which goes off as heat transfer through the internal and external resistances. This self-heating causes the sensing element to stabilize at a temperature higher than its surroundings and constitutes an “error” if the intent is to measure the surrounding temperature. The amount of the self-heating error depends on three factors:

- The amount of power dissipated in the element,
- The internal thermal resistance of the probe, as a consequence of its design, and
- The external thermal resistance between the surface of the probe and the surrounding material.

The self-heating temperature rise is given by Equation (4.6.6):

$$T_{sens} - T_{surr} = W(R_{int} + R_{ext}) \quad (4.6.6)$$

The internal thermal resistance of a probe,  $R_{int}$ , measured in degree C per watt, describes the temperature rise of the sensing element above the surface temperature of the probe, per unit of power dissipated. The internal thermal resistance can be deduced from measurements of the sensor temperature at several different current levels when the probe is maintained in a well-stirred ice bath, where the external thermal resistance is very low. The slope of the apparent temperature vs. power dissipated line, °C/W, is the internal thermal resistance. When an RTD is used in a gas or liquid, the external resistance between the

probe and its surroundings must be estimated from standard heat transfer data. The external resistance is  $1/(hA)$ , °C/W.

A typical cylindrical probe exposed to still air will display self-heating errors on the order of 0.1 to 1.0°C per mW (commercial probes of 1.5 to 5 mm in diameter). At 1 m/sec air velocity, the self-heating error is reduced to between 0.03 and 0.3°C. In water at 1 m/sec velocity, the self-heating effect would be reduced by a factor of four or five compared to the values in moving air, depending on the relative importance of the internal and the external thermal resistances.

*Calibration and Drift.* The relationship between resistance and temperature must be determined for each probe or acquired from the manufacturer. Generally speaking, the reported values will require interpolation.

The resistance–temperature characteristic of a probe may drift (i.e., change with time) while the probe is in service. Manufacturers of laboratory-grade probes will specify the expected drift rate, usually in terms of the expected error in temperature over an interval of time. Two sample specifications are “0.01 C per 100 hours” for a low-resistance, high-temperature probe (0.22 Ω at 0°C, 1100°C maximum service temperature) and “0.01 C per year” for a moderate-resistance, moderate-temperature probe (25.5 Ω at 0°C, 250°C maximum service temperature). Drift of the resistance–temperature relationship takes place more rapidly at high temperatures.

### Radiation Devices

Surface temperatures and gas temperatures can be deduced from radiation measurements. Surface-temperature measurements are based on the emitted infrared energy, while gas-temperature measurements use specific emission lines from the gas itself or from a tracer inserted into the gas.

Commercial surface-temperature measurement systems (single-point) are available, at low cost, which can measure temperature to  $\pm 1\%$  of reading, above 38°C, if the emissivity of the surface is known. The device referenced requires a spot size of 1.25 cm diameter, viewed from 75 cm. Spectroscopic gas-temperature measurements can be accurate to  $\pm 3$  or 4% of reading, but require a significant investment in effort as well as equipment (on the order of 1 to 2 years and \$100,000 to \$200,000). Several techniques based on Raman scattering have been used in combustion systems. Planar-laser-induced fluorescence has shown considerable promise as one of the newer methods.

Infrared emission from a surface is described by two laws: the Stefan Boltzmann law describing the total emitted radiation as a function of temperature, and Planck’s law describing its distribution as a function of temperature. These laws form the basis for all radiation-based surface-temperature detectors.

Early radiometers focused the total infrared energy on a thermopile bolometer and used the temperature rise across its calibrated heat loss path to measure the incident energy flux. Solid-state photon detectors have replaced thermopile bolometers as the detector of choice. Such a detector will respond to any photon having energy above a certain level (specific to the detector). Since the energy of a photon is inversely proportional to its wavelength, detectors respond to all wavelengths below some value. Modern detectors use band-pass filters to limit the wavelength band of photons admitted to the detector and rely on Planck’s law to infer the temperature from the energy flux:

$$E_{b,\lambda} = \frac{C_1 \lambda^{-5}}{e^{C_2/\lambda T} - 1} \quad (4.6.7)$$

where  $E_{b,\lambda}$  = radiated power at the wavelength  $\lambda$ , W/m<sup>2</sup>

$T$  = temperature, K

$C_1$  =  $3.743 \times 10^8$ , W $\mu\text{m}^4/\text{m}^2$

$C_2$  =  $1.4387 \times 10^4$ ,  $\mu\text{mK}$

Commercial radiation temperature detectors use different wave bands for different temperature ranges, with different detectors for each band. The emissivity of the surface must be known, as a function of temperature, in the wavelength band used by the detector.

Radiation detectors are vulnerable to interference from four sources: low signal-to-noise ratio at low temperatures (below a few hundred degrees C); radiation from the surroundings reflecting into the detector (also usually more important at low temperatures); low spatial resolution (also more evident at low temperatures); uncertainty in the emissivity of the surface (at all temperatures); and absorption of radiation into water vapor and CO<sub>2</sub> in the line of sight (at any temperature).

A fiber-optic blackbody temperature detector system is offered by the Luxtron Corporation for standards room and field service above 300°C. The unit consists of a blackbody capsule fiber-optically coupled to a filtered, band-limited photon detector. Accuracy of 0.01 to 0.1°C is claimed, depending on temperature level.

A fluoroptic temperature-measuring system is also offered by the same company, for use only at lower temperatures (−200 to +450°C). This system uses an ultraviolet-stimulated phosphor on the end of an optical fiber as its sensor. The fluorescent signal from the phosphor decays with time, and its “time constant” is a function of temperature. Accuracy of  $\pm 0.5^\circ\text{C}$  is claimed for measurements within  $\pm 50^\circ\text{C}$  of a calibration point, or  $\pm 1^\circ\text{C}$  within 100°C.

### Temperature-Sensitive Paints, Crayons, and Badges

Temperature-sensitive paints, crayons, and badges are available from several suppliers (Omega Engineering, Inc., Stamford, CT, and others in Germany and Japan). Each undergoes an irreversible change (e.g., a change in color or a change from solid to liquid) at one specified temperature. With a range of paints, temperatures from ambient to about 1500°C can be covered. The accuracy generally quoted is about  $\pm 1\%$  of level, although melting standards are available to  $\pm 0.5^\circ\text{C}$ .

The phase-change materials melt at well-defined temperatures, yielding easily discernible evidence that their event temperature has been exceeded. When more than one phase-change paint is applied to the same specimen, there can be interference if the melt from the low-melting paint touches the high-melting material. Color change materials do not interfere, but are more difficult to interpret. The calibration of high-temperature paints (both phase change and color change) may shift when they are used on heavily oxidized materials, due to alloying of the oxide with the paint. Recommended practice is to calibrate the paints on specimens of the application material. The event temperature which will cause transformation depends on the time at temperature: short exposure to a high temperature often has the same effect as long exposure to a lower temperature.

The paints and crayons are nonmetallic and, therefore, tend to have higher emissivities for thermal radiation than metals. They should be used only over small areas of metallic surfaces, compared with the metal thickness, or else their different emissivities may lead to a shift in the operating temperature of the parts.

The principal disadvantages of the paints and crayons are that they require visual interpretation, which can be highly subjective, and they are one-shot, irreversible indicators which respond to the highest temperature encountered during the test cycle. They cannot record whether the peak was reached during normal operation or during soak-back.

Liquid crystals can be divided into three groups, depending on their molecular arrangements: (1) smectic, (2) nematic, and (3) cholesteric. Most of the temperature-sensitive liquid crystals now in use are cholesteric: made from esters of cholesterol. Their molecules are arranged in planar layers of molecules with their long axes parallel and in the plane of the layer. The molecules in each layer are rotated with respect to those in its neighboring layers by about 15 min of arc in a continuous, helical pattern along an axis normal to the layers.

The colors reflected from cholesteric liquid crystals are thought to be due to Bragg diffraction from the aligned layers. The “wrap angle” between adjacent layers increases with temperature; hence, the color of the liquid crystal shifts toward short wavelengths (toward blue) as the temperature is raised. The color can also be affected by electric fields, magnetic fields, pressure, shear stress, and some chemical vapors.

Warm cholesterics are colorless liquids and they pass through a series of bright colors as they are heated through their “color-play” temperature band. The first color to appear is a deep red, followed by

yellow, green, blue, and violet. Further heating yields a colorless liquid again. This cycle is reversible and repeatable, and the color–temperature relationship can be calibrated.

Liquid crystals selectively reflect only a small fraction of the incident light; hence, to enhance the brightness of the color image, they must be backed up with black paint or a nonreflecting surface.

A typical calibration is shown in Figure 4.6.8 for liquid crystals painted over black paint on an aluminum calibration strip. The upper part of Figure 4.6.8 describes the color variation, while the lower part shows the imposed linear temperature distribution. The hot end is blue, the cold end is red. Color-play intervals range from 0.5 to 10.0°C. Liquid crystals whose color-play interval is on the order of 0.5 to 2.0°C are often referred to as *narrow-band* materials, while those whose interval extends to 5.0 to 10°C are called *wide band*. Narrow-band images are easy to interpret by eye. Wide-band images show only subtle variations of color for small changes in temperature, and accurate work requires digital image handling or multiple images taken with different filters.

FIGURE 4.6.8 Schematic representation of a calibration strip.

Several different narrow-band liquid crystals can be mixed together to make a single, multi-event paint covering a wide range of temperatures, provided their color-play intervals do not overlap. Such a mixture yields a set of color-play bands, one for each component.

*Calibration.* Liquid crystals are sold by event temperature and color-play bandwidth, with a nominal accuracy of  $\pm 1^\circ\text{C}$  on the event temperature. In many applications, especially if the image is to be visually interpreted, no further calibration is needed.

The accuracy attainable with a liquid crystal is related to the width of the color-play interval. With narrow-band material (a color-play interval of about  $1.0^\circ\text{C}$ ), visual interpretation can be done with an uncertainty of 0.25 to  $0.5^\circ\text{C}$ . With digital image interpretation, spectrally controlled lighting and appropriate corrections for reflected light interference, the uncertainty can be held below  $0.25^\circ\text{C}$ .

Early users reported that the perceived color of a liquid crystal depended on both the lighting angle and the viewing angle. This dependence can be eliminated by using a light source along the line of sight (coaxial viewing and illumination).

*Multiple-Event Paints.* Several narrow-band paints can be mixed together to make a single paint with all the characteristics of each component, if their color-play intervals do not overlap. Each component retains its original calibration and acts independently of the other components.

Figure 4.6.9 shows the image from a five-event paint used to map the adiabatic wall temperature isotherms around a heated block in mixed convection. The outermost isotherm is  $30^\circ\text{C}$ , and the events are spaced apart at  $5^\circ\text{C}$  intervals. Determination of the temperatures from a multiple-event image requires that the temperature be known at one point in the image.

*Liquid Crystals in Water.* Liquid crystals can be used to mark the temperature distribution in water and some other liquids by adding a small quantity of encapsulated liquid crystal material to the liquid and photographing the color distribution using planar lighting. Velocity and temperature distributions can be

**FIGURE 4.6.9** Multi-event liquid crystal used to visualize the isotherm pattern above a heated spot in mixed convection.

**FIGURE 4.6.10** Liquid crystal visualization of the velocity and temperature distribution in a water-filled tank.

determined by photographing the liquid crystal particles using a known exposure time. The temperature is deduced from the particle color, and the velocity by the length of the streak its image forms. [Figure 4.6.10](#) shows the velocity and temperature distributions in a shear-driven, water-filled cavity 30 sec after the impulsive start of belt motion. In this view, the belt is at the top of the image, and moved from left to right. The water was stably stratified initially, with the top being 4°C hotter than the bottom. This technique was demonstrated by Rhee et al. (1984) and has been used by several workers.

*Image Processing.* Several schemes have been proposed to remove the subjectivity from interpretation of liquid crystal images. Akino et al. (1989), and others, have processed RGB video images of narrow-band images using multiple filters to extract images of specified isochromes, related to temperatures through a calibration. Hollingsworth et al. (1989) processed RGB images of wide-band images using

chromaticity coordinates (hue, saturation, and intensity) and extracted temperature at each pixel, rather than along isochromes.

## Heat Flux

Heat flux to or from a surface can be measured directly, using heat flux meters, or inferred from an overall energy balance, or inferred from temperature–time measurements at the surface or within the body. There are no primary standards for heat flux measurement.

Three general classes of heat flux meters are in common use: slug calorimeters, planar heat flux gauges (sometimes called Schmidt–Boelter gauges), and circular foil gauges (sometimes called Gardon gauges). Sensitivities range from microvolts per kW/m<sup>2</sup> to millivolts per W/m<sup>2</sup>. Planar gauges can be used for radiant or convective heat loads. Circular foil gauges should be used only for radiant loads.

## Slug Calorimeter

The slug calorimeter is an energy balance transducer consisting of a known mass of material instrumented so that its temperature can be measured. A simple version is shown in Figure 4.6.11. If losses are negligibly small and the mass and the specific heat are constant, the instantaneous heat flux is deduced from

$$\dot{q}_{\text{in}}'' A = Mc \frac{\partial T}{\partial t} \quad (4.6.8)$$

where  $T$  = Average temperature of the slug, C

$M$  = Mass of the slug, kg

$c$  = Specific heat, J/kg·C

$A$  = Face area, m<sup>2</sup>

$\tau$  = Time

FIGURE 4.6.11 A simple slug calorimeter.

The variation of slug temperature with time is used to infer net heat transfer rate to the gauge. Slug calorimeters are used mainly when the heat flux, or the heat transfer coefficient, is expected to be relatively constant. They are of less value when the input flux changes arbitrarily because of the inaccuracies inherent in differentiating the signals.

## Planar Heat Flux Gauge

Planar heat flux gauges use Fourier's law to deduce the heat flux from a steady-state measurement of the temperature difference across a thin sheet of thermally insulating material. The planar gauge geometry is shown in Figure 4.6.12. The working equation for a planar gauge is

**FIGURE 4.6.12** A typical planar heat flux gauge.

$$\text{EMF} = N\epsilon \Delta T = \frac{N\epsilon t}{k} \dot{q}'' \quad (4.6.9)$$

where  $N$  = number of junction pairs,

$\epsilon$  = thermoelectric power of the thermoelement, mV/C

$t$  = thickness of the insulator, m

$k$  = conductivity of the insulator, W/m·C

$\dot{q}''$  = heat flux through the gauge, W/m<sup>2</sup>

The figure shows one thermocouple junction on the top and one on the bottom surface of the insulator. Most gauges use multiple junctions. The thermoelements may be wire (down to 0.025 mm diameter) or thin films deposited on the insulator (10 to 20 Å). The assembly is usually sandwiched between two sheets of protective material to form an integral unit. Up to 150°C application temperature, these units are often made of Kapton, and provided with a contact adhesive. They may be as thin as 0.15 mm overall.

Gauges should not be removed and reinstalled without recalibration, as the act of removing them from the surface may delaminate the gauge, changing its thermal resistance, and therefore its calibration.

### Circular Foil Gauges

A circular foil gauge consists of a thin circular disk of metal supported by its edge from a structure of constant and uniform temperature. The circular foil gauge is often called a Gardon gauge. A constantan foil is often used, with a copper support structure. Two copper wires complete the circuit: one attached to the center of the foil disk and one to the support structure. The copper–constantan thermocouple thus formed produces an EMF determined by the temperature difference from the center of the foil disk to its rim. That temperature difference is directly proportional to the average heat flux on the disk. A cross-sectional view of a circular foil gauge is shown in [Figure 4.6.13](#).

**FIGURE 4.6.13** A water-cooled circular foil gauge (Gardon gauge).

The working equation for a circular foil gauge is

$$\text{EMF} = \epsilon \frac{R^2}{4kt} \dot{q}'' \quad (4.6.10)$$

where  $\epsilon$  = thermoelectric power, mV/C

- $R$  = radius of the disk, m  
 $k$  = thermal conductivity of the disk, W/m·C  
 $t$  = thickness of the disk, m  
 $q''$  = heat flux absorbed by the disk, W/m<sup>2</sup> (must be uniform)

The output signal is thus directly proportional to the heat flux on the disk. Cooling passages are frequently built into the support structure to maintain the edge of the disk (the heat sink for the foil disk) at constant temperature.

### Calibration

Calibration of the Gardon-type heat flux meters is most easily done by comparison, using a radiation calibrator.

Planar gauges can be calibrated either by conduction or radiation, but the results will depend on the calibration method for some gauges.

### Sensor Environmental Errors

Temperature sensors generate signals in response to their own temperatures, but are usually installed to measure the temperature of some fluid or solid. There is heat transfer between the sensor and all of its surroundings, with the result that the sensor usually equilibrates at some temperature different from the fluid or solid it is installed in. This difference is considered an error in the measurement.

Similarly, heat flux gauges are generally installed so one can infer the heat flux which would have been there had the gauge not altered the system behavior. But heat flux gauges do disturb the system, and the heat flux at the gauge location, when the gauge is there, may be significantly different from that which would have been there without the gauge. This system disturbance effect must also be considered an error.

### Steady-State Errors in Gas-Temperature Measurement

All immersion-type temperature sensors (thermocouples, resistance detectors, and thermistors) are subject to the same environmental errors, which are frequently larger than the calibration errors of the sensors. Large probes are usually affected more than small ones; hence, RTDs and thermistors (selected by investigators who wish to claim high accuracy for their data) are more vulnerable to environmental errors (due to their larger size and their self-heating errors). This aspect of accuracy is sometimes overlooked.

Sensor installations for gas-temperature measurements should be checked for all three of the usual steady-state environmental errors: velocity error, radiation error, and conduction error. The same equations apply to all sensors, with appropriate dimensions and constants.

$$\text{velocity error: } E_v = (1 - \alpha) \frac{V^2}{2g_c J c_p} \quad (4.6.11)$$

$$\text{radiation error: } E_r = \frac{\sigma \epsilon}{h} (T_{\text{sens}}^4 - T_{\text{surr}}^4) \quad (4.6.12)$$

$$\text{conduction error: } E_c = \frac{T_{\text{gas}} - T_{\text{mount}}}{\cosh \left[ L \sqrt{\frac{hA_c}{kA_k}} \right]} \quad (4.6.13)$$

where  $E_v$  = velocity error, °  
 $\alpha$  = recovery factor, —

- $V$  = velocity, ft/sec  
 $g_c$  = universal gravitational constant  
 $J$  = Joules constant, ff/bf/Btu  
 $c_p$  = specific heat, Btu/lbm, °F  
 and  $E_r$  = radiation error, °R  
 $\sigma$  = Stefan-Boltzmann constant  
 $\epsilon$  = emissivity  
 $h$  = heat transfer coefficient, Btu/secft<sup>2</sup>, °F  
 $T_{\text{sens}}$  = indicated temperature, °R  
 $T_{\text{surr}}$  = surrounding temperature, °R  
 $E_c$  = conduction error, °R  
 $T_{\text{gas}}$  = gas temperature, °R  
 $T_{\text{mount}}$  = mount temperature, °R  
 $L$  = length of exposed junction, ft  
 $h$  = heat transfer coefficient, Btu/secft<sup>2</sup>, °F  
 $A_c$  = heat transfer area, ft<sup>2</sup>  
 $k$  = thermal conductivity, Btu/secft  
 $A_k$  = conduction area, ft<sup>2</sup>

Velocity error depends upon the recovery factor, which varies with the Prandtl number of the fluid. The Prandtl numbers of most liquids are greater than 1; hence, the recovery factor  $\alpha$  is greater than 1 and probes tend to read higher than the stagnation temperature in high-speed liquid flows. With thermistors and RTDs in liquids, the self-heating effect and the velocity error both tend to cause high readings. In gases, where the Prandtl number is less than 1, the two effects are of opposite sign and may partly cancel each other.

Radiation and conduction errors vary inversely with the heat transfer coefficient. Both tend to be larger for larger-diameter probes since, all other factors remaining the same, the heat transfer coefficient will be lower for a large-diameter probe. This results in larger radiation and conduction errors. In liquids, radiation error is not a problem, but velocity error and conduction error may both be significant. Conduction error becomes a problem in liquid-temperature measurements when thermowells are used. The depth of immersion of the well is frequently too short to eliminate conduction error.

### Steady-State Errors in Solid and Surface-Temperature Measurements

When probes are used to measure solid temperature by inserting them into a hole in the specimen, they are subject to conduction errors proportional to their size and conductivity. A general rule of thumb is to keep the insertion depth at least 20 times the diameter (or wall thickness) of the probe. This assumes a close-fitting hole, backfilled with a material with higher thermal conductivity than air. For more-exact advice regarding a specific installation, a careful thermal circuit analysis of the installation should be developed, and its results used to guide the selection of diametrical clearance, backfill materials, and penetration depth.

A thermocouple attached to a hot surface surrounded by cooler fluid will exchange heat with the fluid by convection and with the surrounding solids by radiation. Heat lost from the thermocouple must be made up from the surface by conduction, which will result in a cold spot at the point of attachment.

Figure 4.6.14 shows the system disturbance error caused by a surface-attached thermocouple, as a fraction of the maximum possible error for the installation. If the surface is irradiated (e.g., by heating lamps), the irradiation will raise the surface temperature, but will also affect the system disturbance error. The effect on the system disturbance error caused by turning on the irradiation is similar to that of raising the temperature of the surrounding fluid to a new value,  $T_\infty$ ,

where  $T_{\text{ind}}$  = indicated temperature from an otherwise error-free thermocouple, °C  
 $T_s$  = undisturbed substrate temperature, °C

FIGURE 4.6.14 System disturbance errors caused by an attached thermocouple (worst case).

- $T_{\infty}^{\circ}$  = effective fluid temperature, °C
- $h$  = heat transfer coefficient, TC to fluid, W/m, °C
- $D$  = outside diameter of TC, m
- $k_w$  = effective thermal conductivity of TC, W/m, °C
- $k_s$  = thermal conductivity of substrate, W/m, °C

The effective gas temperature is defined in terms of the incident irradiation and the heat transfer coefficient as

$$T_{\infty}^* = T_{\infty} + \frac{\alpha G A_R}{h A_C} T_{\infty}^* \tag{4.6.14}$$

- where  $T_{\infty}$  = actual gas temperature, °C
- $\alpha$  = absorptivity of the TC for thermal radiation
- $G$  = incident thermal radiation flux, W/m<sup>2</sup>
- $A_R/A_C$  = ratio of irradiated surface to convective surface
- $h$  = heat transfer coefficient between the TC and the gas, W/m<sup>2</sup>°C

**Steady-State Errors in Heat Flux Gauges for Convective Heat Transfer**

If the gauge is not flush with the surface, it may disturb the flow, and if it is not at the same temperature as the surface, it will disturb the heat transfer. Thus, the gauge may properly report the heat flux which is present when the gauge is present, but that may be significantly different from the heat flux which would have been there if the gauge had not been there.

For planar gauges, both effects are usually small. The thermal resistance of such a gauge is generally small, and they are thin enough to avoid disturbing most flows. Circular foil gauges pose a more serious problem, since they are often cooled significantly below the temperature of the surrounding surface. Dropping the wall temperature at the gauge location can significantly increase the local heat load in two ways: one due to the fact that, for a given value of  $h$ , a cold spot receives a higher heat load from the gas stream. The second effect arises because the value of the heat transfer coefficient itself depends on the local wall temperature distribution: a local cold spot under a hot gas flow will experience a higher heat transfer coefficient than would have existed had the surface been of uniform temperature.

## Evaluating the Heat Transfer Coefficient

The heat transfer coefficient is a defined quantity, given by

$$h = \frac{\dot{q}_{\text{conv}}''}{(T_o - T_{\text{ref}})} \quad (4.6.15)$$

where  $h$  = heat transfer coefficient, W/m<sup>2</sup>, °C

$\dot{q}_{\text{conv}}''$  = convective heat flux, W/m<sup>2</sup>

$T_o$  = temperature of the considered surface, °C

$T_{\text{ref}}$  = temperature used as reference for this definition, °C

Different reference temperatures are conventionally used for different situations:

- $T_{\infty}$ : The free-stream temperature. Used for isolated objects of uniform temperature in a uniform free stream, where an average value of  $h$  is desired which describes the overall heat transfer between the object and the flow. Also used in boundary layer heat transfer analyses where local values of  $h$  are needed to deal with locally varying conditions.
- $T_m$ : The mixed mean fluid temperature. Used for internal flows where the intent of the calculation is to describe the changes in mixed mean fluid temperature (e.g., heat exchangers).
- $T_{\text{adiabatic}}$ : The adiabatic surface temperature. Used for isolated objects or small regions of uniform temperature in either internal or external flows, where the overall thermal boundary conditions are neither uniform heat flux nor uniform temperature.

For a given data set, the value of the heat transfer coefficient will depend on the reference temperature chosen, and  $h$  should be subscripted to inform later users which reference was used: e.g.,  $h_{\infty}$ ,  $h_m$ , or  $h_{\text{adiabatic}}$ .

### Direct Methods

The two most commonly used methods for measuring the heat transfer coefficient are both derived from the same energy balance equation:

$$hA(T_o - T_{\text{ref}}) = \dot{e}_{\text{in}} + \dot{q}_{\text{cond,in}} + \dot{q}_{\text{rad,in}} - Mc \frac{dT}{d\tau} \quad (4.6.16)$$

where  $h$  = the heat transfer coefficient, W/m, °C

$A$  = the area available for convective transport, m<sup>2</sup>

$T_{\text{ref}}$  = the reference temperature used in defining  $h$ , °C

$T_o$  = the average surface temperature over the area  $A$ , °C

$\dot{e}_{\text{in}}$  = externally provided input, W

$\dot{q}_{\text{cond,in}}$  = net energy conducted in, W

$\dot{q}_{\text{rad,in}}$  = net energy radiated in, W

$Mc \, dT/d\tau$  = rate of increase of thermal energy stored within the system, W

*Steady State.* In the steady-state method, the transient term is zero (or nearly so), and  $h$  is determined by measuring the input power and the operating temperature, and correcting for losses. Equation (4.6.16) can be applied to differentially small elements or to whole specimens. The considered region must be reasonably uniform in temperature, so the energy storage term and the convective heat transfer term use the same value.

For tests of isolated objects, or embedded calorimeter sections, steady-state tests usually use high-conductivity specimens (e.g., copper or aluminum) with embedded electric heaters. The resulting value of  $h$  is the average over the area of the specimen. The Biot number,  $hL/k$ , for the specimen should be low (on the order of 0.01 or less) if only one temperature sensor is used in the specimen, so the surface temperature can be determined from the embedded sensor.

If a single heated element is used within an array of unheated elements, the resulting heat transfer coefficient is implicitly defined as  $h_{\text{adiabatic}}$  and should be identified as such. Heat transfer coefficients measured with single-active-element tests cannot be used with the mixed mean fluid temperature.

When the variation of  $h$  over a surface is required, one common steady-state technique is to stretch a thin foil (stainless steel, or carbon impregnated paper, or gold deposited on polycarbonate) over an insulating substrate, and electrically heat the foil surface. Liquid crystals or infrared techniques can be used to map the surface temperature, from which the heat transfer coefficient distribution can be determined. The “heated foil with liquid crystal” approach was used by Cooper et al. in 1975 to measure heat transfer coefficients, and has since been used by many others. Hippensteele et al. (1985) have made extensive use of the foil technique in studies of gas turbine heat transfer. An example of their work on the end wall of a turbine cascade is shown in [Figure 4.6.15](#).

**FIGURE 4.6.15** Heat transfer coefficient distribution on the end wall of a turbine cascade. (From Hippensteele, S.A. et al., NASA Technical Memorandum 86900, March, 1985. With permission.)

Hollingsworth et al. (1989) used a stainless steel foil heater for a study in air for an electronics cooling application, illustrated in [Figure 4.6.16](#).

**FIGURE 4.6.16** Visualization of the heat transfer coefficient distribution on a heated plate around three unheated cubes.

Another steady-state technique which reveals the distribution of  $h$  on the surface was introduced by den Ouden and Hoogendoorn (1974) and is currently in use by Meinders (1996). It uses a uniform and constant-temperature substrate (originally, a tank of warm water, now a copper block) covered with a layer of known thermal resistance (originally, a plate of glass, now a thin layer of epoxy). The surface was painted with liquid crystals (now visualized using infrared imaging) and the surface-temperature distribution determined. The inner (uniform) and outer (measured) temperature distributions are then used as boundary conditions to a three-dimensional conduction solver which calculates the total heat flux at each point on the surface. The total heat flux is corrected for radiation to yield the net convective transport at each point, from which  $h$  can be determined.

This method appears to have an advantage in accuracy over the heated foil technique because of the more accurate handling of substrate conduction.

*Transient Lumped Parameter Systems.* In the lumped parameter transient method, the specimen is assumed to be uniform in temperature at every instant through the transient. The power,  $\dot{e}_{in}$ , in Equation (4.6.16) is usually zero, although that is not necessary (one could simply change the power level at time zero to initiate the transient). At time zero, a transient is initiated, and the response curve recorded.

The data can be interpreted, and the validity of the first-order assumption tested at the same time by plotting  $(T - T_{final}) / (T_{initial} - T_{final})$  on the log scale of semilog coordinates, with time on the algebraic scale. If the line is straight, then the system is first order and the characteristic time can be determined from any two points on the line by

$$\tau = \frac{(t_2 - t_1)}{\ln \left\{ \frac{T_{fin} - T_1}{T_{fin} - T_2} \right\}} \quad (4.6.17)$$

where  $\tau$  = characteristic time,  $Mc/hA$ , sec

$t_1$  = time at the first instant

$t_2$  = time at the second instant

$T_1$  = specimen temperature at the first instant, °C

$T_2$  = specimen temperature at the second instant, °C

$T_{fin}$  = specimen temperature after a long time (fluid temperature), °C

The heat transfer coefficient is extracted from the time-constant definition.

### Indirect Methods

An increasingly popular method is the extraction of  $h$  from surface-temperature variations after a step in flow temperature using an inverse calculation method (see the section on inferential methods of heat flux measurement). The simplest inverse method assumes one-dimensional conduction into an infinitely thick plate of constant material properties. Even highly irregular geometries can be studied with this technique, if the streamwise extent of the specimen is small and the testing time is short. A short time interval is necessary so the penetration of the thermal wave is limited to a thin layer near the surface. The short streamwise extent is necessary so the temperature response of the surface upstream does not alter the thermal step applied to the downstream surface. This technique has been used to determine the heat transfer coefficient distribution on the inside walls of passages of irregular shape, by making the passage in a transparent material.

*Naphthalene Sublimation.* The equations for mass diffusion are similar to those for heat transfer, except for replacing the Prandtl number in the heat transfer equation by the Schmidt number in the diffusion equation. Thus, one could expect that the distribution of the mass transfer coefficients on a surface would mimic the distribution of the heat transfer coefficients.

The most commonly used analog technique is naphthalene sublimation. As early as 1940, the mass transfer/heat transfer similarity was used to estimate the heat transfer coefficient distribution. Naphthalene

is a solid material which sublimates at a reasonable rate in air at ambient temperature. Specimens can be cast in naphthalene with good precision, and the recession of the surface mapped as a function of position and time using automated or semiautomated measuring equipment. The surface recession over a known interval of time is a measure of the mass transfer rate, from which the mass transfer coefficient can be deduced.

Naphthalene experiments are generally done at uniform temperature; hence, a uniform vapor pressure exists at the surface. This corresponds to the heat transfer situation of heat transfer from a uniform temperature surface. No counterpart of the uniform heat flux situation has been produced using naphthalene, nor have there been experiments corresponding to variable wall temperature.

Naphthalene sublimation experiments do not suffer from any counterpart of the conduction heat transfer in the substrate. Conduction makes it difficult to work near discontinuities in wall temperature in a heat transfer experiment. Details of the fine structure of mass transfer near obstructions and discontinuities can be resolved in naphthalene experiments, but those details might not exist in a heat transfer process. The Prandtl number of air is much lower than the Schmidt number of naphthalene diffusing in air; hence, thermal conduction would tend to blur out sharp gradients in the temperature field more than diffusion would blur out gradients in naphthalene concentration.

The Schmidt number of naphthalene in air is about 2.5, far different than the Prandtl number of air (0.71); hence, the mass transfer coefficient deduced from a naphthalene experiment is not numerically equal to the heat transfer coefficient which would have existed at those conditions. The usual recommendation is to adjust for the Prandtl number of Schmidt number using a relation of the form:

$$\text{St Pr}^{2/3} = f\{\text{Re}\} = \text{Sh}_j \text{Sc}_j^{2/3} \quad (4.6.18)$$

based on laminar results. That recommendation has not been seriously tested by experiments in turbulent and separated flows. By using nominal values of the Schmidt number and Prandtl number, the heat transfer Stanton number would be 2.3 times higher than the measured Sherwood number and an uncertainty of 10% in that ratio would alter the inferred heat transfer coefficient by 23%.

*System Performance Matching.* Sometimes the “effective average heat transfer coefficient” for a system is inferred from the overall behavior of the system, e.g., estimating  $h$  from the effectiveness of a heat exchanger. Values deduced by this means cannot be expected to agree well with direct measurements unless a very sophisticated system description model is used.

## 4.7 Mass Transfer

*Anthony F. Mills*

### Introduction

Mass transfer may occur in a gas mixture, a liquid solution, or a solid solution. There are several physical mechanisms that can transport a chemical species through a phase and transfer it across phase boundaries. The two most important mechanisms are ordinary diffusion and convection. Mass diffusion is analogous to heat conduction and occurs whenever there is a gradient in the concentration of a species. Mass convection is essentially identical to heat convection: a fluid flow that transports heat may also transport a chemical species. The similarity of mechanisms of heat transfer and mass transfer results in the mathematics often being identical, a fact that can be exploited to advantage. But there are some significant differences between the subjects of heat and mass transfer. One difference is the much greater variety of physical and chemical processes that require mass transfer analysis. Another difference is the extent to which the essential details of a given process may depend on the particular chemical system involved, and on temperature and pressure.

In the next subsection, concentrations, velocities, and fluxes are defined, and special attention is paid to phase interfaces where the concentration of a chemical species is almost always discontinuous. Fick's law of ordinary diffusion is introduced in the third section, where other diffusion phenomena are also discussed. The fourth section presents various forms of the species conservation equation. Results for diffusion in a stationary medium are given in the fifth section, and include steady diffusion across a plane wall, transient diffusion in a semi-infinite solid, and diffusion in a porous catalyst. Results for diffusion in a moving medium are given in the sixth section, and the Stefan flow is introduced for diffusion with one component stationary. Also considered are particle combustion, droplet evaporation, and combustion of a volatile liquid hydrocarbon fuel droplet. The last section deals with mass convection. Low mass transfer rate theory is presented and how to exploit the analogy between convective heat and mass transfer is shown. Particular attention is given to situations involving simultaneous heat and mass transfer associated with evaporation or condensation. The section closes by presenting high mass transfer rate theory for convection, and gives engineering calculation methods for boundary layer flows that account for variable property effects.

### Concentrations, Velocities, and Fluxes

#### Definitions of Concentrations

In a gas mixture, or liquid or solid solution, the local *concentration* of a mass species can be expressed in a number of ways. The *number density* of species  $i$  in a mixture or solution of  $n$  species is defined as

$$\begin{aligned} \text{Number density of species } i &\equiv \text{Number of molecules of } i \text{ per unit volume} \\ &\equiv \mathcal{N}_i \text{ molecules/m}^3 \end{aligned} \quad (4.7.1)$$

Alternatively, if the total number of molecules of all species per unit volume is denoted as  $\mathcal{N}$ , then we define the *number fraction* of species  $i$  as

$$n_i \equiv \frac{\mathcal{N}_i}{\mathcal{N}}; \quad \mathcal{N} = \sum \mathcal{N}_i \quad (4.7.2)$$

where the summation is over all species present,  $i = 1, 2, \dots, n$ . Equations (4.7.1) and (4.7.2) describe *microscopic* concepts and are used, for example, when the kinetic theory of gases is used to describe transfer processes.

Whenever possible, it is more convenient to treat matter as a continuum. Then the smallest volume considered is sufficiently large for macroscopic properties such as pressure and temperature to have their usual meanings. For this purpose we also require *macroscopic* definitions of concentration. First, on a mass basis,

$$\begin{aligned} \text{Mass concentration of species } i &\equiv \text{partial density of species } i \\ &\equiv \rho_i \text{ kg/m}^3 \end{aligned} \quad (4.7.3)$$

The total mass concentration is the total mass per unit volume, that is, the density  $\rho = \sum \rho_i$ . The *mass fraction* of species  $i$  is defined as

$$m_i = \frac{\rho_i}{\rho} \quad (4.7.4)$$

Second, on a molar basis,

$$\begin{aligned} \text{Molar concentration of species } i &\equiv \text{number of moles of } i \text{ per unit volume} \\ &\equiv c_i \text{ kmol/m}^3 \end{aligned} \quad (4.7.5)$$

If  $M_i$  (kg/kmol) is the molecular weight of species  $i$ , then

$$c_i = \frac{\rho_i}{M_i} \quad (4.7.6)$$

The total molar concentration is the molar density  $c = \sum c_i$ . The *mole fraction* of species  $i$  is defined as

$$x_i \equiv \frac{c_i}{c} \quad (4.7.7)$$

A number of important relations follow directly from these definitions. The mean molecular weight of the mixture of solution is denoted  $M$  and may be expressed as

$$M = \frac{\rho}{c} = \sum x_i M_i \quad (4.7.8a)$$

or

$$\frac{1}{M} = \sum \frac{m_i}{M_i} \quad (4.7.8b)$$

There are summation rules

$$\sum m_i = 1 \quad (4.7.9a)$$

$$\sum x_i = 1 \quad (4.7.9b)$$

It is often necessary to have the mass fraction of species  $i$  expressed explicitly in terms of mole fractions and molecular weights; this relation is

$$m_i = \frac{x_i M_i}{\sum x_j M_j} = x_i \frac{M_i}{M} \quad (4.7.10a)$$

and the corresponding relation for the mole fraction is

$$x_i = \frac{m_i/M_i}{\sum m_j/M_j} = m_i \frac{M}{M_i} \quad (4.7.10b)$$

Dalton's law of partial pressures for an ideal gas mixture states that

$$P = \sum P_i, \quad \text{where } P_i = \rho_i R_i T \quad (4.7.11)$$

Dividing partial pressure by total pressure and substituting  $R_i = \mathcal{R}/M_i$  gives

$$\frac{P_i}{P} = \frac{\rho_i}{M_i} \frac{\mathcal{R} T}{P} = c_i \frac{\mathcal{R} T}{P} = x_i \frac{c \mathcal{R} T}{P} = x_i \quad (4.7.12)$$

Thus, for an ideal gas mixture, the mole fraction and partial pressure are equivalent measures of concentration (as also is the number fraction).

A commonly used specification of the composition of dry air is 78.1% N<sub>2</sub>, 20.9% O<sub>2</sub>, and 0.9% Ar, by volume. (The next largest component is CO<sub>2</sub>, at 0.3%.) Since equal volumes of gases contain the same number of moles, specifying composition on a volume basis is equivalent to specifying mole fractions, namely,

$$x_{\text{N}_2} = 0.781; \quad x_{\text{O}_2} = 0.209; \quad x_{\text{Ar}} = 0.009$$

The corresponding mass fractions are calculated to be

$$m_{\text{N}_2} = 0.755; \quad m_{\text{O}_2} = 0.231; \quad m_{\text{Ar}} = 0.014$$

### Concentrations at Interfaces

Although temperature is continuous across a phase interface, concentrations are usually discontinuous. In order to define clearly concentrations at interfaces, we introduce imaginary surfaces, denoted  $u$  and  $s$ , on both sides of the real interface, each indefinitely close to the interface, as shown in [Figure 4.7.1](#) for water evaporating into an airstream. Thus, the liquid-phase quantities at the interface are subscripted  $u$ , and gas-phase quantities are subscripted  $s$ . If we ignore the small amount of air dissolved in the water,  $x_{\text{H}_2\text{O},u} = 1$ . Notice that the subscript preceding the comma denotes the chemical species, and the subscript following the comma denotes location. To determine  $x_{\text{H}_2\text{O},s}$  we make use of the fact that, except in extreme circumstances, the water vapor and air mixture at the  $s$ -surface must be in thermodynamic equilibrium with water at the  $u$ -surface. Equilibrium data for this system are found in conventional steam tables: the saturation vapor pressure of steam at the water temperature,  $T_s$ , ( $T_s = T_u$ ), is the required partial pressure  $P_{\text{H}_2\text{O},s}$ . With the total pressure  $P$  known,  $x_{\text{H}_2\text{O},s}$  is calculated as  $P_{\text{H}_2\text{O},s}/P$ . If  $m_{\text{H}_2\text{O},s}$  is required, Equation (4.7.10a) is used.

FIGURE 4.7.1 Concentrations at a water-air interface.

For example, at  $T_s = 320$  K, the saturation vapor pressure is obtained from steam tables as  $0.10535 \times 10^5$  Pa. If the total pressure is  $1 \text{ atm} = 1.0133 \times 10^5$ ,

$$x_{\text{H}_2\text{O},s} = \frac{0.10535 \times 10^5}{1.0133 \times 10^5} = 0.1040$$

$$m_{\text{H}_2\text{O},s} = \frac{(0.1040)(18)}{(0.1040)(18) + (1 - 0.1040)(29)} = 0.06720$$

For a gas or solid dissolving in a liquid, equilibrium data are often referred to simply as solubility data, found in chemistry handbooks. Many gases are only sparingly soluble, and for such dilute solutions solubility data are conveniently represented by *Henry's law*, which states that the mole fraction of the gas at the  $s$ -surface is proportional to its mole fraction in solution at the  $u$ -surface, the constant of proportionality being the *Henry number*,  $\text{He}_i$ . For species  $i$ ,

$$x_{i,s} = \text{He}_i x_{i,u} \quad (4.7.13)$$

The Henry number is inversely proportional to total pressure and is also a function of temperature. The product of Henry number and total pressure is the *Henry constant*,  $C_{\text{He}_i}$ , and for a given species is a function of temperature only:

$$\text{He}_i P = C_{\text{He}_i}(T) \quad (4.7.14)$$

Solubility data are given in [Table 4.7.1](#).

**TABLE 4.7.1 Henry Constants  $C_{\text{He}}$  for Dilute Aqueous Solutions at Moderate Pressures ( $P_{i,s}/x_{i,u}$  in atm, or in bar =  $10^5$  Pa, within the accuracy of the data).**

Solute	290 K	300 K	310 K	320 K	330 K	340 K
H <sub>2</sub> S	440	560	700	830	980	1,140
CO <sub>2</sub>	1,280	1,710	2,170	2,720	3,220	—
O <sub>2</sub>	38,000	45,000	52,000	57,000	61,000	65,000
H <sub>2</sub>	67,000	72,000	75,000	76,000	77,000	76,000
CO	51,000	60,000	67,000	74,000	80,000	84,000
Air	62,000	74,000	84,000	92,000	99,000	104,000
N <sub>2</sub>	16,000	89,000	101,000	110,000	118,000	124,000

For example, consider absorption of carbon dioxide from a stream of pure CO<sub>2</sub> at 2 bar pressure into water at 310 K. From Table 4.7.1,  $C_{\text{He}} = 2170$  bar; thus

$$H_{\text{CO}_2} = \frac{2170}{2} = 1085; \quad x_{\text{CO}_2,u} = \frac{1}{1085} = 9.22 \times 10^{-4}$$

Dissolution of gases into metals is characterized by varied and rather complex interface conditions. Provided temperatures are sufficiently high, hydrogen dissolution is reversible (similar to CO<sub>2</sub> absorption into water); hence, for example, titanium-hydrogen solutions can exist only in contact with a gaseous hydrogen atmosphere. As a result of hydrogen going into solution in atomic form, there is a characteristic square root relation

$$m_{\text{H}_2,u} \propto P_{\text{H}_2,s}^{1/2}$$

The constant of proportionality is strongly dependent on temperature, as well as on the particular titanium alloy: for Ti-6Al-4V alloy it is twice that for pure titanium. In contrast to hydrogen, oxygen dissolution in titanium is irreversible and is complicated by the simultaneous formation of a rutile (TiO<sub>2</sub>) scale on the surface. Provided some oxygen is present in the gas phase, the titanium-oxygen *phase diagram* (found in a metallurgy handbook) shows that  $m_{\text{O}_2,u}$  in alpha-titanium is 0.143, a value essentially independent of temperature and O<sub>2</sub> partial pressure. Dissolution of oxygen in zirconium alloys has similar characteristics to those discussed above for titanium.

All the preceding examples of interface concentrations are situations where thermodynamic equilibrium can be assumed to exist at the interface. Sometimes thermodynamic equilibrium does not exist at an interface: a very common example is when a chemical reaction occurs at the interface, and temperatures are not high enough for equilibrium to be attained. Then the concentrations of the reactants and products at the *s*-surface are dependent both on the rate at which the reaction proceeds — that is, the *chemical kinetics* — as well as on mass transfer considerations.

### Definitions of Fluxes and Velocities

The mass (or molar) flux of species *i* is a vector quantity giving the mass (or moles) of species *i* that pass per unit time through a unit area perpendicular to the vector (Figure 4.7.2). We denote the absolute mass and molar fluxes of species *i*, that is, relative to stationary coordinate axes, as  $n_i$  (kg/m<sup>2</sup>sec) and  $N_i$  (kmol/m<sup>2</sup>sec), respectively. The absolute mass flux of the mixture (mass velocity) is

$$n = \sum n_i \quad (4.7.15)$$

and the local mass-average velocity is

FIGURE 4.7.2 Flux vectors: (a) mass basis, (b) molar basis.

$$\mathbf{v} = \frac{\mathbf{n}}{\rho} \text{ m/sec} \quad (4.7.16)$$

The velocity  $\mathbf{v}$  is the velocity that would be measured by a Pitot tube and corresponds to the velocity used in considering pure fluids. On a molar basis, the absolute molar flux of the mixture is

$$N = \sum N_i \quad (4.7.17)$$

and the local molar-average velocity is

$$\mathbf{v}^* = \frac{N}{c} \text{ m/sec} \quad (4.7.18)$$

The absolute fluxes at species  $i$  have two components. On a mass basis we write

$$\mathbf{n}_i = \rho_i \mathbf{v} + \mathbf{j}_i \quad (4.7.19)$$

where  $\rho_i \mathbf{n}$  is transport of species  $i$  by bulk motion of the fluid at velocity  $\mathbf{v}$  and is the *convective* component. Thus,  $\mathbf{j}_i$  is transport of species  $i$  relative to the mass average velocity; it is called the *diffusive* component because most commonly it is due to ordinary (concentration) diffusion of the species. On a molar basis the corresponding relation is

$$N_i = c_i \mathbf{v}^* + \mathbf{J}_i^* \quad (4.7.20)$$

Some important relations follow from these definitions:

$$\sum \mathbf{j}_i = \sum \mathbf{J}_i^* = 0 \quad (4.7.21)$$

$$N_i = \frac{\mathbf{n}_i}{M_i} \quad (4.7.22)$$

$$\mathbf{n}_i = \rho_i \mathbf{v} + \mathbf{j}_i = m_i \sum \mathbf{n}_i + \mathbf{j}_i \quad (4.7.23a)$$

$$N_i = c_i \mathbf{v}^* + \mathbf{J}_i^* = x_i \sum N_i + \mathbf{J}_i^* \quad (4.7.23b)$$

## Mechanisms of Diffusion

### Ordinary Diffusion

Fick's law of ordinary diffusion is a linear relation between the rate of diffusion of a chemical species and the local concentration gradient of that species. It is exact for a binary gas mixture, for which the kinetic theory of gases gives

$$\mathbf{j}_1 = -\rho \mathcal{D}_{12} \nabla m_1 \text{ kg/m}^2 \text{ sec} \quad (4.7.24a)$$

on a mass basis, and

$$\mathbf{J}_1^* = -c\mathcal{D}_{12}\nabla x_1 \text{ kg/m}^2 \text{ sec} \quad (4.7.24b)$$

on a molar basis;  $\mathcal{D}_{12}$  ( $\text{m}^2/\text{sec}$ ) is the binary diffusion coefficient (or mass diffusivity), and  $\mathcal{D}_{21} = \mathcal{D}_{12}$ . Equations (4.7.24a) and (4.7.24b) are mathematically equivalent; however, notice that it is incorrect to write

$$\mathbf{j}_i = -\mathcal{D}_{12}\nabla\rho_1 \quad (4.7.25)$$

since  $\nabla\rho_1 \neq \rho \nabla m_1$  in general. Fick's law in the form of Equations (4.7.24a) and (4.7.24b) is also valid for dilute liquid and solid solutions, for which it is often possible to assume  $\rho$  (or  $c$ ) constant, and then Equation (4.7.25) or its molar equivalent are good approximations.

Ordinary diffusion in multicomponent systems is described by the Stefan–Maxwell equations (Hirschfelder et al., 1954). These equations are difficult to use for engineering analysis. In gas mixtures containing species that do not have widely varying molecular weights, it is possible to model approximately the diffusion process by using an effective binary diffusion coefficient in Fick's law. This coefficient is a suitable average over the species in the mixture, and may be calculated from

$$\mathcal{D}_{1m} = \frac{(1-x_1)}{\sum_{i=2}^n (x_i/\mathcal{D}_{1i})}; \quad x_1 \ll 1 \quad (4.7.26)$$

This equation works well for most mixtures of combustion gases (except those containing appreciable concentrations of H or  $\text{H}_2$ ).

Binary diffusion coefficients at 300 K are of the order of  $10^{-5} \text{ m}^2/\text{sec}$  in gases at 1 atm,  $10^{-9} \text{ m}^2/\text{sec}$  in aqueous solutions, and  $10^{-10}$  to  $10^{-13} \text{ m}^2/\text{sec}$  in solids. However, the product  $\rho\mathcal{D}$  or ( $c\mathcal{D}$ ) is, at most, one order of magnitude different for gases and liquids. Data for diffusion coefficients may be found in [Tables 4.7.2 through 4.7.5](#).

Molecules in a gas mixture, and in a liquid or solid solution, can diffuse by mechanisms other than ordinary diffusion governed by Fick's law. *Thermal diffusion* is diffusion due to a temperature gradient and is often called the *Soret effect*. Thermal diffusion is usually negligible compared with ordinary diffusion, unless the temperature gradient is very large. However, there are some important processes that depend on thermal diffusion, the most well known being the large-scale separation of uranium isotopes. *Pressure diffusion* is diffusion due to a pressure gradient and is also usually negligible unless the pressure gradient is very large. Pressure diffusion is the principle underlying the operation of a centrifuge. Centrifuges are used to separate liquid solutions and are increasingly being used to separate gaseous isotopes as well. *Forced diffusion* results from an external force field acting on a molecule. Gravitational force fields do not cause separation since the force per unit mass of a molecule is constant. Forced diffusion occurs when an electrical field is imposed on an electrolyte (for example, in charging an automobile battery), on a semiconductor, or on an ionized gas (for example, in a neon tube or metal-ion laser). Depending on the strength of the electric field, rates of forced diffusion can be very large.

Some interesting diffusion phenomena occur in porous solids. When a gas mixture is in a porous solid, such as a catalyst pellet or silica–gel particle, the pores can be smaller than the mean free path of the molecules. Then, the molecules collide with the wall more often than with other molecules. In the limit of negligible molecule collisions we have *Knudsen diffusion*, also called *free molecule flow* in the fluid mechanics literature. If the pore size approaches the size of a molecule, then Knudsen diffusion becomes negligible and *surface diffusion*, in which adsorbed molecules move along the pore walls, becomes the dominant diffusion mechanism.

<sup>a</sup> Owing to the practical importance of water vapor-air mixtures, engineers have used convenient empirical formulas for  $\mathcal{D}_{\text{H}_2\text{O air}}$ . A formula that has been widely used for many years is

$$\mathcal{D}_{\text{H}_2\text{O air}} = 1.97 \times 10^{-5} \left( \frac{P_0}{P} \right) \left( \frac{T}{T_0} \right)^{1.685} \text{ m}^2/\text{sec}; \quad 273 \text{ K} < T < 373 \text{ K}$$

where  $P_0 = 1$  atm;  $T_0 = 256$  K. More recently, the following formula has found increasing use. (Marrero, T.R. and Mason, E.A. 1992. Gaseous diffusion coefficients, *J. Phys. Chem. Ref. Data*, 1, 3–118):

$$\begin{aligned} \mathcal{D}_{\text{H}_2\text{O air}} &= 1.87 \times 10^{-10} \frac{T^{2.072}}{P}; \quad 280 \text{ K} < T < 450 \text{ K} \\ &= 2.75 \times 10^{-9} \frac{T^{1.632}}{P}; \quad 450 \text{ K} < T < 1070 \text{ K} \end{aligned}$$

for  $P$  in atmospheres and  $T$  in kelvins. Over the temperature range 290 to 330 K, the discrepancy between the two formulas is less than 2.5%. For small concentrations of water vapor in air, the older formula gives a constant value of  $\text{Sc}_{\text{H}_2\text{O air}} = 0.61$  over the temperature range 273 to 373 K. On the other hand, the Marrero and Mason formula gives values of  $\text{Sc}_{\text{H}_2\text{O air}}$  that vary from 0.63 at 280 K to 0.57 at 373 K.

Very small particles of  $10^{-3}$  to  $10^{-1}$   $\mu\text{m}$  size — for example, smoke, soot, and mist — behave much like large molecules. Ordinary diffusion of such particles is called *Brownian motion* and is described in most elementary physics texts. Diffusion of particles due to a temperature gradient is called *thermophoresis* and plays an important role for larger particles, typically in the size range  $10^{-1}$  to  $1$   $\mu\text{m}$ . Diffusion of particles in a gas mixture due to concentration gradients of molecular species is called *diffusiophoresis*. *Forced diffusion* of a charged particle in an electrical field is similar to that for an ionized molecular species. Thermal and electrostatic precipitators are used to remove particles from power plant and incinerator stack gases, and depend on thermophoresis and forced diffusion, respectively, for their operation. Diffusion phenomena are unimportant for particles of size greater than about  $1$   $\mu\text{m}$  in air at 1 atm; the motion of such particles is governed by the laws of Newtonian mechanics. Transport of particles is dealt with in the *aerosol science* literature.

## Species Conservation Equation

The principle of conservation of a chemical species is used to derive the *species conservation equation*. On a mass basis this equation is

**TABLE 4.7.3 Schmidt Number for Vapors in Dilute Mixture in Air at Normal Temperature, Enthalpy of Vaporization, and Boiling Point at 1 atm<sup>a</sup>**

Vapor	Chemical Formula	Sc <sup>b</sup>	$h_{fg}$ , J/kg $\times 10^{-6}$	$T_{BP}$ , K
Acetone	CH <sub>3</sub> COCH <sub>3</sub>	1.42	0.527	329
Ammonia	NH <sub>3</sub>	0.61	1.370	240
Benzene	C <sub>6</sub> H <sub>6</sub>	1.79	0.395	354
Carbon dioxide	CO <sub>2</sub>	1.00	0.398	194
Carbon monoxide	CO	0.77	0.217	81
Chlorine	Cl <sub>2</sub>	1.42	0.288	238
Ethanol	CH <sub>3</sub> CH <sub>2</sub> OH	1.32	0.854	352
Helium	He	0.22	—	4.3
Heptane	C <sub>7</sub> H <sub>16</sub>	2.0	0.340	372
Hydrogen	H <sub>2</sub>	0.20	0.454	20.3
Hydrogen sulfide	H <sub>2</sub> S	0.94	0.548	213
Methanol	CH <sub>3</sub> OH	0.98	1.110	338
Naphthalene	C <sub>10</sub> H <sub>8</sub>	2.35 <sup>c</sup>	—	491
Nitric oxide	NO	0.87	0.465	121
Octane	C <sub>8</sub> H <sub>18</sub>	2.66	0.303	399
Oxygen	O <sub>2</sub>	0.83	0.214	90.6
Pentane	C <sub>5</sub> H <sub>12</sub>	1.49	0.357	309
Sulfur dioxide	SO <sub>2</sub>	1.24	0.398	263
Water vapor	H <sub>2</sub> O	0.61	2.257	373

<sup>a</sup> With the Clausius-Clapeyron relation, one may estimate vapor pressure as

$$P_{\text{sat}} \approx \exp\left\{-\frac{Mh_{fg}}{\mathcal{R}}\left(\frac{1}{T} - \frac{1}{T_{BP}}\right)\right\} \text{ atm for } T \sim T_{BP}$$

<sup>b</sup> The Schmidt number is defined as  $Sc = \mu/\rho\mathcal{D} = \nu/\mathcal{D}$ . Since the vapors are in small concentrations, values for  $\mu$ ,  $\rho$ , and  $\nu$  can be taken as pure air values.

<sup>c</sup> From a recent study by Cho, C., Irvine, T.F., Jr., and Kami, J. 1992. Measurement of the diffusion coefficient of naphthalene into air, *Int. J. Heat Mass Transfer*, 35, 957–966. Also,  $h_{vg} = 0.567 \times 10^6$  J/kg at 300 K.

$$\frac{\partial p_i}{\partial t} + \nabla \cdot \mathbf{n}_i = \dot{i}_i''' \quad (4.7.27)$$

and on a molar basis

$$\frac{\partial c_i}{\partial t} + \nabla \cdot \mathbf{N}_i = \dot{R}_i''' \quad (4.7.28)$$

where  $\dot{i}_i'''$  and  $\dot{R}_i'''$  are the mass and molar rates of production of species  $i$  due to chemical reactions. Summing Equation 4.7.27 over all species gives the mass conservation or continuity equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{v} = 0 \quad (4.7.29)$$

The molar form is

$$\frac{\partial c}{\partial t} + \nabla \cdot c\mathbf{v}^* = \sum_i \dot{R}_i''' \quad (4.7.30)$$

since, in general, moles are not conserved in chemical reactions. A useful alternative form to Equation 4.7.27 can be obtained using Equations (4.7.23a) and (4.7.29) and is

Various sources.

$$\rho \frac{Dm_i}{Dt} = \nabla \cdot (\rho \mathcal{D}_{12} \nabla m_1) + \dot{r}_1''' \quad (4.7.32)$$

When working on a mass basis we define a stationary medium as one in which the mass average velocity  $v$  is zero everywhere. Substituting in Equation (4.7.32) with no chemical reactions and assuming constant properties,

$$\frac{\partial m_1}{\partial t} = \mathcal{D}_{12} \nabla^2 m_1 \quad (4.7.33)$$

which is the *diffusion* equation, and is the mass transfer analog to Fourier's equation for heat conduction. For steady diffusion, Equation (4.7.33) reduces to Laplace's equation

$$\nabla^2 m_1 = 0 \quad (4.7.34)$$

Notice that since properties have been assumed constant, any measure of concentration can be used in Equations (4.7.33) and (4.7.34), for example  $\rho_1$ ,  $c_1$ , and  $x_1$ .

## Diffusion in a Stationary Medium

Many problems involving diffusion in a stationary medium are governed by the diffusion equation (Equation 4.7.33). Often solutions may be obtained from their heat conduction analogs. Some important cases follow.

### Steady Diffusion through a Plane Wall

The mass flow of species 1 across a plane wall of thickness  $L$  and cross-sectional area  $A$  is

$$\dot{m}_1 = \frac{\rho \mathcal{D}_{12} A}{L} (m_{1,u} - m_{1,u'}) \text{ kg/m}^2 \text{ sec} \quad (4.7.35)$$

**FIGURE 4.7.3** Steady diffusion across a plane wall.

where the  $u$ - and  $u'$ -surfaces are shown in [Figure 4.7.3](#). Solubility data are required to relate the  $u$ - and  $u'$ -surface concentrations to  $s$ - and  $s'$ -surface concentrations. Alternatively for systems that obey Henry's law, a solubility  $\mathcal{S}$  can be defined as the volume of solute gas (at STP of 0°C and 1 atm) dissolved in unit volume when the gas is at a partial pressure of 1 atm. Then, defining permeability  $\mathcal{P}_{12}$  as the product  $\mathcal{D}_{12}\mathcal{S}$ , the volume flow of species 1 is

$$\dot{V}_1 = \frac{\mathcal{P}_{12}A}{L}(P_{1,s} - P_{1,s'}) \text{ m}^3 \text{ (STP)/sec} \quad (4.7.36)$$

where the partial pressures  $P_1$  are in atmospheres. The SI units for permeability are  $\text{m}^3 \text{ (STP)/m}^2\text{sec(atm/m)}$ . Permeability and solubility data are given in [Table 4.7.6](#). For example, consider helium at  $10^5$  Pa contained in a 7056-glass vessel with a 1-mm-thick wall at 680 K. For a surface area of  $0.01 \text{ m}^2$ , the leakage rate into ambient air is

$$\dot{V} = \frac{(1.0 \times 10^{-12})(0.01)}{(0.001)}(10^5 - 0) = 1.0 \times 10^{-6} \text{ m}^3 \text{ (STP)/sec}$$

where the value  $\mathcal{P}_{12}$  was obtained from [Table 4.7.6](#).

In general, mass fractions are discontinuous across phase interfaces. Hence, Equation (4.7.35) cannot be generalized to a number of walls in series by simply adding diffusion resistances. However, equilibrium partial pressures  $P_1$  are continuous, and for two walls  $A$  and  $B$ , Equation 4.7.36 becomes

$$\dot{V}_1 = \frac{P_{1,s} - P_{1,s'}}{\frac{L_A}{\mathcal{P}_{1A}A} + \frac{L_B}{\mathcal{P}_{1B}A}} \text{ m}^3 \text{ (STP)/sec} \quad (4.7.37)$$

### Transient Diffusion in a Semi-Infinite Solid

The typically low diffusion coefficients characterizing solids result in many situations where concentration changes are limited to a thin region near the surface (of thickness  $\delta_c \sim (\mathcal{D}_{12}t)^{1/2}$ ). Examples include case-hardening of mild steel and coloring of clear sapphires. Details of the geometry are then unimportant

**FIGURE 4.7.4** Transient diffusion in a plane slab.

and semi-infinite solid model can be used (Figure 4.7.4). For an initial concentration  $m_{1,0}$  and a  $u$ -surface concentration suddenly changed to  $m_{1,u}$  at time  $t = 0$ , the concentration distribution  $m_1(z,t)$  is

$$\frac{m_1 - m_{1,0}}{m_{1,u} - m_{1,0}} = \operatorname{erfc} \frac{z}{(4\mathcal{D}_{12}t)^{1/2}} \quad (4.7.38)$$

and the dissolution rate is

$$\dot{m}_1 = j_{1,u}A = \rho A \left( \frac{\mathcal{D}_{12}}{\pi t} \right)^{1/2} (m_{1,u} - m_{1,0}) \text{ kg/sec} \quad (4.7.39)$$

For example, consider a Pyrex glass slab at 800 K suddenly exposed to helium at  $10^4$  Pa. The molar equivalent to Equation (4.7.39) for an assumed constant solid phase molar concentration  $c$  is

$$\frac{\dot{M}_1}{A} = \left( \frac{\mathcal{D}_{12}}{\pi t} \right)^{1/2} (c_{1,u} - c_{1,0})$$

From Table 4.7.6,  $\mathcal{S}' = c_{1,u}/c_{1,s} \cong 0.024$ ; hence,  $c_{1,u} = (0.024)(10^4)/(8314)(800) = 3.61 \times 10^{-5}$  kmol/m<sup>3</sup>. From Table 4.7.4,  $\mathcal{D}_{12} = 4.76 \times 10^{-8} \exp[-(2.72 \times 10^4)/(10^3)/(8314)(800)] = 7.97 \times 10^{-10}$  m<sup>2</sup>/sec. Hence,

$$\frac{\dot{M}_1}{A} = \left( \frac{7.97 \times 10^{-10}}{\pi t} \right)^{1/2} (3.61 \times 10^{-5} - 0) = 5.75 \times 10^{-10}/t \text{ kmol/sec}$$

### Transient Diffusion in Slabs, Cylinders, and Spheres

Transient heat conduction in slabs, cylinders, and spheres with surface convection is dealt with in Section 4.1. The analogous mass diffusion problem for the slab  $-L < z < L$  is now considered. On a molar basis the governing differential equation is

$$\frac{\partial x_1}{\partial t} = \mathcal{D}_{12} \frac{\partial^2 x_1}{\partial z^2} \quad (4.7.40)$$

with initial condition  $x_1 = x_{1,0}$  at  $t = 0$ . Boundary conditions are  $\partial x_1 / \partial z = 0$  at  $z = 0$ , and at the surface  $z = L$ ,

$$-c\mathcal{D}_{12} \left. \frac{\partial x_1}{\partial z} \right|_{z=L} = \mathcal{G}_{m1} (y_{1,s} - y_{1,e}) \quad (4.7.41)$$

The convective boundary condition is of the same form as Newton's law of cooling, and defines the mole transfer conductance  $\mathcal{G}_{m1}$  (kmol/m<sup>2</sup>sec) (see also the section on mass and mole transfer conductances). Also, we have followed chemical engineering practice and denoted mole fraction  $x$  in the solid (or liquid) phase and  $y$  in the liquid (or gas) phase, to emphasize that generally mole fraction is not continuous across a phase interface. For example, consider absorption of a sparingly soluble gas into a liquid for which Henry's law, Equation (4.7.13), applies: then  $y_{1,s} = \text{Hex}_{1,u}$ .

In using heat conduction charts for mass diffusion problems, particular care must be taken with the evaluation of the Biot number. For heat conduction  $\text{Bi} = h_c L / k$ , where  $k$  is the solid conductivity. For mass diffusion the Biot number accounts for the discontinuity in concentration across the phase interface. Using gas absorption into a plane layer of liquid, for example, when Equation (4.7.41) is put into an appropriate dimensionless form, the mass transfer Biot number is seen to be

$$\text{Bi}_m = \frac{\mathcal{G}_{m1} \text{He}L}{c\mathcal{D}_{12}} \quad (4.7.42)$$

For sparingly soluble gases, e.g., O<sub>2</sub> or CO<sub>2</sub> in water, He, and hence  $\text{Bi}_m$ , are very large, and the absorption process is liquid-side controlled; that is, a uniform gas-phase composition can be assumed. Often interface equilibrium data are in graphical or tabular form; then an effective Biot number at the concentration of concern must be used.

For example, consider a 2-mm-diameter droplet of water at 300 K entrained in an air flow at 1 atm pressure containing 1% by volume CO<sub>2</sub>. From Table 4.7.5,  $\text{He} = C_{\text{He}} = 1710$ . The liquid phase molar density can be approximated by the pure water value of  $c = \rho/M = 996/18 = 55.3$  kmol/m<sup>3</sup>. The liquid phase diffusion coefficient is obtained from Table 4.7.4 as  $\mathcal{D}_{12} = \nu_{\text{H}_2\text{O}} / \text{Sc}_{12} = 0.87 \times 10^{-6} / 420 = 2.07 \times 10^{-9}$  m<sup>2</sup>/sec. For negligible relative motion between the droplet and gas, the Sherwood number (see the section on dimensionless groups) is approximately 2.0, and hence the gas phase mole transfer conductance is  $\mathcal{G}_{m1} = 2c\mathcal{D}_{12}/\mathcal{D}$ . For the gas phase, the molar density  $c = \mathcal{P}/\mathcal{R}T = (1.0133 \times 10^5)/(8314)(300) = 0.0406$  kmol/m<sup>3</sup> and  $\mathcal{D}_{12} = 0.157 \times 10^{-4}$  m<sup>2</sup>/sec from Table 4.7.2. Thus,

$$\mathcal{G}_{m1} = \frac{(2)(0.0406)(0.157 \times 10^{-4})}{(0.002)} = 6.37 \times 10^{-4} \text{ kmol/m}^2 \text{ sec}$$

From Equation 4.7.42 with  $L = R$  the droplet radius, the mass transfer Biot number is

$$\text{Bi}_m = \frac{(6.37 \times 10^{-4})(1710)(0.001)}{(55.3)(2.07 \times 10^{-9})} = 9520$$

Thus, even for a small droplet with a relatively large gas-side mole transfer conductance, the absorption process is liquid-side controlled.

### Diffusion in a Porous Catalyst

Porous catalysts are used to give a large surface area per unit volume of catalyst surface. Current practice for automobile catalytic converters is to use a ceramic matrix as a support for a thin porous alumina layer that is impregnated with the catalyst (called a *washcoat*). A typical matrix has passages of hydraulic diameter 1 mm, and the washcoat may be about 20  $\mu\text{m}$  thick. Pore sizes are of the order of 1  $\mu\text{m}$  for which ordinary and Knudsen diffusion resistances are important. A simple model for diffusion in a porous catalyst is

$$\mathbf{J}_1 = -c\mathcal{D}_{1,\text{eff}}\nabla x_1 \quad \text{kmol/m}^2 \text{ sec} \quad (4.7.43)$$

where the subscript eff denotes an effective diffusivity that accounts for the presence of the solid material. Assuming additive resistances,

$$\frac{1}{\mathcal{D}_{1,\text{eff}}} = \frac{1}{\mathcal{D}_{12,\text{eff}}} + \frac{1}{\mathcal{D}_{K1,\text{eff}}} \quad (4.7.44)$$

and

$$\mathcal{D}_{12,\text{eff}} = \frac{\varepsilon_v}{\tau} \mathcal{D}_{12}; \quad \mathcal{D}_{K1,\text{eff}} = \frac{\varepsilon_v}{\tau} \mathcal{D}_{K1,\text{eff}} \quad (4.7.45)$$

where  $\varepsilon_v$  is the volume void fraction and  $\tau$  is the tortuosity factor (usually between 4 and 8). From the kinetic theory of gases the Knudsen diffusion coefficient is

$$\mathcal{D}_{K1} = 97r_e \left( T/M_1 \right)^{1/2} \text{ m}^2/\text{sec} \quad (4.7.46)$$

for effective pore radius  $r_e$  in meters and  $T$  in kelvins.

When a chemical reaction takes place within a porous layer, a concentration gradient is set up, and surfaces on pores deep within the pellet are exposed to lower reactant concentrations than surfaces near the pore openings. For a first-order reaction it is straightforward to obtain the concentration distribution. The results of such an analysis are conveniently given in the form of an effectiveness  $\eta_p$ , which is defined as the actual consumption rate of the reactant divided by that for an infinite diffusion coefficient. For a layer of thickness  $L$  exposed to reactants on one side, as shown in [Figure 4.7.5](#).

$$\eta_p = \frac{\tanh bL}{bL}; \quad b = \left( \frac{k''a_p}{\mathcal{D}_{1,\text{eff}}} \right)^{1/2} \quad (4.7.47)$$

where  $k''$  (m/sec) is the rate constant for a first-order reaction and  $a_p$  ( $\text{m}^{-1}$ ) is the catalyst area per unit volume. Notice that this effectiveness is analogous to the efficiency of a heat transfer fin.

For example, consider a 30- $\mu\text{m}$ -thick porous alumina washcoat with a volume void fraction  $\varepsilon_v = 0.8$ , a tortuosity factor  $\tau = 4.0$ , average pore radius  $r_e = 1 \mu\text{m}$ , and catalytic surface area per unit volume  $a_p = 7.1 \times 10^5 \text{ cm}^2/\text{cm}^3$ . For carbon monoxide oxidation by copper oxide at 800 K, 1 atm, the rate constant is approximately  $4.2 \times 10^{-4} \text{ m}^2/\text{sec}$ . To calculate the effectiveness of the washcoat, we first need to calculate the effective diffusion coefficient  $\mathcal{D}_{1,\text{eff}}$ :

FIGURE 4.7.5 A catalyst layer.

$$\mathcal{D}_{12,\text{eff}} = \frac{\epsilon_v}{\tau} \mathcal{D}_{12} = \frac{0.8}{4.0} (1.06 \times 10^{-4}) = 2.12 \times 10^{-5} \text{ m}^2/\text{sec}$$

where  $\mathcal{D}_{12}$  is approximated as the CO-air value from Table 4.7.2.

$$\mathcal{D}_{K1,\text{eff}} = \frac{\epsilon_v}{\tau} \mathcal{D}_{12} = \frac{0.8}{4.0} (97) (1 \times 10^{-6}) (800/28)^{1/2} = 1.04 \times 10^{-4} \text{ m}^2/\text{sec}$$

$$\frac{1}{\mathcal{D}_{1,\text{eff}}} = \frac{1}{2.12 \times 10^{-5}} + \frac{1}{1.04 \times 10^{-4}}; \quad \mathcal{D}_{1,\text{eff}} = 1.76 \times 10^{-5} \text{ m}^2/\text{sec}$$

$$b = \left[ \frac{(4.2 \times 10^{-4})(7.1 \times 10^5)(10^2)}{1.76 \times 10^{-5}} \right]^{1/2} = 4.2 \times 10^4 \text{ m}^{-1}; \quad bL = (4.2 \times 10^4)(30 \times 10^{-6}) = 1.236$$

$$\eta_p = \frac{\tanh 1.236}{1.236} = 68.3\%$$

In an automobile catalytic convertor, Equation 4.7.47 applies to the catalyst washcoat. However, the mass transfer problem also involves a convective process for transport of reactants from the bulk flow. Referring to Figure 4.7.6 there are two mass transfer resistances in series, and the consumption rate of species 1 per unit surface area of the washcoat is

$$J_{1,s} = \frac{-x_{1,e}}{\frac{1}{L\eta_p k'' c} + \frac{1}{\mathcal{G}_{m1}}} \text{ kmol/m}^2 \text{ sec} \quad (4.7.48)$$

where  $\mathcal{G}_{m1}$  is the mole transfer conductance describing convective transport to the washcoat surface (see the section on mass and mole transfer conductances). Notice that when  $\mathcal{G}_{m1} \ll L\eta_p k'' c$  the reaction rate is controlled by mass transfer from the gas stream to the washcoat surface; when  $L\eta_p k'' c \ll \mathcal{G}_{m1}$ , the reaction rate is controlled by diffusion within the washcoat and the kinetics of the reaction.

FIGURE 4.7.6 Equivalent circuit for mass transfer in an automobile catalytic convertor.

### Diffusion in a Moving Medium

Net mass transfer across a surface results in a velocity component normal to the surface, and an associated convective flux in the direction of mass transfer. This convective flow is called a *Stefan flow*. The solutions of a number of mass transfer problems, involving a Stefan flow induced by the mass transfer process itself, follow. When necessary to obtain an analytical result, properties are assumed constant. Thus, use of these results requires evaluation of properties at a suitable reference state.

### Diffusion with One Component Stationary

As an example, consider the simple heat pipe shown in Figure 4.7.7 with the evaporator and condenser located at the ends only (a bad design!). Then, if the working fluid is species 1, and a noncondensable gas is species 2, the concentration distribution is

$$\left( \frac{1 - x_1}{1 - x_{1,s}} \right) = \left( \frac{1 - x_{1,e}}{1 - x_{1,s}} \right)^{z/L} \tag{4.7.49}$$

and the vapor flux along the heat pipe is

$$N_1 = \frac{c\mathcal{D}}{L} \ln \frac{1 - x_{1,e}}{1 - x_{1,s}} \text{ kmol/m}^2 \text{ sec} \tag{4.7.50}$$

FIGURE 4.7.7 A simple heat pipe with the evaporator and condenser located at its ends.

Notice that  $N_2 = 0$ ; that is, the gas is stationary. The rate of heat flow for a heat pipe of cross-sectional area of  $A_c$  is  $\dot{Q} = N_1 M_1 h_{fg} A_c$ . Evaluation of the  $c\mathcal{D}$  product at a reference temperature  $T_r = (1/2)(T_s + T_e)$  is adequate for most applications. Equation (4.7.50) applies to any situation where a one-dimensional model of mass transport is appropriate.

### Heterogeneous Combustion

As an example, consider a small carbon particle entrained in a high-temperature airstream, as shown in Figure 4.7.8. The surface reaction is  $2C + O_2 \rightarrow 2CO$  and there are no reactions in the gas phase. The stoichiometric ratio for the reaction is  $r = 4/3$  kg oxygen/kg carbon. The reaction is diffusion controlled at the temperatures under consideration, that is,  $m_{O_2,s} \approx 0$ . The mass transfer rate is  $n_s$ , which we give

the distinctive symbol  $\dot{m}''$  since it is usually the desired result of an analysis; in this situation  $\dot{m}'' = n_{C,u}$  is the combustion rate of carbon, and for a spherical particle of radius  $R$  is given by

$$\dot{m}'' = \frac{\rho \mathcal{D}_{O_2,m}}{R} \ln \left[ 1 + \frac{m_{O_2,e} - m_{O_2,s}}{m_{O_2,s} + 4/3} \right] = 0.160 \frac{\rho \mathcal{D}_{O_2,m}}{R} \text{ kg/m}^2 \text{ sec} \quad (4.7.51)$$

**FIGURE 4.7.8** Combustion of a carbon particle in high-temperature air. The surface reaction is  $2C + O_2 \rightarrow 2CO$ .

The carbon particle temperature depends on its radius, and it is required to evaluate the property product  $\rho \mathcal{D}$  at an appropriate reference temperature: an energy balance on the particle should be performed by this purpose. The resulting particle lifetime  $\tau$  is

$$\tau = \frac{\rho_{\text{solid}} D_0^2}{1.28 (\rho \mathcal{D}_{O_2,m})_r} \text{ sec} \quad (4.7.52)$$

for an initial particle diameter of  $D_0$ . Air properties at an average mean film temperature can be used to evaluate  $\rho \mathcal{D}_{O_2,m}$ .

Consider a 10- $\mu\text{m}$ -diameter carbon particle ignited in an airstream at 1500 K and 1 atm. An energy balance on the particle (including radiation to surroundings at 1500 K) shows that the average temperature of the particle is approximately 2550 K, and, thus,  $T_r = (1/2)(1500 + 2550) = 2025$  K or  $\rho \approx \rho_{\text{air}} = 0.175$  kg/m<sup>3</sup> and  $\mathcal{D}_{O_2,m} \approx \mathcal{D}_{O_2,\text{air}} = 4.89 \times 10^{-4}$  m<sup>2</sup>/sec (from Table 4.7.1). Then

$$\tau = \frac{(1810)(10 \times 10^{-6})^2}{(1.28)(0.175)(4.89 \times 10^{-4})} = 1.65 \times 10^{-3} \text{ sec}$$

### Droplet Evaporation

Consider a small droplet of species 1 entrained in a gas stream, species 2 (Figure 4.7.9). This is a simultaneous heat and mass transfer problem, and the mass transfer rate can be obtained by solving simultaneously

$$\dot{m}'' = \frac{\rho \mathcal{D}_{12}}{R} \ln \left( 1 + \frac{m_{1,e} - m_{1,s}}{m_{1,s} - 1} \right) = \frac{k/c_{p1}}{R} \ln \left( 1 + \frac{c_{p1}(T_e - T_s)}{h_{fg}} \right) \text{ kg/m}^2 \text{ sec} \quad (4.7.53a)$$

$$m_{1,s} = m_{1,s}(T, P) \quad (\text{from vapor-pressure data}) \quad (4.7.53b)$$

**FIGURE 4.7.9** Evaporation of a droplet.

Temperature  $T_s$  is the adiabatic vaporization temperature and is essentially the psychrometric wet-bulb temperature. Properties can be evaluated at mean film temperature and composition; alternatively,  $c_{p1}$  can be set equal to the reference specific heat and all properties evaluated using Hubbard's  $1/3$  rule, namely,

$$m_{1,r} = m_{1,s} + (1/3)(m_{1,e} - m_{1,s}) \quad (4.7.54a)$$

$$T_r = T_s + (1/3)(T_e - T_s) \quad (4.7.54b)$$

### Droplet Combustion

Figure 4.7.10 shows a schematic of a volatile liquid hydrocarbon fuel droplet burning in air at zero gravity. The flame diameter is typically four to six times the droplet diameter. Heat is transferred from the flame to the droplet and serves to vaporize the fuel. In the flame the vapor reacts with oxygen to form gaseous products, primarily  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . When a fuel droplet ignites, there is a short initial transient during which the droplet heats up, until further conduction into the droplet is negligible and the droplet attains a steady temperature (approximately the wet-bulb temperature, which is very close to the boiling point for a typical hydrocarbon fuel). The reaction in the flame can be modeled as a single-step reaction with a constant stoichiometric ratio,  $r$ , and heat of combustion  $\Delta h_c$  J/kg of fuel.

The burning (mass transfer) rate of the droplet is given by the Godsave–Spalding formula,

$$\dot{m}'' = \frac{k/c_p}{R} \ln[1 + \mathcal{B}] \text{ kg/m}^2 \text{ sec} \quad (4.7.55)$$

where

$$\mathcal{B} = \frac{m_{\text{ox},e} \Delta h_c / r + c_p (T_e - T_s)}{h_{fg}}$$

is the *mass transfer driving force* (or *transfer number*). The droplet lifetime is then

$$\tau = \frac{\rho_l D_0^2}{8(k/c_p) \ln(1 + \mathcal{B})} \text{ sec} \quad (4.7.56)$$

Based on experimental data for alkane droplets burning in air, Law and Williams (1972) recommend that properties be evaluated at a reference temperature  $T_r = (1/2)(T_{BP} + T_{\text{flame}})$  where  $T_{\text{flame}}$  is the adiabatic flame temperature. The reference specific heat is  $c_{pr} = c_{pfu}$ , and the reference thermal conductivity is  $k$ ,

**FIGURE 4.7.10** Combustion of a volatile fuel droplet burning in air: (a) schematic showing the flame, (b) concentration and temperature profiles.

$= 0.4k_{fu} + 0.6k_{air}$ . Radiation has been ignored in the analysis leading to Equation (4.7.55) but is accounted for in using the Law and Williams reference-property scheme.

For example, consider a 1-mm-diameter *n*-octane droplet burning in air at 1 atm and 300 K, at near zero gravity. For *n*-octane ( $n\text{-C}_8\text{H}_{18}$ ),  $\rho_l = 611 \text{ kg/m}^3$ ,  $h_{fg} = 3.03 \times 10^5 \text{ J/kg}$ ,  $\Delta h_c = 4.44 \times 10^7 \text{ J/kg}$ , and  $T_{BP} = 399 \text{ K}$ . The flame temperature is  $T_{\text{flame}} = 2320 \text{ K}$ . At a reference temperature of  $(1/2)(T_{\text{flame}} + T_{BP}) = 1360 \text{ K}$ , property values of *n*-octane vapor include  $k = 0.113 \text{ W/m K}$ ,  $c_p = 4280 \text{ J/kg K}$ . The reaction is

Hence, the stoichiometric ratio  $r = 400/114.2 = 3.50$ . Also  $m_{ox,e} = 0.231$  and  $T_s \cong T_{BP} = 399 \text{ K}$ . Thus, the transfer number is

$$\mathcal{B} = \frac{(0.231)(4.44 \times 10^7)/(3.50) + 4280(300 - 399)}{3.03 \times 10^5} = 8.27$$

At  $T_r = 1360 \text{ K}$ ,  $k_{air} = 0.085 \text{ W/m K}$ . Hence,

$$k_r = 0.4k_{fu} + 0.6k_{air} = (0.4)(0.113) + (0.6)(0.085) = 0.096 \text{ W/m K}$$

and the droplet lifetime is

$$\tau = \frac{(611)(1 \times 10^{-3})^2}{(8)(0.096/4280)\ln(1 + 8.27)} = 1.53 \text{ sec}$$

## Mass Convection

The terms *mass convection* or *convective mass transfer* are generally used to describe the process of mass transfer between a surface and a moving fluid, as shown in Figure 4.7.11. The surface may be that

**FIGURE 4.7.11** Notation for convective mass transfer into an external flow.

of a falling water film in an air humidifier, of a coke particle in a gasifier, or of a silica-phenolic heat shield protecting a reentry vehicle. As is the case for heat convection, the flow can be *forced* or *natural*, *internal* or *external*, and *laminar* or *turbulent*. In addition, the concept of whether the mass transfer rate is *low* or *high* plays an important role: when mass transfer rates are low, there is a simple analogy between heat transfer and mass transfer that can be efficiently exploited in the solution of engineering problems.

### Mass and Mole Transfer Conductances

Analogous to convective heat transfer, the rate of mass transfer by convection is usually a complicated function of surface geometry and  $s$ -surface composition, the fluid composition and velocity, and fluid physical properties. For simplicity, we will restrict our attention to fluids that are either binary mixtures or solutions, or situations in which, although more than two species are present, diffusion can be adequately described using effective binary diffusion coefficients, as was discussed in the section on ordinary diffusion. Referring to [Figure 4.7.11](#), we define the *mass transfer conductance* of species 1,  $g_{m1}$ , by the relation

$$j_{1,s} = g_{m1} \Delta m_1; \quad \Delta m_1 = m_{1,s} - m_{1,e} \quad (4.7.57)$$

and the units of  $g_{m1}$  are seen to be the same as for mass flux ( $\text{kg}/\text{m}^2\text{sec}$ ). Equation (4.7.57) is of a similar form to Newton's law of cooling, which defines the heat transfer coefficient  $h_c$ . Why we should not use a similar name and notation (e.g., mass transfer coefficient and  $h_m$ ) will become clear later. On a molar basis, we define the *mole transfer conductance* of species 1,  $g_{m1}$ , by a corresponding relation,

$$J_{1,s} = g_{m1} \Delta x_1; \quad \Delta x_1 = x_{1,s} - x_{1,e} \quad (4.7.58)$$

where  $g_{m1}$  has units ( $\text{kmol}/\text{m}^2\text{sec}$ ).

### Low Mass Transfer Rate Theory

Consider, as an example, the evaporation of water into air, as shown in [Figure 4.7.12](#). The water–air interface might be the surface of a water reservoir, or the surface of a falling water film in a cooling tower or humidifier. In such situations the mass fraction of water vapor in the air is relatively small; the highest value is at the  $s$ -surface, but even if the water temperature is as high as  $50^\circ\text{C}$ , the corresponding value of  $m_{\text{H}_2\text{O},s}$  at 1 atm total pressure is only 0.077. From Equation 4.7.54 the driving potential for diffusion of water vapor away from the interface is  $\Delta m_1 = m_{1,s} - m_{1,e}$ , and is small compared to unity, even if the free-stream air is very dry such that  $m_{1,e} \approx 0$ . We then say that the mass transfer rate is *low* and the rate of evaporation of the water can be approximated as  $j_{1,s}$ ; for a surface area  $A$ ,

$$\dot{m}_1 = (m_{1,s} n_s + j_{1,s}) A \approx j_{1,s} A \text{ kg/sec} \quad (4.7.59)$$

**FIGURE 4.7.12** Evaporation of water into an air flow.

In contrast, if the water temperature approaches its boiling point,  $m_{1,s}$  is no longer small, and of course, in the limit of  $T_s = T_{BP}$ ,  $m_{1,s} = 1$ . The resulting driving potential for diffusion  $\Delta m_1$  is then large, and we say that the mass transfer rate is *high*. Then, the evaporation rate cannot be calculated from Equation 4.7.59, as will be explained in the section on high mass transfer rate theory. For water evaporation into air, the error incurred in using low mass transfer rate theory is approximately  $(1/2) \Delta m_1$ , and a suitable criterion for application of the theory to engineering problems is  $\Delta m_1 < 0.1$  or  $0.2$ .

A large range of engineering problems can be adequately analyzed assuming low mass transfer rates. These problems include cooling towers and humidifiers as mentioned above, gas absorbers for sparingly soluble gases, and catalysis. In the case of catalysis, the *net* mass transfer rate is actually zero. Reactants diffuse toward the catalyst surface and the products diffuse away, but the catalyst only promotes the reaction and is not consumed. On the other hand, problems that are characterized by high mass transfer rates include condensation of steam containing a small amount of noncondensable gas, as occurs in most power plant condensers; combustion of volatile liquid hydrocarbon fuel droplets in diesel engines and oil-fired power plants, and ablation of phenolic-based heat shields on reentry vehicles.

### Dimensionless Groups

Dimensional analysis of convective mass transfer yields a number of pertinent dimensionless groups that are, in general, analogous to dimensionless groups for convective heat transfer. The most important groups are as follows.

1. The Schmidt number,  $Sc_{12} = \mu/\rho\mathcal{D}_{12}$ , which is a properties group analogous to the Prandtl number. For gas mixtures,  $Sc_{12} = O(1)$ , and for liquid solutions,  $Sc_{12} = O(100)$  to  $O(1000)$ . There are not fluids for which  $Sc_{12} \ll 1$ , as is the case of Prandtl number for liquid metals.
2. The Sherwood number (or mass transfer Nusselt number).  $Sh = g_{m1}L/\rho\mathcal{D}_{12}$  ( $= \mathcal{G}_{m1}L/c\mathcal{D}_{12}$ ) is a dimensionless conductance.
3. The mass transfer Stanton number  $St_m = g_{m1}/\rho V$  ( $= \mathcal{G}_{m1}/cV$ ) is an alternative dimensionless conductance.

As for convective heat transfer, forced convection flows are characterized by a Reynolds number, and natural convection flows are characterized by a Grashof or Rayleigh number. In the case of Gr or Ra it is not possible to replace  $\Delta\rho$  by  $\beta\Delta T$  since density differences can result from concentration differences (and both concentration and temperature differences for simultaneous heat and mass transfer problems).

### Analogy between Convective Heat and Mass Transfer

A close analogy exists between convective heat and convective mass transfer owing to the fact that conduction and diffusion in a fluid are governed by physical laws of identical form, that is, Fourier's and Fick's laws, respectively. As a result, in many circumstances the Sherwood or mass transfer Stanton number can be obtained in a simple manner from the Nusselt number or heat transfer Stanton number for the same flow conditions. Indeed, in most gas mixtures  $Sh$  and  $St_m$  are nearly equal to their heat transfer counterparts. For dilute mixtures and solutions and low mass transfer rates, the rule for exploiting the analogy is simple: *The Sherwood or Stanton number is obtained by replacing the Prandtl number by the Schmidt number in the appropriate heat transfer correlation.* For example, in the case of fully developed turbulent flow in a smooth pipe

$$Nu_D = 0.023Re_D^{0.8}Pr^{0.4}; \quad Pr > 0.5 \quad (4.7.60a)$$

which for mass transfer becomes

$$Sh_D = 0.023Re_D^{0.8}Sc^{0.4}; \quad Sc > 0.5 \quad (4.7.60b)$$

Also, for natural convection from a heated horizontal surface facing upward,

$$\overline{Nu} = 0.54(Gr_L Pr)^{1/4}; \quad 10^5 < Gr_L Pr < 2 \times 10^7 \quad (\text{laminar}) \quad (4.7.61a)$$

$$\overline{Nu} = 0.14(Gr_L Pr)^{1/3}; \quad 2 \times 10^7 < Gr_L Pr < 3 \times 10^{10} \quad (\text{turbulent}) \quad (4.7.61b)$$

which for isothermal mass transfer with  $\rho_s < \rho_e$  become

$$\overline{Sh} = 0.54(Gr_L Sc)^{1/4}; \quad 10^5 < Gr_L Sc < 2 \times 10^7 \quad (\text{laminar}) \quad (4.7.62a)$$

$$\overline{Sh} = 0.14(Gr_L Sc)^{1/3}; \quad 2 \times 10^7 < Gr_L Sc < 3 \times 10^{10} \quad (\text{turbulent}) \quad (4.7.62b)$$

With evaporation, the condition,  $\rho_s < \rho_e$  will be met when the evaporating species has a smaller molecular weight than the ambient species, for example, water evaporating into air. Mass transfer correlations can be written down in a similar manner for almost all the heat transfer correlations given in Section 4.2. There are some exceptions: for example, there are no fluids with a Schmidt number much less than unity, and thus there are no mass transfer correlations corresponding to those given for heat transfer to liquid metals with  $Pr \ll 1$ . In most cases it is important for the wall boundary conditions to be of analogous form, for example, laminar flow in ducts. A uniform wall temperature corresponds to a uniform concentration  $m_{1,s}$  along the  $s$ -surface, whereas a uniform heat flux corresponds to a uniform diffusive flux  $j_{1,s}$ . In chemical engineering practice, the analogy between convective heat and mass transfer is widely used in a form recommended by Chilton and Colburn in 1934, namely,  $St_m/St = (Sc/Pr)^{-2/3}$ . The Chilton-Colburn form is of adequate accuracy for most external forced flows but is inappropriate for fully developed laminar duct flows.

For example, air at 1 atm and 300 K flows inside a 3-cm-inside-diameter tube at 10 m/sec. Using pure-air properties the Reynolds number is  $VD/\nu = (10)(0.03)/15.7 \times 10^{-6} = 1.911 \times 10^4$ . The flow is turbulent. Using Equation (4.7.60b) with  $Sc_{12} = 0.61$  for small concentrations of  $H_2O$  in air,

$$Sh_D = (0.023)(1.911 \times 10^4)^{0.8} (0.61)^{0.4} = 50.2$$

$$g_{m1} = \rho \mathcal{D}_{12} \text{Sh}/D = \rho v \text{Sh}/\text{Sc}_{12} D = \frac{(1.177)(15.7 \times 10^{-6})(50.2)}{(0.61)(0.03)} = 5.07 \times 10^{-2} \text{ kg/m}^2 \text{ sec}$$

Further insight into this analogy between convective heat and mass transfer can be seen by writing out Equations (4.7.60a) and (4.7.60b) as, respectively,

$$\frac{(h_c/c_p)D}{k/c_p} = 0.023 \text{Re}_D^{0.8} \left( \frac{\mu}{k/c_p} \right)^{0.4} \quad (4.7.63a)$$

$$\frac{g_m D}{\rho \mathcal{D}_{12}} = 0.023 \text{Re}_D^{0.8} \left( \frac{\mu}{\rho \mathcal{D}_{12}} \right)^{0.4} \quad (4.7.63b)$$

When cast in this form, the correlations show that the property combinations  $k/c_p$  and  $\rho \mathcal{D}_{12}$  play analogous roles; these are *exchange coefficients* for heat and mass, respectively, both having units kg/m sec, which are the same as those for dynamic viscosity  $\mu$ . Also, it is seen that the ratio of heat transfer coefficient to specific heat plays an analogous role to the mass transfer conductance, and has the same units (kg/m<sup>2</sup> sec). Thus, it is appropriate to refer to the ratio  $h_c/c_p$  as the *heat transfer conductance*,  $g_h$ , and for this reason we should not refer to  $g_m$  as the mass transfer *coefficient*.

### Simultaneous Heat and Mass Transfer

Often problems involve simultaneous convective heat and mass transfer, for which the surface energy balance must be carefully formulated. Consider, for example, evaporation of water into air, as shown in Figure 4.7.13. With H<sub>2</sub>O denoted as species 1, the steady-flow energy equation applied to a control volume located between the  $u$ - and  $s$ -surfaces requires that

$$\dot{m}(h_{1,s} - h_{1,u}) = A(q''_{\text{cond}} - q''_{\text{conv}} - q''_{\text{rad}}) W \quad (4.7.64)$$

where it has been recognized that only species 1 crosses the  $u$ - and  $s$ -surfaces. Also, the water has been assumed to be perfectly opaque so that all radiation is emitted or absorbed between the  $u$ -surface and the interface.

If we restrict our attention to conditions for which low mass transfer rate theory is valid, we can write  $\dot{m}/A \approx j_{1,s} = g_{m1}(m_{1,s} - m_{1,e})$ . Also, we can then calculate the convective heat transfer as if there were no mass transfer, and write  $q_{\text{conv}} = h_c(T_s - T_e)$ . Substituting in Equation (4.7.64) with  $q_{\text{conv}} = -k\partial T/\partial y|_u$ ,  $h_{1,s} - h_{1,u} = h_{fg}$ , and rearranging, gives

$$-k \frac{\partial T}{\partial y} \Big|_u = h_c(T_s - T_e) + g_{m1}(m_{1,s} - m_{1,e})h_{fg} + q''_{\text{rad}} W/m^2 \quad (4.7.65)$$

It is common practice to refer to the convective heat flux  $h_c(T_s - T_e)$  as the *sensible* heat flux, whereas the term  $g_{m1}(m_{1,s} - m_{1,e})h_{fg}$  is called the *evaporative* or *latent* heat flux. Each of the terms in Equation 4.7.65 can be positive or negative, depending on the particular situation. Also, the evaluation of the conduction heat flux at the  $u$ -surface,  $-k\partial T/\partial y|_u$ , depends on the particular situation. Four examples are shown in Figure 4.7.13. For a water film flowing down a packing in a cooling tower (Figure 4.7.13b), this heat flux can be expressed in terms of convective heat transfer from the bulk water at temperature  $T_L$  to the surface of the film,  $-k\partial T/\partial y|_u = h_{cL}(T_L - T_s)$ . If the liquid-side heat transfer coefficient  $h_{cL}$  is large enough, we can simply set  $T_s \approx T_L$ , which eliminates the need to estimate  $h_{cL}$ . The evaporation process is then *gas-side controlled*. Figure 4.7.13c shows film condensation from a steam-air mixture on the outside of a vertical tube. In this case we can write  $k\partial T/\partial y|_u = U(T_s - T_c)$ , where  $T_c$  is the coolant

FIGURE 4.7.13 The surface energy balance for evaporation of water into an air stream.

bulk temperature. The overall heat transfer coefficient  $U$  includes the resistances of the condensate film, the tube wall, and the coolant. Sweat cooling is shown in Figure 4.7.13d, with water from a reservoir (or *plenum chamber*) injected through a porous wall at a rate just sufficient to keep the wall surface wet. In this case, the conduction across the  $u$ -surface can be related to the reservoir conditions by application of the steady-flow energy equation to a control volume located between the  $o$ - and  $u$ -surfaces. Finally, Figure 4.7.13e shows drying of a wet porous material (e.g., a textile or wood). During the constant-rate period of the process, evaporation takes place from the surface with negligible heat conduction into the solid; then  $-k\partial T/\partial y|_u \approx 0$ . The term *adiabatic vaporization* is used to describe evaporation when  $q_{\text{cond}} = 0$ ; constant-rate drying is one example, and the wet-bulb psychrometer is another.

Consider a 1-m-square wet towel on a washline on a day when there is a low overcast and no wind. The ambient air is at 21°C, 1 atm, and 50.5% RH. In the constant-rate drying period the towel temperature is constant, and  $q_{\text{cond}} = 0$ . An iterative calculation is required to obtain the towel temperature using correlations for natural convection on a vertical surface to obtain  $h_c$  and  $g_{m1}$ ;  $q_{\text{rad}}$  is obtained as  $q_{\text{rad}} = \sigma\epsilon(T_s^4 - T_e^4)$  with  $\epsilon = 0.90$ . The results are  $T_s = 17.8^\circ\text{C}$ ,  $h_c = 1.69 \text{ W/m}^2\text{K}$ ,  $g_{m1} = 1.82 \times 10^{-3} \text{ kg/m}^2\text{sec}$ , and the energy balance is

$$q_{\text{cond}} = h_c(T_s - T_e) + g_{m1}(m_{1,s} - m_{1,e})h_{fg} + q_{\text{rad}}$$

$$0 = -5.4 + 21.7 - 16.3 \text{ W/m}^2$$

Evaluation of composition-dependent properties, in particular the mixture specific heat and Prandtl number, poses a problem. In general, low mass transfer rates imply small composition variations across a boundary layer, and properties can be evaluated for a mixture of the free-stream composition at the mean film temperature. In fact, when dealing with evaporation of water into air, use of the properties of dry air at the mean film temperature gives results of adequate engineering accuracy. If there are large composition variations across the boundary layer, as can occur in some catalysis problems, properties should be evaluated at the mean film composition and temperature.

### The Wet- and Dry-Bulb Psychrometer

The wet- and dry-bulb psychrometer is used to measure the moisture content of air. In its simplest form, the air is made to flow over a pair of thermometers, one of which has its bulb covered by a wick whose other end is immersed in a small water reservoir. Evaporation of water from the wick causes the wet bulb to cool and its steady-state temperature is a function of the air temperature measured by the dry bulb and the air humidity. The wet bulb is shown in Figure 4.7.14. In order to determine the water vapor mass fraction  $m_{1,e}$ , the surface energy balance Equation (4.7.66) is used with conduction into the wick and  $q_{\text{rad}}''$  set equal to zero. The result is

$$m_{1,e} = m_{1,s} - \frac{c_p}{h_{fg}} \left( \frac{\text{Pr}}{\text{Sc}_{12}} \right)^{-2/3} (T_e - T_s) \quad (4.7.66)$$

Usually  $m_{1,e}$  is small and we can approximate  $c_p = c_{p, \text{air}}$  and  $(\text{Pr}/\text{Sc}_{12})^{-2/3} = 1/1.08$ . Temperatures  $T_s$  and  $T_e$  are the known measured wet- and dry-bulb temperatures. With  $T_s$  known,  $m_{1,s}$  can be obtained using steam tables in the usual way. For example, consider an air flow at 1000 mbar with measured wet- and dry-bulb temperatures of 305.0 and 310.0 K, respectively. Then  $P_{1,s} = P_{\text{sat}}(T_s) = P_{\text{sat}}(305.0 \text{ K}) = 4714 \text{ Pa}$  from steam tables. Hence,  $x_{1,s} = P_{1,s}/P = 4714/10^5 = 0.04714$ , and

$$m_{1,s} = \frac{0.04714}{0.04714 + (29/18)(1 - 0.04714)} = 0.02979$$

**FIGURE 4.7.14** Wet bulb of a wet- and dry-bulb psychrometer.

Also,  $h_{fg}$  (305 K) =  $2.425 \times 10^6$  J/kg, and  $c_{p, \text{air}} = 1005$  J/kg K; thus

$$m_{1,e} = 0.02979 - \frac{1005}{(1.08)(2.425 \times 10^6)}(310 - 305) = 0.02787$$

$$x_{1,e} = \frac{0.02787}{0.02787 + (18/29)(1 - 0.02787)} = 0.04415$$

$$P_{1,e} = x_{1,e}P = (0.04415)(10^5) = 4412 \text{ Pa}$$

By definition, the relative humidity is  $\text{RH} = P_{1,e}/P_{\text{sat}}(T_e)$ ;  $\text{RH} = 4415/6224 = 70.9\%$ .

In the case of other adiabatic vaporization processes, such as constant-rate drying or evaporation of a water droplet,  $m_{1,e}$  and  $T_e$  are usually known and Equation (4.7.66) must be solved for  $T_s$ . However, the thermodynamic wet-bulb temperature obtained from psychrometric charts or software is accurate enough for engineering purposes.

### High Mass Transfer Rate Theory

When there is net mass transfer across a phase interface, there is a convective component of the absolute flux of a species across the  $s$ -surface. From Equation (4.7.23a) for species 1,

$$n_{1,s} = \rho_{1,s}v_s + j_{1,s} \text{ kg/m}^2 \text{ sec} \quad (4.7.67)$$

During evaporation the convection is directed in the gas phase, with a velocity normal to the surface  $v_s$ . When the convective component cannot be neglected, we say that the mass transfer rate is *high*. There are two issues to consider when mass transfer rates are high. First, the rate at which species 1 is transferred across the  $s$ -surface is not simply the diffusive component  $j_{1,s}$  as assumed in low mass transfer rate theory, but is the sum of the convective and diffusive components shown in Equation 4.7.67. Second, the normal velocity component  $v_s$  has a *blowing* effect on the concentration profiles, and hence on the Sherwood number. The Sherwood number is no longer analogous to the Nusselt number of conventional heat transfer correlations, because those Nusselt numbers are for situations involving impermeable surfaces, e.g., a metal wall, for which  $v_s = 0$ .

Substituting for  $j_{1,s}$  from Equation (4.7.57) into Equation (4.7.67) gives

$$\dot{m}'' = g_{m1} \frac{m_{1,e} - m_{1,s}}{m_{1,s} - n_{1,s}/\dot{m}''} = g_{m1} \mathcal{B}_{m1} \quad (4.7.68)$$

where  $\dot{m}'' = n_s$  is the mass transfer rate introduced in the section on heterogeneous combustion and  $\mathcal{B}_{m1}$  is the *mass transfer driving force*. In the special case where only species 1 is transferred,  $n_{1,s}/\dot{m}'' = 1$ , for example, when water evaporates into air, and dissolution of air in the water is neglected. It is convenient to rewrite Equation (4.7.68) as

$$\dot{m}'' = g_{m1}^* (g_{m1}/g_{m1}^*) \mathcal{B}_{m1} \text{ kg/m}^2 \text{ sec} \quad (4.7.69a)$$

where

$$g_{m1}^* = \lim_{\mathcal{B}_{m1} \rightarrow 0} g_{m1} \quad (4.7.69b)$$

Now  $g_{m1}^*$  is the limit value of  $g_{m1}$  for zero mass transfer (i.e.,  $v_s = 0$ ), and  $\text{Sh}^*$  can be obtained from conventional heat transfer Nusselt number correlations for impermeable surfaces. The ratio  $(g_{m1}/g_{m1}^*)$  is termed a *blowing factor* and accounts for the effect of  $v_s$  on the concentration profiles. Use of Equation (4.7.69) requires appropriate data for the blowing factor. For the constant-property laminar boundary layer on a flat plate, Figure 4.7.15 shows the effect of the Schmidt number on the blowing factor. The abscissa is a *blowing parameter*  $B_m = \dot{m}''/g_{m1}^*$ .

The blowing velocity also affects the velocity and temperature profiles, and hence the wall shear stress and heat transfer. The curve for  $\text{Sc} = 1$  in Figure 4.7.15 also gives the effect of blowing on shear stress as  $\tau_s/\tau_s^*$ , and the curve for  $\text{Sc} = 0.7$  gives the effect of blowing on heat transfer for air injection into air as  $h_c/h_c^*$  (since  $\text{Pr} = 0.7$  for air).

### Variable Property Effects of High Mass Transfer Rates

High mass transfer rate situations are usually characterized by large property variations across the flow, and hence property evaluation for calculating  $g_m$  and  $h_c$  is not straightforward. An often-encountered situation is transfer of a single species into an inert laminar or turbulent boundary layer flow. The effect of variable properties can be very large as shown in Figure 4.7.16 for laminar boundary layers, and Figure 4.7.17 for turbulent boundary layers.

A simple procedure for correlating the effects of flow type and variable properties is to use weighting factors in the exponential functions suggested by a constant-property Couette-flow model (Mills, 1995). Denoting the injected species as species  $i$ , we have

$$\frac{g_{m1}}{g_{m1}^*} = \frac{a_{mi} B_{mi}}{\exp(a_{mi} B_{mi}) - 1}; \quad B_{mi} = \frac{\dot{m}''}{g_{mi}^*} \quad (4.7.70a)$$

or

$$\frac{g_{m1}}{g_{mi}^*} = \frac{\ln(1 + a_{mi} B_{mi})}{a_{mi} B_{mi}}; \quad B_{mi} = \frac{\dot{m}''}{g_{mi}^*} = \frac{m_{i,e} - m_{i,s}}{m_{i,s} - 1}$$

$$\frac{\tau_s}{\tau_s^*} = \frac{a_{fi} B_f}{\exp(a_{fi} B_f) - 1}; \quad B_f = \frac{\dot{m}'' u_e}{\tau_s^*} \quad (4.7.70b)$$

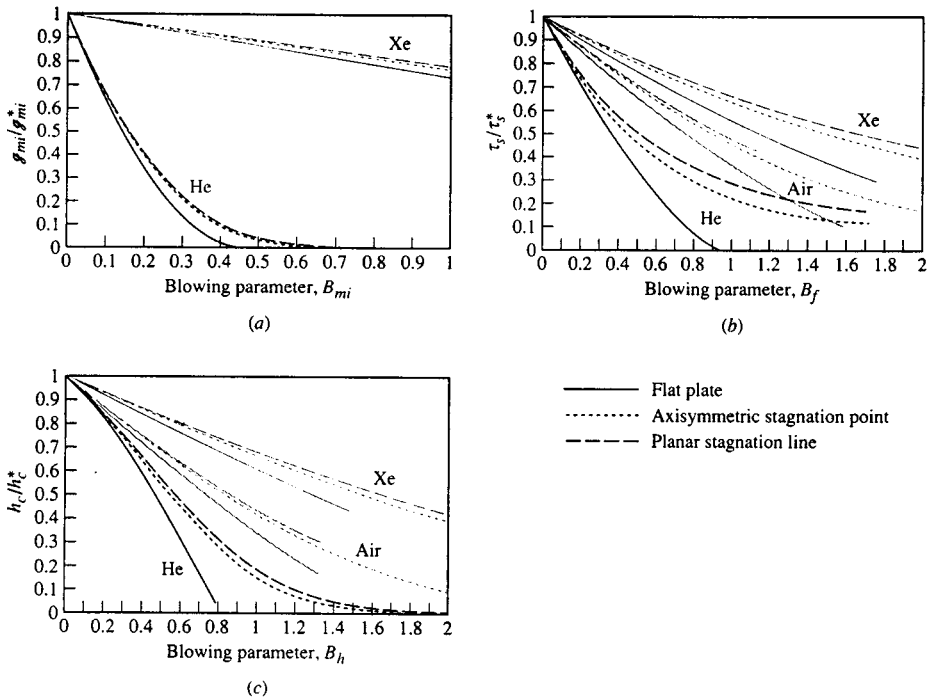

**FIGURE 4.7.15** Effect of mass transfer on the mass transfer conductance for a laminar boundary layer on a flat plate:  $g_m/g_m^*$  vs. blowing parameter  $B_m = \dot{m}''/g_m^*$ .

$$\frac{h_c}{h_c^*} = \frac{a_{hi} B_h}{\exp(a_{hi} B_h) - 1}; \quad B_h = \frac{\dot{m}'' c_{pe}}{h_c^*} \tag{4.7.70c}$$

Notice that  $g_{mi}^*$ ,  $\tau_s^*$ ,  $h_c^*$ , and  $c_{pe}$  are evaluated using properties of the free-stream gas at the mean film temperature. The weighting factor  $a$  may be found from exact numerical solutions of boundary layer equations or from experimental data. Some results for laminar and turbulent boundary layers follow.

1. *Laminar Boundary Layers.* We will restrict our attention to low-speed air flows, for which viscous dissipation and compressibility effects are negligible, and use exact numerical solutions of the self-similar laminar boundary layer equations (Wortman, 1969). Least-squares curve fits of the numerical data were obtained using Equations (4.7.70a) to (4.7.70c). Then, the weighting factors for axisymmetric stagnation-point flow with a cold wall ( $T_s/T_e = 0.1$ ) were correlated as

$$a_{mi} = 1.65(M_{air}/M_i)^{10/12} \tag{4.7.71a}$$

**FIGURE 4.7.16** Numerical results for the effect of pressure gradient and variable properties on blowing factors for laminar boundary layers: low-speed air flow over a cold wall ( $T_s/T_e = 0.1$ ) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Wortman, A., Ph.D. dissertation, University of California, Los Angeles, 1969. With permission.)

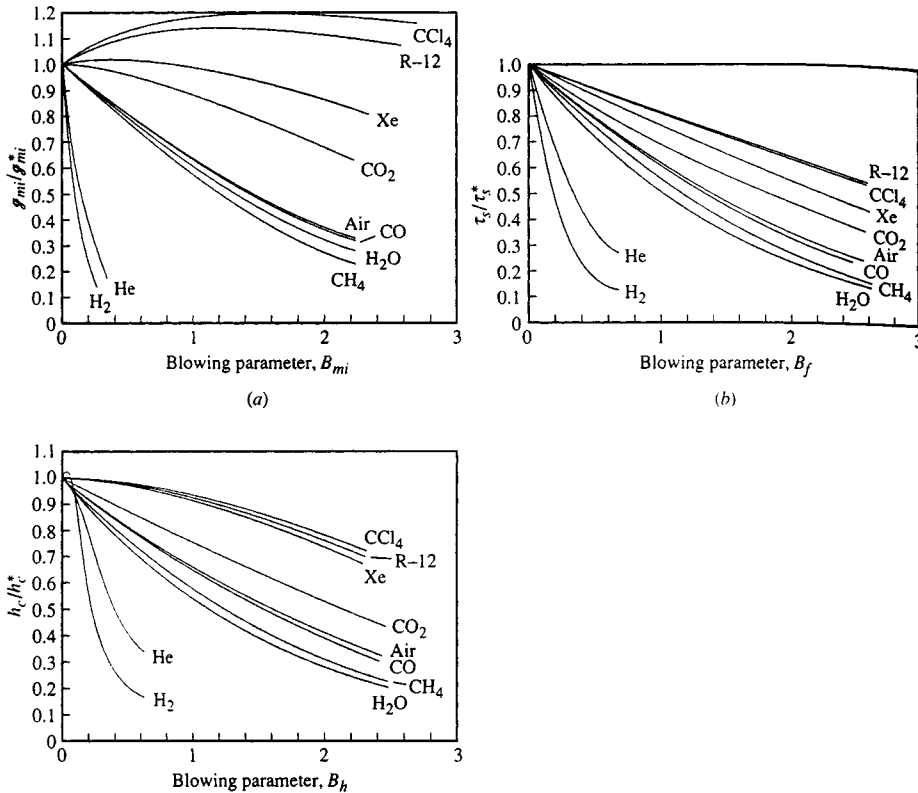

$$a_{fi} = 1.38(M_{air}/M_i)^{5/12} \tag{4.7.71b}$$

$$a_{hi} = 1.30(M_{air}/M_i)^{3/12} \left[ c_{pi} / (2.5\mathcal{R}/M_i) \right] \tag{4.7.71c}$$

Notice that  $c_{pi}/(2.5\mathcal{R}/M_i)$  is unity for a monatomic species. For the planar stagnation line and the flat plate, and other values of the temperature ratio  $T_s/T_e$ , the values of the species weighting factors are divided by the values given by Equations (4.7.71a,b,c) to give correction factors  $G_{mi}$ ,  $G_{fi}$ , and  $G_{hi}$ , respectively. The correction factors are listed in Table 4.7.7.

The exponential relation blowing factors cannot accurately represent some of the more anomalous effects of blowing. For example, when a light gas such as  $H_2$  is injected, Equation (4.7.70c) indicates that the effect of blowing is always to reduce heat transfer, due to both the low density and high specific heat of hydrogen. However, at very low injection rates, the heat transfer is actually increased, as a result of the high thermal conductivity of  $H_2$ . For a mixture,  $k \approx \sum x_i k_i$  whereas  $c_p = \sum m_i c_{pi}$ . At low rates of injection, the mole fraction of  $H_2$  near the wall is much larger than its mass fraction; thus, there is a substantial increase in the mixture conductivity near the wall, but only a small change in the mixture specific heat. An increase in heat transfer results. At higher injection rates, the mass fraction of  $H_2$  is also large, and the effect of high mixture specific heat dominates to cause a decrease in heat transfer.

2. *Turbulent Boundary Layers.* Here we restrict our attention to air flow along a flat plate for Mach numbers up to 6, and use numerical solutions of boundary layer equations with a mixing length turbulence model (Landis, 1971). Appropriate species weighting factors for  $0.2 < T_s/T_e < 2$  are

**FIGURE 4.7.17** Numerical results for the effect of variable properties on blowing factors for a low-speed turbulent air boundary layer on a cold flat plate ( $T_s/T_e = 0.2$ ) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Landis, R.B., Ph.D. dissertation, University of California, Los Angeles, 1971. With permission.)

$$a_{mi} = 0.79(M_{air}/M_i)^{1.33} \tag{4.7.72a}$$

$$a_{fi} = 0.91(M_{air}/M_i)^{0.76} \tag{4.7.72b}$$

$$a_{hi} = 0.86(M_{air}/M_i)^{0.73} \tag{4.7.72c}$$

In using Equation (4.7.70), the limit values for  $\dot{m}'' = 0$  are elevated at the same location along the plate. Whether the injection rate is constant along the plate or varies as  $x^{-0.2}$  to give a self-similar boundary layer has little effect on the blowing factors. Thus, Equation (4.7.72) has quite general applicability. Notice that the effects of injectant molecular weight are greater for turbulent boundary layers than for laminar ones, which is due to the effect of fluid density on turbulent transport. Also, the injectant specific heat does not appear in  $a_{hi}$  as it did for laminar flows. In general,  $c_{pi}$  decreases with increasing  $M_i$  and is adequately accounted for in the molecular weight ratio.

**Reference State Schemes.** The reference state approach, in which constant-property data are used with properties evaluated at some reference state, is an alternative method for handling variable-property effects. In principle, the reference state is independent of the precise property data used and of the

combination of injectant and free-stream species. A reference state for a boundary layer on a flat plate that can be used in conjunction with Figure 4.7.14 is (Knuth, 1963)

$$m_{1,r} = 1 - \frac{M_2}{M_2 - M_1} \frac{\ln(M_e/M_s)}{\ln(m_{2,e}M_e/m_{2,s}M_s)} \tag{4.7.73}$$

$$T_r = 0.5(T_e + T_s) + 0.2r^* \left( u_e^2 / 2c_{pr} \right) + 0.1 \left[ B_{hr} + (B_{hr} + B_{mr}) \frac{c_{p1} - c_{pr}}{c_{pr}} \right] (T_s - T_e) \tag{4.7.74}$$

where species 1 is injected into species 2 and  $r^*$  is the recovery factor for an impermeable wall. Use of the reference state method is impractical for hand calculations: a computer program should be used to evaluate the required mixture properties.

## 4.8 Applications

---

### Enhancement

*Arthur E. Bergles*

#### Introduction

Energy- and materials-saving considerations, as well as economic incentives, have led to efforts to produce more efficient heat exchange equipment. Common thermal-hydraulic goals are to reduce the size of a heat exchanger required for a specified heat duty, to upgrade the capacity of an existing heat exchanger, to reduce the approach temperature difference for the process streams, or to reduce the pumping power.

The study of improved heat transfer performance is referred to as heat transfer *enhancement*, *augmentation*, or *intensification*. In general, this means an increase in heat transfer coefficient. Attempts to increase “normal” heat transfer coefficients have been recorded for more than a century, and there is a large store of information. A survey (Bergles et al., 1991) cites 4345 technical publications, excluding patents and manufacturers’ literature. The literature has expanded rapidly since 1955.

Enhancement techniques can be classified either as passive methods, which require no direct application of external power (Figure 4.8.1), or as active methods, which require external power. The effectiveness of both types of techniques is strongly dependent on the mode of heat transfer, which may range from single-phase free convection to dispersed-flow film boiling. Brief descriptions of these methods follow.

*Treated surfaces* involve fine-scale alternation of the surface finish or coating (continuous or discontinuous). They are used for boiling and condensing; the roughness height is below that which affects single-phase heat transfer.

*Rough surfaces* are produced in many configurations ranging from random sand-grain-type roughness to discrete protuberances. See Figure 4.8.1a. The configuration is generally chosen to disturb the viscous sublayer rather than to increase the heat transfer surface area. Application of rough surfaces is directed primarily toward single-phase flow.

*Extended surfaces* are routinely employed in many heat exchangers. See Figure 4.8.1a to d. Work of special interest to enhancement is directed toward improvement of heat transfer coefficients on extended surfaces by shaping or perforating the surfaces.

*Displaced enhancement devices* are inserted into the flow channel so as indirectly to improve energy transport at the heated surface. They are used with forced flow. See Figure 4.8.1e and f.

*Swirl-flow devices* include a number of geometric arrangements or tube inserts for forced flow that create rotating and/or secondary flow: coiled tubes, inlet vortex generators, twisted-tape inserts, and axial-core inserts with a screw-type winding.

*Surface-tension devices* consist of wicking or grooved surfaces to direct the flow of liquid in boiling and condensing.

*Additives for liquids* include solid particles and gas bubbles in single-phase flows and liquid trace additives for boiling systems.

*Additives for gases* are liquid droplets or solid particles, either dilute-phase (gas-solid suspensions) or dense-phase (fluidized beds).

*Mechanical aids* involve stirring the fluid by mechanical means or by rotating the surface. Surface “scraping,” widely used for batch processing of viscous liquids in the chemical process industry, is applied to the flow of such diverse fluids as high-viscosity plastics and air. Equipment with rotating heat exchanger ducts is found in commercial practice.

*Surface vibration* at either low or high frequency has been used primarily to improve single-phase heat transfer.

**FIGURE 4.8.1** Enhanced tubes for augmentation of single-phase heat transfer. (a) Corrugated or spirally indented tube with internal protuberances. (b) Integral external fins. (c) Integral internal fins. (d) Deep spirally fluted tube. (e) Static mixer inserts. (f) Wire-wound insert.

*Fluid vibration* is the practical type of vibration enhancement because of the mass of most heat exchangers. The vibrations range from pulsations of about 1 Hz to ultrasound. Single-phase fluids are of primary concern.

*Electrostatic fields* (DC or AC) are applied in many different ways to dielectric fluids. Generally speaking, electrostatic fields can be directed to cause greater bulk mixing or fluid or disruption of fluid flow in the vicinity of the heat transfer surface, which enhances heat transfer.

*Injection* is utilized by supplying gas to a stagnant or flowing liquid through a porous heat transfer surface or by injecting similar fluid upstream of the heat transfer section. Surface degassing of liquids can produce enhancement similar to gas injection. Only single-phase flow is of interest.

*Suction* involves vapor removal, in nucleate or film boiling, or fluid withdrawal, in single-phase flow, through a porous heated surface.

Two or more of the above techniques may be utilized simultaneously to produce an enhancement that is larger than either of the techniques operating separately. This is termed *compound enhancement*.

It should be emphasized that one of the motivations for studying enhanced heat transfer is to assess the effect of an inherent condition on heat transfer. Some practical examples include roughness produced by standard manufacturing, degassing of liquids with high gas content, surface vibration resulting from rotating machinery or flow oscillations, fluid vibration resulting from pumping pulsation, and electrical fields present in electrical equipment.

The surfaces in [Figure 4.8.1](#) have been used for both single-phase and two-phase heat transfer enhancement. The emphasis is on effective and cost-competitive (proved or potential) techniques that have made the transition from the laboratory to commercial heat exchangers.

### Single-Phase Free Convection

With the exception of the familiar technique of providing extended surfaces, the passive techniques have little to offer in the way of enhanced heat transfer for free convection. This is because the velocities are usually too low to cause flow separation or secondary flow.

The restarting of thermal boundary layers in interrupted extended surfaces increases heat transfer so as to more than compensate for the lost area.

Mechanically aided heat transfer is a standard technique in the chemical and food industries when viscous liquids are involved. The predominant geometry for surface vibration has been the horizontal cylinder, vibrated either horizontally or vertically. Heat transfer coefficients can be increased tenfold for both low-frequency/high-amplitude and high-frequency/low-amplitude situations. It is, of course, equally effective and more practical to provide steady forced flow. Furthermore, the mechanical designer is concerned that such intense vibrations could result in equipment failures.

Since it is usually difficult to apply surface vibrations to practical equipment, an alternative technique is utilized whereby vibrations are applied to the fluid and focused toward the heated surface. With proper transducer design, it is also possible to improve heat transfer to simple heaters immersed in gases or liquids by several hundred percent.

Electric fields are particularly effective in increasing heat transfer coefficients in free convection. Dielectrophoretic or electrophoretic (especially with ionization of gases) forces cause greater bulk mixing in the vicinity of the heat transfer surface. Heat transfer coefficients may be improved by as much as a factor of 40 with electrostatic fields up to 100,000 V. Again, the equivalent effect could be produced at lower capital cost and without the voltage hazard by simply providing forced convection with a blower or fan.

### Single-Phase Forced Convection

The present discussion emphasizes enhancement of heat transfer *inside* ducts that are primarily of circular cross section. Typical data for turbulence promoters inserted inside tubes are shown in [Figure 4.8.2](#). As shown in [Figure 4.8.2a](#), the promoters produce a sizable elevation in the Nusselt number, or heat transfer coefficient, at constant Reynolds number, or velocity. However, as shown in [Figure 4.8.2b](#), there is an accompanying large increase in the friction factor.

Surface roughness has been used extensively to enhance forced convection heat transfer. Integral roughness may be produced by the traditional manufacturing processes of machining, forming, casting, or welding. Various inserts can also provide surface protuberances. In view of the infinite number of possible geometric variations, it is not surprising that, even after more than 300 studies, no completely satisfactory unified treatment is available.

In general, the maximum enhancement of laminar flow with many of the techniques is the same order of magnitude, and seems to be independent of the wall boundary condition. The enhancement with some rough tubes, corrugated tubes, inner-fin tubes, various static mixers, and twisted-type inserts is about 200%. The improvements in heat transfer coefficient with turbulent flow in rough tubes (based on nominal surface area) are as much as 250%. Analogy solutions for sand-grain-type roughness and for square-repeated-rib roughness have been proposed. A statistical correlation is also available for heat transfer coefficient and friction factor.

The following correlations are recommended for tubes with transverse or helical repeated ribs ([Figure 4.8.1a](#)) with turbulent flow (Ravigururajan and Bergles, 1985):

$$\text{Nu}_{D_{t,a}}/\text{Nu}_{D_{t,s}} = \left\{ 1 + \left[ 2.64\text{Re}^{0.036} (e/D_i)^{0.212} \left( (p/D_i)^{-0.21} \right) (\alpha/90)^{0.29} (\text{Pr})^{-0.024} \right]^7 \right\}^{1/7} \quad (4.8.1)$$

**FIGURE 4.8.2** Typical data for turbulence promoters inserted inside tubes: (a) heat transfer data, (b) friction data. (From Bergles, 1969. With permission.)

$$\begin{aligned}
 f_a/f_s = & \left\{ 1 + \left[ 29.1 Re_{D_i}^{(0.67-0.06p/D_i-0.49\alpha/90)} \times (e/D_i)^{(0.37-0.157p/D_i)} \times (p/D_i)^{(-1.66 \times 10^{-6} Re_{D_i} - 0.33\alpha/90)} \right. \right. \\
 & \left. \left. \times (\alpha/90)^{(4.59+4.11 \times 10^{-6} Re_{D_i} - 0.15p/D_i)} \times \left( 1 + \frac{2.94}{n} \right) \sin \beta \right]^{15/16} \right\}^{16/15} \quad (4.8.2)
 \end{aligned}$$

where the subscript *a* refers to the enhanced tube and the subscript *s* refers to the smooth tube. The special symbols are given as follows: *e* = protuberance height; *p* = repeated-rib pitch;  $\alpha$  = spiral angle for helical ribs,  $^\circ$ ; *n* = number of sharp corners facing the flow; and  $\beta$  = contact angle of rib profile,  $^\circ$ . Also,

$$Nu_s = 0.125 f Re_{D_i} Pr / \left( 1 + 12.7 (0.125 f)^{0.5} Pr^{0.667} - 1 \right)$$

and

$$f_s = \left( 1.82 \log_{10} Re_{D_i} - 1.64 \right)^{-2*}$$

Much work has been done to obtain the enhanced heat transfer of parallel angled ribs in short rectangular channels, simulating the interior of gas turbine blades. Jets are frequently used for heating, cooling, and drying in a variety of industrial applications. A number of studies have reported that roughness elements of the transverse-repeated-rib type mitigate the deterioration in heat transfer downstream of stagnation.

Extended surfaces can be considered “old technology” as far as most applications are concerned. The real interest now is in increasing heat transfer coefficients on the extended surface. Compact heat exchangers of the plate-fin or tube-and-center variety use several enhancement techniques: offset strip fins, louvered fins, perforated fins, or corrugated fins. Coefficients are several hundred percent above the

\* The Fanning friction factor is used throughout this section.

smooth-tube values; however, the pressure drop is also substantially increased, and there may be vibration and noise problems.

For the case of offset strip fins the following correlations are recommended for calculating the  $j$  and  $f$  characteristics (Manglik and Bergles, 1990)

$$j_h = 0.6522 \text{Re}_h^{-0.5403} \alpha^{-0.1541} \delta^{0.1499} \gamma^{-0.0678} \times [1 + 5.269 \times 10^{-5} \text{Re}_h^{1.340} \alpha^{0.504} \delta^{0.456} \gamma^{-1.055}]^{0.1} \quad (4.8.3)$$

$$f_h = 9.6243 \text{Re}_h^{-0.7422} \alpha^{-0.1856} \delta^{0.3053} \gamma^{-0.2659} \times [1 + 7.669 \times 10^{-8} \text{Re}_h^{4.429} \alpha^{0.920} \delta^{3.767} \gamma^{0.236}]^{0.1} \quad (4.8.4)$$

where  $j_H$  (the heat transfer  $j$ -factor  $\text{Nu}_H/\text{Re}_H\text{Pr}^{1/3}$ ), and  $f_h$ , and  $\text{Re}_h$  are based on the hydraulic diameter given by

$$D_h = 4shl/[2(sl + hl + th) + ts] \quad (4.8.5)$$

Special symbols are  $\alpha$  = aspect ratio  $s/h$ ,  $\delta$  = ratio  $t/l$ ,  $\gamma$  = ratio  $t/s$ ,  $s$  = lateral spacing of strip fin,  $h$  = strip fin height,  $l$  = length of one offset module of strip fins, and  $t$  = fin thickness.

These equations are based on experimental data for 18 different offset strip-fin geometries, and they represent the data continuously in the laminar, transition, and turbulent flow regions.

Internally finned circular tubes are available in aluminum and copper (or copper alloys). Correlations (for heat transfer coefficient and friction factor) are available for laminar flow, for both straight and spiral continuous fins.

Turbulent flow in tubes with straight or helical fins (Figure 4.8.1c) was correlated by (Carnavos, 1979)

$$\text{Nu}_h = 0.023 \text{Pr}^{0.4} \text{Re}_h^{0.8} \left[ \frac{A_c}{A_{c,i}} \right]^{0.1} \left[ \frac{A_{s,i}}{A_s} \right]^{0.5} (\sec \alpha)^3 \quad (4.8.6)$$

$$f_h = 0.046 \text{Re}_h^{-0.2} \left[ \frac{A_c}{A_{c,i}} \right]^{0.5} (\sec \alpha)^{0.75} \quad (4.8.7)$$

where  $A_{c,i}$  is based on the maximum inside (envelope) flow area,  $A_{s,i}$  is based on the maximum inside (envelope) surface area, and  $\alpha$  the spiral angle for helical fins, °.

A numerical analysis of turbulent flow in tubes with idealized straight fins was reported. The necessary constant for the turbulence model was obtained from experimental data for air. Further improvements in numerical techniques are expected, so that a wider range of geometries and fluids can be handled without resort to extensive experimental programs.

Many proprietary surface configurations have been produced by deforming the basic tube. The “convoluted,” “corrugated,” “spiral,” or “spirally fluted” tubes (Figure 4.8.1a) have multiple-start spiral corrugations, which add area, along the tube length. A systematic survey of the single-tube performance of condenser tubes indicates up to 400% increase in the nominal inside heat transfer coefficient (based on diameter of a smooth tube of the same maximum inside diameter); however, pressure drops on the water side are about 20 times higher.

Displaced enhancement devices are typically in the form of inserts, within elements arranged to promote transverse mixing (static mixers, Figure 4.8.1e). They are used primarily for viscous liquids, to promote either heat transfer or mass transfer. Displaced promoters are also used to enhance the radiant heat transfer in high-temperature applications. In the flue-tube of a hot-gas-fired hot water heater, there is a trade-off between radiation and convection. Another type of displaced insert generates vortices, which enhance the downstream flow. Delta-wing and rectangular wing promoters, both co-rotating and

counterrotating, have been studied. Wire-loop inserts (Figure 4.8.1f) have also been used for enhancement of laminar and turbulent flow.

Twisted-tape inserts have been widely used to improve heat transfer in both laminar and turbulent flow. Correlations are available for laminar flow, for both uniform heat flux and uniform wall temperature conditions. Turbulent flow in tubes with twisted-tape inserts has also been correlated. Several studies have considered the heat transfer enhancement of a decaying swirl flow, generated, say, by a short twisted-tape insert.

### Performance Evaluation Criteria for Single-Phase Forced Convection in Tubes

Numerous, and sometimes conflicting, factors enter into the ultimate decision to use an enhancement technique: heat duty increase or area reduction that can be obtained, initial cost, pumping power or operating cost, maintenance cost (especially cleaning), safety, and reliability, among others. These factors are difficult to quantitize, and a generally acceptable selection criterion may not exist. It is possible, however, to suggest some performance criteria for preliminary design guidance. As an example, consider the basic geometry and the pumping power fixed, with the objective of increasing the heat transfer. The following ratio is then of interest

$$R_3 = \left( \frac{h_a}{h_s} \right)_{D_i, L, N, P, T_{in}, \Delta T} = \frac{(\text{Nu}/\text{Pr}^{0.4})_a}{(\text{Nu}/\text{Pr}^{0.4})_s} = \frac{q_a}{q_s} \quad (4.8.8)$$

where  $P$  = pumping power,  $T_{in}$  = inlet bulk temperature of fluid, and  $\Delta T$  = average wall-fluid temperature difference.

With the pumping power (neglecting entrance and exit losses) given as

$$P = NVA_c 4f(L/D)\rho V^2/2 \quad (4.8.9)$$

and

$$f_s = 0.046/\text{Re}_s^{0.2} \quad (4.8.10)$$

$$A_{c,a} f_a \text{Re}_a^3 = 0.046 A_{c,s} \text{Re}_s^{2.8} \quad (4.8.11)$$

The calculation best proceeds by picking  $\text{Re}_{D_i,a}$ , and reading  $\text{Nu}_{D_i,a}/\text{Pr}^{0.4}$  and  $f_a$ .  $\text{Re}_{D_i,s}$  is then obtained from Equation (4.8.11) and  $\text{Nu}_{D_i,s}/\text{Pr}^{0.4}$  obtained from a conventional, empty-tube correlation. The desired ratio of Equation (4.8.8) is then obtained. Typical results are presented in Figure 4.8.3 for a repeated-rib roughness (Bergles et al., 1974).

### Active and Compound Techniques for Single-Phase Forced Convection

Under active techniques, mechanically aided heat transfer in the form of surface scraping can increase forced convection heat transfer. Surface vibration has been demonstrated to improve heat transfer to both laminar and turbulent duct flow of liquids. Fluid vibration has been extensively studied for both air (loudspeakers and sirens) and liquids (flow interrupters, pulsators, and ultrasonic transducers). Pulsations are relatively simple to apply to low-velocity liquid flows, and improvements of several hundred percent can be realized.

Some very impressive enhancements have been recorded with electrical fields, particularly in the laminar-flow region. Improvements of at least 100% were obtained when voltages in the 10-kV range were applied to transformer oil. It is found that even with intense electrostatic fields, the heat transfer enhancement disappears as turbulent flow is approached in a circular tube with a concentric inner electrode.

**FIGURE 4.8.3** Constant pumping power performance criterion applied to repeated rib roughness.

Compound techniques are a slowly emerging area of enhancement that holds promise for practical applications, since heat transfer coefficients can usually be increased above each of the several techniques acting along. Some examples that have been studied are as follows: rough tube wall with twisted-tape inserts, rough cylinder with acoustic vibrations, internally finned tube with twisted-tape inserts, finned tubes in fluidized beds, externally finned tubes subjected to vibrations, rib-roughened passage being rotated, gas-solid suspension with an electrical field, fluidized bed with pulsations of air, and a rib-roughened channel with longitudinal vortex generation.

### Pool Boiling

Selected passive and active enhancement techniques have been shown to be effective for pool boiling and flow boiling/evaporation. Most techniques apply to nucleate boiling; however, some techniques are applicable to transition and film boiling.

It should be noted that phase-change heat transfer coefficients are relatively high. The main thermal resistance in a two-fluid heat exchanger often lies on the non-phase-change side. (Fouling of either side can, of course, represent the dominant thermal resistance.) For this reason, the emphasis is often on enhancement of single-phase flow. On the other hand, the overall thermal resistance may then be reduced to the point where significant improvement in the overall performance can be achieved by enhancing the two-phase flow. Two-phase enhancement would also be important in double-phase-change (boiling/condensing) heat exchangers.

As discussed elsewhere, surface material and finish have a strong effect on nucleate and transition pool boiling. However, reliable control of nucleation on plain surfaces is not easily accomplished. Accordingly, since the earliest days of boiling research, there have been attempts to relocate the boiling curve through use of relatively gross modification of the surface. For many years, this was accomplished simply by area increase in the form of low helical fins. The subsequent tendency was to structure surfaces to improve the nucleate boiling characteristics by a fundamental change in the boiling process. Many of these advanced surfaces are being used in commercial shell-and-tube boilers.

Several manufacturing processes have been employed: machining, forming, layering, and coating. In Figure 4.8.4a standard low-fin tubing is shown. Figure 4.8.4c depicts a tunnel-and-pore arrangement produced by rolling, upsetting, and brushing. An alternative modification of the low fins is shown in Figure 4.8.4d, where the rolled fins have been split and rolled to a T shape. Further modification of the internal, Figure 4.8.4e, or external, Figure 4.8.4f, surface is possible. Knurling and rolling are involved in producing the surface shown in Figure 4.8.4g. The earliest example of a commercial structured surface, shown in Figure 4.8.4b is the porous metallic matrix produced by sintering or brazing small particles. Wall superheat reductions of up to a factor of ten are common with these surfaces. The advantage is not

**FIGURE 4.8.4** Examples of commercial structured boiling surfaces. (From Pate, M.B. et al., in *Compact Heat Exchangers*, Hemisphere Publishing, New York, 1990. With permission.)

only a high nucleate boiling heat transfer coefficient, but the fact that boiling can take place at very low temperature differences.

These structured boiling surfaces, developed for refrigeration and process applications, have been used as “heat sinks” for immersion-cooled microelectronic chips.

The behavior of tube bundles is often different with structured-surface tubes. The enhanced nucleate boiling dominates, and the convective boiling enhancement, found in plain tube bundles, does not occur.

Active enhancement techniques include heated surface rotation, surface wiping, surface vibration, fluid vibration, electrostatic fields, and suction at the heated surface. Although active techniques are effective in reducing the wall superheat and/or increasing the critical heat flux, the practical applications are very limited, largely because of the difficulty of reliably providing the mechanical or electrical effect.

Compound enhancement, which involves two or more techniques applied simultaneously, has also been studied. Electrohydrodynamic enhancement was applied to a finned tube bundle, resulting in nearly a 200% increase in the average boiling heat transfer coefficient of the bundle, with a small power consumption for the field.

### Convective Boiling/Evaporation

The structured surfaces described in the previous section are generally not used for in-tube vaporization, because of the difficulty of manufacture. One notable exception is the high-flux surface in a vertical thermosiphon reboiler. The considerable increase in the low-quality, nucleate boiling coefficient is desirable, but it is also important that more vapor is generated to promote circulation.

Helical repeated ribs and helically coiled wire inserts have been used to increase vaporization coefficients and the dry-out heat flux in once-through boilers.

Numerous tubes with internal fins, either integral or attached, are available for refrigerant evaporators. Original configurations were tightly packed, copper, offset strip fin inserts soldered to the copper tube or aluminum, star-shaped inserts secured by drawing the tube over the insert. Examples are shown in [Figure 4.8.5](#). Average heat transfer coefficients (based on surface area of smooth tube of the same diameter) for typical evaporator conditions are increased by as much as 200%. A cross-sectional view of a typical “microfin” tube is included in [Figure 4.8.5](#). The average evaporation boiling coefficient is

**FIGURE 4.8.5** Inner-fin tubes for refrigerant evaporators: (a) Strip-fin inserts, (b) Star-shaped inserts, (c) Microfin.

increased 30 to 80%. The pressure drop penalties are less; that is, lower percentage increases in pressure drop are frequently observed.

Twisted-tape inserts are generally used to increase the burnout heat flux for subcooled boiling at high imposed heat fluxes  $10^7 - 10^8 \text{ W/m}^2$ , as might be encountered in the cooling of fusion reactor components. Increases in burnout heat flux of up to 200% were obtained at near atmospheric pressure.

### Vapor-Space Condensation

As discussed elsewhere, condensation can be either filmwise or dropwise. In a sense, dropwise condensation is enhancement of the normally occurring film condensation by surface treatment. The only real application is for steam condensers, because nonwetting coatings are not available for most other working fluids. Even after much study, little progress has been made in developing permanently hydrophobic coatings for practical steam condensers. The enhancement of dropwise condensation is pointless, because the heat transfer coefficients are already so high.

Surface extensions are widely employed for enhancement of condensation. The integral low fin tubing (Figure 4.8.4a), used for kettle boilers, is also used for horizontal tube condensers. With proper spacing of the fins to provide adequate condensate drainage, the average coefficients can be several times those of a plain tube with the same base diameter. These fins are normally used with refrigerants and other organic fluids that have low condensing coefficients, but which drain effectively, because of low surface tension.

The fin profile can be altered according to mathematical analysis to take full advantage of the Gregorig effect, whereby condensation occurs mainly at the tops of convex ridges. Surface tension forces then pull the condensate into concave grooves, where it runs off. The average heat transfer coefficient is greater than that for an axially uniform film thickness. The initial application was for condensation of steam on vertical tubes used for reboilers and in desalination. According to numerical solutions, the optimum geometry is characterized by a sharp fin tip, gradually changing curvature of the fin surface from tip to root, wide grooves between fins to collect condensate, and periodic condensate strippers. Figure 4.8.6 schematically presents the configuration.

**FIGURE 4.8.6** Recommended flute profile and schematic of condensate strippers.

Recent interest has centered on three-dimensional surfaces for horizontal-tube condensers. The considerable improvement relative to low fins or other two-dimensional profiles is apparently due to multidimensional drainage at the fin tips. Other three-dimensional shapes include circular pin fins, square pins, and small metal particles that are bonded randomly to the surface.

### Convective Condensation

This final section on enhancement of the various modes of heat transfer focuses on in-tube condensation. The applications include horizontal kettle-type reboilers, moisture separator reheaters for nuclear power plants, and air-conditioner condensers.

Internally grooved or knurled tubes, deep spirally fluted tubes, random roughness, conventional inner-fin tubes have been shown to be effective for condensation of steam and other fluids.

The microfin tubes mentioned earlier have also been applied successfully to in-tube condensing. As in the case of evaporation, the substantial heat transfer improvement is achieved at the expense of a lesser percentage increase in pressure drop. By testing a wide variety of tubes, it has been possible to suggest some guidelines for the geometry, e.g., more fins, longer fins, and sharper tips; however, general correlations are not yet available. Fortunately for heat-pump operation, the tube that performs best for evaporation also performs best for condensation.

Twisted-tape inserts result in rather modest increases in heat transfer coefficient for complete condensation of either steam or refrigerant. The pressure drop increases are large because of the large wetted surface. Coiled tubular condensers provide a modest improvement in average heat transfer coefficient.

## Further Information

This section gives some indication as to why heat transfer enhancement is one of the fastest growing areas of heat transfer. Many techniques are available for improvement of the various modes of heat transfer. Fundamental understanding of the transport mechanism is growing, but, more importantly, design correlations are being established. Many effective and cost-competitive enhancement techniques have made the transition from the laboratory to commercial heat exchangers.

Broad reviews of developments in enhanced heat transfer are available (Bergles, 1985; Bergles, 1988; Thome, 1990; Webb, 1994, Bergles, 1997). Also, several journals, especially *Heat Transfer Engineering*, *Enhanced Heat Transfer*, and *International Journal of Heating, Ventilating, Air-Conditioning and Refrigerating Research*, feature this technology.

## Cooling Towers

*Anthony F. Mills*

### Introduction

In a wet cooling tower, water is evaporated into air with the objective of cooling the water stream. Both natural- and mechanical-draft towers are popular, and examples are shown in [Figure 4.8.7](#). Large natural-draft cooling towers are used in power plants for cooling the water supply to the condenser. Smaller mechanical-draft towers are preferred for oil refineries and other process industries, as well as for central air-conditioning systems and refrigeration plant. [Figure 4.8.7a](#) shows a natural draft *counterflow* unit in which the water flows as thin films down over a suitable packing, and air flows upward. In a natural-draft tower the air flows upward due to the buoyancy of the warm, moist air leaving the top of the packing. In a mechanical-draft tower, the flow is forced or induced by a fan. Since the air inlet temperature is usually lower than the water inlet temperature, the water is cooled both by evaporation and by sensible heat loss. For usual operating conditions the evaporative heat loss is considerably larger than the sensible heat loss. [Figure 4.8.7b](#) shows a mechanical draft cross-flow unit. [Figure 4.8.8](#) shows a natural-draft cross-flow tower for a power plant.

### Packing Thermal Performance

*Counterflow units.* Merkel's method (Merkel, 1925) for calculating the number of transfer units required to cool the water stream, for specified inlet and outlet water temperatures and inlet air condition is (Mills, 1995)

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \int_{h_{L,in}}^{h_{L,out}} \frac{dh_L}{h_s - h_G} \quad (4.8.12)$$

$$h_G = h_{G,in} + (\dot{m}_L / \dot{m}_G)(h_L - h_{L,out}) \quad (4.8.13)$$

$$h_s(P, T_s) = h_s(P, T_L) \quad (4.8.14)$$

It is imperative that the usual enthalpy datum states be used, namely, zero enthalpy for dry air and liquid water at 0°C. [Table 4.8.1](#) gives enthalpy data for 1 atm pressure. The important assumptions required to obtain this result include

1. A Lewis number of unity;
2. Low mass transfer rate theory is valid;
3. The liquid-side heat transfer resistance is negligible, that is,  $T_s \approx T_L$ ;
4. The amount of water evaporated is small compared with the water and air flow rates.

**FIGURE 4.8.7** (a) A natural-draft counterflow cooling tower for a power plant. (b) A cross-flow cooling tower for an air-conditioning system.

The method is accurate up to temperatures of about  $60^{\circ}\text{C}$ ; comparisons with more exact results are usually within 3 to 5%, and seldom show errors greater than 10%. Notice that the method does not give the outlet state of the air; however, in situations encountered in practice, the outlet air can be assumed to be saturated for the purposes of calculating its density. It is possible to extend Merkel's method to include a finite liquid-side heat transfer resistance, but such refinement is seldom warranted. For typical operating conditions the bulk liquid temperature is seldom more than 0.3 K above the interface temperature.

*Cross-flow units.* Figure 4.8.9 shows a schematic of a cross-flow packing. If we assume that both the liquid and gas streams are unidirectional, and that there is no mixing in either stream, then use of Merkel's assumptions leads to the following pair of differential equations (Mills, 1995):

**FIGURE 4.8.8** A natural-draft cross-flow cooling tower for a power plant.

$$\frac{\partial h_G}{\partial x} = \frac{g_m a}{G} (h_s - h_G) \quad (4.8.15)$$

$$\frac{\partial h_L}{\partial y} = -\frac{g_m a}{L} (h_s - h_G) \quad (4.8.16)$$

Also  $h_s = h_s(h_L)$  for a negligible liquid-side heat transfer resistance and the required boundary conditions are the inlet enthalpies of both streams. Equations (4.8.15) and (4.8.16) are solved numerically and the solution used to evaluate the average enthalpy of the outlet liquid,

$$\bar{h}_{L,\text{out}} = \frac{1}{X} \int_0^X h_{L,\text{out}} dx \quad (4.8.17)$$

Substituting in an exchanger energy balance on the liquid stream gives the heat transfer as

$$q = \dot{m}_L (h_{L,\text{in}} - h_{L,\text{out}}) \quad (4.8.18)$$

<sup>a</sup> The enthalpies of dry air and liquid water are set equal to zero at a datum temperature of 0°C.

<sup>b</sup> The enthalpy of an unsaturated water vapor-air mixture can be calculated as  $h = h_{\text{dry air}} + (m_v/m_{1,\text{sat}})(h_{\text{sat}} - h_{\text{dry air}})$ .

*Sample calculation.* Consider a counterflow unit that is required to cool water from 40 to 26°C when the inlet air is at 10°C, 1 atm, and saturated. We will calculate the number of transfer units required for balanced flow, that is,  $\dot{m}_G/\dot{m}_L = 1$ . Equation (4.8.12) is to be integrated numerically, with  $h_G$  obtained from Equation 4.8.13. The required thermodynamic properties can be obtained from [Table 4.8.1](#). Using [Table 4.8.1](#),  $h_{G,\text{in}} = h_{\text{sat}}(10^\circ\text{C}) = 29.15$  kJ/kg,  $h_{L,\text{out}} = h_L(26^\circ\text{C}) = 109.07$  kJ/kg. Substituting in Equation (4.8.13),

$$h_G = 29.15 + (h_L - 109.07)$$

$T_L, ^\circ\text{C}$	$h_L, \text{kJ/kg}$	$h_G, \text{kJ/kg}$	$h_s, \text{kJ/kg}$	$h_s - h_g, \text{kJ/kg}$	$\frac{1}{h_s - h_g}$
26	109.07	29.15	79.12	49.97	0.02001
28	117.43	37.51	87.86	50.35	0.01986
30	125.79	45.87	97.36	51.49	0.01942
32	134.15	54.23	107.67	53.44	0.01871
34	142.50	62.58	118.89	56.31	0.01776
36	150.86	70.94	131.10	60.16	0.01662
38	159.22	79.30	144.39	65.09	0.01536
40	167.58	87.66	158.86	71.20	0.01404

Choosing  $2^\circ\text{C}$  intervals for convenient numerical integration, the above table is constructed, with  $h_L$  and  $h_s = h_s(T_L)$  also obtained from Table 4.8.1. Using the trapezoidal rule,

$$\int_{h_{L,\text{out}}}^{h_{L,\text{in}}} \frac{dh_L}{h_s - h_G} = \frac{8.36}{2} [0.02001 + 2(0.01986 + 0.01942 + 0.01871 + 0.01776 + 0.01662 + 0.01536) + 0.01404]$$

$$= 1.043$$

From Equation (4.8.12),  $N_{tu} = 1.043$ . Also, by using Table 4.8.1,  $T_{G,\text{out}} = 27.9^\circ$  for saturated outlet air.

FIGURE 4.8.9 Schematic of a cross-flow cooling tower packing showing the coordinate system.

### Thermal-Hydraulic Design of Cooling Towers

The thermal-hydraulic design of a mechanical-draft cooling tower is relatively straightforward. The flow rate ratio  $\dot{m}_L/\dot{m}_G$  can be specified and varied parametrically to obtain an optimal design, for which the size and cost of the packing is balanced against fan power requirements and operating cost. Data are required for mass transfer conductances and friction for candidate packings. Tables 4.8.2a and b give correlations for a selection of packings. In Table 4.8.2b, the mass transfer conductance is correlated as  $g_m a/L$ , where  $a$  is the transfer area per unit volume and  $L = \dot{m}_L/A_{fr}$  is the superficial mass velocity of the water flow (also called the *water loading* on the packing). Similarly, we define  $G = \dot{m}_G/A_{fr}$ . Typical water loadings are 1.8 to 2.7 kg/m<sup>2</sup> sec, and superficial air velocities fall in the range 1.5 to 4 m/sec. No attempt is made to correlate  $g_m$  and  $a$  separately. The number of transfer units of a packing of height  $H$  is then

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \frac{g_m aH}{L} \quad (4.8.19)$$

7. Marley α-bar, parallel to air flow, 16 × 4 in. spacing
8. Marley ladder, parallel to air flow, 8 × 2 in. spacing

The correlations are in terms of dimensionless mass velocities  $L^+$  and  $G^+$ , and a *hot water correction*  $T_{HW}^+$ . The hot water correction accounts for a number of factors, such as errors associated with Merkel's method, deviations from low mass transfer rate theory at higher values of  $T_s$ , and fluid property dependence on temperature. Frictional resistance to air flow through the packings is correlated as a *loss coefficient*  $N = \Delta P / (\rho V^2 / 2)$  per unit height or depth of packing, as a function of  $L^+$  and  $G^+$ . The velocity  $V$  is superficial gas velocity. No hot water correction is required.

In a natural-draft tower, the thermal and hydraulic performance of the tower are coupled, and the flow rate ratio  $\dot{m}_L / \dot{m}_G$  cannot be specified *a priori*. The buoyancy force producing the air flow depends on the state of the air leaving the packing which in turn depends on  $\dot{m}_L / \dot{m}_G$  and the inlet air and water states. An iterative solution is required to find the operating point of the tower. The buoyancy force available to overcome the shell and packing pressure drops is

$$\Delta P^B = g(\rho_a - \rho_{G,out})H \quad (4.8.20)$$

where  $\rho_a$  is the ambient air density and  $H$  is usually taken as the distance from the bottom of the packing to the top of the shell. The various pressure drops are conveniently expressed as

$$\Delta P_i = N_i \frac{\rho_{Gi} V_i^2}{2} \quad (4.8.21)$$

"Heat transfer and pressure drop data on cooling tower packings, and model studies of the resistance of natural draft towers to airflow" Paper 113, *International Developments in Heat Transfer, Proc. of the International Heat Transfer Conference*, Boulder, CO, ASME, New York; Johnson, B.M., Ed. 1990. *Cooling Tower Performance Prediction and Improvement*, Vols. 1 and 2, EPRI GS-6370, Electric Power Research Institute, Palo Alto, CA. With permission.

Where  $N_i$  is the loss coefficient and  $V_i$  is the air velocity at the corresponding location. The pressure drops are associated with the shell, the packing, the mist eliminators, supports and pipes, and the water spray below the packing. Some sample correlations are given in Table 4.8.3.

Water loadings in counterflow natural-draft towers typically range from 0.8 to 2.4 kg/m<sup>2</sup> sec, and superficial air velocities range from 1 to 2 m/sec. The ratio of base diameter to height may be 0.75 to 0.85, and the ratio of throat to base diameter 0.55 to 0.65. The height of the air inlet is usually 0.10 to 0.12 times the base diameter to facilitate air flow into the tower. In practice the air flow distribution in natural-draft towers is not very uniform. However, the assumption of uniform air and water flows in our model of counterflow packing is adequate for most design purposes.

Cost-optimal design of cooling towers requires consideration of the complete power or refrigeration system. For refrigeration, the economics are determined mainly by the operating cost of the chiller (Kintner-Meyer and Emery, 1955).

**TABLE 4.8.3 Pressure Drop Correlations for Cooling Tower Shells, Sprays, Supports, and Mist Eliminators**

### Cooling Tower Behavior

There are a number of computer programs available that use variations of Merkel's method to calculate the cooling tower performance, for example, TEFRI (Bourillot, 1983), VERA2D-84 (Mujamdar et al., 1985), CTOWER (Mills, 1995). These programs can be used to perform parametric studies to obtain the response of cooling towers to environmental, duty, and design changes. However, before using such programs, some thought should be given to the important characteristics of cooling tower behavior. For this purpose, it is useful to consider a graphical representation of Merkel's theory for a counterflow tower. Figure 4.8.10 shows a chart with moist air enthalpy plotted vs. water enthalpy (or, equivalently, water temperature) at 1 atm pressure. The *saturation curve*  $h_s(T_s)$  is the enthalpy of saturated air. The *operating lines*  $h_G(h_L)$  are given by Equation (4.8.13) and relate the air enthalpy to the water enthalpy at each location in the packing. The slope of an operating line is  $L/G$ . Since the assumption  $T_s = T_L$  is made in Merkel's method, vertical lines on the chart connect  $h_s$  and  $h_G$  at each location in the packing. The driving force for enthalpy transfer,  $(h_s - h_G)$ , is the vertical distance between the saturation curve and the operating line. The integral in Equation (4.8.12) averages the reciprocal of this distance. By using this chart, a number of observations about cooling tower behavior can be made.

- Figure 4.8.10 shows the effect of  $L/G$  for fixed water inlet and outlet temperatures, and fixed inlet air temperature and humidity. If we imagine  $L$  to be fixed as well, we see that as  $G$  decreases, the driving forces decrease, and so a larger NTU is required.
- The minimum NTU required corresponds to  $L/G = 0$ , that is, an infinite air flow rate, for which the operating line is horizontal.
- Due to the curvature of the operating line, it is possible for the operating line to be tangent to the saturation curve. The indicated NTU is then infinite, which tells us that the air flow rate must be increased in order to achieve the desired water cooling range.

**FIGURE 4.8.10** Counterflow cooling tower operating lines for various water-to-air flow-rate ratios shown on an enthalpy chart.

- For a mechanical-draft tower, the optimal value of  $L/G$  lies between the two limits described in items 2 and 3 above. If  $L/G$  is large, the required height of packing is large, and the capital cost will be excessive. If  $L/G$  is small, the fan power will be excessive (since fan power is proportional to air volume flow rate times pressure drop).

### Range and Approach

Cooling tower designers and utility engineers have traditionally used two temperature differences to characterize cooling tower operation. The *range* is the difference between the water inlet and outlet temperatures (also called simply the hot and cold water temperatures). The *approach* is the difference between the outlet water temperature and the wet-bulb temperature of the entering (ambient) air. The approach characterizes cooling tower performance; for a given inlet condition, a larger packing will produce a smaller approach to the ambient wet-bulb temperature, and hence a lower water outlet temperature. (The water cannot be cooled below the ambient wet-bulb temperature.) The approach concept is useful because the ambient dry-bulb temperature has little effect on performance at usual operating conditions (for a specified wet-bulb temperature).

### Cooling Demand Curves

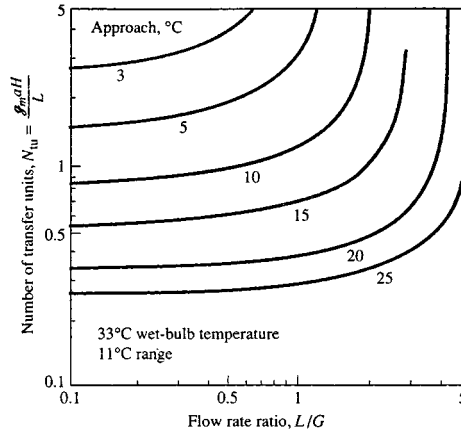

Electrical utility engineers have found it convenient to use charts of *cooling demand curves* to evaluate packing specifications. Figure 4.8.11 is an example of such a chart, on which the required NTU, for a given inlet air wet-bulb temperature and range, is plotted vs.  $L/G$  with the approach as a parameter. Such a plot is possible since the inlet air dry-bulb temperature has only a small effect under usual operating conditions. Now, if it is possible to correlate the mass transfer conductance as

$$\frac{g_m a}{L} = C \left( \frac{L}{G} \right)^{-n} \quad (4.8.22)$$

the NTU of a packing of height  $H$  is

$$\frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} = C \left( \frac{L}{G} \right)^{-n} H \quad (4.8.23)$$

**FIGURE 4.8.11** Example of cooling demand curves for a specified wet-bulb temperature and range: NTU vs. flow rate ratio for a fixed approach.

Equation (4.8.23) can also be plotted on the chart to give the *packing capability line*. For a required approach, the *operating point* of the tower is the intersection of the cooling demand curve and packing capability line. Charts of cooling demand curves are available (Cooling Tower Institute, 1967; Kelly, 1976). Correlations of the form of Equation (4.8.22) do not necessarily fit experimental data well. A dependence  $g_m a \propto L^{-n} G^n$  is implied and, in the past, experimental data were often forced to fit such a relation. If the  $g_m a$  correlation does not have the form of Equation (4.8.22), the NTU cannot be plotted as a line on a cooling demand chart.

With the almost universal use of computers and the availability of suitable computer programs, one can expect less use of cooling demand charts in the future. The major sources of error in the predictions made by these programs are related to nonuniform air and water flow, and the correlations of packing mass transfer and pressure drop experimental data. The experimental data are obtained in small-scale test rigs, in which it is impossible to simulate many features of full-size towers — for example, nonuniform flow due to entrance configuration, nonuniform wetting of the packing, and, in the case of counterflow towers, the effect of spray above the packing and rain below the packing. Furthermore, since testing of packings in small-scale test rigs is itself not easy, considerable scatter is seen in such test data. Correlations of the data typically have root mean square errors of 10 to 20%.

### Legionnaires' Disease

Legionnaires' disease is a form of pneumonia caused by a strain of legionella bacteria (sero group I). Smokers and sick people are particularly vulnerable to the disease. Major outbreaks have occurred at conventions and in hospitals, for which the source of the bacteria has been traced to cooling towers of air-conditioning systems. The bacteria require nutrients such as algae or dead bacteria in sludge, and thrive if iron oxides are present. However, properly designed, installed, and maintained cooling towers have never been implicated in an outbreak of the disease. Key requirements to be met include the following:

1. Mist (drift) eliminators should be effective.
2. The tower should be located so as to minimize the possibility of mist entering a ventilation system.
3. Corrosion in the tower and water lines should be minimized by use of glass fiber, stainless steel, and coated steel.
4. The design should facilitate inspection and cleaning, to allow early detection and remedy of sludge buildup.
5. Water treatment and filtration procedures should meet recommended standards.

## Heat Pipes

Larry W. Swanson

### Introduction

The heat pipe is a vapor-liquid phase-change device that transfers heat from a hot reservoir to a cold reservoir using **capillary forces** generated by a **wick** or porous material and a working fluid. Originally conceived by Gaugler in 1944, the operational characteristics of heat pipes were not widely publicized until 1963 when Grover and his colleagues at Los Alamos Scientific Laboratory independently reinvented the concept. Since then many types of heat pipes have been developed and used by a wide variety of industries.

Figure 4.8.12 shows a schematic of a heat pipe aligned at angle  $\psi$  relative to the vertical axis (gravity vector). The heat pipe is composed of a container lined with a wick that is filled with liquid near its saturation temperature. The vapor-liquid interface, usually found near the inner edge of the wick, separates the liquid in the wick from an open vapor core. Heat flowing into the evaporator is transferred through the container to the liquid-filled wicking material, causing the liquid to evaporate and vapor to flow into the open core portion of the evaporator. The capillary forces generated by the evaporating interface increase the pressure difference between the vapor and liquid. The vapor in the open core flows out of the evaporator through the adiabatic region (insulated region) and into the condenser. The vapor then condenses, generating capillary forces similar, although much less in magnitude, to those in the evaporator. The heat released in the condenser passes through the wet wicking material and container out into the cold reservoir. The condensed liquid is then pumped, by the liquid pressure difference due to the net capillary force between the evaporator and condenser, out of the condenser back into the

FIGURE 4.8.12 Schematic of a typical heat pipe.

evaporator. Proper selection and design of the pipe container, working fluid, and wick structure are essential to the successful operation of a heat pipe. The **heat transfer limitations**, **effective thermal conductivity**, and axial temperature difference define the operational characteristics of the heat pipe.

### Heat Pipe Container, Working Fluid, and Wick Structures

The container, working fluid, and wick structure of a heat pipe determine its operational characteristics. One of the most important considerations in choosing the material for the heat pipe container and wick is its compatibility with the working fluid. Degradation of the container or wick and contamination of the working fluid due to chemical reaction can seriously impair heat pipe performance. For example, noncondensable gas created during a chemical reaction eventually can accumulate near the end of the condenser, decreasing the condensation surface area. This reduces the ability of the heat pipe to transfer heat to the external heat sink. The material and geometry of the heat pipe container also must have a high burst strength, low weight, high thermal conductivity, and low porosity.

Using the proper working fluid for a given application is another critical element of proper heat pipe operation. The working fluid must have good thermal stability properties at the specified operational temperature and pressure. The operational temperature range of the working fluid has to lie between its triple point and its critical point for liquid to exist in the wicking material. The **wettability** of the working fluid contributes to its capillary pumping and priming capability. High-surface-tension fluids are commonly used in heat pipes because they provide the capillary pumping and wetting characteristics necessary for proper operation. Other desirable thermophysical properties include a high liquid thermal

conductivity, high latent heat of vaporization, low liquid viscosity, and a low vapor viscosity. Table 4.8.4 gives the thermophysical properties for three typical heat pipe working fluids that span a fairly wide operating temperature range. The thermophysical properties for other heat pipe working fluids can be obtained from Dunn and Reay (1982) and Peterson (1994).

The wick structure and working fluid generate the capillary forces required to (1) pump liquid from the condenser to the evaporator and (2) keep liquid evenly distributed in the wicking material. Heat pipe wicks can be classified as either homogeneous wicks or composite wicks. Homogeneous wicks are composed of a single material and configuration. The most common types of homogeneous wicks include wrapped screen, sintered metal, axial groove, annular, crescent, and arterial. Composite wicks are composed of two or more materials and configurations. The most common types of composite wicks include variable screen mesh, screen-covered groove, screen slab with grooves, and screen tunnel with

grooves. Regardless of the wick configuration, the desired material properties and structural characteristics of heat pipe wick structures are a high thermal conductivity, high wick porosity, small capillary radius, and high wick permeability. Table 4.8.2 gives the geometric properties of some commonly used homogeneous wicks. The properties of other wick structures, including nonhomogenous types, can be obtained from Peterson (1994). The container, wick structure, and working fluid are used to determine the heat transfer limitations of heat pipes.

### Heat Transfer Limitations

Heat pipes undergo various heat transfer limitations depending on the working fluid, the wick structure, the dimensions of the heat pipe, and the heat pipe operational temperature. Figure 4.8.13 gives a qualitative description of the various heat transfer limitations, which include vapor-pressure, sonic, entrainment, capillary, and boiling limitations. The composite curve enclosing the shaded region in Figure 4.8.13 gives the maximum heat transfer rate of the heat pipe as a function of the operational temperature. The figure shows that as the operational temperature increases, the maximum heat transfer rate of the heat pipe is limited by different physical phenomena. As long as the operational heat transfer rate falls within the shaded region, the heat pipe will function properly.

FIGURE 4.8.13 Heat transfer limitations in heat pipes.

The vapor-pressure limitation (or viscous limitation) in heat pipes develops when the pressure drop in the vapor core reaches the same order of magnitude as the vapor pressure in the evaporator. Under these conditions, the pressure drop due to flow through the vapor core creates an extremely low vapor pressure in the condenser preventing vapor from flowing in the condenser. A general expression for the vapor-pressure limitation is (Dunn and Reay, 1982)

$$Q_{vp,max} = \frac{\pi r_v^4 h_{fg} \rho_{v,e} P_{v,e}}{12 \mu_{v,e} l_{eff}} \quad (4.8.24)$$

where  $r_v$  is the cross-sectional radius of the vapor core (m),  $h_{fg}$  is the latent heat of vaporization (J/kg),  $\rho_{v,e}$  is the vapor density in the evaporator ( $\text{kg/m}^3$ ),  $P_{v,e}$  is the vapor pressure in the evaporator (Pa), and  $\mu_{v,e}$  is the vapor viscosity in the evaporator ( $\text{N sec/m}^2$ ).  $l_{eff}$  is the effective length of the heat pipe (m) equal to  $l_{eff} = 0.5(l_e + 2l_a + l_c)$ . The vapor-pressure limitation can occur during the start-up of heat pipes at the lower end of the working-fluid-temperature range.

The sonic limitation also can occur in heat pipes during start-up at low temperatures. The low temperature produces a low vapor density, thereby reducing the speed of sound in the vapor core. Thus, a sufficiently high mass flow rate in the vapor core can cause sonic flow conditions and generate a shock wave that chokes the flow and restricts the pipes ability to transfer heat to the condenser. Dunn and Reay (1982) give an expression for the sonic limitation that agrees very well with experimental data,

$$Q_{s,\max} = 0.474A_v h_{fg} (\rho_v P_v)^{1/2} \quad (4.8.25)$$

where  $A_v$  is the cross-sectional area of the vapor core ( $m^2$ ). The sonic limitation should be avoided because large temperature gradients occur in heat pipes under choked-flow conditions.

The entrainment limitation in heat pipes develops when the vapor mass flow rate is large enough to shear droplets of liquid off the wick surface causing dry-out in the evaporator. A conservative estimate of the maximum heat transfer rate due to entrainment of liquid droplets has been given by Dunn and Reay (1982) as

$$Q_{e,\max} = A_v h_{fg} \left[ \frac{\rho_v \sigma_l}{2r_{c,\text{ave}}} \right]^{1/2} \quad (4.8.26)$$

where  $\sigma_l$  is the surface tension (N/m) and  $r_{c,\text{ave}}$  is the average capillary radius of the wick. Note that for many applications  $r_{c,\text{ave}}$  is often approximated by  $r_{c,e}$ .

The capillary limitation in heat pipes occurs when the net capillary forces generated by the vapor-liquid interfaces in the evaporator and condenser are not large enough to overcome the frictional pressure losses due to fluid motion. This causes the heat pipe evaporator to dry out and shuts down the transfer of heat from the evaporator to the condenser. For most heat pipes, the maximum heat transfer rate due to the capillary limitation can be expressed as (Chi, 1976).

$$Q_{c,\max} = \left[ \frac{\rho_l \sigma_l h_{fg}}{\mu_l} \right] \left[ \frac{A_w K}{l_{\text{eff}}} \right] \left( \frac{2}{r_{c,e}} - \left[ \frac{\rho_l}{\sigma_l} \right] g L_t \cos \Psi \right) \quad (4.8.27)$$

where  $K$  is the wick permeability ( $m^2$ ),  $A_w$  is the wick cross-sectional area ( $m^2$ ),  $\rho_l$  is the liquid density ( $m^3$ ),  $\mu_l$  is the liquid viscosity (N sec/ $m^2$ ),  $r_{c,e}$  is the wick capillary radius in the evaporator (m),  $g$  is the acceleration due to gravity (9.8 m/sec<sup>2</sup>), and  $L_t$  is the total length of the pipe (m). For most practical operating conditions, this limitation can be used to determine maximum heat transfer rate in heat pipes.

The boiling limitation in heat pipes occurs when the degree of liquid superheat in the evaporator is large enough to cause the nucleation of vapor bubbles on the surface of the wick or the container. Boiling is usually undesirable in heat pipes because local hot spots can develop in the wick, obstructing the flow of liquid in the evaporator. An expression for the boiling limitation is (Chi, 1976)

$$Q_{b,\max} = \frac{4\pi l_{\text{eff}} k_{\text{eff}} T_v \sigma_v}{h_{fg} \rho_l \ln(r_i/r_v)} \left( \frac{1}{r_n} - \frac{1}{r_{c,e}} \right) \quad (4.8.28)$$

where  $k_{\text{eff}}$  is the effective thermal conductivity of the composite wick and working fluid (W/m K),  $T_v$  is the vapor saturation temperature (K),  $r_i$  is the inner container radius (m),  $r_n$  is the nucleation radius (equal to  $2.00 \times 10^{-6}$  m in the absence of noncondensable gas).

### Effective Thermal Conductivity and Heat Pipe Temperature Difference

One key attribute of the heat pipe is that it can transfer a large amount of heat while maintaining nearly isothermal conditions. The temperature difference between the external surfaces of the evaporator and the condenser can be determined from the following expression

$$\Delta T = R_t Q \tag{4.8.29}$$

where  $R_t$  is the total thermal resistance (K/W) and  $Q$  is the heat transfer rate (W). Figure 4.8.14 shows the thermal resistance network for a typical heat pipe and the associated thermal resistances. In most cases, the total thermal resistance can be approximated by

$$R_t = R_1 + R_2 + R_3 + R_4 + R_5 + R_7 + R_8 + R_9 \tag{4.8.30}$$

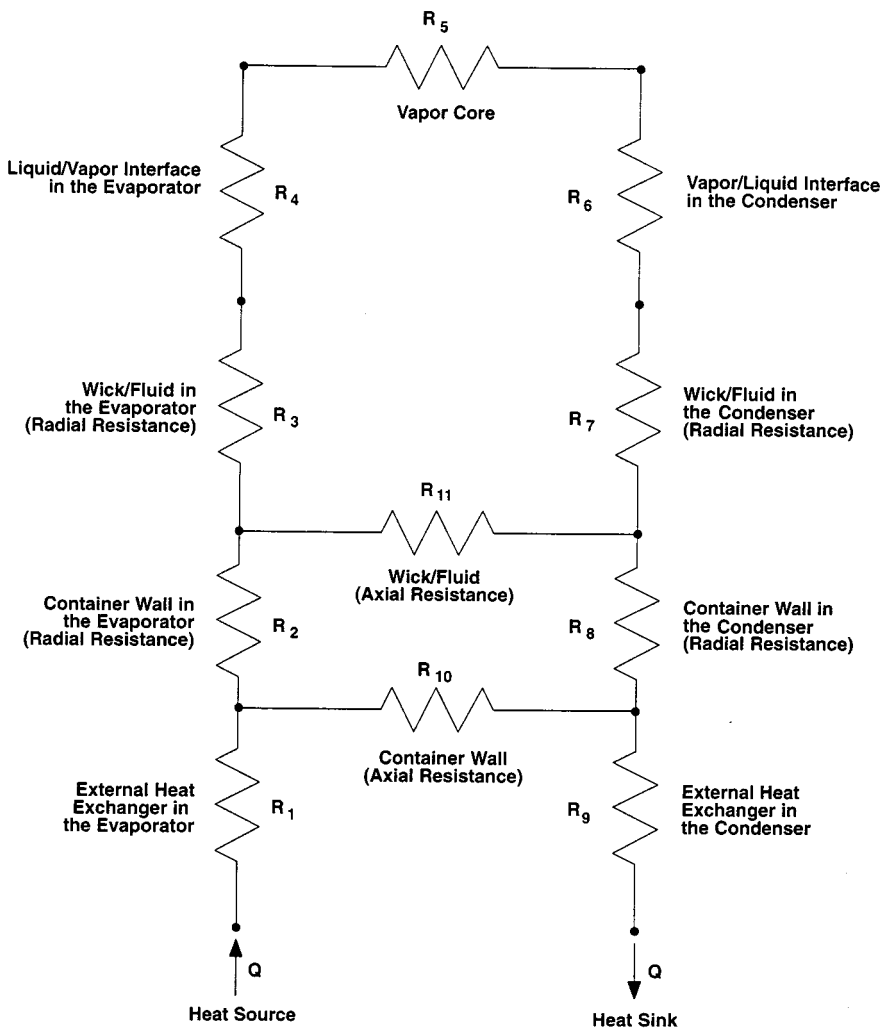

FIGURE 4.8.14 Thermal resistance network in a heat pipe.

The reader is referred to Peterson (1994) for the specific mathematical relationships used to calculate each thermal resistance. The effective thermal conductivity of the heat pipe is defined as the heat transfer rate divided by the temperature difference between the heat source and heat sink,

$$k_{\text{eff}} = \frac{L_t}{R_t A_t} \quad (4.8.31)$$

where  $A_t$  is the overall cross-sectional area of the pipe ( $\text{m}^2$ ). Under normal operating conditions, the total thermal resistance is relatively small, making the external surface temperature in the evaporator approximately equal to that in the condenser. Thus, the effective thermal conductivity in a heat pipe can be very large (at least an order of magnitude larger than that of aluminum).

### Design Example

Design a water heat pipe to transport 80 W of waste heat from an electronics package to cooling water. The heat pipe specifications are

1. Axial orientation — complete gravity-assisted operation (condenser above the evaporator;  $\psi = 180^\circ$ )
2. Maximum heat transfer rate — 80 W
3. Nominal operating temperature —  $40^\circ\text{C}$
4. Inner pipe diameter — 3 cm
5. Pipe length — 25 cm evaporator length, 50 cm adiabatic section, and 25 cm condenser length

The simplest type of wick structure to use is the single-layer wire mesh screen wick shown in [Table 4.8.5](#). The geometric and thermophysical properties of the wick have been selected as (this takes some forethought)

$$\begin{aligned} d &= 2.0 \times 10^{-5} \text{ m} \\ w &= 6.0 \times 10^{-5} \text{ m} \\ \frac{1}{2N} &= r_c = \frac{1}{2}(2.0 \times 10^{-5} + 6 \times 10^{-5}) = 4.0 \times 10^{-5} \text{ m} \\ \varepsilon &= 1 \end{aligned}$$

$$k_{\text{eff}} = k_1 = 0.630 \frac{\text{W}}{\text{mK}}$$

$$t_w = 1.0 \times 10^{-3} \text{ m}$$

$$K = \frac{t_w^2}{12} = \frac{(1 \times 10^{-3})^2}{12} = 8.33 \times 10^{-8} \text{ m}^2$$

The other heat pipe geometric properties are

$$r_v = r_i - t_w = 0.015 - 0.001 = 0.014 \text{ m}$$

$$l_{\text{eff}} = \frac{0.25 + 0.25}{2} + 0.5 = 0.75 \text{ m}$$

$$L_t = 0.25 + 0.50 + 0.25 + 1.0 \text{ m}$$

$$A_w = \pi(r_i^2 - r_v^2) = \pi[(0.015)^2 - (0.014)^2] = 9.11 \times 10^{-5} \text{ m}^2$$

$$A_v = \pi r_v^2 = \pi(0.014)^2 = 6.16 \times 10^{-4} \text{ m}^2$$

The thermophysical properties of water at  $40^\circ\text{C}$  are (see [Table 4.8.4](#)):

$$\rho_l = 992.1 \text{ kg/m}^3$$

$$\rho_v = 0.05 \text{ kg/m}^3$$

$$\sigma_l = 2.402 \times 10^6 \text{ J/kg}$$

$$\mu_l = 6.5 \times 10^{-3} \text{ kg/m sec}$$

$$\mu_v = 1.04 \times 10^{-4} \text{ kg/m sec}$$

$$P_v = 7000 \text{ Pa}$$

The various heat transfer limitations can now be determined to ensure the heat pipe meets the 80 W heat transfer rate specification. The vapor-pressure limitation is

$$Q_{vp,\max} = \frac{\pi(0.014)^4 (2.402 \times 10^6)(0.05)(7000)}{12(1.04 \times 10^{-4})(0.75)} = 1.08 \times 10^5 \text{ W} \quad (4.8.32)$$

The sonic limitation is

$$\begin{aligned} Q_{s,\max} &= 0.474(6.16 \times 10^{-4})(2.402 \times 10^6)[(0.05)(7000)]^{1/2} \\ &= 1.31 \times 10^4 \text{ W} \end{aligned} \quad (4.8.33)$$

The entrainment limitation is

$$\begin{aligned} Q_{e,\max} &= (6.16 \times 10^{-4})(2.402 \times 10^6) \left[ \frac{(0.05)(0.07)}{2(4.0 \times 10^{-5})} \right]^{1/2} \\ &= 9.79 \times 10^3 \text{ W} \end{aligned} \quad (4.8.34)$$

Noting that  $\cos \psi = -1$ , the capillary limitation is

$$\begin{aligned} Q_{c,\max} &= \left[ \frac{(992.1)(0.07)(2.402 \times 10^6)}{6.5 \times 10^{-3}} \right] \left[ \frac{(9.11 \times 10^{-5})(8.33 \times 10^{-8})}{0.75} \right] \left[ \frac{2}{4.0 \times 10^{-5}} + \frac{992.1}{0.07} 9.8(1.0) \right] \\ &= 4.90 \times 10^4 \text{ W} \end{aligned} \quad (4.8.35)$$

Finally, the boiling limitation is

$$\begin{aligned} Q_{b,\max} &= \frac{4\pi(0.75)(0.63)(313)(0.07)}{(2.402 \times 10^6)(992.1) \ln\left(\frac{0.015}{0.014}\right)} \left[ \frac{1}{2.0 \times 10^{-6}} - \frac{1}{4.0 \times 10^{-5}} \right] \\ &= 0.376 \text{ W} \end{aligned} \quad (4.8.36)$$

All of the heat transfer limitations, with the exception of the boiling limitation, exceed the specified heat transfer rate of 80 W. The low value of 0.376 W for the boiling limitation strongly suggests that the liquid will boil in the evaporator and possibly cause local dry spots to develop. The reason the liquid boils is because the effective thermal conductivity of the wick is equal to the conductivity of the liquid, which is very low in this case. Because the liquid is saturated at the vapor-liquid interface, a low effective thermal conductivity requires a large amount of wall superheat which, in turn, causes the liquid to boil. This problem can be circumvented by using a high conductivity wire mesh or sintered metal wick, which greatly increases the effective conductivity. It should be noted, however, that because porous wicks have

TABLE 4.8.5 Physical Properties of Wick Structures

<p>Single-layer wire mesh screens (heat-pipe axis in the plane of the paper in this sketch)</p>  <p style="text-align: center;"><math>1/N = d + w</math> <math>N =</math> number of apertures per unit length</p>				
<p>Annular</p> 	$k_{\text{eff}} = k_e$	$\epsilon = 1$	$r_c = 1/(2N)$	$K = t_w^2/12$
<p>Multiple wire mesh screens,<sup>b</sup> plain or sintered (screen dimensions as for single layers illustrated above)</p> 	$k_{\text{eff}} = \frac{k_e \left[ \frac{k_e + k_s - (1 - \epsilon)(k_e - k_s)}{k_e + k_s + (1 - \epsilon)(k_e - k_s)} \right]}{k_e + k_s + (1 - \epsilon)(k_e - k_s)}$	Estimated from $\epsilon = 1 - (\pi N d)/4$	$r_c = 1/(2N)$	$k = \frac{d^2 \epsilon^2}{122(1 - \epsilon)^2}$

TABLE 4.8.5 Physical Properties of Wick Structures (continued)

	Wick Type <sup>a</sup>	Thermal Conductivity	Porosity	Minimum Capillary Radius	Permeability
	Unconsolidated packed spherical particles ( $d$ = average particle diameter)	$k_{\text{eff}} = \frac{k_e \left[ \frac{2k_e + k_s - 2(1-\varepsilon)(k_e - k_s)}{2k_e + k_s + (1-\varepsilon)(k_e - k_s)} \right]}{k_e \left[ \frac{2k_s + k_e - 2\varepsilon(k_s - k_e)}{2k_s + k_e + \varepsilon(k_s - k_e)} \right]}$	Estimated from (assuming cubic packing) $\varepsilon = 0.48$	$r_c = 0.21d$	$k = \frac{d^2 \varepsilon^2}{150(1-\varepsilon)^2}$
	Sintered metal fibers ( $d$ = fiber diameter)	$k_{\text{eff}} = \varepsilon^2 k_e (1-\varepsilon)^2 k_s + \frac{4\varepsilon(1-\varepsilon)k_e k_s}{k_e + k_s}$	Use manufacturers data	$r_c = \frac{d}{2(1-\varepsilon)}$	$k = C_1 \frac{y^2 - 1}{y^2 - 1}$ where $y = 1 + \frac{C_2 d^2 \varepsilon^3}{(1-\varepsilon)^2}$ $C_1 = 6.0 \times 10^{-10} \text{ m}^2$ $C_2 = 3.3 \times 10^7 \text{ 1/m}^2$

<sup>a</sup> The axis of the pipe and direction of fluid flow are normal to the paper.

<sup>b</sup> These wicks are positioned so that the layers follow the contours of the inner surface of the pipe wall. Revised from Peterson, G.P., *An Introduction to Heat Pipes Modeling, Testing, and Applications*, John Wiley & Sons, New York, 1994.

lower permeabilities, the capillary limitation should be lower as well. Let's try a sintered particle wick made of copper with the following properties (see Table 4.8.5):

$$d = 1.91 \times 10^{-4} \text{ m}$$

$$r_{c,3} = 0.21d = 4.0 \times 10^{-5} \text{ m (same as before)}$$

$$\varepsilon = 0.48$$

$$K = \frac{(1.91 \times 10^{-4})^2 (0.48)}{150(1 - 0.48)^2} = 2.07 \times 10^{-10} \text{ m}^2$$

$$k_s = 400 \frac{\text{W}}{\text{mK}} \text{ (copper)}$$

$$k_1 = 0.630 \frac{\text{W}}{\text{mK}} \text{ (water)}$$

$$k_{\text{eff}} = \frac{400[2(400) + 0.63 - 2(0.48)(400 - 0.63)]}{2(400) + 0.63 + 0.48(400 - 0.63)} = 168 \text{ W/mK}$$

All other geometric and thermophysical properties are the same. The heat transfer limitations affected by the change in wick structure are the capillary and boiling limitations. The sintered metal wick produces a capillary limitation of

$$\begin{aligned} Q_{c,\text{max}} &= \left[ \frac{(992.1)(0.07)(2.402 \times 10^6)}{6.5 \times 10^{-3}} \right] \left[ \frac{(9.11 \times 10^{-5})(2.07 \times 10^{-10})}{0.75} \right] \left[ \frac{2}{4.0 \times 10^{-5}} + \frac{992.1}{0.07} 9.8(1.0) \right] \\ &= 122 \text{ W} \end{aligned} \quad (4.8.37)$$

The boiling limitation for the sintered wick is

$$\begin{aligned} Q_{b,\text{max}} &= \frac{4\pi(0.75)(168)(313)(0.07)}{(2.402 \times 10^6)(992.1)\ln\left(\frac{0.015}{0.014}\right)} \left[ \frac{1}{2.0 \times 10^{-6}} - \frac{1}{4.0 \times 10^{-5}} \right] \\ &= 100 \text{ W} \end{aligned} \quad (4.8.38)$$

This design now meets all the specifications defined in the problem statement.

### Application of Heat Pipes

Heat pipes have been applied to a wide variety of thermal processes and technologies. It would be an impossible task to list all the applications of heat pipes; therefore, only a few important industrial applications are given in this section. In the aerospace industry, heat pipes have been used successfully in controlling the temperature of vehicles, instruments, and space suits. Cryogenic heat pipes have been applied in (1) the electronics industry for cooling various devices (e.g., infrared sensors, parametric amplifiers) and (2) the medical field for cryogenic eye and tumor surgery. Heat pipes have been employed to keep the Alaskan tundra frozen below the Alaskan pipeline. Other cooling applications include (1) turbine blades, generators, and motors; (2) nuclear and isotope reactors; and (3) heat collection from exhaust gases, solar and geothermal energy.

In general, heat pipes have advantages over many traditional heat-exchange devices when (1) heat has to be transferred isothermally over relatively short distances, (2) low weight is essential (the heat pipe is a passive pumping device and therefore does not require a pump), (3) fast thermal-response times are required, and (4) low maintenance is mandatory.

## Defining Terms

**Capillary force:** The force caused by a curved vapor-liquid interface. The interfacial curvature is dependent on the surface tension of the liquid, the contact angle between the liquid wick structure, the vapor pressure, and the liquid pressure.

**Effective thermal conductivity:** The heat transfer rate divided by the temperature difference between the evaporator and condenser outer surfaces.

**Heat transfer limitations:** Limitations on the axial heat transfer capacity imposed by different physical phenomena (i.e., vapor pressure, sonic, entrainment, capillary, and boiling limitations).

**Wettability:** The ability of a liquid to spread itself over a surface. A wetting liquid spreads over a surface whereas a nonwetting liquid forms droplets on a surface.

**Wick:** A porous material used to generate the capillary forces that circulate fluid in a heat pipe.

### Introduction

In electronic packages, the thermal resistances to heat transfer from heat source to heat sink are often grouped into an internal resistance and an external resistance. The **internal thermal resistance**  $R_{\text{int}}$  is conductive and exists between the chip and the module case:

$$R_{\text{int}} = \frac{T_{\text{chip}} - T_{\text{case}}}{P_{\text{chip}}} \quad (4.8.39)$$

where  $P_{\text{chip}}$  is the chip power.

The **external thermal resistance**  $R_{\text{ext}}$  is primarily convective and exists between the surface of the case of the module and some reference point, typically the temperature of the cooling fluid near the module. In a multichip module, the module power  $P_m$  is the sum of the individual chip powers, and the external resistance is

$$R_{\text{ext}} = \frac{T_{\text{case}} - T_{\text{coolant}}}{P_m} \quad (4.8.40)$$

The internal and external resistances are related to the chip junction temperature  $T_j$  through the following expression:

$$T_j = \Delta T_{j\text{-chip}} + P_{\text{chip}} R_{\text{int}} + P_m R_{\text{ext}} + \Delta T_{\text{coolant}} + T_{\text{coolant in}} \quad (4.8.41)$$

Many factors are involved in determining the appropriate cooling mode to be used. If the component junction temperature is constrained to approximately 85°C, Table 4.8.6 may be used to make a preliminary selection of the cooling mode. Extended surfaces can often be used to increase the allowable heat fluxes.

**TABLE 4.8.6 Maximum Component Heat Flux for Various Cooling Modes**

Cooling Mode	W/cm <sup>2</sup>
Free convection air	0.05
Forced convection air	0.5
Impingement air	1.0

Forced convection immersion	50
Pool boiling	20
Forced convection boiling	100
Jet immersion (single phase)	40
Boiling jet immersion	90

### Free Convection Air Cooling of Vertical Printed Circuit Boards

Data have been collected from rack-mounted simulated printed circuit boards (PCBs) (see Figure 4.8.15) and from several actual electronic systems at AT&T Bell Laboratories. Results indicated that existing parallel plate correlations for symmetric isoflux plates (separated by distance “b”) could be adapted to PCB conditions. Specifically, for  $Ra_b < 10$  use the equation corresponding to the fully developed laminar boundary layer condition:

$$Nu_b = 0.144 Ra_b^{0.5} \quad (4.8.42)$$

For  $10 < Ra_b < 1000$ , use

$$Nu_b = \left[ \frac{48}{Ra_b} + \frac{2.5}{Ra_b^{0.4}} \right]^{-0.5} \quad (4.8.43)$$

where

$$Ra_b = \frac{g \beta c_p \rho^2 b^5 q''}{\mu k L}$$

For  $Ra > 1000$ , the expression for an isolated plate in infinite media is recommended:

$$Nu_b = 0.524 Ra_b^{0.2} \quad (4.8.44)$$

**FIGURE 4.8.15** Typical PCB array.

In the previous three expressions air properties are evaluated at the average of the module case and ambient temperatures.

The PCB spacing  $b_{\max}$  for a given power dissipation which yields the lowest PCB component case temperatures (or which maximizes the rate of heat transfer while maintaining PCB temperatures below the maximum allowable) occurs when the developing boundary layers from adjacent PCBs do not interfere, i.e., so the isolated plate condition is approached as follows: If heat is transferred from both sides of the PCB, let  $Ra_{ab} = 17,000$  and the recommended PCB spacing is  $b_{\max} = 7.02\xi^{-0.2}$ . If heat is transferred from only one side of the PCB, let  $Ra_{ab} = 5400$  and the recommended PCB spacing is  $b_{\max} = 5.58\xi^{-0.2}$ . In both cases

$$\xi = \frac{g\beta\rho^2\text{Pr}q''}{\mu^2kL} \quad (4.8.45)$$

### Forced Convection Air Cooling of Vertical PCBs

Sparrow et al. (1982, 1984) studied vertical arrays with simulated modules of uniform size, which was 4 modules wide by 17 module rows deep in the flow direction; the modules were 26.7 mm square and 10 mm high; the space between modules was 6.67 mm, and the distance from the top of the module to the adjoining card  $Hc = 16.7$  mm. The Nusselt number as a function of module row position for a fully populated array may be determined from Figure 4.8.16. Correction factors to the fully developed Nusselt numbers for the effect of missing modules and the presence of modules whose height differs from others in the array are presented in the cited references.

In actual electronic packages, conditions differ from the relatively ideal setups in laboratories because in real packages the flow is disturbed by the PCB supporting hardware and may extend the entry region effect.

Data from actual computer hardware with PCBs containing a  $6 \times 4$  array of 28 mm modules (4 in the flow direction) were used to develop the following expressions:

$$\text{Nu}_x = C \left\{ \text{Re}_{D_h} \left[ 1 + x / (D_h)^{-0.836} \right] \right\}^m \quad (4.8.46)$$

**FIGURE 4.8.16** Nusselt number for fully populated array of modules.

For  $Re < 2000$ ,  $C = 0.072$  and  $m = 0.70$ , and for  $2000 < Re < 10,000$ ,  $C = 0.056$  and  $m = 1.02$ , where  $x$  is the distance in the flow direction. Because the array was only 4 modules deep, all the modules on the PCB were in the entry region.

Tests have been conducted on a  $9 \times 7$  array of 25-mm-square by 6.4-mm-high blocks cooled by a  $3 \times 3$  array of air jets directed normal to the face of each block. The spent flow exited along the channel formed by the orifice plate and the heat transfer surfaces. Test results were correlated by the relation:

$$N_d = 0.213(z/d)^{-0.376} Re_d^{0.743} \quad (4.8.47)$$

where  $d$  is the jet orifice diameter,  $s$  is the orifice-to-orifice spacing, and  $z$  is the distance from the orifice outlet to the face of the module.

### Immersion Cooling

The highly inert perfluorinated liquids, called FC coolants by the 3M Company, are frequently used in **immersion cooling** applications. FC coolants are available with boiling points from 30 to 172°C at atmospheric pressure. FC-75 and FC-77 with boiling points of 100°C are often used in single-phase applications, while FC-72 and FC-87, with boiling points of 56 and 30°C, respectively, are used in systems involving phase change.

Data exist for free convection immersion cooling of a  $3 \times 3$  array of simulated chips mounted on a vertical wall in an enclosure filled with FC-75. Each heat source was 8 mm high by 24 mm wide by 6 mm thick. With the Nusselt and modified Rayleigh numbers based on the heater height,  $L$ , the best fit to the data is

$$Nu_L = 0.279 Ra_b^{0.224} \quad (4.8.48)$$

Air cooling expressions have been modified to make them applicable to free convection immersion cooling of vertical PCB arrays with FC coolants. The Nusselt number (based on PCB spacing “b”) at the top of the PCB is

$$\text{Nu}_L = \left[ \frac{C}{\text{Ra}_b} + \frac{2.78}{\text{Ra}_b^{0.4}} \right]^{-0.5} \quad (4.8.49)$$

$C = 24$  when heat transfer is from one side of the PCB, and  $C = 48$  when from both sides.

### Nucleate Pool Boiling

A number of investigators have tested small flush heat sources boiling in a pool of dielectric liquid. The heaters ranged from  $4 \times 4$  mm to  $12.7 \times 12.7$  mm. Typical saturated pool boiling data for FC-72 and FC-87 are shown in Figure 4.8.17. Note that a temperature overshoot up to  $25^\circ\text{C}$  has been regularly observed for silicon chips in dielectric liquid pools. To estimate the temperature excursion at boiling incipience ( $q_i''$ ), the following approximation is recommended

$$\Delta T_{\text{ex}} = T_{\text{sat}} \left( p - \frac{2\sigma}{r_b} - p_g \right) - T_{\text{sat}} - C(q_i'')^n \quad (4.8.50)$$

where

$$C = \mu h_{fg} \left[ \frac{c_p}{h_{fg} \text{Pr}^b C_{sf}} \right]^{1/a} \left[ \frac{\alpha}{g(\rho_f - \rho_g)} \right]^{0.5} \quad (4.8.51)$$

with  $r_b = 0.25 \mu\text{m}$ ,  $C_{sf} = 0.003$ ,  $a = 0.33$ , and  $b = 1.7$ . (Note that  $n = 1/a = 3$ .)

Park and Bergles (1988) determined the critical heat flux (CHF) as a function of size for flush heaters operating in a saturated pool of R-113. For a 5-mm-wide heater, and for heater heights from 5 to 80 mm, use

$$\frac{q_{c,\text{sat}}''}{q_{c_z}''} = 0.86 \left[ 1 + \frac{152}{L^{*3.29}} \right]^{0.14} \quad (4.8.52)$$

where the CHF prediction of Zuber,  $q_{c_z}'' = \rho_g^{0.5} h_{fg} [\sigma g(\rho_f - \rho_g)]^{0.5}$ , and  $L^* = L[g(\rho_f - \rho_g)/\sigma]^{0.5}$ .

For a 5-mm-high heater, and for heater widths from 2.5 to 70 mm, use

$$\frac{q_{c,\text{sat}}''}{q_{c_z}''} = 0.93 \left[ 1 + \frac{52}{I^{1.02}} \right]^{0.14} \quad (4.8.53)$$

where the induced convection parameter is  $I = (\rho_f W \sigma / \mu^2)^{0.5}$ .

For flush  $12.7 \times 12.7$  mm heaters in FC-72, test data yield  $q_{c,\text{sat}}'' / q_{c_z}'' \approx 1.45$ . These subcooling data were correlated by

$$\frac{q_{c,\text{sub}}''}{q_{c,\text{sat}}''} = 1 + \frac{0.0643 \rho_f c_{p,f}}{\rho_g h_{fg}} \left[ \frac{\rho_g}{\rho_f} \right]^{1/4} \Delta T_{\text{sub}} \quad (4.8.54)$$

### Single-Phase and Boiling Forced Convection in Channel Flow

The average Nusselt numbers for 12 flush  $12.7 \times 12.7$  mm heaters (4 rows of 3 sources per row) operating in FC-77 has been correlated by the following expression:

FIGURE 4.8.17 Typical pool boiling curve for small heater.

$$\overline{Nu}_L = C(\text{Re}_{D_h})^m \text{Pr}^{0.11} \tag{4.8.55}$$

For row 1:  $C = 0.194$  and  $m = 0.60$ ; for row 2:  $C = 0.069$  and  $m = 0.69$ ; for row 3:  $C = 0.041$  and  $m = 0.74$ ; and for row 4:  $C = 0.029$  and  $m = 0.78$ . All properties are determined at the inlet temperature except for  $\mu_h$ , which is evaluated at the heater temperature. Note that when heat sinks are employed, forced convection immersion cooling can support a heat flux of approximately  $50 \text{ W/cm}^2$ .

Test data have been obtained for a vertical column of ten  $6.4 \text{ mm} \times 6.4 \text{ mm}$  heaters, with subcooled R-113 flowing in the upward direction. In general, CHF occurred first at the last downstream element in the array, and that CHF values of  $100 \text{ W/cm}^2$  were easily attained. The CHF data yielded the following equation:

$$q_c'' = C_5 \text{We}^n V \rho_f h_{fg} \left( \frac{\rho_f}{\rho_g} \right)^{15/23} \left( \frac{L}{D_h} \right)^{1/23} \left[ 1 + \frac{c_{pf} \Delta T_{\text{sub}}}{h_{fg}} \right]^{7/23} \left[ 1 + \frac{0.021 \rho_f c_{pf} \Delta T_{\text{sub}}}{\rho_g h_{fg}} \right] \tag{4.8.56}$$

where the Weber number,  $\text{We} = \rho_f V^2 L / \sigma$ . Note that for  $\text{We} > 100$ ,  $C_5 = 0.125$  and  $n = -8/23$ , and for  $\text{We} < 10$ ,  $C_5 = 0.254$  and  $n = -1/2$ .

### Immersion Cooling Using Jets

Two modes have been studied. In the first, a dielectric liquid jet discharges into a miscible liquid and is said to be submerged; in the second, a liquid jet discharges into an immiscible gas (air) and is said to be free. In general, the average Nusselt number can be expressed as

$$\overline{Nu} = f(\text{Re}^m, \text{Pr}^n, L/d, z/d) \quad (4.8.57)$$

where  $L/d$  is the ratio of the chip length to orifice diameter, and  $z/d$  is the ratio of the jet to heat source distance to the orifice diameter. A free jet is virtually unaffected by the orifice-to-chip distance, and as a consequence the  $(z/d)$  term drops out.

Data for single-phase forced convection cooling with free jets are available for  $2 \times 2$  and  $3 \times 3$  heat source arrays. The heat sources were  $12.7 \times 12.7$  mm and the cooling fluid was FC-77. Each heat source was cooled either by a single jet or by a  $2 \times 2$  or  $3 \times 3$  array of jets per source. For all the configurations tested, the average Nusselt number was correlated by a single expression:

$$\overline{Nu}_L = 3.84 \left( 0.008 \frac{L}{d} n + 1 \right) \text{Re}^{1/2} \text{Pr}^{1/3} \quad (4.8.58)$$

where fluid properties are to be evaluated at an average of the heat source and jet inlet temperatures.

Data for single-phase forced convection using submerged jets are available for a  $5 \times 5$  mm vertical heat source cooled by a 1.0-mm-diameter submerged jet of R-113. The Nusselt number at the stagnation point was correlated by

$$\text{Nu}_d = 1.29 \text{Re}_d^{1/2} \text{Pr}^{0.4} \quad (4.8.59)$$

Also note that the performance of a submerged liquid jet should be approximately equivalent to gas jet impingement.

Data for two-phase forced convection using free jets have been collected for a single  $12.7 \times 12.7$  mm heat source cooled by either a single jet or a  $2 \times 2$  or  $3 \times 3$  array of jets. The jet diameter, velocity, and jet-to-source distance were varied. The CHF data was correlated by

$$q_c'' = 0.0742 \text{We}^{-0.365} V \rho_f h_{fg} \left( \frac{\rho_g}{\rho_f} \right)^{0.239} \left[ 1 + 0.952 \left( \frac{\rho_f}{\rho_g} \right)^{0.118} \left( \frac{c_{pf} \Delta T_{\text{sub}}}{h_{fg}} \right) \right]^{1.414} \quad (4.8.60)$$

Experimental evidence in two-phase forced convection using submerged jets indicates that (1) the temperature overshoot at incipient boiling was very small compared with pool or forced boiling; (2) the boiling curves at various velocities merge to a single curve and that this curve coincides approximately with an upward extrapolation of the pool boiling curve; (3) the CHF varies as the cube of the jet velocity; (4) the CHF is greatly improved by increasing the subcooling; and (5) powers in excess of 20 W ( $5 \times 5$ -mm chip) could be accommodated within a  $85^\circ\text{C}$  chip temperature.

## Defining Terms

**External thermal resistance:** The thermal resistance from a convenient reference point on the outside of the electronic package to the local ambient.

**Internal thermal resistance:** The thermal resistance from the device junction inside an electronic package to a convenient reference point on the outside surface of the package.

**Immersion cooling:** Concerns applications where the coolant is in direct physical contact with the electronic components.

## 4.9 Non-Newtonian Fluids — Heat Transfer

*Thomas F. Irvine, Jr., and Massimo Capobianchi*

### Introduction

The general characteristics of non-Newtonian fluids are described in Section 3.9 and will not be repeated here. Topics to be included in this section are laminar and turbulent heat transfer in fully developed duct flow, and laminar free convection heat transfer in vertical channels and plates and several other common geometries.

For non-Newtonian flows, except for certain classes of fluids which exhibit a slip phenomenon at solid boundaries, the boundary condition is taken as no-slip or zero velocity at all solid surfaces. For heat transfer analyses, however, the situation is more complicated because there are many different ways to heat a wall, which in turn affects the type of thermal boundary conditions.

In general, the rate of heat transfer from a surface, or the temperature difference between the wall and the fluid, is calculated using the equation  $q_c = h_c A_q \Delta T$ . Since the heat transfer coefficient can vary considerably for different thermal boundary conditions, it is important that the boundary conditions be specified correctly. Although the number of thermal boundary conditions is in principle infinite, several classical types have been identified and are in common use. They are usually identified in terms of the Nusselt number,  $Nu = h_c L/k$ , with a particular subscript. For example, for duct flow, the symbol  $Nu_T$  is used to specify the Nusselt number when the wall temperature is constant in both the flow and peripheral directions. Other thermal boundary conditions are described in Table 4.9.1 for duct heat transfer and will be used throughout this section.

**TABLE 4.9.1 Thermal Boundary Conditions for Duct Heat Transfer**

1.	Constant wall temperature in both the flow and circumferential direction	$Nu_T$
2.	Constant heat flux in the flow direction and constant temperature in the circumferential direction	$Nu_{H1}$
3.	Constant heat flux in the flow and circumferential directions	$Nu_{H2}$
4.	Constant heat flux per unit volume in the wall with circumferential wall heat conduction	$Nu_{H4}$

It should be noted that because of the symmetry in circular and parallel plate ducts,  $Nu_{H1}$  and  $Nu_{H2}$  are identical and are referred to simply as  $Nu_{H1}$ .  $Nu_{H4}$  with wall conduction is a more-complicated problem where the energy equations must be solved simultaneously in both the wall and the fluid. Such problems are called conjugated. In the  $Nu_{H4}$  situation, the designer has the flexibility of affecting the heat transfer by varying either or both the characteristics of the duct wall or the convective fluid. In the heat transfer relations to be considered later, care will be taken to identify the proper thermal boundary conditions using the nomenclature in Table 4.9.1.

### Laminar Duct Heat Transfer — Purely Viscous, Time-Independent Non-Newtonian Fluids

As discussed in Section 3.9, a convenient and comprehensive constitutive equation for pseudoplastic fluids (flow index,  $n < 1$ ) is the modified power law equation:

$$\mu_a = \frac{\mu_o}{1 + \frac{\mu_o}{K} (\dot{\gamma})^{1-n}} \quad (4.9.1)$$

Equation (4.9.1) has the characteristic that at low shear rates, the equation approaches that for a Newtonian fluid while at large shear rates it describes a power law fluid. In addition, solutions using

Equation (4.9.1) generate a shear rate parameter,  $\beta$ , which describes whether any particular system is in the Newtonian, transitional, or power law region. For duct flow,  $\beta$  is given by

$$\beta = \frac{\mu_o}{K} \left( \frac{\bar{u}}{D_H} \right)^{1-n} \quad (4.9.2)$$

If  $\log_{10} \beta > 2$ : Power law region

If  $\log_{10} \beta < -2$ : Newtonian region

If  $-2 \leq \log_{10} \beta \leq 2$ : Transition region

For fully developed flow, the characteristic length is the hydraulic diameter,  $D_H$ , and the fluid temperature is the “bulk” temperature defined as

$$T_b = \frac{1}{A_c \bar{u}} \int_{A_c} u T dA_c \quad (4.9.3)$$

Figure 4.9.1 illustrates the values of  $Nu_T$  vs.  $\beta$  for a circular duct with the flow index,  $n$ , as a parameter. It is seen from the figure that the effect of  $\beta$  on  $Nu_T$  is only moderate, but for some applications it may be important to know at what value of  $\beta$  the system is operating. The situation is similar for boundary condition  $Nu_H$ .

Although Figure 4.9.1 shows the Nusselt number relation graphically, it is convenient to have simple correlation equations to represent the solutions for both boundary conditions. For fully developed Nusselt numbers with values of  $0.5 \leq n \leq 1.0$  and  $10^{-4} \leq \beta \leq 10^4$ , Irvine et al. (1988) present the following equation which represents both solutions with a maximum difference of 1.5%:

$$Nu = \frac{Nu_N(1+\beta)}{1 + \frac{Nu_N\beta}{Nu_P}} \quad (4.9.4)$$

The Newtonian Nusselt numbers are  $Nu_N = 3.6568$  for  $Nu_T$ , and  $Nu_N = 4.3638$  for  $Nu_H$ . In addition, Table 4.9.2 lists the power law Nusselt numbers,  $Nu_{TP}$  and  $Nu_{HP}$ , for  $\log_{10} \beta = 4$ .

Graetz solutions for the thermal entrance lengths are also available. They assume that the velocity profile is fully developed at the duct entrance and present the duct lengths required for the Nusselt numbers to reach within 1% of the fully developed values. Figure 4.9.2 shows these thermal entrance lengths for  $Nu_T$  thermal boundary condition. The situation is similar for boundary condition  $Nu_H$ .

A correlation equation for the thermal entrance lengths for both the  $Nu_T$  and  $Nu_H$  boundary conditions by Irvine et al. (1988) represents the numerical solutions within 0.5% for  $0.5 \leq n \leq 1.0$  and  $-4 \leq \log_{10} \beta \leq 4$ . Table 4.9.3 lists the power law thermal entrance lengths which are needed to evaluate the following correlation equation:

$$x_{ent,\beta,n}^+ = \frac{x_{ent,N}^+(1+\beta)}{1 + \frac{x_{ent,N}^+(\beta)}{x_{ent,P}^+}} \quad (4.9.5)$$

where  $x_{ent,\beta,n}^+$  is the modified power law dimensionless entrance length defined as  $x_{ent,\beta,n}^+ = (x_{ent,\beta,n}/D_H)/Pe$ , and  $x_{ent,N}^+$  and  $x_{ent,P}^+$  are the Newtonian and power law values, respectively. The Newtonian dimensionless entrance lengths are  $x_{ent,N}^+ = 0.03347$  for  $Nu_T$  and  $x_{ent,N}^+ = 0.04309$  for  $Nu_H$ .

**FIGURE 4.9.1** Variation of the fully developed circular duct Nusselt numbers,  $Nu_T$ , with the shear rate parameter  $\beta$  and  $n$ . (From Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127. With permission.)

Only one noncircular geometry using the modified power law equation has been published in the archival literature for laminar fully developed heat transfer (Capobianchi and Irvine, 1992). A correlation equation for  $Nu_{H1}$  for annuli with constant heat flux at the inner wall and the outer wall insulated is

$$n < 1 \quad Nu_{H1} = \frac{1 + \beta}{\frac{1}{Nu_{H1,N}} + \frac{\beta}{Nu_{H1,P}}} \tag{4.9.6}$$

Nusselt numbers for square ducts and power law fluids can be found in Chandrupatla and Sastri (1977) and, for isosceles triangular ducts, in Cheng (1984). Thermally developing and thermally developed laminar heat transfer in rectangular channels has been studied by Hartnett and Kostic (1989).

For other cross-sectional shapes, a power law approximate correlation has been proposed by Cheng (1984):

**FIGURE 4.9.2** Thermal entrance lengths vs. shear rate parameter  $\beta$  and  $n$  for  $Nu_T$  in circular ducts. (From Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127. With permission.)

$$Nu_p = Nu_N \left[ \frac{(a + bn)}{(a + b)n} \right]^{1/3} \tag{4.9.7}$$

where  $a$  and  $b$  are the Kozicki geometric constants listed in Table 3.9.3 in the section on non-Newtonian flows. Equation (4.9.7) applies to any thermal boundary condition. For circular ducts, Equation 4.9.7 predicts the correct solution for both  $Nu_T$  and  $Nu_H$ .

### Turbulent Duct Flow for Purely Viscous Time-Independent Non-Newtonian Fluids

It is known that in turbulent flow, the type of thermal boundary conditions has much less effect than in laminar flow. Therefore, turbulent flow heat transfer investigations are often reported without specifying the thermal boundary conditions. Yoo (1974) has presented an empirical correlation for turbulent heat transfer in circular ducts for purely viscous time-independent power law fluids.

$$\text{StPr}_a^{2/3} = 0.0152\text{Re}_a^{-0.155} \quad (4.9.8)$$

Equation (4.9.8) describes all of the experimental data available in the literature at the time with a mean deviation of 2.3%. Equation (4.9.8) is recommended in order to predict the turbulent fully developed heat transfer in the ranges  $0.2 \leq n \leq 0.9$  and  $3000 \leq \text{Re}_a \leq 90,000$ . The Reynolds number and Prandtl numbers in Equation (4.9.8) are based on the apparent viscosity at the wall,  $\mu_a$ , i.e.,

$$\text{Re}_a = \frac{\rho \bar{u} D_H}{\mu_a} \quad (4.9.9)$$

$$\text{Pr}_a = \frac{\mu_a c_p}{k} \quad (4.9.10)$$

In order to evaluate Equations (4.9.9) and (4.9.10) in terms of the rheological properties and operating parameters, an expression must be obtained for  $\mu_a$  in terms of these quantities. The value of  $\mu_a$  is evaluated by considering that  $\mu_a$  is determined from fully developed laminar circular tube power law fluid flow for which it can be shown that (Irvine and Karni, 1987)

$$\mu_a = K \left( \frac{3n+1}{4n} \right)^{n-1} \left( \frac{8\bar{u}}{D_H} \right)^{n-1} \quad (4.9.11)$$

assuming that the quantities  $K$ ,  $n$ ,  $c_p$ , and  $k$  are constant. It is also of interest that the Prandtl number is no longer a thermophysical property for power law fluids but depends upon the average velocity,  $\bar{u}$ , and the hydraulic diameter,  $D_H$ .

Hartnett and Rao (1987) have investigated fully developed turbulent heat transfer for a rectangular duct with a 2:1 aspect ratio and propose the following equation which generally agreed with their experimental data within  $\pm 20\%$ :

$$\text{Nu} = (0.0081 + 0.0149n)\text{Re}_a^{0.8}\text{Pr}_a^{0.4} \quad (4.9.12)$$

## Viscoelastic Fluids

An important characteristic of viscoelastic fluids is their large hydrodynamic and thermal entrance lengths. Cho and Hartnett (1982) have reported hydrodynamic entrance lengths of up to 100 diameters and thermal entrance lengths up to 200 to 800 diameters depending upon the Reynolds and Prandtl numbers. These can be compared with Newtonian fluids entrance lengths which are of the order of 10 to 15 diameters. Therefore, care must be used in applying fully developed relations to practical situations.

Cho et al. (1980) reported heat transfer measurements in the thermal entrance region and recommend the following empirical equation for saturated aqueous polymer solutions for  $6000 \leq \text{Re}_a$  and  $x/D_H$  values up to 450:

$$J_H = 0.13 \left( x/D_H \right)^{-0.24} \text{Re}_a^{-0.45} \quad (4.9.13)$$

where  $J_H = \text{St Pr}_a^{2/3}$  and  $\text{St} = h_c/\rho c_p \bar{u}$ .

All of the reported fully developed turbulent flow heat transfer measurements have been plagued by solute and solvent, thermal entrance, and degradation effects, and thus there is considerable scatter in the results. Degradation effects can be reduced or eliminated by using large amounts of polymer (500

to 10,000 wppm) so that the solution becomes saturated. Cho and Hartnett (1982) attempted to eliminate these effects by using a thermal entrance length of 430 diameters and saturated polymer solutions which should yield maximum heat transfer reductions. Their experimental results for fully developed heat transfer were correlated for a Reynolds number range  $3500 \leq Re_a \leq 40,000$  and concentration solutions of 500 to 5000 wppm of polyacrylamide and polyethylene oxide by

$$J_H = 0.03Re_a^{-0.45} \quad (4.9.14)$$

For viscoelastic fluids in fully developed (hydrodynamically and thermally) *laminar flow in circular ducts* there is no apparent viscoelastic effect. Thus, the heat transfer relations are the same as those for time-independent fluids such as power law or modified power law fluids. The same situation holds for thermal entrance region heat transfer (Graetz problem). Relations for laminar Nusselt numbers in thermal entrance regions are presented by Cho and Hartnett (1982).

### Free Convection Flows and Heat Transfer

Free convection information available in the heat transfer literature up to the present time is concentrated on heat transfer to power law fluids for vertical plates and parallel plate channels. For free convection flows, however, the velocities and thus the shear rates are low and care must be taken that the flow for a particular fluid is in the power law shear rate region before using power law solutions or correlations. Comprehensive review articles on free convection with non-Newtonian fluids have been presented by Shenoy and Mashelkar (1982) and Irvine and Karni (1987).

For a single vertical plate with a modified power law fluid and a thermal boundary condition  $\bar{Nu}_T$ , in laminar flow, the following relation is recommended by Shenoy and Mashelkar (1982):

$$\bar{Nu}_{TL} = T(n)Gr_{TL}^{1/(2n+2)}Pr_{TL}^{n/(3n+1)} \quad (4.9.15)$$

where  $\bar{Nu}_{TL}$  is the average Nusselt number and

$$Gr_{TL} = \frac{\rho^2 L^{n+2}}{K^2} [g\alpha(T_s - T_\infty)]^{2-n} \quad (4.9.16)$$

$$Pr_{TL} = \frac{\rho c_p}{k} \left( \frac{K}{\rho} \right)^{2/(n+1)} L^{(n-1)/(2n+2)} [g\alpha(T_s - T_\infty)]^{(3n-3)/(2n+2)} \quad (4.9.17)$$

where  $\alpha$  is the isobaric thermal expansion coefficient.

In the range  $0.5 \leq n \leq 1$ ,  $T(n)$  can be approximated by

$$T(n) = 0.1636n + 0.5139 \quad (4.9.18)$$

The characteristic dimension in the Nusselt and Grashof numbers is the plate height,  $L$ .

For thermal boundary conditions  $Nu_H$ , the following relation is also recommended by Shenoy and Mashelkar (1982). Since the heat flux,  $q_w$  is specified in this case, the local plate temperature at any  $x$  (measured from the bottom of the plate) can be obtained from the local Nusselt number  $Nu_{Hx}$ . The heat transfer coefficient is defined in terms of the difference between the wall and free-stream temperatures.

$$Nu_{Hx} = 0.619 \left[ Gr_{Hx}^{(3n+2)/(n+4)} Pr_{Hx}^n \right]^{0.213} \quad (4.9.19)$$

where

$$\text{Gr}_{Hx} = \frac{\rho^2 x^4}{k^2} \left( \frac{g\alpha q_w}{k} \right)^{2-n} \quad (4.9.20)$$

$$\text{Pr}_{Hx} = \frac{\rho c_p}{K} \left( \frac{K}{\rho} \right)^{5/(n+4)} x^{(2n-2)/(n+4)} \left( \frac{g\alpha q_w}{k} \right)^{(3n-3)/(n+4)} \quad (4.9.21)$$

### Vertical Parallel Plates

For *power law fluids* and laminar flow, [Figure 4.9.3](#) presents the graphical results of a numerical solution. Of interest are the average Nusselt number  $\bar{Nu}_{Tb}$  and the dimensionless average flow velocity between the plates,  $U_o^+$ . These are shown on the left and right ordinates respectively in [Figure 4.9.3](#) (Irvine et al., 1982). The characteristic dimension in the Nusselt and Grashof numbers is the plate spacing,  $b$ . The dimensionless quantities used in [Figure 4.9.3](#) are defined as follows:

$$\bar{Nu}_{Tb} = \frac{\bar{h}_c b}{k} \quad U_o^+ = \frac{b u_o}{Lu^*}$$

$$\text{Pr}_g = \frac{\rho c_p}{k} \left[ \frac{v_k^{1/(2-n)}}{\left( \frac{L}{b} \right)^{(1-n)/(2-n)} b^{(2n-2)/(2-n)}} \right] \quad v_K = \frac{K}{\rho}$$

$$\text{Gr}_g = \frac{g\alpha(T_s - T_\infty) b^{(n+2)/(2-n)}}{v_K^{2/(2-n)} \left( \frac{L}{b} \right)^{n/(2-n)}} \quad u^* = \frac{v_K^{1/(2-n)} b^{(1-2n)/(2-n)}}{L^{(1-n)/(2-n)}}$$

For vertical parallel plates for the average Nusselt number,  $\bar{Nu}_{Hb}$ , and the between plate average velocity, Schneider and Irvine (1984) have presented graphical results similar to [Figure 4.9.3](#).

Lee (1992) has presented a numerical solution for laminar flow of a *modified power law fluid* between vertical plates. Lee has also calculated thermal entrance regions and shown that if a parallel plate system is actually operating in the transition region and if the power law solution is used, both the total heat transfer and the velocity between plates can differ by over an order of magnitude. It is important to consider the shear rate parameter in order to determine which free convection solution to use.

### Sphere and Horizontal Cylinder — Power Law Fluids

For flow over a sphere, the correlation for power law fluids by Amato and Tien (1976) is

$$\bar{Nu}_{Tr} = CZ^D \quad (4.9.22)$$

where

$$Z = \text{Gr}_{Tr}^{1/(2n+2)} \text{Pr}_{Tr}^{n/(3n+1)} \quad (4.9.23)$$

and

$$C = 0.996 \pm 0.120, \quad D = 0.682 \quad \text{for } Z < 10$$

$$C = 0.489 \pm 0.005, \quad D = 1.10 \quad \text{for } 10 \leq Z \leq 40$$

**FIGURE 4.9.3** Free convection average Nusselt number,  $\bar{Nu}_b$ , and dimensionless average velocity  $U_o^+$  between vertical plates for a power law fluid vs. generalized Rayleigh number for the  $Nu_T$  boundary condition. (From Irvine, T.F., Jr. et al., ASME Paper 82-WA/HT-69, 1982. With permission.)

where the characteristic dimension in all dimensionless variables is the sphere radius,  $r$ , and  $Gr_{Tr}$  and  $Pr_{Tr}$  are defined in Equations (4.9.16) and (4.9.17).

For pseudoplastic fluids flowing over a cylinder, an experimental correlation proposed by Gentry and Worllersheim (1974) for the average Nusselt number,  $\bar{Nu}_{TD}$ , is

$$\bar{Nu}_{TD} = \frac{\bar{h}_c D}{k} = 1.19 (Gr_{TD} Pr_{TD})^{0.2} \tag{4.9.24}$$

where  $Gr_{TD}$  and  $Pr_{TD}$  are defined as in Equations (4.9.16) and (4.9.17) with the cylinder diameter,  $D$ , being used instead of  $L$ .

## 6.1 Human-Machine Interaction

---

*Thomas B. Sheridan*

Over the years machines of all kinds have been improved and made more reliable. However, machines typically operate as components of larger systems, such as transportation systems, communication systems, manufacturing systems, defense systems, health care systems, and so on. While many aspects of such systems can be and have been automated, the human operator is retained in many cases. This may be because of economics, tradition, cost, or (most likely) capabilities of the human to perceive patterns of information and weigh subtle factors in making control decisions which the machine cannot match.

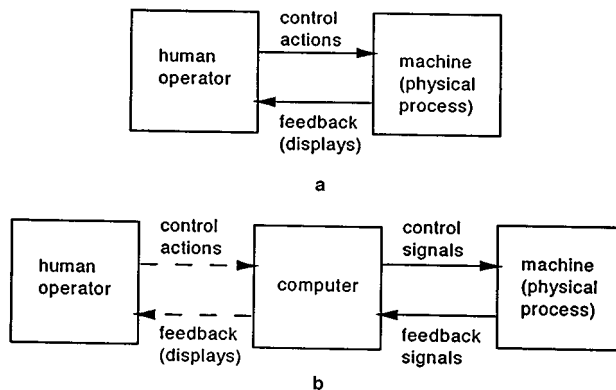

Although the public as well as those responsible for system operation usually demand that there be a human operator, “human error” is a major reason for system failure. And aside from prevention of

error, getting the best performance out of the system means that human and machine must be working together effectively — be properly “impedance matched.” Therefore, the performance capabilities of the human relative to those of the machine must be taken into account in system design.

Efforts to “optimize” the human-machine interaction are meaningless in the mathematical sense of optimization, since most important interactions between human and machine cannot be reduced to a mathematical form, and the objective function (defining what is good) is not easily obtained in any given context. For this reason, engineering the human-machine interaction, much as in management or medicine, remains an art more than a science, based on laboratory experiments and practical experience.

In the broadest sense, engineering the human-machine interface includes all of *ergonomics* or *human factors engineering*, and goes well beyond design of displays and control devices. Ergonomics includes not only questions of sensory physiology, whether or not the operator can see the displays or hear the auditory warnings, but also questions of *biomechanics*, how the body moves, and whether or not the operator can reach and apply proper force to the controls. It further includes the fields of operator selection and training, human performance under stress, human factors in maintenance, and many other aspects of the relation of the human to technology. This section focuses primarily on human-machine interaction in control of systems.

The human-machine interactions in control are considered in terms of [Figure 6.1.1](#). In [Figure 6.1.1a](#) the human directly controls the machine; i.e., the control loop to the machine is closed through the physical sensors, displays, human senses (visual, auditory, tactile), brain, human muscles, control devices, and machine actuators. [Figure 6.1.1b](#) illustrates what has come to be called a *supervisory control system*, wherein the human intermittently instructs a computer as to goals, constraints, and procedures, then turns a task over to the computer to perform automatic control for some period of time.

**FIGURE 6.1.1** Direct manual control (a) and supervisory control (b).

Displays and control devices can be *analogic* (movement signal directions and extent of control action, isomorphic with the world, such as an automobile steering wheel or computer mouse controls, or a moving needle or pictorial display element). Or they can be *symbolic* (dedicated buttons or general-purpose keyboard controls, icons, or alarm light displays). In normal human discourse we use both speech (symbolic) and gestures (analogic) and on paper we write alphanumeric text (symbolic) and draw pictures (analogic). The system designer must decide which type of displays or controls best suits a particular application, and/or what mix to use. The designer must be aware of important criteria such as whether or not, for a proposed design, changes in the displays and controls caused by the human operator correspond in a natural and common-sense way to “more” or “less” of some variable as expected by that operator and correspond to cultural norms (such as reading from left to right in western countries), and whether or not the movement of the display elements correspond geometrically to movements of the controls.

## Direct Manual Control

In the 1940s aircraft designers appreciated the need to characterize the transfer function of the human pilot in terms of a differential equation. Indeed, this is necessary for any vehicle or controlled physical process for which the human is the controller, see Figure 6.1.2. In this case both the human operator  $H$  and the physical process  $P$  lie in the closed loop (where  $H$  and  $P$  are Laplace transforms of the component transfer functions), and the  $HP$  combination determines whether the closed-loop is inherently stable (i.e., the closed loop characteristic equation  $1 + HP = 0$  has only negative real roots).

FIGURE 6.1.2 Direct manual control-loop analysis.

In addition to the stability criterion are the criteria of rapid response of process state  $x$  to a desired or reference state  $r$  with minimum overshoot, zero “steady-state error” between  $r$  and output  $x$ , and reduction to near zero of the effects of any disturbance input  $d$ . (The latter effects are determined by the closed-loop transfer functions  $x = HP/(1 + HP)r + 1/(1 + HP)d$ , where if the magnitude of  $H$  is large enough  $HP/(1 + HP)$  approaches unity and  $1/(1 + HP)$  approaches 0. Unhappily, there are ingredients of  $H$  which produce delays in combination with magnitude and thereby can cause instability. Therefore,  $H$  must be chosen carefully by the human for any given  $P$ .)

Research to characterize the pilot in these terms resulted in the discovery that the human adapts to a wide variety of physical processes so as to make  $HP = K(1/s)(e^{-sT})$ . In other words, the human adjusts  $H$  to make  $HP$  constant. The term  $K$  is an overall amplitude or gain,  $(1/s)$  is the Laplace transform of an integrator, and  $(e^{-sT})$  is a delay  $T$  long (the latter time delay being an unavoidable property of the nervous system). Parameters  $K$  and  $T$  vary modestly in a predictable way as a function of the physical process and the input to the control system. This model is now widely accepted and used, not only in engineering aircraft control systems, but also in designing automobiles, ships, nuclear and chemical plants, and a host of other dynamic systems.

## Supervisory Control

Supervisory control may be defined by the analogy between a supervisor of subordinate staff in an organization of people and the human overseer of a modern computer-mediated semiautomatic control system. The supervisor gives human subordinates general instructions which they in turn may translate into action. The supervisor of a computer-controlled system does the same.

Defined strictly, *supervisory control* means that one or more human operators are setting initial conditions for, intermittently adjusting, and receiving high-level information from a computer that itself closes a control loop in a well-defined process through artificial sensors and effectors. For some time period the computer controls the process automatically.

By a less strict definition, *supervisory control* is used when a computer transforms human operator commands to generate detailed control actions, or makes significant transformations of measured data to produce integrated summary displays. In this latter case the computer need not have the capability to commit actions based upon new information from the environment, whereas in the first it necessarily must. The two situations may appear similar to the human supervisor, since the computer mediates both human outputs and human inputs, and the supervisor is thus removed from detailed events at the low level.

A supervisory control system is represented in Figure 6.1.3. Here the human operator issues commands to a *human-interactive* computer capable of understanding high-level language and providing integrated summary displays of process state information back to the operator. This computer, typically located in a control room or cockpit or office near to the supervisor, in turn communicates with at least one, and probably many (hence the dotted lines), *task-interactive* computers, located with the equipment they are controlling. The task-interactive computers thus receive subgoal and conditional branching information from the human-interactive computer. Using such information as reference inputs, the task-interactive computers serve to close low-level control loops between artificial sensors and mechanical actuators; i.e., they accomplish the low-level automatic control.

FIGURE 6.1.3 Supervisory control.

The low-level task typically operates at some physical distance from the human operator and his human-friendly display-control computer. Therefore, the communication channels between computers may be constrained by multiplexing, time delay, or limited bandwidth. The task-interactive computer, of course, sends analog control signals to and receives analog feedback signals from the controlled process, and the latter does the same with the environment as it operates (vehicles moving relative to air, sea, or earth, robots manipulating objects, process plants modifying products, etc.).

Supervisory command and feedback channels for process state information are shown in Figure 6.1.3 to pass through the left side of the human-interactive computer. On the right side are represented decision-aiding functions, with requests of the computer for advice and displayed output of advice (from a database, expert system, or simulation) to the operator. There are many new developments in computer-based decision aids for planning, editing, monitoring, and failure detection being used as an auxiliary part of operating dynamic systems. Reflection upon the nervous system of higher animals reveals a similar kind of supervisory control wherein commands are sent from the brain to local ganglia, and peripheral motor control loops are then closed locally through receptors in the muscles, tendons, or skin. The brain, presumably, does higher-level planning based on its own stored data and “mental models,” an internalized expert system available to provide advice and permit trial responses before commitment to actual response.

Theorizing about supervisory control began as aircraft and spacecraft became partially automated. It became evident that the human operator was being replaced by the computer for direct control responsibility, and was moving to a new role of monitor and goal-constraint setter. An added incentive was the U.S. space program, which posed the problem of how a human operator on Earth could control a

manipulator arm or vehicle on the moon through a 3-sec communication round-trip time delay. The only solution which avoided instability was to make the operator a supervisory controller communicating intermittently with a computer on the moon, which in turn closed the control loop there. The rapid development of microcomputers has forced a transition from manual control to supervisory control in a variety of industrial and military applications (Sheridan, 1992).

Let us now consider some examples of human-machine interaction, particularly those which illustrate supervisory control in its various forms. First, we consider three forms of vehicle control, namely, control of modern aircraft, “intelligent” highway vehicles, and high-speed trains, all of which have both human operators in the vehicles as well as humans in centralized traffic-control centers. Second, we consider telerobots for space, undersea, and medical applications.

## Advanced Control of Commercial Aircraft

### Flight Management Systems

Aviation has appreciated the importance of human-machine interaction from its beginning, and today exemplifies the most sophisticated forms of such interaction. While there have been many good examples of display and control design over the years, the current development of the flight management systems (FMS) is the epitome. It also provides an excellent example of supervisory control, where the pilot flies the aircraft by communicating in high-level language through a computer intermediary. The FMS is a centralized computer which interacts with a great variety of sensors, communication from the ground, as well as many displays and controls within the aircraft. It embodies many functions and mediates most of the pilot information requirements shown in Figure 6.1.4. Gone are the days when each sensor had its own display, operating independently of all other sensor-display circuits. The FMS, for example, brings together all of the various autopilot modes, from long-standing low-level control modes, wherein the aircraft is commanded to go to and hold a commanded altitude, heading, and speed, to more-sophisticated modes where the aircraft is instructed to fly a given course, consisting of a sequence of way points (latitudes and longitudes) at various altitudes, and even land automatically at a given airport on a given runway.

FIGURE 6.1.4 Pilot information requirements. (From Billings, 1991.)

Figure 6.1.5 illustrates one type of display mediated by the FMS, in this case integrating many formerly separate components of information. Mostly it is a multicolor plan-view map showing position and orientation of important objects relative to one's own aircraft (the triangle at the bottom). It shows heading (compass arc at top, present heading 175°), ground speed plus wind speed and wind direction (upper left), actual altitude relative to desired altitude (vertical scale on right side), programmed course connecting various way points (OPH and FLT), salient VOR radar beacons to the right and left of present position/direction with their codes and frequencies (lower left and right corners), the location of key VORs along the course (three-cornered symbols), the location of weather to be avoided (two gray blobs), and a predicted trajectory based on present turn rate, showing that the right turn is appropriately getting back on course.

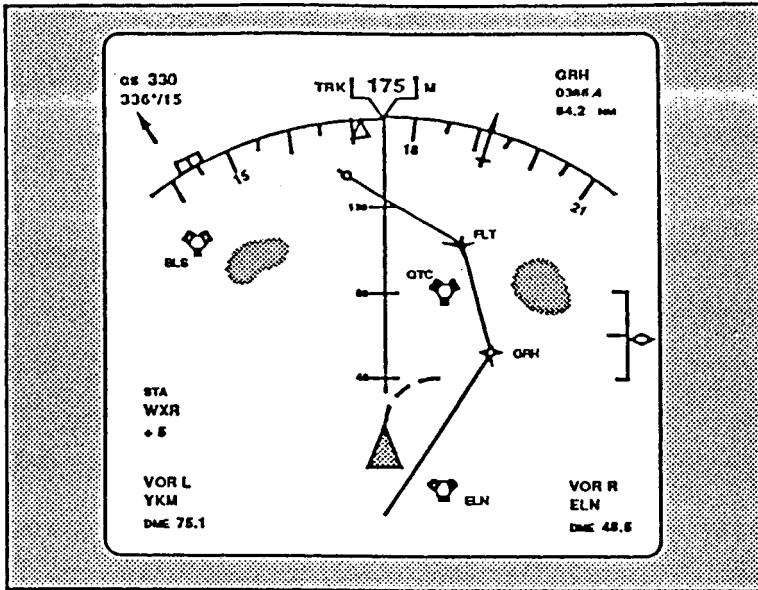

FIGURE 6.1.5 Integrated aircraft map display. (From Billings, 1991.)

Programming the FMS is done through a specialized keyboard and text display unit (Figure 6.1.6) having all the alphanumeric keys plus a number of special function keys. The displays in this case are specialized to the different phases of a flight (taxi, takeoff, departure, enroute approach, land, etc.), each phase having up to three levels of pages.

The FMS makes clear that designing displays and controls is no longer a matter of what can be built — the computer allows essentially any conceivable display/control to be realized. The computer can also provide a great deal of real-time advice, especially in emergencies, based on its many sensors and stored knowledge about how the aircraft operates. But pilots are not sure they need all the information which aircraft designers would like to give them, and have an expression “killing us with kindness” to refer to this plethora of available information. The question is what should be designed based on the needs and capabilities of the pilot.

Boeing, McDonnell Douglas, and Airbus have different philosophies for designing the FMS. Airbus has been the most aggressive in automating, intending to make piloting easier and safer for pilots from countries with less well established pilot training. Unfortunately, it is these most-automated aircraft which have had the most accidents of the modern commercial jets — a fact which has precipitated vigorous debate about how far to automate.

**FIGURE 6.1.6** Flight management system control and display unit. (From Billings, 1991.)

### Air Traffic Control

As demands for air travel continue to increase, so do demands for air traffic control. Given what are currently regarded as safe separation criteria, air space over major urban areas is already saturated, so that simply adding more airports is not acceptable (in addition to which residents do not want more airports, with their noise and surface traffic). The need is to reduce separations in the air, and to land aircraft closer together or on parallel runways simultaneously. This puts much greater demands on air traffic controllers, particularly at the terminal area radar control centers (TRACONs), where trained operators stare at blips on radar screens and verbally guide pilots entering the terminal airspace from various directions and altitudes into orderly descent and landing patterns with proper separation between aircraft.

Currently, many changes are being introduced into air traffic control which have profound implications for human-machine interaction. Where previously communication between pilots and air traffic controllers was entirely by voice, now digital communication between aircraft and ground (a system called *datalink*) allows both more and more reliable two-way communication, so that weather and runway and wind information, clearances, etc. can be displayed to pilots visually. But pilots are not so sure they want this additional technology. They fear the demise of the “party line” of voice communications with which they are so familiar and which permits all pilots in an area to listen in on each other’s conversations.

New aircraft-borne radars allow pilots to detect air traffic in their own vicinity. Improved ground-based radars detect microbursts or wind shear which can easily put an aircraft out of control. Both types of radars pose challenges as to how best to warn the pilot and provide guidance as to how to respond. But they also pose a cultural change in air traffic control, since heretofore pilots have been dependent upon air traffic controllers to advise them of weather conditions and other air traffic. Furthermore, because of the new weather and collision-avoidance technology, there are current plans for radically altering the rules whereby high-altitude commercial aircraft must stick to well-defined traffic lanes. Instead, pilots

will have great flexibility as to altitude (to find the most favorable winds and therefore save fuel) and be able to take great-circle routes straight to their destinations (also saving fuel). However, air traffic controllers are not sure they want to give up the power they have had, becoming passive observers and monitors, to function only in emergencies.

## **Intelligent Highway Vehicles**

### **Vehicle Guidance and Navigation Systems**

The combination of GPS (global positioning system) satellites, high-density computer storage of map data, electronic compass, synthetic speech synthesis, and computer-graphic displays allows cars and trucks to know where they are located on the Earth to within 100 m or less, and can guide a driver to a programmed destination by a combination of a map display and speech. Some human factor challenges are in deciding how to configure the map (how much detail to present, whether to make the map north-up with a moving dot representing one's own vehicle position or current-heading-up and rapidly changing with every turn). The computer graphics can also be used to show what turns to anticipate and which lane to get in. Synthetic speech can reinforce these turn anticipations, can caution the driver if he is perceived to be headed in the wrong direction or off course, and can even guide him or her how to get back on course. An interesting question is what the computer should say in each situation to get the driver's attention, to be understood quickly and unambiguously but without being an annoyance. Another question is whether or not such systems will distract the driver's attention from the primary tasks, thereby reducing safety. The major vehicle manufacturers have developed such systems, they have been evaluated for reliability and human use, and they are beginning to be marketed in the United States, Europe, and Japan.

### **Smart Cruise Control**

Standard cruise control has a major deficiency in that it knows nothing about vehicles ahead, and one can easily collide with the rear end of another vehicle if not careful. In a smart cruise control system a microwave or optical radar detects the presence of a vehicle ahead and measures that distance. But there is a question of what to do with this information. Just warn the driver with some visual or auditory alarm (auditory is better because the driver does not have to be looking in the right place)? Can a warning be too late to elicit braking, or surprise the driver so that he brakes too suddenly and causes a rear-end accident to his own vehicle. Should the computer automatically apply the brakes by some function of distance to obstacle ahead, speed, and closing deceleration. If the computer did all the braking would the driver become complacent and not pay attention, to the point where a serious accident would occur if the radar failed to detect an obstacle, say, a pedestrian or bicycle, or the computer failed to brake? Should braking be some combination of human and computer braking, and if so by what algorithm? These are human factor questions which are currently being researched.

It is interesting to note that current developmental systems only decelerate and downshift, mostly because if the vehicle manufacturers sell vehicles which claim to perform braking they would be open to a new and worrisome area of litigation.

The same radar technology that can warn the driver or help control the vehicle can also be applied to cars overtaking from one side or the other. Another set of questions then arises as to how and what to communicate to the driver and whether or not to trigger some automatic control maneuver in certain cases.

### **Advanced Traffic Management Systems**

Automobile congestion in major cities has become unacceptable, and advanced traffic management systems are being built in many of these cities to measure traffic flow at intersections (by some combination of magnetic loop detectors, optical sensors, and other means), and regulate stoplights and message signs. These systems can also issue advisories of accidents ahead by means of variable message signs or radio, and give advice of alternative routings. In emergencies they can dispatch fire, police,

ambulances, or tow trucks, and in the case of tunnels can shut down entering traffic completely if necessary. These systems are operated by a combination of computers and humans from centralized control rooms. The operators look at banks of video monitors which let them see the traffic flow at different locations, and computer-graphic displays of maps, alarm windows, and textual messages. The operators get advice from computer-based expert systems, which suggest best responses based on measured inputs, and the operator must decide whether to accept the computer's advice, whether to seek further information, and how to respond.

## High-Speed Train Control

With respect to new electronic technology for information sensing, storage, and processing, railroad technology has lagged behind that of aircraft and highway vehicles, but currently is catching up. The role of the human operator in future rail systems is being debated, since for some limited right-of-way trains (e.g., in airports) one can argue that fully automatic control systems now perform safely and efficiently. The train driver's principal job is speed control (though there are many other monitoring duties he must perform), and in a train this task is much more difficult than in an automobile because of the huge inertia of the train — it takes 2 to 3 km to stop a high-speed train. Speed limits are fixed at reduced levels for curves, bridges, grade crossings, and densely populated areas, while wayside signals temporarily command lower speeds if there is maintenance being performed on the track, if there are poor environmental conditions such as rock slides or deep snow, or especially if there is another train ahead. The driver must obey all speed limits and get to the next station on time. Learning to maneuver the train with its long time constants can take months, given that for the speed control task the driver's only input currently is an indication of current speed.

The author's laboratory has proposed a new computer-based display which helps the driver anticipate the future effects of current throttle and brake actions. This approach, based on a dynamic model of the train, gives an instantaneous prediction of future train position and speed based on current acceleration, so that speed can be plotted on the display assuming the operator holds to current brake-throttle settings. It also plots trajectories for maximum emergency braking and maximum service braking. In addition, the computer generates a speed trajectory which adheres at all (known) future speed limits, gets to the next station on time, and minimizes fuel/energy. [Figure 6.1.7](#) shows the laboratory version of this display, which is currently being evaluated.

## Telerobots for Space, Undersea, and Medicine

When nuclear power was first adopted in the late 1940s engineers began the development of master-slave remote manipulators, by which a human operator at one location could position and orient a device attached to his hand, and a servomechanism-controlled gripper would move in correspondence and handle objects at another location. At about the same time, remotely controlled wheeled vehicles, submarines, and aircraft began to be developed. Such manipulators and vehicles remotely controlled by humans are called *teleoperators*. Teleoperator technology got a big boost from the industrial robot technology, which came in a decade or so later, and provided improved vision, force, and touch sensors, actuators, and control software. Large teleoperators were developed for rugged mining and undersea tasks, and small teleoperators were developed for delicate tasks such as eye surgery. Eventually, teleoperators have come to be equipped with sensitive force feedback, so that the human operator not only can see the objects in the remote environment, but also can feel them in his grasp.

During the time of the Apollo flights to the moon, and stimulated by the desire to control lunar manipulators and vehicles from Earth and the fact that the unavoidable round-trip time delays of 3 sec (speed of light from Earth to moon and back) would not permit simple closed loop control, supervisory controlled teleoperators were developed. The human could communicate a subgoal to be reached and a procedure for getting there, and the teleoperator would be turned loose for some short period to perform automatically. Such a teleoperator is called a *telerobot*.

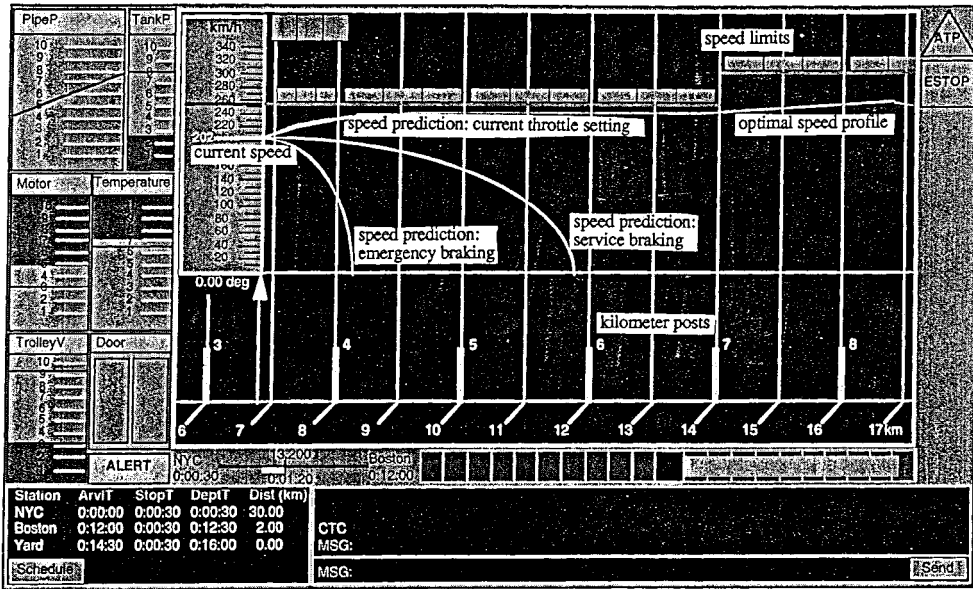

FIGURE 6.1.7 Prototype of computer-generated display for high speed trains. (From Askey, 1995.)

Figure 6.1.8 shows a the Flight Telerobotic Servicer (FTS) developed by Martin Marietta for the U.S. Space Station Freedom. It has two seven-degree of freedom (DOF) arms (including gripper) and one five-DOF “leg” for stabilizing itself while the arms work. It has two video “eyes” to present a stereoisimage to its human operator. It can be configured either as a master-slave teleoperator (under direct human control) or as a telerobot (able to execute small programmed tasks using its own eyes and force sensors). Unfortunately, the FTS project was canceled by Congress.

FIGURE 6.1.8 Flight Telerobotic Servicer prototype design. (Courtesy of NASA.)

Figure 6.1.9 shows the remotely operated submersible *Jason* developed by Woods Hole Oceanographic Institution. It is the big brother of *Jason Junior*, which swam into the interior of the ship *Titanic* and made a widely viewed video record when the latter was first discovered. It has a single manipulator arm, sonar and photo sensors, and four thrusters which can be oriented within limited range and which enable it to move in any direction. It is designed for depths up to 6000 m — rather severe pressures! It too, can be operated either in direct teleoperator mode or as a telerobot.

FIGURE 6.1.9 Deep ocean submersible *Jason*. (Courtesy of Woods Hole Oceanographic Institution.)

## Common Criteria for Human Interface Design

Design of operator control stations for teleoperators poses the same types of problems as design of controls and displays for aircraft, highway vehicles, and trains. The displays must show the important variables unambiguously to whatever accuracy is required, but more than that must show the variables in relation to one another so as to clearly portray the current “situation” (situation awareness is currently a popular test of the human operator in complex systems). Alarms must get the operator’s attention, indicate by text, symbol, or location on a graphic display what is abnormal, where in the system the failure occurred, what is the urgency, if response is urgent, and even suggest what action to take. (For example, the ground-proximity warning in an aircraft gives a loud “Whoop, whoop!” followed by a distinct spoken command “Pull up, pull up!”) Controls — whether analogic joysticks, master-arms, or knobs — or symbolic special-purpose buttons or general-purpose keyboards — must be natural and easy to use, and require little memory of special procedures (computer icons and windows do well here). The placement of controls and instruments and their mode and direction of operation must correspond to the desired direction and magnitude of system response.

## Human Workload and Human Error

As noted above, new technology allows combination, integration, and simplification of displays compared to the intolerable plethora of separate instruments in older aircraft cockpits and plant control rooms. The computer has taken over more and more functions from the human operator. Potentially these changes make the operator’s task easier. However, it also allows for much more information to be presented, more extensive advice to be given, etc.

These advances have elevated the stature of the human operator from providing both physical energy and control, to providing only continuous control, to finally being a supervisor or a robotic vehicle or

system. Expert systems can now answer the operator's questions, much as does a human consultant, or whisper suggestions in his ear even if he doesn't request them. These changes seem to add many cognitive functions that were not present at an earlier time. They make the operator into a monitor of the automation, who is supposed to step in when required to set things straight. Unfortunately, people are not always reliable monitors and interveners.

### **Mental Workload**

Under such complexity it is imperative to know whether or not the mental workload of the operator is too great for safety. Human-machine systems engineers have sought to develop measures of mental workload, the idea being that as mental load increases, the risk of error increases, but presumably measurable mental load comes before actual lapse into error.

Three approaches have been developed for measuring mental workload:

1. The first and most used is the subjective rating scale, typically a ten-level category scale with descriptors for each category from no load to unbearable load.
2. The second approach is use of physiological indexes which correlate with subjective scales, including heart rate and the variability of heart rate, certain changes in the frequency spectrum of the voice, electrical resistance of the skin, diameter of the pupil of the eye, and certain changes in the evoked brain wave response to sudden sound or light stimuli.
3. The third approach is to use what is called a secondary task, an easily measurable additional task which consumes all of the operator's attention remaining after the requirements of the primary task are satisfied. This latter technique has been used successfully in the laboratory, but has shortcomings in practice in that operators may refuse to cooperate.

Such techniques are now routinely applied to critical tasks such as aircraft landing, air traffic control, certain planned tasks for astronauts, and emergency procedures in nuclear power plants. The evidence suggests that supervisory control relieves mental load when things are going normally, but when automation fails the human operator is subjected rapidly to increased mental load.

### **Human Error**

Human error has long been of interest, but only in recent decades has there been serious effort to understand human error in terms of categories, causation, and remedy. There are several ways to classify human errors. One is according to whether it is an error of *omission* (something not done which was supposed to have been done) or *commission* (something done which was not supposed to have been done). Another is *slip* (a correct intention for some reason not fulfilled) vs. a *mistake* (an incorrect intention which was fulfilled). Errors may also be classified according to whether they are in sensing, perceiving, remembering, deciding, or acting. There are some special categories of error worth noting which are associated with following procedures in operation of systems. One, for example, is called a *capture error*, wherein the operator, being very accustomed to a series of steps, say, A, B, C, and D, intends at another time to perform E, B, C, F. But he is "captured" by the familiar sequence B, C and does E, B, C, D.

As to effective therapies for human error, proper design to make operation easy and natural and unambiguous is surely the most important. If possible, the system design should allow for error correction before the consequences become serious. Active warnings and alarms are necessary when the system can detect incipient failures in time to take such corrective action. Training is probably next most important after design, but any amount of training cannot compensate for an error-prone design. Preventing exposure to error by guards, locks, or an additional "execute" step can help make sure that the most critical actions are not taken without sufficient forethought. Least effective are written warnings such as posted decals or warning statements in instruction manuals, although many tort lawyers would like us to believe the opposite.

## Trust, Alienation, and How Far to Go with Automation

### Trust

If operators do not trust their sensors and displays, expert advisory system, or automatic control system, they will not use it or will avoid using it if possible. On the other hand, if operators come to place too much trust in such systems they will let down their guard, become complacent, and, when it fails, not be prepared. The question of operator trust in the automation is an important current issue in human-machine interface design. It is desirable that operators trust their systems, but it is also desirable that they maintain alertness, situation awareness, and readiness to take over.

### Alienation

There is a set of broader social effects that the new human-machine interaction can have, which can be discussed under the rubric of *alienation*.

1. People worry that computers can do some tasks much better than they themselves can, such as memory and calculation. Surely, people should not try to compete in this arena.
2. Supervisory control tends to make people remote from the ultimate operations they are supposed to be overseeing — remote in space, desynchronized in time, and interacting with a computer instead of the end product or service itself.
3. People lose the perceptual-motor skills which in many cases gave them their identity. They become "deskilled", and, if ever called upon to use their previous well-honed skills, they could not.
4. Increasingly, people who use computers in supervisory control or in other ways, whether intentionally or not, are denied access to the knowledge to understand what is going on inside the computer.
5. Partly as a result of factor 4, the computer becomes mysterious, and the untutored user comes to attribute to the computer more capability, wisdom, or blame than is appropriate.
6. Because computer-based systems are growing more complex, and people are being "elevated" to roles of supervising larger and larger aggregates of hardware and software, the stakes naturally become higher. Where a human error before might have gone unnoticed and been easily corrected, now such an error could precipitate a disaster.
7. The last factor in alienation is similar to the first, but all-encompassing, namely, the fear that a "race" of machines is becoming more powerful than the human race.

These seven factors, and the fears they engender, whether justified or not, must be reckoned with. Computers must be made to be not only "human friendly" but also not alienating with respect to these broader factors. Operators and users must become computer literate at whatever level of sophistication they can deal with.

### How Far to Go with Automation

There is no question but that the trend toward supervisory control is changing the role of the human operator, posing fewer requirements on continuous sensory-motor skill and more on planning, monitoring, and supervising the computer. As computers take over more and more of the sensory-motor skill functions, new questions are being raised regarding how the interface should be designed to provide the best cooperation between human and machine. Among these questions are: To what degree should the system be automated? How much "help" from the computer is desirable? What are the points of diminishing returns?

Table 6.1.1 lists ten levels of automation, from 0 to 100% computer control. Obviously, there are few tasks which have achieved 100% computer control, but new technology pushes relentlessly in that direction. It is instructive to consider the various intermediate levels of Table 6.1.1 in terms not only of how capable and reliable is the technology but what is desirable in terms of safety and satisfaction of the human operators and the general public.

**TABLE 6.1.1 Scale of Degrees of Automation**

---

1. The computer offers no assistance; the human must do it all.
  2. The computer offers a complete set of action alternatives, and
  3. Narrows the selection down to a few, or
  4. Suggests one alternative, and
  5. Executes that suggestion if the human approves, or
  6. Allows the human a restricted time to veto before automatic execution, or

## 6.2 The Need for Control of Mechanical Systems

*Peter S. Curtiss*

Process control typically involves some mechanical system that needs to be operated in such a fashion that the output of the system remains within its design operating range. The objective of a process control loop is to maintain the process at the set point under the following dynamic conditions:

- The set point is changed;
- The load on the process is changed;
- The transfer function of the process is changed or a disturbance is introduced.

### The Classical Control System Representation

**Feedback-Loop System.** A *feedback* (or *closed-loop*) system contains a process, a sensor and a controller. Figure 6.2.1 below shows some of the components and terms used when discussing feedback loop systems.

FIGURE 6.2.1 Typical feedback control schematic diagram.

**Process.** A *process* is a system that produces a motion, a temperature change, a flow, a pressure, or many other actions as a function of the actuator position and external inputs. The output of the process is called the process value. If a positive action in the actuator causes an increase in the process value then the process is called *direct acting*. If positive action in the actuator decreases the process value, it is called *reverse acting*.

**Sensor.** A *sensor* is a pneumatic, fluidic, or electronic or other device that produces some kind of signal indicative of the process value.

**Set Point.** The *set point* is the desired value for a process output. The difference between the set point and the process value is called the *process error*.

**Controller.** A *controller* sends signals to an actuator to effect changes in a process. The controller compares the set point and the process value to determine the process error. It then uses this error to adjust the output and bring the process back to the set point. The controller *gain* dictates the amount that the controller adjusts its output for a given error.

**Actuator.** An *actuator* is a pneumatic, fluidic, electric, or other device that performs any physical action that will control a process.

**External Disturbances.** An *external disturbance* is any effect that is unmeasured or unaccounted for by the controller.

**Time Constants.** The *time constant* of a sensor or process is a quantity that describes the dynamic response of the device or system. Often the time constant is related to the mass of an object or other dynamic effect in the process. For example, a temperature sensor may have a protective sheath around

it that must first be warmed before the sensor registers a change of temperature. Time constant can range from seconds to hours.

**Dead Time.** The *dead time* or *lag time* of a process is the time between the change of a process and the time this change arrives at the sensor. The delay time is not related to the time constant of the sensor, although the effects of the two are similar. Large dead times must be properly treated by the control system to prevent unstable control.

**Hysteresis.** *Hysteresis* is a characteristic response of positioning actuators that results in different positions depending on whether the control signal is increasing or decreasing.

**Dead Band.** The *dead band* of a process is that range of the process value in which no control action is taken. A dead band is usually used in two-position control to prevent “chattering” or in split-range systems to prevent sequential control loops from fighting each other.

**Control Point.** The *control point* is the actual, measured value of a process (i.e., the set point + steady-state offset + compensation).

**Direct/Reverse Action.** A *direct-acting* process will increase in value as the signal from the controller increases. A *reverse-acting* process will decrease in value as the signal from the controller increases.

**Stability.** The *stability* of a feedback control loop is an indication of how well the process is controlled or, alternatively, how controllable the process is. The stability is determined by any number of criteria, including overshoot, settling time, correction of deviations due to external disturbances, etc.

**Electric Control.** *Electric control* is a method of using low voltages (typically, 24 VAC) or line voltages (110 VAC) to measure values and effect changes in controlled variables.

**Electronic Control.** *Electronic controls* use solid-state, electronic components used for measurement and amplification of measured signals and the generation of proportional control signals.

**Pneumatic Control.** *Pneumatic controls* use compressed air as the medium for measuring and controlling processes.

**Open-Loop Systems.** An *open-loop system* is one in which there is no feedback. A whole-house attic fan in an example. It will continue to run even though the house may have already cooled off. Also, timed on/off devices are open loops.

## Examples

**Direct-Acting Feedback Control.** A classic control example is a reservoir in which the fluid must be maintained at a constant level. Figure 6.2.2 shows this process schematically. The key features of this direct-acting system are labeled. We will refer to the control action of this system shortly after defining some terms.

**Cascaded (Master-Slave) Control Loops.** If a process consists of several subprocesses, each with a relatively different transfer function, it is often useful to use cascaded control loops. For example, consider a building housing a manufacturing line in which 100% outside air is used but which must also have very strict control of room air temperature. The room temperature is controlled by changing the position of a valve on a coil at the main air-handling unit that supplies the zone. Typically, the time constant of the coil will be much smaller than the time constant of the room. A single feedback loop would probably result in poor control since there is so much dead time involved with both processes. The solution is to use two controllers: the first (the master) compares the room temperature with the thermostat setting and sends a signal to the second (the slave) that uses that signal as its own set point for controlling the coil valve. The slave controller measures the output of the coil, not the temperature of the room. The controller gain on the master can be set lower than that of the slave to prevent excessive cycling.

FIGURE 6.2.2 Example of a controlled process.

**Sequential Control Loops.** Sometimes control action is needed at more than one point in a process. An example of this is an air-handling unit that contains both heating and cooling coils in order to maintain a fixed outlet air temperature no matter the season. Typically, a *sequential* (or *split-range*) system in an air-handling unit will have three temperature ranges of operation, the first for heating mode, the last for cooling mode, and a middle dead-band region where neither the cooling nor heating coils are operating. Most sequential loops are simply two different control loops acting from the same sensor. The term *sequential* refers to the fact that in most of these systems the components are in series in the air or water stream.

**Combined Feed-Forward/Feedback Loops.** As pointed out earlier, feed-forward loops can be used when the effects of an external disturbance on a system are known. An example of this is outside air temperature reset control used to modify supply air temperatures. The control loop contains both a discharge air temperature sensor (the *primary* sensor) and an outdoor air temperature sensor (the *compensation* sensor). The designer should have some idea about the influence of the outside temperature on the heating load, and can then assign an *authority* to the effect of the outside air temperature on the controller set point. As the outdoor temperature increases, the control point decreases, and vice versa, as shown in Figure 6.2.3.

FIGURE 6.2.3 Example of the effect of compensation control.

**Predictive Control.** *Predictive control* uses a model of the process to predict what the process value will be at some point in the future based upon the current and past conditions. The controller then specifies a control action to be taken at the present that will reduce the future process error.

**Adaptive Control.** *Adaptive controllers* modify their gains dynamically so to adapt to current process conditions.

**Supervisory Controllers.** *Supervisory controllers* are used to govern the operation of an entire plant and/or control system. These may be referred to as *distributed control systems* (DCSs) which can be

used to govern the control of individual feedback loops and can also be used to ensure some kind of optimal performance of the entire plant. The controller will vary setpoints and operating modes in an attempt to minimize a cost function. A basic diagram of a supervisory controller in [Figure 6.2.4](#).

**FIGURE 6.2.4** Typical supervisory controller.

## 6.3 Control System Analysis

Peter S. Curtiss

### The Linear Process Approximation

To design controllers it is necessary to have both a dynamic process and control system representation. This section describes the key points of the most common such representation, that of linear processes and their controls. A process is basically a collection of mechanical equipment in which an input is changed or transformed somehow to produce an output. Many processes will be at near-steady-state, while others may be in a more or less constant state of change. We use building control systems as an illustration.

#### Steady-State Operation

The true response of a seemingly simple process can be, in fact, quite complex. It is very difficult to identify and quantify every single input because of the stochastic nature of life. However, practically any process can be approximated by an equation that takes into account the known input variables and produces a reasonable likeness to the actual process output.

It is convenient to use differential equations to describe the behavior of processes. For this reason, we will denote the “complexity” of the function by the number of terms in the corresponding differential equation (i.e., the *order* or *degree* of the differential equation). In a linear system analysis, we usually consider a step change in the control signal and observe the response. The following descriptions will assume a step input to the function, as shown in Figure 6.3.1. Note that a step change such as this is usually unlikely in most fields of control outside of electronic systems and even then can only be applied to a digital event, such as a power supply being switched on or a relay being energized. Zero-order system output has a one-to-one correspondence to the input,

FIGURE 6.3.1 Step change in control signal.

$$y(t) = a_0 \cdot u(t)$$

First-order functions will produce a time-varying output with a step change as input,

$$\frac{dy(t)}{dt} + a_1 \cdot y(t) = b_1 \cdot u(t)$$

and higher-order functions will produce more complex outputs.

The function that relates the process value to the controller input is called the *transfer function* of the process. The time between the application of the step change,  $t_0$ , and the time at which the full extent of the change in the process value has been achieved is called the *transfer period*. A related phenomenon is process dead time. If there is a sufficient physical distance between the process output and the sensor assigned to measuring it, then one observes dead time during which the process output is not affected by the control signal (see Figure 6.3.2). The *process gain* (or *static gain*) is the ratio of the percentage

**FIGURE 6.3.2** Effective dead time of a process subjected to a step change in controlled signal.

change of the process output to the corresponding percentage change of the control signal for a given response. For example, the gain can be positive (as in a heating coil) or negative (as in a cooling coil).

### Dynamic Response

In practice, there are very few processes controlled in a stepwise fashion. Usually, the control signal is constantly modulating much the way that one makes small changes to the steering wheel of a car when driving down the highway. We now consider the dynamic process of level control in buckets filled with water (see Figure 6.3.3). Imagine that the level of water in the bucket on the left of Figure 6.3.3 is the control signal and the level of water in the bucket on the right is the process value. It is obvious that a step change in the control signal will bring about a first-order response of the process value.

**FIGURE 6.3.3** Connected water containers used for example of dynamic response.

Suppose, however, that a periodic signal is applied to the level of the bucket on the left. If the frequency of the signal is small enough, we see a response in the level in the bucket on the right that varies as a function of this driving force, but with a delay and a decrease in the amplitude.

Here the *dynamic process gain* is less than one even though the static process gain is one. There is no dead time in this process; as soon as we begin to increase the control signal the process value will also begin to increase. The dynamic process gain, therefore, can be defined similarly to that of the static gain — it is the ratio of the amplitude of the two signals, comparable with the normalized ranges used in the static gain definition.

The dynamic gain, as its name suggests, is truly dynamic. It will change not only according to the transfer function, but also to the frequency of the control signal. As the frequency increases, the output will lag even farther behind the input and the gain will continue to decrease. At one point, the frequency may be exactly right to cancel any past effects of the input signal (i.e., the phase shift is  $180^\circ$ ) and the dynamic gain will approach zero. If the frequency rises further, the process output may decrease as the control signal increases (this can easily be the case with a building cooling or heating coil due to the mass effects) and the dynamic gain will be negative!

At this point it is convenient to define a feedback loop mathematically. A general feedback loop is shown in Figure 6.3.4. The controller, actuator, and process have all been combined into the *forward transfer function* (or *open-loop transfer function*)  $G$  and the sensor and dead time have all been combined into the *feedback path transfer function*  $H$ . The overall *closed-loop transfer function* is defined as

$$\frac{C}{R} = \frac{C}{1 + G \cdot H}$$

**FIGURE 6.3.4** Generalized feedback loop.

The right-hand side of this equation is usually a ratio of two polynomials when using Laplace or  $z$ -transforms. The roots of the numerator are called the *zeros* of the transfer function and the roots of the denominator are called the *poles* (Shinners, 1978).

The denominator of the closed loop transfer function,  $1 + G \cdot H$ , is called the *characteristic function*. If we set the characteristic function equal to zero we have the *characteristic equation*

$$1 + G \cdot H = 0$$

The characteristic equation can be used to assess process control stability during system design.

### Representation of Processes in $t$ , $s$ , and $z$ Domains

We cannot hope to ever know how a process truly behaves. The world is an inherently stochastic place and any model of a system is going to approximate at best. Nonetheless, we will need to choose some kind of representation in order to perform any useful analysis.

This section will consider three different domains: the continuous-time domain, the frequency domain, and the discrete-time domain. The frequency domain is useful for certain aspects of controller design, whereas the discrete-time domain is used in digital controllers.

#### Continuous-Time-Domain Representation of a Process

In the time domain we represent a process by a differential equation, such as

$$\frac{d^n y}{dt^n} + a_1 \frac{d^{n-1} y}{dt^{n-1}} + a_2 \frac{d^{n-2} y}{dt^{n-2}} + \dots + a_{n-1} \frac{dy}{dt} + a_n y = b_0 \frac{d^m u}{dt^m} + b_1 \frac{d^{m-1} u}{dt^{m-1}} + \dots + b_{m-1} \frac{du}{dt} + b_m u$$

This is just a generalization of the first-order system equation described earlier.

#### Frequency-Domain Representation of a Process — Laplace Transforms

The solution of higher-order system models, closed-form solution is difficult in the time domain. For this reason, process transfer functions are often written using Laplace transforms. A Laplace transform is a mapping of a continuous-time function to the frequency domain and is defined as

$$F(s) = \int_0^{\infty} f(t)e^{-st} dt$$

Laplace transforms are treated in Section 19. This formulation allows us to greatly simplify problems involving ordinary differential equations that describe the behavior of systems. A transformed differential equation becomes purely algebraic and can be easily manipulated and solved. These solutions are not of great interest in themselves in modern control system design but the transformed system (+) controller differential equation is very useful in assessing control stability. This is the single key aspect of Laplace transforms that is of most interest. Of course, it is possible just to solve the governing differential equation for the system directly and explore stability in that fashion.

The Laplace transform of the previous differential equation is

$$s^n Y(s) + A_1 s^{n-1} Y(s) + \dots + A_{n-1} s Y(s) + A_n Y(s) = B_0 s^m U(s) + B_1 s^{n-1} U(s) + \dots + B_{n-1} s U(s) + B_n U(s)$$

This equation can be rewritten as

$$Y(s) \cdot (s^n + A_1 s^{n-1} + \dots + A_{n-1} s + A_n) = U(s) \cdot (B_0 s^m + B_1 s^{n-1} + \dots + B_{n-1} s + B_n)$$

so that the transfer function is found from

$$\frac{Y(s)}{U(s)} = \frac{s^m + B_1 s^{m-1} + \dots + B_{m-1} s + A_m}{s^n + A_1 s^{n-1} + \dots + A_{n-1} s + A_n}$$

This is the expression that is used for stability studies.

**Discrete-Time-Domain Representation of a Process.** A process in the discrete time domain is described (Radke and Isermann, 1989) by

$$y(k) = a_1 y(k-1) + a_2 y(k-2) + a_3 y(k-3) + \dots + b_1 u(k-1) + b_2 u(k-2) + b_3 u(k-3) + \dots$$

This representation is of use when one is designing and analyzing the performance of direct digital control (DDC) systems. Note that the vectors **a** and **b** are *not* the same as for the continuous-time domain equation. The  $z$ -transform uses the backward shift operator and therefore the  $z$ -transform of the discrete-time equation is given by

$$y(1 - a_1 z^{-1} - a_2 z^{-2} - a_3 z^{-3} + \dots) = u(b_1 z^{-1} - b_2 z^{-2} - b_3 z^{-3} + \dots)$$

The transfer function can now be found:

$$\frac{y}{u} = \frac{b_1 z^{-1} - b_2 z^{-2} - b_3 z^{-3} + \dots}{1 - a_1 z^{-1} - a_2 z^{-2} - a_3 z^{-3} + \dots}$$

**$z$ -Transform Details.** Because  $z$ -transforms are important in modern control design and are not treated elsewhere in this handbook, some basics of their use are given below. More and more control applications are being turned over to computers and DDC systems. In such systems, the sampling is not continuous, as required for a Laplace transform. The control loop schematic is shown in Figure 6.3.5.

FIGURE 6.3.5 Sampled feedback loop.

It would be prohibitively expensive to include a voltmeter or ohmmeter on each loop; therefore, the controller employs what is called a *zero-order hold*. This basically means that the value read by the controller is “latched” until the next value is read in. This discrete view of the world precludes the use of Laplace transforms for analyses and makes it necessary, therefore, to find some other means of

simplifying the simulation of processes and controllers. The following indicates briefly how  $z$ -transforms of controlled processes can be derived and how they are used in a controls application. In the design section of this chapter we will use the  $z$ -transform to assess controller stability.

Recall that the Laplace transform is given as

$$\mathcal{L}\{f(t)\} = \int_0^{\infty} f(t)e^{-st} dt$$

Now suppose we have a process that is sampled at a discrete, constant time interval  $T$ . The index  $k$  will be used to count the intervals,

$$\text{at time } t = 0, k = 0,$$

$$\text{at time } t = T, k = 1,$$

$$\text{at time } t = 2T, k = 2,$$

$$\text{at time } t = 3T, k = 3,$$

and so forth. The equivalent Laplace transform of a process that is sampled at a constant interval  $T$  can be represented as

$$\mathcal{L}\{f^*(t)\} = \sum_{k=0}^{\infty} f(kT)e^{-skT}$$

By substituting the *backward-shift operator*  $z$  for  $e^{Ts}$ , we get the definition of the  $z$ -transform:

$$Z\{f(t)\} = \sum_{k=0}^{\infty} f(kT)z^{-k}$$

**Example of Using  $z$ -Transfer Functions.** Suppose we have a cylindrical copper temperature sensor in a fluid stream with material properties as given. We wish to establish its dynamic characteristics for the purpose of including it in a controlled process model using both Laplace and  $z$ -transforms. Figure 6.3.6 shows the key characteristics of the sensor. The sensor measures 0.5 cm in diameter and is 2 cm long. For the purposes of this example we will assume that the probe is solid copper. The surface area of the sensor is then

$$A_s = 2 \cdot \pi \cdot (0.25 \text{ cm})^2 + \pi \cdot (0.5 \text{ cm}) \cdot (2 \text{ cm}) \approx 3.5 \text{ cm}^2$$

and the mass is

$$M_s = (9 \text{ g/cm}^3) \cdot [(2 \text{ cm}) \cdot \pi \cdot (0.25 \text{ cm})^2] \approx 3.5 \text{ g}$$

The thermal capacitance of the sensor is found from the product of the mass and the heat capacity,

$$C_s = M_s \cdot c_p = 3.5 \text{ g} \cdot 0.4 \text{ J/g} \cdot \text{K} = 1.4 \text{ J/K}$$

and the total surface heat transfer rate is the product of the area and the surface heat transfer coefficient,

FIGURE 6.3.6 Fluid temperature sensor used in example.

$$UA_s = 0.005 \text{ W/cm}^2 \cdot \text{K} \cdot 3.5 \text{ cm}^2 = 0.018 \text{ W/K}$$

Now we can perform an energy balance on the sensor by setting the sum of the energy flow into the sensor and the energy stored in the sensor equal to zero:

$$C_s = \frac{dT_s}{dt} + (T_s - T_a) \cdot UA_s = 0$$

where  $T_s$  is the temperature of the sensor and  $T_a$  is the ambient fluid temperature. This relationship is a nonhomogeneous first-order differential equation:

$$\frac{dT_s}{dt} + \frac{UA_s}{C_s} T_s = \frac{UA_s}{C_s} T_a$$

The *time constant* of the sensor is defined as

$$\tau = \frac{C_s}{UA_s} = \frac{1.4 \text{ J/K}}{0.018 \text{ W/K}} \approx 80 \text{ sec}$$

The differential equation that describes this sensor is

$$\frac{dT_s}{dt} + \frac{1}{\tau} T_s = \frac{1}{\tau} T_a$$

This example will find the response of the sensor when the fluid temperature rises linearly by 30°C from time  $t = 0$  to time  $t = 200$  seconds and then remains constant. That is, the driving function is

$$T_a(t) = \frac{30^\circ\text{C}}{200 \text{ sec}} t = 0.15^\circ\text{C/sec } t \quad 0 \leq t < 200 \text{ sec}$$

$$T_a(t) = 30^\circ\text{C} \quad t \geq 200 \text{ sec}$$

Assuming an initial condition of  $T_s = 0$  at  $t = 0$ , we find that

$$T_s(t) = 0.15t - 12 + 12e^{-0.0125t} \quad \text{for } t < 200 \text{ sec}$$

and

$$T_s(t) = 30 - 134.2e^{-t/\tau} \quad \text{for } t > 200 \text{ sec}$$

**FIGURE 6.3.7** Time domain solution of example.

First line:  $T = 0.15t - 12 + 12e^{-0.0125t}$ . Second line:  $T = 30 - 134.2e^{-t/\tau}$ .

A graph of the entire process (rise time and steady state) is shown in [Figure 6.3.7](#). The two lines intersect at  $t = 200$  seconds.

Solution of example in frequency domain

This same process can be solved using Laplace transforms. First we will solve this problem for the first 200 sec. The Laplace transform of a ramp function can be found from the tables (see Section 19) to get

$$T_s(s) = \frac{1}{\tau(s + 1/\tau)} \frac{0.15}{s^2}$$

This can be expanded by partial fractions to get

$$T_s(s) = 0.15 \left[ \frac{\tau}{s} + \frac{1}{s^2} + \frac{\tau}{s + 1/\tau} \right]$$

Using the table for the inverse Laplace transforms gives

$$T_s(t) = 0.15 \left[ -\tau + t + \tau e^{-t/\tau} \right]$$

Substituting  $\tau = 80$ ,

$$T_s(t) = -12 + 0.15t + 12e^{-0.0125t}$$

This is exactly the same as the time-domain solution above. For the steady-state driving force of  $T_a = 30$  for  $t > 200$  sec we also find the same result.

Solution of example in the discrete-time domain

We consider the same problem in the discrete-time domain that a DDC system might use. Recall that the transfer function in the frequency domain was given by

$$\frac{T_s(s)}{T_a(s)} = \frac{\frac{1}{\tau}}{s + \frac{1}{\tau}}$$

We look to the table in this book's appendix and find that the discrete-time equivalent is

$$\frac{T_s(z)}{T_a(z)} = \frac{1}{\tau} \cdot \frac{z}{z - e^{-T/\tau}}$$

where  $T$  is the sampling frequency in seconds. The driving function  $T_a$  is given as

$$T_a(t) = \alpha t$$

where  $\alpha$  is the rate of change of the temperature as above ( $0.15^\circ\text{C}/\text{sec}$ ). Note that to put this into the discrete-time domain we must correct this rate by the sampling interval,

$$T_a(z) = 0.15 \cdot T \cdot \frac{Tz}{(z-1)^2}$$

using  $\alpha = (0.15 \cdot T)^\circ\text{C}/\text{sampling interval}$ .

We can now express the response of the process as

$$T_s(z) = \frac{1}{\tau} \cdot \left( \frac{z}{z - e^{-T/\tau}} \right) \cdot (0.15 \cdot T) \cdot \left( \frac{Tz}{(z-1)^2} \right)$$

since the  $z$  operator acts on the sensed temperature by performing a backward shift of the time index. In other words, the previous equation can be rewritten as

$$T_{s,k} - (2 + e^{-T/\tau})T_{s,k-1} + (1 + 2e^{-T/\tau})T_{s,k-2} - e^{-T/\tau}T_{s,k-3} = \frac{0.15}{\tau} \cdot T^2 z^{-1}$$

So the current temperature is determined by the previous three temperature measurements,

$$T_{s,k} = (2 + e^{-T/\tau})T_{s,k-1} - (1 + 2e^{-T/\tau})T_{s,k-2} + e^{-T/\tau}T_{s,k-3} + \frac{0.15}{\tau} \cdot T^2 z^{-1} \quad \text{for } kT < 200 \text{ sec}$$

Regarding the last term in the equation, recall that the inverse transform of  $z^{-k}$  is given as 1 when  $t = k$ , and zero otherwise. This term provides the initial "jump-start" of the progression. [Table 6.3.1](#) shows the first few time steps for the  $z$ -domain solution using time steps of 0.1 and 1.0 seconds. In general, the accuracy of the  $z$ -domain solution increases as the time step grows smaller. The solution for  $kT > 200$  seconds is similar to that for the Laplace transforms.

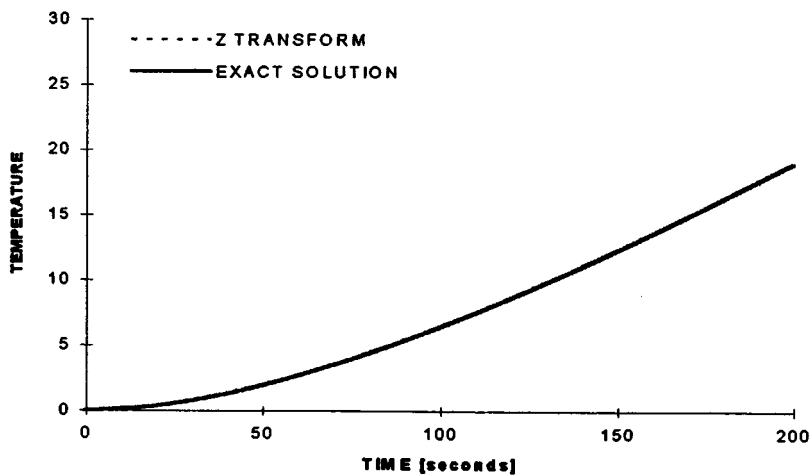

**TABLE 6.3.1 Initial Time Steps for z-Domain Solution of Example**

Initial 10 Steps for $T = 0.1$ sec				Initial 10 Steps for $T = 1.0$ sec			
k	Time	$T_{s,exact}$	$T_{s,z \text{ transform}}$	k	Time	$T_{s,exact}$	$T_{s,z \text{ transform}}$
0	0.00	0.00000	0.00000	0	0.00	0.0000	0.0000
1	0.10	0.00001	0.00002	1	1.00	0.0009	0.0019
2	0.20	0.00004	0.00006	2	2.00	0.0037	0.0056
3	0.30	0.00008	0.00011	3	3.00	0.0083	0.0112
4	0.40	0.00015	0.00019	4	4.00	0.0148	0.0185
5	0.50	0.00023	0.00028	5	5.00	0.0230	0.0277
6	0.60	0.00034	0.00039	6	6.00	0.0329	0.0386
7	0.70	0.00046	0.00052	7	7.00	0.0446	0.0512
8	0.80	0.00060	0.00067	8	8.00	0.0580	0.0656
9	0.90	0.00076	0.00084	9	9.00	0.0732	0.0816
10	1.00	0.00093	0.00103	10	10.00	0.0900	0.0994

The next three figures show the effect of using different time intervals in the z-domain solution. The values shown here are for the example outlined in this section. If one could use an infinitesimally small time step, the z-domain solution would match the exact solution. Of course, this would imply a much larger computational effort to simulate even a small portion of the process. In practice, a time interval will be chosen that reflects a compromise between accuracy and speed of calculation.

Each graph shows two lines, one for the exact solution of the first 200 sec of the example and the other for the z-domain solution. Figures 6.3.8 to 6.3.10 give the z-domain solution using time intervals of 0.1, 1.0 and 10.0 seconds, respectively. Notice that there is not much difference between the first two graphs even though there is an order of magnitude difference between the time intervals used. The latter two graphs show significant differences.

## 6.4 Control System Design and Application

---

*Peter S. Curtiss*

### Controllers

Controllers are akin to processes in that they have gains and transfer functions. Generally, there is no dead time in a controller or it is so small as to be negligible.

#### Steady-State Effects of Controller Gain

Recall that the process static gain can be viewed as the total change in the process value due to a 100% change in the controller output. A proportional controller acts like a multiplier between an *error signal* and this process gain. Under stable conditions, therefore, there must be some kind of error to yield any controller output. This is called the steady-state or static *offset*.

#### Dynamic Effects of Controller Gain

Ideally, a controller gain value is chosen that compensates for the dynamic gain of the process under normal operating conditions. The total loop dynamic gain can be considered as the product of the process, feedback, and controller gains. If the total dynamic loop gain is one, the process will oscillate continuously at the natural frequency of the loop with no change in amplitude of the process value. If the loop gain is greater than one, the amplitude will increase with each cycle until the limits of the controller or process are reached or until something fails. If the dynamic loop gain is less than one, the process will eventually settle down to stable control.

#### Controller Bias

The controller bias is a constant offset applied to the controller output. It is the output of the controller if the error is zero,

$$u = K \cdot e + M$$

where  $M$  is the bias. This is useful for processes that become nonlinear at the extremes or for process in which the normal operating conditions are at a nonzero controller output.

### PID Controllers

Many mechanical systems are controlled by proportional-integral-derivative (PID) controllers. There are many permutations of such controllers which use only certain portions of the PID controllers or use variations of this kind of controller. In this section we consider this very common type of controller.

#### Proportional Control

Proportional control results in action that is linear with the error (recall the error definition in [Figure 6.2.1](#)) The proportional term,  $K_p \cdot e$ , has the greatest effect when the process value is far from the desired setpoint. However, very large values of  $K_p$  will tend to force the system into oscillatory response. The proportional gain effect of the controller goes to zero as the process approaches set point. Purely proportional control should therefore only be used when

- The time constant of the process is small and hence a large controller gain can be used;
- The process load changes are relatively small so that the steady-state offset is limited;
- The steady-state offset is within an acceptable range.

#### Integral Control

Integral control makes a process adjustment based on the cumulative error, not its current value. The integral term  $K_i$  is the reciprocal of the reset time,  $T_r$ , of the system. The reset time is the duration of

each error-summing cycle. Integral control can cancel any steady-state offsets that would occur when using purely proportional control. This is sometimes called *reset* control.

### Derivative Control

Derivative control makes a process adjustment based on the current rate of change of the process control error. Derivative control is typically used in cases where there is a large time lag between the controlled device and the sensor used for the feedback. This term has the overall effect of preventing the actuator signal from going too far in one direction or another, and can be used to limit excessive overshoot.

### PID Controller in Time Domain

The PID controller can be represented in a variety of ways. In the time domain, the output of the controller is given by

$$u(t) = K_p \left[ e(t) + K_i \int_0^t e(t) dt + K_d \frac{de(t)}{dt} \right]$$

### PID Controller in the s Domain

It is relatively straightforward to derive the Laplace transform of the time-domain PID equation. The transfer function of the controller is

$$\frac{U(s)}{E(s)} = \left[ K_p + \frac{K_p K_i}{s} + K_p K_d s \right]$$

This controller transfer function can be multiplied by the process transfer function to yield the overall forward transfer function  $\mathbf{G}$  of an  $s$ -domain process model. The criteria described earlier can then be used to assess overall system stability.

### PID Controller in the z Domain

Process data are measured discretely at time intervals  $\Delta t$ , and the associated PID controller can be represented by

$$u(k) = K_p \left[ e(k) + K_i \Delta t \sum_{i=0}^k e(i) + K_d \frac{e(k) - e(k-1)}{\Delta t} \right]$$

The change of the output from one time step to the next is given by  $u(k) - u(k-1)$ , so the PID *difference equation* is

$$u(k) - u(k-1) = K_p \left[ \left( 1 + \frac{K_d}{\Delta t} \right) e(k) + \left( K_i \Delta t - 1 - 2 \frac{K_d}{\Delta t} \right) e(k-1) + \left( \frac{K_d}{\Delta t} \right) e(k-2) \right]$$

and can be simplified as

$$u(k) - u(k-1) = q_0 e(k) + q_1 e(k-1) + q_2 e(k-2)$$

where

$$q_0 = K_p \left( 1 + \frac{K_d}{\Delta t} \right); \quad q_1 = K_p \left( K_i \Delta t - 1 - 2 \frac{K_d}{\Delta t} \right); \quad q_2 = K_p \left( \frac{K_d}{\Delta t} \right)$$

Note that we can write this as

$$u(1 - z^{-1}) = e(q_0 + q_1z^{-1} + q_2z^{-2})$$

The  $z$ -domain transfer function of the PID controller is then given as

$$\frac{u(z)}{e(z)} = \frac{q_0 + q_1z^{-1} + q_2z^{-2}}{1 - z^{-1}} = \frac{q_0z^2 + q_1z + q_2}{z^2 - z}$$

## Controller Performance Criteria and Stability

### Performance Indexes

Obviously, in feedback loops we wish to reduce the process error quickly and stably. The control systems engineer can use different cost functions in the design of a given controller depending on the criteria for the controlled process. Some of these cost functions (or *performance indexes*) are listed here:

ISE	Integral of the square of the error	$\int e^2$
ITSE	Integral of the time and the square of the error	$\int te^2$
ISTAE	Integral of the square of the time and the absolute error	$\int t e $
ISTSE	Integral of the square of the time and the square of the error	$\int te^2$

These indexes are readily calculated with DDC systems and can be used to compare the effects of different controller settings, gains, and even control methods.

### Stability

Stability in a feedback loop means that the feedback loop will tend to converge on a value as opposed to exhibiting steady-state oscillations or divergence. Recall that the closed-loop transfer function is given by

$$\frac{C}{R} = \frac{G}{1 + GH}$$

and that the denominator,  $1 + GH$ , when equated to zero, is called the characteristic equation. Typically, this equation will be a polynomial in  $s$  or  $z$  depending on the method of analysis of the feedback loop. Two necessary conditions for stability are that all powers of  $s$  must be present in the characteristic equation from zero to the highest order and that all coefficients in the characteristic equation must have the same sign. Note that the process may still be unstable even when these conditions are satisfied.

*Roots of the Characteristic Equation.* The roots of the characteristic equation play an important role in determining the stability of a process. These roots can be real and/or imaginary and can be plotted as shown in [Figure 6.4.1](#). In the  $s$ -domain, if all the roots are in the left half-plane (i.e., to the left of the imaginary axis), then the feedback loop is guaranteed to be asymptotically stable and will converge to a single output value. If one or more roots are in the right half-plane, then the process is unstable. If one or more roots lie on the imaginary axis and none are in the right half-plane, then the process is considered to be marginally stable. In the  $z$ -domain, if all the roots lie within the unit circle about the origin then the feedback loop is asymptotically stable and will converge. If one or more roots lie outside

**FIGURE 6.4.1** Placement of roots in the imaginary plane (showing unit circle).

the unit circle then the process is unstable. If one or more roots lie on the unit circle and none are outside the unit circle, then the process is marginally stable.

Root locus example

Consider the feedback loop shown in [Figure 6.4.2](#). The characteristic equation is given by  $1 + GH = 0$  or

$$1 + K \left( \frac{s}{s + \alpha} \right) \left( \frac{1}{s + \beta} \right) = 0$$

**FIGURE 6.4.2** Simple feedback control loop.

For different values of  $K$  we can plot the roots of this equation. The graph in [Figure 6.4.3](#) shows an example plot when the characteristic equation is given by  $s^2 + (1.25 + K)s + 1.25 = 0$ . The plot shows that a system described by this characteristic demonstrates stable response for a process gain of  $0.0 \leq K \leq 10.0$ . For gains greater than 10, there exists at least one root in the right half-plane and the process is not under stable control.

Note that the root locus plot is always symmetric about the real axis and that the number of separate segments of the locus is equal to the number of roots of the characteristic equation (i.e., the number of poles of the closed-loop transfer function).

*Routh-Hurwitz Stability Criteria.* The Routh-Hurwitz method is a tabular manipulation of the characteristic equation in the frequency domain and is used to assess stability. If the characteristic equation is given by

$$a_0 s^n + a_1 s^{n-1} + \dots + a_{n-1} s + a_n = 0$$

then the Routh-Hurwitz method constructs a table from the coefficients as follows:

$s^n$	$a_0$	$a_2$	$a_4$	$\dots$
$s^{n-1}$	$a_1$	$a_3$	$a_5$	$\dots$
$s^{n-2}$	$X_1$	$X_2$	$X_3$	$\dots$
$s^{n-3}$	$Y_1$	$Y_2$	$Y_3$	$\dots$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\dots$

FIGURE 6.4.3 Root locus of  $s^2 + (1.25 + K)s + 1.25 = 0$ .

where

$$X_1 = \frac{a_1 a_2 - a_0 a_3}{a_1}; \quad X_2 = \frac{a_1 a_4 - a_0 a_5}{a_1}; \quad X_3 = \frac{a_1 a_6 - a_0 a_7}{a_1} \dots$$

$$Y_1 = \frac{X_1 a_3 - a_1 X_2}{X_1}; \quad Y_2 = \frac{X_1 a_5 - a_1 X_3}{X_1} \dots$$

and so forth. The number of roots in the right-hand plane of the  $s$ -domain is equal to the number of sign changes in the first column, i.e., the column containing  $a_0, a_1, X_1, Y_1$ , etc. In other words, if all the elements in the first column have the same sign, then there are no roots in the right-hand plane and the process is stably controlled. Also, for special cases of the characteristic equation,

- If the first element of any row is zero but the remaining elements are not, then use some small value  $\epsilon$  and interpret the final results as  $\epsilon \rightarrow 0$ .
- If one of the rows before the final row is entirely zeros, then (1) there is at least one pair of real roots of equal magnitude but opposite signs, or (2) there is at least one pair of imaginary roots that lie on the imaginary axis, or (3) there are complex roots symmetric about the origin.

## Field Commissioning — Installation, Calibration, Maintenance

### Tuning of Feedback Loops

The *tuning* of a controller involves finding controller gains that will ensure at least a critically damped response of the process to a change in set point or process disturbance. A good starting point for PID constants is that derived during the design phase by the stability assessment approaches described above. However, real processes do not necessarily behave as their models would suggest and actual field tuning of controls is needed during the system-commissioning process.

*Pole-Zero Cancellation.* One method of obtaining the desired critically damped response of a process is to determine the closed-loop transfer function in the form

$$\frac{C}{R} = \frac{(s + A_1)(s + A_2) \dots (s + A_m)}{(s + B_1)(s + B_2) \dots (s + B_n)}$$

The coefficients  $A$  and  $B$  will depend on both the process characteristics and the controller gains. The objective of pole-zero cancellation is to find values for the controller gains that will set some numerator coefficients equal to those in the denominator, effectively canceling terms. As can be imagined, however, this can be a very difficult exercise, particularly when working with complex roots of the equations. This method can only be used with very simple system models.

*Reaction Curve Techniques.* Often it is advisable to test a feedback loop *in situ*. Several techniques have been developed that allow for the derivation of “good” PID constants for a given open-loop response. Consider the process response shown in Figure 6.4.4 where  $\Delta_c$  is the change of process output,  $\Delta_u$  is the change of controller,  $L$  is the time between change and intersection, and  $T$  is the time between lower intersection and upper intersection. We can define the following variables:  $A = \Delta_u/\Delta_c$ ,  $B = T/L$ , and  $R = LT$ . These values can be used with the equations given in Table 6.4.1 to estimate “decent” control constants. The users of these constants should be aware, however, that these constants are based on the typical response of second-order systems and may not provide good values for all processes.

FIGURE 6.4.4 Reaction curve components.

*Ultimate Frequency.* The ultimate frequency test involves increasing the proportional gain of a process until it begins steady-state oscillations.  $K_p^*$  is defined as the proportional gain that results in steady oscillations of the controlled system and  $T^*$  is the period of the oscillations. The desired controller gains are given in Table 6.4.2. Note that the use of the ultimate period test is not always easy to do in practice and may be prohibited in certain cases by the a process operations manager.

## 6.5 Advanced Control Topics

*Peter S. Curtiss, Jan Kreider, Ronald M. Nelson, and Shou-Heng Huang*

### Neural Network-Based Predictive/Adaptive Controllers

Neural networks are powerful modeling tools used for predicting nonlinear behavior of processes and require a minimum of knowledge about the physical system involved. This approach can be used to predict the behavior of a process and can calculate the future value of the process variables. The effects of current modifications to the future value of the controlled process can be easily quantified and used to obtain the desired process response.

#### Overview of Neural Networks

The artificial neural network attempts to mimic a few aspects of the behavior of biological neural networks. Inputs to a biological nerve cell are carried along the dendrites of that cell. These inputs come from the positive impulse signals of other cells but may be converted to negative signals by the chemical interactions at the synapse between the cells. All of the inputs are then carried to the soma where they add or subtract from the overall potential difference between the interior of the soma and the surrounding fluid. Once the cell potential rises above a certain level, the cell “fires” and sends signals to other cells along its axon.

The artificial cell behaves in much the same way, except that the output signal is analog instead of digital. Signals from sending cells are passed along to a receiving cell through a series of connections. Each connection has an associated weighting factor that acts as a multiplier on the signal from the sending cell. All the inputs to a cell are summed (along with a cell bias, if included) and the resulting value is used to generate the output of the receiving cell. The output of the cell is referred to as the cell *activation* and the function that uses the net input to generate the cell activation is called the *activation function*. The activation function can theoretically be of any form, although linear and sigmoidal functions are frequently used. Figure 6.5.1 shows a comparison between a biological cell and an artificial cell.

When many different cells are combined together into a richly connected network (Figure 6.5.2), the result can behave mathematically like a nonlinear regression engine capable of mapping inputs to outputs for complex relationships. The trick is to find a series of weights  $W$  that allow the network to provide the desired outputs using specific inputs.

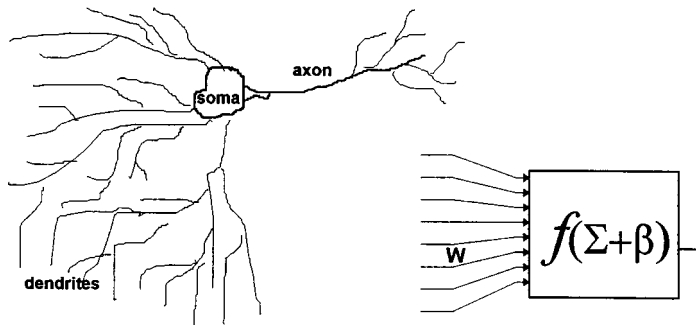

FIGURE 6.5.1 Biological cell vs. artificial cell.

#### Training Neural Networks

The net input to a cell is given by

**FIGURE 6.5.2** Artificial neural network consisting of several layers of mathematical models of biological neurons.

$$I_{NET,i} = \sum_{j=f}^l A_j w_{j \rightarrow i}$$

where  $I_{NET,i}$  is the net input of node  $i$  due to input from nodes  $f$  through  $l$  (as in *first* through *last*),  $A_j$  is the output of cell  $j$ , and  $w_{j \rightarrow i}$  is the weighting factor associated with the connection between the sending node  $j$  and the receiving node  $i$ . The output (*activation*) of cell  $i$  is then going to be a function of the net input to the cell. Typically, the sigmoid function is used to relate activation to cell inputs

$$A_i = \frac{1}{1 + e^{-I_{NET,i}}}$$

Practically any function can be used as the activation function of each node; the sigmoid function is usually chosen because the derivative, used during the training process, is easy to calculate. Traditional training of neural networks seeks to minimize the error function

$$E = \sum_{p=1}^{N_p} \sum_{i=1}^{N_o} (t_{p,i} - A_{p,i})^2$$

where  $N_p$  is the number of input/output pairs of data,  $N_o$  is the number of outputs of the network, and  $t_{p,i}$  is the desired (*target*) output value for a given set of inputs. This error function is minimized by adjusting the values of the weights proportionally to the negative of the derivative of the error with respect to each weight,

$$\Delta w_{j \rightarrow i} = -\epsilon \frac{\partial E}{\partial w_{j \rightarrow i}}$$

where  $\epsilon$  is the *learning rate* of the network. In a multilayered network the training is initiated by stimulating the network with a specific vector of inputs. The outputs of all the cells are then calculated

in order, starting with the input layer and ending with the output layer. The output is then compared with the known target output value, and any errors are compensated for by adjusting the weights from the output layer back toward the input layer. This method of training is, therefore, called *back-propagation*. With such a method, the previous equation for  $\Delta w$  can be rewritten as

$$\Delta w_{j \rightarrow i} = -\varepsilon \delta_i A_j$$

where  $\delta_i$  represents the effect of a change in the net input to cell  $j$  on the output of cell  $i$ . For cells in the output layer,

$$\delta_i = (t_i - A_i) f'(I_{\text{NET},i})$$

where  $f'$  is the derivative of the sigmoid activation function. For nodes in the hidden layers,

$$\delta_i = f'(I_{\text{NET},i}) \sum_{j=f}^1 (\delta_j w_{j \rightarrow i})$$

The product  $d_i A_j$  is something called the *weight-error derivative* (WED). To prevent excessive oscillation of the weights during training, the change of weights can be restricted according to

$$\Delta w(k) = \varepsilon \cdot \text{WED} + \mu \cdot \Delta w(k-1)$$

where  $\mu$  is the *momentum* of the network. Finally, to gradually reduce the rate at which the weights change, the learning rate  $\varepsilon$  can be made subject to exponential decay during the training process. This is sometimes called *simulated annealing*.

*Bias nodes* are like stand-alone cells that connect to each “normal” cell of the network. The output activation of each bias node is always unity and the “weight” connecting the bias node to the normal cell acts as a threshold function that suppresses or augments the output of the cell.

### Using Networks for Controlling Feedback Loop Processes

Neural networks offer the potential for and have demonstrated improved control of processes through predictive techniques. The concept is fairly simple: train a network to predict the dynamic behavior of a process and then use these predictions to modify the controller output to place the process at a desired set point  $R(t)$  at some time in the future. Initial results from computer simulations of such a controller are presented in Curtiss et al. (1993 a,b,c). Anderson (1989) described a computer simulation in which a network was trained to recognize the dynamic properties of an inverted pendulum (e.g., a broom balanced on an open palm). A control system was developed in which the angle and position of the pendulum were used to move the supporting base in order to maintain the pendulum upright. A neural network-based predictive controller is outlined in the classic discussion by Nguyen and Widrow (1989) on the “truck backer-upper” problem in which a tractor-trailer is backed into position at a loading dock.

Properly tuned fixed-gain controllers will usually work over a relatively wide range of process operation provided that the external perturbations and influences are small or time invariant. With nonlinear processes, however, a conventional control algorithm can lead to unstable control if the gains were chosen for a range different from the current operating conditions.

### Architecture of the Network

With the neural network approach it is possible to overcome these problems by using as many additional salient inputs (the *auxiliary* inputs) as necessary and by incorporating an inherently nonlinear model to accomplish the control objectives. The network is trained using examples of the time-dependent relationship between a value of the feedback and previous values of the feedback, the controller output and

the auxiliary inputs. An example of the network architecture required for this is shown in Figure 6.5.3. In practice there does not need to be a limit on the number of previous measurements of any of the inputs, although the final size of the network and the corresponding training time and memory requirements need to be taken into consideration.

FIGURE 6.5.3 Network used for process prediction.

The network, once trained, can predict the future feedback value for any controller output. The trick is to find the controller output that causes the future process value to match the set point. This is accomplished by finding the derivative of the future error with respect to the current controller signal. Starting with the current process conditions, the feedback value is predicted at each time step into the future over a preset time window ( $\Delta t$ ). During each step of the prediction the values for the controller output and auxiliary inputs are held constant. This simulation is performed twice: the first time with a small increase in the controller output and the second time with a small decrease. This allows for the calculation of the change of the future process value (and hence the change of the future error) as a function of the change in the current controller output. The controller output is then modified by

$$\Delta U(t) = -G_{\text{net}} \cdot E_f(t) \frac{\partial E_f(t)}{\partial U(t)}$$

where  $E_f$  is the future error and  $G_{\text{net}}$  is the network controller gain. For a multiple-output controller, the additional outputs are simply added as more outputs of the network and the future predictions repeated several times to find the correct partial derivatives.

Many different variations on this theme are possible, for example, using the sum of the absolute values of all the errors over the prediction window (or the sum of the square of the errors, etc.) instead of simply the future error. Computer-simulated results of such tests are provided by Curtiss et al. (1993).

*Estimating the Size of the Prediction Time Window.* It is possible to use the network model to determine the size of the time window by estimating the amount of time required for the process to reach some future steady state after a simulated change in the controller output. An example of such an open-loop response it is shown in Figure 6.5.5. Here the network is simulating the response of a reverse-acting process after a decrease in actuator position at time step 0. About 70% ( $\ln 2$ ) of total rise time is achieved after 15 time steps. This kind of calculation can be performed during the control sequence and should indicate the proper time window size.

FIGURE 6.5.4 Schematic of procedure for determining future process value and error.

FIGURE 6.5.5 Example of computer-simulated process step change (used to determine size of time window).

**Example of PID vs. Network Controller**

Figure 6.5.6 shows an example of a process under PID control that demonstrates nonlinearity at different ranges of actuator position. Figure 6.5.7 shows the same process under the influence of a predictive neural network controller that had been trained on the process. Note that the network-based controller does not show the same problems of unstable control in certain actuator ranges. The size of the time window (15 time steps) was determined using the method discussed in the previous section.

**Using Networks as Supervisory Controllers**

The previous section discussed the use of neural networks to minimize a predicted error of a feedback-loop process. It is possible to apply a similar methodology for supervisory plant control to optimize the process according to some cost function. A network is first trained to predict the cost function under a wide range of operating conditions. This network is then used to predict what will happen with different control strategies Figure 6.5.8. shows a schematic of this technique. The left side of the figure shows the training mode, where the network is attempting to associate the various plant inputs with the cost function output. There can be multiple inputs, including uncontrollable variables (e.g., ambient conditions, plant loads, etc.) and controlled variables (i.e., the various process set points.)

Once the network is sufficiently trained, it is used to find values for the set points under any set of uncontrolled variables. The technique for doing so is similar to the back-propagation training technique of the network. The inputs corresponding to the controlled variables are replaced with *virtual nodes* whose outputs are always unity. These nodes are connected to the predictor network through adjustable weights. The optimization occurs by finding values for these weights that allow the model to predict a desired output. These weights can be found through any number of search methods, including the gradient descent technique used in back-propagation training. In this case, the predictor network is “trained”

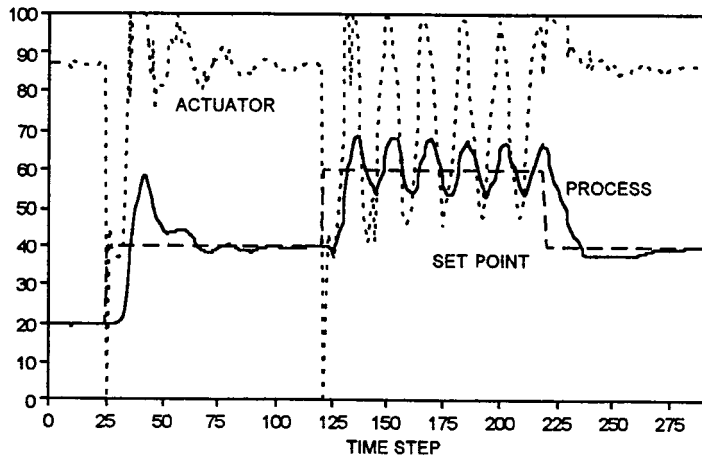

FIGURE 6.5.6 Example of computer simulation using a PID controller.

FIGURE 6.5.7 Example of computer simulation using a neural network controller.

normally, except that all weights in the network are static except those connected to the virtual nodes. Once weights have been found that produce the desired output, the set points can be found from direct interpretation of these weights. Constraints can be imposed on the weights either through physical limitations (e.g., freezing points) or from predictions from local-loop neural network controllers.

## Fuzzy Logic Controllers

Fuzzy logic controllers (FLC) use conditional relationships to analyze one or more inputs. That is, the inputs are subject to a series of *if...then* queries to produce some intermediate values. An example would be something like a simple cruise control on an automobile:

- *If* vehicle speed = much lower than set point, *then* need to increase speed = large
- *If* vehicle speed = slightly lower than set point, *then* need to increase speed = small

These intermediate values are then used to determine the actual change of speed in the car:

- *If* need to increase speed = large, *then* increase of throttle position = 10%
- *If* need to increase speed = small, *then* increase of throttle position = 3%

FIGURE 6.5.8 Using network model to optimize process control.

In fuzzy control, the satisfaction of a particular *if* statement may not lead to or be restricted by a true or false response. A range of weighting coefficients is assigned to a particular conditional, with the coefficients generally decreasing as the certainty of a specific condition decreases. In the example above, “need to increase speed = large” may be assigned a certainty of 1 when the speed of the vehicle is less than 50% of the desired speed of the car. This certainty will decrease as the speed of the car increases, so that “need to increase speed = large” may be 0 when the speed of the car is greater than 90% of the desired speed, but the certainty of “need to increase speed = small” will be large. It is possible that for a given speed of the car, two or more conditions may be satisfied with different magnitudes of certainty. These conditions can then be applied to the output rules along with their respective certainties to determine the actual increase (or decrease) in the controller output. When the speed of the car is below the desired speed, the initial rules may yield, for example,

- Need to increase speed = large with certainty = 0.3
- Need to increase speed = small with certainty = 0.7

the actual output would then be

- Increase of throttle position =  $(0.3 \times 10\% + 0.7 \times 3\%)/(0.3 + 0.7) = 5.1\%$

The following section formalizes some of these ideas and includes a detailed example.

Section 19 Mathematics contains the formalism underlying fuzzy set theory and fuzzy logic. The reader is referred to that section and the one that follows for the technical basis for FLCs.

## Fuzzy Logic Controllers for Mechanical Systems

### Introduction

In the last decade, FLCs have been receiving more attention (Leigh and Wetton 1983; Daley and Gill, 1985; Yasunobu and Miyamoto, 1985; Xu, 1989), not only in test cases, but also in real industrial process control applications, including building mechanical systems (Sakai and Ohkusa, 1985; Ono et al., 1989; Togai and Maski, 1991; Huang and Nelson, 1991; Meijer, 1992). The basic idea of this approach is to incorporate the experience of human operators in the design of controllers. From a set of linguistic rules describing operators’ control strategies, a control algorithm can be constructed (Ralston and Ward, 1985).

Computer simulations and experiments have shown that FLCs may have better performance than those obtained by conventional controllers. In particular, FLCs appear very useful when the processes are too complex for analysis using conventional control algorithms or when the available information is qualitative, inexact, or uncertain. Thus, fuzzy logic control may be viewed as a compromise between conventional precise mathematical control and humanlike decision making, as indicated by Gupta (Gupta and Tsukamoto, 1980).

However, fuzzy logic controllers sometimes fail to obtain satisfactory results with the initial rule set drawn from the operators' experience. This is because there still are some differences between the way a plant is operated by an experienced operator and by an FLC using the rules based directly on his or her experience. It is often difficult to express human experience exactly using linguistic rules in a simple form. Sometimes there is no experience that could be used to construct control rules for FLCs. In these cases it is necessary to design, develop, and modify control rules for FLCs to obtain optimal performance. There have been few discussions about rule development and adjustment strategies for FLCs (Sheridah, 1984; Scharf and Mandic, 1985; Wakileh and Gill, 1988; Ollero and Williams, 1989).

**The Basic Aspects of an FLC**

An FLC includes three parts: fuzzifier, fuzzy reasoning unit, and defuzzifier. The fuzzifier converts ordinary inputs into their fuzzy counterparts, the fuzzy reasoning unit creates fuzzy control signals based on these fuzzy variables, and the defuzzifier converts the fuzzy control signals into the real control outputs. The block diagram of a fuzzy control system is shown in Figure 6.5.9, where  $e$ ,  $d$ , and  $u$  are tracking error, derivative error, and output control action;  $\tilde{e}$ ,  $\tilde{d}$ , and  $\tilde{u}$  are their fuzzy counterparts, respectively;  $y$  is the controlled parameter; and  $r$  is the set point for  $y$ .  $K_p$  is the scale factor for  $e$ ,  $K_d$  is the scale factor for  $d$ , and  $K_o$  is the output gain.

FIGURE 6.5.9 The block diagram of a fuzzy control system.

The control rules expressed in natural language are expressed in the following form:

IF ( $e$  is  $A$ ) AND ( $d$  is  $B$ ) THEN ( $u$  is  $C$ )

where  $A$ ,  $B$ , and  $C$  are fuzzy subsets defined on the universes of discourse of  $e$ ,  $d$ , and  $u$ , respectively. Every rule is interpreted into a fuzzy reasoning matrix:

$$R_k = [A_k(e) \otimes B_k(d)]^\Theta \otimes C_k(u) \quad k = (1, N)$$

where  $N$  is the number of rules, the symbol  $\otimes$  denotes aggregation operator, and the symbol  $\Theta$  denotes an align-turning operator (see Section 19). The general fuzzy relation matrix  $R$  can be constructed as the union of the individual rules:

$$R = \bigcup_{k=1}^N R_k$$

This matrix represents the relationship between the fuzzy inputs and the fuzzy control output. The fuzzy control output can then be calculated from the known fuzzy input  $\tilde{e}$  and  $\tilde{d}$  by

$$\tilde{u} = [\tilde{e} \otimes \tilde{d}]^{\circ} \circ R$$

where the symbol  $\circ$  denotes the max-min composition operator (see Section 19).

The input universe of discourse for tracking error  $e$  or derivative error  $d$  is divided into several degrees connected with a number of fuzzy subsets by membership functions. In this study,  $e$  and  $d$  can each range from  $-6$  to  $+6$ , and 13 degrees are used:

$$-6, -5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5, 6$$

Also, seven fuzzy subsets are defined as:

NL, NM, NS, ZZ, PS, PM, PL.

where the first letters N and P mean negative and positive, the second letters L, M, and S mean large, middle, and small, and ZZ means zero. These degrees and fuzzy subsets are shown in Table 6.5.1 which uses a 1.0–0.8–0.5–0.1 distribution. For example, if  $e = 3$ , then its membership in PL is 0.1, its membership in PM is 0.8, etc.

**TABLE 6.5.1 The Membership Function of Input of an FLC**

$A(e), B(d)$	-6	-5	-4	-3	-2	-1	0	1	2	3	4	5	6
PL	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.1	0.5	0.8	1.0
PM	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.1	0.5	0.8	1.0	0.8	0.5
PS	0.0	0.0	0.0	0.0	0.0	0.1	0.5	0.8	1.0	0.8	0.5	0.1	0.0
ZZ	0.0	0.0	0.0	0.1	0.5	0.8	1.0	0.8	0.5	0.1	0.0	0.0	0.0
NS	0.0	0.1	0.5	0.8	1.0	0.8	0.5	0.1	0.0	0.0	0.0	0.0	0.0
NM	0.5	0.8	1.0	0.8	0.5	0.1	0.0	0.0	0.0	0.0	0.0	0.0	0.0
NL	1.0	0.8	0.5	0.1	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0

A similar analysis is given to the outputs for the control action indicated in Table 6.5.2 which uses a 1.0–0.7–0.2 distribution and where the abbreviations mean that the output control actions are Very Strong (Level 7), STrong (Level 6), SUBstrong (Level 5), MEdium (Level 4), Slightly Small (Level 3), SMall (Level 2), and TIny (Level 1).

**TABLE 6.5.2 The Membership Function of Output of an FLC**

The fuzzifier converts ordinary inputs into their fuzzy counterparts. In this study, a fuzzy singleton is used as a fuzzification strategy, which interprets an input,  $e$  (or  $d$ ), into a fuzzy value,  $\tilde{e}$  (or  $\tilde{d}$ ), with membership function ( $\mu$ ) equal to zero except at the element nearest to the real input, where  $\mu = 1.0$ . For example, if  $e = 3.2$ , the nearest element is 3, then the fuzzy singleton will be

$$\tilde{d} = (0, 0, 0, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0)$$

This fuzzy singleton has membership function  $\mu = 1.0$  at the point of element  $e = 3$ . The defuzzifier converts the fuzzy control output created by the rule-based fuzzy reasoning unit into a real control action. In this study, weighted combination method is used as defuzzification strategy, which can be explained by the following example, if

$$\tilde{u} = (0, 0, 0, 0, 0, 0, 0, 0.2, 0.4, 0.8, 0.7, 0.5, 0.1)$$

then

$$u = [0.2(1) + 0.4(2) + 0.8(3) + 0.7(4) + 0.5(5) + 0.1(6)] / [0.2 + 0.4 + 0.8 + 0.7 + 0.5 + 0.1] = 3.4$$

*Rule Refinement.* An FLC is characterized by a set of linguistic statements which are usually in the form of *if-then* rules. The initial set of rules is usually constructed based on the operators' experience, or sometimes by analyzing the dynamic process of the controlled plant. Both approaches require modifying the initial set of rules to obtain an optimal rule set. This is called *rule refinement*.

Figure 6.5.10 shows an initial rule set analyzed on a "linguistic plane". The horizontal axis expresses the fuzzy subsets defined on the universe of discourse for the tracking error ( $e$ ), and the vertical axis expresses the fuzzy subsets defined on the universe of discourse for the derivative error ( $d$ ). Both have seven fuzzy "values": NL, NM, NS, ZZ, PS, PM, PL. On the cross points of these fuzzy values there are output control action levels, which are also fuzzy subsets having seven "values" from Level 1 (Tiny) to Level 7 (Very Strong). For example, the cross point of  $e = NM$  and  $d = PM$  indicates  $u =$  Level 3. This corresponds to the rule:

IF ( $e$  is NM) AND ( $d$  is PM) THEN ( $u$  is Level 3)

FIGURE 6.5.10 The initial rule set and performance trajectory on the linguistic plane.

For example, the initial rule set could be based on the following control strategies. First, it tries to keep a proportional relationship between the control action ( $u$ ) and the tracking error ( $e$ ). Note that if the derivative error ( $d$ ) is ZZ, then the output control action ( $u$ ) increases from Level 1 to Level 7 when the tracking error ( $e$ ) changes from NL to PL. Second, the influence of derivative error ( $d$ ) is considered such that, if it is positive, then increase the control action ( $u$ ) a little bit, and if it is negative, then decrease the control action ( $u$ ). For example, if the tracking error ( $e$ ) keeps PM, the control action ( $u$ )

increases from Level 6 to Level 7 when the derivative error ( $d$ ) is positive, and it decreases from Level 6 to Level 5 when the derivative error ( $d$ ) is negative.

Consider a second-order plant with a transfer function:

$$H(s) = \frac{1.0}{s^2 + 0.1s + 1.0}$$

that is controlled using the initial rule set to respond to a step input for computer simulation. The performance trajectory of the FLC is shown by the arrows in Figure 6.5.10 and the dynamic process of the normalized controlled parameter (CP) is shown in Figure 6.5.11 where the horizontal axis indicates the number of sample period (SP). The dynamic process can be divided into two stages. At the first stage, there is a strong oscillation with a higher frequency, and, at the second stage, there is a moderate swing with a smaller frequency. Looking at the performance trajectory in the linguistic plane, we can see that the stronger oscillation occurs at the out-cycle (points further from the center). As time increases, the state moves to the in-cycle near the center of the plane and becomes moderate. This shows that FLCs have the desirable property of a structure-variable controller. The rules at the out-cycle belong to one kind of structure for the first stage, and the rules at the in-cycle belong to another structure for the second stage.

**FIGURE 6.5.11** The dynamic process corresponding to Figure 6.5.10.

If the initial rule set does not satisfy a good design for a controller, then it can be modified by intuitive reasoning. A rule set is often symmetrically positioned about the central point, which is the desired stable operating point, where the tracking error ( $e$ ) and the derivative error ( $d$ ) both equal zero and the control action ( $u$ ) is medium. When a positive step increase is imposed to the set point, the tracking error ( $e$ ) has the biggest value and the derivative error ( $d$ ) is zero at the beginning time (point A in the linguistic plane). With the regulating action, the tracking error ( $e$ ) will decrease, the derivative error ( $d$ ) will be negative, and the performance trajectory will enter into the right-bottom block in the linguistic plane. So, the rules in this area have the most important effect on the behavior of the first stage of the dynamic process. The most important area responsible for the behavior of the second stage is the central block.

To avoid strong oscillations, it is apparent that the control actions in the right-bottom block should be decreased. The modified rule set and its simulation of response to a step input are shown in Figure 6.5.12. The performance trajectory expressed in the linguistic plane is a spiral (Figure 6.5.12). We can see that the performance of the control system has been improved, but a small oscillation still exists and there is a little overshoot indicated by point C in Figures 6.5.12 to 6.5.13. Once again, the rule set is modified and the final rule set and its simulation of response to a step input are shown in Figure 6.5.14

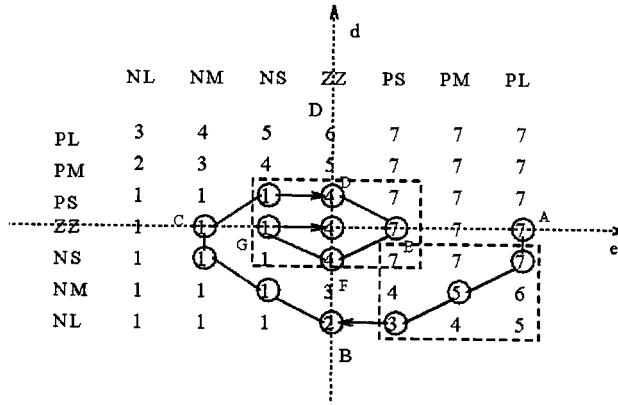

FIGURE 6.5.12 The second rule set on the linguistic plane.

FIGURE 6.5.13 The dynamic process corresponding to Figure 6.5.12.

FIGURE 6.5.14 The third rule set on the linguistic plane.

and Figure 6.5.15. The final rule set gives good performance with a short rise time and a very small overshoot and it is considered satisfactory.

By analyzing the performance trajectory on the linguistic plane, a rule set is refined. It relies heavily on intuitive reasoning when comparing the dynamic process of the controlled parameter for the present rule set with the desired one.

**FIGURE 6.5.15** The dynamic process corresponding to Figure 6.5.14.

*Completeness and Interaction of Rules and Selection of Membership Functions.* The second significant influence on the behavior of an FLC is the membership functions. They should be chosen carefully in the adjustment process. As mentioned in Section 6.3, the fuzzy subsets, language variables NL, NM, NS, ZZ, PS, PM, and PL, are defined on the universe discourse of tracking error ( $e$ ) or derivative error ( $d$ ). Some possible membership functions are shown in Figures 6.5.16 to 6.5.18. The membership functions should be chosen to make these language variables have suitable coverage on the universe of discourse. For the case of Figure 6.5.16, the whole range is not covered by these language variables. There are some values of  $e$  or  $d$ , on which the membership functions of all language variables are zero. In this case, an empty output control action could be created. This means that the control actions are lost for those points which are not covered by any input fuzzy subset. This is referred as the non-completeness of control rules. FLCs should satisfy the condition of completeness for their membership functions. The membership function shown in Figure 6.5.17 cannot be used for an effective FLC. In other words, the union of all fuzzy subsets,  $X_i, i = [1,7]$ , should be greater than zero for all  $e \in E$ , i.e.,

$$\forall e \in E \quad \bigcup_{i=1}^7 X_i(e) > 0$$

**FIGURE 6.5.16** Non-complete membership function.

On the other hand, there can be interaction among the rules if the overlap of fuzzy subsets occurs on the range of the universe of discourse. In this case, the membership functions have the forms shown in Figures 6.5.17 and 6.5.18. The interaction tends to smooth out the set of control rules. Consider the single-input-single-output case for simplicity; the rule set is

$$\text{IF } (e \text{ is } A_i) \text{ THEN } (u \text{ is } C_i) \quad i = [1, M]$$

FIGURE 6.5.17 Heavy overlap membership function.

FIGURE 6.5.18 Moderate overlap membership function

where  $N$  is the number of rules in the set. These rules are incorporated into a fuzzy relation matrix as follows:

$$R = \bigcup_{i=1}^N R_i = \bigcup_{i=1}^N (A_i \otimes C_i)$$

If the fuzzy value of input  $e$  is known as  $\tilde{e}$ , the fuzzy output  $\tilde{u}$  then can be calculated as follows:

$$\tilde{u} = \tilde{e} \circ R$$

If  $\tilde{e}$  is  $A_i$ ,  $\tilde{u}$  is expected to be  $C_i$ . But now the interaction of rules due to overlap results in:

$$C_i \subseteq A_i \circ R$$

The equality is established only when no overlap occurs. This analysis is based on the fuzzy logic scheme including max-min composition operator. A more-detailed example of the numeric calculation is given in the appendices to this section.

If the overlap is heavy as shown in Figure 6.5.17, there will be large deformation and the control rules will lose their original shape. In the limit, as the membership functions become unity for all values, the output of the FLC will always be the same fuzzy quantity. This means that the fuzzy reasoning system conveys no valuable information and the FLC has lost its efficacy.

A moderate overlap, shown in Figure 6.5.18, is desirable to allow for reasoning with uncertainty and the need for completeness of the control rules. How does one determine the “size” of overlap? At present, we use intuitive judgment to choose membership functions when adjusting an FLC. There appears to be some latitude in choosing the amount of overlap, on which the performance of an FLC does not change significantly. The quantitative analysis will be given after further research.

When we modify the control rules in the linguistic plane, the overlapping membership functions let the rules near the performance trajectory have an effect on the output control actions. This is because interactions occur among the neighboring rules.

**Scale Factors and Output Gain**

The scale factors,  $K_p$  and  $K_d$ , and the output gain,  $K_o$ , shown in Figure 6.5.19, also have significant influence on the behavior of an FLC. Their influence is not as complicated as those of rules and membership functions. The adjustment for the scale factors and output gain is comparatively simple. The scale factor  $K_p$  relates the actual range of tracking error ( $e$ ) to the universe of discourse ( $E$ ) defined in the fuzzy logic system. In this work,  $E$  consists of 13 degrees as indicated in earlier sections. Then  $K_p$  is determined as the ratio of the range of  $E$  to the range of the real variable:

$$K_p = \frac{E_{\max} - E_{\min}}{e_{\max} - e_{\min}}$$

**FIGURE 6.5.19** The influence of  $K_o$  on the behavior of FLCs.

For scale factor  $K_d$ , there is the similar analysis leading to

$$K_d = \frac{D_{\max} - D_{\min}}{d_{\max} - d_{\min}}$$

where  $D$  is the universe of discourse for derivative error ( $d$ ) defined in the fuzzy logic system. Small  $K_p$  or  $K_d$  will narrow the control band, while large  $K_p$  or  $K_d$  will lead to loss of control for large inputs.

The output gain  $K_o$  is defined as follows:

$$K_o = \frac{u_{\max} - u_{\min}}{U_{\max} - U_{\min}}$$

It is the ratio of range of real output control action ( $u$ ) to the range of its universe of discourse ( $U$ ) defined in the fuzzy logic system.  $K_o$  acts as an amplification factor of the whole FLC. Figure 6.5.19 shows the influence of  $K_o$  on the step response simulation of an FLC with the final rule set used in Figure 6.5.14. Increasing  $K_o$  results in a shorter rise time. The performance trajectory in the linguistic plane will become steeper for the first stage and oscillation occurs. Decreasing  $K_o$  results in a longer rise time, and the performance trajectory in the linguistic plane will become moderate during the first stage. But, in our simulation, oscillation still occurred. This is because different  $K_o$ , larger or smaller, results in a new route of the performance trajectory which will activate the different rules which might

cause oscillation. So the influence of output gain,  $K_o$ , should be considered together with the change of the activated rules.

### Conclusion

An FLC can perform much better than a conventional controller, such as a PID controller, if the FLC has been well constructed. The main disadvantage of using FLCs today seems to be the lack of a systematic procedure for the design of FLCs. The general method for designing an FLC is to use trial and observation. No useful mathematical tool has yet been developed for the design of an FLC because of its fuzziness, complexity, and nonparameterization.

There are three significant elements that have notable influence on the behavior of an FLC:

1. The control rules expressed in linguistic language,
2. The membership functions defined for fuzzy subsets, and
3. The scale factors attached to the input and the output gains.

The control rules play the main role in forming the dynamics of FLCs. The rule set can be analyzed and modified using the performance trajectory technique and evaluated using the dynamic process curve of the controlled parameter. The membership functions define the “shape” of fuzzy subsets. They should have appropriate width to avoid noncompleteness and suitable interaction among the fuzzy control rules. The scale factors ( $K_p$  and  $K_d$ ) and output gain ( $K_o$ ) serve as amplification factors.

At present, each application must be individually designed. The initial sets of rules are specifically set up for different applications. Work is now underway to develop a self-adaptive FLC which will choose the initial set of rules automatically according to the process dynamics and refine it on the basis of the global performance evaluation.

## Appendices

### Table of Transforms

The following table lists some of the more common transforms used in the analysis of building systems. More-extensive tables can be found in most mathematics and numerical analysis reference books.

**List of Some *s*- and *z*-Transforms**

Continous-Time Domain	Frequency Domain	Discrete-Time Domain
$1 \ t = 0 \ 0 \ t \neq 0$	—	1
$1 \ t = k \ 0 \ t \neq k$	—	$z^{-k}$
1	$\frac{1}{s}$	$\frac{z}{z-1}$
$t$	$\frac{1}{s^2}$	$\frac{Tz}{(z-1)^2}$
$e^{-at}$	$\frac{1}{s+a}$	$\frac{z}{z-e^{-aT}}$
$te^{-at}$	$\frac{1}{(s+a)^2}$	$\frac{Tze^{-aT}}{(z-e^{-aT})^2}$
$1 - e^{-at}$	$\frac{a}{s(s+a)}$	$\frac{z(1-e^{-aT})}{(z-1)(z-e^{-aT})}$
$e^{-at} - e^{-bt}$	$\frac{b-a}{(s+a)(s+b)}$	$\frac{z(e^{-aT} - e^{-bT})}{(z-e^{-aT})(z-e^{-bT})}$

### Special FLC Mathematical Operations

- ⊗ aggregation operator
- ⊖ align-turning operator
- max-min composition operator
- ∪ union operator
- ∃ exists
- ∈ in
- ∀ for all
- ⊆ is the subset of

The aggregation operator (⊗) is used to define a two-dimensional fuzzy variable *F* from fuzzy subsets *A* and *B* (one-dimensional fuzzy variables) as follows:

$$F = A(e) \otimes B(d) = \begin{bmatrix} \mu_F(1,1) & \dots & \dots & \dots & \mu_F(1,N) \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \mu_F(i,j) & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \mu_F(M,1) & \dots & \dots & \dots & \mu_F(M,N) \end{bmatrix}$$

where

$$\mu_F(i, j) = \min(\mu_A(i), \mu_B(j))$$

$$A(e) = (e_i, \mu_A(i))$$

$$B(d) = (d_j, \mu_B(j))$$

$e_i$  is the  $i$ th element of the subset  $A(e)$  and  $\mu_A(i)$  is its membership function;  $d_j$  is the  $j$ th element of the subset  $B(d)$  and  $\mu_B(j)$  is its membership function.

The align-turning operator ( $\Theta$ ) is an operator acting on a two-dimensional fuzzy variable to create a one-dimensional fuzzy variable, which has a set of membership functions aligned according to a certain order, as follows:

$$\begin{aligned} S &= [A \otimes B]^\Theta \\ &= (\mu_S(1,1), \mu_S(1,2), \dots, \mu_S(i,j), \dots, \mu_S(M,N)) \end{aligned}$$

where  $j$  varies from 1 to  $N$  first and  $i$  varies from 1 to  $M$ .

### An Example of Numeric Calculation for Influence of Membership Function

Suppose that there are two rules:

R1: IF ( $e$  is PM) THEN ( $u$  is VS) and

R2: IF ( $e$  is PS) THEN ( $u$  is ST).

For the first rule,

$$\tilde{e}_1 = (0, 0, 0, 0, 0, 0, 0, 0, 0.1, 0.5, 0.8, 1.0, 0.8, 0.5)$$

$$\tilde{u}_1 = (0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0.2, 0.7, 1.0)$$

Then the rule can be interpreted into a fuzzy reasoning matrix as follows:

$$\begin{aligned}
 R_1 &= \tilde{e}_1 \otimes \tilde{u}_1 \\
 &= \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 \end{bmatrix} \\
 &\equiv \mu_{R_1}(i, j)
 \end{aligned}$$

where the membership in  $R_1$  for the element  $(i, j)$  of the matrix,  $\mu_{R_1}(i, j)$  is

$$\mu_{R_1}(i, j) = \min(\mu_{\tilde{e}_1}(i), \mu_{\tilde{u}_1}(j))$$

For the second rule,

$$\tilde{e}_2 = (0, 0, 0, 0, 0, 0, 0.1, 0.5, 0.8, 1.0, 0.8, 0.5, 0.1, 0)$$

$$\tilde{u}_2 = (0, 0, 0, 0, 0, 0, 0, 0, 0.2, 0.7, 1.0, 0.7, 0.2)$$

Then the second rule can be interpreted into a fuzzy reasoning matrix as follows:

$$\begin{aligned}
 R_2 &= \tilde{e}_2 \otimes \tilde{u}_2 \\
 &= \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 & 0.7 & 0.2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \\
 &\equiv \mu_{R_2}(i, j)
 \end{aligned}$$

where the membership in  $R_2$  for the element  $(i, j)$  of the matrix,  $\mu_{R_2}(i, j)$  is

$$\mu_{R_2}(i, j) = \min(\mu_{\tilde{e}_2}(i), \mu_{\tilde{u}_2}(j))$$

The general fuzzy relation matrix  $R$  is then constructed as the union of these two rules:

$$\begin{aligned}
 R_2 &= R_1 \cup R_2 \\
 &= \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 & 0.7 & 0.5 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.8 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.7 & 1.0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.2 & 0.7 & 0.8 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 \end{bmatrix} \\
 &\equiv \mu_R(i, j)
 \end{aligned}$$

where

$$\mu_R(i, j) = \max(\mu_{R_1}(i), \mu_{R_2}(j))$$

Assume that there is an input ( $e$ ) and its fuzzy value  $\tilde{e} = \text{PM}$ , then the output is expected to be VS according to the first rule. But now the output is calculated through the fuzzy matrix  $R$  as follows:

$$\begin{aligned}\tilde{u} &= \tilde{e} \circ R \\ &= \text{PM} \circ R \\ &= (0, 0, 0, 0, 0, 0, 0, 0, 0.1, 0.5, 0.8, 1.0, 0.8, 0.5) \circ R \\ &= (0, 0, 0, 0, 0, 0, 0, 0, 0.2, 0.7, 0.8, 0.7, 1.0)\end{aligned}$$

where

$$\mu_{\tilde{u}}(j) = \max_i(\min(\mu_{\tilde{e}}(i), \mu_R(i, j)))$$

While

$$\begin{aligned}\tilde{u}_1 &= \text{VS} \\ &= (0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0.2, 0.7, 1.0)\end{aligned}$$

So,

$$\tilde{u}_1 \subseteq \tilde{u}$$

This chapter describes the primary as well as derived energy sources. The objective is to provide information on the extent, availability, measurements and estimation, properties, and limitations of each type of resource. These considerations are important for an engineer to know and understand before attempting selection and design of an energy conversion system. The chapter also includes environmental impacts of energy resources since the environmental aspects are expected to play a major role in the selection of energy resources. In addition, there is a brief discussion of the costs associated with each resource to help in the economic analysis and comparison the resources.

The chapter starts with an introduction and background of a historical perspective on energy use and projections of the future energy needs in the U.S., the industrialized countries, and the world. The primary energy sources described in this chapter include fossil fuels such as coal, natural gas, petroleum (including their synthetic derivatives), biomass (including refuse-derived biomass fuels), nuclear, solar radiation, wind, geothermal, and ocean. In addition there is a brief section on derived energy sources including electricity. So, the terminology and units used for each energy resource and their equivalence are provided.

## 7.1 Introduction

*D. Yogi Goswami*

Global energy consumption in the last 50 years has increased at a very rapid rate. Present trends in global population growth, rapid industrialization, and urbanization in major population centers of the world suggest that the world energy demand will continue to increase in the next 50 years (U.S. DOE, 1991). [Figure 7.1.1](#) shows the historical and projected world energy consumption compiled by the Energy Information Agency.

**FIGURE 7.1.1** Historical and projected energy consumption. (From EIA. *Annual Energy Outlook 1992*, U.S. DOE, DOE/EIA-0484(92), Washington, D.C.)

The energy resources available to fulfill the world demand include

- Fossil fuels (oil, coal, natural gas)
- Nuclear fuels
- Geothermal
- Solar radiation
- Hydropower

- Biomass (crops, wood, municipal solid waste)
- Wind
- Ocean

Out of all the energy resources, fossil fuels have been used the most (88% of total consumption) because of their extremely high energy densities and simplicity of conversion and use. Figure 7.1.2 shows the world energy production by resource.

**FIGURE 7.1.2** World energy production by resource. (From EIA. *World Energy Outlook*, International Energy Agency, Paris, 1994. With permission.)

Recent concerns about the environment are expected to increase the use of natural gas for power production. Renewable energy resources, such as solar energy, wind, and biomass, are also expected to increase their share of the energy use. There is a strong sentiment in the world in favor of exploiting renewable energy resources, especially because of environmental concerns. How far that sentiment translates into practical use will depend on the development of the renewable energy technologies and prices of the fossil fuels.

### Defining Terms

**MTOE:** Mega tons of oil equivalent; 1 MTOE =  $42.63 \times 10^{12}$  Btu.

**Quadrillion Btu:**  $10^{15}$  British thermal units (Btu), also known as Quad; 1 Btu = 1055 joules).

### Further Information

Historical and projected energy consumption are published annually by the Energy Information Agency, U.S. Department of Energy, Washington, D.C., and International Energy Agency, Paris.

## 7.2 Types of Derived Energy

*D. Yogi Goswami*

Energy from renewable and nonrenewable fuels can be converted to the derived energy forms — thermal, mechanical, and electrical, which are useful for various end uses such as transportation, buildings (heating, cooling, lighting), agricultural, and industrial end uses. The derived energy forms are easily transformed from one type to the other. Figure 7.2.1 shows the projected U.S. energy use by end-use sector.

**FIGURE 7.2.1** Projected U.S. energy use by end-use sector. (From EIA. *Annual Energy Outlook 1992*, U.S. DOE, DOE/EIA-0484(92), Washington, D.C., 1992.)

Transportation is mainly dependent on oil resources. Efforts to reduce urban air pollution are expected to increase the use of electricity as the preferred energy form for urban transportation. For most of the other end uses electricity will continue to be the preferred energy form. Therefore, it is important to understand the activity in the area of electricity production. Figure 7.2.2 shows the world installed electricity generation capacity by primary energy sources. The United States produces 700 GW (gigawatts or  $10^9$  W), representing more than 25% of the world electricity capacity. Other major electricity producers are Russia, Europe, Japan, and China. It is expected that China, India, and Southeast Asian countries will add major electricity capacity in the next 20 years.

**Integrated resource planning (IRP)**, or least-cost planning, is the process used to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be attributed to the resource. IRP examines all of the options, including the demand-side options, to minimize the total costs. There is considerable emphasis on IRP in a number of states in United States for future electric capacity and on **demand-side management (DSM)** for the current capacity (Kreith and Burmeister, 1993). The IRP process generally includes some combination of the following steps (Kreith and Burmeister, 1993): development of a load forecast; inventory of existing resources; identification of additional electrical capacity needs; demand-side management programs; screening and identification of options that are feasible; uncertainty analysis in view of uncertainty of future load, fuel prices, capital costs, etc; and selection of a resource or a mix of resources.

**Demand Side Management DSM** refers to a mix of electrical utility-sponsored custom incentives and disincentives that influence the amount and timing of customer demand in order to better utilize the available resources. Kreith and Burmeister (1993) and SERI (1991) list a number of DSM strategies.

**FIGURE 7.2.2** World electricity output. (From EIA, *World Energy Outlook*, International Energy Agency, Paris, 1994. With permission.)

## Defining Terms

**Demand-side management (DSM):** Refers to a mix of incentives and disincentives that influence the amount and timing of energy use in order to better utilize the available resources.

**Integrated resource planning (IRP):** The process to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be all attributed to the resource.

## Further Information

Annual reviews published by the EIA, U.S. Department of Energy, and the International Energy Agency (see References) provide a wealth of information on electricity capacity and energy consumption by end-use sectors.

## 7.3 Fossil Fuels

### Coal

*Robert Reuther*

#### Coal Composition and Classification

Coal is a sedimentary rock formed by the accumulation and decay of organic substances derived from plant tissues and exudates that have been buried over periods of geological time along with various mineral inclusions. Coal is classified by **type and rank**. Coal type classifies coal by the plant sources from which it was derived. Coal rank classifies coal by its degree of metamorphosis from the original plant sources and is therefore a measure of the age of the coal. The process of metamorphosis or aging is termed **coalification**.

The study of coal by type is known as coal petrography. Coal type is determined from the examination of polished sections of a coal sample using a reflected-light microscope. The degree of reflectance and color of a sample are identified with specific residues of the original plant tissues. These various residues are referred to as **macerals**. Macerals are collected into three main groups: vitrinite, inertinite, and exinite (sometimes referred to as liptinite). The maceral groups and their associated macerals are listed in [Table 7.3.1](#) along with a description of the plant tissue from which each distinct maceral type is derived.

**TABLE 7.3.1 Coal Maceral Groups and Macerals**

Maceral Group	Maceral	Derivation
Vitrinite	Collinite	Humic gels
	Telinite	Wood, bark, and cortical tissue
	Pseudovitrinite	? (Some observers place in the inertinite group)
Exinite	Sporinite	Fungal and other spores
	Cutinite	Leaf cuticles
	Resinite	Resin bodies and waxes
	Alginite	Algal remains
Inertinite	Micrinite	Unspecified detrital matter, <10 μm
	Macrinite	Unspecified detrital matter, 10–100 μm
	Semifusinite	“Burned” woody tissue, low reflectance
	Fusinite	“Burned” woody tissue, high reflectance
	Sclerotinite	Fungal sclerotia and mycelia

Modified from Berkowitz, N., *An Introduction to Coal Technology*. Academic Press, New York, 1979.

Coal rank is the most important property of coal, since it is rank which initiates the classification of coal for use. Rank is a measure of the age or degree of coalification of coal. Coalification describes the process which the buried organic matter goes through to become coal. When first buried, the organic matter has a certain elemental composition and organic structure. However, as the material becomes subjected to heat and pressure, the composition and structure slowly change. Certain structures are broken down, and others are formed. Some elements are lost through volatilization while others are concentrated through a number of processes, including being exposed to underground flows which carry away some elements and deposit others. Coalification changes the values of various properties of coal. Thus, coal can be classified by rank through the measurement of one or more of these changing properties.

In the United States and Canada, the rank classification scheme defined by the American Society of Testing and Materials (ASTM) has become the standard. In this scheme, the properties of **gross calorific value** and **fixed carbon** or **volatile matter content** are used to classify a coal by rank. Gross calorific value is a measure of the energy content of the coal and is usually expressed in units of energy per unit mass. Calorific value increases as the coal proceeds through coalification. Fixed carbon content is a measure of the mass remaining after heating a dry coal sample under conditions specified by the ASTM.

Fixed carbon content increases with coalification. The conditions specified for the measurement of fixed carbon content result in being able alternatively to use the volatile matter content of the coal measured under dry, ash-free conditions as a rank parameter. The rank of a coal proceeds from lignite, the “youngest” coal, through subbituminous, bituminous, and semibituminous, to anthracite, the “oldest” coal. There exist subdivisions within these rank categories which are defined in [Table 7.3.2](#). (Some rank schemes include meta-anthracite as a rank above, or “older” than, anthracite. Others prefer to classify such deposits as graphite. Graphite is a minimal resource and is valuable primarily for uses other than as a fuel.) According to the ASTM scheme, coals are ranked by calorific value up to the high volatile A bituminous rank, which includes coals with calorific values (measured on a moist, mineral matter-free basis) greater than 14,000 Btu/lb (32,564 kJ/kg). At this point, fixed carbon content (measured on a dry, mineral matter-free basis) takes over as the rank parameter. Thus, a high volatile A bituminous coal is defined as having a calorific value greater than 14,000 Btu/lb, but a fixed carbon content less than 69 wt%. The requirement for having two different properties with which to define rank arises because calorific value increases significantly through the lower-rank coals, but very little (in a relative sense) in the higher-ranks, whereas fixed carbon content has a wider range in higher-rank coals, but little (relative) change in the lower-ranks. The most widely used classification scheme outside of North America is that developed under the jurisdiction of the International Standards Organization, Technical Committee 27, Solid Mineral Fuels.

### Coal Analysis

The composition of a coal is typically reported in terms of its **proximate analysis** and its **ultimate analysis**. The proximate analysis of a coal is made up of four constituents: volatile matter content, fixed carbon content, moisture content, and ash content, all of which are reported on a weight percent basis. The measurement of these four properties of a coal must be carried out according to strict specifications codified by the ASTM.

Volatile matter in coal includes carbon dioxide, inorganic sulfur- and nitrogen-containing species, and organic compounds. The percentage of various species present depends on rank. Volatile matter content can typically be reported on a number of bases, such as moist; dry, mineral matter-free (dmmf); moist, mineral matter-free; moist, ash-free; and dry, ash-free (daf); depending on the condition of the coal on which measurements were made.

Mineral matter and ash are two distinct entities. Coal does not contain ash, even though the ash content of a coal is reported as part of its proximate analysis. Instead, coal contains mineral matter, which can be present both as distinct mineral entities or inclusions and intimately bound with the organic matrix of the coal. Ash, on the other hand, refers to the solid inorganic material remaining *after combusting* a coal sample. Proximate ash content is the ash remaining after the coal has been exposed to air under specific conditions (ASTM Standard Test Method D 3174). It is reported as the mass percent remaining upon combustion of the original sample on either a dry or moist basis.

Moisture content refers to the mass of water which is released from the solid coal sample when it is heated under specific conditions of temperature and residence time as codified in ASTM Standard Test Method D 3173.

The fixed carbon content refers to the mass of organic matter remaining in the sample after the moisture and volatile matter are released. It is primarily made up of carbon with lesser amounts of hydrogen, sulfur, and nitrogen also present. It is typically reported by difference from the total of the volatile matter, ash, and moisture contents on a mass percent of the original coal sample basis. Alternatively, it can be reported on a dry basis; a dmmf basis; or a moist, mineral matter-free basis.

The values associated with the proximate analysis vary with rank. In general, volatile matter content decreases with increasing rank, while fixed carbon content correspondingly increases. Moisture and ash also decrease, in general, with rank. Typical values for proximate analysis as a function of the rank of a coal are provided in [Table 7.3.3](#).

The ultimate analysis of a coal reports the composition of the organic fraction of coal on an elemental basis. Like the proximate analysis, the ultimate analysis can be reported on a moist or dry basis and on

TABLE 7.3.2 Classification of Coals by Rank

Class	Group	Fixed Carbon Limits, % (dmmf)		Volatile Matter limits, % (dmmf)		Gross Calorific Value Limits, Btu/lb (moist, mmf)		Agglomerating Character
		Equal or Greater Than	Less Than	Greater Than	Equal or Less Than	Equal or Greater Than	Less Than	
Anthracitic	Meta-anthracite	98	—	—	2	—	—	Nonagglomerating
	Anthracite	92	98	2	8	—	—	Nonagglomerating

an ash-containing or ash-free basis. The moisture and ash reported in the ultimate analysis are found from the corresponding proximate analysis. Nearly every element on Earth can be found in coal. However, the important elements which occur in the organic fraction are limited to a few. The most important of these include carbon, hydrogen, oxygen, sulfur, nitrogen, and, sometimes, chlorine. The scope, definition of the ultimate analysis, designation of applicable standards, and calculations for reporting results on different moisture bases can be found in ASTM Standard Test Method D 3176M. Typical values for the ultimate analysis for various ranks of coal found in the United States are provided in [Table 7.3.4](#).

### Coal Properties

Other important properties of coal include swelling, caking, and coking behavior; ash fusibility; reactivity; and calorific value.

Calorific value measures the energy available in a unit mass of coal sample. It is measured by ASTM Standard Test Method D 201 5M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. In the absence of a directly measured value, the gross calorific value,  $Q$ , of a coal (in Btu/lb) can be estimated using the Dulong formula (Elliott and Yohe, 1981):

$$Q = 14,544C + 62,028[H - (O/8)] + 4,050S$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur, respectively, obtained from the ultimate analysis.

Swelling, caking, and coking all refer to the property of certain bituminous coals, when slowly heated in an inert atmosphere to between 450 and 550 or 600°F, to change in size, composition, and, notably, strength. Under such conditions, the coal sample initially becomes soft and partially devolatilizes. With further heating, the sample takes on a fluid characteristic. During this fluid phase, further devolatilization causes the sample to swell. Still further heating results in the formation of a stable, porous, solid material with high strength. There are several tests which have been developed based on this property to measure the degree and suitability of a coal for various processes. Some of the more popular are the free swelling index (ASTM Test Method D 720), the Gray-King assay test (initially developed and extensively used in Great Britain), and the Gieseler plastometer test (ASTM Test Method D 2639), as well as a whole host of dilatometric methods (Habermehl et al., 1981). The results of these tests are often correlated with the ability of a coal to form a coke suitable for iron making. In the iron-making process, the high carbon content and high surface area of the coke are utilized to reduce iron oxide to elemental iron. The solid coke must also be strong enough to provide the structural matrix upon which the reactions take place. Bituminous coals which have good coking properties are often referred to as metallurgical coals. (Bituminous coals which do not have this property are, alternatively, referred to as steam coals because of their historically important use in raising steam for motive power or electricity generation.)

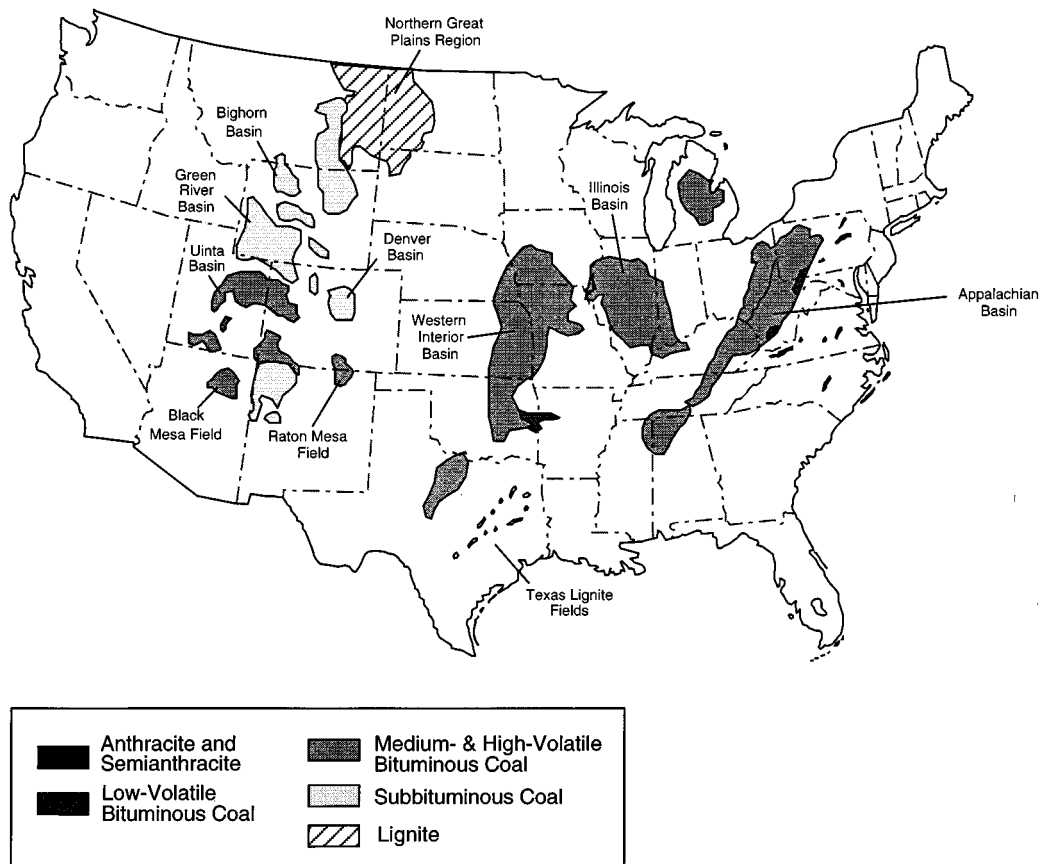

Ash fusibility is another important property of coals. This is a measure of the temperature range over which the mineral matter in the coal begins to soften and eventually to melt into a slag and to fuse together. This phenomenon is important in combustion processes; it determines if and at what point the resultant ash becomes soft enough to stick to heat exchanger tubes and other boiler surfaces or at what temperature it becomes molten so that it flows (as slag), making removal as a liquid from the bottom of a combustor possible.

Reactivity of a coal is a very important property fundamental to all coal conversion processes (the most important of which are combustion, gasification, and liquefaction). In general, lower-rank coals are more reactive than higher-rank coals. This is due to several different characteristics of coals, which vary with rank as well as with type. The most important characteristics are the surface area of the coal, its chemical composition, and the presence of certain minerals which can act as catalysts in the conversion reactions. The larger surface area present in lower-rank coals translates into a greater degree of penetration of gaseous reactant molecules into the interior of a coal particle. Lower-rank coals have a less aromatic structure than higher-rank coals, which, along with contributing to larger surface area, also corresponds to a higher proportion of lower-energy, more-reactive chemical bonds. Lower-rank coals also tend to have higher proximate ash contents, and the associated mineral matter is more distributed — down to the atomic level. Any catalytically active mineral matter is thus more highly dispersed, also. However, the reactivity of a coal also varies depending upon what conversion is being attempted. That is, the reactivity of a coal toward combustion (oxidation) is not the same as its reactivity toward liquefaction, and the order of reactivity established in a series of coals for one conversion process will not necessarily be the same as for another process.

## Coal Reserves

Coal is found throughout the United States and the world. It is the most abundant fossil energy resource in the United States and in the world. It comprises 95% of United States fossil energy resources and

70% of world fossil energy resources on an energy content basis. All coal ranks can be found in the continental United States. The largest resources in the United States are made up of lignite and subbituminous coals, which are found primarily in the western United States and Alaska. Bituminous coals are found principally in the Midwest, northern Alaska, and the Appalachian region. Principal deposits of anthracite coal are found in northeastern Pennsylvania. The Alaskan coals have not been extensively mined because of their remoteness and the harsh climate. Of the other indigenous coal resources, the anthracite coals have been extensively mined to where there is little economic resource left; the bituminous coals are being heavily mined in the lower 48 states, especially those with low sulfur contents (less than 2.5 wt%); and the low-rank coals in the West have historically been less heavily mined because of their low calorific value, high moisture and ash contents, and their distance from large markets, although with the enactment of the 1990 Amendments to the Clean Air Act of 1970, these coals are replacing high-sulfur Eastern coals in the marketplace. A map showing the general distribution of coal in the lower 48 states is included as [Figure 7.3.1](#).

**FIGURE 7.3.1** Coal fields of the conterminous (From Averitt, P., *Coal Resources of the United States*, January 1, 1974. U.S. Geological Survey Bulletin 1412, Government Printing Office, Washington, D.C., 1975.)

The amount of coal (or, for that matter, any minable resource) that exists is not known exactly and is continually changing as old deposits are mined out and new deposits are discovered or reclassified. Estimates are published by many different groups throughout the world. In the United States, the Energy Information Administration, an office within the U.S. Department of Energy, gathers and publishes estimates from various sources, including the World Energy Council and British Petroleum, Ltd. These

latter groups subscribe to a set of definitions for classifying the estimates which are acknowledged both in the United States and the United Kingdom. The most commonly used terms are defined below (as taken from Averitt, (1981):

*Resources:* The total quantity of coal in the ground within specified limits of thickness of bed overburden. The thickness of overburden defining this term varies from region to region in the world.

*Hypothetical Resources:* The quantity of coal estimated to be in the ground in unmapped and unexplored parts of known coal basins to an overburden depth of 6000 ft; determined by extrapolation from the nearest areas of identified resources.

*Identified Resources:* The quantity of coal in the measured, indicated, and inferred resource categories.

*Measured Resources:* The quantity of coal in the ground based on assured coal bed correlations and on observations spaced about 0.5 mi apart.

*Indicated Resources:* The quantity of coal in the ground based partly on specific observations and partly on reasonable geological projections; the points of observation and measurement are about 1 mi apart but may be 1.5 mi apart for beds of known continuity.

*Inferred Resources:* The quantity of coal in the ground based on continuity of coal beds downdip from and adjoining areas containing measured and indicated resources. Generally, inferred resources lie 2 mi or more from outcrops or from points of more precise information.

*Demonstrated Reserve Base:* The quantity of coal in the ground in the measured and indicated resources categories; restricted primarily to coal in thick and intermediate beds less than 1000 ft below the surface and deemed to be economically and legally available for mining.

*Reserves, or Recoverable Reserves:* The quantity of coal in the ground that can be recovered from the demonstrated reserve base by application of the recoverability factor.

*Recoverability Factor:* The percentage of coal in the demonstrated reserve base that can be recovered by established mining practices.

The demonstrated reserve base for coals in the United States as of January 1, 1993, is approximately 474.1 billion (short) tons. It is broken out by rank, state, and mining method (surface or underground) in [Table 7.3.5](#). As of December 31, 1990 (December 30, 1991, for the United States), the world recoverable reserves are estimated to be 1145 billion (short) tons. A breakdown by region and country is provided in [Table 7.3.6](#). The recoverability factor for all coals can vary from approximately 40% to over 90% depending on the individual deposit. The recoverable reserves in the United States represent approximately 56% of the demonstrated reserve base. Thus, the United States contains (by weight) approximately 23% of the recoverable reserves of coal in the world.

## **Environmental Aspects**

### *Richard Bajura*

Along with coal production and use comes a myriad of potential environmental problems, most of which can be ameliorated or effectively addressed during recovery, processing, conversion, or reclamation.

Underground coal reserves are recovered using the two principal methods of room-and-pillar mining (60%) and longwall mining (40%). In room-and-pillar mining, coal is removed from the seam in a checkerboard pattern (the “room”) as viewed from above, leaving pillars of coal in an alternate pattern to support the roof of the mine. When using this technology, generally half of the reserves are left underground. Depending upon the depth of the seam and characteristics of the overburden, subsidence due to the removal of the coal may affect the surface many years after the mining operation is completed. Because of the danger of collapse and movement of the surface, undermined lands are not used as building sites for large, heavy structures.

Longwall mining techniques employ the near-continuous removal of coal in rectangular blocks with a vertical cross section equal to the height of the seam multiplied by the horizontal extent (width) of the panel being mined. As the longwall cutting heads advance into the coal seam, the equipment is

<sup>1</sup> Includes subbituminous coal.

<sup>2</sup> Includes 3,396.4 million short tons of surface mine reserves, of which 3,380.8 million tons are in Pennsylvania and 15.6 million tons are in Arkansas.

<sup>3</sup> There are no underground demonstrated reserves of lignite.

<sup>4</sup> Georgia, Maryland, North Carolina, and Tennessee.

<sup>5</sup> Arkansas, Kansas, Louisiana, and Michigan.

<sup>6</sup> Less than 0.05 billion short tons.

<sup>7</sup> Arizona, Idaho, Oregon, and South Dakota.

Notes: Data represent 100 percent of known measured and indicated coal, with qualifying seam thicknesses and depths, in place as of January 1, 1993. Recoverability varies from less than 40 percent to more than 90 percent for individual deposits. Fifty-six percent of the demonstrated reserve base of coal in the United States is estimated to be recoverable.

Totals may not equal sum of components due to independent rounding.

<sup>1</sup> See Note 3 at end of Section.

<sup>2</sup> U.S. data are more current than other data on this table. They represent recoverable reserves as of December 31, 1991; data for the other countries are as of December 31, 1990, the most recent period for which they are available. U.S. reserves represent both measured and indicated tonnage. The U.S. term "measured" approximates the term "proved," which is used by the World Energy Council and British Petroleum. The U.S. "measured and indicated" data have been combined prior to depletion adjustments and cannot be recaptured as "measured alone."

— = Not applicable.

Notes: The EIA does not certify the international reserves data but reproduces the information as a matter of convenience for the reader.

Totals may not equal sum of components due to independent rounding.

Source: EIA, *International Energy Annual 1992* (January 1994), Table 37.

automatically moved forward. The roof of the mine collapses behind the shields, and most of the effects of subsidence are observed on the surface within several days of mining. If the longwall mining operation proceeds in a continuous fashion, subsidence may occur smoothly so that little damage occurs to surface structures. Once subsidence has occurred, the surface remains stable into the future. Longwall mining operations may influence water supplies as a result of fracturing of water-bearing strata far removed from the panel being mined.

When coal occurs in layers containing quartz dispersed in the seam or in the overburden, miners are at risk of being exposed to airborne silica dust, which is inhaled into their lungs. Coal workers pneumoconiosis, commonly called black lung disease, reduces the ability of a miner to breathe because of the effects of fibrosis in the lungs.

Surface mining of coal seams requires the removal of large amounts of overburden, which must eventually be replaced into the excavated pit after the coal resource is extracted. When the overburden contains large amounts of pyrite, exposure to air and water produces a discharge known as acid mine drainage, which can contaminate streams and waterways. Iron compounds formed as a result of the chemical reactions precipitate in the streams and leave a yellow- or orange-colored coating on rocks and gravel in the streambeds. The acid caused by the sulfur in the pyrite has been responsible for significant destruction of aquatic plants and animals. New technologies have been and continue to be developed to neutralize acid mine drainage through amendments applied to the soil during the reclamation phases of the mining operation. Occasionally, closed underground mines fill with water and sufficient pressure is created to cause “blowouts” where the seams reach the surface. Such discharges have also been responsible for massive fish kills in receiving streams.

The potential for acid rain deposition from sulfur and nitrogen oxides released to the atmosphere during combustion is a significant concern. About 95% of the sulfur oxide compounds can be removed through efficient stack gas cleaning processes such as wet and dry scrubbing. Also, techniques are available for removing much of the sulfur from the coal prior to combustion. Combustion strategies are also being developed which reduce the formation and subsequent release of nitrogen oxides.

The potential for greenhouse warming due to emissions of carbon dioxide during combustion (as well as methane during mining and mine reclamation) has also been raised as a significant concern. Since coal is largely composed of carbon with relatively little hydrogen, its combustion leads to a higher level of carbon dioxide emissions per unit of energy released than for petroleum-based fuels or natural gas.

## Transportation

*Larry Grayson*

According to figures compiled by the United States Department of Energy’s Energy Information Administration (Coleman, 1994), 878 million (short) tons of coal were distributed domestically in 1993, primarily via rail (59.6%), followed by barge (13.9%), truck (13.2%), and conveyor and slurry pipeline (10.8%). Shipments to electric utilities amounted to 773.5 million (short) tons during the same year, with 61.5% transported by rail, followed by 14.0% by barge, 11.7% by truck, and 11.0% by conveyor and slurry pipeline.

Villagran (1989) compared the cost advantage of barge transportation over rail transportation. For distances between 100 and 300 mi, the advantage is between \$11 and 38/kilo ton-mi; while the advantage drops to \$7 to 11/kilo ton-mi for distances greater than 300 mi. For distances less than 100 mi, rail hauls are very expensive, leading to the predominance of truck haulage in this range when river transportation is not possible.

## Defining Terms:

**Coalification:** The physicochemical transformation which coal undergoes after being buried and subjected to elevated temperature and pressure. The classification of a particular coal by rank is a measure of the extent of its coalification. Thus, coalification is a measure of the “age” of a particular coal.

**Fixed carbon content:** Fixed carbon content is one of the constituents which make up the proximate analysis of a coal. It is normally measured by difference. That is, one measures the volatile matter content and the moisture and ash contents, if the fixed carbon content is reported on a basis containing one or both of those constituents, and subtracts the result(s) from 100% to find the fixed carbon content. One should not confuse the fixed carbon content of a coal with its (elemental) carbon content found in the ultimate analysis. Although there is certainly carbon in the material making up the fixed carbon content, it is not all of the carbon present in the original coal, and other elements are also present.

**Gross calorific value:** Calorific value is a measure of the energy content of a material, in this case, a coal sample. Calorific value is measured by ASTM Standard Test Method D 2015M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. The *gross* calorific value takes into account the additional heat gained by condensing any water present in the products of combustion, in contrast to the *net* calorific value, which assumes that all water remains in the vapor state.

**Maceral:** Macerals are organic substances or optically homogeneous aggregates of organic substances in a coal sample that possess distinctive physical and chemical properties.

**Proximate Analysis:** Proximate analysis is a method to measure the content of four separately identifiable constituents in a coal: volatile matter content, fixed carbon content, moisture content, and ash content, all of which are reported on a weight percent basis. The standard method for obtaining the proximate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3172.

**Rank:** Coal rank is a classification scheme for coals which describes the extent of coalification which a particular coal has undergone. The structure, chemical composition, and many other properties of coals vary systematically with rank. The standard method for determining the rank of a coal sample is defined by the ASTM in Standard Test Method D 388.

**Type:** Coal type is a classification scheme for coals which references the original plant material from which the coal was derived.

**Ultimate Analysis:** Ultimate analysis is a method to measure the elemental composition of a coal sample. Typical ultimate analyses include carbon, hydrogen, oxygen, sulfur, and nitrogen contents, but other elements can also be reported. These other elements are usually not present to any appreciable extent. However, if they are reported, the sum of all the elements reported (including moisture and ash content) should equal 100%. The standard method for the ultimate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3176.

**Volatile matter content:** Volatile matter content measures the mass of material released upon heating the coal sample under specific conditions, defined by the ASTM Standard Test Method D 3175.

## Further Information

An excellent resource for understanding coal, its sources, its uses, and its limitations and potential problems is the book by Elliott referenced above under Averitt (1981), Habermehl et al. (1981), and Neavel (1981). A reader wishing an understanding of coal topics could find no better resource.

Another comprehensive book which includes more-recent information but is not quite as weighty as Elliott's (664 pages vs. 2374 pages) is *The Chemistry and Technology of Coal*, edited (second edition, revised and expanded) by James G. Speight.

For up-to-date information specific to the environmental problems associated with the use of coal, the reader is referred to Norbert Berkowitz's chapter entitled "Environmental Aspects of Coal Utilization" in *An Introduction to Coal Technology*.

For information on the standards for coal analyses and descriptions of the associated procedures, the reader is referred to any recent edition of the American Society for Testing and Materials's *Annual Book of ASTM Standards*. Section 5 covers petroleum products, lubricants, and fossil fuels, including coal and coke.

## Oil

*Philip C. Crouse, P.E.*

### Overview

Fossil fuel energy accounted for 86.3% of all world energy in 1990. The Energy Information Administration (EIA) of the U.S. Department of Energy estimates that in the year 2010, fossil fuels will account for 85.9% of all world energy consumption — only a 0.4% percentage decrease in usage (Figure 7.3.2). According to EIA estimates, coal is expected to decline slightly from about a 27% to about a 25% share of consumption, and consumption of natural gas is expected to increase from 21 to 24% over the 20-year period. Over the same period, oil is forecasted to continue to be world major energy source with only slight declines from the present 39% of consumption.

Recent efforts in the United States have been to foster growth in natural gas usage as an energy source, causing an estimated growth of 2.3% per year. Total energy usage is expected to grow from 345.6 to 476.0 quadrillion Btu — or a 38% growth in energy usage over 20 years.

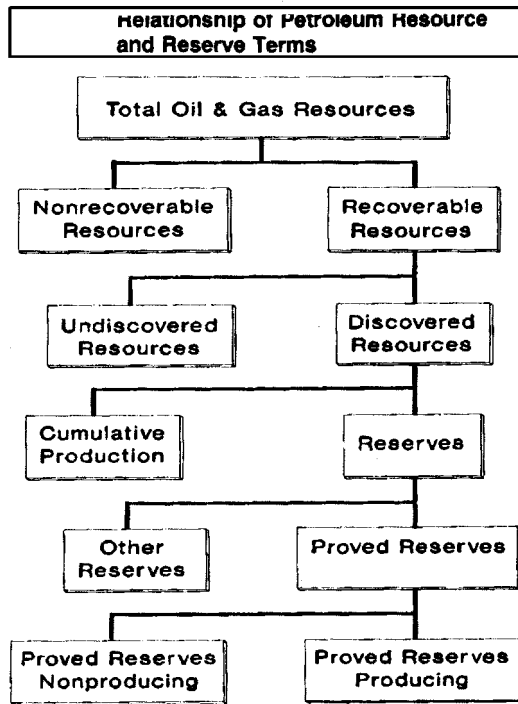

### Crude Oil Classification and World Reserves

Obtaining accurate estimates of world petroleum and natural gas resources and reserves is difficult and uncertain. Terminology used by industry to classify resources and reserves has no broadly accepted standard classification. Such classifications have been a source of controversy in the international oil and gas community. Confusion persists in regard to classification. This section uses information provided by the Department of Energy classification system. The next chart shows the relationship of resources to reserves. **Recoverable resources** include discovered and undiscovered resources. **Discovered resources** are those resources that can be economically recovered (Figure 7.3.3).

Discovered resources include all production already out of the ground and reserves. Reserves are further broken down into proved reserves and other reserves. Again, there are many different groups that classify reserves in different ways, such as *measured*, *indicated*, *internal*, *probable*, and *possible*. Most groups break reserves into producing and nonproducing categories. Each of the definitions is quite voluminous and the techniques for qualifying reserves vary globally.

**FIGURE 7.3.2** Share of world energy consumption by primary energy source, 1990–2010. (From EIA, *International Energy Outlook 1994*, EIA, Washington, D.C., July 1994.)

**Proved reserves** are generally defined as: “Those volumes of oil and gas that geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions.”

OPEC (the Organization of Petroleum-Exporting Countries) has been key in setting global fossil fuel prices over the last two decades. With very large reserves, OPEC can provide much of the world future needs for crude oil and petroleum products. About two-thirds of the world known petroleum reserves are located in the Middle East as shown in [Table 7.3.7](#).

[Table 7.3.8](#) shows that the annual world crude oil production has steadily grown from 16.7 billion barrels in 1970 to 22 billion barrels in 1990.

Both crude oil demand and production are forecast to increase over the next 20 years. OPEC production is relatively level at 8.6 billion barrels in 1990 compared with 8.5 billion barrels in 1970. During the same time, non-OPEC production increased from 8.1 to 13.6 billion barrels. As the “swing producer”, OPEC’s production in 1980 increased by over 1 billion barrels when non-OPEC production could not meet total demand. They then decreased production by a similar amount in 1990 when production in the rest of the world increased by 1 billion to a non-OPEC total of 13.6 billion barrels. With a low price environment, OPEC is expected to gain market share in global production over the next 20 years.

### Standard Fuels

Petroleum is refined into petroleum products that are used to meet individual product demands. The general classifications of products are

## 1. NATURAL GAS LIQUIDS AND LIQUEFIED REFINERY GASES

This category includes ethane (C<sub>2</sub>H<sub>6</sub>), ethylene (C<sub>2</sub>H<sub>4</sub>), propane (C<sub>3</sub>H<sub>8</sub>), propylene (C<sub>3</sub>H<sub>6</sub>), butane and isobutane (C<sub>4</sub>H<sub>10</sub>), and butylene and isobutylene (C<sub>4</sub>H<sub>8</sub>).

## 2. FINISHED PETROLEUM PRODUCTS

This category includes motor gasoline, aviation gasoline, jet fuel, kerosene, distillate, fuel oil, residual fuel oil, petrochemical feed stock, naphthas, lubricants, waxes, petroleum coke, asphalt and road oil, and still gas.

- *Motor gasoline* includes reformulated gasoline for vehicles and oxygenated gasoline such as gasohol (a mixture of gasoline and alcohol).
- *Jet fuel* is classified by use such as industrial or military and naphtha and kerosene-type. Naphtha fuels are used in turbo jet and turbo prop aircraft engines and excludes ram-jet and petroleum rocket fuel.
- *Kerosene* is used for space heaters, cook stoves, wick lamps, and water heaters.
- *Distillate fuel oil* is broken into subcategories: No. 1 distillate, No. 2 distillate, and No. 4 fuel oil which is used for commercial burners.
- *Petrochemical feedstock* is used in the manufacture of chemicals, synthetic rubber, and plastics.
- *Naphthas* are petroleum with an approximate boiling range of 122 to 400°F.
- *Lubricants* are substances used to reduce friction between bearing surfaces, used as process materials, and as carriers of other materials. They are produced from distillates or residues. Lubricants are paraffinic or naphthenic and separated by viscosity measurement.
- *Waxes* are solid or semisolid material derived from petroleum distillates or residues. They are typically a slightly greasy, light colored or translucent, crystallizing mass.
- *Asphalt and road oil*. Asphalt is a cementlike material containing bitumens. Road oil is any heavy petroleum oil used as a dust pallatine and road surface treatment.
- *Still Gas* is any refinery by-product gas. It consists of light gases of methane, ethane, ethylene, butane, propane, and the other associated gases. Still gas typically used as a refinery fuel.

*World Refining Capacity*. Refining capacity grew from 48 million barrels per day in 1970 to about 75 million barrels per day in 1990 — a 55% growth in capacity. Table 7.3.9 shows world refining capacity beginning in 1970. The peak year was 1982 in which capacity was 81.4 million barrels per day. Utilization of refinery capacity was about 80% in 1990, pointing to underutilization.

**TABLE 7.3.9 World Refining Capacity**

	1970	1980	1990
North America	13.2	20.2	17.4

Asia-Pacific	5.1	10.4	10.3
Central Planned Economies	7.5	15.4	17.6
Total world	48.2	80.0	73.4

## Natural Gas

*Philip C. Crouse, P.E.*

Natural gas has been called the environmentally friendly fossil fuel since it releases fewer harmful contaminants. World production of dry natural gas was 73.7 trillion ft<sup>3</sup> and accounted for over 20% of world energy production. In 1990 Russia accounted for about one third of world natural gas. The second largest producer was the United States having about one quarter of world 1990 natural gas production.

### Natural Gas Production Measurement

Natural gas production is generally measured as “dry” natural gas production. It is determined as the volume of natural gas withdrawn from a reservoir less (1) the volume returned for cycling and repressuring reservoirs; (2) the shrinkage resulting from the removal of lease condensate and plant liquids; (3) the nonhydrocarbon gases. The parameters for measurement are 60°F and 14.73 lb standard per square inch absolute.

### World Production and Reserves of Dry Natural Gas

From 1983 to 1992, dry natural gas production rose from 54.4 to 75 trillion ft<sup>3</sup>. The breakdown by region of world is shown in [Table 7.3.10](#).

**TABLE 7.3.10 World Dry Natural Gas Production — trillion ft<sup>3</sup>**

	1983	1992
North, Central, and South America	21.20	25.30
Western Europe	6.20	7.85
Eastern Europe and former U.S.S.R.	21.09	28.60
Middle East and Africa	2.95	6.87
Far East and Oceania	<u>2.96</u>	<u>6.38</u>
World total	54.40	75.00

Source: EIA, *Annual Energy Review 1993*, EIA, Washington, D.C., July 1994, 305.

World natural gas reserves estimated by the *Oil and Gas Journal* as of December 31, 1991 are in [Table 7.3.11](#). OPEC accounted for 40% of world reserves yet processes only about 12% of the world production. The former U.S.S.R. accounts for about 40% and Iran another 15% of world reserves.

**TABLE 7.3.11 World Natural Gas Reserves — billion ft<sup>3</sup>**

North America	343,677
South America	166,850
Western Europe	177,844
Eastern Europe	1,766,358
Middle East	1,319,823
Africa	310,241
Asia-Pacific	<u>299,288</u>
Total	4,384,081
OPEC	1,729,205
Non-OPEC	2,654,876

### Compressed Natural Gas

Environmental issues have countries examining and supporting legislation to subsidize the development of cleaner vehicles that use compressed natural gas (CNG). Even with a push toward the use of CNG-burning vehicles, the numbers are quite small when compared with gasoline vehicles. Italy has used

CNG since 1935 and has the largest usage with 300,000 vehicles. The United States ranked fifth with an estimated 30,000 vehicles in 1994. Argentina, which ranked sixth, had 15,000 vehicles.

### Liquefied Natural Gas (LNG)

Natural gas can be liquefied by lowering temperature until a liquid state is achieved. It can be transported by refrigerated ships. The process of using ships and providing special-handling facilities adds significantly to the final LNG cost. If oil prices stay low, prospects for LNG development will remain low in the future. However, LNG projects planned by OPEC member countries may become significant over the next 20 years with shipments of LNG exports ultimately accounting for up to 25% of all gas exports.

### Physical Properties of Hydrocarbons

The most important physical properties from a crude oil classification standpoint are density or specific gravity and the viscosity of liquid petroleum. Crude oil is generally lighter than water. A Baume-type scale is predominantly used by the petroleum industry and is called the **API (American Petroleum Institute) gravity** scale (see [Table 7.3.12](#)). It is related directly to specific gravity by the formula:

$$\phi = (141.5) / (131.5 + \text{°API})$$

where  $\phi$  = specific gravity. Temperature and pressure are standardized at 60°F and 1 atm pressure.

**TABLE 7.3.12 Relation of API Gravity, Specific Gravity, and Weight per Gallon of Gasoline**

Degree API	Specific Gravity	Weight of gallon in lbs.
8	1.014	8.448
9	1.007	8.388
10	1.000	8.328
15	0.966	8.044
20	0.934	7.778
25	0.904	7.529
30	0.876	7.296
35	0.850	7.076
40	0.825	6.870
45	0.802	6.675
50	0.780	6.490
55	0.759	6.316
58	0.747	6.216

*Note:* The specific gravity of crude oils ranges from about 0.75 to 1.01.

Other key physical properties involve the molecular weight of the hydrocarbon compound and the boiling point and liquid density. [Table 7.3.13](#) shows a summation of these properties.

### Defining Terms

**API Gravity:** A scale used by the petroleum industry for specific gravity.

**Discovered resources:** Discovered resources include all production already out of the ground and reserves.

**Proved resources:** Resources that geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions.

**Recoverable resources:** Recoverable resources include discovered resources.

**TABLE 7.3.13 Other Key Physical Properties of Hydrocarbons**

<b>Compound</b>	<b>Molecular Weight</b>	<b>Boiling Point at 14.7 psia in °F</b>	<b>Liquid Density at 14.7 psia and 60°F-lb/gal</b>
Methane	16.04	-258.7	2.90
Ethane	30.07	-125.7	4.04
Propane	44.09	-43.7	4.233
Isobutane	58.12	10.9	4.695
<i>n</i> -Butane	58.12	31.1	4.872
Isopentane	72.15	82.1	5.209
<i>n</i> -Pentane	72.15	96.9	5.262
<i>n</i> -Hexane	86.17	155.7	5.536
<i>n</i> -Heptane	100.2	209.2	5.738
<i>n</i> -Octane	114.2	258.2	5.892
<i>n</i> -Nonane	128.3	303.4	6.017
<i>n</i> -Decane	142.3	345.4	6.121

### Further Information

The Energy Information Agency of the U.S. Department of Energy, Washington, D.C., publishes *International Energy Outlook* periodically.

## 7.4 Biomass Energy

---

*Michael C. Reed, Lynn L. Wright, Ralph P. Overend, and Carlton Wiles*

Biomass energy encompasses a wide variety of renewable energy technologies that use plant matter, plant residues, or plant-derived process wastes as fuel. These biomass resources can be used directly as solid fuels to produce heat, or they can be converted to other energy carriers such as liquid and gaseous fuels and electricity. Because the energy in biomass is less concentrated than the energy in fossil fuels, high-efficiency conversion technologies are necessary to make this energy resource cost competitive.

### Photosynthesis

Biomass fuels are derived from green plants which capture solar energy and store it as chemical energy through the **photosynthetic** reduction of atmospheric carbon dioxide. Plant leaves are biological solar collectors while the stems, branches, and roots are the equivalent of batteries storing energy-rich complex carbon compounds. Elemental analysis shows both wood and grasses to be about 50% carbon. The average photosynthetic efficiency of converting solar energy into organic carbon compounds on an annual basis varies from less than 0.5% in temperate and tropical grasslands to about 1.5% in moist tropical forests (Cralle and Vietor, 1989). While quite low, it represents stored energy on an annual basis and the diversity and adaptability of plants allows this solar collection to occur on most parts of Earth's surface. The worldwide annual storage of photosynthetic energy in terrestrial biomass is huge, representing approximately ten times world annual use of energy (Hall et al., 1993).

### Biomass Production, Yield, and Potential

#### Forest Land

The amount of harvestable woody biomass produced by natural forests on an annual basis ranges from about 2 to 6 dry t/ha/year (metric ton/hectare/year), or 0.9 to 2.7 dry ton/acre/year with the higher yields usually in tropical regions. Managed forests often accumulate biomass at approximately double the rate of natural unmanaged stands. The productivity rates of natural forests could be increased to 4 to 12 dry t/ha/year (1.8 to 5.4 dry t/acre/year) if brought under active management. Such management might include optimizing harvesting strategies for production, fertilization, and replanting natural stands with faster-growing species. At present 10% of world forests, or 355 million ha (876 million acres), are actively managed. If managed forests were increased to 20%, and if 20% of the harvested material were used for energy, the annual worldwide resource of wood for energy from currently forested land would amount to somewhere between 284 and 852 million t (315 to 946 million dry tons) of available wood or about 5.6 to 17 Exajoules (5 to 14.5 quadrillion Btu) of primary energy based on potential yield ranges of managed forests. The most optimistic estimates of biomass potential would provide a total primary energy resource of about 30 Exajoules from managed forests (Sampson et al., 1993).

#### Cropland and Grassland

The production of perennial plants (either woody crops grown for 3 to 10 years between harvests or perennial grasses), using genetically superior materials, established on agricultural land and managed as an agricultural crop is believed to be the method of choice for producing biomass for energy on a large scale. Temperate shelterbelts and tropical agroforestry plantings could also contribute greatly to biomass energy resources. Energy crop yields are highest in locations where genetically superior material is planted on land with plenty of access to sunshine and water. Operational yields in the range of 20 to 30 dry t/ha/year (9 to 13 dry ton/acre/year) are achievable now. Such yields have been observed over large areas with eucalyptus and tropical grasses in the moist tropics and subtropics, and with hybrid poplars in irrigated portions of the dry Pacific Northwest of the United States. In many areas, however, suitable genetically superior materials are not yet available, water is a limiting factor, and irrigation may not be an economically or environmentally desirable alternative. Temperate wood energy yields are more

commonly in the range of 9 to 13 dry t/ha/year (4 to 6 dry ton/acre/year) today with the expectation that they could increase to the 12 to 20 dry t/ha/year (5.5 to 9 dry ton/acre/year) relatively rapidly with continued genetic improvement and clonal selection (Wright, 1994). Yields of properly managed perennial grasses in field test plots are currently in the range of 11 to 22 dry t/ha/year (5 to 10 dry ton/acre/year) with the expectation that yields of 16 to 27 dry t/ha/year (7 to 12 dry ton/acre/year) could be attained with further breeding and improvement of management regimes. The best current perennial grass yields on nonirrigated test plots have averaged around 25 dry t/ha/year (11 dry ton/acre/year) for 6 years in the southeastern U.S. where a long growing season favors warm season grasses.

The total amount of biomass potentially available from cropland conversion can only be speculated on since it requires making a number of assumptions involving such issues as land availability, food crop requirements, development of biomass energy markets, and crop yields. Such speculations have been made to attempt to evaluate the potential effect of biomass energy use on carbon emission reduction. These speculations have assumed that 10 to 15% of cropland worldwide could be available for the production of biomass resources as energy crops, shelterbelts, or for agroforestry use with energy as one product (Hall et al., 1993; Sampson et al., 1993). The primary energy resource potential of cropland conversion has been estimated to range from a low of 18 Exajoules to a high of 49 Exajoules (Sampson et al., 1993). Another 25 to 110 Exajoules has been estimated to be available from the conversion of grasslands and degraded areas to the production of biomass energy resources worldwide (Sampson et al., 1993).

### **Biomass Residues**

Biomass residues are the organic by-products of food, fiber, and forest production and processing. Major sources of residues include the residues of grain crops such as corn, wheat, rice; animal dung; and forest roundwood harvest and processing. A significant portion of residues is not economically collectible for energy because of wide dispersal and low bulk density, which makes recovery, transport, and storage too costly. In many cases, residues have greater economic value being left on the land to restore nutrients, reduce erosion, and stabilize soil structure, or they may be recovered for other domestic, industrial, or agricultural uses. Recoverable crop residues in the United States are estimated to range between 70 and 190 million dry tons (Day, 1989) and recoverable forest residues are about double the level of crop residues (Hall et al., 1993). Recoverable crop and forest residues worldwide are estimated to have an energy value of 12.5 and 13.5 Exajoules respectively (Hall et al., 1993).

### **Terrestrial Limitations**

The biomass productivity of forests, grasslands, and energy crop plantings is considerably less than theoretically possible based on calculations of maximum photosynthetic potential. Under artificially optimal conditions of temperature, water, and nutrients, average solar radiation near Des Moines, Iowa, would theoretically be sufficient to produce maximum total tree dry weight yields (above and below ground) as high as 102 t/ha/year (45 ton/acre/year) (Sampson et al., 1993). Actual seasonal temperature variations alone, however, reduce the maximum yield potential to 60 t/ha/year (27 ton/acre/year). Of that, the usable biomass portion of trees (the stems and branches only) amounts to only about 35 t/ha/year (15 ton/acre/year). Yet this is many times the harvestable biomass dry weight yield of trees from natural forest stands and more than double the best tree yields observed in experimental trials in that region. Water stress is a major reason for reduced yields. Perennial grasses may have a slightly higher harvestable yield potential in the region because of their higher water use efficiency and the more-efficient carbon metabolism of warm season grasses in temperate climates (Jones, 1985). While water stress, pests outbreaks, and inadequate nutrients all contribute to reduced yields, it is also clear that the genetic potential of perennials is yet to be fully explored. Genetic improvement of perennials for energy is only beginning in most regions of the United States; thus, the potential for finding substantially higher-yielding varieties and clones is excellent.

## Environmental Impact

An emerging consensus of environmentalists, forestry organizations, researchers, and others is that if energy crops are treated as an agricultural crop and established and tended in a considered and informed way on appropriate land, environmental damage can be avoided. In fact, preliminary data suggests that there can be significant environmental and ecological benefits achieved in association with the development of a fully sustainable energy resource. Global benefits include the reduced emission of carbon into the atmosphere, while local benefits include soil conservation, reduction of chemical use, and wildlife biodiversity in an agricultural setting.

## Biomass Conversion Technologies

As noted previously, biomass can be used to produce heat, electricity, and prepared fuels such as charcoal and liquid fuels. To do this, the biomass conversion technologies have to treat a wide range of biomass resources efficiently and convert them into the desired products. For example, biomass resources may include fuelwood, agricultural residues, farm animal wastes, forest industry processing residues (e.g., sawdust, black liquor from pulping processes), agricultural processing by-products (e.g., bagasse from sugarcane processing, food-processing by-products such as olive pits), and crops (e.g., grains, oil seeds, energy crops).

Each of these resources has different handling requirements and different process characteristics. Worldwide, the most common biomass resources are fuelwood and agricultural residues such as cereal straws. However, many other biomass resources offer opportunities not just for heat, but also in improving the environment (as when animal wastes are converted into methane and fertilizer through anaerobic fermentation processes). Each conversion process must take into account the differences in biomass composition which can vary widely in terms of moisture and ash content.

## Biomass Composition

As received, biomass can range from very clean wood chips at 50% moisture to urban wood residues that are dry but contaminated with ferrous and other materials, animal residues, sludges, and the organic component of municipal solid waste (MSW). Most biomass is a **lignocellulosic** material, such as wood or straw, which is composed of **cellulose**, **hemicellulose**, and **lignin**. Although different plant species have differing proportions of these polymers, it turns out that on a moisture and ash-free basis, the majority have essentially the same calorific values in the range of 16 to 19.6 GJ/t (8000 to 8500 Btu/lb). Biomass ash content varies considerably, being lowest in the clean wood fraction and very high in cereal straws such as rice straw, as can be seen in [Table 7.4.1](#).

**TABLE 7.4.1 Some Fuel Properties of Four Different Biomass Types**

Property	Pine Shavings	Switchgrass	Rice Hull	Rice Straw
Ash %	1.43	10.10	18.34	15.90
Carbon	48.54	47.79	40.96	41.78
Hydrogen	5.85	5.76	4.30	4.63
Nitrogen:	0.47	1.17	0.40	0.70
Sulfur	0.01	0.10	0.02	0.08
Oxygen	43.69	35.07	35.86	36.57
Btu/lb	8337	7741	6944	7004
GJ/t	19.38	17.99	16.14	16.28

## Direct Combustion, Combined Heat, and Power and Steam Electric Generation

By far the most frequent use of biomass is in direct-combustion applications, with combustion devices ranging from 5 kW cook stoves (Prasad, 1985) to 125 MW boilers burning wood chips and producing 150 t/hm/hr of steam at 11 MPa and 540°C superheat temperatures (Anonymous, 1994). The available types of combustors range from pile burners or Dutch-oven-type burners, which can accept biomass in

a large size range, to units that are suspension fired and require not only extensive fuel preparation but also fuel drying. The most popular types of boilers seem to be stoker-fired units with moving grates. More recently, the trend has been to bubbling and circulating fluidized-bed units, which offer a high degree of fuel flexibility by accepting fuel mixes ranging from coal to paper mill sludges that have very high moisture and ash contents. Boiler efficiency for typically moist biomass feedstocks ranges from 65 to 75%.

Biomass-fired steam turbine power generation technology is very similar to that of conventional fossil-fueled cycles. Biomass is combusted in a boiler, and the heat which is liberated is used to produce steam with conditions ranging from 28 bar and 398°C (400 psig and 750°F) for typical 25 MW units to 86 bar and 510°C (1250 psig and 950°F) for larger systems. The superheated steam generated in the boiler is used to drive a steam turbine generator. Net plant efficiency ranges from 20 to 30% (17,060 to 11,373 Btu/kWhr). Larger-scale boilers would permit several stages of reheat and the use of supercritical steam cycles. Developers of the Whole Tree Energy™ System have proposed the combustion of whole trees that are dried in a flue gas-assisted dome in order to provide supercritical steam to a turbine. System efficiencies are projected to be in the range of 40% (heat rate 8530 Btu/kWhr) and would be comparable to gas turbine-based combined-cycle units. The ability to utilize whole trees, as opposed to having to process wood feedstocks to “chip” size is a key advantage of the Whole Tree Energy System, as it can significantly reduce feedstock-handling costs.

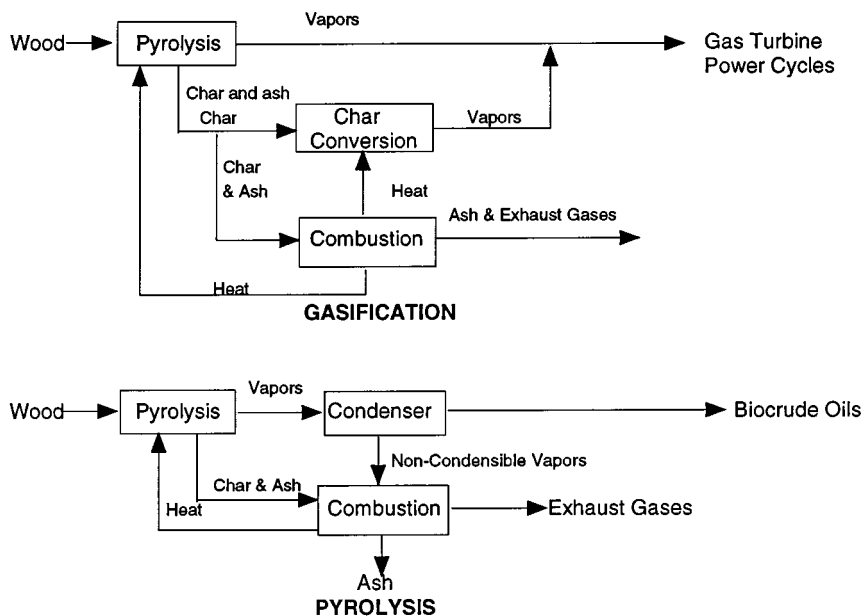

### Gasification

Biomass gasification processes can convert biomass materials into gaseous fuels (carbon- and hydrogen-rich fuel gases) that can be more easily utilized, often with a gain in efficiency and environmental performance. Gasification is a two-step, endothermic process in which a solid fuel (biomass or coal) is thermochemically converted into a low- or medium-Btu gas (see [Figure 7.4.1](#)). In the first reaction, pyrolysis, the volatile components of the fuel are vaporized at temperatures below 600°C (1100°F) by a set of complex reactions. Included in the volatile vapors are hydrocarbon gases, hydrogen, carbon monoxide, carbon dioxide tar, and water vapor. Because biomass fuels tend to have more volatile components (70 to 86% on a dry basis) than coal (30%), pyrolysis plays a larger role in biomass gasification than in coal gasification. Char (fixed carbon) and ash are the by-products of pyrolysis which are not vaporized. The second reaction, char conversion, involves the gasification and/or combustion of the carbon that remains after pyrolysis. In this reaction a portion of the char is burned to provide the heat required for pyrolysis and for gasification of any remaining char.

Thermal gasification is typically 80 to 85% efficient in converting the organic content of the feed into a fuel gas mixture mainly composed of hydrogen, carbon monoxide, and methane along with inert constituents. As a comparison, natural gas energy content, measured on a dry gas basis, is typically 37.8 MJ · m<sup>-3</sup>, or 1000 Btu/ft<sup>3</sup>. Biomass gases produced through thermal gasification with air as the oxidant typically have gas energy content of less than 5.6 MJ · m<sup>-3</sup> or 150 Btu/ft<sup>3</sup>, while gasification with oxygen and steam or indirect gasification (which eliminates the nitrogen dilution of the product) results in a heating value of 13 to 17 MJ · m<sup>-3</sup> or about 350 to 450 Btu/ft<sup>3</sup>. Typically, an air-blown gasifier would have over 50% nitrogen, a 25 to 30% by volume mix of hydrogen and carbon monoxide, and a small amount of methane, and the balance would be carbon dioxide.

Gasifier systems usually comprise the biomass fuel-handling and -feeding system which is coupled by means of air locks to the gasifier. In the thermal processes, the gasifier is usually a refractory-lined vessel and the gasification is carried out at high temperatures of approximately 850°C, at either atmospheric or elevated pressures. In a fluidized-bed gasifier, a continuous feed of biomass and inert heat-distributing material (e.g., sand) is “fluidized” by an oxidant and/or steam, and heat is supplied to the gasifier either “directly” or “indirectly” (U.S. Department of Energy, 1992).

In a directly heated fluidized-bed gasifier, heat required for gasification comes from char combustion in the gasifier reactor. The Institute of Gas Technology RENU GAS™ Pressurized Gasifier is an example of a direct-gasification technology. In the RENU GAS process, biomass is fed into a single, fluidized-bed gasifier vessel that operates at 300 to 500 psig. Inert solids in the vessel form the stable fluidized

**FIGURE 7.4.1.** A diagram illustrating biomass gasification and pyrolysis processes. (From U.S. Department of Energy, *Electricity from Biomass: A Development Strategy*. DOE/CH10093-152, DE92010590. Washington, D.C., 1992.)

bed into which the biomass is fed. All of the biomass ash is carried overhead with the product gases. By using a deep, single-stage bed of inert solids, the RENUGAS process is able to achieve high carbon conversion with low oils and tars production. The gasifier is capable of producing either an industrial fuel gas or a chemical synthesis gas, depending on air- or oxygen-blown operation.

In an indirectly heated fluidized-bed gasifier, char is removed from the gasifier and burned in a separate vessel. The resulting heat is transferred to the gasifier by either in-bed heat exchangers or by recirculating the inert bed material heated in the char combustor. The advantage of indirect heating of the gasifier is that the gasification product is not diluted with the char combustion by-products (U.S. Department of Energy, 1992). The Battelle Gasification System is an example of an indirect gasification technology (see Figure 7.4.2). The Battelle system is a two-zone circulating-bed gasifier that produces a medium-energy content gas with a heating value of 500 Btu/ft<sup>3</sup> (18.63 MJ/m<sup>3</sup>). The product gas can be used in existing natural gas-fired equipment including boilers, kilns, or gas turbines. The Battelle process produces this medium-Btu gas without the need for an oxygen plant, and uses two physically separate reactors (a gasification reactor in which biomass is converted into the product gas and residual char, which is then burned in a separate combustion reactor to provide the heat required for gasification). Heat transfer between the reactors is accomplished by circulating sand between the gasifier reactor and the combustor reactor. The separation of the gasifier from the combustor provides a means to maintain a constant heating value of the product gas regardless of changes in the feed moisture or ash content.

Biomass fuels can provide significant environmental advantages over competing fossil fuels, especially with regard to coal products. These advantages include little or no sulfur content and zero net carbon dioxide production. Additionally, chemicals produced during biomass combustion are absorbed in the photosynthesis process of new biomass growth. However, the fuel conversion process (gasification/combustion) generates emissions such as particulates, tar, and alkali that can cause erosion, corrosion, and deposition problems within the components of advanced conversion systems, especially combustion turbines. As such, some form of gas cleanup must be employed to ensure dependable system performance.

FIGURE 7.4.2. A diagram illustrating the Battelle Biomass Indirect Gasification System.

### Biological Gasification or Anaerobic Digestion

The biological gasification process is carried out on feedstock which is either dissolved or slurried in water and typically produces a medium-energy-content gas composed of methane and carbon dioxide. A variety of designs are available, but all of them put anaerobic and methane-forming bacteria in contact with the biomass, the products are the gas (a mixture of methane and carbon dioxide) and a slurry of nonreacted feedstock which can usually be converted into a compost/fertilizer. In the case of landfill gas, the landfill “naturally” produces methane, which is currently being managed for greenhouse gas emissions. The contaminants, which can be highly odoriferous and include hydrogen sulfide, are removed with available technology prior to combustion in either a medium-speed diesel or turbine engine.

### Liquefaction to Produce a Biofuel Oil

Biomass feedstocks can also be utilized to create biofuel oils, also known as biocrude. Through a process known as rapid pyrolysis, biofuel oils can be produced and used as fuel for gas turbines, diesel engines, or by co-firing the oil in an existing pulverized coal- or oil-fired boiler. Rapid pyrolysis occurs when heat is transferred to prepared biomass feedstocks (typical thickness <2 mm, moisture <8%) and the solid particles are thermochemically converted to a mixture of noncondensable gases, water vapor, char particles, and pyrolysis oil vapors. The pyrolysis oil vapors typically have a yield of 60 to 80% and are condensed to form a black, viscous, medium-Btu (9000 Btu/lb or 18.6 MJ/kg) mixture of organic compounds. Because the fuel oils can be stored and transported, the pyrolysis process can be decoupled from the power generation cycle, increasing the flexibility with respect to the proximity of the pyrolysis process to the end user.

Biofuel oil can be produced by pyrolyzing dried wood chips in a **vortex reactor**, followed by removal of solids and condensation of the vapors to recover the higher-molecular-weight hydrocarbons (see [Figure 7.4.3](#)). Noncondensable and light hydrocarbons are recycled as carrier gas, or burned with char to generate steam and/or electricity for internal use and export. [Table 7.4.2](#) contains a comparison of biocrude oil characteristics and those of No. 6 fuel oil.

FIGURE 7.4.3. A diagram illustrating the biomass fast pyrolysis process for biocrude oil production.

TABLE 7.4.2 Fuel Oil Characteristics

Type	Biocrude Oil	No. 6 Fuel Oil
Source	Biomass pyrolysis	Petroleum distillation
Sulfur, ppm	5	3,000–30,000
Ash %	0.1–1.0	0.2–1.5
HHV, MJ/kg (BTU/lb)	21–24 (9,000–10,300)	43 (18,400)
HHV, MJ/l (Btu/gal)	25.2 (90,000)	42.1 (150,500)
Density, kg/m <sup>3</sup> @ 16°C (lb/gal @ 60°F)	1,200 (10.14)	950 (8.0)

## Biomass Liquefaction

### Ethanol

Ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) is a renewable liquid fuel that can be produced by fermenting a wide range of biomass materials, including sugars, starches, and lignocellulosics. It is an excellent fuel for spark-ignition internal combustion engines with a high octane number. The automobile industry has developed specifications for E85, an 85% by volume blend with gasoline. Lower-level blends such as E10 are in broad commercial use. Heavy-duty compression ignition engines are usually modified to provide ignition assistance such as glow or spark plugs because of the low cetane and poor autoignition qualities. Although the volumetric energy density of ethanol is two thirds that of gasoline, it has properties, such as the increased octane number, that allow the use of more-efficient high-compression engines. The heat of vaporization is twice that of gasoline, thus increasing the cooled fuel/air mixture that reaches each cylinder. This same property, however, increases cold-starting difficulties.

Currently, corn is used to provide the starch substrate for ethanol production in the United States which is about 1.4 billion gal. Lignocellulosic materials, such as short-rotation woody crops (SRWC) and herbaceous energy crops (HEC), offer an alternative feedstock, one that is dependent on the development of new technology that will allow the cellulose and hemicelluloses that make up

approximately 70% of the lignocellulosic feedstocks to produce ethanol. Technology developments in the last decade in lignocellulosic-to-ethanol conversion have shown major potential for cost reductions that have positioned ethanol from lignocellulosics as a near commercial opportunity. These improvements have been in pretreatment, cellulase enzyme production, xylose fermentation, and cellulose conversion.

A typical flow sheet for ethanol production from lignocellulosics such as SRWC or HEC comprises the following operations: feedstock handling; pretreatment to expose the polymers such as hemicellulose and cellulose; production of the biocatalysts such as **cellulase** and hemicellulase that liberate the sugars glucose and xylose; fermentation to convert sugars into ethanol; ethanol recovery process such as distillation; and waste treatment with combined heat and power production from the lignin and other unconverted process residues. A combination of revolutionary advances and incremental improvements in this process chain has reduced costs of ethanol from \$3.60 in 1980 to an estimated \$1.27/gal in 1996; this latter is already below the cost of production of ethanol from corn. Further development promises to bring the cost into the range of \$0.7 to 0.8/gal. This projected cost is competitive with equivalent fuels produced from oil costing \$25/barrel.

Pretreatments to expose the carbohydrate polymers have been systematically optimized and developed to be low cost and to have low environmental impact. Dilute acid **hydrolysis** has been found to be effective at exposing cellulose for further hydrolysis. This pretreatment step is followed by a separation of the soluble hemicellulose sugars from the lignin and cellulose fiber. The cellulose material is used both to produce the cellulase enzymes for the hydrolysis and as the major source of sugar that produces ethanol in a combined saccharification and fermentation step. This combines the release of glucose with its immediate fermentation to ethanol in a single process step that results in a large capital cost saving, decreased fermentation times, and increased enzyme productivity, factors that have made a major reduction in overall cost. Work continues on improving the cellulase productivity, the tolerance of the fermentation yeasts to ethanol, and increases in the solids concentration in the fermenters. The current yield of xylose from the hemicellulose polymer, xylan, is also being improved from 80 to 90% (Zhang et al., 1995).

### **Methanol from Biomass**

Methanol ( $\text{CH}_3\text{OH}$ ) can easily be produced by gasifying biomass and then catalytically combining the carbon monoxide and the hydrogen. It is the one-carbon analog of ethanol and shares many of the same fuel properties such as a very high octane number. For spark-ignition engine use, M85, an 85% by volume blend with gasoline, is usually specified. The 15% gasoline provides added fuel volatility, which assists cold starting and adds luminosity to the flame for added safety since neat methanol (M100) burns with a nearly invisible flame.

Methanol is very toxic to humans, but is not a great threat to either soil or water environments, and like ethanol, it is essentially nonthreatening to the environment. In any case, methanol is an important industrial chemical and represents one third of the mass of the MTBE (methyl tertiarybutylether) oxygenate used in auto-fuel oxygenate programs. Currently, it is produced from natural gas using technology that has existed for over 50 years.

### **Biodiesel**

Biodiesel is a diesel fuel that in the United States is derived from oil seed crops such as sunflower, soybean, and rape seed (canola). The oil is esterified in a simple process by reacting it with an alcohol such as methanol or ethanol to produce an ester that has been shown to be an attractive diesel fuel with an excellent cetane number and with much-reduced particulate emissions. The oil is isolated by pressing and solvent extraction from the seed cake, and the meal that remains is a nutritious animal feed. The esterification process produces a glycerine by-product. Both the meal and the glycerine have to be marketed in parallel with the oil production and currently the basic price of the oil seed — a food or feedstuff — is still too high, even though in subsidized markets in Europe production is increasing.

## Municipal Solid Waste

### Quantities, Characteristics, and Fuel Value

MSW contains energy, typically ranging from about 4000 to 6500 Btu/lb. MSW includes waste discarded from residential, commercial, institutional, and industrial sources. In 1993, over 200 million tons were generated with approximately 16% combusted for energy recovery. The quantities and heating values available will vary depending on the materials collected and processed into fuel. For instance, tires may be defined as MSW, but most will not be collected and processed into refuse-derived fuel (RDF). Yard waste contains some fuel value but may be composted. Of the approximate 207 million tons of MSW generated in the United States in 1993, paper and paperboard contributed about 77.8 million tons; plastics, 19.3 million tons; wood, 13.7 million tons. Paper has a typical heating value of 7200 Btu/lb; cardboard, 7000 Btu/lb; plastics, 14,000 Btu/lb; and wood, 8500 Btu/lb. Other components, such as leather, textiles, yard trimmings, rubber, etc., also have significant heating values. Processed RDF will have higher heating values depending on the degree of processing to remove noncombustibles and the components used to prepare the fuel. The average passenger tire has a heating value of 13,000 to 15,000 Btu/lb. However, there are only two dedicated tires-to-energy facilities in the United States combusting tires for energy recovery; a third was scheduled to begin operation some time in 1995. There are a number of cement kilns, pulp and paper mills, electric-generating utility boilers, and industrial boilers that use tire-derived fuel as a portion of their fuel.

### Refuse-Derived Fuels

Fuels derived from MSW have been classified according to the degree of processing. They range from waste used as a fuel in its discarded form with only bulky waste removed (RDF-1) to the combustible fraction of the waste processed into gaseous fuel (RDF-7). Some RDF may be densified (d-RDF) into pellets, cubes, or briquets for use in industrial and utility boilers as a supplement to coal.

### MSW-to-Energy Conversion Technologies

Although there are several potential methods to recover energy from MSW (e.g., conversion to ethanol, anaerobic digestion, gasification, pyrolysis, etc.), combustion is the most-advanced and the most-applied conversion technology.

*Combustion.* Direct combustion is the most prevalent technology used to reclaim the energy value in MSW. In 1993, there were 125 municipal waste-to-energy facilities in the United States with a rated MSW capacity of approximately 2500 MW of energy. The most common options are mass burn and RDF facilities, with mass burn being the most prevalent.

In a typical mass burn facility, waste is received into a pit where an overhead crane mixes the waste and removes oversize materials. The waste is fed onto a grate of the furnace, which agitates and moves the waste across the combustion chamber. Air for combustion is introduced from under the grate (underfire air) and from nozzles located above the grate (overfire air). The formation and emission of pollutants (e.g., CO, NO<sub>x</sub>, SO<sub>x</sub>, hydrocarbons, dioxins, etc.) are affected significantly by the design and operation of the combustor. Energy is recovered from the hot flue gases in a waterwall boiler and is recovered as hot water and steam.

The cooled flue gases then pass through air pollution control (APC) equipment which normally includes combinations of scrubbers to remove acid gases (e.g., HCl) electrostatic precipitators (particulate removal), and/or fabric filters (fine particulates).

*Anaerobic Digestion.* Anaerobic digestion is the biological degradation of biodegradable materials, in the absence of oxygen. Anaerobic microorganisms convert the biodegradable fraction of the waste to carbon dioxide and methane, which can be collected and used as an energy source. Commercial-scale anaerobic digestion of MSW has not been successful in the U.S. There are approximately 24 plants operating outside of the U.S.

## Defining Terms

**Cellulase:** A group of enzymes, found in many fungi and bacterial organisms, that hydrolyze the cellulose molecule into the component glucose molecules.

**Cellulose:** A complex carbohydrate found in stems, bark, and fibrous parts of plants and in products such as paper made from plant material. The insoluble molecule is a long chain of six carbon, glucose molecules linked together.

**Hemicellulose:** A complex carbohydrate molecule also found in plant material. This molecule is more soluble than cellulose and made up of five carbon sugars such as xylose.

**Hydrolysis:** Chemical decomposition involving the formation of water. Enzymes are capable of catalyzing the breakdown of cellulose resulting in the release of a water molecule and glucose molecules.

**Lignin:** A hard material embedded in the cellulose matrix of vascular plant cell walls. The molecule is a branched chain of organic rings, and gives strength to the fibers. This material is insoluble and must be removed in order to hydrolyze the cellulose.

**Lignocellulosics:** Substances composed of lignin and cellulose and/or hemicellulose, for example, wood. Lignocellulosic materials are the initial form of biomass feedstock before pretreatment removes or loosens the lignin and liberates the cellulose for further treatment

**Photosynthesis:** A process by which plants combine water and carbon dioxide in the presence of light and chlorophyll to make carbohydrates for food.

**Vortex reactor:** A pyrolysis reaction chamber design whereby a carrier gas and a dry feed stream are injected into a cylindrical reaction chamber, entering the reactor in a helical pattern and flowing over the inside surface of the cylinder, where heat is transferred to the biomass.

## 7.5 Nuclear Resources

---

*James S. Tulenko*

### The Nuclear Fuel Cycle

#### Sources of Nuclear Fuels and World Reserves

Nuclear power can use two naturally occurring elements, uranium and thorium, as the sources of its fissioning energy. Uranium can be a fissionable source (fuel) as mined (Candu Reactors in Canada), while thorium must be converted in a nuclear reactor into a fissionable fuel. Uranium and thorium are relatively plentiful elements ranking about 60th out of 80 naturally occurring elements. All isotopes of uranium and thorium are radioactive. Today, natural uranium contains, in atomic abundance, 99.2175% Uranium-238 ( $U^{238}$ ); 0.72% Uranium-235 ( $U^{235}$ ); and 0.0055% Uranium-234 ( $U^{234}$ ). Uranium has atomic number 92, meaning all uranium atoms contain 92 protons, with the rest of the mass number being composed of neutrons. Uranium-238 has a half-life of  $4.5 \times 10^9$  years (4.5 billion years), U-235 has a half-life of  $7.1 \times 10^8$  years (710 million years), and U-234 has a half-life of  $2.5 \times 10^5$  years (250 thousand years). Since the age of the earth is estimated at 3 billion years, roughly half of the U-238 present at creation has decayed away, while the U-235 has changed by a factor of sixteen. Thus, when the earth was created, the uranium-235 enrichment was on the order of 8%, enough to sustain a natural reactor of (there is evidence of such an occurrence in Africa). The U-234 originally created has long disappeared, and the U-234 currently present occurs as a product of the decay of U-238.

Uranium was isolated and identified in 1789 by a German scientist, Martin Heinrich Klaproth, who was working with pitchblend ores. No one could identify this new material he isolated, so in honor of the planet Uranus which had just been discovered, he called his new material Uranium. It wasn't until 1896, when the French scientist Henri Becquerel accidentally placed some uranium salts near some paper-wrapped photographic plates, that radioactivity was discovered.

Until 1938, when the German scientists Otto Hahn and Fritz Shassroen succeeded in uranium fission by exposure to neutrons, uranium had no economic significance except in coloring ceramics, where it proved valuable in creating various shades of orange, yellow, brown, and dark green. When a uranium atom is fissioned it releases 200 million electron volts of energy; the burning of a carbon (core) atom releases 4 electron volts. This difference of 50 million times in energy release shows the tremendous difference in magnitude between chemical and nuclear energy.

Uranium is present in the earth's crust to the extent of four parts per million. This concentration makes uranium about as plentiful as beryllium, hafnium, and arsenic; and greater in abundance than tungsten, molybdenum, and tantalum. Uranium is an order of magnitude more plentiful than silver and a hundred times more plentiful than gold. It has been estimated that the amount of uranium in the earth's crust to a depth of 12 miles is of the order of 100 trillion tons.

Thorium, which is composed of only one isotope, Thorium-232, has a half-life of 14 billion years ( $1.4 \times 10^{10}$  yr), is more than three times more abundant than uranium, and is in the range of lead and gallium in abundance. Thorium was discovered by Berzelius in 1828 and named after Thor, the Scandinavian god of war. For reference, copper is approximately five times more abundant than thorium and twenty times more abundant than uranium.

Uranium is chemically a reactive element; therefore, while it is relatively abundant, it is found chemically combined as an oxide ( $U_3O_8$  or  $UO_2$ ) and never as a pure metal. Uranium is obtained in three ways, either by underground mining, open pit mining, or in situ leaching. An economic average ore grade is normally viewed as .2% (4 pounds per short ton), though recently ore grades as low as .1% have been exploited. A large quantity of uranium exists in sea-water which has an average concentration of  $3 \times 10^{-3}$  ppm, yielding an estimated uranium quantity available in sea-water of 4000 million tons. A pilot operation was successfully developed by Japan to recover uranium from sea-water, but the cost was about \$900/lb, and the effort was shut down as uneconomical.

The major countries with reserves of uranium in order of importance are Australia, United States, Russia, Canada, South Africa, and Nigeria. The countries with major thorium deposits are India, Brazil, and the United States. It is estimated that for a recovery value of \$130/kg (\$60/lb), the total uranium reserves in these countries are approximately 1.5 million tonnes of uranium in the U.S., 1 million tonnes of uranium in Australia, .7 million tonnes of uranium in Canada, and 1.3 million tonnes of uranium in the former Soviet Union. As mentioned earlier, thorium reserves are approximately four times greater. With the utilization of breeder reactors, there is enough uranium and thorium to provide electrical power for the next thousand years at current rates of usage.

## Processing of Nuclear Fuel

Once the uranium ore is mined it is sent to a concentrator (mill) where it is ground, treated, and purified. Since the ore is of a grade of .1 to .2% uranium, a ton of ore contains only between 1 to 2 kilograms of uranium per 1000 kilograms of ore. Thus, thousands to tonnes of ore have to be extracted and sent to a mill to produce a relatively small quantity of uranium. In the concentration process approximately 95% of the ore is recovered as  $U_3O_8$  (yellowcake) to a purity grade of about 80%. Thus, assuming 0.15% uranium ore, the milling and processing of a metric ton (1000 kg) of ore yields a concentrate of 1.781 kg (1.425 kg of uranium and 0.356 kg of impurities). For this reason the mills must be located relatively close to the mine site. The ore tailings (waste) amounts to 998.219 kg and contains quantities of radon and other uranium decay products and must be disposed of as a radioactive waste.

The  $U_3O_8$  concentrate is then taken to a conversion plant where the concentrate is further purified (the 20% impurities are removed) and the uranium yellowcake is converted to uranium hexafluoride ( $UF_6$ ). The uranium hexafluoride is a gas at fairly low temperature and is an ideal material for the U-235 isotope enriching processes of either gaseous diffusion or gaseous centrifuge. The  $UF_6$  is shipped in steel cylinders in a solid state, and  $UF_6$  is vaporized by putting the cylinder in a steam bath.

If the uranium is to be enriched to 4%  $U^{235}$ , then 1 kilogram of 4%  $U^{235}$  product will require 7.4 kilograms of natural uranium feed and will produce 6.4 kilograms of waste uranium (tails or depleted uranium) with a  $U^{235}$  isotope content of 0.2%. This material is treated as a radioactive waste. Large quantities of tails (depleted uranium) exist as  $UF_6$  in their original shipping containers at the enriching plants. Depleted uranium (a dense material) has been used as shields for radioactive sources, armor piercing shells, balancing of helicopter rotor tips, yacht hold ballast, and balancing of passenger aircraft.

The enriched  $UF_6$  is then sent to a fabrication plant where it is converted to a uranium dioxide ( $UO_2$ ) powder. The powder is pressed and sintered into cylindrical pellets which are placed in zircaloy tubes (an alloy of zirconium), pressurized with helium, and sealed. The rods are collected in an array ( $\sim 17 \times 17$ ) bound together by spacer grids, with top and bottom end fittings connected by tie rods or guide tubes. Pressurized water reactor fuel assemblies, each containing approximately 500 kilograms of uranium, are placed in a reactor for 3 to 4 years. A single fuel assembly produces 160,000,000 kilowatt hours of electricity and gives 8,000 people their yearly electric needs for its three years of operation. When the fuel assembly is removed from the reactor it must be placed in a storage pond to allow for removal of the decay heat. After approximately five years of wet storage, the fuel assembly can be removed to dry storage in concrete or steel containers. In the United States the current plan is to permanently store the nuclear fuel, with the Department of Energy assuming responsibility for the "spent" fuel. The money for the government to handle the storage comes from a fee of 1 mill per kilowatt hour paid by consumers of nuclear-generated electricity. A mill is a thousandth of a dollar or a tenth of a penny. Thus, the fuel assembly described above would have collected \$160,000 in the waste fund for the Department of Energy to permanently store the fuel. In Europe, when the fuel is taken out of wet storage it is sent to a reprocessing plant where the metal components are collected for waste disposal; and the fuel is chemically recovered as 96% uranium, which is converted to uranium dioxide for recycling to the enrichment plant, 1% plutonium, which is converted to fuel or placed in storage, and 3% fission products which are encased in glass and permanently stored.

The important thing to remember about the fuel cycle is the small quantity of radioactive fission products (1.5 kilograms) which are created as radioactive waste in producing power which can serve the yearly electricity needs of 8,000 people for the three years that it operates. The schematic of the entire fuel cycle showing both the United States system (once-through) and the European (recycle) system is given in Figure 7.5.1.

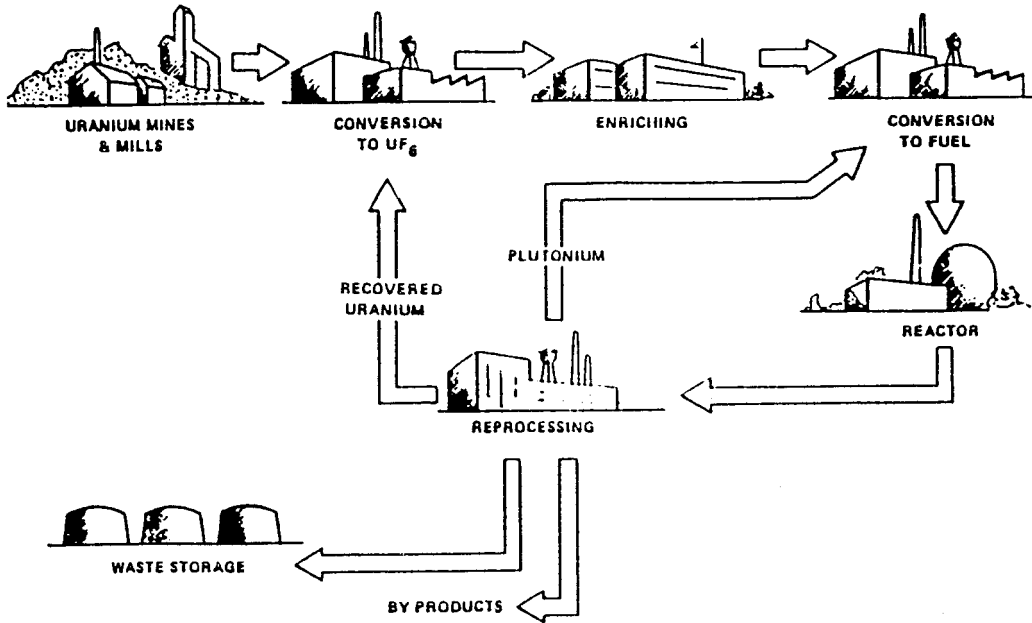

FIGURE 7.5.1 The nuclear fuel cycle.

## 7.6 Solar Energy Resources

### *D. Yogi Goswami*

The sun is a vast nuclear power plant of the fusion variety which generates power in the form of radiant energy at a rate of  $3.8 \times 10^{23}$  kW. An extremely small fraction of this is intercepted by Earth, but even this small fraction amounts to the huge quantity of  $1.8 \times 10^{14}$  kW. On the average, about 60% of this energy, incident at the outer edge of the atmosphere, reaches the surface. To compare these numbers with our energy needs, consider the present electrical-generating capacity in the United States, which is approximately of  $7 \times 10^8$  kW. This is equivalent to an average solar radiation falling on only 1000 square miles in a cloudless desert area. It must, however, be remembered that solar energy is distributed over the entire surface of Earth facing the sun, and it seldom exceeds  $1.0 \text{ kW/m}^2$ . Compared to other sources, such as fossil fuels or nuclear power plants, solar energy has a very low energy density. However, solar radiation can be concentrated to achieve very high energy densities. Indeed, temperatures as high as 3000 K have been achieved in solar furnaces.

Solar energy technology has been developed to a point where it can replace most of the fossil fuels or fossil fuel-derived energy. In many applications it is already economical, and it is a matter of time before it becomes economical for other applications as well.

This section deals in the availability of solar radiation, including methods of measurement, calculation, and available data.

### Solar Energy Availability

Detailed information about solar radiation availability at any location is essential for the design and economic evaluation of a solar energy system. Long-term measured data of solar radiation are available for a large number of locations in the United States and other parts of the world. Where long-term measured data are not available, various models based on available climatic data can be used to estimate the solar energy availability. The solar energy is in the form of electromagnetic radiation with the wavelengths ranging from about  $0.3 \mu\text{m}$  ( $10^{-6} \text{ m}$ ) to over  $3 \mu\text{m}$ , which correspond to ultraviolet (less than  $0.4 \mu\text{m}$ ), visible ( $0.4$  and  $0.7 \mu\text{m}$ ), and infrared (over  $0.7 \mu\text{m}$ ). Most of this energy is concentrated in the visible and the near-infrared wavelength range (see Figure 7.6.1). The incident solar radiation, sometimes called **insolation**, is measured as irradiance, or the energy per unit time per unit area (or power per unit area). The units most often used are watts per square meter ( $\text{W/m}^2$ ), British thermal units per hour per square foot ( $\text{Btu/hr-ft}^2$ ), and Langleys (calories per square centimeter per minute,  $\text{cal/cm}^2\text{-min}$ ).

The amount of solar radiation falling on a surface normal to the rays of the sun outside the atmosphere of the earth (extraterrestrial) at mean Earth-sun distance ( $D$ ) is called the **solar constant**,  $I_o$ . Measurements by NASA indicated the value of solar constant to be  $1353 \text{ W/m}^2$  ( $\pm 1.6\%$ ). This value was revised upward and the present accepted value of the solar constant is  $1377 \text{ W/m}^2$  (Quinlan, 1979) or  $437.1 \text{ Btu/hr-ft}^2$  or  $1.974$  langleys. The variation in seasonal solar radiation availability at the surface of Earth can be understood from the geometry of the relative movement of Earth around the sun.

### Earth-Sun Relationships

Figure 7.6.2 shows the annual motion of Earth around the sun. The **extraterrestrial solar radiation** varies throughout the year because of the variation in the Earth-sun distance ( $D$ ) as:

$$I = I_o \left( D/D_o \right)^2 \quad (7.6.1)$$

which may be approximated as (Spencer, 1971)

FIGURE 7.6.1 Spectral distribution of solar energy at sea level. (Reprinted by permission from Kreith, F. and Kreider, J.F., *Principles of Solar Engineering*, Hemisphere, Washington, D.C., 1978.)

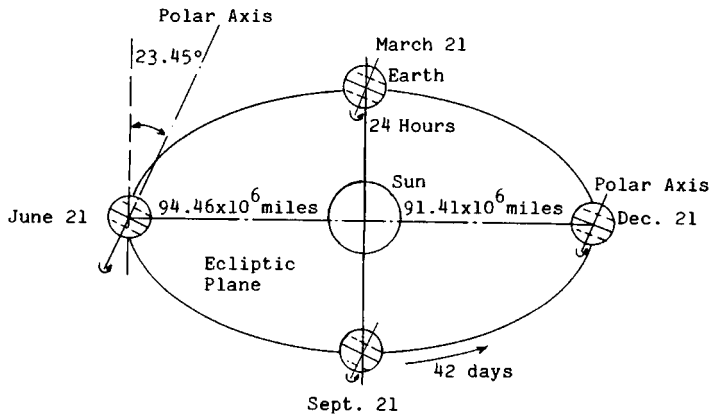

FIGURE 7.6.2 Annual motion of the Earth around the sun.

$$\left(\frac{D}{D_o}\right)^2 = 1.00011 + 0.034221\cos(x) + 0.00128\sin(x) + 0.000719\cos(2x) + 0.000077\sin(2x) \quad (7.6.2)$$

where

$$x = 360(N - 1)/365^\circ \quad (7.6.3)$$

and  $N =$  Day number (starting from January 1 as 1). The axis of the Earth is tilted at an angle of  $23.45^\circ$  to the plane of its elliptic path around the sun. This tilt is the major cause of the seasonal variation of solar radiation available at any location on Earth. The angle between the Earth-sun line and a plane through the equator is called **solar declination**,  $\delta$ . The declination varies between  $-23.45^\circ$  to  $+23.45^\circ$  in 1 year. It may be estimated by the relation:

**FIGURE 7.6.3** Apparent daily path of the sun across the sky from sunrise to sunset, showing the solar altitude and azimuth angles.

$$\delta = 23.45^\circ \sin[360(284 + N)/365^\circ] \quad (7.6.4)$$

The apparent motion of the sun around the earth is shown in [Figure 7.6.3](#). The **solar altitude angle**,  $\beta$ , and the **solar azimuth angle**,  $\Phi$ , describe the position of the sun at any time.

## Solar Time

The sun angles are found from the knowledge of solar time, which differs from the local time. The relationship between solar time and local standard time (LST) is given by

$$\text{Solar Time} = \text{LST} + \text{ET} + 4(L_{\text{st}} - L_{\text{loc}}) \quad (7.6.5)$$

where ET is the **equation of time**, which is a correction factor in minutes that accounts for the irregularity of the motion of the Earth around the sun.  $L_{\text{st}}$  is the standard time meridian and  $L_{\text{loc}}$  is the local longitude. ET can be calculated from the following empirical equation:

$$\text{ET}(\text{in minutes}) = 9.87 \sin 2B - 7.53 \cos B - 1.5 \sin B \quad (7.6.6)$$

where  $B = 360(N - 81)/365^\circ$ .

The sun angles  $\beta$  (altitude) and  $\Phi$  (azimuth) can be found from the equations:

$$\sin \beta = \cos \ell \cos \delta \cos H + \sin \ell \sin \delta \quad (7.6.7)$$

where  $\ell$  = latitude angle,

$$\sin \Phi = \cos \delta \sin H / \cos \beta \quad (7.6.8)$$

and

$$H = \text{Hour angle} = \frac{\text{Number of minutes from local solar noon}}{4 \text{ min/degree}} \tag{7.6.9}$$

(At solar noon,  $H = 0$ , so  $\beta = 90 - |\ell - \delta|$  and  $\Phi = 0$ .)

### Solar Radiation on a Surface

As solar radiation,  $I$ , passes through the atmosphere, some of it is absorbed by air and water vapor, while some gets scattered by molecules of air, water vapor, aerosols, and dust particles. The part of solar radiation that reaches the surface of the Earth with essentially no change in direction is called **direct or beam normal radiation**,  $I_{bN}$ . The scattered radiation reaching the surface from the atmosphere is called **diffuse radiation**,  $I_d$ .

$I_{bN}$  can be calculated from the extraterrestrial solar irradiance,  $I$ , and the atmospheric optical depth  $\tau$  as (Goswami et al., 1981; ASHRAE, 1995)

$$I_{bN} = Ie^{-\tau \sec \theta_z} \tag{7.6.10}$$

where  $\theta_z$  is the solar zenith angle (angle between the sun rays and the vertical). The atmospheric optical depth determines the attenuation of the solar radiation as it passes through the atmosphere. Threlkeld and Jordan (1958) calculated values of  $\tau$  for average atmospheric conditions at sea level with a moderately dusty atmosphere and amounts of precipitable water vapor equal to the average value for the United States for each month. These values are given in [Table 7.6.1](#). To account for the differences in local conditions from the average sea level conditions Equation (7.6.10) is modified by a parameter called Clearness Number,  $C_n$ , introduced by Threlkeld and Jordan (1958):

$$I_{bN} = C_n I e^{-\tau \sec \theta_z} \tag{7.6.11}$$

values of  $C_n$  vary between 0.85 and 1.15.

**TABLE 7.6.1 Average Values of Atmospheric Optical Depth ( $\tau$ ) and Sky Diffuse Factor ( $C$ ) for 21st Day of Each Month**

Month	1	2	3	4	5	6	7	8	9	10	11	12

$C$	0.058	0.060	0.071	0.097	0.121	0.134	0.136	0.122	0.092	0.073	0.063	0.057

Source: Threlkeld, J.L. and Jordan, R.C., *ASHRAE Trans.*, 64, 45, 1958.

### Solar Radiation on a Horizontal Surface

Total incident solar radiation on a horizontal surface is given by

$$I_{t, \text{Horizontal}} = I_{bN} \cos \theta_z + C I_{bN} \tag{7.6.12}$$

$$= I_{bN} \sin \beta + C I_{bN} \tag{7.6.13}$$

where  $\theta_z$  is called the solar zenith angle and  $C$  is called the sky diffuse factor, as given in [Table 7.6.1](#).

### Solar Radiation on a Tilted Surface

For a surface of any orientation and tilt as shown in [Figure 7.6.4](#), the angle of incidence,  $\theta$ , of the direct solar radiation is given by

**FIGURE 7.6.4** Definitions of solar angles for a tilted surface.

$$\cos\theta = \cos\beta\cos\gamma\sin\Sigma + \sin\beta\cos\Sigma \tag{7.6.14}$$

where  $\gamma$  is the angle between horizontal projections of the rays of the sun and the normal to the surface.  $\Sigma$  is the tilt angle of the surface from the horizontal.

For a tilted surface with angle of incidence  $\theta$ , the total incident solar radiation is given by

$$I_b = I_{bN} \cos\theta + I_{diffuse} + I_{reflected} \tag{7.6.15}$$

where

$$I_{diffuse} = CI_{bN} (1 + \cos\Sigma)/2 \tag{7.6.16}$$

and

$$I_{reflected} = \rho I_{bN} (C + \sin\beta)(1 - \cos\Sigma)/2 \tag{7.6.17}$$

where  $\rho$  is the reflectivity of the surroundings. For ordinary ground or grass,  $\rho$  is approximately 0.2 while for ground covered with snow it is approximately 0.8.

### Solar Radiation Measurements

Two basic types of instruments are used in measurements of solar radiation. These are (see [Figure 7.6.5](#)):

1. *Pyranometer*: An instrument used to measure global (direct and diffuse) solar radiation on a surface. This instrument can also be used to measure the diffuse radiation by blocking out the direct radiation with a shadow band.
2. *Pyrheliometer*: This instrument is used to measure only the direct solar radiation on a surface normal to the incident beam. It is generally used with a tracking mount to keep it aligned with the sun.

More-detailed discussions about these and other solar radiation measuring instruments can be found in Zerlaut (1989).

**FIGURE 7.6.5** Two basic instruments for solar radiation: (a) pyranometer; (b) pyrheliometer.

### Solar Radiation Data

Measured values of solar radiation data for locations in the United States are available from the National Climatic Center in Asheville, NC. A number of states have further presented solar radiation data for locations in those states in readily usable form. Weather services and energy offices in almost all the countries have available some form of solar radiation data or climatic data that can be used to derive solar radiation data for locations in those countries. [Tables 7.6.2 to 7.6.8](#) give solar radiation data for clear days for south-facing surfaces in the Northern Hemisphere (and northern-facing surfaces in the Southern Hemisphere) tilted at  $0^\circ$ ,  $15^\circ$ ,  $30^\circ$ ,  $45^\circ$ ,  $60^\circ$ ,  $75^\circ$ , and vertical, for latitudes  $0^\circ$ ,  $10^\circ$ ,  $20^\circ$ ,  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$ , and  $60^\circ$ . The actual average solar radiation data at a location is less than the values given in these tables because of the cloudy and partly cloudy days in addition to the clear days. The actual data can be obtained either from long-term measurements or from modeling based on some climatic parameters, such as percent sunshine. [Tables 7.6.9 to 7.6.12](#) give hourly solar angles for northern latitudes  $0^\circ$ ,  $20^\circ$ ,  $40^\circ$ , and  $60^\circ$ .

## Defining Terms

**Diffuse radiation:** Scattered solar radiation coming from the sky.

**Direct or beam normal radiation:** Part of solar radiation coming from the direction of the sun on a surface normal to the sun's rays.

**Equation of time:** Correction factor in minutes, to account for the irregularity of the Earth's motion around the sun.

**Extraterrestrial solar radiation:** Solar radiation outside Earth's atmosphere.

**Insolation:** Incident solar radiation measured as W/m<sup>2</sup> or Btu/hr-ft<sup>2</sup>.

**Solar altitude angle:** Angle between the solar rays and the horizontal plane.

**Solar azimuth angle:** Angle between the true south horizontal line and the horizontal projection of the sun's rays.

**Solar constant:** Extraterrestrial solar radiation at the mean Earth-sun distance.

**Solar declination:** Angle between the Earth-sun line and a plane through the equator.

## 7.7 Wind Energy Resources\*

*Dale E. Berg*

The mechanical devices that are used to convert kinetic energy in the wind into useful shaft power are known as windmills (the earliest machines were used to mill grain), wind machines, or wind turbines. The earliest use of wind machines appears to have been in ancient Persia, where they were used for grinding grain and pumping water. By the 14th century, completely different types of mills known as post and cap mills had become a major source of energy for milling, water pumping, and other tasks throughout northern Europe, and they remained so well into the 19th century, when the steam engine displaced them in many applications.

A new form of windmill appeared in United States in the second half of the 19th century — the multivane or annular windmill, also sometimes known as the American windmill (see [Figure 7.7.1](#)). These small, lightweight machines were designed to survive high winds with no human intervention by automatically shedding power, and they played a large role in the settlement of the American West — an arid country where little surface water is available. Many windmills of this basic type are still in use for water pumping around the world today.

**FIGURE 7.7.1** The multiblade American windmill Photograph by Paul Gipe. (Adapted from *Wind Power for Home & Business*, Chelsea Green Publishing, 1993).

By the end of the 19th century, efforts to adapt wind power to electricity generation were underway in several countries. In the early 20th century, small wind turbine generators utilizing only two or three aerodynamic blades and operating at a higher rotational speed than the multibladed windmills were developed. Many thousands of generators of this type have been used to provide electricity in the remote areas of the world over the past 85 years.

Large-scale wind turbines designed to generate electrical power were built and tested in several European countries and the U.S. between 1935 and 1970. However, economic studies showed that the electricity generated by the machines would be every expensive, and no effort was made to develop the machines as a serious alternative energy source.

---

\* This work was supported by the United States Department of Energy under Contract DE-AC04-94AL85000.

As a result of research and development since the mid 1970s, the cost of energy or wind-generated electricity has decreased from around 30¢ per kilowatt-hour (kWhr) in the early 1980s to less than 5¢/kWhr for a modern wind farm at a good site in 1995, and wind turbine availability (the fraction of time the machine is operational; i.e., not disabled for repairs or maintenance) has increased from 50 to 60% to better than 95% over the same period. At the end of 1995, there were over 26,000 wind turbines operating worldwide with an installed capacity of over 5000 MW. Twenty-five percent of that capacity was installed in 1995, and plans for 1996 call for the installation of an additional 25%. About 2500 MW of the 5000 MW was in Europe, 1700 MW was in the U.S., and over 400 MW was in India.

## Wind Characteristics

### Wind Speed and Shear

The primary cause of atmospheric air motion, or wind, is uneven heating of Earth by solar radiation. For example, land and water along a coastline absorb radiation differently, and this creates the light winds or breezes normally found along a coast. Earth's rotation is also an important factor in creating winds.

Wind moving across Earth's surface is slowed by trees, buildings, grass, rocks, and other obstructions in its path. The effect of these obstructions decreases with increasing height above the surface, typically resulting in a wind speed that varies with height above the Earth's surface — phenomenon known as **wind shear**. For most situations, wind shear is positive and wind speed increases with height, but situations in which the wind shear is negative or inverse are not unusual. In the absence of actual data for a specific site, a commonly used approximation for wind shear is

$$U/U_o = (h/h_o)^\alpha \quad (7.7.1)$$

where  $U$  is the velocity at a height  $h$ ,  $U_o$  is the measured velocity at height  $h_o$ , and  $\alpha$  is the non-dimensional wind shear exponent.

The wind shear,  $\alpha$ , varies with terrain characteristics, but usually is between 0.10 and 0.25. Over a smooth, level, grass-covered terrain such as the United States Great Plains,  $\alpha$  is normally about 0.14. For wind over row crops or low bushes with a few scattered trees, a value of 0.20 is more common while a value of 0.25 is normally a good value for wind over a heavy stand of trees, several buildings, or hilly or mountainous terrain.

A specific site may display much different wind shear behavior than that given in Equation 7.7.1, and that will dramatically affect site energy capture, making it important to measure the wind resource at the specific site and height where the wind turbine will be located, if at all possible.

### Wind Energy Resource

The available power in the wind passing through a given area at any given velocity is due to the kinetic energy of the wind and is given by

$$\text{Power} = \frac{1}{2} \rho A U^3 \quad (7.7.2)$$

where the power is in watts,  $\rho$  is the air density in  $\text{kg/m}^3$ ,  $A$  is the area of interest perpendicular to the wind in  $\text{m}^2$ , and  $U$  is the wind velocity in  $\text{m/sec}$ .

Air density decreases with increasing temperature and increasing altitude. The effect of temperature on density is relatively weak and is normally ignored, as these variations tend to average out over the period of a year. The density difference due to altitude, however, is significant and does not average out. For example, the air density at sea level is approximately 14% higher than that at Denver, CO (elevation 1600 m or 5300 ft above sea level), so wind of any velocity at sea level contains 14% more power than wind of the same velocity at Denver.

From Equation 7.7.2, it is obvious that the most important factor in the available power is the velocity of the wind — available wind power is proportional to the cube of the wind speed, so doubling the wind speed increases the available power by a factor of 8. An increase in wind velocity of only 20%, say, from 5 to 6 m/sec (11.2 to 13.4 mph), yields a 73% increase in available power.

The available wind power at a site can vary dramatically with height due to wind shear. For example, for  $\alpha = 0.20$ , Equations (7.7.1) and (7.7.2), reveal that the available power at a height of 30 m is approximately  $\{(30/10)^{0.2}\}^3 = 1.93$  times the available power at 10 m. The amount of energy available from the wind (the **wind energy resource**) is the average amount of power available from the wind over a specified period of time, frequently a year. If the wind speed is 20 m/sec, the available power is very large, but if it only blows at that speed for 10 h/year and the rest of the time the wind speed is 0, the resource for the year is very small. Therefore, the site **wind speed distribution**, or frequency at which each wind speed occurs, is very important. The distribution is often presented in histogram form as the probability that the wind occurs at any particular wind speed between 0 and the maximum wind speed (see Figure 7.7.9). If the actual wind speed distribution is not available, it is frequently approximated with a Rayleigh distribution based on the yearly average wind speed. The Rayleigh distribution is given by

$$f(U) = \frac{\pi}{4} \cdot \frac{U}{\bar{U}} \exp\left[-\frac{\pi U^2}{4\bar{U}^2}\right] \quad (7.7.3)$$

where  $f(U)$  is the frequency of occurrence of wind speed  $U$  and  $\bar{U}$  is the yearly average wind speed.

How big is the wind energy resource? It varies dramatically from site to site. In 1981, scientists at Battelle Pacific Northwest Laboratory (PNL) in the U.S. analyzed national weather data, ship data, and terrain and made an estimate of the world-wide wind energy resource. That estimate is summarized in Figure 7.7.2. Very little data is available over much of the world, but even where excellent data is available, only very crude estimates can be portrayed on a map of this scale. More detailed analysis of available data for a specific country can yield a much better estimate of the wind resource for that country.

For example, the PNL scientists have carefully analyzed and interpreted the available long-term wind data for the U.S. and have summarized their estimate of the wind energy resource in a series of maps in the *Wind Energy Resource Atlas of the United States* (Elliott et al., 1987). A summary for the entire U.S. is reproduced in Figure 7.7.3 which presents the resource in terms of the power class rating. Sites with power class 4 (at least 250 W/m<sup>2</sup> at 10 m height or 500 W/m<sup>2</sup> at 50 m height) and above are considered economic for utility-scale wind power development with available wind technology, while sites with power class 3 are not considered economic today but are likely to become economic with near-term wind technology advances. Sites in power classes 2 or lower are not considered economic for utility-scale wind power development, but may well be economic for remote or hybrid wind power systems.

Much of the land in the United States is not available for wind energy development because it is in environmental exclusion areas such as parks, monuments, wilderness areas, wildlife refuges, and other protected areas, or only a portion of it may be developed because of land-use restrictions for forest, agriculture, range, and urban lands. Schwartz et al. (1992) estimated the wind energy that could be generated (the **wind energy potential**) for the United States land available for wind energy development. For the purposes of this study, they assumed that turbines with a 50-m hub height, arranged in arrays with 10 diameter by 5 diameter spacing, operating at 25% efficiency, and experiencing 25% power losses, were used to capture the available wind. Their results for power class 4 and above are summarized in Figure 7.7.4 and Table 7.7.1. They estimate that the average power that could be produced from this resource is 512,000 MW, significantly above the 1994 U.S. average electricity generation of 350,000 MW. They also estimate that the available windy lands with power class 3 or better resources could yield an average power of 1,241,000 MW, more than three times the current United States electricity generation. However, since wind energy is intermittent, is typically concentrated away from the major

**TABLE 7.7.1** Estimates of Class 4 Wind Land Area and Wind Energy Potential

State	Average Power, MW	Windy Land, km <sup>2</sup>
North Dakota	108,000	98,000
South Dakota	70,900	66,500
Wyoming	49,800	39,600
Montana	48,400	42,800
Minnesota	44,800	42,100
Kansas	35,700	33,600
Texas	28,900	27,100
Oklahoma	27,200	25,500
Colorado	26,400	24,300
Nebraska	22,200	20,900
Iowa	15,800	14,900
New Mexico	5,200	4,600
National	512,300	464,200

*Note:* The top 12 states and total for 48 contiguous states. Wind resource class 4 and above, for a 30-m hub height.

population centers where the electricity demand is highest, and is not always available when the demand is great, it will probably never supply more than 15 to 20% of the U.S. electricity needs.

Similar assessments may be performed for any country of interest. The PNL scientists have recently performed a similar assessment of the available long-term wind data for Mexico and have estimated the wind resource there (Schwartz and Elliott, 1995), as shown in [Figure 7.7.5](#). While wind resources in class 2 are too low to be economic for grid-connected wind power, they are useful for rural power applications. Scientists at Denmark’s Risø National Laboratory have done similar work in Europe,

**FIGURE 7.7.5** Map of Mexican remote application wind energy resources. Reproduced from Schwartz and Elliott, 1995. *Mexico Wind Resource Assessment Project*. (Courtesy of National Renewable Energy Laboratory, Golden, Colorado.)

producing a *European Wind Atlas* (Troen and Petersen, 1989) that examines the wind resources of the European Community countries and summarizes the resource available at a 50 m height above smooth, flat terrain, with no obstacles. These results are presented in [Figure 7.7.6](#). Finland, Sweden, Algeria, and Jordan have produced similar reports, and atlases for Poland, Canada, Egypt, Syria, and Turkey are currently in preparation. Resource maps for several other countries may be found in Rohatgi and Nelson (1994).

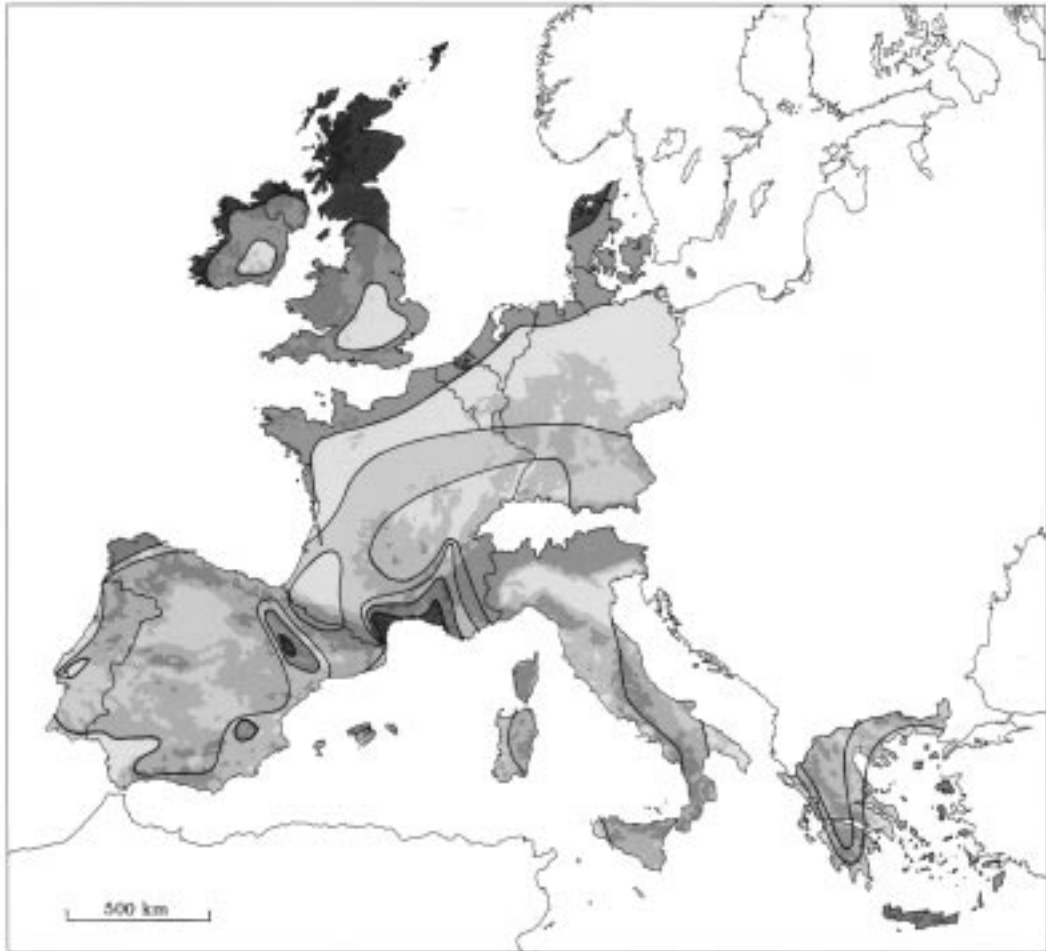

Existing meteorological station data, in general, significantly underestimate the wind energy resources because of lack of maintenance of wind sensors, poor locations at which they are placed, and cursory methods used in analyzing these data. Assessments such as these only identify the wind energy resource or potential on a very coarse grid. The actual wind resources in any specific area can vary dramatically from those estimates and must be determined with site-specific measurements. Even areas with a very low large-scale resource may contain small areas with a very high resources.

## Site Analysis and Selection

### Biological Indicators

Many different methods may be used to identify areas of high wind resource. Persistent winds can cause plant deformation, and careful observation of these plants can be used to compare candidate sites and, in at least some cases, to estimate the average wind speed. The Griggs-Putnam index, shown in [Figure 7.7.7](#) and explained in Hewson, Wade, and Baker (1979), is an example of a genus-specific correlation of tree deformation with wind speed. It should be noted that although wind-flagged trees (i.e., trees with branches bent away from a prevailing wind) may indicate that the annual average wind speed is quite strong, unflagged trees do not necessarily indicate that the winds are light. Unflagged trees may be

1. The resources refer to the power present in the wind. A wind turbine can utilize between 20 and 30% of the available resource. The resources are calculated for an air density of 1.23 kg m<sup>-3</sup>, corresponding to standard sea level pressure and a temperature of 15°C. Air density decreases with height but up to 1000 m a.s.l. the resulting reduction of the power densities is less than 10%.
2. Urban districts, forest and farm land with many windbreaks (roughness class 3).
3. Open landscapes with few windbreaks (roughness class 1). In general, the most favourable inland sites on level land are found here.
4. The classes pertain to a straight coastline, a uniform wind rose and a land surface with few windbreaks (roughness class 1). Resources will be higher, and closer to open sea values, if winds from the sea occur more frequently, i.e. the wind rose is not uniform and/or the land protrudes into the sea. Conversely, resources will generally be smaller, and closer to land values, if winds from land occur more frequently.
5. More than 10 km offshore (roughness class 0).
6. The classes correspond to 50% overspeeding and were calculated for a site on the summit of a single axisymmetric hill with a height of 400 metres and a base diameter of 4 km. The overspeeding depends on the height, length and specific setting of the hill.

exposed to strong winds from all directions, with insufficient persistence in any one direction to cause flagging.

### Effects of Topography

The effects of surrounding terrain on the wind speed at a specific site can be significant. If the proposed site is flat, the terrain texture is the area of most concern. The rougher the terrain, the more the wind flowing over it is retarded near the surface. Flat terrain, such as a large area of flat, open grassland, is the simplest type of terrain for selecting a turbine site. If there are no nearby obstacles (i.e., buildings, trees, or hills), the wind speed at a given height is nearly the same over the entire area, and the best way to increase the available power is to raise the rotor higher above the ground to take advantage of positive wind shear.

Siting turbines on elevated terrain such as hills, ridges, and cliffs takes advantage of the generally higher wind speed at increased altitudes. It may also help keep the turbine exposed to the winds above the calm, cool air that frequently accumulates in valleys and lowlands at night. In some cases, the elevated terrain may cause an acceleration of the wind and thus further improve the resource available to the turbine (see [Figure 7.7.8](#)). Depressions include such terrain features as valleys, basins, gorges, and passes. If the depressions channel the wind flow, they may provide good turbine sites. However, the power is

**FIGURE 7.7.8** Effect of wind flow over a hill.

more likely to vary by time-of-day or by season than it is for elevated terrain. The impact of terrain on the wind resource and the best places to site turbines for various types of terrain are discussed by Wegley, et al. (1980).

**Wind Speed Measurements**

The amount of wind energy that can be captured at a site depends on the characteristics of the wind speed at that site. Wind characteristics (speed, direction, distribution, and shear) can vary widely over fairly short distances in either the horizontal or vertical direction. Therefore, in order to predict the energy capture of a turbine with the greatest possible accuracy, wind measurements at the precise site where the turbine will be located are needed. If the rotor, is relatively small, measurements at the hub height (or middle of the rotor) will suffice; for larger rotors, simultaneous measurements at several heights will be required to model the wind speed variation across the rotor disk.

Complete characterization of the wind resource at a specific site is a very time-consuming and expensive effort. A comprehensive site characterization normally requires measuring the wind for at least 12 months, according to Wegley et al. (1980). Even after acquiring the data, questions remain. Long-term data from the nearest airport or long-term weather recording station can help determine whether or not this was a normal wind year for the site and whether the winds were higher or lower than the long-term average (Gipe, 1993). If the costs and time requirements for on-site measurement are excessive, Wegley et al. (1980) and Gipe (1993) give suggestions on methods of using available data from nearby sites, together with a minimum of on-site data to estimate site wind speed.

In the absence of actual site data a Rayleigh distribution (Equation 7.7.3) for the proper yearly average wind speed may be used to estimate the site wind speed distribution. Wind resource estimates that are made with these approximations to the site wind speed and wind distribution will contain significantly larger errors than would be found if the measured site characteristics were used. Figure 7.7.9 illustrates the discrepancies between the measured wind speed distributions at the Amarillo, TX airport and a Bushland, TX test site 20 miles away, and a Rayleigh distribution for the same average wind speed. The measured distribution at the airport has far more energy in the 9 to 12 m/sec range, and this will yield far more energy production than that estimated with the Rayleigh distribution.

**Wind Energy Capture Potential**

With a wind speed distribution and a turbine power curve (power generated as a function of wind speed) properly adjusted for the local air density, the wind energy potential, or gross annual energy production for a specific site, can be estimated as:

$$\text{Energy} = 8760 \sum_{i=1}^n f(U_i) \cdot \Delta U_i \cdot P(U_i) \tag{7.7.4}$$

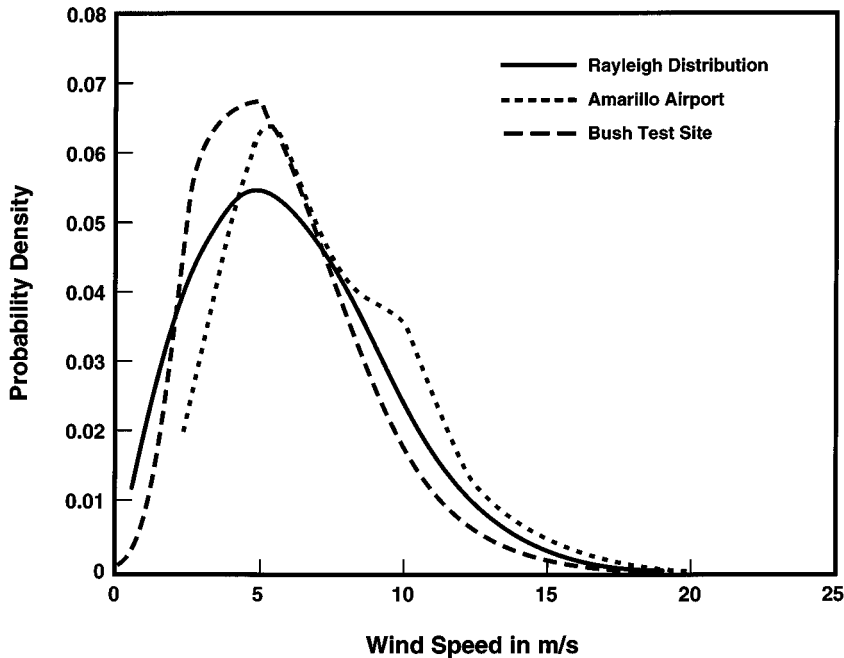

FIGURE 7.7.9 Rayleigh and measured wind frequency distributions.

where 8760 is the number of hours in a year,  $n$  is the number of wind speeds considered,  $f(U_i) \cdot \Delta U_i$  is the probability of a given wind speed occurring, and  $P(U_i)$  is the power produced by the turbine at wind speed  $U_i$ . If the measured wind speed distribution is used, replace  $f(U_i) \cdot \Delta U_i$  by the probability for the appropriate wind speed (the height of the histogram bar for that wind speed times the wind speed increment). If the power curve is for the turbine aerodynamic or rotor power rather than the electrical power, subtract 10% to approximate the losses due to the turbine bearings and drivetrain. To estimate the net annual energy production, or amount of energy actually delivered to the grid by the turbine, subtract an additional 10% to approximate the electrical losses between the turbine and the grid, the control system losses, and the decreased performance due to dirty blades. If the turbine will be operated in an array, subtract another 5% for array-induced losses.

### Environmental Impacts

Although wind turbines generate electricity without causing any air pollution or creating any radioactive wastes, they have an impact on the environment. Wind turbines require a lot of land, but most of that land (90% or so) will remain available for other uses such as farming or livestock grazing. Roads must be built to facilitate installation and maintenance of the wind turbines. Turbines generate noise, but newer turbines are much quieter than earlier models. Current industry standards call for characterization of turbine noise production and rate of decay with distance from the turbine as part of the turbine-testing process. In addition, turbines are large structures that will significantly change the landscape where they are installed, creating visual impact pollution. Another environmental issue facing the wind industry is that of bird deaths as a result of collisions with wind turbines. Preliminary studies indicate that the magnitude of the problem is site specific, and avoiding known bird migration corridors and areas of high bird concentrations when siting turbines and using tubular towers to offer fewer bird perch sites will help to minimize bird collisions with new turbine installations.

## Defining Terms

**Wind energy potential:** The total amount of energy that can actually be extracted from the wind, taking into account the efficiency of the wind turbines and the land available for wind turbine siting.

**Wind energy resource:** The total amount of energy that is present in the wind.

**Wind shear:** The change in wind velocity with increasing height above the ground.

**Wind speed distribution:** The frequency of occurrence of each wind speed over the course of a year. This is site specific.

## Further Information

Wind Characteristics — An Analysis for the Generation of Wind Power, by J. S. Rohatti and V. Nelson, Alternative Energy Institute, West Texas A&M University, Canyon, TX, 1994, is an excellent source for additional information on the wind resource. *Wind Turbine Technology, Fundamental Concepts of Wind Turbine Engineering*, D. Spera, editor, ASME Press, New York, 1994, contains a wealth of information on wind energy history and technology, together with extensive reference lists. Resources for European-community countries are given in the *European Wind Atlas*, by I. Troen and E. L. Petersen, Risø National Laboratory, Roskilde, Denmark, 1989.

## 7.8 Geothermal Energy

*Joel L. Renner and Marshall J. Reed*

The word *Geothermal* comes from the combination of the Greek words *gê*, meaning Earth, and *thérm*, meaning heat. Quite literally, geothermal energy is the heat of the Earth. Geothermal resources are concentrations of the Earth's heat, or geothermal energy, that can be extracted and used economically now or in the reasonable future. Currently, only concentrations of heat associated with water in permeable rocks can be exploited. Heat, fluid, and permeability are the three necessary components of all exploited geothermal fields. This section of Energy Resources will discuss the mechanisms for concentrating heat near the surface, the types of geothermal systems, and the environmental aspects of geothermal production.

### Heat Flow

Temperature within the Earth increases with depth at an average of about 25°C/km. Spatial variations of the thermal energy within the deep crust and mantle of the Earth give rise to concentrations of thermal energy near the surface of the Earth that can be used as an energy resource. Heat is transferred from the deeper portions of the Earth by conduction of heat through rocks, by the movement of hot, deep rock toward the surface, and by deep circulation of water. Most high-temperature geothermal resources are associated with concentrations of heat caused by the movement of magma (melted rock) to near-surface positions where the heat is stored.

In older areas of continents, such as much of North America east of the Rocky Mountains, heat flow is generally 40 to 60 mWm<sup>-2</sup> (milliwatts per square meter). This heat flow coupled with the thermal conductivity of rock in the upper 4 km of the crust yields subsurface temperatures of 90 to 110°C at 4 km depth in the Eastern United States. Heat flow within the Basin and Range (west of the Rocky Mountains) is generally 70 to 90 mWm<sup>-2</sup>, and temperatures are generally greater than 110°C at 4 km. There are large variations in the Western United States, with areas of heat flow greater than 100 mWm<sup>-2</sup> and areas which have generally lower heat flow such as the Cascade and Sierra Nevada Mountains and the West Coast. A more detailed discussion of heat flow in the United States is available in Blackwell et al. (1991).

### Types of Geothermal Systems

Geothermal resources are hydrothermal systems containing water in pores and fractures. Most hydrothermal resources contain liquid water, but higher temperatures or lower pressures can create conditions where steam and water or only steam are the continuous phases (White et al., 1971; Truesdell and White, 1973). All commercial geothermal production is expected to be restricted to hydrothermal systems for many years because of the cost of artificial addition of water. Successful, sustainable geothermal energy usage depends on reinjection of the maximum quantity of produced fluid to augment natural recharge of hydrothermal systems.

Other geothermal systems that have been investigated for energy production are (1) geopressured-geothermal systems containing water with somewhat elevated temperatures (above normal gradient) and with pressures well above hydrostatic for their depth; (2) magmatic systems, with temperature from 600 to 1400°C; and (3) hot dry rock geothermal systems, with temperatures from 200 to 350°C, that are subsurface zones with low initial permeability and little water. These types of geothermal systems cannot be used for economic production of energy at this time.

### Geothermal Energy Potential

The most recent report (Huttrer, 1995) shows that 6800 MW<sub>e</sub> (megawatts electric) of geothermal electric generating capacity is on-line in 21 countries (Table 7.8.1). The expected capacity in the year 2000 is

9960 MW<sub>e</sub>. Table 7.8.2 lists the electrical capacity of U.S. geothermal fields. Additional details of the U.S. generating capacity are available in DiPippo (1995) and McClarty and Reed (1992). Geothermal resources also provide energy for agricultural uses, heating, industrial uses, and bathing. Freeston (1995) reports that 27 countries had a total of 8228 MW<sub>t</sub> (megawatts thermal) of direct use capacity. The total energy used is estimated to be 105,710 TJ/year (terajoules per year). The thermal energy used by the ten countries using the most geothermal resource for direct use is listed in Table 7.8.3.

The U.S. Geological Survey has prepared assessments of the geothermal resources of the U.S. Muffler(1979) estimated that the identified hydrothermal resource, that part of the **identified accessible base** that could be extracted and utilized at some reasonable future time, is 23,000 MW<sub>e</sub> for 30 years. This resource would operate power plants with an aggregate capacity of 23,000 MW<sub>e</sub> for 30 years. The undiscovered U.S. resource (inferred from knowledge of Earth science) is estimated to be 95,000 to 150,000 MW<sub>e</sub> for 30 years.

## Geothermal Applications

In 1991, geothermal electrical production in the United States was 15,738 GWh (gigawatt hours), and the largest in the world (McLarty and Reed, 1992).

Most geothermal fields are water dominated, where liquid water at high temperature, but also under high (hydrostatic) pressure, is the pressure-controlling medium filling the fractured and porous rocks of the reservoir. In water-dominated geothermal systems used for electricity, water comes into the wells from the reservoir, and the pressure decreases as the water moves toward the surface, allowing part of the water to boil. Since the wells produce a mixture of flashed steam and water, a separator is installed

between the wells and the power plant to separate the two phases. The flashed steam goes into the turbine to drive the generator, and the water is injected back into the reservoir.

Many water-dominated reservoirs below 175°C used for electricity are pumped to prevent the water from boiling as it is circulated through heat exchangers to heat a secondary liquid that then drives a turbine to produce electricity. **Binary geothermal plants** have no emissions because the entire amount of produced geothermal water is injected back into the underground reservoir. The identified reserves of lower-temperature geothermal fluids are many times greater than the reserves of high-temperature fluids, providing an economic incentive to develop more-efficient power plants.

Warm water, at temperatures above 20°C, can be used directly for a host of processes requiring thermal energy. Thermal energy for swimming pools, space heating, and domestic hot water are the most widespread uses, but industrial processes and agricultural drying are growing applications of geothermal use. In 1995, the United States was using over 500 TJ/year of energy from geothermal sources for direct use (Lienau, et al., 1995). The cities of Boise, ID; Elko, NV; Klamath Falls, OR; and San Bernardino and Susanville, CA have geothermal district-heating systems where a number of commercial and residential buildings are connected to distribution pipelines circulating water at 54 to 93°C from the production wells (Rafferty, 1992).

The use of geothermal energy through ground-coupled heat pump technology has almost no impact on the environment and has a beneficial effect in reducing the demand for electricity. Geothermal heat pumps use the reservoir of constant temperature, shallow groundwater and moist soil as the heat source during winter heating and as the heat sink during summer cooling. The energy efficiency of geothermal heat pumps is about 30% better than that of air-coupled heat pumps and 50% better than electric-resistance heating. Depending on climate, advanced geothermal heat pump use in the United States reduces energy consumption and, correspondingly, power-plant emissions by 23 to 44% compared to advanced air-coupled heat pumps, and by 63 to 72% compared with electric-resistance heating and standard air conditioners (L'Ecuyer et al., 1993).

## Environmental Constraints

Geothermal energy is one of the cleaner forms of energy now available in commercial quantities. Geothermal energy use avoids the problems of acid rain, and it greatly reduces greenhouse gas emissions and other forms of air pollution. Potentially hazardous elements produced in geothermal brines are removed from the fluid and injected back into the producing reservoir. Land use for geothermal wells, pipelines, and power plants is small compared with land use for other extractive energy sources such as oil, gas, coal, and nuclear. Geothermal development projects often coexist with agricultural land uses, including crop production or grazing. The average geothermal plant occupies only 400 m<sup>2</sup> for the production of each gigawatt hour over 30 years (Flavin and Lenssen, 1991). The low life-cycle land use of geothermal energy is many times less than the energy sources based on mining, such as coal and nuclear, which require enormous areas for the ore and processing before fuel reaches the power plant. Low-temperature applications usually are no more intrusive than a normal water well. Geothermal development will serve the growing need for energy sources with low atmospheric emissions and proven environmental safety.

All known geothermal systems contain aqueous carbon dioxide species in solution, and when a steam phase separates from boiling water, CO<sub>2</sub> is the dominant (over 90% by weight) **noncondensable gas**. In most geothermal systems, noncondensable gases make up less than 5% by weight of the steam phase. Thus, for each megawatt-hour of electricity produced in 1991, the average emission of carbon dioxide by plant type in the United States was 990 kg from coal, 839 kg from petroleum, 540 kg from natural gas, and 0.48 kg from geothermal flashed-steam (Colligan, 1993). Hydrogen sulfide can reach moderate concentrations of up to 2% by weight in the separated steam phase from some geothermal fields.

At The Geysers geothermal field in California, either the Stretford process or the incineration and injection process is used in geothermal power plants to keep H<sub>2</sub>S emissions below 1 ppb (part per billion). Use of the Stretford process in many of the power plants at The Geysers results in the production and disposal of about 13,600 kg of sulfur per megawatt of electrical generation per year. [Figure 7.8.1](#), shows a typical system used in the Stretford process at The Geysers (Henderson and Dorighi, 1989).

The incineration process burns the gas removed from the steam to convert H<sub>2</sub>S to SO<sub>2</sub>, the gases are absorbed in water to form SO<sub>3</sub><sup>-2</sup> and SO<sub>4</sub><sup>-2</sup> in solution, and iron chelate is used to form S<sub>2</sub>O<sub>3</sub><sup>-2</sup> (Bedell and Hammond, 1987). [Figure 7.8.2](#) shows an incineration abatement system (Bedell and Hammond, 1987). The major product from the incineration process is a soluble thiosulfate which is injected into the reservoir with the condensed water used for the reservoir pressure-maintenance program. Sulfur emissions for each megawatt-hour of electricity produced in 1991, as SO<sub>2</sub> by plant type in the United

**FIGURE 7.8.1** Typical equipment used in the Stretford process for hydrogen sulfide abatement at The Geysers geothermal field. (Based on the diagram of Henderson, J.M. and Dorighi, G.P., *Geotherm. Resour. Counc. Trans.*, 13, 593–595, 1989.)

**FIGURE 7.8.2** Equipment used in the incineration process for hydrogen sulfide abatement at The Geysers geothermal field. (Based on the diagram of Bedell, S.A. and Hammond, C.A., *Geotherm. Resour. Counc. Bull.*, 16(8), 3–6, 1987.)

States was 9.23 kg from coal, 4.95 kg from petroleum, and 0.03 kg from geothermal flashed-steam (Colligan, 1993). Geothermal power plants have none of the nitrogen oxide emissions that are common from fossil fuel plants.

The waters in geothermal reservoirs range in composition from 0.1 to over 25 wt% dissolved solutes. The geochemistry of several representative geothermal fields is listed in [Table 7.8.4](#). Temperatures up to 380°C have been recorded in geothermal reservoirs in the United States, and many chemical species have a significant solubility at high temperature. For example, all of the geothermal waters are saturated

in silica with respect to quartz. As the water is produced, silica becomes supersaturated, and, if steam is flashed, the silica becomes highly supersaturated. Upon cooling, amorphous silica precipitates from the supersaturated solution. The high flow rates of steam and water from geothermal wells usually prevent silica from precipitating in the wells, but careful control of fluid conditions and residence time is needed to prevent precipitation in surface equipment. Silica precipitation is delayed in the flow stream until the water reaches a crystallizer or settling pond. There the silica is allowed to settle from the water, and the water is then pumped to an injection well.

## Operating Conditions

For electrical generation, typical geothermal wells in the United States have production casing pipe in the reservoir with an inside diameter of 29.5 cm, and flow rates usually range between 150,000 and 350,000 kg/hr of total fluid (Mefferd, 1991). The geothermal fields contain water, or water and steam, in the reservoir, and production rates depend on the amount of boiling in the reservoir and the well on the way to the surface. The Geysers geothermal field in California has only steam filling fractures in the reservoir, and, in 1987 (approximately 30 years after production began), the average well flow had decreased to 33,000 kg/hr of dry steam (Mefferd, 1991) supplying the maximum field output of 2000 MW<sub>2</sub>. Continued pressure decline has decreased the production.

In the Coso geothermal field near Ridgecrest, CA initial reservoir conditions formed a steam cap at 400 to 500 m depth, a two-phase (steam and water) zone at intermediate depth, and a liquid water zone at greater depth. Enthalpy of the fluid produced from individual wells ranges from 840 to 2760 kJ/kg (Hirtz et al., 1993), reservoir temperatures range from 200 to 340°C, and the fluid composition flowing from the reservoir into the different wells ranges from 100% liquid to almost 100% steam. Production wells have a wide range of flow rates, but the average production flow rate is 135,000 kg/hr (Mefferd, 1991). Much of the produced fluid is evaporated to the atmosphere in the cooling towers of the power plant, and only about 65% of the produced mass is available for injection into the reservoir at an average rate of 321,000 kg/hr (Mefferd, 1991).

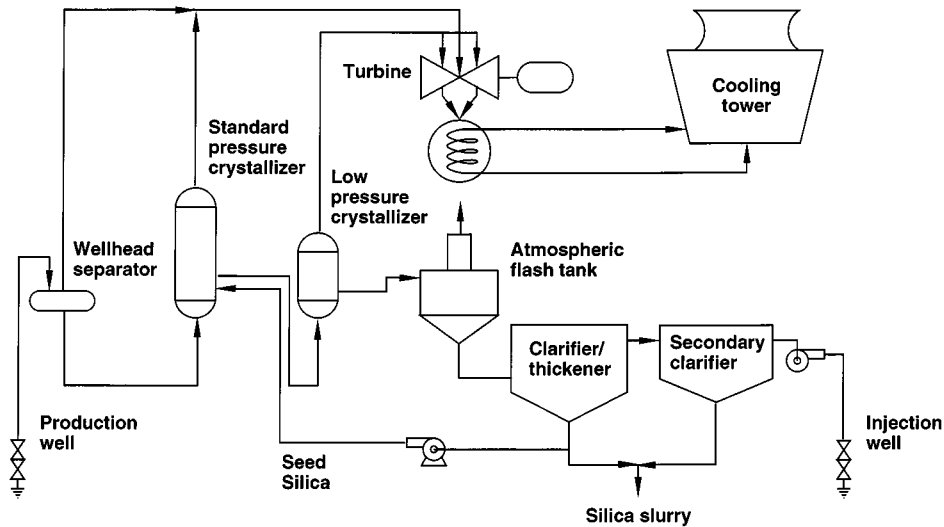

The Salton Sea geothermal system in the Imperial Valley of southern California has presented some of the most difficult problems in brine handling. Water is produced from the reservoir at temperatures between 300 and 350°C and total dissolved solid concentrations between 20 and 25% by weight at an average rate of 270,000 kg/hr (Mefferd, 1991). When up to 20% of the mass of brine boils during production, the salts are concentrated in the brine causing supersaturation with respect to several solid phases. Crystallizers and clarifier and thickener tanks are needed to remove solids from the injection water. [Figure 7.8.3](#) shows the flow stream for removal of solids from the vapor and brine (Signorotti and Hunter, 1992). Other power plants use the addition of acid to lower the pH and keep the solutes in solution (Signorotti and Hunter, 1992). The output from the crystallizers and clarifiers is a slurry of brine and amorphous silica. The methods used to dewater the salt and silica slurry from operations in the Salton Sea geothermal system are described by Benesi (1992). Approximately 80% of the produced water is injected into the reservoir at an average rate of 310,000 kg/hr.

## Acknowledgments

This study was supported in part by the U.S. Department of Energy, Assistant Secretary for Energy Efficiency and Renewable Energy, Geothermal Division, under DOE Idaho Operations Office Contract DE-AC07-941D13223.

## Defining Terms

**Binary geothermal plant:** A geothermal electric generating plant that uses the geothermal fluid to heat a secondary fluid that is then expanded through a turbine.

**FIGURE 7.8.3** The flow stream for removal of solids from the vapor and brine in typical power plants in the Salton Sea geothermal field. (Modified from the diagram of Signorotti, V. and Hunter, C.C., *Geotherm. Resour. Counc. Bull.*, 21(9), 277–288, 1992).

**Identified accessible base:** That part of the thermal energy of the Earth that is shallow enough to be reached by production drilling in the foreseeable future. *Identified* refers to concentrations of heat that have been characterized by drilling or Earth science evidence. Additional discussion of this and other resource terms can be found in Muffler (1979).

**Noncondensable gases:** Gases exhausted from the turbine into the condenser that do not condense into the liquid phase.

## 8.1 Steam Power Plant

*Lawrence Conway*

### Introduction

This section provides an understanding, at an overview level, of the steam power cycle. References were selected for the next level of study if required. There are noteworthy omissions in the section: site selection, fuel handling, civil engineering-related activities (like foundations), controls, and nuclear power.

Thermal power cycles take many forms, but the majority are fossil steam, nuclear, simple cycle gas turbine, and combined cycle. Of those listed, conventional coal-fired steam power is predominant. This is especially true in developing third-world countries that either have indigenous coal or can import coal inexpensively. These countries make up the largest new product market. A typical unit is shown in [Figure 8.1.1](#).

The Rankine cycle is overwhelmingly the preferred cycle in the case of steam power and is discussed first.

Topping and bottoming cycles, with one exception, are rare and mentioned only for completeness. The exception is the combined cycle, where the steam turbine cycle is a bottoming cycle. In the developed countries, there has been a move to the combined cycle because of cheap natural gas or oil. Combined cycles still use a reasonably standard steam power cycle except for the boiler. The complexity of a combined cycle is justified by the high thermal efficiency, which will soon approach 60%.

The core components of a steam power plant are boiler, turbine, condenser and feedwater pump, and generator. These are covered in successive subsections.

The final subsection is an example of the layout/and contents of a modern steam power plant.

As a frame of reference for the reader, the following efficiencies/effectivenesses are typical of modern fossil fuel steam power plants. The specific example chosen had steam conditions of 2400 psia, 1000°F main steam temperature, 1000°F reheat steam temperature: boiler thermal 92; turbine/generator thermal 44; turbine isentropic 89; generator 98.5; boiler feedwater pump and turbine combined isentropic 82; condenser 85; plant overall 34 (Carnot 64).

Nuclear power stations are so singular that they are worthy of a few closing comments. Modern stations are all large, varying from 600 to 1500 MW. The steam is both low temperature and low pressure (~600°F and ~1000 psia), compared with fossil applications, and hovers around saturation conditions

**FIGURE 8.1.1** Modern steam turbine generator.

or is slightly superheated. Therefore, the boiler(s), superheater equivalent (actually a combined moisture separator and reheater), and turbines are unique to this cycle. The turbine generator thermal efficiency is around 36%.

## Rankine Cycle Analysis

Modern steam power plants are based on the Rankine cycle. The basic, ideal Rankine cycle is shown in [Figure 8.1.2](#). The ideal cycle comprises the processes from state 1:

- 1–2: Saturated liquid from the condenser at state 1 is pumped isentropically (i.e.,  $S_1 = S_2$ ) to state 2 and into the boiler.
- 2–3: Liquid is heated at constant pressure in the boiler to state 3 (saturated steam).
- 3–4: Steam expands isentropically (i.e.,  $S_3 = S_4$ ) through the turbine to state 4 where it enters the condenser as a wet vapor.
- 4–1: Constant-pressure transfer of heat in the condenser to return the steam back to state 1 (saturated liquid).

**FIGURE 8.1.2** Basic Rankine cycle.

If changes in kinetic and potential energy are neglected, the total heat added to the rankine cycle can be represented by the shaded area on the T-S diagram in [Figure 8.1.2](#), while the work done by this cycle can be represented by the crosshatching within the shaded area. The thermal efficiency of the cycle ( $\eta$ ) is defined as the work ( $W_{NET}$ ) divided by the heat input to the cycle ( $Q_H$ ).

$$\eta = W_{NET}/Q_H = (h_3 - h_4)/(h_3 - h_2)$$

The Rankine cycle is preferred over the Carnot cycle for the following reasons:

The heat transfer process in the boiler has to be at constant temperature for the Carnot cycle, whereas in the Rankine cycle it is superheated at constant pressure. Superheating the steam can be achieved in the Carnot cycle during heat addition, but the pressure has to drop to maintain constant temperature. This means the steam is expanding in the boiler while heat added which is not a practical method.

The Carnot cycle requires that the working fluid be compressed at constant entropy to boiler pressure. This would require taking wet steam from point 1' in [Figure 8.1.2](#) and compressing it to saturated liquid condition at 2'. A pump required to compress a mixture of liquid and vapor isentropically is difficult to design and operate. In comparison, the Rankine cycle takes the saturated liquid and compresses it to boiler pressure. This is more practical and requires much less work.

The efficiency of the Rankine cycle can be increased by utilizing a number of variations to the basic cycle. One such variation is superheating the steam in the boiler. The additional work done by the cycle is shown in the crosshatched area in [Figure 8.1.3](#).

**FIGURE 8.1.3** Rankine cycle with superheat.

The efficiency of the Rankine cycle can also be increased by increasing the pressure in the boiler. However, increasing the steam generator pressure at a constant temperature will result in the excess moisture content of the steam exiting the turbine. In order to take advantage of higher steam generator pressures and keep turbine exhaust moistures at safe values, the steam is expanded to some intermediate pressure in the turbine and then reheated in the boiler. Following reheat, the steam is expanded to the cycle exhaust pressure. The reheat cycle is shown in [Figure 8.1.4](#).

Another variation of the Rankine cycle is the regenerative cycle, which involves the use of feedwater heaters. The regenerative cycle regains some of the irreversible heat lost when condensed liquid is pumped directly into the boiler by extracting steam from various points in the turbine and heating the condensed liquid with this steam in feedwater heaters. [Figure 8.1.5](#) shows the Rankine cycle with regeneration.

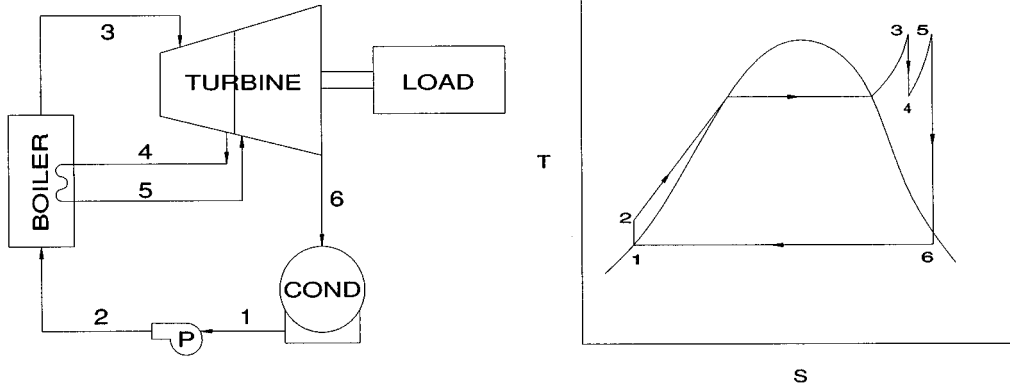

FIGURE 8.1.4 Rankine cycle with reheat.

FIGURE 8.1.5 Rankine cycle with regeneration.

The actual Rankine cycle is far from ideal as there are losses associated with the cycle. They include the piping losses due to friction and heat transfer, turbine losses associated with steam flow, pump losses due to friction, and condenser losses when condensate is subcooled. The losses in the compression (pump) and expansion process (turbine) result in an increase in entropy. Also, there is lost energy in heat addition (boiler) and rejection (condenser) processes as they occur over a finite temperature difference.

Most modern power plants employ some variation of the basic Rankine cycle in order to improve thermal efficiency. For larger power plants, economies of scale will dictate the use of one or all of the variations listed above to improve thermal efficiency. Power plants in excess of 200,000 kW will in most cases have 300°F superheated steam leaving the boiler reheat, and seven to eight stages of feedwater heating.

## Topping and Bottoming Cycles

Steam Rankine cycles can be combined with topping and/or bottoming cycles to form binary thermodynamic cycles. These topping and bottoming cycles use working fluids other than water. Topping cycles change the basic steam Rankine cycle into a binary cycle that better resembles the Carnot cycle and improves efficiency. For conventional steam cycles, state-of-the-art materials allow peak working fluid temperatures higher than the supercritical temperature for water. Much of the energy delivered into the cycle goes into superheating the steam, which is not a constant-temperature process. Therefore, a significant portion of the heat supply to the steam cycle occurs substantially below the peak cycle temperature. Adding a cycle that uses a working fluid with a boiling point higher than water allows more of the heat supply to the thermodynamic cycle to be near the peak cycle temperature, thus improving efficiency. Heat rejected from the topping cycle is channeled into the lower-temperature steam cycle. Thermal energy not converted to work by the binary cycle is rejected to the ambient-temperature reservoir. Metallic substances are the working fluids for topping cycles. For example, mercury was used as the topping cycle fluid in the 40-MW plant at Schiller, New Hampshire. This operated for a period of time but has since been dismantled. Significant research and testing has also been performed over the years toward the eventual goal of using other substances, such as potassium or cesium, as a topping cycle fluid.

Steam power plants in a cold, dry environment cannot take full advantage of the low heat rejection temperature available. The very low pressure to which the steam would be expanded to take advantage of the low heat sink temperature would increase the size of the low-pressure (LP) turbine to such an extent that it is impractical or at least inefficient. A bottoming cycle that uses a working fluid with a vapor pressure higher than water at ambient temperatures (such as ammonia or an organic fluid) would enable smaller LP turbines to function efficiently. Hence, a steam cycle combined with a bottoming cycle may yield better performance and be more cost-effective than a stand-alone Rankine steam cycle.

## Steam Boilers

A boiler, also referred to as a steam generator, is a major component in the plant cycle. It is a closed vessel that efficiently uses heat produced from the combustion of fuel to convert water to steam. Efficiency is the most important characteristic of a boiler since it has a direct bearing on electricity production.

Boilers are classified as either drum-type or once-through. Major components of boilers include an economizer, superheaters, reheaters, and spray attemperators.

### Drum-Type Boilers

Drum-type boilers (Figure 8.1.6) depend on constant recirculation of water through some of the components of the steam/water circuit to generate steam and keep the components from overheating. Drum-type boilers circulate water by either natural or controlled circulation.

*Natural Circulation.* Natural circulation boilers use the density differential between water in the downcomers and steam in the waterwall tubes for circulation.

*Controlled Circulation.* Controlled circulation boilers utilize boiler-water-circulating pumps to circulate water through the steam/water circuit.

### Once-Through Boilers

Once-through boilers, shown in Figure 8.1.7, convert water to steam in one pass through the system.

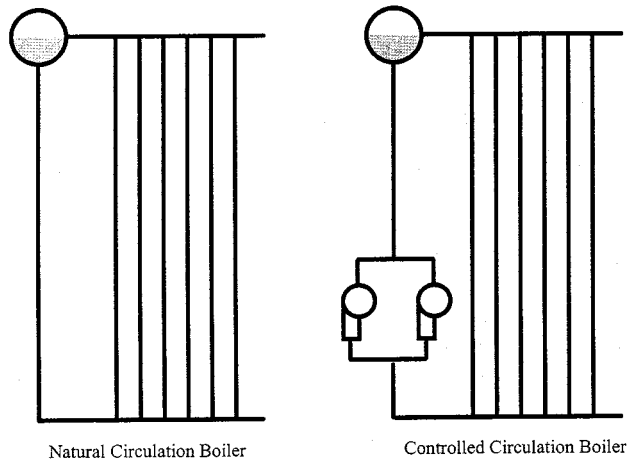

FIGURE 8.1.6 Drum boilers.

FIGURE 8.1.7 Once-through boilers.

**Major Boiler Components**

*Economizer.* The economizer is the section of the boiler tubes where feedwater is first introduced into the boiler and where flue gas is used to raise the temperature of the water.

*Steam Drum (Drum Units Only).* The steam drum separates steam from the steam/water mixture and keeps the separated steam dry.

*Superheaters.* Superheaters are bundles of boiler tubing located in the flow path of the hot gases that are created by the combustion of fuel in the boiler furnace. Heat is transferred from the combustion gases to the steam in the superheater tubes.

Superheaters are classified as primary and secondary. Steam passes first through the primary superheater (located in a relatively cool section of the boiler) after leaving the steam drum. There the steam receives a fraction of its final superheat and then passes through the secondary superheater for the remainder.

*Reheaters.* Reheaters are bundles of boiler tubes that are exposed to the combustion gases in the same manner as superheaters.

*Spray Attemperators.* Attemperators, also known as desuperheaters, are spray nozzles in the boiler tubes between the two superheaters. These spray nozzles supply a fine mist of pure water into the flow path of the steam to prevent tube damage from overheating. Attemperators are provided for both the superheater and reheater.

## Steam Turbines

### General

Each turbine manufacturer has unique features in their designs that impact efficiency, reliability, and cost. However, the designs appear similar to a non-steam-turbine engineer. Steam turbines for power plants differ from most prime movers in at least three ways. (1) All are extremely high powered, varying from about 70,000 to 2 million hp, and require a correspondingly large capital investment, which puts a premium on reliability. (2) Turbine life is normally between 30 and 40 years with minimal maintenance. (3) Turbines spend the bulk of their life at constant speed, normally 3600 or 1800 rpm for 60 Hz. These three points dominate the design of the whole power station, particularly of the steam turbine arrangement and materials.

In an earlier subsection it was shown that high steam supply temperatures make for more-efficient turbines. Even so, the range of steam conditions in modern service has narrowed because of these three points. Figure 8.1.8 shows the distribution of steam conditions of one manufacturer for turbines recently put in service. They are reasonably typical of the industry. This is one of the primary reasons that the steam turbines appear similar.

FIGURE 8.1.8 Steam turbine operating conditions.

### Blading

The most highly stressed component in steam turbines are the blades. Blades are loaded by centrifugal and steam-bending forces and also harmonic excitation (from nonuniform circumferential disturbances

in the blade path). All blades are loaded by centrifugal and steam-bending loads, and, in general, blades are designed to run when the harmonic excitation is resonant with the natural modes of the blade. If harmonic excitation is permitted on very long blades, the blades become impractically big. Fortunately, as the turbine runs at constant speed, the blade modes can be tuned away from resonant conditions so that the harmonic loads are significantly reduced. This forms a split in blade design, commonly referred to as tuned and untuned blading.

Blades guide steam throughout the turbine in as smooth and collision-free a path as possible. Collisions with blades (incidence) and sudden expansions reduce the energy available for doing work. Until recently, designers would match flow conditions with radially straight blades (called parallel sided). Turbine physics does not recognize this convenience for several reasons. The most visually obvious is the difference in tangential velocity between blade hub and tip. Twisted blades better match the flow (and area) conditions. The manufacturing process was costly and this cost confined application to long blades. Now, with numerical control machine tools, twist is being spread throughout the turbine. Twisted blades are a two-dimensional adjustment for a three-dimensional steam flow. The latest blades address the full three-dimensional nature of the flow by curving in three dimensions (bowed blades). Examples of all three classes of blades are shown in [Figure 8.1.9](#).

**FIGURE 8.1.9** Typical steam turbine blades.

### **Rotors**

After blades, steam turbine rotors are the second most critical component in the machine. Rotor design must account for (1) a large forging with uniform chemistry and properties in the high-strength alloys needed; (2) centrifugal force from the rotor itself and the increase from the centrifugal pull of the blades; (3) resistance to brittle fracture potentially occurring in the LP cylinder when the machine is at high speed, but the material is still not up to operational temperature; (4) creep of the high-pressure (HP) and intermediate-pressure (IP) rotors under steady high-temperature load. The life cycle is further complicated by the various transient fatigue loads occurring during load changes and start-up. Two further events are considered in rotor design: torsional and lateral vibrations caused by both harmonic steam and electrical loads. As with tuned blades, this is normally accommodated by tuning the primary modes away from running resonance.

### **Choosing the Turbine Arrangement**

The turbine shaft would be too flexible in one piece if all the blades were to follow sequentially. It is therefore cut up into supportable lengths. The “cuts” in the shaft result in HP, IP, and LP cylinders. Manufacturers address the grouping of cylinders in many different ways, depending upon steam conditions. It is U.S. practice to combine HPs and IPs into one cylinder for the power range of about 250 to 600 MW (rare in the rest of the world). One manufacturer’s grouping, shown in [Figure 8.1.10](#), is fairly

representative of the industry. So far, the text has discussed the steam flow as though it expanded monotonically through the turbine. This is usually not the case for two reasons. The most common steam conditions, shown in Figure 8.1.10, would cause the steam exiting the last row of blades to be very wet and cause excessive erosion. Thermal efficiency can be raised by removing the steam from the turbine, reheating, and then returning it to the blade path; this increases the “average” heat supply temperature. The turbine position for reheat is normally between the HP and IP turbines.

FIGURE 8.1.10 Steam turbine product combinations.

There is one further geometric arrangement. Cylinders need not be all on one shaft with a single generator at the end. A cross-compound arrangement exists in which the steam path is split into two separate parallel paths with a generator on each path. Commonly, the split will be with paths of HP-LP-generator and IP-LP-generator. Torsional and lateral vibration difficulties are more easily prevented with shorter trains, which make the foundation more compact. The primary shortcoming is the need for two generators and resultant controls.

Historically, steam turbines have been split into two classes, reaction and impulse, as explained in Basic Power Cycles. This difference in design makes an observable difference between machines. Impulse turbines have fewer, wider stages than reaction machines. As designs have been refined, the efficiencies and lengths of the machines are now about the same. For a variety of reasons, the longer blades in the LP ends are normally reaction designs. As each stage may now be designed and fabricated uniquely, the line between impulse and reaction turbines will probably disappear. Turbine blading is broadly split between machines as follows:

	Cylinder				
	HP		IP	LP	
	Control Stage	Remainder		Short Blades	End Blade(s)
Reaction turbines	Impulse	Reaction	Reaction	Reaction	Reaction
Impulse turbines	Impulse	Impulse	Impulse	Impulse	Reaction

**Materials**

Materials are among the most variable of all turbine parts with each manufacturer striving to improve performance by using alloying and heat-treatment techniques. It follows that accurate generalizations are difficult. Even so, the following is reasonably representative:

Item	Common Material Description								
	Moderate and cold temperature HP and IP blades	Moderate temperature rotating stator blades	Cold LP rotating blades	High temperature rotors	Low temperature rotors	Hot	LP	High-temperature bolting	Cold bolting
Mod'd SS403	SS304	SS403	SS403 or 17/4 PH	1CrMoV, occasionally 12Cr	3.5 NiCrMoV	1.25Cr or 2.25Cr	Carbon, steel	SS422	B16

## Cylinders and Bolting

These items are relatively straightforward, especially the LP cylinder, except for the very large sizes and precision required for the castings and fabrications. A large HP-IP cylinder has the temperature and pressure loads split between an inner and outer cylinder. In this case, finding space and requisite strength for the bolting presents a challenge for the designer.

## Valves

The turbine requires many valves for speed control, emergency control, drains, hydraulics, bypasses, and other functions. Of these, there are four valves distinguished by their size and duty. They are throttle or stop, governor or control, reheat stop, and reheat interceptor.

The throttle, reheat stop, and reheat interceptor valves normally operate fully open, except for some control and emergency conditions. Their numbers and design are selected for the appropriate combination of redundancy and rapidity of action. The continuous control of the turbine is accomplished by throttling the steam through the governor valve. This irreversible process detracts from cycle efficiency. In some circumstances, the efficiency detraction is reduced by a combination of throttling and reducing the boiler pressure (normally called sliding pressure).

## Heat Exchangers, Pumps, and Other Cycle Components

### Heater Exchangers

*Heaters.* There are two classifications of condensate and feedwater heaters: the open or direct contact heater and the closed or tube-and-shell heater.

*Open Heaters.* In an open heater, the extraction or heating steam comes in direct contact with the water to be heated. While open heaters are more efficient than closed heaters, each requires a pump to feed the outlet water ahead in the cycle. This adds cost, maintenance, and the risk of water induction to the turbine, making the closed heater the preferred heater for power plant applications.

*Closed Heaters.* These employ tubes within a shell to separate the water from the heating steam (see [Figure 8.1.11](#)). They can have three separate sections where the heating of the feedwater occurs. First is the drain cooler section where the feedwater is heated by the condensing heating steam before cascading back to the next-lower-pressure heater. The effectiveness of the drain cooler is expressed as the drain cooler approach (DCA), which is the difference between the temperature of the water entering the heater and the temperature of the condensed heating steam draining from the heater shell. In the second section (condensing section), the temperature of the water is increased by the heating steam condensing around

**FIGURE 8.1.11** Shell and tube feedwater heater.

the tubes. In the third section (desuperheating section), the feedwater reaches its final exit temperature by desuperheating the extraction steam. Performance of the condensing and superheating sections of a heater is expressed as the terminal temperature difference (TTD). This is the difference between the saturation temperature of the extraction steam and the temperature of the feedwater exiting the heater. Desuperheating and drain cooler sections are optional depending on the location of the heater in the cycle (i.e., desuperheating is not necessary in wet extraction zones) and economic considerations.

The one exception is the deaerator (DA), which is an open heater used to remove oxygen and other gases that are insoluble in boiling water. The DA is physically located in the turbine building above all other heaters, and the gravity drain from the DA provides the prime for the boiler feed pump (BFP).

Two other critical factors considered in heater design and selection are (1) venting the heater shell to remove any noncondensable gases and (2) the protection of the turbine caused by malfunction of the heater system. Venting the shell is required to avoid air-bounding a heater, which reduces the performance or, in extreme cases, puts the heater out of service. Emergency drains to the condenser open when high water levels are present within the shell. Check valves on the heating steam line are also used, and a water detection monitor can be installed to enable operators to take prompt action when water is present.

**Condenser.** The steam turbines employ surface-type condensers comprising large shell-and-tube heat exchangers operating under vacuum. The condenser (1) reduces the exhaust pressure at the last-stage blade exit to extract more work from the turbine and (2) collects the condensed steam and returns it to the feedwater-heating system. Cooling water circulates from the cooling source to the condenser tubes by motor-driven pumps, which may be centrifugal, propeller, or mixed-flow type. Multiple pumps, each rated less than 100% of required pumping power, are used to allow to operation with one or more pumps out of service and operate more efficiently at part load. Cooling water is supplied from either a large heat sink water source, such as a river, or from cooling towers. The cooling in the cooling tower is assisted by evaporation of 3 to 6% of the cooling water. Airflow is natural draft (hyperbolic towers) or forced draft. The noncondensable gases are removed from the condenser by a motor-driven vacuum pump or, more frequently, steam jet air ejectors which have no moving parts.

## Pumps

**Condensate Pump.** Condensate is removed from the hot well of the condenser and passed through the LP heater string via the condensate pump. Typically, there will be two or more vertical (larger units) or horizontal (medium and small units) motor-driven centrifugal pumps located near the condenser hot well outlet. Depending on the size of the cycle, condensate booster pumps may be used to increase the pressure of the condensate on its way to the DA.

**Feedwater Booster Pump.** The DA outlet supplies the feedwater booster pump which is typically a motor-driven centrifugal pump. This pump supplies the required suction head for the BFP.

**FIGURE 8.1.12** Boiler feed pump turbine.

*Boiler Feed Pump.* These pumps are multiple-stage centrifugal pumps, which, depending on the cycle, can be turbine or motor driven. BFP turbines (BFPT), [Figure 8.1.12](#), are single-case units which draw steam from the main turbine cycle and exhaust to the main condenser. Typical feedpump turbines require 0.5% of the main unit power at full-load operation. Multiple pumps rated at 50 to 100% each are typically used to allow the plant to operate with one pump out of service.

### Generators

The electric generator converts rotating shaft mechanical power of the steam turbine to three-phase electrical power at voltages of between 13.8 and 26 kV, depending upon the power rating. The generator comprises a system of ventilation, auxiliaries, and an exciter. [Figure 8.1.13](#) shows an installed hydrogen-cooled generator and brushless exciter of about 400 MW. Large generators greater than 25 MW usually have a solid, high-strength steel rotor with a DC field winding embedded in radial slots machined into the rotor. The rotor assemblage then becomes a rotating electromagnet that induces voltage in stationary conductors embedded in slots in a laminated steel stator core surrounding the rotor (see [Figure 8.1.14](#)).

The stator conductors are connected to form a three-phase AC armature winding. The winding is connected to the power system, usually through a step-up transformer. Most steam turbines driven by fossil-fired steam use a two-pole generator and rotate at 3600 rpm in 60-Hz countries and 3000 rpm in

FIGURE 8.1.13 Generator and exciter.

FIGURE 8.1.14 Generator magnetic paths.

50-Hz countries. Most large steam turbines driven by nuclear steam supplies use a four-pole generator and rotate at 1800 or 1500 rpm for 60 and 50 Hz, respectively.

### **Generator Ventilation**

Cooling the active parts of the generator is so important that generators are usually classified by the type of ventilation. Air-cooled generators are used commonly up to 100 MW, though some applications exist up to 200 MW. Some use ambient air drawing air through filters and others recirculate air through air-to-water heat exchangers. Above 100 MW, most manufacturers offer hydrogen for the overall cooling, sometimes up to 1400 MW. Hydrogen has 14 times the specific heat of air and is used at lower density. This contributes to much better cooling and much lower windage and blower loss. The frame must be designed to withstand the remote circumstance of a hydrogen explosion and requires shaft seals. Hydrogen is noncombustible with purities greater than 70%. Generator purities are usually maintained well above 90%. Depending upon the manufacturer, generators with ratings above 200 to 600 MW may have water-cooled stator winding, while the remaining components are cooled with hydrogen.

### **Generator Auxiliaries**

Large generators must have a lubrication oil system for the shaft journal bearings. Major components of this system are pumps, coolers, and a reservoir. In most cases, the turbine and generator use a combined system. For hydrogen-cooled generators, a shaft seal system and hydrogen supply system are needed. The shaft seal system usually uses oil pumped to a journal seal ring at a pressure somewhat higher than the hydrogen pressure. Its major components are pumps, coolers, and reservoir, similar to the lubrication system. The hydrogen supply system consists of a gas supply and regulators. A CO<sub>2</sub> supply is used to purge the generator when going from air to hydrogen or vice versa to avoid a combustible hydrogen/air mixture. The stator winding water supply again uses pumps, coolers, and a reservoir. It needs demineralizers to keep the water nonconducting and provisions to control oxygen content to avoid copper oxide corrosion which might break off and clog water passages.

### **Excitation**

The rotor field winding must have a DC source. Many generators use rotating “collector” rings with stationary carbon brushes riding on them to transfer DC current from a stationary source, such as a thyristor-controlled “static” excitation system, to the rotor winding.

A rotating exciter, known as a brushless exciter, is used for many applications. It is essentially a small generator with a rotating rectifier and transfers DC current through the coupling into the rotor winding without the need for collectors and brushes.

### **Modern Steam Power Plant — An Example**

The purpose of a power plant is to generate electric power. It does so by converting chemical energy contained in fuel into thermal energy in steam; thermal energy in steam into mechanical energy in the turbine/generator; and mechanical energy in the turbine/generator into electrical energy.

Operating efficiency of a typical modern steam plant is about 35 to 45%. The primary losses result from (1) heat sink losses in the condenser, (2) boiler losses, and (3) electrical losses.

Steam plant capacities have ranges from 50 to 1600 MW; however, modern plants are being designed for more than 250 MW due to energy demands, system load requirements, and economies of scale in the larger centralized stations.

### Major Steam Plant Components

Steam plants comprise three major components (1) boiler, (2) turbine, and (3) main steam condenser. The boiler and turbine are covered in earlier subsections and neither will be repeated here. A graphic of the entire fluid or work cycle is shown in [Figure 8.1.15](#).

**FIGURE 8.1.15** Steam power plant schematic.

**Condenser.** The condenser (also discussed earlier) is a large heat exchanger that takes the LP turbine exhaust steam and converts it back to water. The steam passes over a bundle of tubes located in the condenser and is cooled by the circulating water which passes through the tubes. The steam is condensed into water drops and collected in the condenser hot well. The condensate is delivered from the condenser hot well through the condensate and feedwater systems and back to the boiler where it becomes steam again.

**Fuels.** Coal, oil, and gas are used to fuel fossil plants. Although coal possesses the highest carbon content, it also possesses the highest sulfur, nitrogen, and ash content, thereby requiring air pollution-control equipment. Controlling these pollutants requires the installation of scrubbers for sulfur control; overfire air or gas recirculation for in-furnace nitrous oxides ( $\text{NO}_x$ ) control; selective catalytic reduction (SCR) for post-combustion  $\text{NO}_x$  control; electrostatic precipitators (ESP) or baghouse for fly ash control; and pneumatic, hydraulic, or mechanical ash-handling systems for bottom ash removal. Fuel oil and natural gas are chiefly composed of compounds of hydrogen and carbon (hydrocarbons) with very low percentages of sulfur, nitrogen, and ash and do not require pollution-control equipment.

### Power Plant System

Power plants comprise the following main systems: fuel handling, air handling, gas handling, main steam, reheat steam, auxiliary steam, extraction steam, condensate, feedwater, circulating water, and air removal.

*Fuel-Handling System.* The fuel-handling system consists of delivery, transfer, and processing. Fuel is delivered to the plant from the fuel source by truck, boat, rail (coal and oil), or pipeline (oil and gas). Once delivered, the fuel is transferred from the delivery point to various locations throughout the fuel-handling system. For coal and oil, the fuel is either transferred to storage or sent directly to the boiler. For gas, the fuel is directly transferred to the boiler without any storage. Prior to delivery to the boiler for burning, the fuel must be processed so that it will readily mix with air and burn completely. Coal must be broken down into smaller pieces by breakers and crushers. Oil requires steam, air, or mechanical atomization. Gas requires no processing.

*Air/Gas-Handling Systems.* Steam plants are classified as either pressurized or balance draft. Pressurized systems include forced-draft fans to provide the necessary air for fuel, an air heater to transfer heat from the exit gas to the inlet air, and a wind box where the air is stored and then directed to the individual burner ports. A balanced draft system includes all of the components of the pressurized systems and induced-draft fans to exhaust the combustion products from the boiler, thus maintaining the furnace under slightly negative pressure.

*Main Steam System.* The main steam system controls and regulates the flow of high-temperature, HP steam generated in the boiler furnace as it moves from the boiler to the turbine. The components in this system include main steam piping, safety valves, main steam stop valve, steam chest, and turbine control valve.

*Reheat Steam System.* The reheat steam system improves overall plant efficiency by increasing the energy of steam that has been exhausted from the HP turbine. Steam from the hot reheat steam system is delivered to the IP turbine. The components of the reheat steam system are cold reheat piping, the reheater section of the boiler, hot reheat piping, safety relief valves, reheat stop valves, reheater desuperheater, and intercept valves.

*Auxiliary Steam System.* The auxiliary steam system directs and regulates auxiliary steam from the cold reheat line to the auxiliary steam users. The auxiliary steam system users are typically steam/air preheating coils, outdoor freeze protection/heat tracing, deaerating heater pegging, turbine-driven BFP testing, turbine seals, and plant heating.

*Extraction Steam System.* The extraction steam system directs and regulates the flow of the extraction steam from the turbine to the feedwater heaters, BFPT, and auxiliary steam system. The extraction steam heats the feedwater that flows through the heaters, thus improving overall plant efficiency. In large steam plants, six to eight stages of feedwater heating are typical.

*Condensate System.* The condensate system consists of condensate pumps, LP feedwater heaters, and DA. The condensate pumps remove condensate from the main condenser hot well, increase condensate pressure, and deliver it through the LP heaters to the DA. During this process, the condensate is heated, deaerated, and chemically treated.

*Feedwater System.* The feedwater system consists of BFPs, HP feedwater heaters, piping, and valves. The boiler feedwater pumps deliver water from the DA storage tank, through the HP heaters, and into the boiler. Feedwater is supplied at sufficient quantities and pressure to satisfy unit demands during startups, shutdowns, and normal operation. The BFP is also the primary source of spray water for the superheater and reheater desuperheaters for control of the main and reheat steam temperatures, respectively.

BFPs can either be turbine or motor driven. Booster pumps may be required to provide additional net positive suction head (NPSH) to the main and start-up BFPs for plants designed with a low DA setting.

*Circulating Water System.* The circulating water system pumps cooling water through the condenser tubes at sufficient capacity, temperature, and pressure to absorb the latent heat in the LP exhaust steam.

Circulating water systems are classified as once-through systems, when a large water source is available, or recirculating systems employing cooling towers. In once-through systems, circulating water pumps deliver water from the plant water supply (river, lake, or ocean) through the condenser tubes to absorb latent heat in the exhaust steam. Water flows through the system once and is returned to its source. The major parts of this system are screens, pumps, expansion joints, valves, and piping. In recirculating systems, the cooling tower cools the heated circulating water from the main condenser by exposing it to air. The cooled water is stored in a basin located below the tower and is then circulated back through the system by the circulating water pumps.

*Air Evacuation System.* The air evacuation system removes air and noncondensable gases in the main steam condenser and helps maintain the vacuum created by the volume reduction of the condensing steam during normal operation. The system also establishes a normal vacuum in the condenser prior to turbine start-up.

## 8.2 Gas Turbines

---

*Steven I. Freedman*

### Overview

Gas turbines are steady-flow power machines in which a gas (usually air) is compressed, heated, and expanded for the purpose of generating power. The term *turbine* is the component which delivers power from the gas as it expands; it is also called an expander. The term *gas turbine* refers to a complete power machine. The term gas turbine is often shortened to simply turbine, which can lead to confusion with the term for an expander.

The basic thermodynamic cycle on which the gas turbine is based is known as the Brayton cycle. Gas turbines may deliver their power in the form of torque or one of several manifestations of pneumatic power, such as the thrust produced by the high-velocity jet of an aircraft propulsion gas turbine engine.

Gas turbine machines vary in size from large, 250,000-hp utility machines, to small automobile, truck, and motorcycle turbochargers producing as little as 5 hp.

Gas turbines are used in electric power generation, propulsion, and compressor and pump drives. The most efficient power generation systems in commercial service are gas turbine combined cycle plants with power-to-fuel energy efficiencies of more than 50% (higher heating value basis) or 55% (lower heating value basis). Systems five points higher in efficiency are now under development and are being offered commercially, and systems of even higher efficiency are considered feasible.

### History

The fourth quarter of the 19th century was one of great innovation in power machinery. Along with the spark-ignited gasoline engine, the compression-ignited diesel engine, and the steam turbine, engineers applied their skills to several hot-air engines. Charles Curtis received the first U.S. patent for a complete gas turbine on June 24, 1895. Aegidius Elling built the first gas turbine in 1903, which produced 11 hp.

The first commercial stationary gas turbine engineered for power generation was a 4000-kW machine built by the Brown Boveri Company in Switzerland in 1939.

Aviation provided the impetus for gas turbine development in the 1930s. In Germany, Hans von Ohain's first engine ran in March 1937. Frank Whittle's first engine ran in England in April 1937. The first airplane flight powered by a gas turbine jet engine was in Germany on August 27, 1939. The first British airplane powered by a gas turbine flew on May 15, 1941.

A Swiss railway locomotive using a gas turbine was first run in 1941. The first automobile powered by a gas turbine was a British Rover, which ran in 1950. And, in 1956, a gas turbine-powered Plymouth car drove over 3000 miles on a coast-to-coast exhibition trip in the United States.

### Fuels and Firing

The first heat engines were external combustion steam engines. The combustion products never came in contact with the working fluid, so ash, corrosive impurities, and contaminants in the fuel or exhaust did not affect the internal operation of the engine. Later, internal combustion (piston) engines were developed. In these engines, a mixture of air and fuel burned in the space enclosed by the piston and cylinder walls, thereby heating the air. The air and combustion products formed the working fluid, and contacted internal engine parts.

Most gas turbines in use today are internal combustion engines and consequently require clean fuels to avoid corrosion and erosion of critical turbine components. Efforts were made to develop gas turbines rugged enough to burn residual or crude oil. However, due to the higher efficiencies obtainable by burning extremely clean fuel at higher temperatures, there is little current interest in using liquid fuel other than (clean) distillate oil in gas turbines. Interest in the use of residual oil is now centered on gasifying and cleaning these fuels prior to use.

A few externally heated gas turbines have been built for use with heavy oil, coal, nuclear reactor, radioisotope, and solar heat sources. However, none of these has become commercial. The added cost and pressure drop in the externally fired heater make externally fired gas turbines expensive. Because the working fluid temperature cannot be greater than that of the walls of the fired heater, externally fired gas turbines are substantially less efficient than modern internal combustion gas turbines with internally cooled blades.

The only internal combustion coal-fired gas turbine entering commercial service is the pressurized fluidized bed (PFB) combustion system. In the PFB, air discharged from the compressor of the turbine is used to fluidize a bed of limestone or dolomite in which coal is burned. The bed is maintained at modest temperature so that the ash in the coal does not form sticky agglomerates. Fortunately, this temperature range also minimizes  $\text{NO}_x$  formation and allows capture of sulfur dioxide ( $\text{SO}_2$ ) in the bed. Bed temperature is maintained in the desired range by immersed boiler tubes. Carryover fly ash is separated from gaseous combustion products by several stages of cyclone inertial separators and, in some cases, ceramic filters. The power turbine is modified to accommodate the combustion products, which after mechanical cleanup may still contain particles as large as 3 to 5  $\mu\text{m}$ .

The most common gas turbine fuels today are natural gas and distillate oil. To avoid hot corrosion by alkali metal sulfates, the total sodium and potassium content of the fuel is typically limited to less than 5 ppm. Liquid fuels may also contain vanadium, which also causes corrosion. Fuels must be ash-free because particles larger than 3 to 5  $\mu\text{m}$  rapidly erode blades and vanes. Experimental prototype gas turbines using pulverized coal pressurized combustors have not demonstrated adequate life. Hybrid systems — in which the moderate-temperature coal combustion products are mechanically cleaned and heated to higher temperature by use of a clean fuel such as natural gas or distillate oil — are the subject of ongoing development.

## Efficiency

The term *efficiency* is applied not only to complete power generation machines but also to the individual compression, expansion, and combustion processes that make up the gas turbine operating cycle. Different definitions of efficiency apply in each case. In an **expansion process**, the **turbine efficiency** is the ratio of the actual power obtained to the maximum power that could have been obtained by expanding the gas reversibly and adiabatically between the same initial and final pressures.

Gas turbines typically involve high-speed gas flows, so appreciable differences exist between the static pressure and temperature and the total (or stagnation) pressure and temperature. Care must be taken in interpreting data to be sure that the pressure condition — static or stagnation — at each component interface is properly used.

Irreversible losses in one stage of an expansion process show up as heat (increased temperature) in later stages and add to the power delivered by such stages. Hence, a distinction exists between the polytropic efficiency (used to describe the efficiency of a process of differential pressure change) and the adiabatic (complete pressure change) efficiency. The efficiency of compressors and turbines based on their inlet and outlet pressures is called the isentropic or adiabatic efficiency. Unfortunately, both terms are reported in the literature, and confusion can exist regarding the meaning of the term *efficiency*.

**Combustion efficiency** in well-engineered and well-built internal combustion gas turbines is almost always close to 100%. The combustion losses appear as carbon monoxide, unburned hydrocarbons, and soot, which are typically below 100 ppm, with clean fuels.

The **gas turbine or engine efficiency** is the ratio of the net power produced to the energy in the fuel consumed. The principal gas turbine fuels are liquid and gaseous hydrocarbons (distillate oil and natural gas) which have high hydrogen content. Consequently, the term *engine efficiency* needs to be qualified as to whether it is based on the higher or the lower heat content of the fuel (the difference between the two being the latent heat of condensation of the water vapor in the products of combustion). Utility fuel transactions are traditionally based on higher heating values, and most engine publications presume the lower heating value of the fuel as the efficiency basis.

Engineers analyze gas turbine machines to evaluate improvements in component performance, in higher temperature and pressure ratio designs, and in innovative cycles. Ideal case cycle calculations generally assume the following:

- Air (with either constant or temperature-dependent specific heats) is the working fluid in both turbine and compressor (with equal mass flows);
- Air is the working fluid in both turbine and compressor but with the turbine mass flow greater by the amount of fuel used.

Components are modeled with or without frictional pressure drops, and heat transfer effectiveness may be ideal (unity) or actual, depending on the purpose of the analysis. Use of compressor air for cooling of high-temperature structure, nozzles, and blades are modeled in varying degrees of complexity. Two-dimensional temperature profiles or pattern factors exist. Component inlet and exit total pressure losses should be included in cycle analyses.

## Gas Turbine Cycles

Gas turbine cycles are usually plotted on temperature-entropy (T-S) coordinates. Readers unfamiliar with entropy are referred to the chapter on thermodynamics. The T-S plot is useful in depicting cycles because in an adiabatic process — as is the case for turbines and compressors — the power produced or consumed is the product of the mass flow and the enthalpy change through the process. Thus, temperature difference, which is found on a T-S plot, is proportional to the power involved. Additionally, the heat exchange in a process involving zero power — such as a combustor or heat exchanger — is the product of the absolute temperature and the entropy change. On a T-S chart, the area under a process line for a combustor or heat exchanger is the heat exchanged.

The slope of a constant-pressure line on a T-S diagram is proportional to the absolute temperature. Consequently, lines of constant pressure become steeper, and diverge as the temperature increases. This illustrates that more work is obtained expanding a gas between fixed pressures at higher temperatures than at lower temperatures. [Figure 8.2.1](#) shows a comparison of the process of an ideal and an actual simple cycle gas turbine on a T-S diagram. The increased compressor power consumption and the decreased turbine power generation in the actual cycle are shown to provide an understanding of the differences that component efficiencies make on machine performance.

**FIGURE 8.2.1** T-S diagram for a simple cycle illustrating the differences in compressor and turbine power for ideal (100% efficient) and actual components.

The incremental amount of power produced per differential pressure change in the gas is given by

$$d(\text{Power/mass flow}) = -RT dp/p$$

Two phenomena are illustrated by this equation. First, power is proportional to the absolute temperature of the gas. Second, power is proportional to the percent change in pressure. This latter point is important in understanding the effect of pressure losses in cycle components. In heat exchangers, the proper measure of power lost is the percent pressure drop.

### Cycle Configurations

The basic Brayton cycle consists of a compressor, a combustor or burner, and an expander. This configuration is known as the simple cycle. In idealizing the actual cycle, combustion is replaced by constant-pressure heat addition, and the cycle is completed by the assumption that the exhaust to ambient pressure could be followed by a zero-pressure-loss cooling to inlet conditions.

A T-S diagram of the simple cycle gas turbine with an upper temperature limit set by metallurgical conditions is illustrated in Figure 8.2.2 for cycles of low, medium, and high pressure ratios. The heat addition is only by fuel combustion, simplified here to be without mass addition or change in specific heat of the working fluid.

FIGURE 8.2.2 T-S diagram illustrating the power and heat (fuel) requirements at low, best, and high cycle pressures.

It is seen that the low-pressure-ratio cycle requires a large heat addition, which leads to a low efficiency, and the high-pressure-ratio cycle has turbine power output barely greater than the compressor power requirement, thereby leading to low net output and low efficiency. At intermediate pressure ratios, the turbine power output is substantially higher than the compressor power requirement, and the heat addition is modest in comparison with the difference between the turbine and compressor powers. There is an optimum pressure ratio for maximum efficiency, which is a function mainly of the maximum gas temperature in the machine, and to a lesser extent, by the component efficiencies, internal pressure losses, and the isentropic exponent. There is another optimum pressure ratio for maximum specific power (power per unit mass flow).

As the achievable turbine inlet temperature increases, the optimum pressure ratios (for both maximum efficiency and maximum specific power) also increase. The optimum pressure ratio for maximum specific power is at a lower pressure level than that for maximum efficiency for all cycles not employing a recuperator. For cycles with a recuperator, the reverse is true: maximum efficiency occurs at a lower

pressure ratio than maximum specific power. Heavy-duty utility and industrial gas turbines are typically designed to operate near the point of maximum specific power, which approximates lowest equipment cost, while aeroderivative gas turbines are designed to operate near the point of maximum efficiency, approximating highest thrust. Figure 8.2.3 shows a performance map (efficiency as a function of power per unit of air flow) for a simple cycle gas turbine for two turbine inlet temperatures. It is seen that at higher temperature, both the efficiency and specific power increase, as well as the optimum pressure ratios for both the maximum efficiency and maximum specific power conditions.

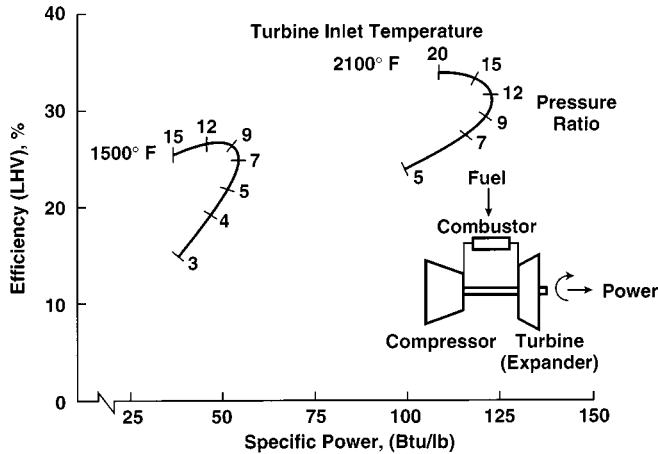

FIGURE 8.2.3 Performance map of a simple cycle gas turbine.

Aircraft gas turbines operate at temperatures above the limit of turbine materials by using blades and vanes with complex internal cooling passages. The added cost is economically justified because these machines can command high prices in the aircraft propulsion marketplace. Aeroderivative engines have higher pressure ratios, higher efficiencies, and lower exhaust temperatures than heavy-duty machines. The stationary power markets served by aeroderivative gas turbines are principally pipeline compressor stations and oil/gas production wells. Aeroderivative gas turbines also are economically advantageous for intermediate-duty applications.

## Components Used in Complex Cycles

**Recuperators** and **regenerators** recover heat from the turbine exhaust and use it to preheat the air from the compressor before it enters the combustor, thereby saving fuel. This heat transfer is shown in Figure 8.2.4. While recuperators and regenerators are quite similar thermodynamically, they are totally different in design. Recuperators are conventional heat exchangers in which hot and cold gases flow steadily on opposite sides of a solid (usually metal) wall.

Regenerators are periodic-flow devices. Fluid streams flow in opposite directions through passages in a wheel with heat storage walls. The wheel rotates, transferring heat from one stream to the other. Regenerators usually use a nest of very small parallel passages oriented axially on a wheel which rotates between hot and cold gas manifolds. Such regenerators are sometimes used in industrial processes for furnace heat recovery, where they are referred to as heat wheels. Because regenerators are usually more compact than recuperators, they are used in automotive gas turbines (under development). The difficulty in using regenerators on gas turbines intended for long life is that the two gas streams are at very different pressures. Consequently, the seals between the manifolds and the wheel must not leak excessively over the maintenance overhaul interval of the engine. If they do, the power loss due to seal leakage will compromise engine power and efficiency. Figure 8.2.5 shows a performance map for the regenerative

**FIGURE 8.2.4** T-S diagram illustrating the heat transfer from the turbine exhaust to the compressor discharge accomplished by a recuperator/regenerator.

**FIGURE 8.2.5** Performance map of a regenerative cycle gas turbine.

gas turbine cycle for two temperatures. It is seen that as the temperature increases, the efficiency, specific power, and optimum pressure ratio all increase.

Current research on the recovery of gas turbine exhaust heat includes examination of thermochemical recuperation, where exhaust heat is used to effect a chemical reaction (reforming) of the fuel with steam, thereby increasing the heating value of the fuel. Although this process is feasible, research is underway to determine if it is practical and economic.

Industrial process compressors frequently use **intercoolers** to reduce compressor power when the compressor has a high pressure ratio and operates for a large number of hours per year. When analyzing cycles with intercoolers, the added pressure drops in the compressor interstage entrance and exit diffuser and scroll and the pressure drop in the intercooler itself should be included.

In a similar manner, turbine reheat can be used to increase the power output of a large-pressure-ratio turbine. This is the thermodynamic principle in turbojet afterburner firing. Turbine reheat increases

power, but decreases efficiency unless the turbine exhaust heat is used for additional power generation, as is the case with a combined cycle, or is used with a recuperator to preheat combustor inlet air.

Intercoolers and reheat burners increase the temperature difference between the compressor and turbine discharges, thereby increasing the opportunity to use a recuperator to preheat the burner air with exhaust heat. An intercooled recuperated (ICR) machine is at present in development. The efficiency decrease at part load of an ICR gas turbine is much less than of conventional simple cycle machines.

Small gas turbines have uncooled turbine blades as a result of the difficulty in manufacturing extremely small cooling passages in small blades. This results in low efficiencies, making it difficult for such turbines to compete with high-volume production (low-cost) reciprocating (piston) engines. The low-pressure-ratio recuperated cycle has greater efficiency, although at higher cost. The recuperated cycle is finding favor in programs for small (under 300-kW) gas turbines used for stationary power. The recuperated cycle is efficient enough in comparison with piston engines (Otto cycles) to be of interest to automotive power plant engineers. Current designs of automotive gas turbines (AGT) have ceramic turbines and combustors and use ceramic regenerators made from a spirally wound corrugated structure with gas passages about a millimeter in diameter.

Because of their compact size, low emissions, and light weight, gas turbines are also being considered for hybrid engine-battery vehicles. Proponents are pursuing the low-pressure-ratio recuperated gas turbine as the way to obtain high efficiency and low emissions in a compact power plant.

An ingenious gas turbine cycle is the closed cycle in which the working fluid is sealed in the system. Heat is added to the fluid with an externally fired heater and extracted from the fluid through heat exchangers. The working fluid may be any gas, and the density of the gas may be varied — to vary the power delivered by the machine — by using a gas storage cylinder connected to the compressor discharge and inlet. The gas storage system is at an intermediate pressure so that it can discharge gas into the lowest pressure point in the cycle and receive gas from the highest pressure point in the cycle. About ten such units were built between 1938 and 1968; however, in spite of its sophistication, the added cost and low efficiency prevented this system from becoming economic.

The exhaust from a gas turbine is quite hot and can be used to raise steam, which can then be used to generate additional power with a steam turbine. Such a compound gas turbine-steam turbine system is referred to as a **combined cycle**. Figure 8.2.6 shows a schematic diagram of the equipment in a combined cycle. Because the exhaust of heavy-duty machines is hotter than that of aeroderivative machines, the gain in combined cycle system efficiency through use of the steam bottoming cycle described above is greater for heavy-duty machines than for aeroderivatives. Indeed, heavy-duty machines are designed with two criteria in mind: achieving lowest cost for peaking (based on the simple cycle configuration) and achieving highest efficiency in combined cycle configuration for baseload use. The optimum pressure ratios for these two system configurations are very close. Steam bottoming cycles used in combined cycles usually use steam at multiple pressure levels to increase efficiency.

**FIGURE 8.2.6** Combined (Brayton-Rankine) cycle.

Another system in which the power and efficiency of a gas turbine is increased through the use of steam is the **steam-injected gas turbine**. Figure 8.2.7 shows a schematic diagram of a steam-injected gas turbine cycle. Here the turbine exhaust flows into a heat recovery steam generator (HRSG) operating at a pressure somewhat higher than the compressor discharge pressure. The steam is introduced into the gas turbine at the combustor. The steam-air mixture then passes into the turbine, where the augmented mass flow increases the power produced by the turbine. Additional fuel is required by the combustor because the steam must be heated from the HRSG delivery temperature to the combustor discharge temperature. Typical turbines can accommodate only a limited additional mass flow — from 5 to 15%, depending on the design of the original gas turbine. Steam-injected gas turbines enable the host to use the steam for industrial purposes, space heating, or for the generation of additional power.

**FIGURE 8.2.7** Steam-injected gas turbine.

A group of cycles under consideration for development involve the use of **adiabatic saturators** to provide steam at compressor discharge pressure to augment greatly the mass flow through the turbine, and consequently increase cycle power and efficiency. In the adiabatic saturator, water flows in a countercurrent path to the compressor discharge air in a mass transfer tower. Such equipment is often used in the chemical processing industries. The saturated air is preheated in a turbine exhaust heat recuperator. This cycle is called the **humid air turbine**, or HAT, cycle. The HAT cycle is particularly useful in using the low-temperature heat generated in coal-gasification-fueled gas turbine power plants. As the mass flow through the turbine is significantly augmented, engineers can no longer use the expansion turbine which was matched to the compressor in a conventional simple cycle gas turbine.

Figure 8.2.8 shows performance maps for the gas turbine cycles of major interest for a turbine inlet temperature typical of new products. Intercooling increases the specific power appreciably when compared with a simple cycle; however, such improvement requires an increase in pressure ratio. Recuperated cycles have considerably higher efficiency than similar cycles without recuperation. The effect of pressure ratio on the performance of recuperated cycles is opposite to that of similar cycles without recuperation. For recuperated cycles, the pressure ratio for maximum efficiency is considerably lower than for maximum specific power. Performance maps such as these are used in screening cycle alternatives for improved performance. Individual curves are generated for specific component performance values for use as a guide in developing new or improved machines.

## Upper Temperature Limit

Classically, gas turbine engineers often spoke of a metallurgical limit in reference to maximum turbine inlet temperature. Later, turbine vane and blade cooling became standard on large machines. This situation creates a temperature difference between the combustion products flowing through the turbine and the turbine blade wall. Thus, because heat can be removed from the blades, the turbine can be operated with a combustion gas temperature higher than the metallurgical limit of the blade material. As a rule, the blades and vanes in new large gas turbines contain complex internal passages, through which up to 20% of compressor discharge air is directed. The cooling air first flows through internal convective cooling

FIGURE 8.2.8 Specific power (Btu/lb).

passages, then through impingement passages, where the air is directed at the blade and vane walls, and finally through small holes in the blade, where it is used to provide a low-temperature film over the blade surface. This film cooling of the surface reduces heat transfer to the blade.

The design of blade and vane cooling passages is an extremely competitive endeavor because greater cooling enables use of higher combustion temperatures without exceeding the metallurgical limit of the blade material. However, a balance between air flow for cooling and air flow for power must be achieved; the cooling air flowing within a blade drops in pressure without producing any power within that stage (although it is available for power in later stages). In the newest gas turbines, blade cooling, the difference between turbine inlet gas temperature and blade metal temperature, is around 1000°F.

Some of the latest large gas turbines being introduced to the market in the 1997 to 2000 period are being offered for combined cycle application with closed-circuit **steam cooling** of selected hot section parts. Steam cooling reduces the need for air cooling, so that more of the compressor discharge air can be used for NO<sub>x</sub> reduction in the combustor and for power generation. The heat transferred to the steam increases the efficiency of the bottoming cycle. The additional combustion products which flow through the high-pressure portions of the turbine generate substantially more power, thereby increasing both the power output and the efficiency of the machine. With more air for combustion, the fuel can be burned as a leaner mixture, with either less NO<sub>x</sub> produced, or, as is preferred, with higher-temperature gases going to the turbine and the same NO<sub>x</sub> (or a combination of these benefits).

## Materials

The high-technology parts of a gas turbine are its hot section parts: blades, vanes, combustors and transition pieces. Gas turbine power, efficiency, and economics increase with the temperature of the gas flowing through the turbine blade passages. It is in the fabrication of these hot section parts that manufacturers are most competitive. Materials are selected to survive in serviceable condition for over 50,000 hr and associated numbers of thermal cycles. Ceramic coatings protect materials from oxidation and corrosion and provide thermal insulation, permitting higher gas temperatures.

Gas turbine alloys are frequently referred to as superalloys because of their extremely high strength at high temperatures. These superalloys are nickel based (such as IN 738), cobalt based (such as FSX-414), or with a nickel-iron base such as Inconel 718. Nickel resists oxidation and is creep resistant, but is subject to corrosive sulfidation. Alloy and manufacturing advancements have been led by the needs of military aircraft engines. Coating developments for corrosion resistance have been led by the needs

of stationary power for overhaul intervals as large as 50,000 hr. The developmental needs of automotive gas turbines have led to significant advances in strength and reliability of high-temperature ceramic components, including radial inflow turbines. Ceramic materials, principally silicon nitride, are expected to enter service soon in small gas turbines.

## Combustion

Gas turbine combustors appear to be simple in design, yet they solve several difficult engineering challenges. Until relatively recently, gas turbine combustors employed a (turbulent) diffusion flame design approach, which created the most compact flame. European heavy-duty gas turbine manufacturers — with substantial interest in burning heavy fuel oils — preferred large, off-engine combustors, often called silo combustors because of their appearance, in order to obtain lower flame velocities and longer residence times. American heavy-duty gas turbine manufacturers use compact on-engine combustors and design for gaseous and clean (distillate) liquid fuels. Aeropropulsion gas turbines require the smallest possible frontal area and use only clean liquid fuels; hence, they use on-engine combustors.

Recently, stationary engines have been required to reduce  $\text{NO}_x$  emissions to the greatest extent possible, and combustors on stationary gas turbines first modified their diffusion flame combustors and employed water and steam injection to quench flame hot spots. Most recently, designs changed to the lean-premixed process. With the improved blade cooling, materials, and coatings now in use, the material limits on turbine inlet temperature and the  $\text{NO}_x$  emission limits on combustor temperature appear to be converging on a combustion-temperature asymptote around 2700°F (1482°C). This may be increased if catalytic combustors prove practical.

## Mechanical Product Features

In view of the need to achieve all the performance features described above, one must keep in mind that a gas turbine is a high-speed dynamic machine with numerous machine design, materials, and fabrication features to consider. Major issues include the following: critical shaft speed considerations, bearing rotational stability, rotor balancing, thrust bearing design, bearing power loss, oil lubrication system, oil selection, air filter design and minimization of inlet and exhaust diffuser pressure drops, instrumentation, controls, diagnostic systems, scheduled service and inspection, overhaul, and repair. All of these topics must be addressed to produce a cost-effective, reliable, long-lived, practical gas turbine product that will satisfy users while also returning to investors sufficient profit for them to continue to offer better power generation products of still higher performance.

## Defining Terms

**Adiabatic saturator:** A combined heat-and-mass-exchanger whereby a hot gas and a volatile liquid pass through a series of passages such that the liquid is heated and evaporates into the gas stream.

**Combined cycle:** An arrangement of a gas turbine and a steam turbine whereby the heat in the exhaust from the gas turbine is used to generate steam in a heat recovery boiler which then flows through a steam turbine, thereby generating additional power from the gas turbine fuel.

**Combustion efficiency:** Ratio of rate of heat delivered in a device which burns fuel to the rate of energy supplied in the fuel.

**Expansion process:** Process of power generation whereby a gas passes through a machine while going from a condition of high pressure to one of low pressure, usually the machine produces power.

**Gas turbine or engine efficiency:** The ratio of the net power delivered (turboexpander power minus compressor and auxiliary power) to the rate of energy supplied to the gas turbine or engine in the form of fuel, or, in certain cases such as solar power, heat.

**Humid air turbine:** A gas turbine in which the flow through the expander is augmented by large amounts of steam generated by use of an adiabatic saturator.

**Intercooler:** A heat exchanger used to cool the flow between sections of a compressor such that the high pressure section acts on a stream of reduced volumetric flow rate, thereby requiring less overall power to compress the stream to the final pressure.

**Recuperator:** A heat exchanger in which the hot and cold streams pass on opposite sides of a wall through which heat is conducted.

**Regenerator:** A heat exchanger in which the hot and cold streams alternately heat and cool a wall whose temperature rises and falls, thereby transferring heat between the streams.

**Steam cooling:** A process in which steam is used as the heat transfer fluid to cool a hot component.

**Steam-injected gas turbine:** A system in which the gas turbine flow is augmented by steam, thereby generating additional power.

**Turbine efficiency:** Ratio of the power delivered in an expansion process employing a turbine as the expander to the maximum power which could be produced by expanding the gas in a reversible adiabatic (isentropic) process from its initial pressure and temperature to its final pressure to the actual power.

Cycle efficiency:

$$\eta = \frac{m_i \Delta h_i - m_c \Delta h_c}{m_f HV}$$

where  $HV$  = heating value of fuel.

For specific heat independent of temperature and small mass flow of fuel in comparison to air:

$$\eta = \frac{\Delta T_t - \Delta T_c}{\Delta T_b}$$

Isentropic efficiency (finite pressure ratio):

$$\eta_t = \Delta T \text{ actual} / \Delta T \text{ isentropic}$$

$$\eta_t = \frac{1 - T_e/T_i}{1 - r^{(\gamma-1)/\gamma}}$$

or

$$\eta_t = \frac{1 - r^{(n-1)/n}}{1 - r^{(\gamma-1)/\gamma}}$$

and

$$\eta_c = \Delta T \text{ isentropic} / \Delta T \text{ actual}$$

$$\eta_c = \frac{r^{(\gamma-1)/\gamma} - 1}{T_e/T_i - 1}$$

or

$$\eta_c = \frac{r^{(\gamma-1)/\gamma} - 1}{r^{(n-1)/n} - 1}$$

Polytropic efficiency (differential pressure ratio):

$$\eta_t = \frac{(n-1)/n}{(\gamma-1)/\gamma}$$

and

$$\eta_c = \frac{(\gamma-1)/\gamma}{(n-1)/n}$$

Relationships between isentropic and polytropic efficiencies:

$$\eta_{s,c} = \frac{r^{(\gamma-1)/\gamma} - 1}{r^{(\gamma-1)/\gamma} \eta_{p,c} - 1}$$

$$\eta_{s,t} = \frac{1 - r^{(\gamma-1)/\gamma} \eta_{p,t}}{1 - r^{(\gamma-1)/\gamma}}$$

$$\eta_{p,c} = \frac{\ln r^{(\gamma-1)/\gamma}}{\ln \left[ \frac{r^{(\gamma-1)/\gamma} - 1}{\eta_{s,c}} + 1 \right]}$$

$$\eta_{p,t} = \frac{\ln \left[ 1 - \eta_{s,t} \left( 1 - r^{(\gamma-1)/\gamma} \right) \right]}{\ln r^{(\gamma-1)/\gamma}}$$

## 8.3 Internal Combustion Engines

*David E. Klett and Elsayed M. Afify*

### Introduction

This section discusses the two most common reciprocating internal combustion (IC) engine types in current use; the **spark ignition (SI)** and the **compression ignition (CI or diesel) engine**. Both the Stirling engine (technically, an external combustion engine) and the gas turbine engine are covered in other sections of this chapter. Space limitations do not permit detailed coverage of the very broad field of IC engines. For a more detailed treatment of SI and CI engines and for information on variations, such as the Wankel rotary engine and the Miller cycle engine (a variation on the reciprocating four-stroke SI engine introduced in production by Mazda in 1993), the reader is referred to the several excellent textbooks on the subject, technical papers, and other sources that are included in the list of references and the Further Information section.

Basic SI and CI engines have not fundamentally changed since the early 1900s with the possible exception of the introduction of the Wankel rotary SI engine in the 1960s (Norbye, 1971). However, major advances in the areas of materials, manufacturing processes, electronic controls, and computer-aided design have led to significant improvements in dependability, longevity, thermal efficiency, and emissions during the past decade. Electronic controls, in particular, have played a major role in efficiency gains in SI automotive engines through improved control of the fuel injection and ignition systems that control the combustion process. Electronic control of diesel fuel injection systems is also becoming more common and is producing improvements in diesel emissions and fuel economy.

This section presents the fundamental theoretical background of IC engine function and performance, including **four-stroke** and **two-stroke** SI and CI engines. Sections on combustion, emissions, fuels, and intake pressurization (**turbocharging** and **supercharging**) are also included.

### Engine Types and Basic Operation

IC engines may be classified by a wide variety of characteristics, the primary ones being SI vs. CI, four-stroke vs. two-stroke, and reciprocating vs. rotary. Other possible categories of classification include intake type (naturally aspirated vs. turbocharged or supercharged), number of cylinders, cylinder arrangement (in-line, vee, opposed), cooling method (air vs. water), fueling system (injected vs. carbureted), valve gear arrangement (overhead cam vs. pushrod), type of **scavenging** for two-stroke engines (cross, loop, or uniflow), and type of injection for diesel engines (direct vs. indirect).

#### Four-Stroke SI Engine

**Figure 8.3.1** is a cross-section schematic of a four-stroke SI engine. The SI engine relies on a spark plug to ignite a volatile air-fuel mixture as the piston approaches **top dead center (TDC)** on the compression stroke. This mixture may be supplied from a carburetor, a single throttle-body fuel injector, or by individual fuel injectors mounted in the intake port of each cylinder. One combustion cycle involves two revolutions of the crankshaft and thus four strokes of the piston, referred to as the intake, compression, power, and exhaust strokes. Intake and exhaust valves control the flow of mixture and exhaust gases into and out of the cylinder, and an ignition system supplies a spark-inducing high voltage to the spark plug at the proper time in the cycle to initiate combustion. On the intake stroke, the intake valve opens and the descending piston draws a fresh combustible charge into the cylinder. During the compression stroke, the intake valve closes and the fuel-air mixture is compressed by the upward piston movement. The mixture is ignited by the spark plug, typically somewhat before TDC. The rapid **premixed homogeneous combustion** process causes a sharp increase in cylinder temperature and pressure that forces the piston down for the power stroke. Near **bottom dead center (BDC)** the exhaust valve opens and the cylinder pressure drops rapidly to near atmospheric. The piston then returns to TDC, expelling the

FIGURE 8.3.1 Schematic diagram of four-stroke SI engine.

exhaust products. At TDC, the exhaust valve closes and the intake valve opens to repeat the cycle again. Figure 8.3.2 is a cutaway drawing of a modern high-performance automotive SI engine. This is a fuel-injected normally aspirated aluminum alloy V-8 engine of 4.6 L displacement with dual overhead cams for each cylinder bank. Peak power output is 228 kw at 5800 rpm.

### Two-Stroke SI Engine

The two-stroke SI engine completes a combustion cycle for every revolution of the crankshaft by essentially overlapping the power and exhaust functions in one downward stroke and the intake and compression processes in one upward stroke. A single-cylinder, crankcase-scavenged, two-stroke SI engine is illustrated schematically in Figure 8.3.3. The operation is as follows. On the upward stroke, the piston first covers the transfer port and then the exhaust port. Beyond this point the fresh charge is compressed and ignited near TDC. During the upward stroke, the negative pressure created in the crankcase below the piston draws in a fresh charge of fuel-air mixture through a one-way valve. On the downward power stroke, the mixture in the crankcase is pressurized. The piston uncovers the exhaust port and the high-pressure exhaust gases exit. Near BDC the transfer port is uncovered and the pressurized mixture flows from the crankcase into the cylinder and the cycle repeats. Since the crankcase is part of the induction system, it does not contain oil, and lubrication is accomplished by mixing oil with the fuel. With the cross-flow scavenging configuration illustrated in Figure 8.3.3, there will be a certain degree of mixing of the fresh charge with the combustion products remaining in the cylinder and some loss of fresh charge out the exhaust port.

Since two-stroke engines produce twice the power impulses of four-stroke engines for the same rpm, a two-stroke engine has a higher **power density** and is thus smaller and lighter than a four-stroke engine of equal output. The disadvantages of the two-stroke engine have historically been lower fuel efficiency and higher exhaust emissions because of the overlapping of the intake and exhaust processes and the

FIGURE 8.3.2 Ford 4.6-L aluminum V-8 SI engine. (Courtesy of Ford Motor Company.)

FIGURE 8.3.3 Schematic drawing of two-stroke SI engine.

loss of some fresh intake mixture with the exhaust products. For this reason, two-stroke SI engines have largely been confined to small-displacement applications, such as motorcycles, outboard marine engines, and small equipment. Several manufacturers have addressed these shortcomings in recent years and have achieved significant improvements in two-stroke engine fuel economy and emissions (Blair, 1988). The Orbital OCP (Orbital Combustion Process) engine, illustrated in Figure 8.3.4, is a modern two-stroke engine that utilizes direct injection of fuel into the cylinder in conjunction with a high-turbulence combustion chamber design and an electronically controlled exhaust port scavenging control valve to achieve very favorable fuel economy and significantly reduced levels of  $\text{NO}_x$  and hydrocarbon emissions. This engine, in three and six cylinder versions, is currently being used in automotive and marine applications.

FIGURE 8.3.4 Orbital OCP two-stroke SI engine. (Courtesy of Orbital Engine Company.)

### Compression Ignition Engine

The basic valve and piston motions are the same for the CI, or diesel, engine as discussed above for the SI engine. The CI engine relies on the high temperature and pressure of the cylinder air resulting from the compression process to cause **autoignition** of the fuel, which is injected directly into the combustion chamber of **direct injection (DI)** engines or into the prechamber of **indirect injection (IDI)** engines, when the piston approaches TDC on the compression stroke. The compression ratios are typically much higher for CI than for SI engines to achieve the high air temperatures required for autoignition, and the fuels used must have favorable autoignition qualities.

The time period between the start of fuel injection and the occurrence of autoignition is called the **ignition delay period**. Long ignition delay periods allow more time for fuel vaporization and fuel-air mixing, resulting in objectionable diesel knock when this larger premixed charge ignites. Combustion chambers and fuel injection systems must be designed to avoid extended ignition delay periods. Diesel

engines may be classified as DI or IDI. In DI engines, the combustion chamber consists of a bowl formed in the top of the piston and the fuel is injected into this volume. The injector tip generally has from four to eight holes to form multiple spray cones. Two variations are illustrated in Figure 8.3.5. The quiescent chamber engine utilizes a large-diameter shallow bowl shape that produces low **swirl** and low turbulence of the air during compression. Fuel is injected at high pressure through a multihole nozzle, and mixing of the fuel and air relies primarily on the energy of the injected fuel to cause air entrainment in the spray cone and diffusion of vaporized fuel into the air. This system is suited to large slow-speed engines that are operated with significant excess air.

**FIGURE 8.3.5** Examples of DI diesel combustion chamber design.

The toroidal bowl combustion chamber is used in conjunction with intake ports and/or valve shrouds designed to produce air swirl to enhance fuel-air mixing. The **swirl ratio** is defined by  $\text{swirl ratio} = \text{swirl speed (rpm)} / \text{engine speed (rpm)}$ . The swirl velocity component is normal to the fuel spray direction and tends to promote mixing in the regions between the individual spray cones. This system makes better use of the available air and is utilized extensively in moderate-speed engines such as over-the-road truck engines. DI does not lend itself well to high-speed operation, as the time available for proper mixing and combustion is less. Diesel engines for passenger car applications are generally designed for higher-speed operation to produce higher specific output, and typically utilize IDI combustion systems, two of which are illustrated in Figure 8.3.6.

IDI systems make use of small prechambers incorporated in the cylinder head to promote rapid mixing of fuel and air and shorten the ignition delay period. Swirl chambers are designed to produce a strong vortex in the prechamber during compression. The fuel is sprayed into the chamber through a single-hole nozzle and the high vorticity promotes rapid mixing and short ignition delay periods. Precombustion chambers do not attempt to generate an orderly vortex motion within the chamber, but instead rely on a high level of turbulence, created by the rush of air into the chamber during compression, to promote mixing. Both types of prechambers generally include a lining of low-conductivity material (ceramic) to increase the surface temperature to promote further fuel evaporation. Prechambers can be used in small-displacement diesel engines to achieve operating speeds up to 5000 rpm. Disadvantages of the IDI system include poor cold-start characteristics due to high heat-transfer rates from the compressed air to the chamber wall that result from the high velocities and turbulence levels in the chamber. **Glow plugs** are often installed in each prechamber to heat the air to improve cold starting. Higher compression ratios are also used for IDI engines to further improve cold starting. The compression ratios, typically 18 to 24, are higher than the optimum for fuel efficiency (due to decreased mechanical efficiency), and IDI

**FIGURE 8.3.6** Two examples of IDI combustion chambers.

engines are typically less efficient than larger, slower, DI engines. The use of IDI is generally restricted to high-speed automotive engines, with displacements in the range of 0.3 to 0.8 liter per cylinder, and some degree of fuel economy is sacrificed in the interest of improved driveability.

CI engines are produced in both two-stroke and four-stroke versions. Since the fuel is injected directly into the combustion chamber of CI engines just prior to TDC, two-stroke CI engines do not suffer the same emission and efficiency shortcomings as do two-stroke SI engines. Hence, they are available in much larger displacements for high-power-requirement applications such as locomotive and ship propulsion and electric power generation systems. Two-stroke CI engines are generally of the DI type as the use of IDI in a two-stroke engine would lead to aggravated cold-start problems.

## Air Standard Power Cycles

The actual operation of IC engines is idealized at a very basic level by the air standard power cycles (ideal thermodynamic models for converting heat into work on a continuous basis). The following simplifying assumptions are common to the air standard cycles: (1) the working substance is air, (2) the air is assumed to behave as an ideal gas with constant specific heats, (3) heat is added to the cycle from an external source, and (4) expansion and compression processes not involving heat transfer occur isentropically. The air standard cycles, while grossly oversimplified in terms of the complex processes occurring within actual engines, are nevertheless useful in understanding some fundamental principles of SI and CI engines. The simplified models also lend insight into important design parameters, e.g., **compression ratio**, that govern theoretical maximum cycle thermal efficiencies.

### Constant-Volume Heat Addition — Ideal Otto Cycle

The theory of operation of the SI engine is idealized by the Otto cycle which assumes that heat is added to the system at constant volume. Constant-volume heat addition is approximated in the SI engine by virtue of the combustion process taking place rapidly when the piston is near TDC. A  $P$ - $V$  diagram for the Otto cycle is illustrated in [Figure 8.3.7](#). The cycle consists of the following processes: 1  $\rightarrow$  2 isentropic compression, 2  $\rightarrow$  3 constant-volume heat addition, 3  $\rightarrow$  4 isentropic expansion, and 4  $\rightarrow$  1 constant-volume heat rejection. The constant-volume heat rejection process is approximated in SI engines by the exhaust valve opening near BDC and the rapid blow down of exhaust gases.

Thermal efficiency for a power cycle is defined as the ratio of work output to heat input per cycle,

FIGURE 8.3.7 Schematic pressure-volume diagram for the ideal Otto cycle.

$$\eta = \frac{W_{\text{out}}}{Q_{\text{in}}} \quad (8.3.1)$$

For the Otto cycle, the basic efficiency expression can be manipulated into the form

$$\eta = 1 - \frac{1}{r^{\gamma-1}} \quad (8.3.2)$$

where  $\gamma$  is the ratio of specific heats ( $\gamma = C_p/C_v$ ) and  $r$  is the compression ratio, or ratio of the maximum to minimum cycle volumes ( $r = V_1/V_2$ ). In actual IC engines, the minimum cycle volume is referred to as the **clearance volume** and the maximum cycle volume is the **cylinder volume**. The ideal Otto cycle efficiency for air, with  $\gamma = 1.4$ , is shown plotted in Figure 8.3.8. The theoretical efficiency of the constant volume heat addition cycle increases rapidly with compression ratio, up to about  $r = 8$ . Further increases in compression ratio bring moderate gains in efficiency. Compression ratios in practical SI engines are limited because of autoignition (knock) and high  $\text{NO}_x$  emission problems that accompany high compression ratios. Production SI automotive engines typically have compression ratios in the range 8 to 10, whereas high-performance normally aspirated racing engines may have compression ratios as high as 14, but they require the use of special fuels to avoid autoignition.

### Constant-Pressure Heat Addition — Ideal Diesel Cycle

The air standard diesel cycle is the idealized cycle underlying the operation of CI or diesel engines. The diesel cycle, illustrated by the  $P$ - $V$  diagram in Figure 8.3.9, consists of the following processes: 1  $\rightarrow$  2 isentropic compression from the maximum to the minimum cycle volume, 2  $\rightarrow$  3 constant-pressure heat addition during an accompanying increase in volume to  $V_3$ , 3  $\rightarrow$  4 isentropic expansion to the maximum cycle volume, and 4  $\rightarrow$  1 constant-volume heat rejection.

Actual diesel engines approximate constant-volume heat addition by injecting fuel for a finite duration which continues to burn and release heat at a rate that tends to maintain the pressure in the cylinder over a period of time during the expansion stroke. The efficiency of the ideal diesel cycle is given by

FIGURE 8.3.8 Efficiency of the ideal Otto cycle.

FIGURE 8.3.9 Schematic pressure-volume diagram of ideal diesel cycle.

$$\eta = 1 - \frac{1}{r^{\gamma-1}} \left[ \frac{r_c^\gamma - 1}{\gamma(r_c - 1)} \right] \tag{8.3.3}$$

The efficiency of the ideal diesel cycle depends not only on the compression ratio,  $r$ , but also on the **cut-off ratio**,  $r_c = V_3/V_2$ , the ratio of the volume when heat addition ends to the volume when it begins. Equation (8.3.3) is shown plotted in Figure 8.3.10 for several values of  $r_c$  and for  $\gamma = 1.4$ . An  $r_c$  value of 1 is equivalent to constant-volume heat addition, i.e., the Otto cycle. The efficiency of the ideal Diesel cycle is less than the efficiency of the ideal Otto cycle for any given compression ratio and any value of the cut-off ratio greater than 1. The fact that CI engines, by design, operate at much higher compression ratios than SI engines (generally between 12 and 24) accounts for their typically higher operating efficiencies relative to SI engines.

### Actual Cycles

IC engines do not operate on closed thermodynamic cycles, such as the air standard power cycles, but rather on open mechanical cycles, and heat addition occurs neither at constant volume or constant

FIGURE 8.3.10 Efficiency of the ideal diesel cycle.

pressure. Figure 8.3.11 is a schematic representation of an **indicator diagram** (pressure-volume history) of a four-stroke IC engine; it could be either SI or CI. The pressure changes during the intake and exhaust strokes are exaggerated in the diagram. The **indicated work** performed per cycle can be calculated by taking the integral of  $PdV$  for the complete cycle. The **indicated mean effective pressure, imep**, is defined as the ratio of the net indicated work output to the **displacement volume**:

$$\text{imep} = \frac{\text{indicated work output per cycle}}{\text{displacement volume}} \tag{8.3.4}$$

FIGURE 8.3.11 Schematic indicator diagram.

The shaded area in Figure 8.3.11 thus represents the net indicated work output per cycle. During intake and exhaust, the negative work performed represents pumping losses and acts to decrease the net work output of the engine. The magnitude of the pumping losses depends on the flow characteristics of the intake and exhaust systems including the valves, ports, manifolds, piping, mufflers, etc. The more

restrictive these passages, the higher will be the pumping losses. SI engines control power output by throttling the intake air. Thus, under partial-load conditions, the pressure drop resulting from the air throttling represents a significant increase in pumping loss with a corresponding decrease in operating efficiency. SI engines are therefore less efficient at partial-load operation than at full load. The power level of CI engines, on the other hand, is controlled by varying the amount of fuel injected, as opposed to throttling the intake air, making them significantly more efficient than SI engines under partial-load conditions.

**Brake work** (or power) is the actual work (or power) produced at the output shaft of an engine, as measured by a dynamometer. The brake work will be less than the indicated work due to friction losses and any parasitic power requirements for oil pumps, water pumps, etc. The **brake mean effective pressure, bmep**, is defined as

$$\text{bmep} = \frac{\text{brake work output per cycle}}{\text{displacement volume}} \quad (8.3.5)$$

The mechanical efficiency can then be defined as

$$\eta_m = \frac{\text{brake work (power)}}{\text{indicated work (power)}} = \frac{\text{bmep}}{\text{imep}} \quad (8.3.6)$$

Engine thermal efficiency can be determined from the ratio of power output to rate of fuel energy input, or

$$\eta_t = \frac{\text{Power}}{m_f Q_c} \quad (8.3.7)$$

where  $m_f$  is the rate of fuel consumption per unit time and  $Q_c$  is the heat of combustion per unit mass of fuel. The thermal efficiency in Equation (8.3.7) could be either indicated or brake depending on the nature of the power used in the calculation. Uncertainty associated with variations of energy content of fuels may present a practical difficulty with determining engine thermal efficiency. In lieu of thermal efficiency, **brake specific fuel consumption (bsfc)**, is often used as an efficiency index.

$$\text{bsfc} = \frac{\text{fuel consumption rate (kg/hr)}}{\text{brake power (kW)}} \quad (8.3.8)$$

The efficiency of engines operating on the same fuel may be directly compared by their bsfc.

**Volumetric efficiency**,  $\eta_v$ , is an important performance parameter for four-stroke engines defined as

$$\eta_v = \frac{m_{\text{actual}}}{m_d} \quad (8.3.9)$$

where  $m_{\text{actual}}$  is the mass of intake mixture per cycle at inlet conditions (pressure and temperature near the inlet port) and  $m_d$  is the mass of mixture contained in the displacement volume at inlet conditions. For SI engines the mixture mass includes both air and fuel; for CI engines only air is present during intake. With the intake mixture density determined at inlet conditions,  $\eta_v$  accounts for flow losses associated with the intake ports, valves, and cylinder. Sometimes, for convenience, the mixture density is taken at ambient conditions. In this case,  $\eta_v$  is called the overall volumetric efficiency and includes the flow performance of the entire intake system. Since a certain minimum amount of air is required for complete combustion of a given amount of fuel, it follows that the maximum power output of an engine

is directly proportional to its air-flow capacity. Thus, while not affecting in any way the thermal efficiency of the engine, the volumetric efficiency directly affects the maximum power output for a given displacement, and thus can affect the efficiency of the overall system in which the engine is installed because of the effect on system size and weight. Volumetric efficiency is affected primarily by intake and exhaust valve geometry, valve lift and timing, intake port and manifold design, mixing of intake charge with residual exhaust gases, engine speed, ratio of inlet pressure to exhaust back pressure, and heat transfer to the intake mixture from warmer flow passages and combustion chamber surfaces. For further information on the fundamentals of IC engine design and operation see Taylor (1985), Ferguson (1986), Heywood (1988), and Stone (1993).

## Combustion in IC Engines

### Combustion in Spark Ignition Engines

*Background.* In SI engines, combustion of the fuel-air mixture is initiated by a spark generated between the electrodes of a spark plug. The intake and compression strokes are designed to prepare the mixture for combustion by completely vaporizing the fuel and heating the mixture to just below its autoignition temperature. This is one reason, in addition to controlling emissions, for the current practice of limiting the maximum compression ratio of SI engines to about 10:1. Near the end of compression, the mixture is well conditioned for combustion and the spark is discharged to initiate the combustion process. For best fuel economy, the combustion process must be completed as close as possible to TDC. This requires that the spark timing be controlled for varying operating speed and load conditions of the engine. Fuel metering and control, according to the engine load requirements, and with minimum variation from cylinder to cylinder and cycle to cycle, is essential for good fuel economy, power output, and emission control of the engine.

Both carburetors and fuel injection systems are used for fuel-metering control. Because of the superior control capabilities of fuel injection systems, they are nearly universally used today in production automotive applications. Carburetors are used for applications with less-stringent emission requirements, e.g., small engines for lawn and garden equipment. [Figure 8.3.12](#) illustrates the effect of **fuel-air ratio** on the indicated performance of an SI engine. The **equivalence ratio** ( $\gamma$ ) is defined by the ratio  $\text{Fuel-Air}_{\text{actual}}/\text{Fuel-Air}_{\text{stoichiometric}}$ . Rich mixtures have fuel-air ratios greater than stoichiometric ( $\gamma > 1$ ) and lean mixtures have fuel-air ratios less than stoichiometric ( $\gamma < 1$ ). Optimum fuel economy, coinciding with maximum thermal efficiency, is obtained at part throttle with a lean mixture as a result of the fact that the heat release from lean mixtures suffers minimal losses from dissociation and variation of specific heat effects when compared with stoichiometric and rich fuel-air ratios. Maximum power is obtained at full throttle with a slightly rich mixture, an indication of the full utilization of the air inside the cylinders. Idling, with a nearly closed throttle, requires a rich mixture because of the high percentage of exhaust gas residuals that remains in the cylinders. The fuel-air mixture requirement under transient operation, such as acceleration, requires a rich mixture to compensate for the reduced evaporation caused by the sudden opening of the throttle. Cold starting also requires a rich mixture to ensure the vaporization of sufficient amounts of the highly volatile components in the fuel to achieve proper ignition.

*Normal Combustion Process.* The combustion processes in SI engines can be divided into two categories, normal and abnormal. The normal combustion process occurs in three stages: initiation of combustion, flame propagation, and termination of combustion. Combustion normally starts across the spark plug gap when the spark is discharged. The fuel molecules in and around the spark discharge zone are ignited and a small amount of energy is released. The important criterion for the initial reaction to be self-sustaining is that the rate of heat release from the initial combustion be larger than the rate of heat transfer to the surroundings. The factors that play an important role in making the initial reaction self-sustaining, and thereby establishing a flame kernel, are the ignition energy level, the spark plug gap, the fuel-air ratio, the initial turbulence, and the condition of the spark plug electrodes.

**FIGURE 8.3.12** Effect of fuel-air mixture on indicated performance of an SI engine.

After a flame kernel is established, a thin spherical flame front advances from the spark plug region progressively into the unburned mixture zone. Flame propagation is supported and accelerated by two processes. First, the combined effect of the heat transfer from the high-temperature flame region and the bombardment by the active radicals from the flame front into the adjacent unburned zone raises the temperature and accelerates the rate of reactivity of the unburned mixture region directly adjacent to the flame front. This helps condition and prepare this zone for combustion. Second, the increase in the temperature and pressure of the burned gases behind the flame front will cause it to expand and progressively create thermal compression of the remaining unburned mixture ahead of the flame front. It is expected that the flame speed will be low at the start of combustion, reach a maximum at about half the flame travel, and decrease near the end of combustion. Overall, the flame speed is strongly influenced by the degree of turbulence in the combustion chamber, the shape of the combustion chamber, the mixture strength, the type of fuel, and the engine speed.

When the flame front approaches the walls of the combustion chamber, the high rate of heat transfer to the walls slows down the flame propagation and finally the combustion process terminates close to the walls because of surface quenching. This leaves a thin layer of unburned fuel close to the combustion chamber walls which shows up in the exhaust as unburned hydrocarbons.

**Abnormal Combustion.** Abnormal combustion may occur in SI engines associated with two combustion phenomena: **knock** and **surface ignition**. Knock occurs near the end of the combustion process if the end portion of the unburned mixture, which is being progressively subjected to thermal compression, autoignites prematurely before the flame front reaches it. As a result of the sudden energy release, a violent pressure wave propagates back and forth across the combustion chamber, causing the walls or other parts of the engine to vibrate, producing a sharp metallic noise called knock. If knock persists for a period of time, the high rate of heat transfer caused by the traveling high pressure and temperature wave may overheat the spark plug electrode or ignite carbon deposits that may be present in the

combustion chamber, causing uncontrolled combustion and preignition. As a result, loss of power and serious engine damage may occur.

Knock is sensitive to factors that increase the temperature and pressure of the end portion of the unburned mixture, as well as to fuel composition and other time factors. Factors that increase the probability of knock include (1) increasing the temperature of the mixture by increasing the charge intake temperature, increasing the compression ratio, or turbo/supercharging; (2) increasing the density of the mixture by turbo/supercharging or increasing the load; (3) advancing the spark timing; (4) increasing the time of exposure of the end portion of the unburned mixture to autoignition conditions by increasing the length of flame travel or decreasing the engine speed and turbulence; and (5) using low-octane fuel and/or maximum power fuel-air ratios. Engine design factors that affect knock in SI engines include the shape of the combustion chamber and the location of the spark plug and inlet and exhaust valves relative to the location of the end portion of the unburned mixture.

Surface ignition is the ignition of the unburned mixture by any source in the combustion chamber other than the normal spark. Such sources could include overheated exhaust valves or spark plug electrodes, glowing carbon deposits, or other hot spots. Surface ignition will create secondary flame fronts which cause high rates of pressure rise resulting in a low-pitched, thudding noise accompanied by engine roughness. Severe surface ignition, especially when it occurs before spark ignition, may cause serious structural and/or component damage to the engine.

### Combustion in Compression Ignition Engines

Unlike the SI engine, in which the charge is prepared for combustion as a homogeneous mixture during the intake and compression strokes, fuel preparation for combustion in CI engines occurs in a very short period of time called the ignition delay period. During this period, the fuel injected into the high-temperature air near the end of the compression stroke undergoes two phases of transformation. A physical delay period, during which the fuel is vaporized, mixed with the air, and raised in temperature, is followed by a chemical delay period during which fuel cracking and decomposition occur which leads to autoignition and combustion of the fuel.

The combustion process is **heterogeneous** and involves two modes, usually identified as premixed combustion and diffusion combustion. Premixed combustion occurs early in the process when the fuel which has evaporated and mixed with air during the ignition delay period ignites. This mode is characterized by uncontrolled combustion and is the source of combustion noise since it is accompanied by a high rate of heat release which produces a high rate of pressure rise. When the premixed fuel-air mixture is depleted, diffusion combustion takes over, characterized by a lower rate of heat release and producing controlled combustion during the remainder of the process. [Figure 8.3.13](#) depicts the different stages of the combustion process in CI engines.

The ignition delay period plays a key role in controlling the time duration of the two modes of combustion. Prolonging the ignition delay period, either through engine design factors or variations in operating conditions, will generate a larger portion of premixed fuel-air mixture and will thus tend to increase the premixed combustion mode duration and decrease the diffusion mode duration. This may lead to higher peak cylinder pressure and temperature which may improve thermal efficiency and reduce CO and **unburned hydrocarbon (UHC)** emissions at the expense of increased emissions of oxides of nitrogen ( $\text{NO}_x$ ). Large increases in the ignition delay period will cause high rates of pressure rise during the premixed combustion and may lead to objectionable diesel knock. Reducing the ignition delay period causes the premixed combustion duration to decrease while increasing the diffusion combustion duration. A large reduction in ignition delay may lead to loss of power, decrease in thermal efficiency, and possible deterioration of exhaust emissions. Several factors related to the fuel-air mixture temperature and density, engine speed, combustion chamber turbulence, injection pressure, rate of injection, and fuel composition influence the duration of the ignition delay period.

*Knock in CI Engines.* As the combustion process in CI engines is triggered by autoignition of the fuel injected during the ignition delay period, factors that prolong the ignition delay period will increase the

FIGURE 8.3.13 Combustion process in a CI engine.

premixed combustion duration causing very high rates of energy release and thus high rates of pressure rise. As a result, diesel knock may occur. The phenomenon is similar to knock in SI engines except that it occurs at the beginning of the combustion process rather than near the end, as observed in SI combustion. Factors that reduce the ignition delay period will reduce the possibility of knock in diesel engines. Among them are increasing the compression ratio, supercharging, increasing combustion chamber turbulence, increasing injection pressure, and using high-**cetane-number (CN)** fuel. For a more detailed discussion of the combustion process in IC engines, see Henein (1972), Lenz (1992), and Keating (1993).

## Exhaust Emissions

### Harmful Constituents

The products of combustion from IC engines contain several constituents that are considered hazardous to human health, including CO, UHCs  $\text{NO}_x$ , and **particulates** (from diesel engines). These emission products are discussed briefly below followed by a description of the principal schemes for their reduction.

**Carbon Monoxide.** CO is a colorless, odorless, and tasteless gas that is highly toxic to humans. Breathing air with a small volumetric concentration (0.3%) of CO in an enclosed space can cause death in a short period of time. CO results from the incomplete combustion of hydrocarbon fuels. One of the main sources of CO production in SI engines is the incomplete combustion of the rich fuel mixture that is present during idling and maximum power steady state conditions and during such transient conditions as cold starting, warm-up, and acceleration. Fuel maldistribution, poor condition of the ignition system, very lean combustion, and slow CO reaction kinetics also contribute to increased CO production in SI engines. CO production is not as significant in CI engines since these engines are always operated with significant excess air.

**Unburned Hydrocarbons.** When UHCs combine with  $\text{NO}_x$  (see below) in the presence of sunlight, ozone and photochemical oxidants form that can adversely affect human health. Certain UHCs are also

considered to be carcinogenic. The principal cause of UHC in SI engines is incomplete combustion of the fuel-air charge, resulting in part from flame quenching of the combustion process at the combustion chamber walls, and engine misfiring. Additional sources in four-stroke engines may include fuel mixture trapped in crevices of the top ring land of the piston and outgassed fuel during the expansion (power) stroke that was absorbed into the lubricating oil film during intake. In two-stroke SI engines, the scavenging process often results in a portion of the fresh mixture exiting the exhaust port before it closes, resulting in large UHC emissions.

The presence of UHC in CI engines is related to the heterogeneous nature of the fuel-air mixture. Under certain conditions, fuel-air mixtures that lie outside the flammability limits at both the lean and rich extremes can exist in portions of the combustion chamber and escape combustion, thus contributing significantly to UHC in the exhaust. Fuel injected near the end of the combustion process, and fuel remaining in the nozzle **sac volume** at the end of injection, both contribute to UHC emission in CI engines. Engine variables that affect UHC emissions include the fuel-air ratio, intake air temperature, and cooling water temperature.

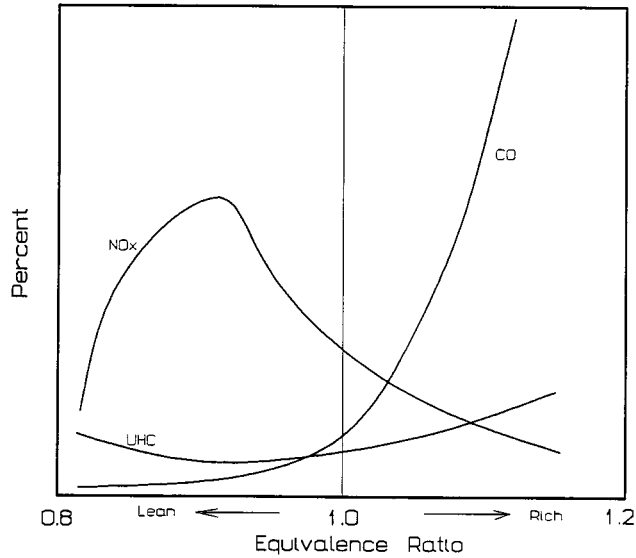

*Oxides of Nitrogen.* Nitric oxide (NO) is formed from the combination of nitrogen and oxygen present in the intake air under the high-temperature conditions that result from the combustion process. As the gas temperature drops during the expansion stroke, the reaction is frozen, and levels of NO persist in the exhaust products far in excess of the equilibrium level at the exhaust temperature. In the presence of additional oxygen in the air, some NO transforms to nitrogen dioxide (NO<sub>2</sub>), a toxic gas. The NO and NO<sub>2</sub> combined are referred to as oxides of nitrogen or NO<sub>x</sub>. The production of NO<sub>x</sub> is in general aggravated by conditions that increase the peak combustion temperature. In SI engines the most important variables that affect NO<sub>x</sub> production are the air/fuel ratio, spark timing, intake air temperature, and amount of residual combustion products remaining in the cylinder after exhaust. In CI engines, ignition delay, which affects the degree of premixed combustion, plays a key role in NO<sub>x</sub> formation. A larger premixed combustion fraction will produce higher combustion temperatures and higher levels of NO<sub>x</sub>.

*Particulates.* Particulates are a troublesome constituent in the exhaust from CI engines. Particulates are defined by the US Environmental Protection Agency (EPA) as any exhaust substance (other than water) that can be trapped on a filter at a temperature of 325 K or below. Particulates trapped on a filter may be classified as soot plus an organic fraction of hydrocarbons and their partial oxidation products. Soot consists of agglomerates of solid uncombusted carbon particles. Particulates are of concern because their small size permits inhalation and entrapment in the lung walls, making them potential lung carcinogens.

Soot is formed in CI engines under conditions of heavy load when the gas temperature is high and the concentration of oxygen is low. Smoke production is affected by such parameters as fuel CN, rate of fuel injection, inlet air temperature, and the presence of secondary injection.

### Control of Emissions from IC Engines

Figure 8.3.14 depicts the relative concentrations of CO, NO<sub>x</sub>, and UHC in the exhaust products of an SI engine as a function of the fuel-air mixture. Lean mixture combustion, which promotes good thermal efficiency, also results in low UHC and CO production but causes high levels of NO<sub>x</sub> emission. Increasing the fuel/air ratio to reduce NO<sub>x</sub> results in increased CO and UHC emission. Approaches to reduce total emissions fall under two categories; the first concentrates on engine design and fuel modifications and the second involves treatment of exhaust gases after leaving the engine. In SI engines, the first approach focuses on addressing engine variables and design modifications which improve in-cylinder mixing and combustion in an effort to reduce CO and UHC emissions. To reduce NO<sub>x</sub>, attention is focused on factors that reduce peak combustion temperature and reduce the oxygen available in the flame front. Design and operating parameters that have been implemented or modified for decreased emissions include compression ratio reduction, increased coolant temperature, modification of the combustion chamber shape to minimize surface-to-volume ratio and increase turbulence, improvement of intake manifold design for better charge distribution, use of fuel injection instead of carburetors for better mixture control,

**FIGURE 8.3.14** Emission levels from an SI engine vs. fuel-air mixture.

use of exhaust gas recirculation to reduce NO<sub>x</sub> by lowering combustion temperatures, positive crankcase ventilation to reduce UHC, and increased aromatic content in gasoline.

Engine modifications that have been implemented to reduce emissions from CI engines include modifications to the combustion chamber shape to match the air swirl pattern and fuel spray pattern for better mixing and complete combustion, use of exhaust gas recirculation to limit NO<sub>x</sub> production, use of higher injection pressure for better atomization to reduce soot and UHC, and the use of precise injection timing with electronic control.

In the second approach, several devices have been developed for after treatment of exhaust products. A thermal reactor may be used to oxidize UHC and CO. These typically consist of a well-insulated volume placed close to the exhaust manifold, with internal baffles to increase the gas residence time and an air pump to supply fresh oxygen for the oxidation reactions. Thermal reactors are ineffective for NO<sub>x</sub> reduction and thus have limited application.

Catalytic converters utilize a catalyst, typically a noble metal such as platinum, rhodium, or palladium, deposited on a ceramic substrate to promote reactions at lower temperatures. Two types are in use, oxidation converters and reduction converters. Oxidation catalytic converters use the excess air available in lean mixtures (or supplied from an external air pump) to oxidize CO and UHC emissions. Reduction catalytic converters operate with low levels of oxygen to cause reduction of NO<sub>x</sub>. Sometimes, dual catalytic converters are employed to treat all three pollutants with a reducing converter, to reduce NO<sub>x</sub>, placed upstream of an oxidation converter for treating CO and UHC. This arrangement requires that the engine be operated with a rich mixture which decreases fuel economy.

Three-way catalytic converters are a recent development that permits treatment of NO<sub>x</sub>, CO, and UHC in a single device, thus reducing size and weight of the exhaust system. Proper operation of a three-way catalyst requires very nearly stoichiometric combustion. If the combustion is too lean, NO<sub>x</sub> is not adequately reduced, and if it is too rich, UHC and CO are not adequately oxidized. There is a narrow band for equivalence ratio from about 0.999 to 1.007 within which conversion efficiency is 80% or better for all three pollutants (Kummer, 1980). Maintaining engine operation within this narrow mixture band requires a closed-loop fuel-metering system that utilizes an oxygen sensor placed in the exhaust system to monitor excess oxygen and control the fuel injection to maintain near stoichiometric combustion.

Reduction catalytic converters cannot be used with CI engines to reduce NO<sub>x</sub> since they normally run lean with significant amounts of excess oxygen in the exhaust. Thus, engine design factors must be relied on to keep NO<sub>x</sub> as low as possible. Soot emission may be reduced by after treatment using a

device called a trap oxidizer. A trap oxidizer filters particulate matter from the exhaust stream and oxidizes it, usually with the aid of a catalyst for reducing the oxidation temperature. They have been used on small, high-speed automotive diesel engines, but their application to larger, slower-speed engines is limited because of the higher level of particulate production and the lower exhaust temperature. For additional information on emissions see Henein (1972), Obert (1973), and *SAE Surface Vehicle Emissions Standards Manual* (1993).

## Fuels for SI and CI Engines

### Background

The primary distinguishing factor between SI and CI engines is the fundamental difference in the combustion process. SI engines rely on homogeneous, premixed combustion, while CI engines are designed for heterogeneous combustion with a premixed combustion period followed by a diffusion combustion period. The differences in the combustion process call for quite different qualities in the fuels to achieve optimum performance.

By far the most common fuel for SI engines is gasoline, although other fuels can be used in special circumstances including alcohol, natural gas, and propane. Even such low-grade fuels as wood gas and coal gas have been used to fuel SI engines during wartime when conventional fuels were in short supply. Diesel fuel is the predominant fuel for CI engines, but they too can be designed to operate on a variety of other fuels, such as natural gas, bio-gas, and even coal slurries. This discussion is confined to gasoline and diesel fuel, both of which are distilled from crude oil.

Crude oil is composed of several thousand different hydrocarbon compounds, which upon heating are vaporized at different temperatures. In the distillation process, different “fractions” of the original crude are separated according to the temperatures at which they vaporize. The more volatile fraction, naphtha, is followed in order of increasing temperature of vaporization by fractions called distillate, gas oil, reduced crude, and residual oil. These fractions may be further subdivided into light, middle, and heavy classifications. Light virgin naphtha can be used directly as gasoline, although it has relatively poor antiknock quality. The heavier fractions can be chemically processed through coking and catalytic cracking to produce additional gasoline. Diesel fuel is derived from the light to heavy virgin gas oil fraction and from further chemical processing of reduced crude.

### Gasoline

Gasoline fuels are mixtures of hydrocarbon compounds with boiling points in the range of 32 to 215°C. The two most important properties of gasoline for SI engine performance are volatility and octane rating. Adequate volatility is required to ensure complete vaporization, as required for homogeneous combustion, and to avoid cold-start problems. If the volatility is too high, however, vapor locking in the fuel delivery system may become a problem. Volatility may be specified by the distillation curve (the distillation temperatures at which various percentages of the original sample have evaporated). Higher-volatility fuels will be characterized by lower temperatures for given fixed percentages of evaporated sample, or conversely, by higher percentages evaporated at or below a given temperature. Producers generally vary the volatility of gasoline to suit the season, increasing the volatility in winter to improve cold-start characteristics and decreasing it in summer to reduce vapor locking.

The octane rating of a fuel is a measure of its resistance to autoignition or knocking; higher-octane fuels are less prone to autoignition. The octane rating system assigns the value of 100 to iso-octane ( $C_8H_{18}$ , a fuel that is highly resistant to knock) and the value 0 to *n*-heptane ( $C_7H_{16}$ , a fuel that is prone to knock). Two standardized methods are employed to determine the octane rating of fuel test samples, the research method and the motor method; see ASTM Standards Part 47 — Test Methods for Rating Motor, Diesel and Aviation Fuels (ASTM, 1995). Both methods involve testing the fuel in a special variable-compression-ratio engine (cooperative fuels research or CFR engine). The test engine is operated on the fuel sample and the compression ratio is gradually increased to obtain a standard knock intensity reading from a knock meter. The octane rating is obtained from the volumetric percentage of iso-octane

in a blend of iso-octane and *n*-heptane that produces the same knock intensity at the same compression ratio. The principal differences between the research method and the motor method are the higher operating speed, higher mixture temperature, and greater spark advance employed in the motor method. Ratings obtained by the research method are referred to as the **research octane number (RON)**, while those obtained with the motor method are called the motor octane number (MON). MON ratings are lower than RON ratings because of the more stringent conditions, i.e., higher thermal loading of the fuel. The octane rating commonly advertised on gasoline pumps is the **antiknock index,  $(R + M)/2$** , which is the average of the values obtained by the two methods. The typical range of antiknock index for automotive gasolines currently available at the pump is 87 to 93. In general, higher compression SI engines require higher-octane fuels to avoid autoignition and to realize full engine performance potential from engines equipped with electronic control systems incorporating a knock sensor.

Straight-run gasoline (naphtha) has a poor octane rating on the order of 40 to 50 RON. Higher-octane fuels are created at the refinery by blending with higher-octane components produced through alkylation wherein light olefin gases are reacted with isobutane in the presence of a catalyst. Iso-octane, for example, is formed by reacting isobutane with butene. Aromatics with double carbon bonds shared between more than one ring, such as naphthalene and anthracene, serve to increase octane rating because the molecules are particularly difficult to break.

Additives are also used to increase octane ratings. In the past, a common octane booster added to automotive fuels was lead alkyls, either tetraethyl or tetramethyl lead. For environmental reasons, lead has been removed from automotive fuels in most countries. It is, however, still used in aviation fuel. Low-lead fuel has a concentration of about 0.5 g/L which boosts octane rating by about five points. The use of leaded fuel in an engine equipped with a catalytic converter to reduce exhaust emissions will rapidly deactivate the catalyst (typically a noble metal such as platinum or rhodium), quickly destroying the utility of the catalytic converter. Octane-boosting additives that are in current use include the oxygenators methanol, ethanol, and methyl tertiary butyl ether (MTBE).

RON values of special-purpose high-octane fuels for racing and aviation purposes can exceed 100 and are arrived at through an extrapolation procedure based on the knock-limited indicated mean effective pressure (klimep). The klimep is determined by increasing the engine intake pressure until knock occurs. The ratio of the klimep of the test fuel to that for iso-octane is used to extrapolate the octane rating above 100.

## Diesel Fuels

Diesel fuels are blends of hydrocarbon compounds with boiling points in the range of 180 to 360°C. Properties that are of primary importance for CI fuels include the density, viscosity, cloud point, and ignition quality (CN). Diesel fuel exhibits a much wider range of variation in properties than does gasoline. The density of diesel fuels tends to vary according to the percentages of various fractions used in the blend. Fractions with higher distillation temperatures tend to increase the density. Variations in density result in variations in volumetric energy content and hence fuel economy, since fuel is sold by volume measure. Higher-density fuel will also result in increased soot emission. Viscosity is important to proper fuel pump lubrication. Low-viscosity fuel will tend to cause premature wear in injection pumps. Too high viscosity, on the other hand, may create flow problems in the fuel delivery system. Cloud point is the temperature at which a cloud of wax crystals begins to form in the fuel. This property is critical for cold-temperature operation since wax crystals will clog the filtration system. ASTM does not specify maximum cloud point temperatures, but rather recommends that cloud points be no more than 6°C above the tenth percentile minimum ambient temperature for the region for which the fuel is intended; see ASTM D 975 (ASTM 1995).

CN provides a measure of the autoignition quality of the fuel and is the most important property for CI engine fuels. The CN of a fuel sample is obtained through the use of a CI CFR engine in a manner analogous to the determination of octane rating. The test method for CN determination is specified in standard ASTM D 613. *n*-Cetane (same as hexadecane, C<sub>16</sub>H<sub>34</sub>) has good autoignition characteristics and is assigned the cetane value of 100. The bottom of the cetane scale was originally defined in terms

of  $\alpha$ -methyl naphthalene ( $C_{11}H_{10}$ ) which has poor autoignition characteristics and was assigned the value 0. In 1962, for reasons of availability and storability, the poor-ignition-quality standard fuel used to establish the low end of the cetane scale was changed to heptamethylnonane (HMN), with an assigned CN of 15. The CN of a fuel sample is determined from the relative volumetric percentages of cetane and HMN in a mixture that exhibits the same ignition delay characteristics as the test sample using the relation

$$CN = \% \text{ n-Cetane} + 0.15 (\% \text{ HMN}) \quad (8.3.10)$$

ASTM standard D 976 (ASTM, 1995) provides the following empirical correlation for calculating the **cetane index** of straight petroleum distillate fuels (no additives) as an approximation to the measured CN:

$$\text{Cetane Index} = 454.74 - 1641.416D + 774.74D^2 - 0.554B + 97.803 (\log B)^2 \quad (8.3.11)$$

where  $D$  = density at 15°C (g/mL) and  $B$  = mid-boiling temperature (°C).

ASTM standard D 975 (ASTM, 1995) establishes three classification grades for diesel fuels (No. 1-D, No. 2-D, and No. 4-D) and specifies minimum property standards for these grades. No. 1-D is a volatile distillate fuel for engines that must operate with frequent changes in speed and load. No. 2-D is a lower-volatility distillate fuel for industrial and heavy mobile service engines. No. 4-D is a heavy fuel oil for low- and medium-speed engines. Nos. 1-D and 2-D are principally transportation fuels, while No. 4-D is for stationary applications. The ASTM minimum CN for No. 1-D and No. 2-D is 40, and for No. 4-D the minimum is 30. Typical CNs for transportation fuels lie in the range 40 to 55. Use of a low-cetane fuel aggravates diesel knock because of the longer ignition delay period which creates a higher fraction of premixed combustion.

Antiknock quality (octane number) and ignition quality (CN) are opposing properties of distillate fuels. The CN increases with decreasing octane rating of various fuels. Gasoline, with good antiknock quality, has a CN of approximately 10, while a diesel fuel with a CN of 50 will have an octane number of about 20. Thus, gasoline is not a suitable fuel for CI engines because of its poor autoignition quality, and diesel fuel is inappropriate for use in SI engines as a result of its poor antiknock quality. For additional information on fuels for IC engines see Owen and Coley (1995) and the *SAE Fuels and Lubricants Standards Manual* (1993).

## Intake Pressurization — Supercharging and Turbocharging

### Background

Pressurizing the intake air (or mixture) by means of a compressor may be used to boost the specific power output of both SI and CI engines. Supercharging generally refers to the use of compressors that are mechanically driven from the engine crankshaft, while turbocharging refers to compressors powered by a turbine which extracts energy from the exhaust stream. Increasing the intake pressure increases the density and hence the mass flow rate of the intake mixture, allowing an increase in the fueling rate, thereby producing additional power. The mere process of increasing the cylinder pressure results in increased work output per cycle, as illustrated in the  $P$ - $V$  diagram in [Figure 8.3.15](#) which compares supercharged and naturally aspirated, air standard Otto cycles having the same compression ratio. The work done for the compressed intake cycle (Area 1,2,3,4,1 and Area 5,6,7,1,5) is greater than that for the naturally aspirated cycle (Area 1',2',3',4',1') due to the boost of the intake pressure. Positive-displacement superchargers are capable of producing higher boost pressures than turbochargers, which are nearly always centrifugal-type fans. From a practical standpoint, the maximum useful boost pressure from either system is limited by the onset of autoignition in SI engines, and by the permissible mechanical and thermal stresses in CI engines.

**FIGURE 8.3.15** Comparison of supercharged and naturally aspirated Otto cycle.

### Supercharging

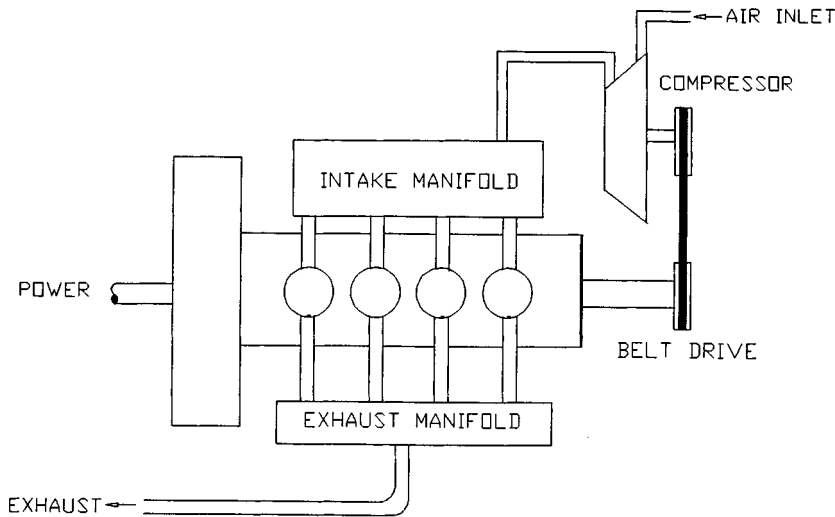

The principal applications of supercharging of SI engines are in high-output drag-racing engines and in large aircraft piston engines to provide high specific output at takeoff and to improve power output at high altitudes. For diesel applications, supercharging is used mainly in marine and land-transportation applications. It is common to use either supercharging or turbocharging to improve the scavenging process in two-stroke diesel engines. Figure 8.3.16 is a schematic of an engine with a mechanically driven supercharger. Superchargers may be belt, chain, or gear driven from the engine crankshaft.

Two types of superchargers are in use: the positive displacement type (Roots blower) and the centrifugal type. Roots blowers may be classified as: (1) straight double lobe, (2) straight triple lobe, and (3) helix triple lobe (twisted 60%). The helix-triple-lobe-type runs quieter than the others and is generally recommended, especially for diesel engines operating under high torque at various speed conditions. The centrifugal-type, because of its high capacity and small weight and size, is best suited for applications where power and volumetric efficiency improvement are required at high engine speed, e.g., with aircraft engines. A centrifugal blower will also survive a backfire more readily than a Roots blower in SI applications. Since superchargers are directly driven from the engine output shaft, there is no inherent lag in the rate of pressure increase with engine speed, as is typically the case with turbochargers.

### Turbocharging

Turbochargers utilize a centrifugal compressor that is directly connected to a turbine which extracts energy from the exhaust gases of the engine and converts it to the shaft work necessary to drive the compressor. Turbocharging is widely used to increase power output in automotive and truck applications of four-stroke SI and CI engines and to improve scavenging of two-stroke CI engines.

There are three methods of turbocharging: the constant-pressure, the pulse, and the pulse converter methods. In the constant-pressure method, as illustrated in Figure 8.3.17, the exhaust pressure is main-

**FIGURE 8.3.16** Schematic diagram of supercharged engine.

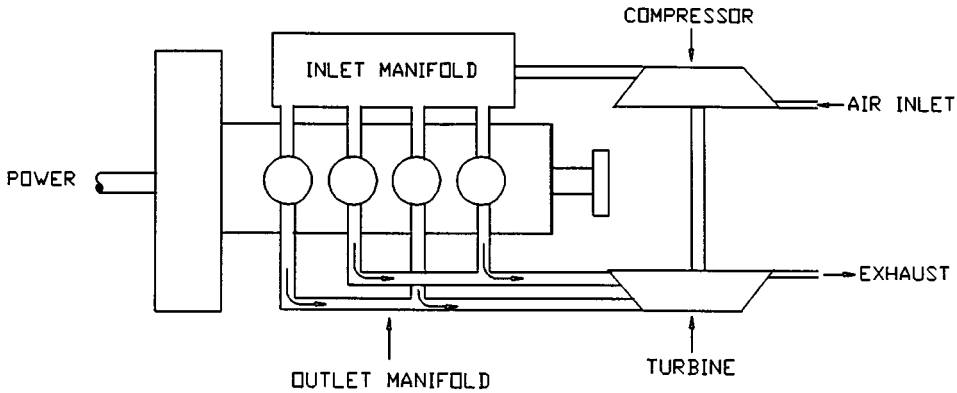

**FIGURE 8.3.17** Schematic diagram of a constant-pressure turbocharger.

tained at a nearly constant level above atmospheric. To accomplish this, the exhaust manifold must be large enough to damp out the pressure fluctuations caused by the unsteady flow characteristic of the engine exhaust process. In this method, the turbine operates efficiently under steady-flow conditions; however, some engine power is lost because of the increased backpressure in the exhaust manifold.

The pulse turbocharger, as illustrated in [Figure 8.3.18](#), utilizes the kinetic energy generated by the exhaust blow-down process in each cylinder. This is accomplished by using small exhaust lines grouped together in a common manifold to receive the exhaust from the cylinders which are blowing down sequentially. In this method, the pressure at the turbine inlet tends to fluctuate, which is not conducive to good turbine efficiency. This is offset to a large degree, however, by improved engine performance as a result of the lower exhaust backpressure relative to the constant-pressure method. The pulse converter method represents a compromise between the previous two techniques. In principle, this is accomplished by converting the kinetic energy in the blow-down process into a pressure rise at the turbine by utilizing one or more diffusers. Details of the different methods of turbocharging may be found in Watson and Janota (1982).

Recent advances in turbocharging technology have focused mainly on (1) improvement of the turbine transient response (turbo-lag), (2) improvement of the torque-speed characteristics of the engine, and (3) increasing the power output by increasing the boost pressure and using charge cooling (intercooling).

**FIGURE 8.3.18** Schematic diagram of a pulse turbocharger.

The use of ceramic materials in fabricating turbine rotors improves the turbine transient response since they are lighter in weight and have less rotational inertia. Ceramic rotors also have greater thermal operating range because of their lower thermal expansion. The use of variable-geometry turbochargers can improve the low-speed torque characteristics of the engine and help reduce the transient response time. This is due to the ability of the variable-geometry turbocharger to change its internal geometry to accommodate low flow rates at low engine speeds and higher-volume flow rates at high engine speeds. However, since the geometry of the turbine rotor remains unchanged while the internal geometry varies, the turbine efficiency will be reduced for all internal geometries other than the optimum design geometry. In response to increased demand for diesel engines with high boost pressure and with size constraints, advances in the aerothermodynamics of axial/radial flow and of two-stage turbochargers, and also in the design of compressor and turbine blades, have allowed high boost pressure at improved overall turbocharger efficiency.

Charge cooling by means of a heat exchanger (intercooler) between the compressor and the intake ports is effective in reducing  $\text{NO}_x$  emissions and improving the power output of turbocharged diesel engines and in reducing the probability of knock in SI engines. There are two types of charge cooling in use, air-to-air and air-to-water. Air-to-water cooling is used in marine applications, where a source of cool water is available, while air-to-air intercoolers are used for automotive and truck applications.

## Defining Terms

**Antiknock index:** The average of the two octane numbers obtained by the research method and the motor method.

**Autoignition:** The ability of a fuel-air mixture to spontaneously ignite under conditions of high temperature and pressure.

**Bottom dead center (BDC):** Piston located at its lowest position in the cylinder. Cylinder volume is maximum at BDC.

**Brake mean effective pressure (bmep):** Ratio of brake work output per cycle to the displacement volume.

**Brake specific fuel consumption (bsfc):** The ratio of fuel consumption rate in kg/hr to the engine output in kw.

**Brake work:** Work produced at the output shaft of an IC engine as measured by a dynamometer.

**Cetane index:** An approximation to the measured cetane number determined from an empirical relationship specified in ASTM D 976.

**Cetane number:** A measure of the autoignition quality of a fuel important for proper performance of CI engines determined experimentally through use of a CI CFR test engine.

**Clearance volume:** Combustion chamber volume remaining above the piston at TDC.

**Compression ignition (CI) engine:** Air alone is compressed in the cylinder and fuel is injected near TDC. Combustion results from autoignition of the fuel-air mixture due to the high temperature of the air.

**Compression ratio:** The ratio of the cylinder volume at BDC to the volume at TDC.

**Cut-off ratio:** Ratio of cylinder volume at the end of heat addition to the volume at the start of heat addition in the ideal diesel cycle.

**Cylinder volume:** Volume above piston at BDC. Equals displacement volume plus clearance volume.

**Direct injection (DI):** Method of fuel injection in low- and medium-speed CI engines wherein fuel is injected into the main combustion chamber which is formed by a bowl in the top of the piston.

**Displacement volume:** Difference in cylinder volume between TDC and BDC.

**Equivalence ratio:** Actual fuel-air ratio divided by stoichiometric fuel-air ratio.

**Four-stroke engine:** Entire cycle completed in two revolutions of the crankshaft and four strokes of the piston.

**Fuel-air ratio:** Ratio of mass of fuel to mass of air in the cylinder prior to combustion.

**Glow plug:** Electric heater installed in prechamber of an IDI diesel engine to aid cold starting.

**Heterogeneous combustion:** Refers to the mixture of liquid fuel droplets and evaporated fuel vapor and air mixture that is present in CI engine combustion chambers prior to ignition.

**Ignition delay period:** Period between start of injection and onset of autoignition in a CI engine.

**Indicated mean effective pressure (imep):** Ratio of net indicated work output of an IC engine to the displacement volume.

**Indicated work:** Work output of an IC engine cycle determined by an area calculation from an indicator diagram.

**Indicator diagram:** Pressure-volume trace for an IC engine cycle. Area enclosed by diagram represents work.

**Indirect injection (IDI):** Method of fuel injection used in high-speed CI engines wherein the fuel is injected into a precombustion chamber to promote fuel-air mixing and reduce ignition delay.

**Knock:** In SI engines: the noise that accompanies autoignition of the end portion of the uncombusted mixture prior to the arrival of the flame front. In CI engines: The noise that accompanies autoignition of large premixed fractions that are generated during prolonged ignition delay periods. Knock is detrimental to either type of engine.

**NO<sub>x</sub>:** Harmful oxides of nitrogen (NO and NO<sub>2</sub>) appearing in the exhaust products of IC engines.

**Octane number:** Antiknock rating for fuels important for prevention of autoignition in SI engines.

**Particulates:** Any exhaust substance, other than water, that can be collected on a filter. Harmful exhaust product from CI engines.

**Power density:** Power produced per unit of engine mass.

**Premixed homogeneous combustion:** Fuel and air are mixed in an appropriate combustible ratio prior to ignition process. This is the combustion mode for SI engines and for the initial combustion phase in CI engines.

**Sac volume:** Volume of nozzles below the needle of a diesel fuel injector that provides a source of UHC emissions in CI engines.

**Scavenging:** The process of expelling exhaust gases and filling the cylinder with fresh charge in two-stroke engines. This is often accomplished in SI engines by pressurizing the fresh mixture in the crankcase volume beneath the piston and in CI engines by using a supercharger or turbocharger.

**Spark ignition (SI) engine:** Homogeneous charge of air-fuel mixture is compressed and ignited by a spark.

**Stroke:** Length of piston movement from TDC to BDC, equal to twice the crankshaft throw.

**Supercharging:** Pressurizing the intake of an IC engine using a compressor that is mechanically driven from the crankshaft.

**Surface ignition:** A source of autoignition in SI engines caused by surface hot spots.

**Swirl:** Circular in-cylinder air motion designed into CI engines to promote fuel-air mixing.

**Swirl ratio:** Ratio of rotational speed of in-cylinder air (rpm) to engine speed (rpm).

**Top dead center (TDC):** Piston located at its uppermost position in the cylinder. Cylinder volume (above the piston) is minimum at TDC.

**Turbocharging:** Pressurizing the intake of an IC engine with a compressor that is driven by a turbine which extracts energy from the exhaust gas stream.

**Two-stroke engine:** Entire cycle completed in one revolution of the crankshaft and two strokes of the piston.

**Unburned hydrocarbons (UHC):** Harmful emission product from IC engines consisting of hydrocarbon compounds that remain uncombusted.

**Volumetric efficiency:** Ratio of the actual mass of air intake per cycle to the displacement volume mass determined at inlet temperature and pressure.

## Further Information

The textbooks on IC engines by Ferguson (1986), Heywood (1988), Obert (1973), Stone (1993), and Taylor (1985) listed under the references all provide excellent treatments of this subject. The book by Stone, in particular, is up-to-date and informative. The *Handbook of Engineering* (1966) by CRC Press, Boca Raton, FL, contains a chapter on IC Engines by A. Kornhauser. The Society of Automotive Engineers (SAE) publishes transactions, proceedings, and books related to all aspects of automotive engineering, including IC engines. Two very comprehensive handbooks distributed by SAE are the *Bosch Automotive Handbook*, and the *SAE Automotive Handbook*. ## 8.4 Hydraulic Turbines

Roger E. A. Arndt

### Introduction

A hydraulic turbine is a mechanical device that converts the potential energy associated with a difference in water elevation (**head**) into useful work. Modern hydraulic turbines are the result of many years of gradual development. Economic incentives have resulted in the development of very large units (exceeding 800 mW in capacity) with efficiencies that are sometimes in excess of 95%.

The emphasis on the design and manufacture of very large turbines is shifting to the production of smaller units, especially in developed nations, where much of the potential for developing large-base-load plants has been realized. At the same time, the escalation in the cost of energy has made many smaller sites economically feasible and has greatly expanded the market for smaller turbines. The increased value of energy also justifies the cost of refurbishment and increasing the capacity of older facilities. Thus, a new market area is developing for updating older turbines with modern replacement **runners** having higher efficiency and greater capacity.

### General Description

#### Typical Hydropower Installation

As shown schematically in [Figure 8.4.1](#), the hydraulic components of a hydropower installation consist of an intake, penstock, guide vanes or distributor, turbine, and **draft tube**. Trash racks are commonly provided to prevent ingestion of debris into the turbine. Intakes usually require some type of shape transition to match the passageway to the turbine and also incorporate a gate or some other means of stopping the flow in case of an emergency or for turbine maintenance. Some types of turbines are set in an open flume; others are attached to a closed-conduit penstock.

**FIGURE 8.4.1** Schematic of a hydropower installation.

## Turbine Classification

There are two types of turbines, denoted as impulse and reaction. In an impulse turbine, the available head is converted to kinetic energy before entering the **runner**; the power available is extracted from the flow at approximately atmospheric pressure. In a reaction turbine, the runner is completely submerged and both the pressure and the velocity decrease from inlet to outlet. The velocity head in the inlet to the turbine runner is typically less than 50% of the total head available.

*Impulse Turbines.* Modern impulse units are generally of the Pelton type and are restricted to relatively high-head applications (Figure 8.4.2). One or more jets of water impinge on a wheel containing many curved buckets. The jet stream is directed inward, sideways, and outward, thereby producing a force on the bucket, which in turn results in a torque on the shaft. All kinetic energy leaving the runner is “lost.” A draft tube is generally not used since the runner operates under approximately atmospheric pressure and the head represented by the elevation of the unit above tailwater cannot be utilized.\* Since this is a high-head device, this loss in available head is relatively unimportant. As will be shown later, the Pelton wheel is a low-**specific-speed** device. Specific speed can be increased by the addition of extra nozzles, the specific speed increasing by the square root of the number of nozzles. Specific speed can also be increased by a change in the manner of inflow and outflow. Special designs such as the Turgo or cross-flow turbines are examples of relatively high specific speed impulse units (Arndt, 1991).

**FIGURE 8.4.2** Cross section of a single wheel, single jet Pelton turbine. This is the third-highest-head pelton turbine in the world,  $H = 1447$  m,  $n = 500$  rpm,  $P = 35.2$  MW,  $N_s \sim 0.038$ . (Courtesy of Vevey Charmilles Engineering Works, Adapted from J. Raabe, *Hydro Power: The Design, Use, and Function of Hydromechanical, Hydraulic, and Electrical Equipment*, VDI Verlag, Dusseldorf, Germany.)

Most Pelton wheels are mounted on a horizontal axis, although newer vertical-axis units have been developed. Because of physical constraints on orderly outflow from the unit, the maximum number of nozzles is generally limited to six or fewer. While the power of a reaction turbine is controlled by the **wicket gates**, the power of the Pelton wheel is controlled by varying the nozzle discharge by means of an automatically adjusted needle, as illustrated in Figure 8.4.2. Jet deflectors, or auxiliary nozzles are provided for emergency unloading of the wheel. Additional power can be obtained by connecting two wheels to a single generator or by using multiple nozzles. Since the needle valve can throttle the flow while maintaining essentially constant jet velocity, the relative velocities at entrance and exit remain unchanged, producing nearly constant efficiency over a wide range of power output.

\* In principle, a draft tube could be used, which requires the runner to operate in air under reduced pressure. Attempts at operating an impulse turbine with a draft tube have not met with much success.

*Reaction Turbines.* Reaction turbines are classified according to the variation in flow direction through the runner. In radial- and mixed-flow runners, the flow exits at a radius different than from the radius at the inlet. If the flow enters the runner with only radial and tangential components, it is a radial-flow machine. The flow enters a mixed-flow runner with both radial and axial components. Francis turbines are of the radial- and mixed-flow types, depending on the design specific speed. A Francis turbine is illustrated in [Figure 8.4.3](#).

**FIGURE 8.4.3** Francis turbine,  $N_s \sim 0.66$ . (Adapted from J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

Axial-flow propeller turbines are generally either of the fixed-blade or Kaplan (adjustable-blade) variety. The “classical” propeller turbine, illustrated in [Figure 8.4.4](#), is a vertical-axis machine with a scroll case and a radial wicket gate configuration that is very similar to the flow inlet for a Francis turbine. The flow enters radially inward and makes a right-angle turn before entering the runner in an axial direction. The Kaplan turbine has both adjustable runner blades and adjustable wicket gates. The control system is designed so that the variation in blade angle is coupled with the wicket gate setting in a manner which achieves best overall efficiency over a wide range of flow rates.

Some modern designs take full advantage of the axial-flow runner; these include the tube, bulb, and Straflo types illustrated in [Figure 8.4.5](#). The flow enters and exits the turbine with minor changes in direction. A wide variation in civil works design is also permissible. The tubular-type can be fixed propeller, semi-Kaplan, or fully adjustable. An externally mounted generator is driven by a shaft which extends through the flow passage either upstream or downstream of the runner. The bulb turbine was originally designed as a high-output, low-head unit. In large units, the generator is housed within the bulb and is driven by a variable-pitch propeller at the trailing end of the bulb. Pit turbines are similar in principle to bulb turbines, except that the generator is not enclosed in a fully submerged compartment (the bulb). Instead, the generator is in a compartment that extends above water level. This improves access to the generator for maintenance.

## Principles of Operation

### Power Available, Efficiency

The power that can be developed by a turbine is a function of both the head and flow available:

$$P \approx \eta \rho g Q H \quad (8.4.1)$$

**FIGURE 8.4.4** Smith-Kaplan axial flow turbine with adjustable-pitch runner blades  $N_s \sim 2.0$ . (From J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

where  $\eta$  is the turbine efficiency,  $\rho$  is the density of water ( $\text{kg/m}^3$ ),  $g$  is the acceleration due to gravity ( $\text{m/sec}^2$ ),  $Q$  is the flow rate ( $\text{m}^3/\text{sec}$ ), and  $H$  is the *net head* in meters. Net head is defined as the difference between the total head at the inlet to the turbine and the total head at the tailrace as illustrated in [Figure 8.4.1](#). Different definitions of net head are used in practice, which depend on the value of the exit velocity head,  $V_e^2/2g$ , used in the calculation. The International Electrotechnical Test Code uses the velocity head at the draft tube exit.

The efficiency depends on the actual head and flow utilized by the turbine runner, flow losses in the draft tube, and the frictional resistance of mechanical components.

### Similitude and Scaling Formulae

Under a given head, a turbine can operate at various combinations of speed and flow depending on the inlet settings. For reaction turbines, the flow into the turbine is controlled by the wicket gate angle,  $\alpha$ . The flow is typically controlled by the nozzle opening in impulse units. Turbine performance can be described in terms of nondimensional variables:

**FIGURE 8.4.5** Comparison between bulb (upper) and Straflow (lower) turbines. (Courtesy of U.S. Department of Energy.)

$$\psi = \frac{2gH}{\omega^2 D^2} \quad (8.4.2)$$

$$\phi = \frac{Q}{\sqrt{2gHD^2}} \quad (8.4.3)$$

where  $\omega$  is the rotational speed of the turbine in radians per second and  $D$  is the diameter of the turbine.

The hydraulic efficiency of the runner alone is given by

$$\eta_h = \frac{\phi}{\sqrt{\psi}} (C_1 \cos \alpha_1 - C_2 \cos \alpha_2) \quad (8.4.4)$$

where  $C_1$  and  $C_2$  are constants that depend on the specific turbine configuration and  $\alpha_1$  and  $\alpha_2$  are the inlet and outlet angles that the absolute velocity vectors make with the tangential direction. The value of  $\cos \alpha_2$  is approximately zero at peak efficiency. The terms  $\phi$ ,  $\psi$ ,  $\alpha_1$ , and  $\alpha_2$  are interrelated. By using model test data, isocontours of efficiency can be mapped in the  $\phi$ - $\psi$  plane. This is typically referred to as a hill diagram as shown in [Figure 8.4.6](#).

The specific speed is defined as

$$N_s \equiv \frac{\omega \sqrt{Q}}{(2gH)^{3/4}} = \sqrt{\frac{\phi}{\psi}} \quad (8.4.5)$$

A given specific speed describes a specific combination of operating conditions that ensures similar flow patterns and same efficiency in geometrically similar machines regardless of size and rotational speed of the machine. It is customary to define the design specific speed in terms of the value at the design head and flow where peak efficiency occurs. The value of specific speed so defined permits a classification of different turbine types.

**FIGURE 8.4.6** Typical hill diagram. (Adapted from T.L. Wall, Draft tube surging times two: the twin vortex problem, in *Hydro Rev.* 13(1): 60–69, 1994. With permission.)

The specific speed defined herein is dimensionless. Many other forms of specific speed exist which are dimensional and have different numerical values depending on the system of units used (Arndt, 1991).<sup>\*</sup> The similarity arguments used to arrive at the concept of specific speed indicate that a given machine of diameter  $D$  operating under a head  $H$  will discharge a flow  $Q$  and produce a torque  $T$  and power  $P$  at a rotational speed  $\omega$  given by

$$Q = \phi D^2 \sqrt{2gH} \tag{8.4.6}$$

$$T = T_{11} \rho D^3 2gH \tag{8.4.7}$$

$$P = P_{11} \rho D^2 (2gH)^{3/2} \tag{8.4.8}$$

$$\omega = \frac{2u_1}{D} = \omega_{11} = \frac{\sqrt{2gH}}{D} \quad \left[ \omega_{11} = \frac{1}{\sqrt{\psi}} \right] \tag{8.4.9}$$

<sup>\*</sup> The literature also contains two other minor variations of the dimensionless form. One differs by a factor of  $1/\pi^{1/2}$  and the other by  $2^{3/4}$ .

with

$$P_{11} = T_{11}\omega_{11} \quad (8.4.10)$$

where  $T_{11}$ ,  $P_{11}$ , and  $\omega_{11}$  are also nondimensional.\* In theory, these coefficients are fixed for a machine operating at a fixed value of specific speed, independent of the size of the machine. Equations 8.4.6 through 8.4.10 can be used to predict the performance of a large machine using the measured characteristics of a smaller machine or model.

## Factors Involved in Selecting a Turbine

### Performance Characteristics

Impulse and reaction turbines are the two basic types of turbines. They tend to operate at peak efficiency over different ranges of specific speed. This is due to geometric and operational differences.

*Impulse Turbines.* Of the head available at the nozzle inlet, a small portion is lost to friction in the nozzle and to friction on the buckets. The rest is available to drive the wheel. The actual utilization of this head depends on the velocity head of the flow leaving the turbine and the setting above tailwater. Optimum conditions, corresponding to maximum utilization of the head available, dictate that the flow leaves at essentially zero velocity. Under ideal conditions, this occurs when the peripheral speed of the wheel is one half the jet velocity. In practice, optimum power occurs at a speed coefficient,  $\omega_{11}$ , somewhat less than 1.0. This is illustrated in Figure 8.4.7. Since the maximum efficiency occurs at fixed speed for fixed  $H$ ,  $V_j$  must remain constant under varying flow conditions. Thus, the flow rate  $Q$  is regulated with an adjustable nozzle. However, maximum efficiency occurs at slightly lower values of  $\omega_{11}$  under partial power settings. Present nozzle technology is such that the discharge can be regulated over a wide range at high efficiency.

**FIGURE 8.4.7** Ideal and actual variable-speed performance for an impulse turbine. (Adapted from J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

\* The reader is cautioned that many texts, especially in the American literature, contain dimensional forms of  $T_{11}$ ,  $P_{11}$ , and  $\omega_{11}$ .

A given head and penstock configuration establishes the optimum jet velocity and diameter. The size of the wheel determines the speed of the machine. The design specific speed is approximately

$$N_s = 0.77 \frac{d_j}{D} \quad (\text{Pelton turbines}) \quad (8.4.11)$$

Practical values of  $d_j/D$  for Pelton wheels to ensure good efficiency are in the range 0.04 to 0.1, corresponding to  $N_s$  values in the range 0.03 to 0.08. Higher specific speeds are possible with multiple-nozzle designs. The increase is proportional to the square root of the number of nozzles. In considering an impulse unit, one must remember that efficiency is based on net head; the net head for an impulse unit is generally less than the net head for a reaction turbine at the same *gross head* because of the lack of a draft tube.

*Reaction Turbines.* The main difference between impulse and reaction turbines is the fact that a pressure drop takes place in the rotating passages of the reaction turbine. This implies that the entire flow passage from the turbine inlet to the discharge at the tailwater must be completely filled. A major factor in the overall design of modern reaction turbines is the draft tube. It is usually desirable to reduce the overall equipment and civil construction costs by using high-specific speed runners. Under these circumstances the draft tube is extremely critical both flow-stability and efficiency viewpoints.\* At higher specific speed, a substantial percentage of the available total energy is in the form of kinetic energy leaving the runner. To recover this efficiently, considerable emphasis should be placed on the draft tube design.

The practical specific speed range for reaction turbines is much broader than for impulse wheels. This is due to the wider range of variables which control the basic operation of the turbine. The pivoted guide vanes allow for control of the magnitude and direction of the inlet flow. Because there is a fixed relationship among blade angle, inlet velocity, and peripheral speed for shock-free entry, this requirement cannot be completely satisfied at partial flow without the ability to vary blade angle. This is the distinction between the efficiency of fixed-propeller and Francis-types at partial loads and the fully adjustable Kaplan design.

Referring to Equation 8.4.4, optimum hydraulic efficiency of the runner would occur when  $\alpha_2$  is equal to  $90^\circ$ . However, the overall efficiency of the turbine is dependent on the optimum performance of the draft tube as well, which occurs with a little swirl in the flow. Thus, the best overall efficiency occurs with  $\alpha_2 \approx 75^\circ$  for high-specific speed turbines.

The determination of optimum specific speed in a reaction turbine is more complicated than for an impulse unit since there are more variables. For a radial-flow machine, an approximate expression is

$$N_s = 1.64 \left[ C_v \sin \alpha_1 \frac{B}{D_1} \right]^{1/2} \omega_{11} \quad (\text{Francis turbines}) \quad (8.4.12)$$

where  $C_v$  is the fraction of net head that is in the form of inlet velocity head and  $B$  is the height of the inlet flow passage (Figure 8.4.3). Value of  $N_s$  for Francis units is normally found to be in the range 0.3 to 2.5.

Standardized axial-flow machines are available in the smaller sizes. These units are made up of standard components, such as shafts and blades. For such cases,

$$N_s \sim \frac{\sqrt{\tan \beta}}{n_B^{3/4}} \quad (\text{propeller turbines}) \quad (8.4.13)$$

\* This should be kept in mind when retrofitting an older, low-specific-speed turbine with a new runner of higher capacity.

where  $\beta$  is the blade pitch angle and  $n_b$  is the number of blades. The advantage of controllable pitch is also obvious from this formula, the best specific speed simply being a function of pitch angle.

It should be further noted that  $\omega_{11}$  is approximately constant for Francis units and  $N_s$  is proportional to  $(B/D_1)^{1/2}$ . It can be also shown that velocity component based on the peripheral speed at the throat,  $\omega_{11e}$ , is proportional to  $N_s$ . In the case of axial-flow machinery,  $\omega_{11}$  is also proportional to  $N_s$ . For minimum cost, peripheral speed should be as high as possible, consistent with cavitation-free performance. Under these circumstances,  $N_s$  would vary inversely with the square root of head:

$$N_s = \frac{C}{\sqrt{H}} \quad (H \text{ is in meters}) \quad (8.4.14)$$

where the range of  $C$  is 21 to 30 for fixed propeller units, 21 to 32 for Kaplan units, and 16 to 25 for Francis units.

*Performance Comparison.* The physical characteristics of various runner configurations are summarized in Figure 8.4.8. It is obvious that the configuration changes with speed and head. Impulse turbines are efficient over a relatively narrow range of specific speed, whereas Francis and propeller turbines have a wider useful range. An important consideration is whether or not a turbine is required to operate over a wide range of load. Pelton wheels tend to operate efficiently over a wide range of power loading because of their nozzle design. In the case of reaction machines that have fixed geometry, such as Francis and propeller turbines, efficiency can vary widely with load. However, Kaplan and Deriaz\* turbines can maintain high efficiency over a wide range of operating conditions. The decision of whether to select a simple configuration with a relatively “peaky” efficiency curve or go to the added expense of installing a more complex machine with a broad efficiency curve will depend on the expected operation of the plant and other economic factors.

Note in Figure 8.4.8 that there is an overlap in the range of application of various types of equipment. This means that either type of unit can be designed for good efficiency in this range, but other factors, such as generator speed and cavitation, may dictate the final selection.

### Speed Regulation

The speed regulation of a turbine is an important and complicated problem. The magnitude of the problem varies with size, type of machine and installation, type of electrical load, and whether or not the plant is tied into an electrical grid. Note that runaway or no-load speed can be higher than design speed by factors as high as 2.6. This is an important design consideration for all rotating parts, including the generator.

The speed of a turbine has to be controlled to a value that matches the generator characteristics and the grid frequency:

$$n = \frac{120f}{N_p} \quad (8.4.15)$$

where  $n$  is turbine speed in rpm,  $f$  is the required grid frequency in Hz, and  $N_p$  is the number of poles in the generator. Typically,  $N_p$  is in multiples of 4. There is a tendency to select higher speed generators to minimize weight and cost. However, consideration has to be given to speed regulation.

It is beyond the scope of this section to discuss the question of speed regulation in detail. Regulation of speed is normally accomplished through flow control. Adequate control requires sufficient rotational inertia of the rotating parts. When load is rejected, power is absorbed, accelerating the flywheel; and when load is applied, some additional power is available from deceleration of the flywheel. Response

\* An adjustable blade mixed-flow turbine (Arndt, 1991).

**FIGURE 8.4.8** Application chart for various turbine types ( $n/n_s$  is the ratio of turbine speed in rpm,  $n$ , to specific speed defined in the metric system,  $n_s = nP^{1/2}/H^{3/4}$  with  $P$  in kilowatts). (From Arndt, R.E.A., in *Hydropower Engineering Handbook*, J.S. Gulliver and R.E.A. Arndt, Eds., McGraw-Hill, New York, 1991, 4.1–4.67. With permission.)

time of the governor must be carefully selected, since rapid closing can lead to excessive pressures in the penstock.

A Francis turbine is controlled by opening and closing the wicket gates, which vary the flow of water according to the load. The actuator components of a governor are required to overcome the hydraulic and frictional forces and to maintain the wicket gates in fixed position under steady load. For this reason, most governors have hydraulic actuators. On the other hand, impulse turbines are more easily controlled, because the jet can be deflected or an auxiliary jet can be bypassed from the power-producing jet without changing the flow rate in the penstock. This permits long delay times for adjusting the flow rate to the new flywheel; and when load is applied power conditions. The spear or needle valve controlling the flow rate can close quite slowly, say, in 30 to 60 sec, thereby minimizing pressure rise in the penstock.

Several types of governors are available, which vary with the work capacity desired and/or the degree of sophistication of control. These vary from pure mechanical to mechanical-hydraulic and electrohydraulic. Electrohydraulic units are sophisticated pieces of equipment and would not be suitable for remote regions. The precision of governing necessary will depend on whether the electrical generator is synchronous or asynchronous (induction type). There are advantages to the induction type of generator. It is less complex and therefore less expensive, but has typically slightly lower efficiency. Its frequency is controlled by the frequency of the grid it is feeding into, thereby eliminating need of an expensive conventional governor. It cannot operate independently but can only feed into a network and does so with lagging power factor which may or may not be a disadvantage, depending on the nature of the load. Long transmission lines, for example, have a high capacitance and in this case the lagging power factor may be an advantage.

Speed regulation is a function of the flywheel effect of the rotating components and the inertia of the water column of the system. The start-up time of the rotating system is given by

$$t_s = \frac{I\omega^2}{P} \quad (8.4.16)$$

where  $I$  = moment of inertia of the generator and turbine,  $\text{kg} \cdot \text{m}^2$  (Bureau of Reclamation, 1966).

The start-up time of the water column is given by

$$t_p = \frac{\sum LV}{gH} \quad (8.4.17)$$

where  $L$  = length of water column

$V$  = velocity in each component of the water column

For good speed regulation, it is desirable to keep  $t_s/t_p > 4$ . Lower values can also be used, although special precautions are necessary in the control equipment. Higher ratios of  $t_s/t_p$  can be obtained by increasing  $I$  or decreasing  $t_p$ . Increasing  $I$  implies a larger generator, which also results in higher costs. The start-up time of the water column can be reduced by reducing the length of the flow system, by using lower velocities, or by adding **surge tanks**, which essentially reduce the effective length of the conduit. A detailed analysis should be made for each installation, since for a given length, head, and discharge the flow area must be increased to reduce  $t_p$ , which leads to associated higher construction costs.

### Cavitation and Turbine Setting

Another factor that must be considered prior to equipment selection is the evaluation of the turbine with respect to tailwater elevations. Hydraulic turbines are subject to pitting due to cavitation (Arndt, 1981, 1991). For a given head, smaller, lower-cost, high-speed runner must be set lower (i.e. closer to tailwater or even below tailwater) than a larger, higher-cost, low-speed turbine runner. Also, atmospheric pressure or elevation above sea level is a factor, as are tailwater elevation ion variations and operating requirements. This is a complex concept which can only be accurately resolved by model tests. The runner design will have different cavitation characteristics. Therefore, the anticipated turbine location or setting with respect to tailwater elevations is an important consideration in turbine selection.

Cavitation is not normally a problem with impulse wheels. However, by the very nature of their operation, cavitation is an important factor in reaction turbine installations. The susceptibility for cavitation to occur is a function of the installation and the turbine design. This can be expressed conveniently in terms of Thoma's sigma defined as

$$\sigma_T = \frac{H_a - H_v - z}{H} \quad (8.4.18)$$

where  $H_a$  is the atmospheric pressure head,  $H_v$  is the vapor pressure need (generally negligible), and  $z$  is the elevation of a turbine reference plane above the tailwater (see [Figure 8.4.1](#)). Draft tube losses and the exit velocity head have been neglected.

$\sigma_T$  must be above a certain value to avoid cavitation problems. The critical value of  $\sigma_T$  is a function of specific speed (Arndt, 1991). The Bureau of Reclamation (1966) suggests that cavitation problems can be avoided when

$$\sigma_T > 0.26N_s^{1.64} \quad (8.4.19)$$

Equation 8.4.19 does not guarantee total elimination of cavitation, only that cavitation is within acceptable limits. Cavitation can be totally avoided only if the value  $\sigma_T$  at an installation is much greater than the limiting value given in Equation 8.4.19. The value of  $\sigma_T$  for a given installation is known as

the plant sigmas,  $\sigma_p$ . Equation 8.4.19 should only be considered as a guide in selecting  $\sigma_p$ , which is normally determined by a model test in the manufacturer's laboratory. For a turbine operating under a given head, the only variable controlling  $\sigma_p$  is the turbine setting  $z$ . The required value of  $\sigma_p$  then controls the allowable setting above tailwater:

$$z_{\text{allow}} = H_a - H_v - \sigma_p H \quad (8.4.20)$$

It must be borne in mind that  $H_a$  varies with elevation. As a rule of thumb,  $H_a$  decreases from the sea-level value of 10.3 m by 1.1 m for every 1000 m above sea level.

## Defining Terms

**Draft tube:** The outlet conduit from a turbine which normally acts as a diffuser. This is normally considered to be an integral part of the unit.

**Forebay:** The hydraulic structure used to withdraw water from a reservoir or river. This can be positioned a considerable distance upstream from the turbine inlet.

**Head:** The specific energy per unit weight of water. *Gross head* is the difference in water surface elevation between the forebay and tailrace. *Net head* is the difference between *total head* (the sum of velocity head  $V^2/2g$ , pressure head  $p/\rho g$ , and elevation head  $z$  at the inlet and outlet of a turbine. Some European texts use specific energy per unit mass, e.g., specific kinetic energy is  $V^2/2$ ).

**Runner:** The rotating component of a turbine in which energy conversion takes place.

**Specific speed:** A universal number for a given machine design.

**Spiral case:** The inlet to a reaction turbine.

**Surge tank:** A hydraulic structure used to diminish overpressures in high-head facilities due to water hammer resulting from the sudden stoppage of a turbine

**Wicket gates:** Pivoted, streamlined guide vanes that control the flow of water to the turbine.

## 8.5 Stirling Engines

*William B. Stine*

### Introduction

The Stirling engine was patented in 1816 by Rev. Robert Stirling, a Scottish minister ([Figure 8.5.1](#)). Early Stirling engines were coal-burning, low-pressure air engines built to compete with saturated steam engines for providing auxiliary power for manufacturing and mining. In 1887, John Ericsson built an enormous marine Stirling engine with four 4.2-m-diameter pistons. Beginning in the 1930s, the Stirling engine was brought to a high state of technology development by Philips Research Laboratory in Eindhoven, The Netherlands with the goal of producing small, quiet electrical generator sets to be used with high-power-consuming vacuum tube electronic devices. Recently, interest in Stirling engines has resurfaced, with solar electric power generation (Stine and Diver, 1994) and hybrid automotive applications in the forefront.

**FIGURE 8.5.1** The original patent Stirling engine of Rev. Robert Stirling.

In theory, the **Stirling cycle** engine can be the most efficient device for converting heat into mechanical work with high efficiencies requiring high-temperatures. In fact, with regeneration, the efficiency of the Stirling cycle equals that of the Carnot cycle, the most efficient of all ideal thermodynamic cycles. (See West, 1986 for further discussion of the thermodynamics of Stirling cycle machines.)

Since their invention, prototype Stirling engines have been developed for automotive purposes; they have also been designed and tested for service in trucks, buses, and boats (Walker, 1973). The Stirling engine has been proposed as a propulsion engine in yachts, passenger ships, and road vehicles such as city buses (Meijer, 1992). The Stirling engine has also been developed as an underwater power unit for submarines, and the feasibility of using the Stirling for high-power space-borne systems has been explored by NASA (West, 1986). The Stirling engine is considered ideal for solar heating, and the first solar application of record was by John Ericsson, the famous British-American inventor, in 1872 (Stine and Diver, 1994).

Stirling engines are generally externally heated engines. Therefore, most sources of heat can be used to drive them, including combustion of just about anything, radioisotopes, solar energy, and exothermic

chemical reactions. High-performance Stirling engines operate at the thermal limits of the materials used for their construction. Typical temperatures range from 650 to 800°C (1200 to 1470°F), resulting in engine conversion efficiencies of around 30 to 40%. Engine speeds of 2000 to 4000 rpm are common

## Thermodynamic Implementation of the Stirling Cycle

In the ideal Stirling cycle, a **working gas** is alternately heated and cooled as it is compressed and expanded. Gases such as helium and hydrogen, which permit rapid heat transfer and do not change phase, are typically used in the high-performance Stirling engines. The ideal Stirling cycle combines four processes, two constant-temperature heat-exchange processes and two constant-volume heat-exchange processes. Because more work is done by expanding high-temperature, high-pressure gas than is required to compress low-temperature, low-pressure gas, the Stirling cycle produces net work, which can drive an electric alternator or other mechanical devices.

### Working Gases

In the Stirling cycle, the working gas is alternately heated and cooled in constant-temperature and constant-volume processes. The traditional gas for Stirling engines has been air at atmospheric pressure. At this pressure, air has a reasonably high density and therefore can be used directly in the cycle with loss of working gas through seals a minor problem. However, internal component temperatures are limited because of the oxygen in air which can degrade materials rapidly.

Because of their high heat-transfer capabilities, hydrogen and helium are used for high-speed, high-performance Stirling engines. To compensate for the low density of these gases, the mean pressure of the working gas is raised by charging the gas spaces in the engine to high pressures. Compression and expansion vary above and below this **charge pressure**. Hydrogen, thermodynamically a better choice, generally results in more-efficient engines than does helium (Walker, 1980). Helium, on the other hand, has fewer material-compatibility problems and is safer to work with. To maximize power, high-performance engines typically operate at high pressure, in the range of 5 to 20 MPa (725 to 2900 psi). Operation at these high gas pressures makes sealing difficult, and seals between the high-pressure region of the engine and those parts at ambient pressure have been problematic in some engines. New designs to reduce or eliminate this problem are currently being developed.

### Heat Exchange

The working gas is heated and cooled by heat exchangers that add heat from an external source, or reject heat to the surroundings. Further, in most engines, an internal heat storage unit stores and rejects heat during each cycle.

The **heater** of a Stirling engine is usually made of many small-bore tubes that are heated externally with the working gas passing through the inside. External heat transfer by direct impingement of combustion products or direct adsorption of solar irradiation is common. A trade-off between high heat-transfer rate using many small-bore tubes with resulting pumping losses, and fewer large-bore tubes and lower pumping losses drives the design. A third criterion is that the volume of gas trapped within these heat exchangers should be minimal to enhance engine performance. In an attempt to provide more uniform and constant-temperature heat transfer to the heater tubes, **reflux** heaters are being developed (Stine and Diver, 1994). Typically, by using sodium as the heat-transfer medium, liquid is evaporated at the heat source and is then condensed on the outside surfaces of the engine heater tubes.

The **cooler** is usually a tube-and-shell heat exchanger. Working gas is passed through the tubes, and cooling water is circulated around the outside. The cooling water is then cooled in an external heat exchanger. Because all of the heat rejected from the power cycle comes from the cooler, the Stirling engine is considered ideal for cogeneration applications.

Most Stirling engines incorporate an efficiency-enhancing **regenerator** that captures heat from the working gas during constant-volume cooling and replaces it when the gas is heated at constant volume. Heating and cooling of the regenerator occurs at over 60 times a second during high-speed engine operation. In the ideal cycle, all of the heat-transferred during the constant volume heating and cooling

processes occurs in the regenerator, permitting the external heat addition and rejection to be efficient constant-temperature heat-transfer processes. Regenerators are typically chambers packed with fine-mesh screen wire or porous metal structures. There is enough thermal mass in the packing material to store all of the heat necessary to raise the temperature of the working gas from its low to its high temperature. The amount of heat stored by the regenerator is generally many times greater than the amount added by the heater.

### Power Control

Rapid control of the output power of a Stirling engine is highly desirable for some applications such as automotive and solar electric applications. In most Stirling engine designs, rapid power control is implemented by varying the density (i.e., the mean pressure) of the working gas by bleeding gas from the cycle when less power is desired. To return to a higher power level, high-pressure gas must be reintroduced into the cycle. To accomplish this quickly and without loss of working gas, a complex system of valves, a temporary storage tank, and a compressor are used.

A novel method of controlling the power output is to change the length of stroke of the power piston. This can be accomplished using a variable-angle swash plate drive as described below. Stirling Thermal Motors, Inc., uses this method on their STM 4-120 Stirling engine (Figure 8.5.2).

**FIGURE 8.5.2** Stirling Thermal Motors 4-120 variable swash plate Rinia configuration engine. (Courtesy Stirling Thermal Motors, Ann Arbor, Michigan.)

## Mechanical Implementation of the Stirling Cycle

### Piston/Displacer Configurations

To implement the Stirling cycle, different combinations of machine components have been designed to provide for the constant-volume movement of the working gas between the high- and low-temperature regions of the engine, and compression and expansion during the constant-temperature heating and

cooling. The compression and expansion part of the cycle generally take place in a cylinder with a piston. Movement of the working gas back and forth through the heater, regenerator, and cooler at constant volume is often implemented by a **displacer**. A displacer in this sense is a hollow plug that, when moved to the cold region, displaces the working gas from the cold region causing it to flow to the hot region and vice versa. Only a small pressure difference exists between either end of the displacer, and, therefore, sealing requirements and the force required to move it are minimal.

Three different design configurations are generally used (Figure 8.5.3). Called the alpha-, beta-, and gamma-configurations. Each has its distinct mechanical design characteristics, but the thermodynamic cycle is the same. The **alpha-configuration** uses two pistons on either side of the heater, regenerator, and cooler. These pistons first move uniformly in the same direction to provide constant-volume processes to heat or cool the gas. When all of the gas has been moved into one cylinder, one piston remains fixed and the other moves to compress or expand the gas. Compression work is done by the **cold piston** and expansion work done on the **hot piston**. The alpha-configuration does not use a displacer. The Stirling Power Systems V-160 engine (Figure 8.5.4) is an example of this configuration.

**FIGURE 8.5.3** Three fundamental mechanical configurations for Stirling Engines.

A variation on using two separate pistons to implement the alpha-configuration is to use the front and back side of a single piston called a **double-acting piston**. The volume at the front side of one piston is connected, through the heater, regenerator, and cooler, to the volume at the back side of another piston. With four such double-acting pistons, each  $90^\circ$  out of phase with the next, the result is a four-cylinder alpha-configuration engine. This design is called the *Rinia* or *Siemens configuration* and the United Stirling 4-95 (Figure 8.5.5) and the Stirling Thermal Motors STM 4-120 (Figure 8.5.2) are current examples.

FIGURE 8.5.4 Stirling Power Systems/Solo Kleinmotoren V-160 alpha-configuration Stirling engine.

FIGURE 8.5.5 The 4-95 high-performance Siemens configuration Rinia engine by United Stirling (Malmo, Sweden).

The **beta-configuration** is a design incorporating a displacer and a power piston in the same cylinder. The displacer shuttles gas between the hot end and the cold end of the cylinder through the heater, regenerator, and cooler. The power piston, usually located at the cool end of the cylinder, compresses the working gas when the gas is in the cool end and expands the working gas when the gas has been moved to the hot end. The original patent engine by Robert Stirling and most free-piston Stirling engines discussed below are of the beta-configuration.

The third configuration, using separate cylinders for the displacer and the power piston, is called the **gamma-configuration**. Here, the displacer shuttles gas between the hot end and the cold end of a cylinder through the heater, regenerator, and cooler, just as with the beta-configuration. However, the power piston is in a separate cylinder, pneumatically connected to the displacer cylinder.

### Piston/Displacer Drives

Most Stirling engine designs dynamically approximate the Stirling cycle by moving the piston and displacer with **simple harmonic motion**, either through a crankshaft, or bouncing as a spring/mass second-order mechanical system. For both, a performance penalty comes from the inability of simple harmonic motion to perfectly follow the desired thermodynamic processes. A more desirable dynamic from the cycle point of view, called overdriven or **bang-bang motion**, has been implemented in some designs, most notably the **Ringbom configuration** and engines designed by Ivo Kolin (West, 1986).

*Kinematic Engines.* Stirling engine designs are usually categorized as either kinematic or free-piston. The power piston of a **kinematic Stirling engine** is mechanically connected to a rotating output shaft. In typical configurations, the power piston is connected to the crankshaft with a connecting rod. In order to eliminate side forces against the cylinder wall, a **cross-head** is often incorporated, where the connecting rod connects to the cross-head, which is laterally restrained so that it can only move linearly in the same direction as the piston. The power piston is connected to the cross-head and therefore experiences no lateral forces. The critical sealing between the high-pressure and low-pressure regions of the engine can now be created using a simple **linear seal** on the shaft between the cross-head and the piston. This design also keeps lubricated bearing surfaces in the low-pressure region of the engine, reducing the possibility of fouling heat-exchange surfaces in the high-pressure region of the engine. If there is a separate displacer piston as in the beta- and gamma configurations, it is also mechanically connected to the output shaft.

A variation on crankshaft/cross-head drives is the **swash plate** or **wobble-plate drive**, used with success in some Stirling engine designs. Here, a drive surface affixed to the drive shaft at an angle, pushes fixed piston **push rods** up and down as the slanted surface rotates beneath. The length of stroke for the piston depends on the angle of the plate relative to the axis of rotation. The STM 4-120 engine (Figure 8.5.2) currently being commercialized by Stirling Thermal Motors incorporates a **variable-angle swash plate drive** that permits variation in the length of stroke of the pistons.

*Free-Piston Engine/Converters.* An innovative way of accomplishing the Stirling cycle is employed in the free-piston engine. In this configuration, the power piston is not mechanically connected to an output shaft. It bounces alternately between the space containing the working gas and a spring (usually a gas spring). In many designs, the displacer is also free to bounce on **gas springs** or mechanical springs (Figure 8.5.6). This configuration is called the **Beale free-piston Stirling engine** after its inventor, William Beale. Piston stroke, frequency, and the timing between the two pistons are established by the dynamics of the spring/mass system coupled with the variations in cycle pressure. To extract power, a magnet can be attached to the power piston and electric power generated as it moves past stationary coils. These Stirling engine/alternator units are called **free-piston Stirling converters**. Other schemes for extracting power from free-piston engines, such as driving a hydraulic pump, have also been considered.

Free-piston Stirling engines have only two moving parts, and therefore the potential advantages of simplicity, low cost, and ultra-reliability. Because electricity is generated internally, there are no dynamic seals between the high-pressure region of the engine and ambient, and no oil lubrication is required. This design promises long lifetimes with minimal maintenance. A number of companies are currently

**FIGURE 8.5.6** Basic components of a Beale free-piston Stirling converter incorporating a sodium heat pipe receiver for heating with concentrated solar energy.

**FIGURE 8.5.7** The Sunpower 9-kWe free-piston beta-configuration Stirling engine.

developing free-piston engines including Sunpower, Inc. (Figure 8.5.7), and Stirling Technology Company.

**Seals and Bearings**

Many proposed applications for Stirling engine systems require long-life designs. To make systems economical, a system lifetime of at least 20 years with minimum maintenance is generally required. Desired engine lifetimes for electric power production are 40,000 to 60,000 hr — approximately ten times longer than that of a typical automotive internal combustion engine. Major overhaul of engines, including replacement of seals and bearings, may be necessary within the 40,000- to 60,000-hr lifetime, which adds to the operating cost. A major challenge, therefore, in the design of Stirling engines is to reduce the potential for wear in critical components or to create novel ways for them to perform their tasks.

Piston seals differ from those used in internal combustion engines in a number of ways. Sealing of the power piston is critical since **blow-by loss** of the hydrogen or helium working gas must be captured and recompressed, or replaced from a high-pressure cylinder. Displacer sealing is less critical and only necessary to force most of the working gas through the heater, regenerator, and cooler. Oil for friction reduction or sealing cannot be used because of the danger of it getting into the working gas and fouling the heat-exchange surfaces. This leads to two choices for sealing of pistons, using **polymer sealing rings** or **gas bearings** (simply close tolerance fitting between piston and wall).

Free-piston engines with gas springs have special internal sealing problems. Small leakage can change the force-position characteristics of the “spring” and rapidly upset the phase and displacement dynamics designed into the engine. In order to prevent this, *centering ports* are used to ensure that the piston stays at a certain location; however, these represent a loss of potential work from the engine.

### Materials

Materials used in Stirling engines are generally normal steels with a few exceptions. Materials that can withstand continuous operation at the cycle high temperature are required for the heater, regenerator, and the hot side of the displacement volume. Because most engines operate at high pressure, thick walls are often required. In the hot regions of the engine, this can lead to *thermal creep* due to successive heating and cooling. In the cool regions, large spaces for mechanical linkages can require heavy, thick walls to contain the gas pressure. Use of composite structure technology or reducing the size of the pressurized space can eliminate these problems.

### Future of the Stirling Engine

The principal advantages of the Stirling engine, external heating and high efficiency, make this the engine of the future, replacing many applications currently using internal combustion engines and providing access to the sun as an inexpensive source of energy (Figure 8.5.6). For hybrid-electric automotive applications, the Stirling engine is not only almost twice as efficient as modern spark-ignition engines, but because of the continuous combustion process, it burns fuel more cleanly and is not sensitive to the quality or type of fuel. Because of the simplicity of its design, the Stirling engine can be manufactured as an inexpensive power source for electricity generation using biomass and other fuels available in developing nations.

Most importantly, the Stirling engine will provide access to inexpensive solar energy. Because it can receive its heat from a resource 93 million miles away using concentrating solar collectors, and because its manufacture is quite similar to the gasoline or diesel engine, and because economies of scale are certain when producing thousands of units per year, the Stirling engine is considered to be the least expensive alternative for solar energy electric generation applications in the range from 1 kWe to 100 MWe.

### Defining Terms

**Alpha-configuration:** Design of a Stirling engine where two pistons moving out of phase, and cause the working gas between them to go through the four processes of the Stirling cycle.

**Beale free-piston Stirling engine:** Stirling engine configuration where the power piston and displacer in a single cylinder are free to bounce back and forth along a single axis, causing the enclosed working gas to go through the four processes of the Stirling cycle. Restoration forces are provided by the varying pressure of the working gas, springs (gas or mechanical), and the external load which can be a linear alternator or a fluid pump.

**Beta-configuration:** Design of a Stirling engine where the displacer and power piston are located in the same cylinder and cause the enclosed working gas to go through the four processes of the Stirling cycle.

**Blow-by:** The gas that leaks past a seal, especially a piston-to-cylinder seal.

**Charge pressure:** Initial pressure of the working gas.

**Cooler:** Heat exchanger that removes heat from the working fluid and transfers it out of the cycle.

**Cross-head:** A linear sliding bearing surface connected to a crankshaft by a connecting rod. Its purpose is to provide linear reciprocating motion along a single line of action.

**Displacer:** Closed volume ‘plug’ that forces the working fluid to move from one region of the engine to another by displacing it.

**Double-acting piston:** A piston in an enclosed cylinder where pressure can be varied on both sides of the piston, resulting a total amount of work being the sum of that done on or by both sides.

**Dynamic seals:** Seals that permit transfer of motion without permitting gas or oil leakage. These can be either *linear seals* permitting a shaft to move between two regions (i.e., the piston rod seals in a Stirling engine), or *rotating seals* that permit rotating motion to be transmitted from one region to another (i.e., the output shaft of a Stirling engine).

**Free-piston Stirling converters:** A name given to a hermetically sealed free-piston Stirling engine incorporating an internal alternator or pump.

**Gamma-configuration:** A design of a Stirling engine where the displacer and power piston are located in separate, connected cylinders and cause the enclosed working gas to go through the four processes of the Stirling cycle.

**Gas bearing:** A method of implementing the sliding seal between a piston and cylinder as opposed to using piston rings. Uses a precision-fitting piston that depends on the small clearance and long path for sealing and on the viscosity of the gas for lubrication.

**Gas spring:** A piston that compresses gas in a closed cylinder where the restoration force is linearly proportional to the piston displacement. This is a concept used in the design of free-piston Stirling engines.

**Heater:** A heat exchanger which adds heat to the working fluid from an external source.

**Kinematic stirling engine:** Stirling engine design that employ physical connections between the power piston, displacer, and a mechanical output shaft.

**Linear seal:** see **dynamic seals**.

**Overdriven (bang-bang) motion:** Linear motion varying with time as a square-wave function. An alternative to simple harmonic motion and considered a better motion for the displacer of a Stirling engine but difficult to implement.

**Phase angle:** The angle difference between displacer and power piston harmonic motion with a complete cycle representing  $360^\circ$ . In most Stirling engines, the harmonic motion of the power piston follows (lags) the motion of the displacer by approximately  $90^\circ$ .

**Push rod:** A thin rod connected to the back of the piston that transfers linear motion through a dynamic linear seal, between the low- and high-pressure regions of an engine.

**Reflux:** A constant-temperature heat-exchange process where a liquid is evaporated by heat addition and then condensed as a result of cooling.

**Regenerator:** A heat-transfer device that stores heat from the working gas during part of a thermodynamic cycle and returns it during another part of the cycle. In the Stirling cycle the regenerator stores heat from one constant-volume process and returns it in the other constant-volume process.

**Ringbom configuration:** A Stirling engine configuration where the power piston is kinematically connected to a power shaft, and the displacer is a free piston that is powered by the difference in pressure between the internal gas and atmospheric pressure.

**Simple harmonic motion:** Linear motion varying with time as a sine function. Approximated by a piston connected to a crankshaft or a bouncing of a spring mass system.

**Stirling cycle:** A thermodynamic power cycle with two constant-volume heat addition and rejection processes and two constant-temperature heat-addition and rejection processes.

**Swash plate drive:** A disk on a shaft, where the plane of the disk is tilted away from the axis of rotation of the shaft. Piston push rods that move parallel to the axis of rotation but are displaced from the axis of rotation, slide on the surface of the rotating swash plate and therefore move up and down.

**Variable-angle swash plate drive:** A swash plate drive where the tilt angle between the drive shaft and the plate can be varied, resulting in a change in the displacement of the push rods.

**Wobble plate drive:** Another name for a swash plate drive.

**Working gas:** Gas within the engine that exhibits pressure and temperature change as it is heated or cooled and/or compressed or expanded.

## 8.6 Advanced Fossil Fuel Power Systems

---

*Anthony F. Armor*

### Introduction

The generation of electric power from fossil fuels has undergone significant and, in some cases, dramatic changes over the last 20 years or so. Technology improvements in fossil fuel combustion have been largely driven by environmental issues, by the need to conserve fossil fuel resources, and by the economics of the competitive marketplace. The importance of fossil fuel-fired electric generation to the world is undeniable — more than 70% of all power in the U.S. is fossil fuel based, and worldwide the percentage is higher and growing. Today, most power plants worldwide burn coal, but increasingly generating companies are turning to natural gas, as the cost of gas-fired generation and the long-term supply of gas appear favorable. This section reviews the current status and likely future deployment of competing generation technologies based on fossil fuels.

It is likely, particularly in the developed world, that gas turbine-based plants will dominate the new generation market in the immediate future. The most advanced combustion turbines (CTs) now achieve more than 40% **lower heating value** (LHV) efficiency in simple cycle mode and greater than 50% efficiency in **combined cycle** (CC) mode. In addition, combustion turbine/combined cycle (CT/CC) plants offer siting flexibility, swift construction schedules, and capital costs between \$400/kW and \$800/kW. These advantages, coupled with adequate natural gas supplies and the assurance, in the longer term, of **coal gasification** backup, make this technology currently the prime choice for green field and repowered plants in the United States and in Europe.

But for the developing world, particularly China and India, there is good reason why the direct coal-fired power plant may still be the primary choice for many generation companies. Fuel is plentiful and inexpensive, and sulfur dioxide scrubbers have proved to be more reliable and effective than early plants indicated. In fact, as high as 99% SO<sub>2</sub> removal efficiency is now possible.

Combustion of coal can occur in three basic forms, direct combustion of pulverized coals (PC), combustion of coal in a suspended bed of coal and inert matter, and coal gasification. The pulverized coal (PC) plant, the most common form of coal combustion, has the capability for much improved efficiency even with full **flue gas desulfurization** (FGD), because materials technology has now advanced to the point where higher steam pressures and temperatures are possible. In the United States, Europe, Japan, and Russia, the advanced superficial PC plant is moving ahead commercially.

Worldwide, the application of atmospheric and pressurized fluidized bed combustion (FBC) plants has increased, and such plants offer reductions in both SO<sub>2</sub> and NO<sub>x</sub> while permitting the efficient combustion of vast deposits of low-rank fuels such as lignites. In the United States, there are now over 150 large operating units for power generation, and throughout Europe, China, and the former Soviet Union countries small FBC units have been extensively deployed.

Coal gasification power plants exist at the 100 and 160 MW levels and are planned up to 450 MW. Much of the impetus is now coming from the U.S. Department of Energy (DOE) clean coal program where three gasification projects are in progress and four more are planned, and gasification plants are under construction in Europe and Japan. Gasification not only leads to minimum atmospheric and solid emissions, but also provides an opportunity to take advantage of gas turbine advances. With the rapid advances now being introduced in CT technology, the coal gasification option is a leading turn-of-the-century candidate for new plant construction.

### Clean Coal Technology Development

At an increasing rate in the last few years, innovations have been developed and tested that are aimed at reducing emissions through improved combustion and environmental control, in the near term, and, in the longer term, through fundamental changes in the way coal is preprocessed before converting its

chemical energy to electricity. Such technologies are referred to as “clean coal technologies” described as a family of precombustion, combustion/conversion, and postcombustion technologies (Torrens, 1990). They are designed to provide the coal user with added technical capabilities and flexibility and the world with an opportunity to exploit our most abundant fossil source. They can be categorized as

- *Precombustion*, where sulfur and other impurities are removed from the fuel before it is burned;
- *Combustion*, where techniques to prevent pollutant emissions are applied in the boiler while the coal burns;
- *Postcombustion*, where the flue gas released from the boiler is treated to reduce its content of pollutants;
- *Conversion*, where coal, rather than being burned, is changed into a gas or liquid that can be cleaned and used as a fuel.

### Coal Cleaning

Cleaning of coal to remove sulfur and ash is well established in the United States with more than 400 operating plants, mostly at the mine. Coal cleaning removes primarily pyritic sulfur (up to 70% SO<sub>2</sub> reduction is possible) and in the process increases the heating value of the coal, typically about 10% but occasionally 30% or higher. Additionally, if slagging is a limiting item, increased megawatts may be possible, as occurred at one station which increased generation from 730 to 779 MW. The removal of organic sulfur, chemically part of the coal matrix, is more difficult, but may be possible using microorganisms or through chemical methods; research is underway (Couch, 1991). Finally, heavy metal trace elements can be removed also, conventional cleaning removing (typically) 30 to 80% of arsenic, mercury, lead, nickel, antimony, selenium, and chromium.

### Cleaning of Low-Rank Coal

With large deposits of high-moisture, and sometimes high-ash, low-rank coals and lignites, there is interest, but as yet no large-scale activity, in cleaning these coals. Improvement in heating value and reduction of boiler **slagging and fouling** problems are outcomes. Economics will decide whether precleaning or direct combustion (perhaps in a fluidized bed) will be the future choice. Large subbituminous and lignite fields exist in the United States, the former U.S.S.R., Germany, and Eastern Europe, as [Table 8.6.1](#) indicates.

**TABLE 8.6.1 World Coal Production**

Country	Total Coal Production, Mt	Bituminous, Mt	Subbituminous and Lignite, Mt	Approximate Amount Bituminous Cleaned, %

## Pulverized Coal Plants

There has been a perception that the PC power plant has come to the end of the road, that advanced coal technologies will quite soon make obsolete the PC plant with a scrubber, whose efficiency hovers around 35%. This perception may be premature. In fact, the PC plant has the capability for much improved heat rate (about 8500 Btu/kWh) even with full FGD. Beyond these units, the PC-fired CC with topping turbine (Figure 8.6.1) has a projected heat rate of 7200 Btu/kWhr, which includes full scrubbing capability. The PC plant is a proven, reliable power source with unit capabilities demonstrated at more than to 1000 MW using a single-shaft steam turbine. One plant, commercially available now, uses steam at 4500 psig and 1100°F, all ferritic materials for major boiler and turbine components, leading-edge technology in environmental controls, and the latest techniques in waste heat utilization (Poe et al., 1991). It is modular, fuel flexible, and designed for **on/off cycling capability**.

**FIGURE 8.6.1** A PC CC with topping steam turbine has a projected heat rate of 7200 Btu/kWhr. The air turbine uses 1800°F air, or 2300°F air with supplemental firing. The topping turbine uses steam at 1300°F.

Higher steam temperatures (to 1150°F) and **supercritical steam pressures** are an important aspect of the modern advanced PC plant. They are possible now because of advances in ferritic materials technology that will extend life, provide greater creep and fatigue strength, and be resistant to **temper embrittlement** and, in the boiler, to coal ash corrosion (Armor et al., 1988).

Of particular note are

- **Coextruded tubing** or monotubing for superheaters and reheaters, resistant to coal ash corrosion.
- Super-9-chrome steel (P91), for steam piping, valves, headers, casings.
- Improved creep-resistant 12-chrome forgings for high-pressure/intermediate-pressure (HP/IP) turbines.
- “Superclean” 3.5 NiCrMoV rotors for low-pressure (LP) turbines, resistant to temper embrittlement.

Built in 1959, Eddystone 1 at PECO Energy was, and still is, the supercritical power unit with the highest steam conditions in the world. When constructed in the early 1960s, Eddystone 1 had a main steam pressure of 5000 psi, and main steam temperature of 1200°F. **Double reheat** of the steam was employed. PECO Energy continues to operate Eddystone 1, an impressive achievement for a prototype unit. More-recent advanced plants include the Chuba Electric Kawagoe unit in Japan, a 700-MW double-reheat supercritical with steam conditions of 4750 psi, 1050°F, and the Esbjerg unit of Elsam in Denmark, a 400-MW supercritical with steam conditions of 3700 psi, 1040°F. Both plants use advanced ferritic steels for turbine and boiler thick wall components. There are over 170 supercritical units in the United States, more than 220 in Russia (Oliker and Armor 1992), and over 60 in Japan. A number are installed in Germany, Denmark, Holland, and other European countries, and increasingly in the Far East.

## Emissions Controls for Pulverized Coal Plants

Today, worldwide, about 40% of electricity is generated from coal and the total installed coal-fired generating capacity is more than 1000 GW, largely made up of 340 GW in North America; 220 GW in Western Europe, Japan, and Australia; 250 GW in Eastern Europe and the former U.S.S.R., and 200 GW in China and India. In the decade 1990 to 2000, 190 GW of new coal-fired capacity will likely be added. So the control of particulates, sulfur dioxides, and nitrogen oxides from those plants is one of the most pressing needs of today and of the future, together with the potential impact of carbon dioxide emissions, with their contribution to global warming. To combat these concerns, a worldwide move toward environmental retrofitting of older fossil-fired power plants is underway, focused largely on sulfur dioxide scrubbers and combustion or postcombustion optimization for nitrogen oxides.

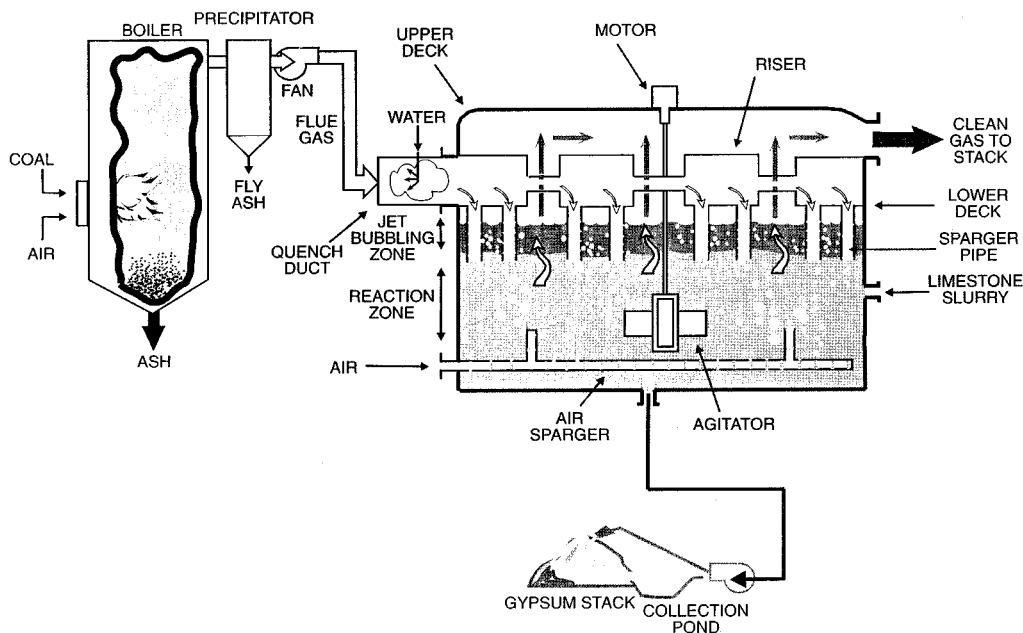

### Conventional Lime/Limestone Wet Scrubber

The dominant  $\text{SO}_2$  scrubbing system is the wet limestone design, limestone being one quarter the cost of lime as a reagent. In this system (Figure 8.6.2) the limestone is ground and mixed with water in a reagent preparation area. It is then conveyed to a spray tower called an absorber, as a slurry of 90% water and 10% solids, and sprayed into the flue gas stream. The  $\text{SO}_2$  in the flue gas is absorbed in the slurry and collected in a reaction tank where it combines with the limestone to produce water and calcium sulfate or calcium sulfate crystals. A portion of the slurry is then pumped to a thickener where these solids/crystals settle out before going to a filter for final dewatering. Mist eliminators installed in the system ductwork at the spray tower outlet collect slurry/moisture entrained in the flue gas stream. Calcium sulfate is typically mixed with fly ash (1:1) and lime (5%) and disposed of in a landfill.

**FIGURE 8.6.2** The conventional lime/limestone wet scrubber is the dominant system in operation in the United States. With recent refinements this system can be 98 to 99% effective in removing  $\text{SO}_2$ .

Various improvements can be made to this basic process, including the use of additives for performance enhancement and the use of a hydrocyclone for dewatering, replacing the thickener, and leading to a salable gypsum by-product. The Chiyoda-121 process (Figure 8.6.3) reverses the classic spray scrubber and bubbles the gas through the liquid. This eliminates the need for spray pumps, nozzle headers, separate oxidation towers, and thickeners. The Chiyoda process is being demonstrated in a DOE Clean Coal Technology (CCT) project on a 100-MW unit at the Yates plant of the Georgia Power Company.

**FIGURE 8.6.3** The Chioda-121 scrubber simplifies the process by bubbling the flue gas through the liquid, eliminating some equipment needs.

### Spray Drying

**Spray drying** (Figure 8.6.4) is the most advanced form of dry  $\text{SO}_2$  control technology. Such systems tend to be less expensive than wet FGD but remove typically a smaller percentage of the sulfur (90% compared with 98%). They are usually used when burning low-sulfur coals, and utilize fabric filters for particle collection, although recent tests have shown applicability to high-sulfur coals also.

Spray driers use a calcium oxide reagent (quicklime) which when mixed with water produces a calcium hydroxide slurry. This slurry is injected into the spray drier where it is dried by the hot flue gas. As the drying occurs, the slurry reacts to collect  $\text{SO}_2$ . The dry product is collected at the bottom of the spray tower and in the downstream particulate removal device where further  $\text{SO}_2$  removal may take place. It may then be recycled to the spray drier to improve  $\text{SO}_2$  removal and alkali utilization.

For small, older power plants with existing **electrostatic precipitators** (ESPs), the most cost-effective retrofit spray-dry configuration locates the spray drier and fabric filter downstream of the ESP, separating in this manner the spray drier and fly ash waste streams. The fly ash can then be sold commercially.

### Control of Nitrogen Oxides

Nitrogen oxides can be removed either during or after coal combustion. The least-expensive option and the one generating the most attention in the United States is combustion control, first through adjustment of the fuel/air mixture and second through combustion hardware modifications. Postcombustion processes seek to convert  $\text{NO}_x$  to nitrogen and water vapor through reactions with amines such as ammonia and urea. Selective catalytic reduction (SCR) injects ammonia in the presence of a catalyst for greater effectiveness. So the options (Figure 8.6.5) can be summarized as

- Operational changes.* Reduced excess air and biased firing, including taking burners out of service;
- Hardware combustion modifications.* Low- $\text{NO}_x$  burners, air staging, and fuel staging (reburning);
- Postcombustion modifications.* Injection of ammonia or urea into the convection pass, SCR, and wet or dry  $\text{NO}_x$  scrubbing (usually together with  $\text{SO}_2$  scrubbing).

FIGURE 8.6.4 Spray dryers use a calcium oxide reagent mixed with water, which is dried by the flue gas. A dry product is collected in a fabric filter.

FIGURE 8.6.5 Control options for NO<sub>x</sub> include operational, hardware, and postcombustion modifications.

Low-NO<sub>x</sub> burners can reduce NO<sub>x</sub> by 50% and SCR by 80%, but the low-NO<sub>x</sub> burner option is much more cost-effective in terms of cost per ton of NO<sub>x</sub> removed. Reburning is intermediate in cost per removed ton and can reduce NO<sub>x</sub> 50 or 75% in conjunction with low-NO<sub>x</sub> burners.

### Fluidized Bed Plants

Introduced nearly 30 years ago, the **fluidized bed** combustion boiler has found growing application for power generation. From the first FBC boiler, generating 5000 lb/hr of steam in 1967, the technology has matured to the 250-MW-size units available today. In North America more than 170 units now

**FIGURE 8.6.6** An illustration of the distinguishing features of PC and fluidized bed boilers. Noticeable in this diagram are the in-bed tubes characteristic of bubbling beds and the cyclone separator of the circulating bed.

generate in excess of 6000 MW. Burning coal in a suspended bed with limestone or dolomite permits effective capture of sulfur, and fuel flexibility allows a broad range of opportunity fuels. These fuels might include coal wastes (culm from anthracite, gob from bituminous coal), peat, petroleum coke, and a wide range of coals from bituminous to lignite. A low (1500°F) combustion temperature leads to low  $\text{NO}_x$  formation. The salient features of atmospheric fluidized bed boilers, compared with a PC boiler, are shown in Figure 8.6.6.

Utility-size demonstration projects at the Tennessee Valley Authority in 1989 (Shawnee, 160 MW) (Manaker, 1992) and Northern States Power in 1986 (Black Dog, 133 MW) (Hinrichsen, 1989) are examples of successful atmospheric bubbling bed units. The Black Dog unit has been dispatched in a daily cycling mode and has successfully fired a blend of coal and petroleum coke. But the focus of atmospheric FBC (AFBC) in the United States is now on the circulating fluid bed (CFB). In fact, more than 70% of operating fluid bed boilers in the United States are of the circulating type. The CFB unit at Nucla (Tri-State G&T Association) (Blunder, 1989) has been successful in demonstrating the technology at the 110-MW level, and commercial CFB plants have now reached 250 MW in size. Most fluidized bed units for electricity generation are being installed by independent power producers in the 50- to 100-MW-size range, where the inherent  $\text{SO}_2$  and  $\text{NO}_x$  advantages over the unscrubbed PC plant have encouraged installations even in such traditional non-coal arenas as California (Melvin and Friedman, 1994). Worldwide, the AFBC boiler is employed largely for steam heat, with hundreds of them in operation in Russia and India, and thousands in China. The extension of the concept of fluidized beds to units where the fuel mixture is burned under several atmospheres pressure (PFBC) has now opened the way to smaller modular units with opportunities to move to efficient PFBC CCs.

### Atmospheric Fluidized Bed Combustion

In the bubbling bed version of the AFBC, the fuel and inert matter, together with limestone or dolomite for  $\text{SO}_2$  capture, is suspended through the action of fluidizing air, which flows at a velocity of 3 to 8 ft/sec in essentially a one-pass system. CFBs differ from bubbling beds in that much of the bed material passes through a cyclone separator before being circulated back to the boiler (Figure 8.6.7). In-bed tubes are generally not used for CFB units, permitting a much higher fluidizing velocity of 16 to 26 ft/sec. Since the early AFBC designs, attention has been directed toward increasing unit efficiency, and reheat designs are now usual in large units. When  $\text{SO}_2$  capture is important, a key parameter is the ratio of calcium in the limestone to sulfur in coal. Typical calcium-to-sulfur ratios for 90%  $\text{SO}_2$  reduction are

**FIGURE 8.6.7** A Pyropower circulating fluid bed boiler installed at the ACE Cogeneration Company at Trona, California. This 108-MW unit burns low sulfur, western bituminous coal with limestone in a bed which circulates back to the boiler after passing through a cyclone separator.

in the range of 3.0 to 3.5 for bubbling beds and 2.0 to 2.5 for circulating beds. This depends on the fuel, however, and the 200-MW CFB units at the Conoco/Entergy plant in Lake Charles, Louisiana burning 100% **petroleum coke** (4.5% S), have a Ca/S ratio of below 1.7 for more than 90% sulfur capture.  $\text{NO}_x$  levels in AFBCs are inherently low and nominally less than 0.2 lb/MM Btu.

It is important to note that for CFBs, boiler efficiencies can be as high as a PC unit (Table 8.6.2). In fact, designs now exist for AFBCs with supercritical steam conditions, with prospects for cycles up to 4500 psia, 1100°F with **double reheat** (Skowrya et al., 1995).

**TABLE 8.6.2 Typical Boiler Efficiencies, PC and Fluidized Beds**

Loss/Gain Parameter	PC	Calculated Heat Loss %		
		Highest-Efficiency CFB	Lowest-Efficiency CFB	Bubbling Bed
Moisture in limestone	NA	0.06	0.10	0.10

### Pressurized Fluidized Bed Combustion

In a PFBC CC unit (Figure 8.6.8), coal in a fluid bed is burned with dolomite or limestone in a pressurized steel chamber, raising steam for a steam turbine generator. The pressurized flue gases are expanded through a gas turbine. Commercial plants at about the 80-MW level in Sweden, the United States, and Spain have demonstrated that bubbling bed PFBC plants with a calcium-to-sulfur molar ratio of about 1.5 offer sulfur capture up to 95%, together with inherently low NO<sub>x</sub> emissions due to low combustion temperatures. Cleanup of the flue gas before entry to the gas turbines is a key technical objective, and first-generation units have used cyclones together with gas turbines ruggedized with special blade coatings. For more-advanced, higher-efficiency PFBC systems, hot-gas cleanup technology, where the gas is directed through large ceramic filter units, will likely be needed.

To date, the 80-MW units at Vaertan (Sweden) and Escatron (Spain) and the 70-MW unit at Tidd (AEP) have operated satisfactorily, and larger units up to 350 MW are now under development. The modular aspect of the PFBC unit is a particularly attractive feature leading to short construction cycles and low-cost power. This was particularly evident in the construction of the Tidd plant, which first generated power from the CC on November 29, 1990. The heat rate and capital cost of the PFBC plant are forecast to reach very competitive levels which, when combined with shortened construction schedules, will position the technology for a role in future generation plans, particularly where modular additions have advantages.

One promising use for PFBC units is for small in-city cogeneration plants where the inherent size advantages, high efficiencies, and effective coal gas cleanup approach permit compact plants to be retrofitted in place of heating boilers, while the small steam turbines can be easily adapted to both electricity and hot water supply (Olesen, 1985).

### Advanced PFBCs

In conventional PFBC plants, the overall cycle efficiency is limited to less than 42%. That is because the operating temperature of the combustor — which must be held to 1650°F (900°C) or less to avoid sintering the ash and releasing alkali metals that could foul or corrode the gas turbine — in effect sets the gas turbine inlet temperature far below the 2350°F (1290°C) or so featured in the most-efficient heavy-frame machines currently in use firing natural gas or oil.

**FIGURE 8.6.8** Pressurized fluidized bed with combined cycle. This 70-MW system has operated at the Tidd plant of American Electric Power.

Increasing the inlet temperature of the gas turbine, which typically provides 20 to 25% of the power in a PFBC plant, could raise the overall cycle efficiency to more than 45%. A simple means of boosting the flue gas temperature would be to fire a topping fuel, such as natural gas, ahead of the gas turbine. But 2350°F would be well above the **ash-softening temperature**, so high temperature, HP filtration systems would be essential to remove all particulate matter before firing the natural gas.

A further advance would be to use gas from coal rather than natural gas as the topping fuel. The coal would be pyrolyzed in a low-oxygen environment under pressure to produce both a low-Btu fuel gas and a residual char. The fuel gas would be passed through its own hot-gas cleanup filters before being fired in a topping combustor ahead of the gas turbine; the char would be burned in a circulating bed PFBC, from which the flue gas would also be filtered and then combined with the topping cycle gas stream. (Or the char could be simply fired in an AFBC.) With net heat rates below 7600 Btu/kWhr (45% efficiency), carbon dioxide emissions would be correspondingly low.

A U.S. DOE CCT project known as the Four Rivers Energy Modernization Project, involves building a Foster-Wheeler 95-MW advanced circulating-type PFBC unit at the Air Products chemical manufacturing facility in Calvert City, Kentucky. Steam from the unit, which will feature a coal-gas-fired topping combustor and a hot-gas cleanup system, will be used in chemical production, and the power will be sold to the Tennessee Valley Authority. The project is scheduled to begin commercial operation in October, 1998 (Carpenter and Dellefield, 1994).

## Gasification Plants

One option of growing interest to coal-burning utilities is that of coal gasification. After the EPRI Cool Water demonstration in 1984 at the 100-MW level, the technology has moved ahead in the United States largely through demonstrations under the CCT program (U.S. DOE, 1994). Overseas, the 250-MW Buggenham plant in Holland is now operational, and the PSI/Destec 262-MW and TECO Energy 250-MW gasification plant demonstrations are also on-line. Beyond this, there is a 300-MW gasification unit scheduled for Endesa, Spain and a 330-MW unit for RWE in Germany (Figure 8.6.9).

**FIGURE 8.6.9** By building on the early success of the 100-MW Cool Water gasification-CC plant in California, demonstrations in the 250 to 350 MW range will be carried out in the 1995 to 2000 time frame.

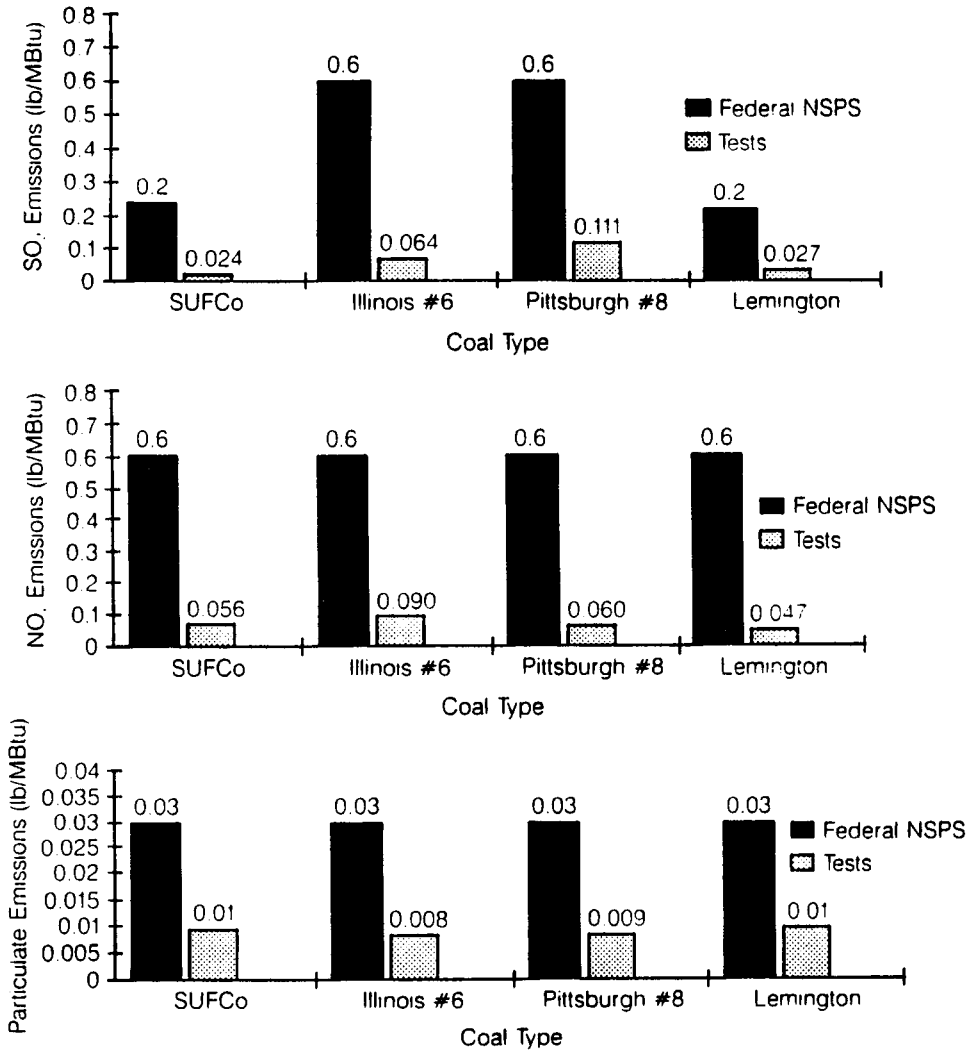

Gasification-based plants have among the lowest emissions of pollutants of any central station fossil technology. Through use of the efficiency advantages of CCs, CO<sub>2</sub> emissions are also low. Fuel flexibility is an additional benefit since the gasifier can accommodate a wide range of coals, plus petroleum coke. Integrated gasification CC (IGCC) plants permit a hedge against long-term increases in natural gas prices since natural gas-fired CTs can be installed initially, and gasifiers at a later time when a switch to coal becomes prudent (Douglas, 1986).

The pioneering Cool Water plant, the first of its kind in the world, operated for more than 4 years, gasifying 1.1 million tons of coal and producing 2.8 million MWhr of electricity. The project was a collaborative effort of the industry involving the utility (Southern California Edison), equipment manufacturers (Texaco, General Electric), and consultants/research consortia (Bechtel, EPRI, and others). Particularly notable was the achievement of exceptionally low levels of emissions of SO<sub>2</sub>, NO<sub>x</sub>, and particulates, as shown in Figure 8.6.10.

Basically, IGCC plants replace the traditional coal combustor with a gasifier and gas turbine. Ultra-low emissions are realized, over 99% of the sulfur in the coal being removed before the gas is burned in the gas turbine. A gasification cycle can take advantage of all the technology advances being made in CTs and steam turbines, so as to enhance overall cycle efficiency. Net system efficiencies of 45% are expected to be demonstrated by the turn of the century, and when, in the next decade, the **fuel cell** begins to replace the gas turbine, plant efficiencies will climb to the 60% level. Major demonstrations are underway, as part of the CCT program, at Sierra Pacific Power, Pinon Pine (a KRW 99-MW air-blown, pressurized, fluidized bed coal gasifier); Tampa Electric, Polk County (a Texaco, 250-MW oxygen-blown, entrained-flow gasifier); at Tamco Power, Toms Creek (a 190-MWV joint gasification/PC plant with a Tampella Power fluidized bed gasifier); and at PSI Energy/Destec Energy, Wabash River (a 262-MW plant based on the Destec two-stage, entrained-flow, oxygen-blown gasifier). More-detailed descriptions of the Pinon Pine and Polk County gasification systems follow.

### Pinon Pine IGCC

At the Sierra Pacific Power Pinon Pine plant (Figure 8.6.11), dried and crushed coal is introduced into a pressurized, air-blown, fluidized bed gasifier. Crushed limestone is added to the gasifier to capture a portion of the sulfur and to inhibit conversion of fuel nitrogen to ammonia. The sulfur reacts with the limestone to form calcium sulfide, which, after oxidation, exits along with the coal ash in the form of agglomerated particles suitable for landfill.

**FIGURE 8.6.10** Tests at Cool Water on four coals show emissions of SO<sub>2</sub>, NO<sub>x</sub>, and particulates substantially below the Federal New Source Performance Standards.

Hot, low-Btu coal gas leaving the gasifier passes through cyclones, which return most of the entrained particulate matter to the gasifier. The gas, which leaves the gasifier at about 1700°F, is cooled to about 1100°F before entering the hot-gas cleanup system. During cleanup, virtually all of the remaining particulates are removed by ceramic candle filters, and final traces of sulfur are removed by reaction with metal oxide sorbent.

The hot, cleaned gas then enters the CT, which is coupled to a generator designed to produce 61 MW. Exhaust gas is used to produce steam in a heat-recovery steam generator. Superheated HP steam drives a condensing steam turbine/generator designed to produce about 46 MW.

Owing to the relatively low operating temperature of the gasifier and the injection of steam into the combustion fuel stream, the NO<sub>x</sub> emissions are likely to be below 0.053 lb/M Btu. Because of the combination of in-bed sulfur capture and **hot-gas cleanup**, SO<sub>2</sub> emissions will be below 0.045 lb/M Btu (98% reduction).

**FIGURE 8.6.11** Integrated gasification CC at Sierra Pacific Power, Pinon Pine plant. This uses a KRW air-blown, pressurized fluidized bed coal gasifier, and produces 99 MW (net).

At Pinon Pine, 880 ton/day of coal are converted into 107 MW (gross), or 99 MW (net), for export to the grid. Western bituminous coal (0.5 to 0.9% sulfur) from Utah is the design coal although tests will be done using West Virginia or Pennsylvania bituminous coal containing 2 to 3% sulfur.

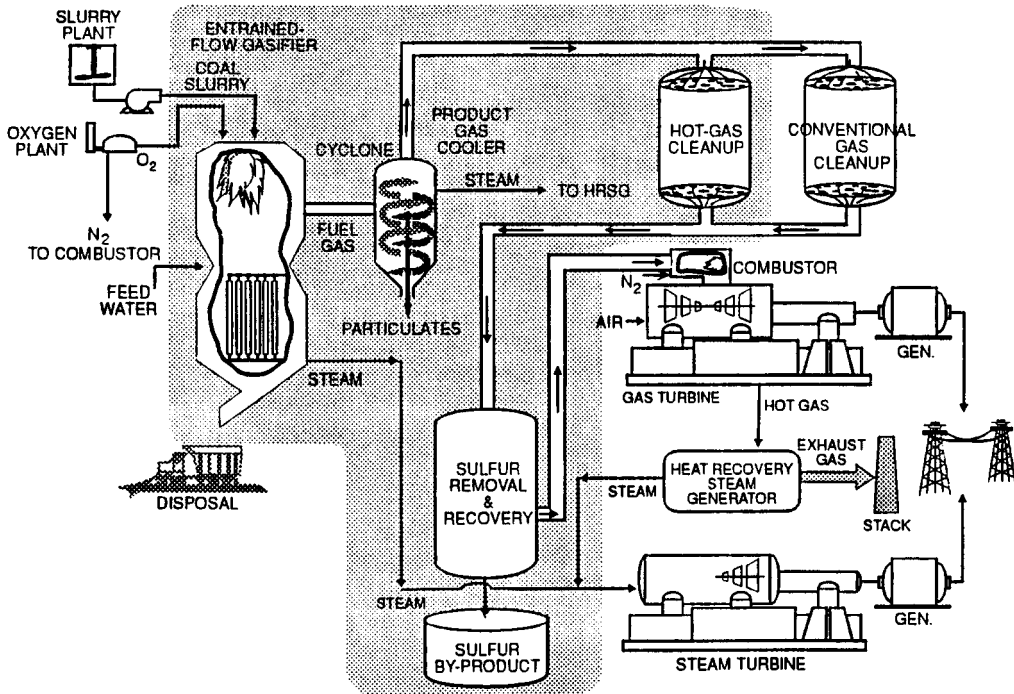

### Polk County IGCC

The Texaco pressurized, oxygen-blown, entrained-flow gasifier will be used at the Tampa Electric Polk County plant to produce a medium-Btu fuel gas (Figure 8.6.12). Coal/water slurry and oxygen are combined at high temperature and pressure to produce a high-temperature syngas. Molten coal ash flows out of the bottom of the vessel and into a water-filled quench tank, where it is turned into a solid slag. The syngas from the gasifier moves to a high-temperature heat-recovery unit which cools the gases.

The cooled gases flow to a particulate-removal section before entering gas cleanup trains. A portion of the syngas is passed through a moving bed of metal oxide absorbent to remove sulfur. The remaining syngas is further cooled through a series of heat exchangers before entering a conventional gas cleanup train where sulfur is removed by an acid-gas removal system. These cleanup systems combined are expected to maintain sulfur levels below 0.21 lb/M Btu (96% capture). The cleaned gases are then routed to a CC system for power generation. A gas turbine generates about 192 MW. Thermally generated  $\text{NO}_x$  is controlled to below 0.27 lb/M Btu by injecting nitrogen as a diluent in the combustion section of the turbine. A heat-recovery steam generator uses heat from the gas turbine exhaust to reduce HP steam. This steam, along with the steam generated in the gasification process, is routed to the steam turbine to generate an additional 120 MW. The IGCC heat rate for this demonstration is expected to be approximately 8600 Btu/kWhr (40% efficient).

The demonstration project involves only the first 250-MW portion of the planned 1150-MW Polk County power station. Coals being used in the demonstration are Illinois 6 and Pittsburgh 8 bituminous coals having sulfur contents ranging from 2.5 to 3.5%.

**FIGURE 8.6.12** Integrated gasification CC at Tampa Electric, Polk County plant. A Texaco oxygen-blown gasifier is used. Total net generation is 250 MW.

By-products from the process — sulfuric acid and slag — can be sold commercially, sulfuric acid by-products as a raw material to make agricultural fertilizer and the nonleachable slag for use in roofing shingles and asphalt roads and as a structural fill in construction projects.

### Buggenum IGCC

Meanwhile, tests are in progress on the 250-MW IGCC plant in Buggenum, Netherlands. After successful operations running on natural gas, a switch was made to coal gas using Columbia coals. Buggenum comprises a 2000-ton/day single reactor coal gasification unit and an air separation plant able to produce 1700 ton/day of 95% pure oxygen. Syngas drives a Siemens CC power unit, including a 156-MW V94.2 gas turbine and a 128-MW steam turbine. The gasifier, operating at 28 bar pressure and 2700°F is designed to produce syngas containing 42% nitrogen, 25% carbon monoxide, and 12% hydrogen, with a combustion value of 4.3 MJ/kg.

The environmental constraints are defined by permit requirements fixing upper limits of  $\text{SO}_2$  at 0.22 g/kWhr,  $\text{NO}_x$  at 0.62g/kWhr, and particulates at 0.007 g/kWhr.

Key steps for limiting emissions include

- Removing fly ash with cyclone and candle filters after gas cooling;
- Removing halogens and other soluble pollutants with water scrubbing;
- Desulfurizing gas by catalytic and chemical processes. Sulfur is fixed in sulfinol-M solvent, which is further treated to produce elemental sulfur; and
- Desulfurized gas is mixed with nitrogen from the air separation units and saturated with water vapor to reduce its lower heating value from about 11,000 to 4300 kJ/kg greatly reducing  $\text{NO}_x$  production.

## Combustion Turbine Plants

CT-based plants are the fastest growing technology in power generation. Through the turn of the century natural gas-fired CTs and CCs burning gas will account for 50 to 70% of the 900 to 1000 GW of new generation to be ordered worldwide. Almost all of these CT and CC plants will be gas fired, leading to a major expansion of gas for electricity generation (Armor et al., 1992).

It is likely that CTs and CCs will grow steadily more important in all generation regimes, peaking, midrange, and base load. If the present 2300°F firing temperature machines operate reliably and durably, CT and CC plants will begin to replace older steam plants and uneconomic nuclear plants. So until the emergence of large-scale fuel cells, CT plants will be a competitive choice for new fossil generation, and advanced CT cycles, with intercooling, reheat, possibly chemical recuperation, and most likely with humidification, will spearhead the drive to higher efficiencies and lower capital costs. Gasification, which guarantees a secure bridge to coal in the near term, will come into its own if natural gas prices rise under demand pressure, and by 2015 coal through gasification may be the economic fuel for a significant fraction of new base-load generation. The rate at which these trends develop depends in large measure on the speed of deregulation and advent of competition in the electricity industry.

Modern gas turbines for power generation are mostly heavy-frame machines, with ratings in a simple cycle configuration around 150 to 170 MW for the high firing temperatures (~2300°F) of the “**F-class**” machines. Efficiencies (LHV) are 36 to 38% in simple cycles. In CCs, the units are 220 to 350 MW in size and 53 to 55% efficient. The next generation of CTs, with efficiencies from 57 to 60% has recently been announced (Table 8.6.3). Smaller-scale aeroderivative machines have benefited from turbofan engines designed for wide-body aircraft and today are available in ratings of 35 to 65 MW and with efficiencies of 40% or more for turbine inlet temperatures around 2250°F. Beyond this, work is underway to design and build an advanced **aeroderivative turbine**, and three teams are involved: United Technologies/Fluor Daniel is looking at a humid air turbine at 200 MW and 55% efficiency; Rolls-Royce/Bechtel is studying an intercooled, regenerative design based on the Aero-Trent machine; and General Electric/Bechtel is melding the GE LM 6000 and the GE heavy-frame designs to achieve close to 60% efficiency in a 100-MW combined cycle.

Recently, General Electric announced a new concept which uses steam from the steam turbine to cool the gas turbine blades permitting a firing temperature of 2600°F. This avoids the losses due to the normal method of diverting compressor air for cooling. This “H” class turbine, it is said, will break the 60% barrier for a 400-MW CC. Comparison of the F- and H-class machines for General Electric is shown in Table 8.6.4.

**Humidified Air Power Plants (Cohn, 1994)**

A new class of CTs has been designed based on humidifying the combustion air. In these combustion turbine cycles the compressor exit air is highly humidified prior to combustion. This reduces the mass of dry air needed and the energy required to compress it, raising plant efficiency.

The continuous plant cycle for this concept is termed the **humid air turbine** (HAT). This cycle has been calculated to have a heat rate for natural gas about 5% better than current high-technology CCs. The HAT cycle is adaptable to coal gasification leading to the low emissions and high-efficiency characteristics of gasification CC plants but at a low capital cost since the steam turbine bottoming cycle is eliminated. A simple humidified air turbine cycle is shown in Figure 8.6.13. The addition of moisture means that perhaps 25% more mass flow goes through the turbine, than through the compressor. This suggests the use of separate spools for the turbine and compressor. By using present-day 2350°F firing temperatures it is reasonable to expect a HAT heat rate of about 6100 Btu/kWhr from this cycle.

**FIGURE 8.6.13** The HAT cycle adds moisture to the compressor exit air, reducing the air mass flow needed and increasing cycle efficiency.

As noted above, the ideal natural gas-fired HAT plant has been calculated to have higher efficiency (about 2 points higher) than a CC for the same turbine cooling technology. Thus, it would provide the lowest heat rate for a natural gas-fired thermal plant and would be utilized in base-load or long intermediate dispatch. The capital cost of this power plant has been calculated to be only slightly higher

than that of a CC. However, the anticipated development cost for the ideal turbomachinery has been estimated to be very high, in excess of \$250 million.

In contrast, the CHAT (cascaded humid air turbine) plant utilizes turbine components, which are now available, with few exceptions, in a cascade arrangement that allows them to match together. The development cost of the CHAT equipment is currently estimated to be only in the \$5 to 10 million range, making its development much more practical.

The HAT and CHAT cycles can be integrated with gasification. Because these cycles directly incorporate humidification, they can make direct use of hot water generated in the gasification plant, but cannot readily utilize steam. Thus, they match well with the lower-capital-cost, but lower-efficiency, quench types of gasifier. This provides an overall power plant with efficiency about the same as an IGCC. Moreover, the capital cost of the IGHAT plant has been calculated to be about \$150/kW less than an IGCC plant. These humidification cycles have yet to be offered commercially. The main obstacle is the need to demonstrate experimentally low-emission, high-efficiency, full-scale combustors utilizing very humid air.

### Other Combustion Turbine Cycle Enhancements

There are several variants of the CT-based Brayton cycle which increase plant efficiency and capacity (Lukas, 1986). **Regenerative cycles** use storage-type heat exchangers, where porous or honeycomb wall structures store energy from the hot gases. This is released later to the cold gases. A **recuperative cycle** uses a heat exchanger where the hot and cold streams are separated by walls through which heat transfer occurs. This is the approach commonly used in CTs allowing gains in efficiency and reduced fuel consumption, but no specific output increase.

**Intercooling** between compressor stages increases useful output by about 30% for a given air mass flow, by reducing the volume flow and increasing available energy to the power turbine. It has minimal effect on efficiency, since heat removed must be added back in the combustion chamber, but is commonly used in conjunction with recuperation.

In a reheat cycle the fuel is introduced at two locations, increasing the total energy available to produce work. A combination of intercooling, reheat, and recuperation is shown in [Figure 8.6.14](#).

**Steam injection**, where the steam is injected directly into the combustion chamber, increases the mass flow through the turbine and results in increased output power. Steam-injected gas turbine (SIGT) cycles have been compared from the viewpoints of efficiency, power generation, capital and operating costs, and environmental impacts with CC systems (Esposito, 1989). Above 50-MW size, it was found that CC plants were more economical and achieved significantly better heat rates, although cooling tower fog, visible plumes, and drift deposition favored SIGT plants for a flat site.

## Capital and Operating Costs of Power Plants

[Table 8.6.5](#) lists typical costs for constructing and operating fossil fuel plants as of 1993. These costs are variable depending on plant design and location; the table assumes a plant in the Northeast United States burning Pittsburgh bituminous coal. Fuel costs, not listed explicitly, will be affected by the plant efficiency, listed in the table.

Costs will vary according to type of coal burned, the size of the unit, the plant location in the United States, and the extent of environmental control employed. In this table, Pittsburgh bituminous coal is assumed, which has 7% ash, 2% sulfur, 5% moisture, and a higher heating value of 13,395 Btu/lb. Wet scrubbers for PC plants use limestone-forced oxidation. Fixed O&M costs include labor, maintenance, and overhead. Variable O&M costs are largely consumables: water, chemicals, other materials.

### Summary

The preceding section has described how the future for electric power generation will increasingly be dominated by environmental control needs, putting an emphasis on the base efficiency of new generation and on heat rate recovery for existing units. The PC-fired power plant with FGD will remain a focus of

**FIGURE 8.6.14** Improvement in CT performance is illustrated in this schematic, which combines an intercooler for the compressor, with a recuperator using CT exhaust heat, and a reheat cycle for the turbine to improve efficiency.

**TABLE 8.6.5 Cost Projections for Representative Generation Technologies for a Plant in the Northeast U.S.**

Plants	PC Plants

<sup>a</sup> Costs of new plants are likely to reduce, in real terms, over the next 10 years due to technology developments and increased worldwide competition for markets in the developing countries. New technologies (PFBC, IGCC, fuel cells) will lower capital costs as production capacity grows.

Source: Technical Assessment Guide, EPRI TR-102275-V1R7, Electrical Power Research Institute, Palo Alto, CA, June, 1993. With permission.

most near-term activity related to upgrades and retrofits. But new technology, based on coal gasification, is under development and being tested in a growing number of demonstration plants which promise extremely low emissions.

The future for many nations will be based on exploiting the opportunities offered by clean and efficient use of coal. This implies access to the range of new technologies now being tested at large scale in the United States and other developed nations. This strategy is both timely and prudent on a global basis, as the world increasingly voices concerns related to carbon combustion.

Base-load, central generation plants will largely be focused in the immediate future on the rapidly developing areas of the world — Asia (particularly China and India) and Latin America. In these areas the fuel of choice will likely be coal, particularly in Asia, and the generating unit most often will be a conventional PC unit, but also could be an atmospheric or pressurized fluidized bed unit. In North America, Europe, and Japan, gas-fired central plants using CTs, often in a CC, will dominate through the next decade. As the cost of natural gas, relative to coal, increases, this will then encourage the installation of gasification units enabling the enormous world coal reserves to be utilized. Then, sometime after the turn of the century, smaller distributed generating sources will begin to emerge, based on gas-fired fuel cells, small CTs, or possibly photovoltaics. As the economics for the distributed option become favorable, these smaller generating units could encourage broad electrification of the developing countries of the world.

## Defining Terms

**Aeroderivative turbine:** In the 1960s gas turbines derived from military jet engines formed a source of utility peaking capacity. Now, modern airline fan-jets are being converted to utility service. These lighter CTs are highly efficient and can have low  $\text{NO}_x$  emissions, high pressure ratios, and low capital cost.

**Ash-softening temperature:** The tendency for fly ash to adhere to tube banks is increased as the ash softens and melts. The point at which the ash begins to soften is dependent on the type of coal and is difficult to predict, depending on the many coal constituents. Slagging and fouling of tubes can lead to severe tube corrosion.

**Coal gasification:** Coal can be converted into a mixture of carbon monoxide and hydrogen by burning it with a controlled deficiency of oxygen. Use of pure oxygen produces a medium-calorific-value gas, and air a low calorific value gas. This “syngas” can then be used to power a CT.

**Coextruded tubing:** Tubing for superheaters and reheaters must be strong enough to withstand the pressures and temperatures expected, and also corrosion resistant to depositions of fly ash. By making tubing with a strong inner layer and corrosion-resistant outer layer through an extrusion process, both concerns can be dealt with.

**Cogeneration:** Cogeneration refers to the production of multiple products from a power plant. Typically, process steam, or hot water for heating, is produced in addition to electricity. This approach leads to high plant utilization, the “effective” heat rate being 70% or more.

**Combined cycle:** Power stations which employ both CTs (Brayton cycle) and condensing steam turbines (Rankine cycle) where the waste heat from the CTs generates steam for the steam turbines, are called *combined* cycle plants. Overall plant efficiency improves.

**Electrostatic precipitators:** Flue gas particles, when electrically charged in an ionized gas flow, collect on electrodes in the presence of a strong electrostatic field. Collected dust is discharged by rapping into hoppers. A collection efficiency above 99% is possible.

**Double reheat:** Modern designs of fossil steam-generating units remove a portion of the steam before full expansion through the turbine and reheat it in the boiler before returning it to the turbine. This enhances the thermal efficiency of the cycle by up to 5%. For supercritical cycles two stages of reheat can be justified — double reheat.

**F-class machines:** Recent designs of CTs have increased efficiencies resulting from increased firing temperatures. The first generation of these machines has firing temperatures of about 2300°F. They have been termed F-class machines (for example the GE 7F). Even higher temperatures have now been incorporated into “G-class” turbines.

- Flue gas desulfurization:** Removal of sulfur dioxide,  $\text{SO}_2$ , from combustion gases is accomplished in a number of FGD methods. Most of these involve wet “scrubbing” of the gas using lime or limestone and result in a calcium sulfate waste product. A 95% removal efficiency, or higher, is possible.
- Fluidized bed:** A process of burning solid fuels, particularly coal, by suspending the fuel within a column of air supplied from below the furnace. This method permits effective combustion of poor-quality fuels, lowers  $\text{NO}_x$  emissions due to low combustion temperatures, and captures sulfur in the bed by mixing limestone or dolomite in with the fuel.
- Fuel cell:** Fuel cells convert gaseous or liquid fuels directly to electricity without any combustion process. Like a continuous battery, the fuel cell has electrodes in an electrolyte medium. Typically, hydrogen and air are supplied and DC electricity, water, and carbon dioxide are produced. They are currently high-cost, low-size devices, but with minimum environmental emissions.
- Hot-gas cleanup:** Cycles which use gas from the combustion of coal, typically pressurized fluidized bed or gasification cycles, need to clean up the ash particles before passing them through a gas turbine. This prevents severe erosion of the turbine blades and other components. Hot-gas cleanup can involve the application of hanging particulate traps, using ceramic filters.
- Humid air turbine:** A new type of CT uses humidified compressor exit air for the combustor. The mass of dry air needed is thus lessened for a given mass flow, and turbine efficiency increases. Several applications of this HAT appear attractive in gasification and compressed air storage cycles.
- Intercooling:** Increased output from a CT can be obtained by cooling the air between compressor stages. This reduces volume flow and increases energy to the power turbine.
- Lower heating value:** Fuels containing hydrogen produce water vapor as a product of combustion. The fuel heating value is said to be “lower” if the combustion process leaves all products in the gaseous state, but “higher” if the fuel heating value includes the latent heat of vaporization. Practice in the United States is to use the higher value.
- On/off cycling capability:** Generating units are often not required on a 24-hr basis. Some are shut down during low-demand times and started up perhaps hours later. This form of on/off cycling imposes thermal stresses on the equipment, leading to premature equipment failure unless special measures are taken to deal with this.
- Petroleum coke:** Petroleum coke is a residual product of the oil-refining process, and in its fuel-grade form is an almost pure carbon by-product. About 19 million tons of fuel-grade pet coke is produced each year in the United States. It is inexpensive although it may have high sulfur and vanadium content.
- Recuperative cycle:** Recuperative cycles for CTs use walls between the hot and cold streams through which heat is transferred. This improves efficiency and reduces fuel consumption.
- Regenerative cycles:** Combustion turbine cycles using heat exchangers to store and transfer heat from the hot gases to the cold gases are termed regenerative cycles.
- Slagging and fouling:** The mineral matter in coal can attach itself following combustion to the boiler walls and heat-exchanger surfaces. Oxides of silicon, aluminum, iron, calcium, and magnesium can foul all boiler surfaces, requiring soot blowers for cleaning. Hot ash can melt, becoming sticky and sometimes coalescing in the furnace to cause slagging problems.
- Spray drying:** Spray driers, for desulfurization, used typically when burning lower-sulfur coals, use a spray of quicklime which is dried by the hot flue gas and results in a dry solid product. A 90% removal efficiency is typical.
- Steam injection:** Injecting steam directly into the combustion chamber of a CT increases turbine mass flow and thus increases the output power.
- Temper embrittlement:** Tempering of steel in the manufacturing process removes some of the brittleness and is carried out by a heating and cooling process. During operation, though, it is possible that ductility can worsen close to specific tempering temperatures. The material is then said to be temper embrittled, and premature cracking may follow.

## 8.7 Energy Storage

*Chand K. Jotshi and D. Yogi Goswami*

### Introduction

Energy storage is very important for utility load leveling, electrical vehicles, solar energy systems, uninterrupted power supply, and energy systems at remote locations. Two important parameters for energy storage are duration of storage and **specific energy** or **energy density**. Duration of energy storage may vary from many years to a fraction of a second. In a nuclear power plant, nuclear fuel is stored within a reactor for a year. Coal piles, gas and oil storage tanks, or pumped hydro are kept by power utilities for several days use, depending upon the need. Similarly for a solar energy system, requirement of energy storage may be on an hourly, daily, or weekly basis. Specific energy or energy density is a critical factor for the size of a storage system.

Energy can be stored as mechanical, thermal, chemical, electrical, or magnetic energy. In this section, storage of thermal, mechanical, and electrical energy are described.

### Thermal Energy Storage (TES)

Thermal energy can be stored as sensible heat, latent heat, or as the heat of chemical reaction (thermochemical).

*Sensible heat,  $Q$* , is stored in a material of mass  $m$  and specific heat  $C_p$  by raising the temperature of the storage material and is expressed by Equation (8.7.1):

$$Q = mc_p \Delta T \quad (8.7.1)$$

Most common sensible heat storage materials are water, organic oils, rocks, ceramics, and molten salts. Some of these materials along with their physical properties are listed in [Table 8.7.1](#). Water has the highest specific heat value of 4190 J/kg · C.

**TABLE 8.7.1 Physical Properties of Some Sensible Heat Storage Materials**

Storage Medium	Temperature Range, °C	Density ( $\rho$ ), kg/m <sup>3</sup>	Specific Heat (C), J/kg K	Energy Density ( $\rho C$ ) kWhr/m <sup>3</sup> K	Thermal Conductivity (W/m K)
Water	0–100	1000	4190	1.16	0.63 at 38°C
Water (10 bar)	0–180	881	4190	1.03	—
50-ethylene glycol–50 water	0–100	1075	3480	0.98	—
Dowtherm A® (Dow Chemical, Co.)	12–260	867	2200	0.53	0.112 at 260°C
Therminol 66® (Monsanto Co.)	–9–343	750	2100	0.44	0.106 at 343°C
Draw salt (50NaNO <sub>3</sub> -50KNO <sub>3</sub> ) <sup>a</sup>	220–540	1733	1550	0.75	0.57
Molten Salt (53KNO <sub>3</sub> /40NaNO <sub>2</sub> /7NaNO <sub>3</sub> ) <sup>a</sup>	142–540	1680	1560	0.72	0.61
Liquid sodium	100–760	750	1260	0.26	67.5
Cast iron	m.p. (1150–1300)	7200	540	1.08	42.0
Taconite	—	3200	800	0.71	—
Aluminum	m.p. 660	2700	920	0.69	200
Fireclay	—	2100–2600	1000	0.65	1.0–1.5

<sup>a</sup> Composition in percent by weight.

Note: m.p. = melting point.

Thermal energy,  $Q$ , can be stored as latent heat in a material of mass,  $m$ , that undergoes phase transformation as given by Equation (8.7.2):

$$Q = m\lambda \quad (8.7.2)$$

where  $\lambda$  = heat of phase transformation.

Four types of phase transformations useful for latent heat storage are: solid  $\rightleftharpoons$  liquid, liquid  $\rightleftharpoons$  vapor, solid  $\rightleftharpoons$  vapor, and solid  $\rightleftharpoons$  solid. Since phase transformation is an isothermal process, thermal energy is stored and retrieved at a fixed temperature known as the transition temperature. Some common phase change materials (PCMs) used for thermal storage are paraffin waxes, nonparaffins, inorganic salts (both anhydrous and hydrated), and eutectics of organic and/or inorganic compounds. Table 8.7.2 lists some PCMs with their physical properties.

**TABLE 8.7.2 Physical Properties of Latent Heat Storage Materials or PCMs**

Storage Medium	Melting Point °C	Latent Heat, kJ/kg	Specific Heat (kJ/kg °C)		Density (kg/m <sup>3</sup> )		Energy Density (kWhr/m <sup>3</sup> K)	Thermal Conductivity (W/m K)
			Solid	Liquid	Solid	Liquid		
LiClO <sub>3</sub> · 3H <sub>2</sub> O	8.1	253	—	—	1720	1530	108	—
Na <sub>2</sub> SO <sub>4</sub> · 10H <sub>2</sub> O	32.4	251	1.76	3.32	1460	1330	92.7	2.25
Na <sub>2</sub> S <sub>2</sub> O <sub>3</sub> · 5H <sub>2</sub> O	48	200	1.47	2.39	1730	1665	92.5	0.57

LiNO <sub>3</sub>	252	530	2.02	2.041	2310	1776	261	1.35
LiCO <sub>3</sub> /K <sub>2</sub> CO <sub>3</sub> , (35:65) <sup>a</sup>	505	345	1.34	1.76	2265	1960	188	—
LiCO <sub>3</sub> /K <sub>2</sub> CO <sub>3</sub> /Na <sub>2</sub> CO <sub>3</sub> (32:35:33) <sup>a</sup>	397	277	1.68	1.63	2300	2140	165	—
<i>n</i> -Tetradecane	5.5	228	—	—	825	771	48	0.150
<i>n</i> -Octadecane	28	244	2.16	—	814	774	52.5	0.150
HDPE (cross-linked)	126	180	2.88	2.51	960	900	45	0.361
Steric acid	70	203	—	2.35	941	847	48	0.172 $\ell$

<sup>a</sup> Composition in percent by weight.

Note:  $\ell$  = liquid.

Thermochemical energy can be stored as heat of reaction in reversible chemical reactions. In this mode of storage, the reaction in the forward direction is endothermic (storage of heat), while the reverse reaction is exothermic (release of heat). For example,

The amount of heat  $Q$  stored in a chemical reaction depends on the heat of reaction and the extent of conversion as given by Equation (8.7.4):

$$Q = a_r m \Delta H \quad (8.7.4)$$

where  $a_r$  = fraction reacted,  $\Delta H$  = heat of reaction per unit mass, and  $m$  = mass.

Chemical reaction is generally a highly energetic process. Therefore, a large amount of heat can be stored in a small quantity of a material. Another advantage of thermochemical storage is that the products of reaction can be stored at room temperature and need not be insulated. For sensible and latent heat storage materials, insulation is very important. Examples of reactions include decomposition of metal hydrides, oxides, peroxides, ammoniated salts, carbonates, sulfur trioxide, etc. Some useful chemical reactions are reported in Table 8.7.3.

TABLE 8.7.3 Properties of thermochemical storage media

Reaction	Condition of Reaction		Component (Phase)	Pressure, kPa	Temperature, °C	Density, kg/m <sup>3</sup>	Volumetric Storage Density, kWhr/m <sup>3</sup>
	Pressure, kPa	Temperature, °C					
MgCO <sub>3</sub> (s) + 1200 kJ/kg = MgO(s) + CO <sub>2</sub> (g)	100	427–327	MgCO <sub>3</sub> (s) CO <sub>2</sub> (ℓ)	100 7400	20 31	1500 465	187
Ca(OH) <sub>2</sub> (s) + 1415 kJ/kg = CaO(s) + H <sub>2</sub> O(g)	100	572–402	Ca(OH) <sub>2</sub> (s) H <sub>2</sub> O(ℓ)	100 100	20 20	1115 1000	345
SO <sub>3</sub> (g) + 1235 kJ/kg = SO <sub>2</sub> (g) + 1/2 O <sub>2</sub> (g)	100	520–960	SO <sub>3</sub> (ℓ) SO <sub>2</sub> (ℓ) O <sub>2</sub> (g)	100 630 10000	45 40 20	1900 1320 130	280

Note: s = solid, ℓ = liquid, g = gas.

### Applications and Examples

**Cool Storage** has major applications in space cooling of buildings, food and medicine preservation, and transportation of items that need to be stored at low temperatures. A major application of cool storage is in the use of off-peak electricity for air-conditioning during peak hours. During off-peak hours electricity can be used to make ice or chilled water, which can be used later for air-conditioning of buildings during the peak hours. The advantage of using ice as a storage medium over chilled water is that a much larger amount of coolness can be stored in ice; 1 kg of ice stores 335 kJ, whereas 1 kg of water stores only 42 kJ for a temperature swing of 10°C. The disadvantage of ice is its lower thermal conductivity, which is responsible for lower heat-transfer rates.

Cool storage systems have been used in several buildings in the United States and Canada. The Merchandise Mart of Chicago boasts the largest ice storage system in the world: each day more than 2 million lb of ice are made and melted. For long-term cool storage, aquifers have been used for chilled water storage. Examples include cooling of buildings at the University of Alabama and the United States Postal Service in Long Island, NY, using chilled water stored in aquifers (Tomlinson and Kannberg, 1990). Other materials which have been found to have cool storage potential are PCMs like LiClO<sub>3</sub> · 3H<sub>2</sub>O, a eutectic of Glauber's salt, paraffins and their mixtures, and some gas hydrates or clathrates.

**Heat Storage** has major applications in space heating, crop drying, cooking, electric power generation, industrial process heat (air and steam), waste heat utilization, and solar energy utilization, etc. Heat storage in water is the most economical and well-developed technology. Epoxy-lined steel, fiberglass-reinforced polymer, concrete with plastic liner, and wood tanks are suitable containment materials for systems using water as the storage material. The storage tanks may be located above or below ground. In North America and China, aquifers have been used for long-term storage of hot water and chilled water. Pressurized water tanks are used to store heat from off-peak electricity (ASHRAE, 1995). For example, water is heated to maximum temperatures of about 138°C in a tank at a pressure of 50 psig.

Molten nitrate salt (50 wt% NaNO<sub>3</sub>/50 wt% KNO<sub>3</sub>) also known as Draw salt, which has a melting point of 222°C, has been used as a storage and a heat-transfer fluid in an experiment in Albuquerque, NM. It was the first commercial demonstration of generating power from storage (Delameter and Bergen, 1986). Solar Two, a 10-MW solar thermal power demonstration project in Barstow, CA, is also designed to use this molten salt to store solar energy (Chavez et al., 1995). Another molten nitrate salt is 40 wt% NaNO<sub>2</sub>/7 wt% NaNO<sub>3</sub>/53 wt% KNO<sub>3</sub>, known as HTS (heat-transfer salt) with a melting point of 142°C. This salt has been widely used in the chemical industry.

For applications in heating and cooling of buildings the containment of PCM can become an integral part of the building. It may be part of the ceiling, wall, or floor of the building and may serve a structural or a nonstructural function. Tubes, trays, rods, panels, balls, canisters, and tiles containing PCMs have been studied in the 1970s and 1980s for space-heating applications (Moses and Lane, 1983). The PCMs used were mostly salt hydrates such as Glauber's salt (Na<sub>2</sub>SO<sub>4</sub> · 10H<sub>2</sub>O), Hypo (Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> · 5H<sub>2</sub>O),

$\text{NaCH}_3\text{COO} \cdot 3\text{H}_2\text{O}$ ,  $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ ,  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ ,  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ , and  $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ . Paraffin mixtures have been used for thermal storage in wall boards. Some PCMs, such as salt hydrates, exhibit supercooling and phase segregation problems during heat removal. Low thermal conductivity and complex mechanism of heat transfer during melting and freezing introduce complexities in the design of their containment systems.

## Mechanical Energy Storage

Mechanical energy may be stored as potential or kinetic energy.

### Kinetic Energy

Kinetic energy can be stored in the rotating mass of a wheel, commonly known as a flywheel. Kinetic energy of a rotating body is given by Equation (8.7.5):

$$KE = \frac{1}{2} I \omega^2 \quad (8.7.5)$$

where  $I$  = moment of inertia, and  $\omega$  = angular velocity.

The maximum specific energy of a flywheel is expressed by the following equation (Jenser, 1980):

$$\frac{KE_{\max}}{m} = A \frac{\rho_{\max}}{\rho} \quad (8.7.6)$$

where  $A$  = shape factor, and its value depends on the geometry of flywheel;  $A = 1.0$  for a constant stress disk and  $0.5$  for a thin-rimmed flywheel. This equation shows that high tensile strength and low density are the key parameters to store maximum energy. Tensile strength, density, and specific energy of some materials are given in Table 8.7.4.

**TABLE 8.7.4 Flywheel Rotor Materials**

Material	Design Stress, MN/m <sup>2</sup>	Density, kg/m <sup>3</sup>	Specific Energy, Whr/kg
Composite fiber <sup>a</sup> /epoxy	750	1550	51.5
E-glass fiber <sup>a</sup> /epoxy	250	1990	14.0
S-glass fiber <sup>a</sup> /epoxy	350	1900	19.6
Kevlar fiber <sup>a</sup> /epoxy	1000	1400	76.2
Maraging steel	900	8000	24.2
Titanium alloy	650	4500	30.8

<sup>a</sup> 60% fiber.

Storing energy in a flywheel is one of the oldest techniques used in ancient potteries. Present-day flywheels are much more advanced as a result of superstrong/ultralight composite materials and frictionless high-performance magnetic bearings.

### Potential Energy

If a body of mass  $m$  is elevated against the gravitational force  $g$  to a height  $\Delta h$ , the potential energy stored is given by

$$PE = mg\Delta h \quad (8.7.7)$$

From Equation (8.7.7), 1 Wh of energy can be stored in 1 kg mass of a body by raising it to a height of 367 m.

Potential energy is also stored in a spring, either by compressing or expanding. Here, energy stored is given by

$$PE = (1/2)kx^2 \quad (8.7.8)$$

where  $k$  = spring constant and  $x$  is the distance to which the spring is compressed or expanded. Springs have been widely used to power toys and watches mainly because of very low values of energy density.

### Pumped Hydro

Water may be pumped from a lower reservoir to a higher reservoir using electricity during off-peak hours, which may be used to generate electricity using hydraulic turbines during peak hours. Figure 8.7.1a shows a schematic diagram of an above-ground pumped hydro system. Advantages of pumped hydro units include simple operation, high reliability, low maintenance, long life, quick start from standstill, and economic generation of peaking electrical energy. In the United States a large number of such systems are in operation. Power-generating capacities of these systems vary between 5 and 2000 MW (Makansi, 1994). The overall efficiencies of these power plants vary between 65 and 90%, which includes the efficiencies of pumps, hydraulic turbines, generators, and losses from the upper reservoir. In spite of the technical and economic viability of pumped hydro, the requirement of a specific type of topography and some environmental concerns limit its application. To overcome these problems, a concept of underground pumped hydro storage as shown in Figure 8.7.1b can be used. In this case, large caverns or aquifers can be used as the lower reservoir.

FIGURE 8.7.1 Pumped hydrostorage: (a) above ground; (b) underground.

### Compressed Air Storage

In a fossil fuel power plant, approximately half of the output of a conventional gas turbine is used to drive the compressors. If the air is compressed during off-peak hours and stored, it can be used later during peak hours. Compressed air can be stored underground in abandoned mines, oil or gas fields, sealed aquifers, or natural caverns. A compressed air storage plant in Huntorf, Germany that has been in operation since 1978 is the oldest unit. A 110-MW demonstration facility at the Alabama Electric Cooperative (AEC), Inc., McIntosh, Alabama, site has been in operation since 1991. The Huntorf unit is a 4-hr facility and the AEC site is a 26-hr facility (Makansi, 1994).

## Electrical Energy Storage

Electrochemical energy storage, more commonly known as battery storage, stores electrical energy as chemical energy. Batteries are classified as primary and secondary batteries. Only secondary batteries are rechargeable and are therefore suitable for energy storage applications. Lead-acid and nickel-cadmium are well-known rechargeable batteries that are most commonly used. Lead-acid batteries have been used for over a century and are still the most popular batteries.

Electrochemical operation of a cell during discharge and charge is shown in Figures 8.7.2a and b. During discharge when a cell is connected to a load, electrons flow from the anode to the cathode. In this operation oxidation, or loss of electrons, takes place at the anode, and reduction, or gain of electrons, occurs at the cathode. The cell chemistry of a lead-acid battery is as follows: the anode is lead (Pb) and the cathode is lead oxide (PbO<sub>2</sub>); the electrolyte is H<sub>2</sub>SO<sub>4</sub>. The cell reaction is

Theoretical voltages and capacities of some known batteries are reported in Table 8.7.5.

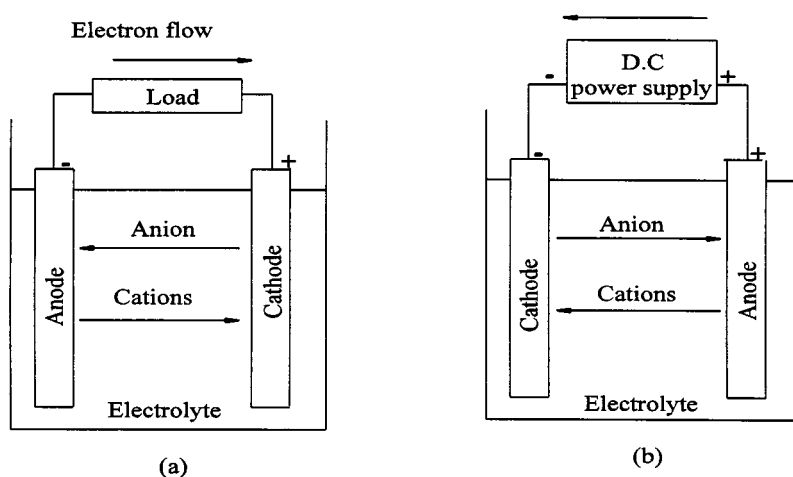

FIGURE 8.7.2 Electrochemical operation of a cell: (a) discharge; (b) charge.

TABLE 8.7.5 Properties of Some Rechargeable Batteries

No.	System	Electrolyte	Temp. °C	O.C.V. (V)	Energy Density (Theoretical), Whr/kg	Energy Density (Achievable), Whr/kg	In/Out Electrical Efficiency	Cycle Life
1	Lead-Acid	H <sub>2</sub> SO <sub>4</sub>	20–30	2.05	171	50	75	1000
2	Nickel-Iron	KOH	20–30	1.37	267	60	55	2000
3	Zinc-Iron	KOH	50–60	1.65	1084	90	45	600
4	Sodium-Sulfur	β-Al <sub>2</sub> O <sub>3</sub>	300–375	1.76–2.08	664	120	75	2000
5	Lithium-Iron Sulfide	LiCl-KCl (eutectic)	400–450	1.6	869	150	75	1000

Note: O.C.V. = open cell voltage.

## Applications

Battery storage is used in a wide range of applications. Currently, the main emphasis of research is on applications in vehicles and load leveling.

*Electric Vehicles.* For electric vehicles, the specific energy and specific power are two important parameters. The greater the specific energy, the farther a vehicle can travel. If specific power is high, a vehicle can accelerate more quickly and have a higher top speed. Other important requirements are the ability to charge and discharge a large number of times, to retain charge over an extended period of time, and to charge and discharge over a wide range of temperatures. [Table 8.7.5](#) provides information about some rechargeable batteries.

*Power Plants.* Recent start-up of a commercial unit for the Puerto Rico Electric Power Authority (PREPA) is the latest development in large-scale application of lead-acid batteries. The facility stores 20 MW for 20 min, both for peaking requirement and voltage and frequency control. Maximum discharge is limited to 10 MW (Makanasi, 1994).

## Defining Terms

**Cool storage:** The storage of thermal energy at temperatures below the nominal temperature required by the space or process.

**Heat storage:** The storage of thermal energy at temperatures above the nominal temperature required by the space or process.

**Energy density:** Amount of energy stored per unit volume,  $\text{kJ/m}^3$  or  $\text{kWhr/m}^3$ .

**Specific energy:** Amount of energy stored per unit mass,  $\text{kJ/kg}$  or  $\text{kWhr/kg}$ .

## 8.8 Nuclear Power

*Roberto Pagano and James S. Tulenko*

Nuclear power refers to power generated through reactions involving atomic nuclei (i.e., nuclear reactions). These reactions fall into three broad categories — fusion reactions, fission reactions, and radioisotopes. In fusion, two light nuclei (most commonly isotopes of hydrogen) combine to form a heavier nucleus (usually helium), with energy being released in the process. Nuclear fusion is the source of energy generated in the stars (our sun). In artificial applications, the technology to induce fusion reactions has been available for several decades, but such reactions have been essentially uncontrolled (the hydrogen bomb). Once initiated, fusion reactions generate huge amounts of energy, which is subsequently released explosively. Means to produce and release energy from fusion in a sustained, controlled manner are still being developed. Extensive research is ongoing, both in the United States and abroad, on the development of nuclear fusion as a controlled source of power.

Nuclear fission, in contrast, is the basis of a mature technology applied to the generation of power. Fission is the fragmentation of a heavy nucleus into two, sometimes three, lighter nuclei. Certain nuclides found in nature fission spontaneously, that is, with no external intervention. However, spontaneous fission in naturally occurring nuclides takes place at a very slow rate. Fission can be induced through a nuclear reaction. Of primary interest here is the fissioning of several specific nuclei through interactions with neutrons. Again, the fissioning of a nucleus is accompanied by the release of energy.

At present, the element of primary importance with respect to nuclear fission power is uranium. Naturally occurring uranium consists of three isotopes —  $^{238}\text{U}$ ,  $^{235}\text{U}$ , and  $^{234}\text{U}$ . In a mixture of isotopes of an element, the abundance of any one is usually expressed as the number of atoms of that isotope present per 100 atoms of the mixture, abbreviated as atom percent a/o or weight percent w/o. Natural uranium consists of 99.2745 a/o  $^{238}\text{U}$ , 0.7200 a/o  $^{235}\text{U}$ , and 0.0055 a/o  $^{234}\text{U}$ .

Radioisotope power is the third form of nuclear energy. When radioisotopes decay, high-energy electrons (beta particles), helium atoms (alpha particles), and gamma rays (photons) are emitted. When the energy of these radiations is stopped and converted to heat, a power source is created. Radioisotopes decay energies range from 0.01 to 10 MeV. Radioisotopes are generally separated from radioactive wastes produced from nuclear power plants. The most common radioisotopes are polonium-210 (alpha emitter of 5.3 MeV), plutonium-238 (alpha emitter of 5.46 MeV), cesium-137 (beta emitter of 1.25 MeV), and strontium-90 (beta emitter of 1.10 MeV).

### The Fission Process

Consider first the fission of a nucleus of  $^{235}\text{U}$  caused by an interaction with a neutron. A compound nucleus of  $^{236}\text{U}$  is initially formed. If fission occurs, it does so within a very short time. Normally with thermal reaction, 85% of the interaction leads to fission. Alternatively, the compound nucleus dissipates energy by emitting a gamma photon, no fission occurs and the nucleus remains as  $^{236}\text{U}$ . This latter process occurs in 20% of the interaction of  $^{235}\text{U}$  with a neutron.

The fissioning of a nucleus produces fission fragments called fission products, a number of neutrons and gamma photons. Most frequently, the number of neutrons is 2 or 3, ranging in extreme cases from 0 to 8. In the fissioning of  $^{235}\text{U}$ , the average number of neutrons released, designated by  $\nu$ , has a value of 2.42. This value applies strictly if the fission is induced by a neutron of relatively low kinetic energy, called a thermal neutron.

In a nuclear reactor, which is a special material medium in which  $^{235}\text{U}$  is dispersed for the reactor to work, one of the neutrons liberated in the fissioning of a nucleus must go on to induce a fission in another nucleus. This leads to the idea of a self-sustaining chain reaction or, more specifically, a **critical configuration** in which a self-sustaining chain reaction can be maintained indefinitely. To this end, an adequate supply of  $^{235}\text{U}$  must be on hand and replenished as needed. Further, the configuration must be

such that the likelihood that any particular neutron ultimately induces a fission is adequately high to ensure that on average one neutron will induce a fission.

The energy liberated in fission results from Einstein's equation  $E = Mc^2$ , which says that mass and energy are equivalent. A summation of the masses of the fission fragments and the neutrons resulting from fission shows that the combined mass of the products of a fission is less than the mass of the compound nucleus before fission occurs. It is found that the energy released is equal to  $E = \Delta Mc^2$  when  $\Delta M$  is the difference in the masses. This nuclear energy is traditionally expressed in units of electron volts (eV), with the equivalence of  $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$ . The single fission of a single uranium atom releases approximately  $200 \times 10^6 \text{ eV}$ , or 200 MeV, of energy. When one realizes that the combustion of a single carbon atom ( $\text{C} + \text{O}_2 \rightarrow \text{CO}_2$ ) releases 4 eV, a quantity 50 million times smaller, one gets a true appreciation of the concentrated power of nuclear energy.

Most of the energy liberated in a fission appears as the kinetic energy of the fission fragments (168 MeV, or 84%) and the kinetic energy of the neutrons (5 MeV, or 2.5%). The remainder is distributed among the gamma photons appearing instantaneously with the fission and the energy associated with the radioactive decay of the fission fragments. These fragments are readily stopped in the reactor. Their range is of the order of 0.01 to 0.001 mm. Thus, the major portion of the energy from a fission is deposited within a very short distance from the site of the fission.

In the largest power reactors in operation in the United States today, heat is generated at the rate of 3800 MW. At 200 MeV per fission, fissioning in such reactors must occur at the rate of  $1.2 \times 10^{20}$  fissions/sec to produce the power. In terms of  $^{235}\text{U}$ , this requires the fissioning of all the nuclei contained in 0.047 g of  $^{235}\text{U}$ , or the fissioning of approximately 4 kg per day. Thus, as a rule of thumb, the fissioning of all the nuclei present in 1 g of  $^{235}\text{U}$  is sufficient to generate 1 MW day of thermal energy. In contrast, the generation of the same amount of energy from coal requires the combustion of 4 tons of coal of typical heating value. With the combustion of coal there is the associated release of a large quantity of carbon dioxide (~14 tons) to the atmosphere with its effects on global warming.

## Cross Sections

A measure of the probability of a particular nuclide to interact with a neutron is provided by a quantity known as a **cross section**. Numerical values of cross sections are determined experimentally and are expressed in units of barns (b), with 1 b defined as  $10^{-24} \text{ cm}^2$ , or  $10^{-28} \text{ m}^2$ .

As a quantity, a cross section may be interpreted as a target area — the larger the cross section, the more likely the interaction of the nucleus with a neutron in its vicinity. For example, the cross section for fission of  $^{235}\text{U}$ , denoted by  $\sigma_f^{235}$ , has a value of 582 b if the interacting neutron is traveling at the velocity associated with thermal energy (2200 m/sec). If the neutron is traveling at high energy, the cross section may drop to a value of approximately 2 b. With respect to the radiative capture of a neutron in  $^{235}\text{U}$  leading to the formation of  $^{236}\text{U}$ , the cross section is given by  $\sigma_c^{235} = 99 \text{ b}$ , if the neutron is thermal. In summary, a cross section is a property specific to a given nuclide, but it is a property whose value depends on the energy of the interacting neutron.

Cross sections are additive. Thus, the cross section for the absorption of a thermal neutron in  $^{235}\text{U}$  — whether the absorption gives rise to a fission or a radiative capture — is given by  $\alpha_a = \alpha_f + \alpha_c = 582 \text{ b} + 99 \text{ b} = 681 \text{ b}$ . Further, the probability of a fission occurring as a result of a thermal neutron being absorbed in  $^{235}\text{U}$  is given by  $\alpha_f/\alpha_a = 582 \text{ b}/681 \text{ b} = 0.85$ . Fission is, therefore, the more likely outcome of an interaction between a  $^{235}\text{U}$  nuclide and a thermal neutron.

On average, the neutrons arising from the fissioning of  $^{235}\text{U}$  have a kinetic energy of 2 MeV, corresponding to a speed of  $2 \times 10^7 \text{ m/sec}$ . These neutrons are four orders of magnitude greater than the speed at which a neutron is considered to be thermal (2200 m/sec).

## Categories of Nuclear Reactors

A prerequisite for a self-sustaining chain reaction is that sufficient  $^{235}\text{U}$  be present in the medium to ensure that the absorption of a neutron in a nucleus of  $^{235}\text{U}$  is a likely occurrence. If the population of neutrons present in the medium at any instant consists predominantly of slow neutrons, a far lesser amount of  $^{235}\text{U}$  is needed to ensure criticality than would be the case if the population were to consist of fast neutrons. This comes about because of the difference in the values of the cross sections mentioned previously.

There is, from this particular standpoint, an incentive to slow down the neutrons originating in fission in order to reduce the inventory of  $^{235}\text{U}$  needed to maintain criticality. In the power reactors operating today, means are provided to slow down the neutrons. The slowing down is effected through multiple elastic scatterings of the neutrons with the nuclei of light elements deliberately present in the medium acting as so-called **moderators**. Notable among such elements are hydrogen present in water, deuterium in heavy water, and carbon in the form of graphite.

All of the reactors in which substantive moderation of the neutrons occurs are categorized as **thermal reactors**. This term stems from the distinguishing feature that the neutron population is in, or near, thermal equilibrium with the nuclei of the moderator. As a consequence, there is no net exchange of energy between the neutron population and its surroundings. The neutrons are then referred to as thermal neutrons.

In a population of **thermal neutrons**, the distribution of the speeds of the neutrons is characterized, adequately in many cases, by the Maxwell-Boltzmann distribution, originally formulated to apply to the molecules of an ideal gas. According to this distribution, the most probable speed of the neutrons at the reference temperature of  $20^\circ\text{C}$  is 2200 m/sec and the kinetic energy corresponding to the most probable speed is 0.025 eV.

Reactors that are not thermal reactors fall in the category of **fast reactors**. In these reactors, the moderation of neutrons is much reduced for reasons discussed later.

## Nuclear Fuel

In light-water reactors (LWR), the type of power reactors most commonly in service today, the nuclear fuel is uranium with a content of 2 to 4% of  $^{235}\text{U}$ . This fuel is produced by enriching natural uranium in  $^{235}\text{U}$  by one of several technologies, principally gaseous diffusion and gaseous centrifugation (Benedict et al., 1981). Neutrons of all energies, down to and including thermal energies, can induce fission in  $^{235}\text{U}$ . For this reason,  $^{235}\text{U}$  is said to be fissile.

In contrast,  $^{238}\text{U}$ , present to the extent of 96 to 98% in the fuel, can be fissioned to a significant extent by neutrons with energies in excess of a threshold of roughly 2 MeV. Fissions of  $^{238}\text{U}$ , referred to as fast fissions, play only a slight role in the chain reaction in an LWR. However,  $^{238}\text{U}$  absorbs neutrons radiatively to yield  $^{239}\text{U}$ . This nuclide is radioactive and decays to  $^{239}\text{Np}$  which, in turn, decays to  $^{239}\text{Pu}$ , a **fissile nuclide**. Thus, in LWR fuel  $^{239}\text{Pu}$ , produced from  $^{238}\text{U}$ , is available for fissioning by neutrons of all energies and contributes to the chain reaction. Because of its ability to form fissile  $^{239}\text{Pu}$ ,  $^{238}\text{U}$  is termed a **fertile nuclide**.

## Conversion and Breeding

To characterize the unique capability of nuclear fuel simultaneously to produce and consume fissile material, a figure of merit known as the **conversion ratio** (CR) is informative. It is defined by the relation:

$$\text{CR} = \frac{\text{number of fissile nuclei produced from fertile nuclei}}{\text{number of fissile nuclei consumed}}$$

In fuel irradiated in an LWR, the conversion ratio typically has a value of 0.5. If the appropriate combination of materials, design, and operating parameters could be found to raise the conversion ratio

to a value greater than unity, a reactor would become a breeder reactor, that is, one that produces more fissile material than it consumes in its operation.

To illustrate the possibility of breeding, consider a parameter known as the reproduction factor and given by

$$\eta = \nu \frac{\text{number of neutrons causing fission in fuel}}{\text{total number of neutrons absorbed in fuel}} = \nu \frac{\sigma_f^{\text{fuel}}}{\sigma_a^{\text{fuel}}}$$

In the case of  $^{235}\text{U}$  and thermal neutrons, the value of  $\eta$  is given by  $\eta_{235} = 2.42 \times 582 / (589 + 99) = 2.42 \times 0.85 = 2.07$ .

If a chain reaction is to be self-sustaining in a reactor, the condition  $\eta > 1$  must apply. To achieve breeding requires that  $\eta > 2$ . In other words, one neutron from fission would be available to sustain the chain reaction and another to produce a fissile nucleus from a fertile nucleus. Practical considerations indicate that the value of  $\eta$  must be substantially greater than 2, since neutrons will be lost by absorption in structural materials, heat removal medium, fission fragments, the moderator, if present, and by escaping from the physical confines of the reactor.

As shown,  $^{235}\text{U}$  has a value of  $\eta$  slightly above 2 with neutrons at thermal energies. Breeding or near-breeding conditions could arise, in principle, if very judicious choices of materials and parameters prevail. A more attractive fuel from the standpoint of breeding is  $^{233}\text{U}$ . This isotope of uranium is produced artificially by placing the naturally occurring nuclide  $^{232}\text{Th}$  in a reactor. A radiative capture of a neutron in  $^{232}\text{Th}$  leads to the formation of the radioactive nuclide  $^{233}\text{Th}$ . Two successive radioactive decays yield  $^{233}\text{U}$ . In a thermal reactor, the value of  $\eta$  with  $^{233}\text{U}$  is 2.29, approaching the level where breeding might be contemplated. Intermediate between the two fissile isotopes of uranium is  $^{239}\text{Pu}$ , which at thermal energies yields a value of  $\eta$  of 2.15.

Figure 8.8.1 shows the behavior of  $\eta$  as the energy of the neutrons inducing fission increases. A little above thermal energies the value of  $\eta$  for  $^{239}\text{Pu}$  and  $^{235}\text{U}$  drops below 2, indicating that breeding is impossible at such energies. As energy increases, the values of  $\eta$  for both reach the threshold of 2 and continue to increase steadily, with  $^{239}\text{Pu}$  clearly the more attractive fuel from the standpoint of breeding. The value of  $^{239}\text{Pu}$  for  $^{235}\text{U}$  is relatively insensitive to increases in energy and remains continuously above 2. Again, at higher energies,  $\eta$  is the more attractive fuel.

Research on the development of **breeder reactors** has focused on the  $^{239}\text{Pu}$  fuel cycle, both in the U.S. and abroad. Representative of these reactors is the liquid metal fast breeder reactor (LMFBR) in which liquid sodium is the heat-removal fluid and provides the small amount of moderation needed. Breeder reactors with  $^{233}\text{U}$  as fuel, represented by an adaptation of the high-temperature gas-cooled reactor (HTGCR), in which the heat-removal fluid is helium and the moderator is graphite, although less attractive, in principle, as breeders, might with further research and development prove to be viable alternatives to the LMFBR.

### LWR Fuel

Nuclear fuel in light water is in the form of small cylindrical pellets of the ceramic  $\text{UO}_2$ , with the uranium enriched to 2 to 4% in  $^{235}\text{U}$ , as mentioned previously. These pellets are stacked vertically in tubes and the ends of the tubes are sealed off. The dimensions and further details given here apply strictly to the more common type of LWR, known as the pressurized water reactor (PWR), but may be taken as generally representative of LWRs.

The tubes containing the fuel pellets are referred to as fuel rods. They are 4.3 to 4.7 m in length and 0.0095 m in outside diameter. An array typically of  $17 \times 17$  rods constitutes a fuel assembly, as shown in Figure 8.8.2. Certain fuel rods within the assembly are replaced by guide sheaths in which absorber rods can be moved vertically. These rods absorb neutrons, thus providing one of the means of controlling the chain reaction as the rods are inserted or withdrawn. Within the fuel assembly the fuel rods are placed on a pitch of 0.0127 m, leaving vertical passages through which water can flow. A total of

FIGURE 8.8.1 Dependence of reproduction factor of neutron energy.

approximately 200 fuel assemblies, juxtaposed to form a roughly cylindrical configuration constitute the core of the reactor. Water is circulated through the core where the water serves both to moderate the neutrons and to remove the heat generated by fissions in the nuclear fuel.

### Light-Water Reactors

LWRs currently make up the largest portion of the installed nuclear generating capacity throughout the world. Among these, the PWRs are more numerous. By operating at a sufficiently high pressure, bulk boiling of the reactor coolant is suppressed in a PWR. In contrast, the coolant is allowed to boil in a boiling water reactor (BWR) and a portion of the coolant is converted to steam as it circulates through the core.

### Pressurized Water Reactors

A schematic of a PWR system is shown in Figure 8.8.3. At the heart of the system is the core made up of fuel assemblies and associated control rods. The core is contained in a reactor vessel, or pressure vessel, designed to operate at a pressure typically of 15.5 mPa. Water is circulated through the core where it acts as a moderator and also removes the heat generated through fission. Typical operating temperatures at full power are 295°C at the inlet and 330°C at the outlet, an increase of 35°C as a result of the water passing through the core.

From the reactor vessel, the coolant is circulated to steam generators and returned to the reactor vessel to complete the so-called primary loop. This loop constitutes the nuclear steam supply (NSS). Steam emerging from the steam generators is directed toward the secondary loop, or balance of plant, consisting of turbine generator, condenser, and feedwater pumps. Extremely small quantities of radioactive contaminants may be present in the steam generated in PWRs, and all releases to the environment from the secondary side of the plant are carefully monitored and controlled. Otherwise, steam from the NSS differs from steam generated in fossil fueled plants only inasmuch as its grade is inferior.

FIGURE 8.8.2 PWR fuel assembly.

### Boiling Water Reactors

Figure 8.8.4 is a schematic of a BWR system. A reduced operating pressure of 7.2 MPa causes a portion of the coolant to flash to steam. Steam separators and driers allow dry steam to emerge from the reactor vessel, thus eliminating the need for separate steam generators and a secondary loop. Steam from the reactor vessel flows through a turbine generator and condenser, from which circulating pumps return the condensate to the reactor. Large quantities of radioactive contamination may be present in the steam produced by a BWR because of the direct cycle, so releases must be carefully monitored. A distinguishing feature of the BWR are the jet pumps, typically 24 in number, placed along the periphery of the core. These pumps augment the flow of coolant through the core.

### Defining Terms

**Breeder reactors:** Reactors in which the conversion ratio is greater than unity.

**Conversion ratio:** The ratio of the number of fissile nuclei produced in a reactor to the number of fissile nuclei consumed.

FIGURE 8.8.3 Schematic of a pressurized water reactor.

FIGURE 8.8.4 Schematic of a boiling water reactor.

**Critical configuration:** A medium containing nuclear fuel in which a self-sustaining chain reaction can be maintained.

**Cross section:** A numerical quantity, determined experimentally, related to the probability that a specific nuclide will undergo a given nuclear reaction.

**Fast reactors:** Reactors in which little moderation of the neutrons occurs and the neutron populations consist of neutrons of relatively high speeds.

**Fertile nuclide:** A nuclide that, through the absorption of a neutron and subsequent radioactive decays, can produce a fissile nuclide.

**Fissile nuclide:** A nuclide that can be fissioned by neutrons of all energies, down to and including thermal energies.

**Moderator:** A component of a reactor present expressly to slow down neutrons and produce a population of thermal neutrons.

**Thermal neutrons:** A population of neutrons in, or near, thermal equilibrium with the nuclei of a medium in which the populations exists.

**Thermal reactors:** Reactors in which the neutron populations consist predominantly of thermal neutrons.

## 8.9 Nuclear Fusion

---

*Thomas E. Shannon*

### Introduction

Nuclear fusion holds the promise of providing almost unlimited power for future generations. If the process can be commercialized as envisioned by reactor design studies (Najmabadi et al., 1994), many of the problems associated with central electric power stations could be eliminated. Fusion power plants would not produce the pollution caused by the burning of fossil fuel and would eliminate the concern for meltdown associated with nuclear fission. The amount of radioactive waste material produced by a fusion reactor will be much less than that of a fission reactor since there is essentially no radioactive ash from the fusion reaction. If **low activation advanced materials** such as silicon carbide composites can be developed for the reactor structural material, the problem of disposal of activated components can also be eliminated.

### Fusion Fuel

Although a number of different atomic nuclei can combine to release net energy from fusion, the reaction of **deuterium and tritium** (D-T) is the basis of planning for the first generation of fusion reactors. This choice is based on considerations of reactor economy. The D-T reaction occurs at the lowest temperature, has the highest probability for reaction, and provides the greatest output of power per unit of cost (Shannon, 1989). The disadvantages of D-T as a fusion fuel are twofold. Tritium does not occur naturally in nature and must be bred in the fusion reactor or elsewhere. Second, tritium is a radioactive isotope of hydrogen with a relatively long **half-life** of 12.3 years. Since tritium can readily combine with air and water, special safety procedures will be required to handle the inventory necessary for a fusion reactor. There is hope that a less reactive fuel, such as deuterium alone (D-D) will eventually prove to be an economically acceptable alternative (Shannon, 1989).

### Confinement Concepts

Magnetic fusion, based on the tokamak concept, has received the majority of research funding for fusion energy development. However, other magnetic fusion concepts, such as the stellarator, the spherical torus, reversed-field pinch, and field-reversed configurations, are being developed as possible alternatives to the tokamak (Sheffield, 1994). It may also be possible to develop fusion power reactors by inertial confinement concepts (Waganer et al., 1992). Research on these concepts has been done primarily in support of weapons development; therefore, the level of scientific understanding for power reactor applications is significantly less than that of magnetic fusion. The remainder of this discussion on reactor development, fusion energy conversion, and transport will consider only the tokamak magnetic fusion concept.

### Tokamak Reactor Development

The tokamak device has proved to be the most effective means of producing the conditions necessary for magnetic fusion energy production. In 1994, researchers at the Princeton Plasma Physics Laboratory achieved in excess of 10 MW of D-T fusion power in a research tokamak, the Tokamak Fusion Test Reactor (TFTR). This accomplishment, coupled with worldwide progress in 40 years of magnetic fusion research, has established the scientific feasibility of the tokamak concept. The next major step, the International Thermonuclear Experimental Reactor (ITER) is being carried out under an international agreement among Europe, Japan, Russia, and the United States (Conn et al., 1992). A drawing of the ITER tokamak is shown in [Figure 8.9.1](#). If the project is approved for construction, it will be in operation

**FIGURE 8.9.1** The International Thermonuclear Experimental Reactor (ITER).

around 2005. The ITER is being designed to produce a fusion power in excess of 1000 MW. This will be a significant step on the path to commercial fusion power.

The U.S. Department of Energy has proposed a strategy, shown in [Figure 8.9.2](#), which will lead to a demonstration power reactor by the year 2025. Supporting research and development programs necessary to achieve this goal are shown in this figure.

**FIGURE 8.9.2** The U.S. Department of Energy magnetic fusion energy strategy.

## Fusion Energy Conversion and Transport

The energy from fusion is created in the form of charged particles and neutrons. The D-T reaction produces a neutron with an energy of 14.1 MeV and an alpha particle (helium) with an energy of 3.5 MeV in the reaction

In the tokamak device, the reaction will take place in the toroidal vacuum vessel as previously shown in the ITER drawing, [Figure 8.9.1](#). The D-T fuel, in the form of a **plasma**, will absorb energy from the positively charged alpha particles to sustain the temperature necessary for the reaction to continue. The neutron, having no charge, will escape from the plasma and pass through the wall of the vessel and penetrate into the surrounding blanket/shield structure. The kinetic energy of the alpha particles from the fusion reaction is eventually deposited on the wall of the vacuum vessel by radiation and conduction heat transfer from the plasma while the neutron deposits most of its energy within the cross section of the blanket/shield. The resulting thermal energy is transferred by a coolant such as water to a steam generator where a conventional steam to electric generator system may be used to produce electricity. An overall schematic diagram of the energy conversion and heat-transport system is shown in [Figure 8.9.3](#).

FIGURE 8.9.3 Schematic Diagram of a Magnetic Fusion Reactor Power Plant.

## Defining Terms

**Deuterium and tritium:** Isotopes of hydrogen as the fuel for fusion reactors.

**Half-life:** The time required for half of the radioactive material to disintegrate.

**Low activation advanced materials:** Structural materials that significantly reduce the radioactivity induced by exposure to fusion neutrons.

**Plasma:** A gas such as a mixture of deuterium and tritium raised to a very high temperature at which the electrons and the nuclei of the atoms separate. The plasma, consisting of electrons and ions, can conduct electricity and react to magnetic fields.

## 8.10 Solar Thermal Energy Conversion

*D. Yogi Goswami*

### Introduction

Solar thermal energy applications such as space and water heating have been known for a long time. Researchers over the past few decades have developed a number of additional solar thermal applications, such as industrial process heat, refrigeration and air-conditioning, drying and curing of agricultural products, and electric power production by solar thermal conversion. This section will cover solar thermal energy conversion including solar thermal collectors and conversion systems.

### Solar Thermal Collectors

A simple **solar thermal collector** consists of (1) an absorber surface (usually a dark, thermally conducting surface), (2) some insulation behind the surface to reduce heat loss, (3) a trap for thermal reradiation from the surface such as glass, which transmits the shorter-wavelength solar radiation but blocks the longer-wavelength radiation from the absorber, and (4) a heat-transfer medium such as air, water, etc. High-temperature collectors require reflectors of sunlight that concentrate solar radiation on the absorber. The technology of solar collectors is developed to achieve temperatures as high as 1000°C or even higher. The design of a solar collector and the choice of working fluids depend on the desired temperature and the economics of the application. [Table 8.10.1](#) lists the types of solar thermal collectors based on their temperature range.

**TABLE 8.10.1 Types of Solar Collectors and Their Typical Temperature Range**

Type of Collector	Concentration Ratio	Typical Working Temperature Range (°C)
Flat plate collector	1	≤70
High-efficiency flat plate collector	1	60–120
Fixed concentrator	2–5	100–150
Parabolic trough collector	10–50	150–350
Parabolic dish collector	200–2000	250–700
Central receiver tower	200–2000	400–1000

*Source:* Compiled from Goswami, D.Y., *Alternative Energy in Agriculture*, Vol. 1, CRC Press, Boca Raton, FL, 1980.

### Flat Plate Collectors

Flat plate collectors may be designed to use liquids (water, oil, etc.) or air as the heat-transfer fluid. [Figure 8.10.1](#) shows a typical liquid-type flat plate collector. The choice of materials for glazing and absorber needs special attention.

**Glazing.** The purpose of **glazing** is to (1) transmit the shorter-wavelength solar radiation, but block the longer-wavelength reradiation from the absorber plate, and (2) reduce the heat loss by convection from the top of the absorber plate. Glass is the most widely used glazing material. Transmittance of low iron glass in the visible and near infrared wavelength range can be as much as 91%, while for the longer-wavelength radiation (>3 μm) its transmittance is almost zero. Other materials than can be used as glazings include certain plastic sheets such as polycarbonates (Lexan® and Tuffac® — transmittance ~75%), acrylics (Plexiglass® and Lucite® — transmittance ~92%), and thin plastic films such as polyethylene. A major advantage of the plastics is that they are shatterproof; however, they scratch easily and lose transparency over time.

**Absorbers.** Copper is the most common material used for absorber plates and tubes because of its high thermal conductivity and high corrosion resistance. For low-temperature applications such as swimming pool heating, a plastic material called ethylene propylene polymer (trade names EPDM, HCP,

**FIGURE 8.10.1** A typical liquid flat plate collector. (Courtesy of American Energy Technologies, Green Cove Springs, FL.)

etc.) can be used to provide inexpensive absorber material. To compensate for low thermal conductivity of these materials, a large surface area is provided for heat transfer. In order to increase the absorption of solar radiation and to reduce the emission from the absorber, the metallic absorber surfaces are painted or coated with flat black paint or some selective coating. Absorptivities and emissivities of some common **selective surfaces** are given in [Table 8.10.2](#).

**TABLE 8.10.2** Absorptivity and Emissivity of Common Selective Surfaces

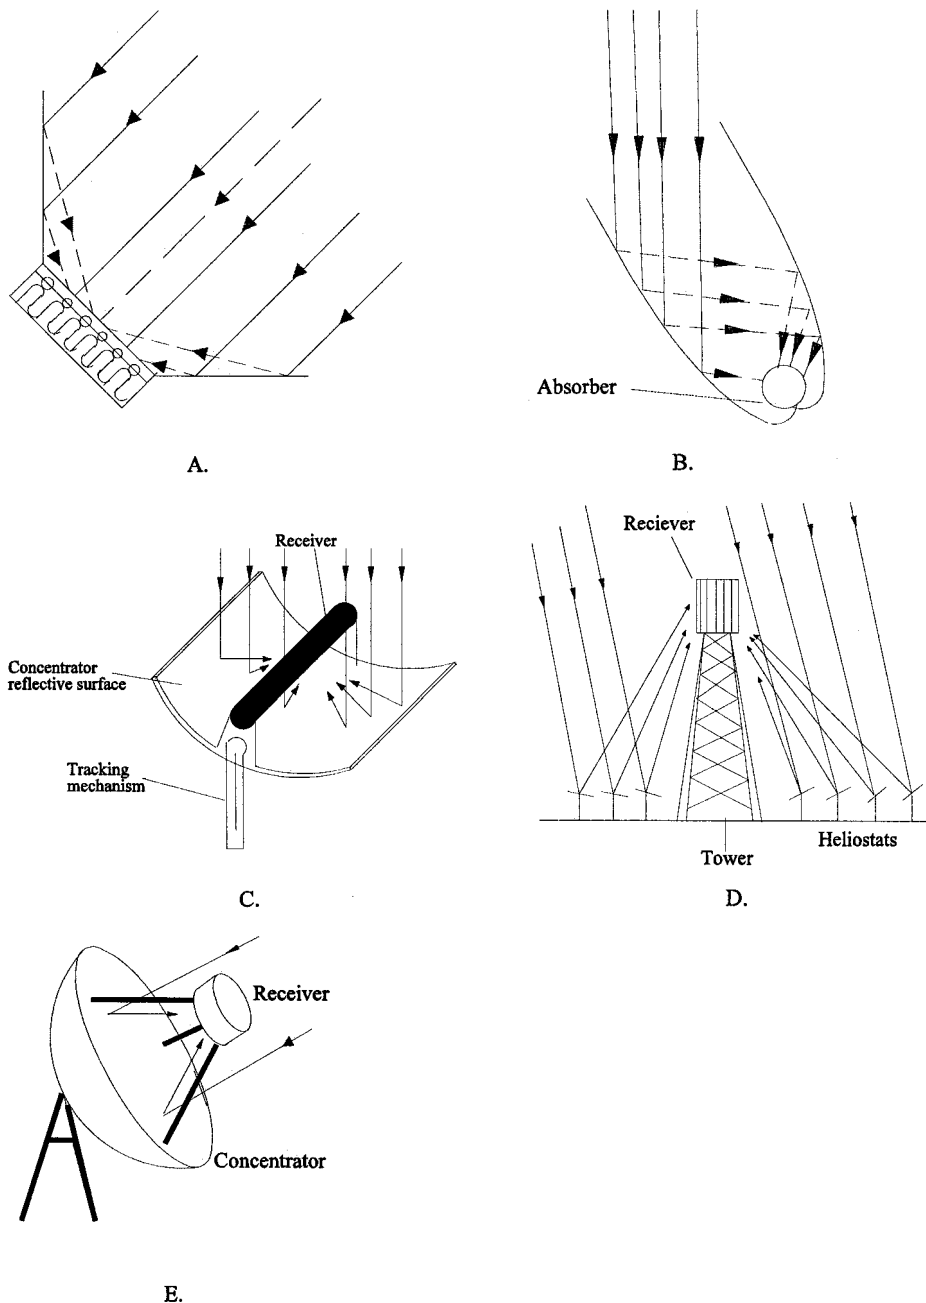

Surface	Absorptivity	Emissivity
Black chrome	0.95	0.1
Black nickel	0.9	0.08
Copper oxide	0.9	0.17
Lead sulfide	0.89	0.2
Flat black paint	0.98	0.98

Source: Compiled from Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, John Wiley and Sons, New York, 1980.

**Evacuated Tube Collectors.** Evacuated tube collectors have essentially a vacuum between the absorber and the glazing tube. This eliminates most of the heat loss by conduction and convection. Therefore, these collectors give a very high efficiency at higher temperatures. Evacuated tube collectors are typically used in the temperature range of 80 to 140°C

**Concentrating Collectors.** Concentrating collectors use reflectors or lenses to focus solar radiation from a large area onto a small area, thereby creating higher temperatures. Such collectors are usually used for temperatures higher than 100°C. [Figure 8.10.2](#) shows schematics of some of the concentrating collectors.

**Nontracking Concentrators.** The simplest concentrating collector can be made by using flat wall reflectors to concentrate the solar radiation on a flat plate collector. Concentration ratios of two to three can be

**FIGURE 8.10.2** Types of concentrating collectors. (A) Flat plate collector with reflective wings; (B) Compound parabolic concentrator; (C) parabolic trough; (D) central receiver; (E) parabolic dish.

achieved this way. For slightly higher concentration ratios, a novel design, developed by Roland Winston, called a “compound parabolic concentrator” (CPC) can be used (Winston, 1974).

*Tracking Concentrators.* For temperatures up to 350°C, cylindrical parabolic trough collectors are used. These collectors focus solar radiation on a line focus where the absorber is located. These collectors usually require tracking on one axis only with seasonal adjustment on the other axis. A reflecting spherical or paraboloidal bowl is used when temperatures of the order of 250 to 500°C are needed. These collectors

require two-axis tracking. In some cases, the dish is kept stationary while the receiver is moved to track the focus of the reflected solar radiation. Finally, for extremely high temperatures (500 to 1000°C) needed for large-scale thermal power generation, a large field of tracking flat mirrors (called heliostats) is used to concentrate solar radiation on a receiver that is located on top of a central tower.

## Collector Thermal Performance

The instantaneous efficiency of a collector is given by

$$\eta = \frac{\text{Useful energy collected}}{\text{Incident solar energy}} = \frac{Q_u/A}{I} \quad (8.10.1)$$

where

$$Q_u = mC_p(T_o - T_i) \quad (8.10.2)$$

and  $A$  = area of the collector,  $I$  = incident solar energy per unit area,  $m$ ,  $C_p$ ,  $T_i$ , and  $T_o$  are the mass flow rate, specific heat, and inlet and outlet temperatures of the heat-transfer fluid.

The efficiency of a flat plate solar collector can also be written by the Hottel–Whillier–Bliss equation:

$$\eta = F_{R\Box}(\tau\alpha)_e - F_R U_L \frac{(T_{i\Box} - T_{amb})}{I} \quad (8.10.3)$$

where  $F_R$ , called the collector heat-removal factor, is a convenient parameter that gives the ratio of the actual useful energy gain of a flat plate collector to the useful gain if the whole collector surface were at the inlet fluid temperature;  $(\tau\alpha)_e$  = effective transmittance absorptance product; and  $U_L$  = collector heat-loss coefficient.

Equation 8.10.2 suggests that if the efficiency,  $\eta$ , is plotted against  $(T_i - T_{amb})/I$ , the resulting curve will have a  $y$  intercept equal to  $F_R(\tau\alpha)_e$  and a slope of  $F_R U_L$ . A linear curve usually gives an adequate approximation. Figure 8.10.3 shows an example of a performance curve for a water-heating flat plate collector, which is a linear least square curve fit to the actual test data.

## Solar Ponds

A solar pond combines collector and energy storage in one unit. Solar radiation that enters the pond travels some distance through the water before being totally absorbed, thus increasing the temperature of the water at that depth. The heat thus collected can be stored in the pond by creating a stagnant, transparent, insulating layer in the top part of the pond. The most common method is by the addition of a salt into the pond to increase the density of water in the lower section of the pond. This type of pond is called a **salt gradient solar pond**. Reid (1987) reviewed the progress in the design and applications of salt gradient solar ponds. Figure 8.10.4 shows a schematic of a salt gradient pond along with a density profile in the pond.

The theory of salt gradient solar ponds has been described by Tabor (1981). The most important aspect of such ponds is the creation and maintenance of the salt gradient. Theory shows that the condition for maintaining stability is

$$\frac{\partial S}{\partial Z} > -1.14 \frac{\partial \rho}{\partial T} \times \frac{\partial T}{\partial Z} \frac{\partial \rho}{\partial S} \quad (8.10.4)$$

**FIGURE 8.10.3** Thermal efficiency curve for a double-glazed flat plate liquid-type of solar collector. **FIGURE 8.10.4** Schematic of a salt gradient solar pond.

where  $S$  is the salt concentration in kilograms per cubic meter,  $Z$  is the depth from the surface in meters,  $\rho$  is the density in kilograms per cubic meter, and  $T$  is the temperature in Kelvin. The two most common salts considered for solar pond applications are  $\text{NaCl}$  and  $\text{MgCl}_2$ . According to the above criteria, there is no difficulty in obtaining stability with  $\text{MgCl}_2$  and it is somewhat difficult but possible to get stability with  $\text{NaCl}$ .

### Solar Water-Heating Systems

Solar water-heating systems represent the most common application of solar energy at the present time. Small systems are used for domestic hot water applications while larger systems are used in industrial process heat applications. There are basically two types of water-heating systems: **natural circulation or passive solar system** (thermosyphon) and **forced circulation or active solar system**.

#### Natural Circulation

Figure 8.10.5 shows a schematic of a natural circulation solar water-heating system. It is also called a thermosyphon or passive solar water heater because it does not require a pump to circulate water. The storage tank is located above the collector. When the water in the collector gets heated, it rises into the tank, because of density change, setting up a circulation loop.

**FIGURES 8.10.5** Schematic of a thermosyphon solar water-heating system.

### Forced Circulation

Figure 8.10.6 shows three configurations of forced circulation systems: (1) open loop, (2) closed loop, and (3) closed loop with drainback. In an open loop system, the collectors are empty when they are not providing useful heat and the storage tank is at atmospheric pressure. A disadvantage of this system is the high pumping power required to pump the water to the collectors every time the collectors get hot. This disadvantage is overcome in the pressurized closed loop system (Figure 8.10.6B) since the pump has to overcome only the resistance of the pipes. Because water always stays in the collectors of this system, antifreeze (propylene glycol or ethylene glycol) is required for locations where freezing conditions can occur. During stagnation conditions (in summer), the temperature in the collector can become very high, causing the pressure in the loop to increase. This can cause leaks in the loop unless some fluid is allowed to escape through a pressure-relief valve. In both cases, air enters the loop causing the pump to run dry. This disadvantage can be overcome in a closed loop drainback system (Figure 8.10.6C). In this system, when the pump shuts off, the water in the collectors drains back into a small holding tank, which can be located where freezing does not occur. The holding tank can be located at a high level to reduce pumping power.

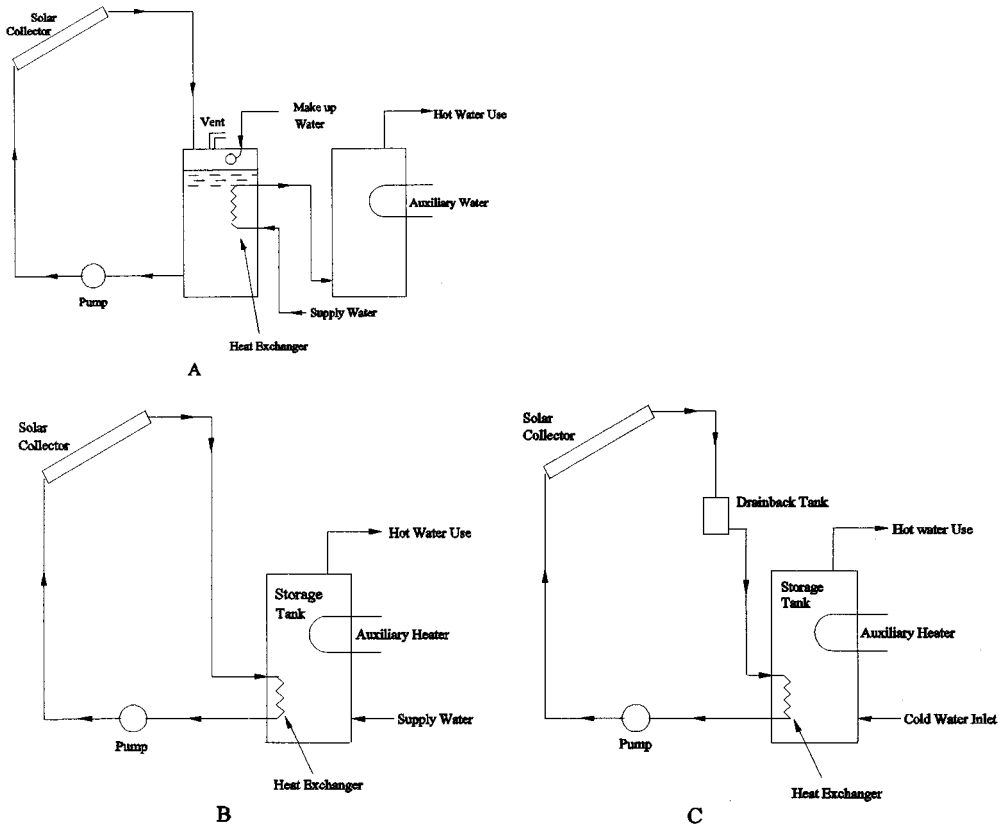

### Industrial Process Heat Systems

For temperatures of up to about 100°C, required for many industrial process heat applications, forced circulation water-heating systems described above can be used. The systems, however, will require a large collector area, storage and pumps, etc. For higher temperatures, evacuated tube collectors or concentrating collectors must be used.

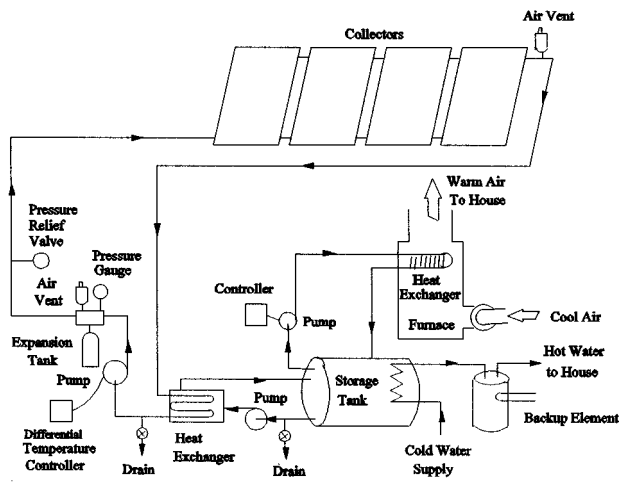

### Space-Heating Systems

Solar space-heating systems can be classified as active or passive depending on the method utilized for heat transfer. A system that uses pumps and/or blowers for fluid flow in order to transfer heat is called an *active system*. On the other hand, a system that utilizes natural phenomena for heat transfer is called a *passive system*. Examples of passive solar space-heating systems include direct gain, attached greenhouse, and storage wall (also called Trombe wall).

Active space-heating systems store solar collected heat in water or rocks. Heat from water storage can be transferred to the space by convertors or by fan-coil units. A system using a fan-coil unit can be integrated with a conventional air system as shown in Figure 8.10.7. Heat from rock storage can be transferred to air by simply blowing air over the rocks.

**FIGURE 8.10.6** Typical configurations of solar water-heating systems: (A) open loop system, (B) closed loop system, (C) closed loop drainback system. (Adapted from Goswami, D.Y., *Alternative Energy in Agriculture*, Vol. 1, CRC Press, Boca Raton, FL, 1986.)

**FIGURE 8.10.7** Schematic of an active solar space-heating system.

## Solar Thermal Power

Solar thermal energy can be used to produce electrical power using conventional thermodynamic power cycles such as Rankine, Stirling, and Brayton cycles. The choice of power cycle and the working fluids depends on the temperature obtainable in the solar system, which depends on the type of solar collectors used. At present, developed solar thermal power systems include

- Parabolic trough systems
- Central receiver systems
- Parabolic dish-Stirling engine system

### Parabolic Trough Systems

Parabolic trough systems are simple in concept and, therefore, the most developed commercially. In 1984, Luz Company installed a Solar Electric Generating System (SEGS I) of 14 MW<sub>e</sub> capacity in Southern California, utilizing parabolic trough solar collectors and natural gas fuel for superheat and backup. From 1984 to 1991, Luz Company installed eight additional plants, SEGS II to SEGS IX, with the total capacity of the nine plants being 354 MW<sub>e</sub>. With each successive SEGS plant the technology was improved and the cost reduced. The cost of electricity was reduced from about 30¢/kWhr for the first plant to about 8¢/kWhr for the last plant. A schematic of the SEGS IX is shown in [Figure 8.10.8](#), and some important data for the system are given in [Table 8.10.3](#).

FIGURE 8.10.8 Schematic of SEGS IX power plant.

TABLE 8.10.3 Plant Characteristics — SEG IX

Power Block		Solar Field	
Gross power	88 MWe	Number of collectors	888
Net power	80 MWe	Aperture area	483,960 m <sup>2</sup>
Steam inlet pressure	100 bar	Inlet temperature	293°C
Steam inlet temperature	371°C	Outlet temperature	390°C
Reheat pressure	17.2 bar	Annual thermal efficiency	50%
Reheat temperature	371°C	Peak optical efficiency	80%
Conversion efficiency	37.6%	Heat-transfer fluid (HTF)	Oil (VP-1)
Annual gas use	25.2 × 10 <sup>9</sup> m <sup>3</sup>	HTF volume	1289 m <sup>3</sup>

Source: DeLaquil, P. et al., in *Renewable Energy Sources for Fuel and Electricity*, Island Press, Washington, D.C., 1993. With permission.

It has been recognized that this design does not utilize the energy of the natural gas efficiently. It has been suggested that energy of natural gas can be better utilized by combining the solar system with a natural gas turbine combined-cycle power plant (DeLaquil et al., 1993; Washom et al., 1994). Such a

hybrid system would use the exhaust of a natural gas turbine for superheating and preheating of water, while the solar field would be used for steam generation. Such a hybrid system can achieve conversion efficiency as high as 60%. A schematic of a **solar hybrid combined cycle** is shown in Figure 8.10.9.

**FIGURE 8.10.9** Solar hybrid combined cycle. (Adapted from Washom, B. et al., paper presented at the 1994 ASES Annual Conference, San Jose, CA, 1994.)

### Central Receiver System

A central receiver system can potentially operate at very high temperature and therefore can have much higher efficiency than parabolic trough systems. However, the system can be economical only at larger capacities, such as 100 MW and above. The central receiver absorber can heat the working fluid or an intermediate fluid to a temperature as high as 600 to 1000°C which can be used to drive a Rankine cycle or Brayton cycle.

Solar One, a 10-MW<sub>e</sub> central receiver power plant started operating in 1982 in Barstow, California. This plant generated superheated steam at 510°C and 10.3 MPa in the receiver absorber, which was used to drive a simple steam Rankine power cycle. The plant operated successfully for 6 years and provided a good learning experience. The plant has now been redesigned as Solar Two in which molten sodium nitrate is used as the heat-transfer fluid as well as for storage. Use of molten salt allows operation of the receiver absorber at much lower pressures. The constraint is that the salt must always be above its melting point (220°C). Figure 8.10.10 shows a schematic of the Solar Two power plant.

### Parabolic Dish Systems

Parabolic dish systems can achieve very high temperatures. The high temperatures produced by parabolic dishes can be used to drive Rankine, Stirling, and Brayton power cycles. So far, Rankine and Stirling cycles have been successfully demonstrated with parabolic dishes for electrical power production.

Early versions of parabolic dishes were made from die-stamped aluminum petals made reflective using a metallized polymer film. Later designs used simpler flat mirror facets fixed on a structure in such a way as to approximate a parabolic dish. The latest designs use a polymer film stretched on a circular frame (Mancini, 1994). The film is given a slight concave curvature by providing a vacuum behind it. These stretched polymer films are fixed on a structure to approximate a parabolic dish. Because of the low weight of the polymer film, the dish structure can be made out of light tubular members, thereby reducing the cost of the dish considerably. Parabolic dishes require two-axis tracking.

McDonnell Douglas Corporation successfully demonstrated a 25-KW<sub>e</sub> parabolic dish system using a Stirling engine and a generator assembly fixed at the focal point of the dish in 1985 (Gupta, 1987). The concept is very attractive because it provides a modular design of stand-alone power plants for small

FIGURE 8.10.10 Schematic of Solar Two.

communities and independent power applications. Cummins Power Generation Company, in Indiana, has developed this concept further (Mancini, 1994). The Cummins system uses stretched polymer film facets for a parabolic dish, a heat pipe receiver absorber, a free-piston Stirling engine, and a linear alternator, resulting in a very compact power generation system. Figures 8.10.11 shows the latest version of the Cummins Dish Stirling power system. A detailed discussion of Stirling engines is given in Section 8.5.

## Nomenclature

$A$	= area of collector
$C_p$	= specific heat
$m$	= mass flow rate
$T$	= temperature
$I$	= incident solar radiation
$Q_n$	= useful heat collected
$F_R$	= collector heat-removal factor
$U_L$	= collector heat-loss coefficient
$S$	= salt concentration
$Z$	= depth

### Greek Symbols

$\alpha$	= absorptance
$\tau$	= transmittance
$\eta$	= efficiency
$\rho$	= density

### Subscripts

$i$	= inlet
$o$	= outlet
amb	= ambient
$e$	= effective

## Defining Terms

**Forced circulation or active solar system:** A solar thermal system that uses active means, such as pumps, for fluid flow and heat transfer.

**Figures 8.10.11** A parabolic dish — Stirling Engine Power System.

**Glazing:** A material used in a solar collector that transmits short-wavelength solar radiation and blocks longer-wavelength reradiation from the absorber plate.

**Natural circulation passive solar system:** A solar thermal system that uses natural means, such as the thermosyphon effect, for fluid flow and heat transfer.

**Salt gradient solar pond:** A solar pond that uses high salt concentration in the lowest layer and a concentration gradient in the middle layer to make those layers nonconvective.

**Selective surface:** A surface that has high absorptance in short wavelengths and low emittance in longer wavelengths.

**Solar hybrid combined cycle:** A hybrid of solar and natural gas turbine combined cycle.

**Solar thermal collector:** A solar collector that absorbs sunlight and converts it to heat.

## 8.11 Wind Energy Conversion\*

*Dale E. Berg*

### Introduction

Wind energy conversion machines have evolved over the past 2000 years, mostly by trial and error. Although there are many different configurations of wind machines, most of them can be classified as either horizontal-axis wind turbines (HAWTs), which utilize rotors that rotate about a horizontal axis parallel to the wind, or vertical-axis wind turbines (VAWTs), which have rotors that rotate about a vertical axis. Figure 8.11.1 illustrates the main features of both HAWTs and VAWTs. Figure 8.11.2 shows both types of turbines in a wind farm in the Altamont Pass area of California. HAWTs have all of their drivetrain equipment located on a tower, which makes servicing somewhat difficult, their blades are subjected to cyclic stresses due to gravity as they rotate, and they must be oriented with respect to the wind. However, they may be placed on tall towers to access the stronger winds typically found at greater heights. VAWTs, on the other hand, have most of their drivetrain on the ground, do not experience cyclic gravitational stresses, and do not require orientation with the wind. VAWTs, however, cannot be placed on tall towers to exploit the stronger winds at greater height, and their blades are subject to severe alternating aerodynamic loading due to rotation. The most common type of modern HAWT is the propeller-type machine, and these machines are generally classified according to the rotor orientation (upwind or downwind of the tower), blade articulation (rigid or teetering), and number of blades (generally two or three). The most common types of modern VAWTs are the Darrieus, with curved blades that are fixed in pitch, and the fixed-pitch, straight-bladed machines. The following discussion will focus on these types of turbines.

FIGURE 8.11.1 Wind turbine configurations.

\* This work was supported by the United States Department of Energy under Contract DE-AC04-94AL 85000.

**FIGURE 8.11.2** Wind farm both horizontal-axis and vertical-axis turbines.

While small and even medium-sized machines have been developed primarily through trial and error, developing larger, more-complex, and highly efficient machines this way becomes very expensive and time-consuming. A large cost-effective machine can be developed at a reasonable cost only if the designers can accurately predict the performance of conceptual machines and investigate the effects of design alternatives. In the past two decades numerous techniques to predict the aerodynamic and structural dynamic performance of wind turbines have been developed. These analytical models are not, in general, amenable to simple approximations, but must be solved with the use of computer codes of varying complexity. These models and codes will be summarized in the following sections.

## Wind Turbine Aerodynamics

Items exposed to the wind are subjected to both drag (in the direction of the wind) and lift (perpendicular to the wind) forces. The earliest wind machines used drag to produce power. The European and American windmills discussed in Section 7 of Chapter 7 were primarily drag devices, but they did make some use of lift. Modern wind turbines rely on airfoil-shaped blades that generate large amounts of lift to produce power more efficiently than the drag machines. Let us consider how efficient these machines are at extracting energy from the wind.

Figure 8.11.3 illustrates the flow field about a translating drag device. The drag results from the relative velocity between the wind and the device, and the power that is generated by the device (the product of the drag force and the translation velocity) is given by

$$P = DV = [0.5\rho(U - v)^2]C_D cv \quad (8.11.1)$$

FIGURE 8.11.3 Schematic of translating drag device.

where

- $P$  = power extracted in watts
- $D$  = drag force per unit spanwise length in n/m
- $l$  = length of device (distance into the page) in m
- $v$  = translation velocity in m/sec
- $\rho$  = air density in  $\text{kg/m}^3$
- $U$  = steady free-stream wind velocity in m/sec
- $C_D$  = drag coefficient; function of device geometry function
- $c$  = width of device (perpendicular to wind) in m

The velocity of the device must always be less than the wind velocity, or no drag is generated. The **power coefficient** (the ratio of the power extracted to the power available in the area occupied by the device) for this machine is

$$C_p = \frac{P}{0.5\rho U^3 cl} = \frac{v}{U} \left[ 1 - \frac{v}{U} \right]^2 C_D \quad (8.11.2)$$

Now consider a device that utilizes lift to extract power from the wind. Figure 8.11.4 illustrates an airfoil that is translating at right angles to the wind direction and is subject to both lift and drag forces. The relative velocity across this surface is the vector sum of the free-stream wind velocity and the wind speed induced by translation. The angle between the direction of the relative velocity and the chord line of the airfoil is termed the angle of attack  $\alpha$ . In this case, the power is given by

$$P = 0.5\rho U^3 cl \frac{v}{U} \left[ C_L - C_D \frac{v}{U} \right] \sqrt{1 + \left( \frac{v}{U} \right)^2} \quad (8.11.3)$$

where  $c$  = airfoil chord length in m and  $C_L$ ,  $C_D$  = lift and drag coefficients, respectively; functions of airfoil shape and  $\alpha$ . The power coefficient then is

$$C_p = \frac{v}{U} \left[ C_L - C_D \frac{v}{U} \right] \sqrt{1 + \left( \frac{v}{U} \right)^2} \quad (8.11.4)$$

Figure 8.11.5 compares Equations (8.11.2) and (8.11.4) using  $C_L = 1.0$  and  $C_D = 0.10$  for the airfoil (easily achieved with modern airfoils) and a maximum drag coefficient of 2.0 for the drag machine. The airfoil has a maximum power coefficient of 15, compared with 0.3 for the drag device, or 50 times more power per unit of projected area. Moreover, operating a lifting device at velocities well in excess of the wind velocity is easily achieved with rotating machines.

FIGURE 8.11.4 Schematic of translating lift device.

Airfoil is moving at right angles to the wind  
 Drag device is moving with the wind.

FIGURE 8.11.5 Comparison of power coefficients for a translating airfoil and a translating drag device. The airfoil is moving at right angles to the wind direction. The drag device is moving in the wind direction.

Machines discussed in this section utilize lift-producing blades to capture wind energy.

### Aerodynamic Models

The aerodynamic analysis of a wind turbine has two primary objectives: (1) to predict the power produced by of the turbine and (2) to predict the detailed aerodynamic loads which will act on the turbine rotor blades. In general, the same models are used to accomplish both objectives. The aerodynamics of wind turbines are far too complex to model with simple formulas that can be solved with hand-held calculators; computer based models ranging from very simplified to very complex are required. The various models commonly used today are described below.

### Momentum Models

The simplest aerodynamic model of a wind turbine is the actuator disk model or **momentum theory** in which the turbine is modeled as a single porous disk. In this model the axial force acting on the rotor or disk is equated to the time rate of change of momentum of the airstream passing through the rotor

or disk. By utilizing the conservation of mass, the conservation of axial momentum, the Bernoulli equation, and the first law of thermodynamics and by assuming isothermal flow, the power produced by the turbine (the product of the axial force and the air velocity at the disk) may be found to be

$$P = 2\rho AV^3 a(1-a)^2 \quad (8.11.5)$$

where  $V$  is the freestream wind velocity,  $a = (V - v)/V$  and  $v$  is the wind velocity at the disk. The power coefficient for the turbine becomes

$$C_p = 4a(1-a)^2 \quad (8.11.6)$$

This is maximized for  $a = 1/3$ , and we get  $C_{p,max} = 16/27 = 0.593$ , the **Betz limit**, as the maximum fraction of available energy that can be extracted from the wind by a turbine.

The typical performance of various types of wind machines is compared with the Betz limit in [Figure 8.11.6](#) where the variation of the turbine power coefficients with the **tip-speed ratio** (the ratio of the speed of the blade tip to the free-stream wind speed) are presented. Even though the maximum performance of modern HAWTs and VAWTs is well above that of the older machines, it still falls more than 10% below the Betz limit.

**FIGURE 8.11.6** Typical performance of various types of wind turbines.

For HAWTs, momentum theory can be expanded to the blade element or strip theory, which includes the effects of blade lift and drag, wake rotation, and number and type of blades. Numerous corrections are applied to account for the three-dimensional flow near blade tips, the thick blade sections near the root, and gaps along the blade span. Additional information on these models may be found in Hansen and Butterfield (1993) and Wilson (1994).

Momentum theory may also be expanded for vertical-axis turbines into the multiple streamtube and the double-multiple streamtube theories that are the VAWT equivalent of the HAWT blade element theory. Additional information on these models may be found in Touryan et al. (1987) and Wilson (1994).

Wind shear and local Reynolds number variations may be readily accounted for with both the blade element and multiple streamtube methods. These models are extremely popular with wind turbine designers because they are simple, fast, and fairly accurate for performance prediction. However, they are very approximate methods based upon the assumption of steady flow and streamtubes that are fixed in time and space. More-complex models such as vortex and local circulation models are needed for the analysis of yawed flow, unsteady aerodynamics, and other complex flows, all of which can have large impacts on turbine performance and loads.

### **Vortex Models**

Vortex models, based on the vorticity equation, can use either lifting line or lifting surface formulations for the blades with either free-wake or fixed- (or prescribed- ) wake models, although there are a number of variations of these models. The three-dimensional, lifting-surface, free-wake formulation is the most physically realistic model, but a computer program implementing such a model will require a tremendous amount of computer resources and time. The problem with vortex codes is one of finding a balance between model simplification (and limitation) and computation time. Additional information on vortex models may be found in Strickland et al. (1981) and Kocurek (1987).

### **Local Circulation Method**

The local circulation method (LCM) utilizes a balance between the force on the blade and the change in wind momentum as it passes through the rotor, similar to what is done with the momentum models. The blade, however, is represented as a superposition of imaginary blades of different spans with elliptical circulation distributions. Unlike the streamtube models, LCM models may be formulated to analyze unsteady flow, and are able to yield detailed flow field velocity and blade-loading information. The LCM yields better answers than the momentum models, avoids the convergence problems of the vortex models, and, with an appropriate wake model, requires far less computer time than the vortex models. However, this model has not been widely used. Additional information may be found in Nasu and Azuma (1983), Masse (1986), and Oler (1989).

### **Common Model Limitations**

All of the aerodynamic models in use today use airfoil section characteristic tables (lift and drag coefficients as functions of angle of attack and Reynolds number) to determine the blade loading and turbine performance. Static two-dimensional wind tunnel test results or two-dimensional static airfoil design code predictions are modified with empirical, semiempirical, or analytic methods and used to estimate blade loads under three-dimensional, dynamic conditions. The greatest difficulty in obtaining accurate load predictions with any performance code is the determination of the appropriate airfoil section characteristics.

Additional information and references on turbine aerodynamics may be found in Hansen and Butterfield (1993) and Wilson (1994) for HAWTs and in Touryan et al. (1987) and Wilson (1994) for VAWTs.

## **Wind Turbine Loads**

Wind turbine aerodynamic loads are of two types — the narrowband harmonic or cyclic loads resulting from the steady atmospheric wind, wind shear, rotor rotation, and other steady effects; and the broadband random loads resulting from nonuniformity or turbulence in the wind. The prediction of these loads is more complicated than the prediction of the aerodynamic performance and requires the use of computer-based models. The harmonic loads are generally predicted with the same codes that are used to predict wind turbine performance. The random loads are typically estimated with empirical relations, although a few analysts do utilize a performance code with a nonuniform wind model to predict them. A wind

turbine will experience hundreds of millions of loading cycles in a 30-year lifetime, and small errors that lead to underpredicting component loads can result in costly short-term component failure.

Accurate prediction of turbine performance does not guarantee accurate prediction of detailed aerodynamic loads — the performance predictions result from the integration of loads over the entire turbine, and significant errors may be present in the detailed loads but balance out in the performance predictions. While there is a considerable body of data showing good agreement of predicted performance with measured performance, there are very few data available against which to compare detailed aerodynamic load predictions.

## Wind Turbine Dynamics

### Horizontal-Axis Turbines

Horizontal-axis turbine designs usually use fairly rigid, high-aspect-ratio blades, cantilevered from a rigid hub and main shaft, although they may sometimes use relatively slender, quite flexible blades, attached to a less rigid hub and/or main shaft. This assembly rotates and yaws about a tower which may be flexible. These structures have many natural vibration modes, and some of them may be excited by the wind or the rotation frequency to cause a **resonance** condition in which the vibrations are amplified and cause large stresses in one or more components. Careful structural analysis during the design can ensure that the turbine that is built is dynamically stable under turbine operating conditions. Ignoring the structural analysis or failing to properly conduct parts of it will likely result in a machine that experiences resonances and fails very quickly. Relatively rigid systems are less likely to experience these stability problems than are very flexible, highly dynamic systems.

Detailed analysis of the structural response of a turbine is a rather daunting task requiring the formulation and solution of the full governing equations of motion, usually performed with a finite-element structural model. Those equations must account for the interaction between the blades and the steady centrifugal forces, the time-dependent gravitational forces, the steady and oscillatory aerodynamic forces, and the Coriolis forces. They must also model nonsteady airflow, the yaw motion of the nacelle, pitch control of the blades, teetering blades, the interaction between the rotor and the supporting tower, starting and braking sequences, etc. The rotor must be modeled in a rotating coordinate frame with time-dependent coefficients, while the tower must be modeled in a fixed coordinate frame, with the exciting forces arising from the nonlinear, time-dependent coupling of the rotor and the time-dependent loading of the wind.

Malcolm and Wright (1994) provide a list of some of the available HAWT dynamics codes that have been developed, together with their limitations.

### Vertical-Axis Turbines

Darrieus turbine designs normally use relatively slender, high-aspect-ratio structural elements for the blades and supporting tower. The result is a very flexible, highly dynamic structure, with many natural modes of vibration which, again, must be carefully analyzed to ensure that the turbine is dynamically stable under all operating conditions. Typically, the guy cables and turbine support structure can be analyzed with conventional methods, but the tower and blades require a more refined analysis, usually performed with a finite-element structural program.

The blades and tower must be modeled in the rotating coordinate frame with time-independent coefficients. The equations of motion are determined by the steady centrifugal and gravitational forces, the steady and oscillatory aerodynamic forces, and the Coriolis forces, together with the turbine physical properties. Detailed information on the modeling may be found in Lobitz and Sullivan (1983).

### Aerodynamic Loads/Blade Motion Coupling

The blades themselves are driven by aerodynamic as well as structural dynamic forces. The motion of slender, high-aspect-ratio blades may couple with the aerodynamic loads acting on them. This coupling may increase the motion of the blades, creating a potentially fatal condition known as flutter instability,

or it may decrease the motion of the blades, creating a beneficial condition known as aerodynamic damping.

### Stochastic Wind Effects

The wind is **stochastic** in nature, with significant short-term variations in both direction and velocity. As turbines become larger, the relative extent of these variations becomes smaller than the size of the turbine, and the effects become more pronounced. Analysis of the effect of fluctuating wind loads on the response of the turbine shows an increase in the broadband response, accompanied by a decrease in the magnitude of the dominant narrowband responses at multiples of the rotation frequency. This increase in broadband response can include excitation of turbine vibration modes that are close to a narrowband response frequency, but that are not predicted to be excited by a uniform wind (Lobitz, 1984).

## Wind Turbine Controls

In general, wind turbines are designed to operate when the incident wind is high enough to generate electricity and to shut down when the wind speeds exceed 25 to 30 m/sec. In spite of the tremendous amount of power which is present in the high winds, the amount of energy that can be captured is usually more than offset by the fatigue damage that is sustained by the turbine.

### Brakes

Most turbines utilize mechanical brakes, frequently in conjunction with aerodynamic brakes, to stop the rotor and to keep it from rotating when the turbine is not generating electricity. A few turbines rely solely on aerodynamic braking devices to accomplish this. Whatever type of braking system is used, it should be a fail-safe design that will automatically activate to slow or stop the rotor in the event of an electrical system failure.

### Yaw Systems

Virtually all upwind and a few downwind HAWT turbines incorporate an active yaw control system, using wind-direction sensors and electric or hydraulic drive motors, to orient the rotor with respect to the wind. VAWTs do not require yaw systems.

### Peak Power Regulation

All turbines incorporate some method of limiting the peak power produced. This enables the generator to operate near its design power rating, where it is most efficient, over a range of wind speeds. The increase in generator efficiency at lower wind speeds, together with the lower cost of the drivetrain, more than offset the energy that is lost as a result of power limiting. Most horizontal-axis turbines use one of three common techniques to limit peak power — stall regulation with fixed-pitch blades (passive control), full- or partial-span pitch control, or partial-span control surfaces such as ailerons and/or flaps. With stall regulation, the blades are designed so that airfoil **stall**, which creates decreased lift and increased drag, limits the power output in high winds. However, rotor drag loads continue to increase as the wind speed increases. Another disadvantage is the difficulty of controlling aerodynamic loads in deep stall. With full- or partial-span blade pitch control, peak power is controlled by decreasing blade pitch angle as wind speed increases, limiting peak power and decreasing rotor drag loads. A major disadvantage of pitch control is the poor peak power control during high-wind stochastic (or turbulent) conditions — power excursions can exceed twice the rated power levels before the pitch-control system can respond. Partial-span control surfaces limit the peak power by decreasing the lift and increasing the drag of a portion of the airfoil. They can respond to wind changes somewhat faster than full-span pitch control systems can. Sample power curves for both stall and pitch-regulated turbines are shown in [Figure 8.11.7](#).

Several other methods of pitch control have also been used, but on a limited basis. Passive pitch-control techniques automatically adjust the blade pitch angle using cams activated by centrifugal loads or using tailored blade materials that permit the blade to twist as the aerodynamic loads increase. The

FIGURE 8.11.7 Sample power curves for stall-regulated and pitch-regulated wind turbines.

Italian Gamma 60 turbine utilizes a novel means to control peak power — it is the only large-scale turbine that yaws a fixed-pitch rotor out of the wind to limit rotor power.

Virtually all VAWTs utilize stall regulation with fixed-pitch blades to control peak power.

### Controller

Every wind turbine contains a controller, usually a microprocessor-based system, to control turbine operations. The basic turbine controller will start and stop the machine and connect or disconnect the generator output lines to the grid, as needed; control the operation of the brake system; control the operation of the yaw and pitch systems, if present; perform diagnostics to monitor the operation of the machine; and perform normal or emergency shutdown of the turbine as required. However, the controller can incorporate many other functions as well, functions such as recording turbine performance characteristics and controlling the operating state of a variable-speed machine.

### Wind Turbine Electrical Generators

Once a wind turbine has converted the kinetic energy in the wind into rotational mechanical energy, the energy is usually converted into electricity which can be readily transported to where it is needed. While small wind turbines may utilize permanent magnet alternators to generate electricity, most grid-connected turbines today use either synchronous or induction electrical generators. Induction machines are cheaper than synchronous machines, are easier to control, and provide some power train damping, but they require reactive power that must be supplied by the grid. This can cause problems, but those problems can be usually be solved fairly quickly and at low cost.

Generator efficiency drops off rapidly as the generated power falls below the rated generator capacity, and single-generator systems tend to be very inefficient at low wind speeds where there is little power available in the wind. Some systems address this by having a second, smaller generator which is used for low-wind operation, where it operates close to its rated power. At higher winds, the smaller generator is disconnected and the larger generator is used. Similar results can be obtained with a single generator utilizing pole switching or dual windings. The two-generator operation may yield a sizeable increase in energy capture, but the additional costs of the smaller generator or the generator modification and additional controls must be balanced against the increased energy capture to determine if this is cost-effective.

While most turbines operate at a single fixed rotational speed, some operate at two or more fixed rotational speeds, and some operate anywhere within a range of speeds. Variable-speed turbine operation offers two major advantages over fixed-speed operation:

1. The aerodynamic efficiency of the rotor at low to moderate wind speeds may be improved by more closely matching the rotor speed to the short-term average wind speed. At higher wind speeds, the blades are either in stall or are pitched to control peak power, so matching rotor speed to wind speed is less important.
2. System dynamic loads are attenuated by the “flywheel” action of the rotor as it speeds up and slows down in response to wind gusts.

In addition, variable speed permits the operation of the turbine in a variety of modes, including operation at maximum efficiency for all wind speeds to maximize energy capture or operation to minimize fatigue damage. However, certain rotational speeds within the operating-speed range will likely excite turbine vibration modes, causing resonance and increased rates of fatigue damage. These rotational speeds must be avoided during operation, and turbine control can become quite a complicated issue.

Variable-speed operation, in general, generates variable-frequency power. Most applications, including interfacing with power grids, require high-quality power at a reference frequency. Sophisticated power electronics may be used to accomplish this interface (Smith, 1989).

## Wind-Diesel Systems

Wind turbines are increasingly being coupled with diesel engine-powered generators to create **wind-diesel systems**. In these systems, the diesel engine provides dependable, consistent power and the wind turbines generate some of the power, reducing the engine fuel consumption and the system cost of energy. A large variety of wind-diesel systems and concepts have been investigated over the past decade (Infield, et. al., 1992). Although quite a few of these have been technically successful, very few of them have been commercially successful. While the potential market for wind-diesel systems appears to be very large, it has yet to materialize, for the reliability of the technology has not yet been well proven.

## Water-Pumping Applications

The multibladed, mechanical windmill (the so-called “American” windmill) with a mechanical piston pump has been used for over a century to pump water in remote areas. Over the past few years some changes to improve operation in low wind speeds have been made to the design of these machines.

Researchers at the U.S. Department of Agriculture facility at Bushland, Texas have reported considerable success in using variable-voltage, variable-frequency electricity produced by small stand-alone wind turbines to directly power submersible water pumps. Clark (1994) compares the pumping performance of one of these wind–electric systems and that of the traditional American windmill with a piston pump. He found that the wind–electric system performed significantly better than the mechanical system, even though the price of the two systems was nearly identical. The wind–electric system offers another advantage as well — while the windmill for the mechanical pump must be mounted directly over the well, the wind turbine for a wind–electric system may be mounted some distance away, at a better wind location.

## Defining Terms

**Betz limit:** Maximum fraction of available wind energy that can be extracted by a wind turbine rotor, according to momentum theory.

**Momentum theory:** A method of estimating the performance of a turbine by equating the time rate of change of air stream momentum through the turbine to the force acting on turbine blades.

**Power coefficient:** The ratio of captured energy to the energy available in the reference area.

**Resonance:** A vibration of large amplitude caused by a relatively small excitation at or near a system natural frequency.

**Stall:** A condition in which an airfoil experiences a decrease in lift and a large increase in drag.

**Stochastic:** Containing variations from a smooth, uniform flow.

**Tip-speed ratio:** The ratio of the speed of the blade tip to the free-stream wind speed.

**Wind–diesel system:** An electrical-generation system that utilizes both diesel engine–powered generators and wind turbines to create a dependable, consistent power system.

## 8.12 Energy Conversion of the Geothermal Resource

*Carl J. Bliem and Gregory L. Mines*

This section discusses the uses of the geothermal resource. The primary use of the energy from geothermal resources to date has been in the production of electrical energy. Other applications, such as process heat and space conditioning, have also been made and will be discussed under the topic of direct use. This section begins with a discussion of the geothermal resource as it applies to the use of the energy. Then discussion of the three types of electrical generating facilities presently in use: — the **direct steam system**, the **flashed steam system**, and the **binary system** — is given. Finally, some discussion of direct-use applications is given.

### Geothermal Resource Characteristics Applicable to Energy Conversion

*Geothermal energy* as defined here applies to hot fluids under pressure found at a reasonable depth (1 to 2 km) in the earth's crust. If one disregards the complex geological details relating to the formation of such naturally occurring reservoirs of hot fluids, [Figures 8.12.1](#) and [8.12.2](#) present schematic representations of these reservoirs. High-temperature fluid (200 to 300°C) is created by the convection of water through the porous rock. As the water circulates, it dissolves various amounts of minerals containing sodium, potassium, calcium, silica, carbonates, and chlorides and gases such as nitrogen and carbon dioxide. In **geopressed resources** of the Gulf of Mexico, high pressures and significant amounts of dissolved methane are seen.

**FIGURE 8.12.1** Schematic diagram of the convective cells in a geothermal reservoir. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

The convective cells operate over large horizontal distances of as much as 30 km. The time in which the transfer of energy from the magma to the water takes place is of the order of  $10^5$  to  $10^6$  years. At the present time, it is difficult to say whether or not the resource can be considered “renewable.” If natural circulation or the injection of spent geothermal liquid into the reservoir can make up for the liquid extracted during the energy conversion process, the reservoir can be considered at least of a very long life. (Individual wells generally have a life of about 10 years.)

The resources considered in this section are said to be **hydrothermal**. (Work is being done on creating artificial reservoirs by injecting water into hot dry rock, but this development is in its early stages and will not be considered here. The geopressed resource will not be considered either.)

As the geofluid is extracted from a reservoir, it flows to a region of lower static pressure. If this pressure falls below the saturation pressure for the temperature of the geofluid (close to but not equal to the saturation pressure of pure water because of the presence of the dissolved solids and gases), the

**FIGURE 8.12.2** Schematic diagram of a characteristic geothermal reservoir. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

geofluid will flash into steam. Therefore, the person using this energy source may have a number of different physical forms to consider:

1. Wet steam from a *vapor-dominated resource*;
2. Superheated or saturated steam from a vapor-dominated resource;
3. Liquid at a pressure above the saturation pressure from a *liquid-dominated resource*;
4. A mixture of liquid and vapor at a relatively low quality from a liquid-dominated resource.

## Electrical Energy Generation from Geothermal Resources

The type of energy conversion system used to produce electrical power depends on the type and quality (temperature) of the geothermal resource. Vapor-dominated resources use systems where steam is expanded directly through a turbine, similar to conventional fossil fuel steam plants. Liquid-dominated resources use flash steam systems and binary systems, with binary systems predominantly used for the lower-quality resources. The term **binary system** is used to describe a power cycle where the geothermal fluid provides the source of thermal energy for a closed-loop Rankine cycle using a secondary working fluid. In this closed loop, the working fluid is vaporized using the energy in the geofluid, expanded through a turbine, condensed, and pumped back to the heater completing the closed loop.

Hydrothermal resources typically contain varying amounts of numerous dissolved minerals and dissolved gases. In power cycles where steam is extracted from the geothermal resource directly (vapor dominated) or indirectly (flashing liquid dominated) and expanded through a condensing turbine, the design and operation of the power cycle must account for the removal of the noncondensable gases. If the gases are not removed from the condenser, they will accumulate in the condenser, raising the turbine back pressure and decreasing the power output. In systems where the liquid geofluid is handled (binary cycle heat exchangers and piping and flash steam flash tanks and piping), measures must be taken to

prevent the precipitation of the dissolved solids and/or to provide a means of removal of the resulting scale.

### Direct Steam Systems — Vapor-Dominated Resources

For a geothermal resource producing a superheated or saturated vapor steam (Case 2), the vapor from the geothermal production well is sent to a conventional steam turbine as shown in Figure 8.12.3. (This is done after appropriate removal of rocks and debris and possibly after scrubbing with water to remove corrosive substances.) Normally, the turbine is a condensing type, as shown in the figure, although in some applications a back-pressure turbine is used, exhausting the steam to the atmosphere. The back-pressure turbine is typically used for small systems with the possible later addition of another turbine and a condenser to increase the power generated by the geofluid flow from the wells.

Figure 8.12.3 shows a system with a direct-contact condenser and a wet cooling tower. In this type of system, the condensate from the condenser is more than enough to make up the evaporation and blowdown from the cooling tower. Therefore, the figure shows some of the condensate being injected into the reservoir. In many cases, direct-contact condensers are not feasible because of the hydrogen sulfide in the steam which would be released in the cooling tower exhaust. When hydrogen sulfide is in the steam, the majority of it appears as noncondensable and the noncondensable gas from the condensers must be treated. For these systems, surface condensers are normally used in conjunction with wet cooling towers. The actual hardware configuration is dictated by the process for removal of the sulfur. Again, some of the condensate can be used for cooling tower makeup if the sulfur is removed from the process. A number of processes have been developed to remove sulfur from the process.

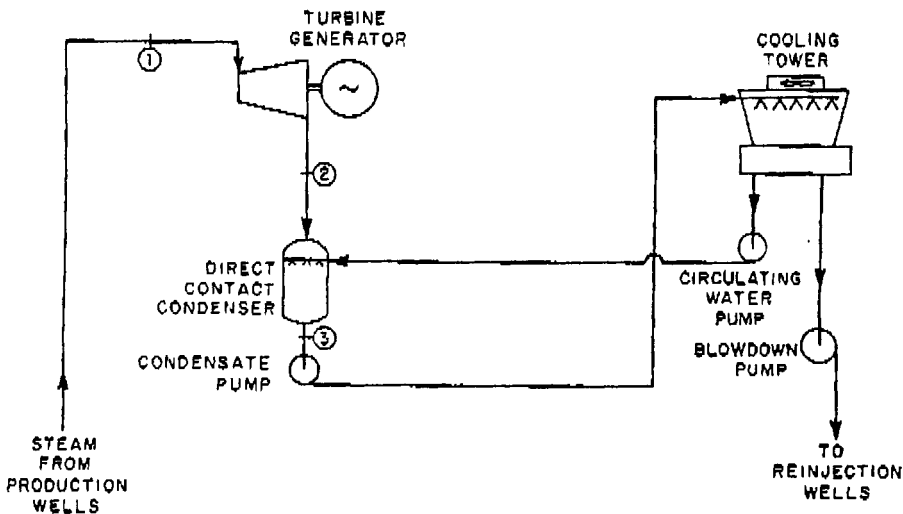

FIGURE 8.12.3 Schematic diagram of a direct dry-steam plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

Figure 8.12.4 depicts a system which is similar to the one described above, but one which receives wet steam (Case 1). Here, the liquid is separated from the vapor prior to the entry of the vapor into the turbine. Otherwise, the system is the same as the one in Figure 8.12.3 and the same comments apply.

### Flash Steam Systems — Liquid Dominated Resources

When the geofluid is flashed before it leaves the well, flash steam systems are generally used. This indicates that the resource is at a relatively high temperature. Figures 8.12.5 and 8.12.6 depict single- and dual-flash systems schematically. The single-flash system in Figure 8.12.5 is quite similar to the system in Figure 8.12.4. The only difference is that the geofluid pressure is dropped further before the steam is separated and sent to the turbine. An optimum flash pressure exists because the lower the flash

FIGURE 8.12.4 Schematic diagram of a plant using a two-phase resource. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

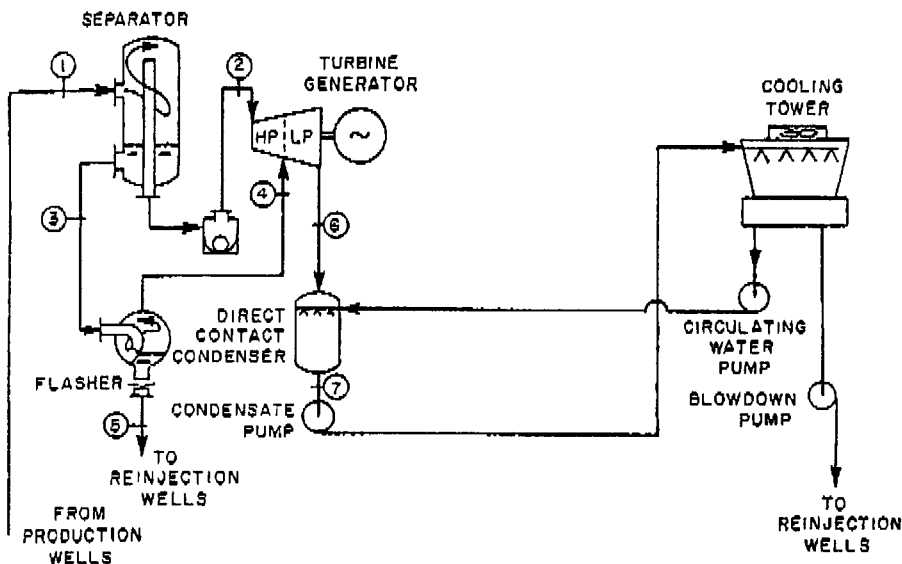

FIGURE 8.12.5 Schematic diagram of a single-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

pressure, the more steam which is evolved. However, the work done per unit mass of steam flowing through the turbine will also decrease with the lower flash pressure. For a given set of geofluid conditions entering the plant, a flash pressure exists that will maximize the energy produced per unit mass of geofluid and also minimize the levelized energy cost (LEC). The performance and cost optima will be near, but not generally at the same pressure.

The flash steam system can also be utilized in applications where the fluid enters the plant as a liquid (single phase). In these systems, the geothermal fluid is throttled with an expansion valve to the desired flash pressure. This flashing process can be considered adiabatic, where the amount of steam evolved can be determined from energy and mass balances of a simple throttling calculation.

**FIGURE 8.12.6** Schematic diagram of a dual-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

Most successful flash systems are dual flash. The first flash is generally near the well-head pressure and the second flash near atmospheric pressure. The low-pressure flash is normally kept above atmospheric pressure to prohibit leakage of air into the system in the flasher. Some recent studies have indicated that for low-temperature resources, a subatmospheric second flash would produce a cost-effective system. Again, optimization of the two flash pressures is necessary to minimize the LEC. In cases in which the geofluid has a high dissolved solid content, flash crystallizers are used to remove the precipitated dissolved solids. The flashing process releases carbon dioxide dissolved in lowering the geofluid pH, which causes the precipitation of insoluble carbonates. The solubility of silica is temperature dependent; lowering the geofluid temperature causes the precipitation of silica.

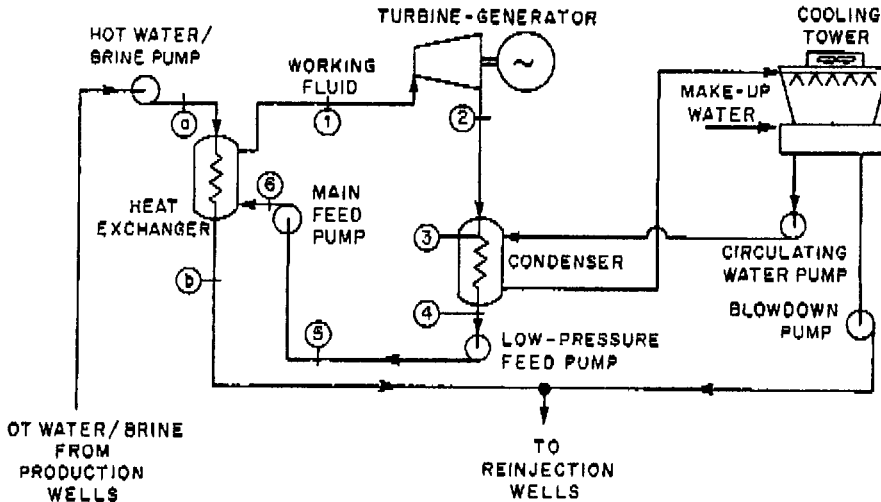

None of the steam cycles depicted provides for the removal of the noncondensable gases from the condenser. This removal is typically accomplished with steam ejectors or compressors which continuously remove the small stream of vapor from the condenser. Some steam is lost in this process of removing the noncondensable gases.

### Binary Systems — Liquid-Dominated Resources

Recent studies have shown that for resources below 200°C, current technology binary systems have lower LEC than flash steam plants for liquid-dominated resources. Figure 8.12.7 shows a typical binary system with an evaporative heat-rejection system. This type of heat-rejection system has been replaced by air-cooled condensers in most applications. In the areas where the geothermal resource exists, there is little excess water for makeup in the cooling tower, as shown in Figure 8.12.7. All of the cooled geofluid in a binary system is typically injected back into the reservoir. This provides an environmentally acceptable means of disposal of the fluid and, more important, provides a recharge of the reservoir to maintain the reservoir productivity.

The binary cycle is an attempt to reduce the scaling potential of the geofluid. Carbonates are precipitated when the pressure of the geofluid is reduced and carbon dioxide comes out of solution as the geofluid flashes. With downhole pumps in the wells, this can be eliminated by keeping the fluid pressurized. Some resources do not require pumps to maintain the flow and pressure necessary to eliminate flashing (artesian flow). Similarly, if the exit temperature of the geofluid remains above some minimum value, silica will not be precipitated. These two operational strategies limit the scaling in a binary plant. Any constraint imposed on the geofluid exit temperature will impact the design of the

**FIGURE 8.12.7** Schematic diagram of a binary plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

binary plant, affecting the selection of turbine inlet conditions as well as the possible choice of working fluid.

The binary cycle consists of a closed loop of a working fluid normally performing a Rankine cycle. Most existing binary cycles use isobutane, pentane, or isopentane as working fluids. Studies have indicated that mixtures of hydrocarbons, e.g., 96% isobutane/4% hexane, will produce better utilization of a 180°C resource and in some instances lower LEC.

The performance of the binary system depends on a number of factors. Some plant designs incorporate multiple or staged boiling cycles, where the working fluid flow is split and boiling occurs at multiple pressures. In these cycles, multiple or staged turbines are required. The advantage of these cycles is the fact that the working fluid heat-addition process more closely matches the sensible cooling of the liquid geofluid (as shown on the T-Q or T-h diagram). This lowers temperature differences through the cycle, reducing cycle irreversibilities and increasing performance. The same effect can be achieved by heating the working fluid at supercritical pressures (pressures above the critical pressure). While the supercritical cycle will have higher component, material, and pumping costs because of higher operating pressures, they have fewer components because they are less complex than multiple boiling cycles. (In many cases, the maximum pressure can be kept below 600 psi with hydrocarbons such as isobutane.) Lowering the mean temperature difference in heat exchangers tends to require larger units so that capital costs are increased. In general, the LEC is reduced because the effects of increased performance more than outweigh the increase in capital cost.

The choice of the working fluid for the power cycle will also impact the cycle performance. In general, as resource temperature decreases, the more volatile fluids will produce more power per unit mass of geofluid. Power cycles using the more volatile fluids typically operate at higher pressures and have higher associated material and equipment cost. These higher costs may offset the gains in performance and produce higher LECs in some cases.

Working fluid mixtures have been shown to provide superior performance to the single component or pure working fluids. This performance improvement is due to the nonisothermal phase changes of this type of fluid at constant-pressure (both boiling and condensing), which allows the working fluid to match more closely the sensible cooling of the geofluid. More importantly in the reduction of irreversibilities, the desuperheating and condensing process more closely matches the sensible heating of cooling water or air in the heat-rejection process.

One additional type of binary cycle that has been proposed uses an ammonia-water mixture for the working fluid. A great deal of recuperative preheat of the working fluid is accomplished by splitting the duty of the geofluid, turbine exhaust, and preheated liquid flows through a more complex heat-transfer train than is shown in Figure 8.12.7. These systems are known as **Kalina systems**. In general, these systems do not change the composition of the mixture in the cycle as the Kalina cycle for applications such as is the case for gas turbine bottoming.

There is some consideration of using a binary cycle as a bottoming cycle for a flash steam or direct steam system. Similarly, a binary cycle could be used to bottom another binary system, perhaps with a different working fluid.

### Design Considerations

The selection of the working fluid in binary cycles imposes safety considerations to be considered in the design of the power plant. Equipment and facility designs must take into account the flammable characteristic of the hydrocarbon working fluids.

The selection of materials of construction for the piping and components exposed to the geofluid will be resource specific. Typically, carbon steel is used for piping and pressure vessels. Turbines that use the steam directly may have stainless steel components, although the use of stainless may be limited by the presence of chlorides and the potential for stress cracking. The standard design for heat exchangers in binary cycles is for the geofluid to be on the tube side. This facilitates the cleaning of the exchanger if scaling or fouling occurs on the surfaces exposed to the geofluid. If the geofluid has a high scaling potential, components and piping should be designed to allow for periodic cleaning.

### Direct Use of the Geothermal Resource

A number of direct-use applications of the heat in a geothermal resource have been successfully implemented. These include

1. Space conditioning (heating with the resource or a secondary fluid and cooling with heat pumps);
2. Heating of greenhouses;
3. Aquaculture;
4. Process heating (drying vegetable products);
5. Ground coupled heat pumps.

Although the United States is one of the world leaders for the production of electrical power from geothermal energy, other nations take the lead for the direct use of this energy source. In Iceland, over 85% of the buildings are supplied with heat and domestic hot water from geothermal systems (Ragnorson, 1995).

Typical direct-use applications are either closed systems with produced fluids being injected back into the geothermal reservoir or systems where the produced water is pure enough for beneficial use or disposal to surface waterways. Experience has shown that it is usually worthwhile to inject as much of the cooled fluid as possible back into the reservoir to maintain pressure and production rates.

### Defining Terms

**Binary system:** A binary system that uses thermal energy from the geofluid to vaporize a secondary working fluid in a Rankine cycle.

**Direct steam system:** A geothermal energy conversion system that utilizes steam directly from a geothermal well.

**Flashed steam system:** A geothermal energy conversion system that utilizes steam flashed from the liquid geofluid.

**Geopressurized resource:** Naturally occurring reservoirs of hot pressurized fluid created by convection of water through hot porous rock.

**Hydrothermal resource:** Artificial reservoirs created by injecting water into hot dry rock in the earth's core.

**Kalina system:** A binary system using a mixture of ammonia and water as the working fluid in the power cycle.

## 8.13 Direct Energy Conversion

---

### Solar Photovoltaic Cells

*Kitt C. Reinhardt*

#### Introduction

Solar photovoltaic cells convert sunlight directly into electrical energy via the collection of solar photon-generated semiconductor charge carriers. The collection of charge carriers within the cell produces a voltage across the terminals of the cell, called the **photovoltaic effect**, that can drive an external electrical circuit or charge a storage battery. Photovoltaic cells are useful in both space and terrestrial power applications. Silicon, Si, photovoltaic cells have provided the main source of electrical power to virtually all Earth-bound satellites since the advent of the space program in the late 1950s. In the early 1970s, photovoltaics generated a significant amount of interest for use in terrestrial power systems when oil supplies to the industrial world were disrupted. Today, while photovoltaic power remains the primary energy source for most communication and surveillance satellites, issues concerning system efficiency, reliability, and cost currently prevent its widespread use in residential and power utility applications. For example, in the United States the average price for conventional utility electricity is 6¢/kWhr, compared with ~35¢/kWhr for terrestrial photovoltaic electricity (Zweibel, 1995). Thus, the cost of photovoltaic power must be reduced by a factor of ~6 for it to become economically viable. At present, photovoltaic power is generally only cost-competitive for use in remotely located systems where conventional power is cost-prohibitive, such as in remote water-pumping and communications stations, signal and emergency lighting, and for village power. Factors that influence photovoltaic system energy costs include cell panel efficiency, total system lifetime, and cost per unit area. The present discussion will focus on issues concerning photovoltaic cells and panels. Detailed literature on power conditioning electronics and energy storage systems can be found elsewhere. A large number of different photovoltaic cell designs have been demonstrated by researchers over the years. However, the most common and practical cell designs are fabricated using single-crystal Si. Consequently, Si will be used to describe basic principles of semiconductors and photovoltaic cell operation.

#### Introduction to Semiconductors

We begin with a description of the concept of covalent bonding, valence electrons, and energy bands, which relates to conduction in semiconductors (Sze, 1981). The crystalline structure of Si is diamond, where each Si atom in the lattice is covalently bonded to four equidistant nearest neighbors that lie at the corners of a tetrahedron. Each Si atom has four electrons in its outer orbit, called valence electrons, and each atom shares these electrons with its four neighbors to form four covalent bonds. The atomic configuration of the 14 electrons of Si is  $1s^2 2s^2 2p^6 3s^2 3p^2$ . At practical temperatures, only the  $3s^2 3p^2$  valence electrons contribute to the electrical conductivity; the  $1s^2 2s^2 2p^6$  core electrons are too tightly bounded to the nucleus to participate. In a simplified model, as  $N$  Si atoms are brought together at 0 K to form a crystal, two distinct and nearly continuous bands of electronic energy levels form that are separated by an energy gap called the semiconductor **band gap**,  $E_g$ . The resulting upper **conduction band** contains  $4N$  states, as does the lower **valence band**. The  $4N$  electrons that come from the Si  $3s^2 3p^2$  states completely fill the  $4N$  states in the valence band at 0 K, and the conduction band states are completely empty. Since there are no unoccupied states in the valence band for electrons to move and the conduction band is empty, Si is a perfect insulator at 0 K.

As the temperature of the crystal increases, electrons in the valence band gain sufficient thermal energy ( $>E_g$ ) to be excited across the band gap into the conduction band, leaving holes (missing electrons) behind in the valence band. When current conduction in a semiconductor is dominated by thermally generated electrons and holes, it is called intrinsic. In this case, the resulting number of electrons per unit volume in the conduction band,  $n$ , equals the number of holes per volume in the valence band,  $p$ , that is  $n = p = n_i$ , where  $n_i$  is called the intrinsic carrier concentration. In the presence of an electric

field, intrinsic electrons and holes gain kinetic energy and conduct electricity. However, since at room temperature  $n_i$  for Si is only  $1.45 \times 10^{10} \text{ cm}^{-3}$ , compared with a free-electron density of more than  $10^{22} \text{ cm}^{-3}$  in metals, Si behaves as a very good insulator, i.e., electrical conductivity,  $\sigma$ , is given by  $\sigma = q(n\mu_n + p\mu_p)$ , where  $q$  is the electronic charge and  $\mu$  is the respective carrier mobility.

In order to increase the conductivity to values useful for solid-state devices, the level of  $n$  and  $p$  can be increased by purposely adding impurity atoms into the crystal, called doping, that liberate extra electrons or holes. In the case of Si, which is in column IV of the periodic table, and hence has four valence electrons for bonding, doping is achieved using either column III elements (boron, aluminum, gallium, or indium), which have three valence electrons, or column V elements (phosphorus, arsenic, or antimony), which have five valence electrons. When an arsenic atom with five valence electrons replaces (substitutes) an Si atom, four of its electrons are used to form covalent bonds with the four neighboring Si atoms. The fifth electron is loosely bound to the arsenic nucleus, and at room temperature is ionized and “donated” to the conduction band. Arsenic is therefore called a donor, and Si becomes an n-type (mostly electrons) semiconductor. Similarly, when a boron atom with three valence electrons substitutes for an Si atom, one of the boron four covalent bonds becomes deficient of one electron. Boron can then accept one electron from the valence band to satisfy the bond requirement, which creates a positively charged hole in the valence band. Boron is therefore called an acceptor, and Si becomes a p-type (mostly holes) semiconductor. In this way the electrical conductivity of semiconductors can be precisely controlled by varying the concentration of donor and acceptor impurities. In practical solid-state devices, typical values of  $n$  and  $p$  range between  $10^{15}$  and  $10^{19} \text{ cm}^{-3}$ .

### The p-n Junction Diode

The p-n junction is a basic structure used for solid-state device rectification, amplification, and switching, as well as for photocarrier collection in photovoltaic cells. A p-n junction is formed when a p-type semiconductor is metallurgically joined with an n-type semiconductor (Streetman, 1980). Before they are joined, the p-material has a large concentration of holes and very few electrons, whereas the converse is true for the n-material. Upon joining the two materials, holes instantaneously diffuse from the p-side into the n-side and electrons diffuse from the n-side into the p-side. The transport of these carriers constitutes a “diffusion” current from the p-side to n-side; electron current is opposite in direction to electron flow by convention. As shown in [Figure 8.13.1](#), negative acceptor ions are left behind as holes leave the p-side of the junction, creating a negative space-charge region (SCR), and positive donor ions are left behind as electrons leave the n-side of the junction, creating a positive SCR. Consequently, an electric field directed from the positive SCR to the negative SCR results that opposes the further diffusion of electrons and holes; i.e., the electric field creates a drift component of current from the n-side to p-side that opposes the diffusion component. In the absence of any external fields a condition of equilibrium is established, and the net current flow across the junction is zero. As will be discussed, the p-n junction electric field is also responsible for separating and collecting photon-generated carriers in photovoltaic cells.

When a voltage is applied across a p-n junction, the balance between the electron and hole drift and diffusion currents is disturbed and a net current results. Under forward bias, a positive voltage is applied to the p-side relative to the n-side, and the electric field across the junction is reduced; i.e., the electric field associated with the applied voltage subtracts from the zero-bias field. The reduced field enhances hole diffusion from the p-side to the n-side and electron diffusion from the n-side to the p-side, thereby increasing the “positive” current; the transport of current from the p-side to the n-side is positive by convention. Conversely, under reverse bias a negative voltage is applied to the p-side relative to the n-side, and the electric field across the junction increases. Consequently, the diffusion component of current decreases relative to the drift component, and a net “negative” current results across the junction.

The dark current-voltage ( $I$ - $V$ ) characteristics for an Si p-n junction are generally well described by the ideal Shockley diode equation (Sze, 1981),

**FIGURE 8.13.1** Schematic diagram illustrating an abrupt p-n junction with a uniform concentration of donor impurities in the n-region and acceptor impurities in the p-region.

$$I_D = I_o [\exp(qV/nkT) - 1] \tag{8.13.1}$$

where  $I_D$  is the junction dark current,  $I_o$  is the reverse saturation current,  $V$  is the forward-bias voltage,  $n$  is the diode ideality factor, and  $T$  is the absolute temperature. The value of  $n$  is  $\sim 1.0$  when the current is dominated by carrier diffusion, but increases and approaches values of  $\sim 2$  or greater when other current mechanisms become important, such as carrier recombination or tunneling. In high-quality Si p-n junction photovoltaic cells, the value of  $n$  is  $\sim 1.0$  near the relevant operating voltage. The parameter  $I_o$  varies with  $T$  and  $E_g$  according to

$$I_o = qA \left[ \frac{D_n n_p}{L_n} + \frac{D_p p_n}{L_p} \right] \propto T^3 \exp\left(-E_g/kT\right) \tag{8.13.2}$$

where  $A$  is the junction area and  $D_n$  and  $D_p$ ,  $n_p$  and  $p_n$ , and  $L_n$  and  $L_p$  are the diffusion coefficients, minority carrier densities, and diffusion lengths for electrons and holes, respectively. The value of  $I_o$  decreases strongly as  $E_g$  increases, which, as will be shown, increases the photovoltage obtainable from a photovoltaic cell.

### Cell Operation and Efficiency

**Cell Operation.** Photovoltaic energy conversion in a p-n junction is a two-step process where free electrons and holes (photocarriers) are generated in the semiconductor via the absorption of solar energy and then simultaneously collected across the junction (Fahrenbruch and Bube, 1983). Consider the schematic of a typical photovoltaic cell shown in Figure 8.13.2 which consists of a p-n junction formed very close to the top surface of the cell. Front metal ohmic contact grid fingers allow solar energy to pass into the absorber layers. The entire top surface is covered with an antireflection coating to minimize reflective losses, and the entire back surface is covered with an ohmic contact. The ohmic contacts form n and p region terminals that transfer (conduct) current from the semiconductor to the external circuit with a negligible amount of voltage drop.

When the photovoltaic cell is exposed to solar radiation, photons with energies greater than  $E_g$  (super-band-gap photons) are absorbed in the n and p layers, and free electrons and holes are generated via the breaking of covalent bonds. These electron-hole pairs, or **photocarriers**, are shown in Figure 8.13.1. The energy of the free photocarriers is converted directly into a current and voltage via photocarrier collection by the junction. The absorbed photons effectively contribute an energy  $E_g$  to the cell output,

**FIGURE 8.13.2** Schematic diagram of a typical p-n junction photovoltaic cell.

and energy greater than  $E_g$  is lost as heat. Photons with energies less than  $E_g$  (sub-band-gap photons) are transmitted through the cell. After generation, minority photocarriers, that is, holes on the n-side and electrons on the p-side, diffuse toward the edges of the junction due to a gradient of carriers that exists there. If the minority carriers are generated within a diffusion length,  $L$ , of the junction, they will reach it and be swept across it by the electric field of the junction. Hence, electrons are swept from the p-side to the n-side and holes from the n-side to the p-side, and thus they are separated. The minority carrier gradient present at the edges of the junction is due to the depletion of minority carriers that results from their transfer across the junction. The diffusion flux of minority carriers toward and across the junction constitutes a light-generated current,  $I_L$ , or photocurrent, that is directed from the n-side to the p-side of the cell. The build-up of positive holes on the p-side and negative electrons on the n-side gives rise to a **photovoltage** across the junction. The polarity of both the photovoltage and photocurrent is identical to that of a battery, and power is delivered from the junction to the external circuit.

*Cell Efficiency.* In order to derive the solar conversion efficiency, it is convenient to model the photovoltaic cell as an ideal p-n diode in parallel with a **light-generated (constant) current source**,  $I_L$ , as shown in the equivalent circuit of Figure 8.13.3. Parasitic series and shunt resistance losses,  $R_s$  and  $R_{sh}$ , respectively, are also shown, where  $R_s$  is due to ohmic contact and semiconductor resistances, and  $R_{sh}$  is due to defect-related carrier recombination and/or tunneling phenomena (Stirn, 1972). A qualitative expression for  $I_L$  is given by Tada et al. (1982):

$$I_L = qAG(L_n + W_b + L_p) \tag{8.13.3}$$

where  $G$  is the photocarrier generation rate in carriers/cm<sup>3</sup>-sec due to solar photon absorption, which depends on  $E_g$  and the photon energy (wavelength) and intensity (concentration), and  $W_b$  is the sum of the negative and positive SCR widths. As mentioned,  $I_L$  is directed from the n-side to the p-side. In

**FIGURE 8.13.3** Schematic of equivalent circuit model for a p-n photovoltaic cell.

contrast, the dark diode current given by Equation (8.13.1) is directed oppositely from the p-side to the n-side. The **dark current** is due to the forward-bias photovoltage that appears across the cell p-n junction when it is illuminated. Thus, the dark current opposes the light current. In the ideal case, that is, when  $R_s = 0$  and  $R_{sh} = \infty$ , the total forward current,  $I_T$ , is given by

$$I_T = I_D - I_L = I_0 \left[ \exp\left(\frac{qV}{nkT}\right) - 1 \right] - I_L \tag{8.13.4}$$

A plot of dark and light current-voltage ( $I$ - $V$ ) curves resulting from Equations (8.13.1) and (8.13.4), respectively, is shown in **Figure 8.13.4** for a typical p-n solar cell. Under illumination, the forward-bias dark  $I$ - $V$  curve is displaced downward into the fourth quadrant by the **photocurrent**,  $I_L$ . It is noted from **Figure 8.13.3** that the voltage drop across the load resistance,  $R_L$ , is  $V = -I_T R_L$ . Under short-circuit conditions, that is, when the n and p terminals are tied to each other,  $R_L$  is negligible. The resulting voltage drop across the p-n junction will also be negligible, and from Equation (8.13.1),  $I_D \approx 0$ . As shown in **Figure 8.13.4**, the resultant current is termed the **short-circuit current**,  $I_{sc}$ , or  $I_T = -I_{sc} = -I_L$ . As the value of  $R_L$  increases, a voltage appears across the junction,  $V = -I_T R_L$ , called the **photovoltage**, and  $I_D$  increases in accordance with Equation 8.13.1. Under this condition the cell is operating in the fourth quadrant of the  $I$ - $V$  characteristic (i.e., the junction voltage is positive and the current is negative), and, consequently, the cell delivers power (product of the current and voltage) to  $R_L$ . As the value of  $R_L$  continues to increase, so too does  $V$  and  $I_D$ . When the value of  $R_L$  approaches infinity, that is, under open-circuit conditions,  $I_D$  approaches  $I_L$  and  $I_T$  goes to zero. The resulting **open-circuit voltage**,  $V_{oc}$ , is shown in **Figure 8.13.4**.  $V_{oc}$  can be obtained by setting  $I_T = 0$  in Equation (8.13.4) and solving for  $V$ . For  $V \gg kT/q$ ,

$$V_{oc} = \frac{nkT}{q} \ln \left[ \frac{I_L}{I_0} + 1 \right] \tag{8.13.5}$$

Thus, the operating point on the  $I$ - $V$  curve in the fourth quadrant can be swept from  $(I_{sc}, 0)$  to  $(0, V_{oc})$  by varying the value of  $R_L$ . When the optimum load is chosen (i.e.,  $R_L \approx V_{oc}/I_{sc}$ ), approximately 80% of the product  $I_{sc} V_{oc}$  can be extracted as useful power as shown by the shaded maximum-power rectangle in **Figure 8.13.4**. Also shown in **Figure 8.13.4** are the parameters  $I_m$  and  $V_m$ , which correspond to values of current and voltage, respectively, that yield the maximum cell power,  $P_m$ , where  $P_m = I_m V_m$ . The knee that appears at  $P_m$  is due to the parasitic effects of  $R_s$  and  $R_{sh}$ . The curvature of the knee at  $P_m$  is described by the **fill factor**, **FF**, where

$$FF = \frac{I_m V_m}{I_{sc} V_{oc}} \tag{8.13.6}$$

The photovoltaic cell **conversion efficiency**,  $\eta$ , is defined as

$$\eta = \frac{I_m V_m}{P_{in} A}$$

or

FIGURE 8.13.4 Typical dark and light current-voltage characteristics for a p-n photovoltaic cell.

$$\eta = FF I_{sc} V_{oc} / P_{in} \tag{8.13.7}$$

where  $P_{in}$  is the incident power in  $W/m^2$  equal to the sum in energy of the incident photons per time per area. Values for  $V_{oc}$ ,  $I_{sc}$ ,  $FF$ , and  $\eta$  can be obtained in the laboratory under various air mass conditions from light  $I-V$  curves measured using a carefully controlled (calibrated) light source to illuminate the cell.

**Cell Material vs. Efficiency**

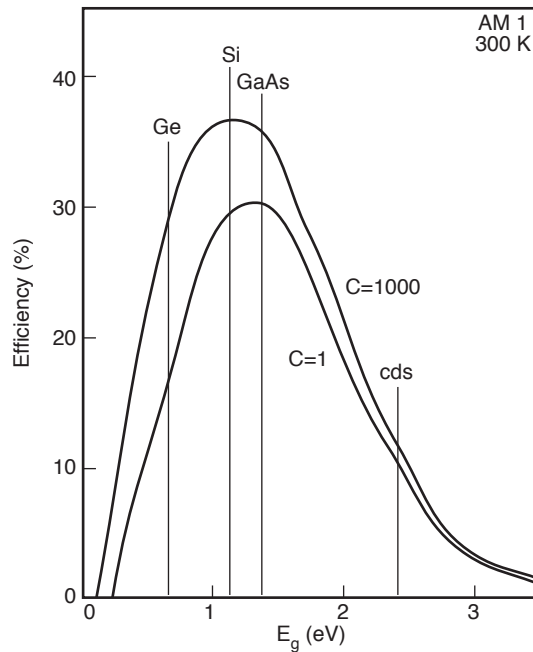

The optimum value of material  $E_g$  for solar photovoltaic conversion is  $\sim 1.0$  to  $1.5$  eV. To understand how the choice of cell material affects conversion efficiency, an ideal expression can be derived using Equation 8.13.4 for the theoretical conversion efficiency. The output power can be expressed as (Henry, 1980)

$$P = IV = I_o V \left[ \exp\left(\frac{qV}{nkT}\right) - 1 \right] - I_L V \tag{8.13.8}$$

The maximum output power is obtained when  $dP/dV = 0$ , and an expression for  $I_m$  and  $V_m$  can be obtained from Equation (8.13.8) and multiplied to give  $P_m$ , where

$$P_m = I_m V_m = I_L \left[ V_{oc} - \frac{kT}{q} \ln\left(\frac{qV_m}{kT} + 1\right) - \frac{kT}{q} \right] \tag{8.13.9}$$

In practical cells, values for  $V_m$  and  $V_{oc}$  are typically  $1/2 E_g/q$  to  $2/3 E_g/q$ . Thus, for materials with  $E_g \sim 1 - 2$  eV, the quantity in the large brackets of Equation (8.13.9) becomes  $\sim V_{oc}$ , and the factors that determine  $I_L$  and  $V_{oc}$  also determine  $P_m$ . From Equations (8.13.2) and (8.13.5), it is clear that  $V_{oc}$  increases with  $E_g$  through the reduction in  $I_o$ . In contrast, as  $E_g$  increases,  $I_L$  decreases because a smaller portion of the solar spectrum is energetic enough to be absorbed; i.e.,  $I_L$  is the product of  $q$  and the number of available photons with energy greater than  $E_g$ . Hence, for a given solar spectrum there is an optimum value of  $E_g$  that maximizes the product of  $V_{oc}$  and  $I_L$ . A plot of ideal AM1 conversion efficiency vs.  $E_g$  is shown in Figure 8.13.5 for “one sun” ( $925 W/m^2$ ) and “1000 suns” ( $925 kW/m^2$ ) concentrations (Henry, 1980). The efficiency curves were obtained using Equations (8.13.1) through (8.13.7) at 300 K. A maximum in efficiency occurs for  $E_g \sim 1.0 - 1.5$  eV.

**FIGURE 8.13.5** Theoretical AM1 efficiency vs. semiconductor band gap  $E_g$  for an ideal photovoltaic cell under 1 sun and 1000 suns concentrations.

### Manufacture of Cells and Panels

There are basically five important solar cell design concepts, and each offers a trade-off between efficiency and cost: (1) Large-area single-crystal planar cells, typically  $1 \times 1 \text{ cm}^2$  to  $6 \times 6 \text{ cm}^2$ , yield high efficiencies under normal light conditions, (2) single-crystal small-area concentrator cells, typically less than  $1 \times 1 \text{ cm}^2$ , are potentially less costly and yield higher efficiencies under concentrated light, i.e., concentration ratios of 20 to 1000 are typical; (3) more-complex single-crystal multijunction cells yield the highest efficiencies measured to date, but are substantially more expensive; (4) cells made from polycrystalline materials are less expensive than single-crystalline cells, but are less efficient; and (5) cells made from thin film amorphous materials provide the lowest-cost approach yet, but are generally less efficient than polycrystalline cells.

A typical 15%  $4 \times 4 \text{ cm}^2$  photovoltaic cell produces only  $\sim 0.25 \text{ W}$  under AM1.5 conditions. Therefore, individual cells must be electrically wired together to form larger submodules or panels to increase the total output power. The cells can be connected in series to increase the total voltage or in parallel to increase the current. The modular nature of photovoltaic power allows the design of systems that can deliver electrical power from a few watts to many megawatts. In terrestrial applications the cells are typically supported and held in place with a rigid substrate, i.e., typically aluminum, Plexiglas, fiberglass, or glass, and are encapsulated with glass or a polymeric material; in space applications the support structure may be rigid or flexible, and the cells are protected from the space environment with quartz cover slides. The electrical power generated by the cells is conducted to an electrical load or storage battery. Metal interconnects soldered to the ohmic contacts of the cells conduct electrical current from one cell to the next. Current is then conducted from the network of series- and parallel-connected cells by wires to a distribution terminal “bus” that transfers the power to either the load or battery.

*Single-Crystal Cells.* The p-n photovoltaic cells made from **single-crystal** Si dominate in space and terrestrial applications because of their high efficiency and reliability. The formation of single-crystal p-

type Si results from the selective cooling of pure molten Si to form large cylindrical crystal ingots, called boules, from which thin wafers are sliced and polished. The p-type impurities, usually boron, are added to the melt, to give the desired impurity concentration. A large-area p-n junction is then formed by diffusion of n-type impurity atoms, usually phosphorus. Front and back metal ohmic contacts and an antireflection coating are then formed using standard photolithography thermal evaporation or sputtering techniques (Sze, 1985). The resulting cell structure is shown in Figure 8.13.2, and typical cell areas range from 1 to 36 cm<sup>2</sup>. Different semiconductors absorb sunlight more efficiently than others, described by a factor called the absorption coefficient. Si has a relatively small absorption coefficient compared with other materials, such as InP, GaAs, and amorphous-Si, and consequently requires an absorption layer thickness of ~100 μm to maximize conversion efficiency. Conventional Si cells have a thickness on the order of 250 μm, but can be chemically or mechanically polished to a thickness of 100 μm.

Single-crystal III-V photovoltaic cells, such as InP and GaAs, are made from elements in the III and V columns of the periodic table. The band gaps of these cells, 1.35 and 1.42 eV, respectively, are close to the optimum value. These materials involve the growth of single-crystal semiconductor layers upon a single-crystal semiconductor substrate. This technique is called epitaxy and it provides a method to produce both n-type and p-type layers to form the p-n junction. Epitaxial growth of n and p layers is required for InP and GaAs because diffusion of impurities at high temperatures is confounded by the high vapor pressure of the material. The formation of ohmic contacts and antireflection coating employ the same techniques as used for Si cells. The required absorption layer thickness for these cells is only a few microns because of their large absorption coefficients. However, issues concerning yield and mechanical strength limit their minimum thickness to ~100 μm. The best reported efficiencies for single-crystal Si, GaAs, and InP cells under AM1.5 conditions are 24, 25, and 22%, respectively (Green et al., 1995).

*Polycrystalline Cells.* In the case of **polycrystalline** Si cells, molten Si is directly deposited into either cylindrical or rectangular ingots. As the material solidifies, individual crystalline regions form that are separated by grain boundaries which contain large numbers of structural defects. When the cell is illuminated, these defects capture a portion of the light-generated electron-hole pairs through recombination processes before they can reach the junction and be collected. Thus, the grain boundaries diminish the light-generated current and overall efficiency of the cell. However, polycrystalline silicon cells are sufficiently inexpensive to be commercially viable (Stone, 1993). An area that requires improvement is the slicing of polycrystalline ingots, where yields as low as 50% are common. An approach that eliminates the expense of sawing and polishing altogether is the growth of polycrystalline Si directly into the form of thin ribbons using a technique called edge-defined film-fed growth (EFG) (Fahrenbruch and Bube, 1983). In this approach, a carbon die with a slot-shaped aperture is immersed in a crucible of molten Si. The liquid Si wets the die and flows through the slot where it cools and is pulled to form a thin ribbon. This material also has high crystalline defect densities, but has good overall yields. An additional approach involves the growth of films of nearly single-crystal quality, where two parallel supporting dendrites form the boundaries of a web or ribbon pulled from a supercooled melt of Si. The best efficiency for polycrystalline Si cells under AM1.5 conditions is ~18%; that for Si cells grown by the EFG technique is 14%; and that for Si dendritic web cells is 15.5% (Stone, 1993). It is important to note that although these lower-cost films yield lower cell efficiencies compared with single-crystal cells, the cost of cells depends on the cost of the starting material and the cost per watt is more important than efficiency (Zweibel, 1995).

*Thin Film Cells.* Thin films cells provide an even lower-cost (and lower-efficiency) approach because they require a very small amount of semiconductor. An excellent review on thin film photovoltaic technologies, particularly on present and future cost issues, is given by Zweibel (1995). The general approach involves depositing only a few microns of material on a low-cost substrate using various vacuum deposition techniques, although a multitude of other deposition techniques have also been demonstrated. The top thin film cell candidates are amorphous Si, a-Si, cadmium telluride, CdTe, and copper indium diselenide, CIS (and related alloys). The highest reported thin film AM1.5 efficiencies

are 17% for CIS, followed by 15.8% for CdTe, and ~11% for a-Si (Zweibel, 1995). However, the relative level of maturity of each design for commercial application must be put into perspective. While the best CIS cell efficiency is quite high, the best CIS square foot panel efficiency reported back in 1988 was, and still is today, only 11%. Significant manufacturing problems have plagued the CIS cell, and currently it is still not commercially available. CdTe is believed to be the easiest of the thin film cells to fabricate, and probably represents the closest to large-scale commercialization. Two U.S. companies have publicly announced CdTe manufacturing plants, and commercial efficiencies are likely to be in the range of 6 to 8% in the first plants. The future of a-Si cells is currently believed to be limited if it cannot overcome a 10% efficiency at the module level. Development problems include electrochemical instability to light that results in a 20 to 40% degradation. However, it appears that the use of multijunction thin film a-Si layers may solve the problem, and modules of 7 to 9% are expected in the near term.

*Concentrator Cells.* Photovoltaic modules are typically either of the flat plate or concentrator configuration. Flat plate modules can be fixed with respect to the sun or mounted to track the sun in one or two axis. Concentrator modules use large-area mirrors or lenses to concentrate sunlight onto smaller-area cells. Concentrator cells operate at higher efficiencies. However, concentrator modules require one- or two-axis tracking which adds system complexity and cost that generally offsets the module efficiency and lower area cost benefits. The increase in conversion efficiency with illumination intensity is shown in the 1000-sun concentration curve of Figure 8.13.5. Values for  $I_L$  increase linearly with concentration through the factor  $G$  in Equation (8.13.3) and  $V_{oc}$  increases logarithmically with concentration through  $I_L$  in Equation (8.13.5). Under solar concentration of “20 suns” or greater, a significant amount of cell heating can occur. While  $J_{sc}$  increases slightly with increasing temperature, values of  $V_{oc}$  and FF drop strongly. Thus, on adequate heat sink or active cooling is required at high concentrations. The reported AM1.5 efficiency for Si cells increases from 24 to 26.5% under a concentration of 255; and that for GaAs cells increases from 25 to 27.6% under a concentration of 140 (Green et al., 1995).

*Multijunction Cells.* Another approach to increase photovoltaic cell efficiency is through the use of multijunction tandem cells. The simplest multijunction cell is a two-junction, two-terminal device. In this design, a high-band-gap ( $E_{g1}$ ) p-n junction is vertically stacked (mechanically) or epitaxially grown atop a bottom lower-band-gap ( $E_{g2}$ ) p-n junction as shown in Figure 8.13.6. The top junction absorbs photons with energy  $\geq E_{g1}$ , and the bottom junction absorbs photons with energy  $E$ , where  $E_{g1} > E \geq E_{g2}$ , that passed through the top cell. This increases the utilization of the solar spectrum, since the excess energy of the high-energy photons is not wasted. The values of  $E_{g1}$  and  $E_{g2}$  must be chosen to achieve maximum solar absorption and current matching; i.e., the two cells must generate equal currents when illuminated. The band gap combinations of ~0.7 and 1.4, 1.0 and 1.4, 1.1 and 1.4, and 1.4 and 1.9 eV are current matched, where  $E_g$  for GaSb, CuInSe<sub>2</sub>, Si, GaAs, AlGaAs, and GaInP<sub>2</sub> are ~0.7, 1.0, 1.1, 1.4, and 1.9 eV, respectively. Multijunction concentrator cells have reported efficiencies in excess of 30% (Green, 1995).

## Design of a Photovoltaic Generating System

A schematic diagram depicting the basic components of a typical photovoltaic power generation system is shown in Figure 8.13.7 (Pulfrey, 1978). The system includes a photovoltaic array that consists of many smaller submodules, each containing many hundreds or thousands of photovoltaic cells. The DC output power from the array is controlled by a power conditioning unit that contains an inverter for developing AC power and an input power tracking device to maintain the optimal array load to achieve maximum output power. Power is directly fed to the electrical load and/or storage system by the conditioning unit. The storage system is needed to save energy when power is generated in excess of the immediate demand, or when the load demand exceeds the immediate generation level. Total photovoltaic power system efficiency is the product of the efficiencies of the individual components. Typical efficiencies for the power conditioning unit (determined by the inverter) and energy storage system are about 95% and 50-80%, respectively. Thus, an array efficiency of 10% would result in a total system

FIGURE 8.13.6 Schematic diagram of a multijunction (two-junction) photovoltaic cell under illumination.

FIGURE 8.13.7 Schematic diagram depicting the basic components of a typical photovoltaic power system.

efficiency of about 5 to 8%, and a total system efficiency of 10% would require an array efficiency in excess of 13%.

### Defining Terms

**Band gap ( $E_g$ ):** The difference in energy between the energy level of the bottom of the conduction band and the energy level of the top of the valence band.

**Conduction band:** A range of allowable energy states in a solid in which electrons can move freely.

**Conversion efficiency ( $\eta$ ):** The ratio of the available power output photovoltaic cell to the total incident radiant power.

**Dark current:** Any current that flows through the p-n junction in the absence of external irradiation.

**Fill factor ( $ff$ ):** The ratio of the maximum photovoltaic cell output power to the product of the open-circuit voltage and short-circuit current.

**Light-generated current ( $I_l$ ):** The electrical current obtained from an illuminated p-n junction resulting from the collection of photocarriers across the junction.

**Open-circuit voltage ( $V_{oc}$ ):** The voltage obtained across the terminals of an illuminated p-n photovoltaic cell under open-circuit conditions.

**Photocarriers:** Electrons and holes generated within a semiconductor via the absorption of photon energy.

**Photocurrent:** Synonymous with light-generated current.

**Photovoltaic effect:** The production of a voltage difference across a p-n junction resulting from the absorption of photon energy.

**Photovoltage:** The voltage resulting from the photovoltaic effect.

**Polycrystalline:** A material characterized by an array or agglomerate of small single-crystal sections of various crystal orientations separated from one another by grain boundaries, which are localized regions of very severe lattice disruptions and dislocations.

**Short-circuit current ( $I_{sc}$ ):** The electrical current measured through the terminals of an illuminated p-n photovoltaic cell under short-circuit conditions.

**Single crystal:** A material characterized by a perfect periodicity of atomic structure; the basic arrangement of atoms is repeated throughout the entire solid.

**Valence band:** A range of allowable energy states in a solid crystal in which lie the energies of the valence electrons that bind the crystal together.

## Further Information

An excellent presentation of the basic theory of the various photovoltaic cell designs is given in *Fundamentals of Solar Cells: Photovoltaic Solar Energy Conversion*, by Alan L. Fahrenbruch and Richard H. Bube. This text covers the basics of solar insolation, semiconductors, p-n junctions, and single-crystal, polycrystalline, thin film, and concentrator photovoltaic cells.

An excellent review of the progress achieved in terrestrial and space photovoltaics can be traced in the *Proceedings of the IEEE (Institute of Electrical and Electronics Engineers) Photovoltaics Specialists Conference (PVSC)* that dates back to 1961. These proceedings include thousands of papers that address nearly every aspect of photovoltaic cell development: basic theory, design, fabrication, and application.

The monthly journal *Solar Energy Materials and Solar Cells* covers many aspects of improving device efficiency, reducing costs, and testing and applications.

The monthly journal *Progress in Photovoltaics* documents recent results of research work conducted in photovoltaics worldwide. This journal is an excellent source for currently reported cell conversion efficiencies.

Proceedings of the conference *Space Photovoltaics Research and Technology* is an excellent source for the reader interested in the development of photovoltaics for use in space.

## Fuel Cells

*D. Yogi Goswami*

### Introduction

A *fuel cell* is an electrochemical device in which a fuel and an oxidant react in such a controlled manner that the chemical energy of reaction is converted directly into electrical energy. Ordinarily, a fuel reacts violently with an oxidant in a combustion reaction resulting in the release of heat of combustion. The heat of combustion can, then, be converted into electrical energy via mechanical work with the constraint of the second law of thermodynamics. The overall efficiency of the series of conversion processes is of the order of 40%. A fuel cell bypasses these processes resulting in potential efficiencies of the order of 80%. As an example, when hydrogen is burned in an atmosphere of oxygen it results in the following reaction:

In this reaction, two hydrogen atoms bond with an oxygen atom by sharing their electrons with the outermost orbit of oxygen, which becomes full, resulting in a stable structure.

The reactants  $\text{H}_2$  and  $\text{O}_2$  may be combined to form the same product ( $\text{H}_2\text{O}$ ) by first stripping the electrons away from the hydrogen atoms and allowing the electrons to pass through an external circuit before combining with oxygen. [Table 8.13.1](#) gives typical electrochemical reactions in fuel cells.

[Figure 8.13.8](#) shows a schematic of an arrangement that would allow the above reaction to proceed.

**TABLE 8.13.1 Electrochemical Reactions in Fuel Cells**

Fuel Cell	Anode Reaction	Cathode Reaction	Overall Reaction
Proton exchange	$\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$	$\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$	$\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$
Alkaline	$\text{H}_2 + 2(\text{OH})^- \rightarrow 2\text{H}_2\text{O} + 2\text{e}^-$	$\frac{1}{2}\text{O}_2 + \text{H}_2\text{O} + 2\text{e}^- \rightarrow 2(\text{OH})^-$	$\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$
Phosphoric acid	$\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$	$\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$	$\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$
Molten carbonate	$\text{H}_2 + \text{CO}_3^- \rightarrow \text{H}_2\text{O} + \text{CO}_2 + 2\text{e}^-$ $\text{CO} + \text{CO}_3^- \rightarrow 2\text{CO}_2 + 2\text{e}^-$	$\frac{1}{2}\text{O}_2 + \text{CO}_2 + 2\text{e}^- \rightarrow \text{CO}_3^-$	$\text{H}_2 + \frac{1}{2}\text{O}_2 + \text{CO}_2$ (cathode) $\rightarrow \text{H}_2\text{O} + \text{CO}_2$ (anode)
Solid oxide	$\text{H}_2 + \text{O}^- \rightarrow \text{H}_2\text{O} + 2\text{e}^-$ $\text{CO} + \text{O}^- \rightarrow \text{CO}_2 + 2\text{e}^-$ $\text{CH}_4 + 4\text{O}^- \rightarrow 2\text{H}_2\text{O} + \text{CO}_2 + 8\text{e}^-$	$\frac{1}{2}\text{O}_2 + 2\text{e}^- \rightarrow \text{O}^-$	$\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$ $\text{CO} + \frac{1}{2}\text{O}_2 \rightarrow \text{CO}_2$ $\text{CH}_4 + 2\text{O}_2 \rightarrow \text{H}_2\text{O} + \text{CO}_2$

In order for the above reactions to occur according to the schematic of [Figure 8.13.8](#):

FIGURE 8.13.8 Conceptual schematic of a hydrogen fuel cell.

1. Electrodes must be porous to let the fuel and electrolyte penetrate.
2. The electrolyte must be permeable to  $H^+$  and  $(OH)^-$  ions.
3. Electrode materials must be catalysts for the reaction (Pt, Ni, etc.).

In 1839, William Grove, an English investigator, constructed a chemical battery in which he noticed that the water-forming reaction of hydrogen and oxygen generated an electrical current. However, it was not until 50 years later that two English chemists, Ludwig Mond and Carl Langer, developed a device they actually called a fuel cell (Angrist, 1982). There has been a strong resurgence in research and development of fuel cells in the last four decades.

### Thermodynamic Performance

The energy released or needed in any chemical reaction ( $\Delta H$ ) is equal to the difference between the enthalpy of formation of the products and the reactants.

$$\Delta H = \sum (\Delta H)_{\text{products}} - \sum (\Delta H)_{\text{reactants}} \quad (8.13.13)$$

In an exothermic reaction the change in enthalpy of formation ( $\Delta H$ ) is negative. Table 8.13.2 gives values of  $\Delta H$  for various compounds at 25°C at 1 atm. All naturally occurring elements have a  $\Delta H$  value of zero.

TABLE 8.13.2 Enthalpy of Formation  $\Delta H^0$  and Gibbs Free Energy  $\Delta G^0$  of Compounds at 1 atm and 298 K

Compound or Ion	Enthalpy of Formation, $\Delta H^0$ , J/kg · mol	Gibbs Free Energy $\Delta G^0$ , J/kg · mol
CO	$-110.0 \times 10^6$	$-137.5 \times 10^6$
CO <sub>2</sub>	$-394.0 \times 10^6$	$-395.0 \times 10^6$
CH <sub>4</sub>	$-74.9 \times 10^6$	$-50.8 \times 10^6$
Water	$-286.0 \times 10^6$	$-237.0 \times 10^6$
Steam	$-241.0 \times 10^6$	$-228.0 \times 10^6$
C, H <sub>2</sub> , O <sub>2</sub>	0	0
O(g)	$+249.2 \times 10^6$	$+231.8 \times 10^6$
H(g)	$+218.0 \times 10^6$	$+203.3 \times 10^6$

Source: Adapted from Wark, K., *Thermodynamics*, McGraw-Hill, New York, 1988. With permission.

In a combustion reaction all of the change in the enthalpy of formation ( $\Delta H$ ) is converted to heat and is, therefore, called the higher heating value (HHV).

$$-(\Delta H)_{\text{reaction}} = \text{HHV of fuel} \quad (8.13.14)$$

For example, for complete combustion of hydrogen according to the following reaction:

Change in the enthalpy of formation is

$$\Delta H = \Delta H_{\text{H}_2\text{O}} - \Delta H_{\text{H}_2} - \frac{1}{2}(\Delta H_{\text{O}_2}) = (-286 \times 10^6) - 0 - 0 = -286 \times 10^6 \text{ J/kg} \cdot \text{mol H}_2 \quad (8.13.16)$$

In a fuel cell, most of  $\Delta H$  can be converted to electricity directly. The part that cannot be converted to work directly gets converted into heat. The minimum amount that must be converted to heat is represented by reversible heat transfer  $\int T dS$ . If a fuel cell operates isothermally, the maximum amount of electrical work ( $W_e$ ) produced is given by

$$W_{e,\text{max}} = \Delta H - T\Delta S \quad (8.13.17)$$

In an irreversible reaction

$$W_{e,\text{max}} < \Delta H - T\Delta S \quad (8.13.18)$$

Gibbs free energy,  $G$ , is given by:

$$G = H - TS \quad (8.13.19)$$

Therefore, in a reversible isothermal process

$$\Delta G = \Delta H - T\Delta S = W_{e,\text{max}} \quad (8.13.20)$$

The actual electrical work in a fuel cell is given by

$$W_e \leq \Delta G \quad (\text{change in Gibbs free energy for the reaction}) \quad (8.13.21)$$

$$\Delta G_{\text{reaction}} = \sum (\Delta G)_{\text{products}} - \sum (\Delta G)_{\text{reactants}} \quad (8.13.22)$$

The electrical work,  $W_e$ , is associated with the work of electrons passing through an external resistance. 1 g · mol of electrons is equal to Avogadro's number ( $6.022 \times 10^{23}$ ) and the charge of these electrons is equal to 96,439 C which is called a **faraday** ( $F$ ). If  $n$  g · mols of electrons are generated and  $E$  is the internal reversible cell voltage, then the maximum electrical work is given by

$$W_{e,\text{max}} = \Delta G = -nFE \quad (8.13.23)$$

denoting values under standard conditions (25°C, 1 atm) by superscript 0, we have

$$\Delta G^0 = -nFE^0 \quad (8.13.24)$$

Values of  $G^0$  for various compounds are given in Table 8.13.2. For fuel cell reactions as below:

if the reactants ( $A$  and  $B$ ) and the products ( $C$  and  $D$ ) are assumed to be ideal gases with partial pressures  $P_A$ ,  $P_B$ ,  $P_C$ , and  $P_D$  the change in Gibbs free energy  $\Delta G$  and the internal reversible cell voltage,  $E$ , are given by

$$\Delta G = \Delta G^0 + RT \ln \frac{(P_C)^c (P_D)^d}{(P_A)^a (P_B)^b} \quad (8.13.26)$$

$$E = E^0 + RT \ln \frac{(P_A)^a (P_B)^b}{(P_C)^c (P_D)^d} \quad (8.13.27)$$

Equation 8.13.27 is also called the Nernst equation.

Table 8.13.3 gives Nernst equations for the electrochemical reactions listed in Table 8.13.1.

**TABLE 8.13.3 Fuel Cell Reactions and the Corresponding Nernst Equations**

Cell Reactions	Nernst Equation
$\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$	$E = E^0 + (RT/2F) \ln [P_{\text{H}_2}(P_{\text{O}_2})^{1/2} / P_{\text{H}_2\text{O}}]$
$\text{H}_2 + \frac{1}{2}\text{O}_2 + \text{CO}_2(\text{c}) \rightarrow \text{H}_2\text{O} + \text{CO}_2(\text{a})$	$E = E^0 + (RT/2F) \ln [P_{\text{H}_2}(P_{\text{O}_2})^{1/2} (P_{\text{CO}_2}(\text{c}) / (P_{\text{H}_2\text{O}}(P_{\text{CO}_2}(\text{a})))]$
$\text{CO} + \frac{1}{2}\text{O}_2 \rightarrow \text{CO}_2$	$E = E^0 + (RT/2F) \ln [P_{\text{CO}}(P_{\text{O}_2})^{1/2} / P_{\text{CO}_2}]$
$\text{CH}_4 + 2\text{O}_2 \rightarrow \text{H}_2\text{O} + \text{CO}_2$	$E = E^0 + (RT/8F) \ln [P_{\text{CH}_4} (P_{\text{O}_2})^2 / P_{\text{H}_2\text{O}}^2 P_{\text{CO}_2}]$

Note: (a) = anode; (c) = cathode;  $E$  = equilibrium potential.

Source: Hirschenhofer, J.H. et al., *Fuel Cells, A Handbook*, Gilbert/Commonwealth, Morgantown, WV, 1994. With permission.

The maximum conversion efficiency of a fuel cell is given by

$$\eta_{\max} = \frac{W_e, \max}{\Delta H} = \frac{\Delta G}{\Delta H} = 1 - \frac{T\Delta S}{\Delta H} = \frac{-nFE}{\Delta H} \quad (8.13.28)$$

As current is drawn through an external circuit, the actual voltage drop ( $V$ ) will be less than the internal cell voltage ( $E$ ). Therefore, the actual conversion efficiency of a fuel cell will be lower than above and may be calculated as

$$\eta_{\text{actual}} = \frac{-nFV}{\Delta H} = \frac{ItV}{\Delta H} \quad (8.13.29)$$

where  $I$  is the current drawn through an external circuit for a period of time,  $t$ .

### Types of Fuel Cells

Fuel cells are primarily classified by type of electrolyte, since many other characteristics, particularly operating temperatures, are limited by the electrolyte properties (Hirschenhofer et al., 1994). Major fuel cells under active development at this time are the **phosphoric acid fuel cell (PAFC)**, the **molten carbonate fuel cell (MCFC)**, the **solid oxide fuel cell (SOFC)**, the **polymer electrolyte fuel cell (PEFC)**, and the **alkaline fuel cell (AFC)**.

*Phosphoric Acid Fuel Cell.* PAFC uses concentrated phosphoric acid ( $\text{H}_3\text{PO}_4$ ) as the electrolyte, hydrogen as the fuel, and oxygen (from air) as the oxidant. Table 8.13.4 provides information on the electrodes and other materials for PAFC as well as other fuel cells.

The reactions take place at the porous electrodes on highly dispersed electrocatalyst Pt particles supported on carbon black and a polymeric binder, usually polytetrafluoroethylene (PTFE) (about 30 to 50% by weight) (Kinoshita et al., 1988; Hirschenhofer et al., 1994). A porous carbon paper substrate provides structural support for the electrocatalyst and serves as the current collector. A typical carbon paper electrode impregnated with the electrocatalyst has a porosity of about 60%, consisting of micropores of about 34 Å diameter and macropores of 3 to 50 μm diameter.

Dipolar plates (usually graphite) are used to separate the individual cells and electrically connect them in series in a fuel cell stack. In PAFC stacks, provisions are included to remove the waste heat, by liquids (usually water) or gases (usually air) which flow through channels provided in the cell stack.

*Molten Carbonate Fuel Cells.* MCFCs use as electrolytes mixtures of molten carbonates of lithium ( $\text{Li}_2\text{CO}_3$ ), potassium ( $\text{K}_2\text{CO}_3$ ), and sodium ( $\text{Na}_2\text{CO}_3$ ) in proportions as shown in Table 8.13.4. The operating temperature of the cell (~650°C) is higher than the melting temperature of the carbonate electrolytes. Besides  $\text{H}_2$  (fuel) and  $\text{O}_2$  (oxidant from air) the cell uses  $\text{CO}_2$  which transfers from the cathode to the anode according to the reactions in Table 8.13.1.

According to the reactions, 1 g · mol of  $\text{CO}_2$  is transferred along with 2 g · mol of electrons (2F). The reversible potential for an MCFC, taking into account the transfer of  $\text{CO}_2$ , is given by the Nernst equation in Table 8.13.3.

It is usual practice to recycle the  $\text{CO}_2$  generated at the anode to the cathode where it is consumed. An early process used to fabricate electrolyte structures involved hot processing mixtures of  $\text{LiAlO}_2$  and alkali carbonates at temperatures slightly below the melting point of carbonates. These electrolyte structures had problems of void spaces, nonuniformity of microstructure, poor mechanical strength, and high  $iR$  drop. To overcome these problems, processes have been developed recently that include tape casting (Man et al., 1984; Hirschenhofer et al., 1994) and electrophoretic deposition (Baumgartner et al., 1985; Hirschenhofer et al., 1994).

Increasing the operating pressures results in enhanced cell voltages. Increasing the operating temperature above 550°C also enhances the cell performance. However, beyond 650°C the gains are diminished and the electrolyte loss and material corrosion are increased. Therefore, 650°C is about the optimum operating temperature.

*Solid Oxide Fuel Cell.* SOFCs offer a number of advantages over MCFCs for high-temperature operation, since there is no liquid electrolyte. Solid electrolyte allows flexibility in cell shape design based on application. Cells of several shapes, as shown in Figure 8.13.9, are being developed. Because of the high temperature of operation (~1000°C) carbon monoxide (CO) and hydrocarbons such as methane ( $\text{CH}_4$ ) can be used as fuels. At 1000°C, these fuels can easily produce  $\text{H}_2$  that is used at the anode by steam reforming and water-gas reactions as

Because of very high operating temperatures the choice of cell materials is limited by (1) chemical stability in oxidizing and reducing atmosphere; (2) chemical stability of contacting materials; and (3) conductivity and thermomechanical compatibility. A detailed description of the current status is given by Minh (1991; 1993) and Appleby and Foulkes (1989). Present SOFC designs make use of thin film wall concepts where films of electrodes, electrolyte, and interconnect material are deposited on each other and sintered to form cell structure. Electrochemical vapor deposition (EVD) is now used to deposit thin layers.

**FIGURE 8.13.9** Solid oxide fuel cell designs at the cathode: (a) tubular; (b) monolithic; (c) flat plate.

Increasing pressure and temperature enhances the performance of SOFC.

*Polymer Electrolyte Fuel Cell.* The basic cell consists of a proton-conducting membrane such as perfluoro sulfonic acid polymer sandwiched between two Pt-impregnated porous electrodes. The backs of the electrodes are made hydrophobic by coating with Teflon<sup>®</sup>, which provides a path for gas to diffuse to the catalyst layer.

The electrochemical reactions for PEFC are similar to PAFC as given in Table 8.13.1.

The protons from the anode diffuse through the membrane with the help of water molecules soaked in the membrane. The cell operates at low temperature (80°C) and can have very high current densities. Therefore, the cell can be made very compact and can have fast start. There are no corrosive fluids (acids or alkalis) in the cell. Because of these attributes the cell is particularly suited for vehicle-power operation. Present research includes investigation of using methanol and natural gas as the fuel for the cell.

*Alkaline Fuel Cell.* Alkaline electrolytes have faster kinetics, which allows the use of non-noble metal electrocatalysts. However, AFCs suffer a drastic performance loss if CO<sub>2</sub> is present in the fuel or the oxidant, for example, air. Therefore, AFCs are restricted for use where pure H<sub>2</sub> and O<sub>2</sub> can be used. They have been used in the past in the space program.

### Fuel Cell Performance

The performance of fuel cells is affected by the operating variables (e.g., temperature, pressure, gas composition, reactant utilization, and current density) and other factors that influence the reversible cell potential (impurities) and the magnitude of the irreversible voltage losses (polarization, contact resistance, exchange current).

The cell voltage ( $V_{\text{cell}}$ ) is given by

$$V_{\text{cell}} = E - iR - \mu_p \quad (8.13.32)$$

where  $i$  is the current through the cell,  $R$  is the cell resistance, and  $\mu_p$  is the polarization loss.

FIGURE 8.13.10 Losses affecting current-voltage characteristics.

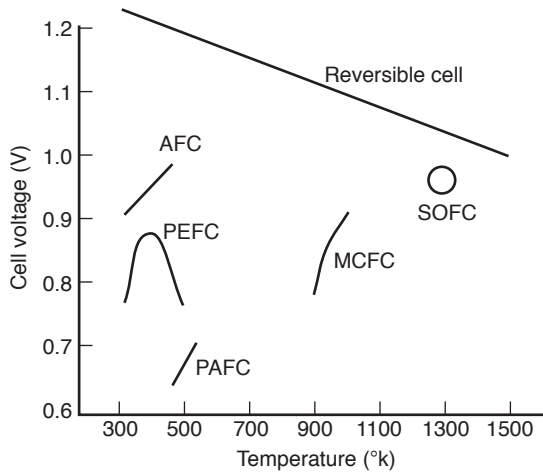

FIGURE 8.13.11 Dependence of the initial operating cell voltage of typical fuel cells on temperature. .

*Current Density.* Current density has a major impact on the cell voltage. Figure 8.13.10 shows how various losses affect the current-voltage characteristics.

*Temperature and Pressure.* Increase in pressure generally has a beneficial effect on the cell performance. Increased reactant pressure increases gas solubility and mass transfer rates. In addition, electrolyte loss due to evaporation is decreased.

Theoretically, the reversible potential of an  $H_2/O_2$  fuel cell decreases with an increase in temperature. The practical effect of temperature is mixed, as shown in Figure 8.13.11.

**Fuel Cell Power Systems**

A general fuel cell power system consists of a fuel processor, fuel cell stack, power conditioner, and possibly a cogeneration or bottoming system to utilize the rejected heat. A schematic of a basic system is shown in Figure 8.13.12.

FIGURE 8.13.12 Basic fuel cell power system.

*Fuel Processors.* If pure hydrogen is available, no additional fuel processor is needed. However, in most applications hydrogen needs to be generated from other fuels, such as natural gas, methane, methanol, etc.

*Natural Gas Processing.* Natural gas is mostly methane ( $\text{CH}_4$ ) with small amounts of other hydrocarbons. It can be converted to  $\text{H}_2$  and  $\text{CO}$  in a steam-reforming reactor according to Equation (8.13.31). Fuels are typically steam reformed at temperatures of 760 to 980°C.

*Liquid Fuel Processing.* Liquid fuels such as distillate, naphtha, diesel oil, and fuel oil can be reformed by noncatalytic partial oxidation of the fuel by oxygen in the presence of steam with flame temperatures of 1300 to 1500°C.

## Nomenclature

- $E$  = internal cell voltage
- $F$  = faraday, charge of 1 g-mol of electrons
- $G$  = Gibbs free energy
- $H$  = enthalpy
- $\Delta H$  = heat of reaction, enthalpy of formation
- $I$  = current
- $n$  = number of g-mol
- $P$  = Pressure
- $R$  = gas constant
- $S$  = entropy
- $t$  = time
- $T$  = temperature
- $V$  = voltage drop
- $W_e$  = electrical work

## Superscript

- 0 = values under standard conditions — 25°C, 1 atm

## Defining Terms

**Alkaline fuel cell (AFC):** A fuel cell using KOH as the electrolyte.

**Faraday:** Change of 1 g · mol of electrons, which equals 96,439 C.

**Molten carbonate fuel cell (MCFC):** A fuel cell using molten carbonate as the electrolyte.

**Phosphoric acid fuel cell (PAFC):** A fuel cell using phosphoric acid as the electrolyte.

**Polymer electrolyte fuel cell (PEFC):** A fuel cell using Zirconia as the electrolyte.

**Solid oxide fuel cell (SOFC):** A fuel cell using potassium as the electrolyte.

## Thermionic Energy Conversion

*Mysore L. Ramalingam*

### Introduction

**Thermionic energy conversion** (TEC) is the process of converting heat directly to useful electrical work by the phenomenon of thermionic electron emission. This fundamental concept can be applied to a cylindrical version of the planar converter, considered the building block for space nuclear power systems (SNPS) at any power level. Space nuclear reactors based on TEC can produce power in the range of 5 kWe to 5 MWe, a spectrum that serves the needs of current users such as National Aeronautics and Space Administration (NASA), United States Air Force (USAF), United States Department of Energy (USDOE), and Ballistic Missile Defense Organization (BMDO). Electrical power in this range is currently being considered for commercial telecommunication satellites, navigation, propulsion, and planetary exploration missions.

The history of thermionic emission dates back to the mid-1700s when Charles Dufay observed that electricity is conducted in the space near a red-hot body. Although Thomas Edison requested a patent in the late 1800s, indicating that he had observed thermionic electron emission while perfecting his electric light system, it was not until the 1960s that the phenomenon of TEC was adequately described theoretically and experimentally (Hatsopoulos and Gryftopoulos, 1973). These pioneering activities have led to the development of thermionic SNPS that could potentially be augmented by Brayton and Stirling

cycle generators to produce additional power from waste heat in NASA manned lunar and martian exploration missions (Ramalingam and Young, 1993).

### Principles of Thermionic Energy Conversion

Figure 8.13.13 represents a schematic of the essential components and processes in an elementary thermionic converter (TC). Electrons “boil-off” from the emitter material surface, a refractory metal such as tungsten, when heated to high temperatures (2000 K) by a **heat source**. The electrons then traverse the small interelectrode gap, to a colder (1000 K) collector surface where they condense, producing an output voltage that drives the current through the electrical load and back to the emitter. The flow of electrons through the electrical load is sustained by the temperature difference and the difference in **surface work functions** of the electrodes.

FIGURE 8.13.13 Schematic of an Elementary TEC.

*Surface Work Function.* In a simple form, the energy required to separate an electron from a metal surface atom and take it to infinity outside the surface is termed the electron work function or the work function of the metal surface. The force experienced by an electron as it crosses an interface between a metal and a rarefied vapor can be represented by the **electron motive**,  $\Psi$ , which is defined as a scalar quantity whose negative gradient at any point is a measure of the force exerted on the electron at that point (Langmuir and Kingdon, 1925). At absolute zero the kinetic energy of the **free electrons** would occupy quantum energy levels from zero to some maximum value called the Fermi level. Each energy level contains a limited number of free electrons, similar to the electrons contained in each electron orbit surrounding the nucleus of an atom. Fermi energy,  $\mu$ , corresponds to the highest energy of all free electrons at absolute zero. At temperatures other than absolute zero some of the free electrons begin to experience energies greater than that at the Fermi level. Thus, the electron work function  $\Phi$ , would be defined as

$$\Phi = \Psi_T - \mu \quad (8.13.33)$$

where  $\Psi_T$  represents the electron motive or energy at some temperature,  $T$ , above absolute zero.

*Interelectrode Motive Distribution.* Figure 8.13.14 provides a schematic representation of the electron motive distribution in the interelectrode space of a thermionic converter. Under ideal conditions of particle transport, the motive varies linearly from  $\Psi_{EM}$ , the motive just outside the emitter, to  $\Psi_{CO}$ , the motive outside the collector surface. The magnitudes of the Fermi energies of the emitter and collector relative to  $\Psi_{EM}$  and  $\Psi_{CO}$  are clearly indicated. The internal voltage drop of the converter is defined as;

$$\Delta V = (\Psi_{EM} - \Psi_{CO})/e \quad (8.13.34)$$

FIGURE 8.13.14 Electron motive distribution in the interelectrode gap.

In a conventional thermionic converter, the emitter and collector are not at the same temperature, but to a good approximation, the output voltage, neglecting **lead losses** and **particle interaction losses**, can be represented by the relationship.

$$V = (\mu_{CO} - \mu_{EM})/e \tag{8.13.35}$$

Since a real thermionic converter has an ionizing medium to improve its performance, a similar motive distribution can be defined for the ions. It is sufficient to state that the ion interelectrode motive has a slope equal and opposite to the corresponding electron interelectrode motive. The ions are, therefore, decelerated when the electrons are accelerated and vice versa.

*Electron Saturation Current.* In the absence of a strong influence from an external electrical source, the electron current ejected from a hot metal at the emitter surface into the vacuum ionizing medium is termed the *electron saturation current*. As this quantity depends on the number of free electrons  $N(\epsilon_x)$ , Fermi-Dirac statistics provide the means to compute the number of free electrons,  $N(\epsilon_x) d\epsilon_x$ , incident on a unit area within the metal in unit time with energies corresponding to the motion normal to the area, between  $\epsilon_x$  and  $\epsilon_x + d\epsilon_x$ . For energies greater than the Fermi energy, the functional dependence of  $N(\epsilon_x)$  on  $\epsilon_x$  is given by (Fowler, 1955)

$$N(\epsilon_x) \approx \left[ \frac{4\pi m_e kT}{h^3} \right] \exp\{-\epsilon_x - \mu/kT\} \tag{8.13.36}$$

where  $m_e$  is the mass of the electron =  $9.108 \times 10^{-28}$  g and  $h$  is Planck's constant =  $4.140 \times 10^{-15}$  eV · sec.

The electron saturation current density,  $J_{sat}$ , for a uniform surface, is found by integrating  $N(\epsilon_x)$  in the range of  $\epsilon_x$  from  $\Psi_T$  to infinity for all  $\Psi_T - \mu > kT$ , which is the case for almost all materials and practical temperatures. The result of the integration yields

$$J_{\text{sat}} = AT^2 \exp\left[-(\Psi_T - \mu)/kT\right] \quad (8.13.37)$$

or

$$J_{\text{sat}} = AT^2 \exp\left[-(\Phi)/kT\right] \quad (8.13.38)$$

where  $A$  is the Richardson constant  $\approx 120 \text{ A/cm}^2 \cdot \text{K}^2$ .

Equation (8.13.38), which is the most fundamental and important relationship for the design of a thermionic converter, is called the Richardson-Dushman equation (Richardson, 1912). On similar lines, the ion saturation current density for a converter with an ionizing medium is given by the relationship (Taylor and Langmuir, 1933):

$$j_{\text{sat}} = ep_g \left[ \left( 2\pi m_g k T_g \right)^{0.5} \left( 1 + 2 \exp\left\{ \left( V_i - \Phi \right) / kT \right\} \right) \right] \quad (8.13.39)$$

where  $p_g$ ,  $T_g$ ,  $m_g$ , and  $V_i$  are the pressure, temperature, mass, and first ionization energy, respectively, of the ionizing medium.

### Types of Thermionic Converters

Thermionic converters can be broadly classified as vacuum thermionic converters and vapor thermionic converters, depending on the presence of an ionizing medium in the interelectrode gap. In vacuum thermionic converters the interelectrode space is evacuated so that the space is free of particles other than electrons and the two electrodes are placed very close together, thereby neutralizing the negative space charge buildup on the electrode surface and reducing the total number of electrons in transit. Due to machining limitations, vacuum converters have been all but completely replaced by vapor-filled thermionic converters. In vapor-filled thermionic converters, the interelectrode space is filled with a rarefied ionizing medium at a vapor pressure generally on the order of 1 to 10 torr. The vapor generally used is cesium as it is the most easily ionized of all stable gases and this can be provided through an external two-phase reservoir or an internal graphite reservoir (Young et al., 1993). The vapor neutralizes the negative space charge effect by producing positive ions at the electrode surfaces and gets adsorbed on the surfaces, thereby altering the work function characteristics.

### Converter Output Characteristics

Figure 8.13.15 represents the output current-voltage characteristics for various modes of operation of the vacuum and vapor-filled thermionic converters. Characteristics obtained by not considering particle interactions in the interelectrode gap are generally considered ideal output characteristics. The figure essentially displays three types of converter output current-voltage characteristics, an ideal characteristic, an ignited mode characteristic, and an unignited mode characteristic. For an ideal converter in the interelectrode space the net output current density consists of the electron current density,  $J_{\text{EMCO}}$  flowing from emitter to collector diminished by the electron current density  $J_{\text{COEM}}$  flowing from collector to emitter and the ion-current density  $J_{\text{iEMCO}}$  flowing from emitter to collector. Thus,

$$J_{\text{net}} = J_{\text{EMCO}} - J_{\text{COEM}} - J_{\text{iEMCO}} \quad (8.13.40)$$

By expressing the individual terms as functions of  $\phi$ ,  $T$ , and  $V$ ,

$$J_{\text{net}} = AT_{\text{EM}}^2 \exp\left[-(\Phi_{\text{EM}}/kT_{\text{EM}})\right] - AT_{\text{CO}}^2 \exp\left[-(\Phi_{\text{EM}} - eV)/kT_{\text{CO}}\right] - j_{\text{EMS}} \exp\left[-(\Psi_{\text{EM}} - \Psi_{\text{CO}})kT_{\text{EM}}\right] \quad (8.13.41)$$

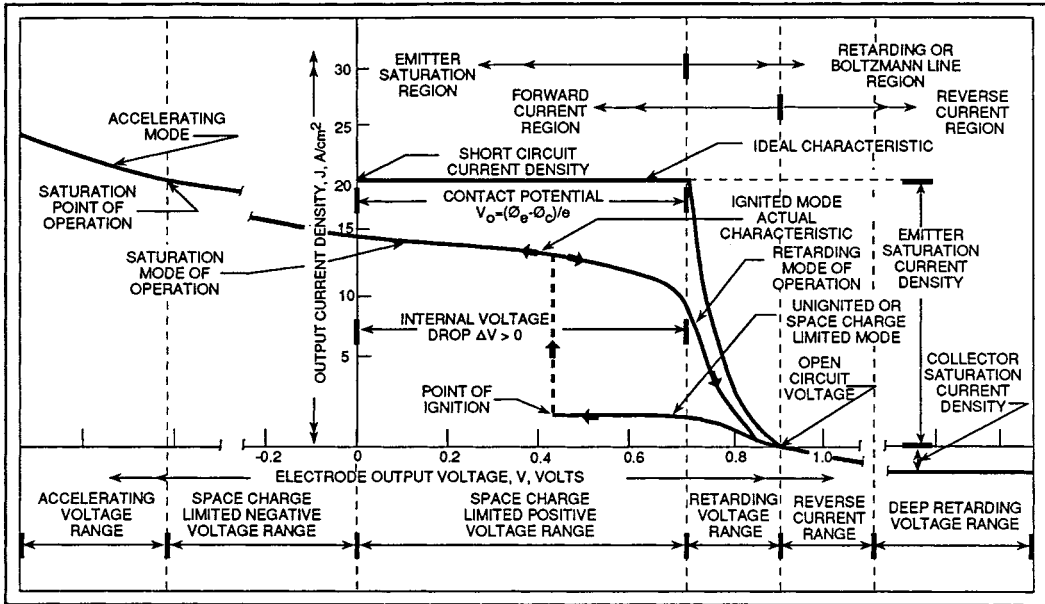

FIGURE 8.13.15 Thermionic diode output current density characteristics and nomenclature.

$$\text{for } eV < \Phi_{EM} - \Phi_{CO}$$

Similar relationships can be generated for various types of thermionic converters.

### Thermodynamic Analysis

In thermodynamic terms a thermionic converter is a heat engine that receives heat at high temperature, rejects heat at a lower temperature, and produces useful electrical work while operating in a cycle analogous to a simple vapor cycle engine. Based on the application of the first law of thermodynamics to the control volumes around the emitter (Houston, 1959; Angrist, 1976),

$$\text{Energy In} = \text{Energy Out} \tag{8.13.42}$$

i.e.,

$$q_{CB} + q_{JH} + q_{HS} = q_{EC} + q_{WB} + q_{CD} + q_{RA} \tag{8.13.43}$$

where, by using the terminology in Figure 8.13.14, each of the terms in Equation (8.13.43) can be elaborated as follows:

- (a) Energy supplied by back emission of the collector:

$$q_{CB} = J_{COEM} \left[ \Phi_{CO} + \delta + V + (2kT_{CO}/e) \right] \tag{8.13.44}$$

- (b) Energy supplied by joule heating of lead wires and plasma:

$$q_{JH} = 0.5 \left[ J_{EMCO} - J_{COEM} \right]^2 (R_{LW} + R_{PL}) \tag{8.13.45}$$

(c) Energy dissipated by electron cooling:

$$q_{EC} = J_{EMCO} \left[ \Phi_{CO} + \delta + V - \Phi_{EM} + (2kT_{EM})/e \right] \quad (8.13.46)$$

(d) Energy dissipated due to phase change by electron evaporation:

$$q_{WB} = J_{EM} \Phi_{EM} \quad (8.13.47)$$

(e) Energy dissipated by conduction through the lead wires and plasma:

$$q_{CD} = \Delta T \left[ (K_{LW} A_{LW} / A_e L_{LW}) + (K_{PL} A_{PL} / A_e L_{IG}) \right] \quad (8.13.48)$$

Here,  $K$  represents thermal conductivity, LW = lead wires, PL = plasma, and IG = interelectrode gap.

(f) Energy dissipated by radiation from emitter to collector:

$$q_{RA} = 5.67 \times 10^{-12} (T_{EM}^2 - T_{CO}^4) (\epsilon_{EM}^{-1} + \epsilon_{CO}^{-1} - 1)^{-1} \quad (8.13.49)$$

Substitution for the various terms in Equation (8.13.42) yields  $q_{HS}$ , the energy supplied to the emitter from the heat source.

The thermal efficiency of the thermionic converter is now expressed as

$$\eta_{TH} = \left[ V (J_{EMCO} - J_{COEM}) / q_{HS} \right] \quad (8.13.50)$$

## Design Transition to Space Reactors — Concluding Remarks

All the fundamentals discussed so far for a planar thermionic converter can be applied to a cylindrical version which then becomes the building block for space power systems at any power level. In a thermionic reactor, heat from the nuclear fission process produces the temperatures needed for thermionic emission to occur. The design of a thermionic SNPS is a user-defined compromise between the required output power and the need to operate reliably for a specified lifetime. Based on the type of contact the emitter has with the nuclear fuel, the power systems can be categorized as “in-core” or “out-of-core” power systems. At this stage it suffices to state that the emitter design for in-core systems is extremely complex because of its direct contact with the hot nuclear fuel.

## Defining Terms

**Electron motive:** A scalar quantity whose negative gradient at any point is a measure of the force exerted on an electron at that point.

**Free electrons:** Electrons available to be extracted from the emitter for thermionic emission.

**Heat source:** Electron bombardment heating of the emitter.

**Lead losses:** Voltage drop as a result of the built-in resistance of the leads and joints.

**Particle interaction losses:** Voltage drop in the interelectrode gap as a result of particle collisions and other interactions.

**Surface work function:** A measure of the electron-emitting capacity of the surface.

**Thermionic energy conversion:** Energy conversion from heat energy to useful electrical energy by thermionic electron emission.

## Thermoelectric Power Conversion

*Jean-Pierre Fleurial*

### Introduction

The advances in materials science and solid-state physics during the 1940s and 1950s resulted in intensive studies of thermoelectric effects and related applications in the late 1950s and through the mid-1960s (Rowe and Bhandari, 1983). The development of semiconductors with good thermoelectric properties made possible the fabrication of thermoelectric generators and refrigerators. Being solid-state devices, thermoelectric systems offer some unique advantages, such as high reliability, long life, small-size and no-vibrations refrigerators, and can be used in a wide temperature range, from 200 to 1300 K. However, because of their limited conversion efficiencies, these devices have remained confined to specialized applications. As the following sections will emphasize, the performance of those devices is closely associated with the magnitude of the **dimensionless figure of merit**,  $ZT$ , of the thermoelectric semiconductor.

$ZT$  represents the relative magnitude of electrical and thermal cross-effect transport in materials. State-of-the-art thermoelectric materials, known since the early 1960s, have been extensively developed. Although significant improvements of the thermoelectric properties of these materials have been achieved, a maximum  $ZT$  value close to 1 is the current approximate limit over the whole 100 to 1500 K temperature range (Figure 8.13.16). To expand the use of thermoelectric devices to a wide range of applications will require improving  $ZT$  by a factor of two to three. There is no theoretical limitation on

FIGURE 8.13.16 Typical temperature variations of  $ZT$  of state-of-the-art n-type thermoelectric alloys.

the value of  $ZT$ , and new promising approaches are now focusing on the investigation of totally different materials and the development of novel thin film heterostructure.

**Thermoelectric Effects**

Thermoelectric devices are based on two transport phenomena: the Seebeck effect for power generation and the Peltier effect for electronic refrigeration. If a steady temperature gradient is applied along a conducting sample, the initially uniform charge carrier distribution is disturbed as the free carriers located at the high-temperature end diffuse to the low-temperature end. This results in the generation of a back emf which opposes any further diffusion current. The open-circuit voltage when no current flows is the Seebeck voltage. When the junctions of a circuit formed from two dissimilar conductors (n- and p-type semiconductors) connected electrically in series but thermally in parallel are maintained at different temperatures  $T_1$  and  $T_2$ , the open-circuit voltage  $V$  developed is given by  $V = S_{pn}(T_1 - T_2)$ , where  $S_{pn}$  is the Seebeck coefficient expressed in  $\mu V \cdot K^{-1}$ .

The complementary Peltier effect arises when an electrical current  $I$  passes through the junction. A temperature gradient is then established across the junctions and the corresponding rate of reversible heat absorption  $\mathcal{Q}$  is given by  $\mathcal{Q} = \Pi_{pn}I$ , where  $\Pi_{pn}$  is the Peltier coefficient expressed in  $W \cdot A^{-1}$  or  $V$ . There is actually a third, less-important phenomenon, the Thomson effect, which is produced when an electrical current passes along a single conducting sample over which a temperature gradient is maintained. The rate of reversible heat absorption is given by  $\mathcal{Q} = \beta I(T_1 - T_2)$ , where  $\beta$  is the Thomson coefficient expressed in  $V \cdot K^{-1}$ . The three coefficients are related by the Kelvin relationships:

$$S_{pn} = \frac{\Pi_{pn}}{T} \quad \text{and} \quad \frac{dS_{pn}}{dT} = \frac{\beta_p - \beta_n}{T} \tag{8.13.51}$$

**Thermoelectric Applications**

The schematic of a thermoelectric device, or module, on Figure 8.13.17, illustrates the three different modes of operation: power generation, cooling, and heating. The *thermoelectric module* is a standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each side (typically alumina). The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples and can operate in a wide range of currents, voltages, powers, and efficiencies. Complex, large-scale thermoelectric systems can be easily designed and built by assembling various numbers of these modules connected in series or in parallel depending on the type of applications.

FIGURE 8.13.17 Schematic of a thermoelectric module.

*Power Generation.* When a temperature gradient is applied across the thermoelectric device, the heat absorbed at the hot junction (Figure 8.13.17, hot side  $T_h - T_1$  and cold side,  $T_c - T_2$ ) will generate a current through the circuit and deliver electrical power to the load resistance  $R_L$  (Harman and Honig, 1967). The conversion efficiency  $\eta$  of a thermoelectric generator is determined by the ratio of the electrical energy, supplied to the load resistance, to the thermal energy, absorbed at the hot junction, and is given by

$$\eta = \frac{R_L I^2}{S_{pn} I T_h + K(T_h - T_c) \square \frac{1}{2} R I^2} \tag{8.13.52}$$

where  $K$  is the thermal conductance in parallel and  $R$  is the electrical series resistance of one p-n thermoelectric couple. The electrical power  $P_L$  generated can be written as

$$P_L = \frac{S_{pn} (T_h - T_c)^2 R_L}{(R_L + R)^2} \tag{8.13.53}$$

The thermoelectric generator can be designed to operate at maximum power output, by matching the load and couple resistances,  $R_L = R$ . The corresponding conversion efficiency is

$$\eta_p = \frac{T_h - T_c}{\frac{3}{2} T_h + \frac{1}{2} T_c + \frac{1}{4} Z_{pn}^{-1}} \tag{8.13.54}$$

where  $Z_{pn}$  is the figure of merit of the p-n couple given by

$$Z_{pn} = \frac{S_{pn}^2}{RK} \tag{8.13.55}$$

The figure of merit can be optimized by adjusting the device geometry and minimizing the  $RK$  product. This results in  $Z_{pn}$  becoming independent of the dimensions of the **thermoelectric legs**. Moreover, if the p- and n-type legs have similar transport properties, the figure of merit,  $Z_{pn} = Z$ , can be directly related to the Seebeck coefficient  $S$ , electrical conductivity  $\sigma$  or resistivity  $\rho$ , and thermal conductivity  $\lambda$  of the thermoelectric material:

$$Z = \frac{S^2}{\rho \lambda} = \frac{S^2 \sigma}{\lambda} \tag{8.13.56}$$

The maximum performance  $\eta_{\max}$  of the generator is obtained by optimizing the load-to-couple-resistance ratio, leading to the maximum energy conversion efficiency expressed as

$$\eta_{\max} = \frac{T_h - T_c}{T_h} \frac{\sqrt{1 + Z_{\text{pn}} T_{\text{av}}} - 1}{\sqrt{1 + Z_{\text{pn}} T_{\text{av}}} + \frac{T_c}{T_h}} \tag{8.13.57}$$

It must be noted that the maximum efficiency is thus the product of the Carnot efficiency, less than unity, and of a material-related efficiency, increasing with increasing  $Z_{\text{pn}}$  values as illustrated in Figure 8.13.18.

FIGURE 8.13.18 Maximum conversion efficiency  $\eta_{\max}$  as a function of the average material figure of merit  $ZT$ , calculated using Equation (8.13.57) for two systems operating in different temperature ranges: the radioisotope generator (RTG) used for deep space missions and an automobile waste heat recovery generator.

*Refrigeration.* When a current source is used to deliver electrical power to a thermoelectric device, heat can be pumped from  $T_1$  to  $T_2$  and the device thus operates as a refrigerator (Figure 8.13.17, hot side  $T_h = T_2$  and cold side,  $T_c = T_1$ ). As in the case of a thermoelectric generator the operation of a thermoelectric cooler depends solely upon the properties of the p-n thermocouple materials expressed in terms of the figure of merit  $Z_{\text{pn}}$  and the two temperatures  $T_c$  and  $T_h$  (Goldsmid, 1986). The conversion efficiency or **coefficient of performance**, COP, of a thermoelectric refrigerator is determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source and is given by

$$\text{COP} = \frac{S_{\text{pn}} T_c I - \frac{1}{2} RI^2 - K(T_h - T_c)}{S_{\text{pn}} (T_h - T_c) I + RI^2} \tag{8.13.58}$$

There are three different modes of operation which are of interest to thermoelectric coolers. A thermoelectric cooler be designed to operate at maximum cooling power,  $Q_{C_{\max}}$ , by optimizing the value of the current:

$$I_{Q_{C_{\max}}} = \frac{S_{\text{pn}} T_c}{R} \text{ and } Q_{C_{\max}} = \frac{1}{2} \frac{(S T_c)^2}{R} - K(T_h - T_c) \tag{8.13.59}$$

Similarly, the conditions required for operating at maximum efficiency,  $COP_{max}$ , across a constant temperature gradient, are determined by differentiating Equation (8.13.58) with respect to  $I$ , with the solution:

$$I_{COP_{max}} = \frac{K(T_h - T_c)_c}{S_{pn} T_{av}} \left( 1 + \sqrt{1 + Z_{pn} T_{av}} \right) \tag{8.13.60}$$

$$COP_{max} = \frac{T_c}{T_h - T_c} \frac{\sqrt{1 + Z_{pn} T_{av}} - \frac{T_h}{T_c}}{\sqrt{1 + Z_{pn} T_{av}} + 1} \tag{8.13.61}$$

By reversing the input current to the device, the thermoelectric refrigerator can become a heat pump, with  $T_1$  being the hot junction temperature. The expression of the maximum conversion efficiency of the heat pump is very similar to Equation (8.13.61) because of the following relationship:

$$\left( COP_{max} \right)^{heat\ pump} = 1 + \left( COP_{max} \right)^{refrigerator} \tag{8.13.62}$$

The maximum COP expression in Equation (8.13.61) is similar to the one derived for the conversion efficiency  $\eta$  of a thermoelectric generator in Equation (8.13.57). However, there is a major difference between the  $COP_{max}$  and  $\eta_{max}$  parameters. Clearly,  $\eta_{max}$  increases with increasing  $\Delta T$  values but is limited by the Carnot efficiency (Equation 8.13.54) which is less than 1, while  $COP_{max}$  in Equation (8.13.52) increases with decreasing  $\Delta T$  values and can reach values much larger than 1. Figure 8.13.19 represents the variations of the  $COP_{max}$  of a thermoelectric cooling device optimized for working voltage and geometry as a function of average  $ZT$  values and temperature differences (hot junction temperature at 300 K). The average  $ZT$  value for current state-of-the-art commercially available materials ( $Bi_2Te_3$ -based alloys) is about 0.8. For example, it can be seen that a  $COP_{max}$  of 4 is obtained for a  $(T_h - T_c)$  difference of 10 K, meaning that to pump 8 W of thermal power only 2 W of electrical power needs to be provided to the thermoelectric cooling device. This also means that 10 W of thermal power will be rejected at the hot side of the cooler.

**FIGURE 8.13.19** Maximum material coefficient of performance  $COP_{max}$  of a single-stage thermoelectric cooler calculated using Equation (8.13.61) as a function of the cold-side temperature (hot-side temperature of 300 K). Curves corresponding to various values of the average material figure of merit are displayed.

The operation of a thermoelectric refrigerator at maximum cooling power necessitates a substantially higher input current than the operation at maximum efficiency. This is illustrated by calculating the variations of the maximum COP and cooling power with the input current and temperature difference which have been plotted in Figures 8.13.20 and 8.13.21. The calculation was based on the properties of a thermoelectric cooler using state-of-the-art  $\text{Bi}_2\text{Te}_3$ -based alloys, and the arbitrary units are the same for both graphs. It can be seen that  $I_{\text{COP,max}}$  increases while  $I_{Q_c,\text{max}}$  decreases with increasing  $\Delta T$ . Also, it is possible to operate at the same cooling power with two different current values.

**FIGURE 8.13.20** Three-dimensional plot of the variations of the COP of a thermoelectric cooler as a function of the operating current and the temperature difference.

**FIGURE 8.13.21** Three-dimensional plot of the variations of the cooling power of a thermoelectric cooler as a function of the operating current and the temperature difference.

Finally, the third problem of interest for thermoelectric coolers is to determine the maximum temperature difference,  $\Delta T_{\text{max}}$ , that can be achieved across the device. As shown on Figure 8.13.21, by operating at maximum cooling power and extrapolating Equation (8.13.59) to  $Q_{c,\text{max}} = 0$ ,  $\Delta T_{\text{max}}$  is given by

$$\Delta T_{\max} = \frac{1}{2} Z_{\text{pn}} T_c^2 \quad \text{and} \quad T_{c \min} = \frac{\sqrt{1 + 2Z_{\text{pn}} T_h} - 1}{Z_{\text{pn}}} \quad (8.13.63)$$

where  $T_{c \min}$  corresponds to the lowest cold-side temperature achievable. If the cooler operates at a  $\Delta T$  close to  $\Delta T_{\max}$  or higher, it becomes necessary to consider a cascade arrangement with several **stages**. The COP of an  $n$ -stage thermoelectric cooler is optimized if the COP of each stage,  $\text{COP}_i$ , is the same, which requires  $\Delta T_i / T_{i-1}$  to be the same for each stage. The overall maximum COP is then expressed as

$$\text{COP}_{\max} = \frac{1}{\left( \prod_{i=1}^n \left( 1 + \frac{1}{\text{COP}_i} \right) - 1 \right)} \quad (8.13.64)$$

### Additional Considerations

When considering the operation of an actual thermoelectric device, several other important parameters must be considered. The thermal and electrical contact resistances can substantially degrade the device performance, in particular for short lengths of the thermoelectric legs. For example, the conversion efficiency of a radioisotope generator system is about 20% lower than the value calculated in [Figure 8.13.18](#) for the thermoelectric materials only. The electrical contact resistance arises from the connection (see [Figure 8.13.17](#)) of all the legs in series. Typical values obtained for actual generators and coolers are 10 to 25  $\mu\Omega \cdot \text{cm}^2$ . The thermal contact resistance is generated by the heat-transfer characteristics of the ceramic plates and contact layers used to build the thermoelectric module. The heat exchangers and corresponding heat losses should also be taken into account.

In addition, the transport properties of the thermoelectric materials vary with temperature, as illustrated in [Figure 8.13.16](#). When a thermoelectric device is operating across a wide temperature range, these variations should be factored in the calculation of its performance.

## Nomenclature

COP	coefficient of performance
$\text{COP}_{\max}$	maximum coefficient of performance
$\text{COP}_i$	coefficient of performance of the $i$ th stage of a multistage thermoelectric cooler
$I$	current intensity
$I_{\text{COP}_{\max}}$	current intensity required to operate a thermoelectric cooler at maximum conversion efficiency
$I_{Q_c \max}$	current intensity required to operate a thermoelectric cooler at maximum cooling power
$K$	thermal conductance
$Q$	rate of reversible heat absorption
$R$	electrical resistance
$R_L$	load resistance
$P_L$	electrical power delivered to the load resistance
$S$	Seebeck coefficient
$S_{\text{pn}}$	Seebeck coefficient of a p-n couple of thermoelements
$T_1$	temperature
$T_2$	temperature
$T_{\text{av}}$	average temperature across the thermoelectric device
$T_c$	cold-side temperature of a thermoelectric device
$T_{c \min}$	minimum cold-side temperature which can be achieved by a thermoelectric cooler
$T_h$	hot-side temperature of a thermoelectric device
$V$	voltage; open-circuit voltage
$Z$	thermoelectric figure of merit

$Z_{pn}$	thermoelectric figure of merit of a p-n couple of thermoelements
$ZT$	dimensionless thermoelectric figure of merit
$\beta$	Thomson coefficient
$\beta_p$	Thomson coefficient for the p-type thermoelement
$\beta_n$	Thomson coefficient for the n-type thermoelement
$\Delta T$	temperature difference across a thermoelectric device
$\Delta T_{\max}$	maximum temperature difference which can be achieved across a thermoelectric cooler
$\eta$	thermoelectric conversion efficiency
$\eta_{\max}$	maximum thermoelectric conversion efficiency
$\lambda$	thermal conductivity
$\Pi_{pr}$	Peltier coefficient
$\rho$	electrical resistivity

## Defining Terms

**Coefficient of performance:** Electrical to thermal energy conversion efficiency of a thermoelectric refrigerator, determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source.

**Dimensionless figure of merit:** The performance of a thermoelectric device depends solely upon the properties of the thermoelectric material, expressed in terms of the dimensionless figure of merit  $ZT$ , and the hot-side and cold-side temperatures.  $ZT$  is calculated as the square of the Seebeck coefficient times the absolute temperature divided by the product of the electrical resistivity to the thermal conductivity. The best  $ZT$  values are obtained in heavily doped semiconductors, such as  $\text{Bi}_2\text{Te}_3$  alloys,  $\text{PbTe}$  alloys, and  $\text{Si-Ge}$  alloys.

**Stage:** Multistage thermoelectric coolers are used to achieve larger temperature differences than possible with a single-stage cooler composed of only one module.

**Thermoelectric leg:** Single thermoelectric element made of n-type or p-type thermoelectric material used in fabricating a thermoelectric couple, the building block of thermoelectric modules. The geometry of the leg (cross-section-to-length ratio) must be optimized to maximize the performance of the device.

**Thermoelectric module:** Standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each. The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples.

## Further Information

The *Proceedings of the Annual International Conference on Thermoelectrics* are published annually by the International Thermoelectric Society (ITS). These proceedings provide the latest information on thermoelectric materials research and development as well as thermoelectric devices and systems. The ITS also publishes a semiannual newsletter. For ITS membership or questions related to thermoelectrics, you may contact the current ITS secretary: Dr. Jean-Pierre Fleurial, Jet Propulsion Laboratory, MS 277-212, Pasadena, CA 91109. Phone (818)-354-4144. Fax (818) 393-6951. E-mail jean-pierre.fleurial@jpl.nasa.gov.

Also, the *CRC Handbook of Thermoelectrics*, edited by D.M. Rowe was published by CRC Press Inc., Boca Raton, FL, became available in 1996. This handbook covers all current activities in thermoelectrics.

## Magnetohydrodynamic Power Generation

*William D. Jackson*

### Introduction

The discipline known as magnetohydrodynamics (MHD) deals with the interactions between electrically conducting fluids and electromagnetic fields. First investigated experimentally by Michael Faraday in 1832 during his efforts to establish the principles of electromagnetic induction, application to energy conversion yields a heat engine which has its output in electrical form and, therefore, qualifies as a direct converter. This is generally referred to as an MHD generator, but could be better described as an electromagnetic turbine as it operates on a thermodynamic cycle similar to that of a gas turbine.

The operating principle is elegantly simple, as shown in Figure 8.13.22. A pressurized, electrically conducting fluid flows through a transverse magnetic field in a channel or duct. Electrodes located on the channel walls parallel to the magnetic field and connected through an external circuit enable the motionally induced “Faraday electromotive force” to drive an electric current through the circuit and thus deliver power to a load connected into it. Taking the fluid velocity as  $\mathbf{u}$  and the magnetic flux density as  $\mathbf{B}$ , the intensity of the motionally induced field is  $\mathbf{u} \times \mathbf{B}$ . The current density,  $\mathbf{J}$ , in the channel for a scalar conductivity  $\sigma$  is then given by Ohm’s law for a moving conductor as

**FIGURE 8.13.22** Principle of electromagnetic turbine or MHD generator.

$$\mathbf{J} = \sigma[\mathbf{E} + \mathbf{u} \times \mathbf{B}]$$

By taking the coordinates of Figure 8.13.22 and assuming that the quantities are constant, the power density flow from the MHD generator is, using  $\mathbf{E} \cdot \mathbf{J}$

$$w_e = \sigma u_x^2 B^2 k(1 - k)$$

where  $k = Ez/uv \times B$  is the “loading factor” relating loaded electric field to open circuit induction and is used in the same manner as the regulation of an electrical machine is applied to its terminal voltage.

It is instructive at this point to determine the power density of an MHD generator using values representative of the most commonly considered type of MHD generator. Combustion gas with  $\sigma = 10$  S/m, a flow velocity of 800 m/sec and an applied field of 5 T for maximum power transfer ( $k = 0.5$ ) yields  $w_e$  as 40 MW/m<sup>3</sup>. This value is sufficiently attractive to qualify MHD generators for bulk power applications. An intensive, worldwide development effort to utilize this and other MHD generator properties has been conducted since the late 1950s. However, this has not yet led to any significant application of MHD generators. To understand how this has come about and what still needs to be accomplished to make MHD attractive will now be summarized.

### Electrical Conductivity Considerations

Two approaches have been followed to obtain adequate ionization and, therefore, conductivity in the working fluid. What may be termed the mainline approach to achieving electrical conductivity is to add a readily ionizable material to “seed” the working fluid. Alkali metals with ionization potentials around 4 V are obvious candidates, although a lower value would be highly desirable. A potassium salt with an ionization potential of 4.09 eV has been widely used because of low cost but cesium with a 3.89-eV value is the preferred seed material when the running time is short or the working fluid is recycled. There are two methods of ionization:

1. Thermal ionization in which recombination ensures a common temperature for electrons, ions, and neutrals; the mass action law (Saha equation) is followed; and the heat of ionization in electron volts is the ionization potential; and
2. Extrathermal or nonequilibrium ionization where electrons and heavy particles are at different temperatures and the concept of entwined fluids (electron, ion, and neutral gases) is involved.

The former is applicable to diatomic combustion gases while the latter occurs in monatomic (noble) gases but is also observed in hydrogen. Only a small amount of seed material is required and is typically around 1% of the total mass flow for maximum conductivity.

The existence of mutually perpendicular **E** and **B** fields in an MHD generator is of major significance in that the electrons are now subjected to the Hall effect. This causes electrons and, therefore, electric currents to flow at an angle with respect to the **E** field in the collision-dominated environment of the MHD generator. The presence of a significant Hall effect requires that the electrical boundary conditions on the channel be carefully selected and also introduces the possibility of working fluid instabilities driven by force fluctuations of electrical origin. A further source of fluctuations and consequent loss of conductivity occurs when nonequilibrium ionization is employed due to current concentration by Joule heating. This latter effect is controlled by operating only in a regime where, throughout the channel, complete ionization of the seed material is achieved.

### Generator Configurations and Loading

The basic consequence of the Hall effect is to set up **E** fields in both transverse and axial directions in the generator channel and these are generally referred to as the Faraday and Hall fields, respectively. The direction of the Faraday field depends on the magnetic field; the Hall field depends on the Hall parameter and is always directed toward the upstream end of the channel. These considerations, in turn, lead to the MHD generator having the characteristics of a gyrator — a two-terminal pair power-producing device in which one terminal pair (Faraday) is a voltage source and the other (Hall) is a current source dependent in this case on the Hall parameter. Electric power can be extracted from either the Faraday or Hall terminals, or both.

This has resulted in several electrical boundary conditions being utilized with the axial flow channel as shown in [Figure 8.13.23](#). These are most readily understood by treating each anode-cathode pair as a generating cell. The segmented Faraday configuration ([Figure 8.13.23a](#)) is then simply a parallel operation of cells which leads to the apparently inconvenient requirement of separate loading of individual

cells: the Hall connection (Figure 8.13.23b) utilizes a single load by series connection but depends on the Hall parameter for its performance; and the diagonal connection (Figure 8.13.23c) connects the cells in series-parallel and so avoids Hall parameter dependence while retaining the single load feature. In all three linear configurations, the channel walls are electrically segmented to support the Hall field, and experience has shown that this must be sufficiently finely graded so that no more than 50 V is supported by the interelectrode gaps to avoid electrical breakdown.

FIGURE 8.13.23 Basic Faraday linear MHD generator.

The MHD generator is a linear version of the homopolar machine originally demonstrated by Faraday and is, as a practical matter, confined to DC generation. Accordingly, some form of DC-AC conversion using power electronics is required for the vast majority of applications. The single load feature loses significance in this situation as the “power conditioning” can readily be arranged to combine (consolidate) the individual cell outputs before conversion to the required AC system conditions. Indeed, to maximize power extraction while limiting interelectrode voltages and controlling electrode currents (to ensure adequate lifetime), the power conditioning is arranged to extract power from both Faraday and Hall terminal pairs.

An alternative geometry is to set up a radial flow (usually but not necessarily outward) with the disk configuration of Figure 8.13.23d. The result is a Hall generator, which is generally favored for nonequilibrium ionization as it avoids the inevitable nonuniformities associated with electrode segmentation with their proclivity for promoting ionization instabilities. A measure of Faraday performance is achievable through the introduction of swirl, and additional ring electrodes enable power conditioning to control (and optimize) the radial electric field.

### Components

An MHD generator per se requires several components to make up a complete powertrain. In addition to the power conditioning needed for DC-AC conversion these include a magnet, seed injector, combustor with fuel and oxidizer supply or an input heat exchanger, nozzle, compressor, diffuser, exhaust gas-cleaning system (for once-through systems), and controls. The need to accommodate a channel between the poles of a magnet qualifies the MHD generator as a large-air-gap machine.

## Systems

Power systems incorporating MHD generators are either of the once-through (open-cycle) or working fluid recycle (closed-cycle) type, and the complete MHD system described in the previous section can either be stand-alone or incorporated into a more complex configuration such as a binary cycle. In the latter case, the high-temperature operation of the MHD unit makes it a topping cycle candidate and it is in this mode that MHD has received most system consideration. An MHD generator operated directly on ionized combustion gas is usually associated with an open cycle while nonequilibrium ionization with seeded noble gases and LMMHD are invariably considered for closed-cycle operation. An exception is nonequilibrium ionization in cesium-seeded hydrogen which has received some attention for open-cycle operation.

## Heat Sources, Applications, and Environmental Considerations

A heat source capable of providing from 1000 K for LMMHD to over 3000 K for open-cycle systems for power production is a candidate. Rocket motor fuels, all fossil fuels, high-temperature nuclear reactors cooled with hydrogen and biomass are suitable for open cycles, while closed cycles can be driven through a heat exchanger by any of these combustion sources. A high-temperature nuclear reactor, probably helium cooled, is also a feasible source for MHD and in the early stages of development of the process received much attention. With the abandonment of efforts to develop commercial reactors to operate at temperatures above 1200 K, attention has focused on high-energy fuels for pulse power (few seconds) operation and coal for utility power generation.

While the debate over the role of fossil energy in the long-term electricity generation scenario continues, it is established that coal is a major resource which must be utilized at maximum efficiency to limit CO<sub>2</sub> production and must be combusted in a manner which reduces SO<sub>2</sub> and NO<sub>x</sub> effluents to acceptable levels. The use of MHD generators significantly advances all of these objectives. Briefly, it was first observed that the “electromagnetic turbine” has the major advantage that it cannot only provide the highest efficiency of any known converter from the Carnot viewpoint but that its operation is not adversely affected by coal slag and ash. Indeed, slag provides an excellent renewable coating for the channel walls and increases lifetime.

System calculations have shown that, when coupled as a topping cycle to the best available steam plant technology, a thermal efficiency with coal and full environmental control is 52.5%. When coupled into a ternary cycle with either a gas turbine or fuel cells and a steam turbine, efficiencies upward of 60% are possible.

## Technology Status

A pulse-type MHD generator was successfully built and operated by Avco (now Textron Defense Industries) in 1963 and a complete natural gas-fired pilot plant with a nominal 20-MW MHD generator was commissioned in the U.S.S.R. on the northern outskirts of Moscow in 1971. In the decade of the 1980s, development was focused on coal firing as a result of the oil crises of the 1970s and in the U.S. progressed to the point where the technology base was developed for a demonstration plant with a 15-MW MHD generator.

## Future Prospects

The two particular attributes of the MHD generator are its rapid start-up to multimegawatt power levels for pulse power applications and its ability to provide a very high overall thermal efficiency for power plants using coal while meeting the most stringent environmental standards. The first has already been utilized in crustal exploration, and the second must surely be utilized when coal is the fuel of choice for electric power production. In the meantime, MHD has been established as a viable technology on which further development work will be conducted for advanced applications such as the conversion system for thermonuclear fusion reactors.

## Further Information

The following proceedings series contain a full and complete record of MHD generator and power system development:

1. *Proceedings of the Symposia for the Engineering Aspects of Magnetohydrodynamics*, held annually in the U.S. since 1960 (except for 1971 and 1980).
2. *Proceedings of 11 International Conferences on Magnetohydrodynamic Electrical Power Generation*, held in 1962, 1964, 1966, 1968, 1971, 1975, 1980, 1983, 1986, 1989, and 1992. The 12th conference will be held in Yokohama, Japan in October 1996.

## 8.14 Ocean Energy Technology

---

*Desikan Bharathan and Federica Zangrando*

The ocean contains a vast renewable energy potential in its waves and tides, in the temperature difference between cold, deep waters and warm surface waters, and in the salinity differences at river mouths (SERI, 1990; WEC, 1993; Cavanagh et al., 1993). Waves offer a power source for which numerous systems have been conceived. Tides are a result of the gravity of the sun, the moon, and the rotation of the Earth working together. The ocean also acts as a gigantic solar collector, capturing the energy of the sun in its surface water as heat. The temperature difference between warm surface waters and cold water from the ocean depths provides a potential source of energy. Other sources of ocean energy include ocean currents, salinity gradients, and ocean-grown biomass.

The following sections briefly describe the status and potential of the various ocean energy technologies, with emphasis placed on those with a near-term applicability.

### Ocean Thermal Energy Conversion

**Ocean thermal energy conversion (OTEC)** technology is based on the principle that energy can be extracted from two reservoirs at different temperatures (SERI, 1989). A temperature difference as little as 20°C can be exploited effectively to produce usable energy. Temperature differences of this magnitude prevail between ocean waters at the surface and at depths up to 1000 m in many areas of the world, particularly in tropical and subtropical latitudes between 24° north and south of the equator. Here, surface water temperatures typically range from 22 to 29°C, while temperatures at a depth of 1000 m range from 4 to 6°C. This constitutes a vast, renewable resource, estimated at 10<sup>13</sup> W, for potential baseload power generation.

Recent research has been concentrated on two OTEC power cycles, namely, **closed-cycle** and **open-cycle**, for converting this thermal energy to electrical energy (Avery and Wu, 1994). Both cycles have been demonstrated, but no commercial system is yet in operation. In a closed-cycle system, warm seawater is used to vaporize a working fluid such as ammonia flowing through a heat exchanger (evaporator). The vapor expands at moderate pressures and turns a turbine. The vapor is condensed in another heat exchanger (condenser) using cold seawater pumped from the ocean depths through a cold-water pipe. The condensed working fluid is pumped back to the evaporator to repeat the cycle. The working fluid remains in a closed system and is continuously circulated. In an open cycle system, the warm seawater is “flash” evaporated in a vacuum chamber to make steam at an absolute pressure of about 2.4 kPa. The steam expands through a low-pressure turbine coupled to a generator to produce electricity. The steam exiting the turbine is condensed by using cold seawater pumped from the ocean depths through a cold-water pipe. If a surface condenser is used, condensed steam provides desalinated water.

Effluent from either a closed cycle or an open cycle system can be further processed to enhance production of desalinated water through a flash evaporator/condenser system in a second stage.

For combined production of power and water, these systems are estimated to be competitive with conventional systems in several coastal markets.

### Tidal Power

The energy from tides is derived from the kinetic energy of water moving from a higher to a lower elevation, as for hydroelectric plants. High tide can provide the potential energy for seawater to flow into an enclosed basin or estuary that is then discharged at low tide (Ryan, 1980). Electricity is produced from the gravity-driven inflow or outflow (or both) through a turbogenerator. The tidal resource is variable but quite predictable, and there are no significant technical barriers for deployment of this technology. Because costs are strongly driven by the civil works required to dam the reservoir, only a few sites around the world have the proper conditions of tides and landscape to lend themselves to this technology.

Although it has benefited from some recent developments in marine and offshore construction that significantly reduce construction time and costs, the economics of tidal power production still does not make it competitive with conventional energy systems.

The highest tides in the world can reach above 17 m, as in the Bay of Fundy between Maine and Nova Scotia, where it is projected that up to 10,000 MW could be produced by tidal systems in this bay alone. A minimum tidal range (difference between mean high and low tides) of 5 m is required for plants using conventional hydroelectric equipment (horizontal axial-flow water turbines housed in underwater bulbs or Straflo turbines). More recently, low-head hydroelectric power equipment has proved adaptable to tidal power and new systems for 2-m heads have been proposed.

There are a few tidal power stations operating in France, the former U.S.S.R., China, and Canada. The largest and longest-operating plant is the 240-MW tidal power station on the Rance River estuary in northern France (Banal and Bichon, 1981), which has operated with 95% availability since 1968. The 400-kW tidal plant in Kislaya Bay on the Barents Sea in the former U.S.S.R. has been operating since 1968; at this favorable site only a 50-m-wide dam was needed to close the reservoir. The 20-MW Canadian plant at Annapolis on the Bay of Fundy uses a Straflo turbine generator and has operated reliably since 1984. A number of small-bulb and Straflo turbine generator plants of up to 4 MW are also installed on the China coastline.

## Wave Power

Waves contain significant power which can be harnessed by shore-mounted or offshore systems, the latter having larger incident power on the device but requiring more costly installations. A myriad of wave-energy converter concepts have been devised, transforming wave energy into other forms of mechanical (rotative, oscillating, or relative motion), potential, or pneumatic energy, and ultimately into electricity; very few have been tested at sea.

The power per unit frontal length of the wave is proportional to wave height squared and to wave period, with their representative values on the order of 2 m and 10 sec. The strong dependence on wave height makes the resource quite variable, even on a seasonal and a yearly average basis. The northeastern Pacific and Atlantic coasts have average yearly incident wave power of about 50 kW/m, while near the tip of South America the average power can reach 100 kW/m. Japan, on the other hand, receives an average of 15 kW/m. Waves during storms can reach 200 kW/m, but these large waves are unsafe for operation because of their severity, and they impose significant constraints and additional costs on the system. Overall, the amount of power that could be harvested from waves breaking against world coastlines is estimated to be on the order of the current global consumption of energy. However, total installed capacity amounts to less than 1 MW worldwide.

A commonly deployed device is the oscillating water column (OWC), which has so far been mounted on shore but is also proposed for floating plants. It consists of an air chamber in contact with the sea so that the water column in the chamber oscillates with the waves. This motion compresses the air in the chamber, which flows in and out of a Wells turbine. This turbine can be self-rectifying, i.e., it uses the airflow in both directions, and it consists of a simple rotor, with symmetrical airfoil blades attached tangentially to a central disk. Inertial energy storage (flywheels) is often used to even out the variable pneumatic energy delivered by the air.

Two of the largest wave-energy power plants were built at Toftehallen, near Bergen, Norway. A Norwegian company, Norwave A.S., built a 350-kW tapered channel (Tapchan) device in 1984, which survived a severe storm in 1989 (the 500 kW multi-resonant OWC plant built by Kvaerner Brug A.S. did not). The channel takes advantage of the rocky coastline to funnel waves through a 60-m-wide opening into a coastal reservoir of 5500 m<sup>2</sup>, while maintaining civil engineering costs to a minimum. Wave height increases as the channel narrows over its 60-m length, and the rising waves spill over the 3-m-high channel walls, filling the reservoir. Continuous wave action maintains the reservoir level at a relatively constant elevation above sea level, providing potential energy for a low-head hydroelectric Kaplan turbogenerator. Estimates by Norwave to rebuild an identical plant at this site suggested capital

costs of \$3500/kW installed, and energy costs of 8¢/kWhr, at a plant capacity factor of 25% (ASCE, 1992). In recent efforts, the National Institute of Ocean Technology has installed a 150-kW wave-energy conversion device in the southern tip of India.

## Concluding Remarks

Among the many ocean energy prospects, OTEC, tides, and tapered channel wave-energy converters offer the most near-term potential and possess applicability for a large variety of sites. To realize their potential, additional research and development is required.

## Defining Terms

**Ocean thermal energy conversion (OTEC):** A system that utilizes the temperature difference between the seawater at the surface and at depths.

**Closed-cycle OTEC:** Uses a working fluid in a closed cycle.

**Open-cycle OTEC:** Uses steam flashed from the warm seawater as the working fluid which is condensed and exhausted.

In the past two decades, several cycles which combine the gas turbine and the steam turbine have become available with good fuel utilization compared with other available power plants. The first ones in the 1970s had net plant efficiencies of about 40% with the most recent ones achieving net plant efficiencies of over 55%.

One way to utilize the energy available in gas turbine exhaust gases is as the energy source for a steam power plant. This is called a *combined cycle* and uses components from two systems which have independently proved themselves. The combined cycle power plant usually consists of one or more gas turbine engines exhausting into a heat-recovery steam generator (HRSG) where the energy is transferred from the exhaust gases to the water in the steam power plant.

The simplest arrangement for a combined cycle power plant is the single-pressure system as illustrated in Figure 8.15.1. It consists of the HRSG, a turbine, condenser, and pump. In this simplified configuration, it is assumed that no additional fuel is burned between the gas turbine and the HRSG.

The gases leaving the gas turbine engine enter the HRSG at state 4 and leave the HRSG at state 5. The water in the steam cycle portion of the combined cycle enters the HRSG economizer as a subcooler liquid (state a). The temperature of the water is increased in the economizer until it is a saturated liquid (state m). This is the point where the minimum temperature difference between the water in the steam cycle and the exhaust gases occurs and is called the *pinch point*. Typical pinch point values range from 10 to 30°C; the smaller the pinch point difference, the larger the required heat-transfer surface area. From state m to state v, the water is changed from a saturated liquid to a saturated vapor. From state v to state d, the water is superheated where it has its maximum temperature. A typical temperature-heat transfer diagram for this single-pressure steam turbine combined cycle is illustrated in Figure 8.15.2.

One should note that there is a significant difference between the desired feedwater conditions of a combined cycle power plant and a conventional steam power plant. In a combined cycle power plant, it is desirable to have the temperature of the water at as low a temperature as possible as it enters the HRSG to permit the maximum amount of energy to be transferred from the exhaust gases to the water

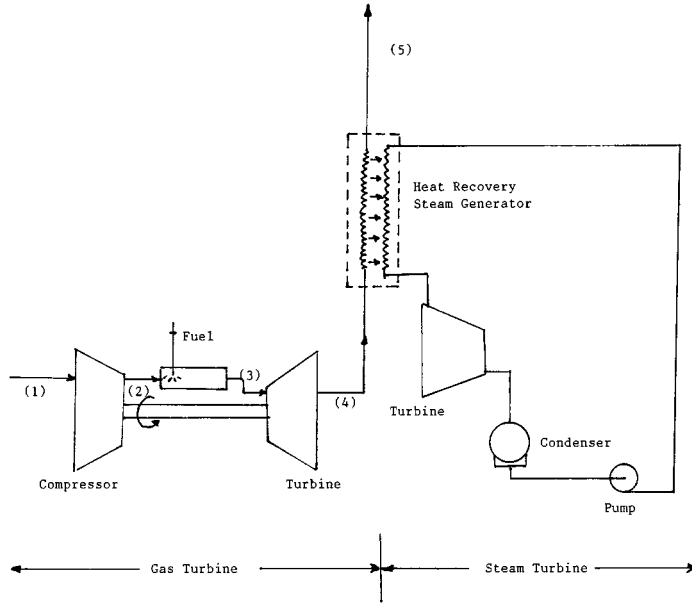

FIGURE 8.15.1 Combined cycle power plant with no supplementary firing.

FIGURE 8.15.2 Typical temperature-heat transfer diagram for a single-pressure combined cycle power plant.

since the more energy transferred, the greater the amount of power produced by the steam turbine and the higher the combined cycle thermal efficiency or the lower the heat rate. In a conventional steam cycle power plant, the higher the feedwater temperature as it enters the steam generator (boiler), the higher the cycle thermal efficiency. Conventional steam cycle power plants achieve the higher feedwater temperature by the use of feedwater heaters.

Table 8.15.2 lists net plant output, heat rate, and net plant efficiency values for several combined cycles. One should observe for the units listed in Table 8.15.2 that

1. The size varies widely from a low of 22,800 kW to a high of 711,000 kW;
2. The heat rates vary from 7880 to 5885 Btu/kWhr. These compare with heat rate values for the gas turbines listed in Table 8.15.1 that vary from a high of 12,544 Btu/kWhr to a low of 8980 Btu/kWhr.
3. The net plant efficiency varies from a low of 42.8% to a high of 57.0%;
4. The fraction of the total net plant output from the steam turbine power plant in most cases ranges from 35 to 39%.

Source: 1995 Handbook, Gas Turbine World, Southport, CT, 1995. With permission.

One should keep in mind that only a few of the combined cycle plants currently available are listed in Table 8.15.2. The ones listed are intended to illustrate the range in net plant output and heat rate values and should not be interpreted as a list of all units currently available.

The amount of energy transferred in the HRSG is dependent on the steam pressure. This is illustrated in Figure 8.15.3. In this comparison, it is assumed in both cases that the steam exit temperature is the same and that the exhaust gas HRSG inlet temperature and flow rate are the same. One observes that the pressure of the water dictates the temperature at which evaporation occurs. The higher the evaporation temperature (and therefore steam pressure), the lower the mass flow rate of the steam, and therefore the lower the power generated by the steam power plant. It is obvious that the lower the steam pressure, the lower the flue gas temperature.

The output of an unfired single-pressure combined cycle power plant is determined by the gas turbine selected since this fixes the temperature and mass flow rate of the exhaust gases. One way to increase the steam cycle output is to introduce supplementary firing in the exhaust duct between the gas turbine exit and HRSG inlet. This is shown schematically in Figure 8.15.4. The advantages of adding supplementary firing are

**FIGURE 8.15.3** Effect of steam cycle pressure on energy transferred for a single-pressure combined cycle power plant.

1. The total output from the combined cycle will increase with a higher fraction of the output coming from the steam turbine cycle;
2. The temperature at the inlet to the HRSG can be controlled. This is important since the temperature and mass flow rate at the exit from the gas turbine are very dependent on the ambient temperature.

Figure 8.15.5 illustrates the effect on the temperature of the exhaust gases at the exit from the HRSG for unfired and supplementary fired combined cycles with the same pinch point temperature.

Combined cycle power plants with a single-pressure steam turbine do not maximize utilization of the energy in the exhaust gases. The ideal temperature-heat transfer diagram would be one where the temperature difference in the HRSG between the water (steam) and the exhaust gases is a constant.

One way to approach this constant temperature difference and improve the utilization of the energy in the exhaust gases is to use multipressures in the steam power plant cycle. Systems which have been used are

1. A dual pressure nonreheat cycle;
2. A dual-pressure reheat cycle; and
3. A triple-pressure reheat cycle.

Each system listed above has advantages and disadvantages. As new gas turbine engines enter the market with increased turbine inlet temperatures and component efficiencies, exhaust temperature from the gas turbine increases. This allows for higher superheated steam temperatures and improved combined cycle power plant efficiencies. This means that each design must be analyzed so that the selected design yields the most economical system.

FIGURE 8.15.4 Combined cycle power plant with supplementary firing.

**FIGURE 8.15.6** Schematic diagram for a three-pressure steam turbine combined cycle with superheating and reheat.

A simplified schematic diagram for a three-pressure combined cycle power plant is shown in [Figure 8.15.6](#). This arrangement results in a high quality at the exit from the low-pressure steam turbine.

## 8.16 EMERGY Evaluation and Transformity

*Howard T. Odum*

**EMERGY** (spelled with an “m”) evaluation is a method of energy analysis that puts all inputs and products on a common basis of what was previously required directly and indirectly to make each from one form of energy.

EMERGY is the available energy of one kind previously used up directly and indirectly to make a service or product.

Its unit is the *emjoule*, defined to measure availability already used up. If average solar insolation at the earth’s surface is chosen as the common base for the convenience of evaluating environmental and technological energy flows, then evaluations are made in units of solar emjoules, abbreviated *sej*.

In every energy transformation, available energy is used up to produce a smaller amount of energy of another kind. The EMERGY of one kind required directly and indirectly to make one unit of energy of another kind is defined as *transformity* (Odum, 1988).

Solar transformity is the solar EMERGY of the inputs divided by the energy of the output.

$$\text{energy (J)} \times \text{transformity (sej/J)} = \text{EMERGY (sej)}$$

If all energy flows are expressed in solar EMERGY, then all kinds of energy may be compared according to their solar transformity. The more successive energy transformations there are, the higher the transformity. The higher the transformity, the more energy flows have converged in the process. Since many energy flows of one kind are usually required to support a smaller energy flow of another type, it is appropriate to describe the converging process as an *energy hierarchy*. The more transformations there are, the higher the transformity and the higher the position in a universal energy hierarchy. [Figure 8.16.1](#) shows an environmental food chain with more energy flow but lower quality units (lower transformity) on the left and small total energy flow through high transformity units on the right. A land example is sunlight-grass-sheep-people. An aquatic series is sunlight-phytoplankton-zooplankton-small fish-large fish.

In environment, engineering, and economics the selective process of self organization generates higher quality energy capable of amplifying other processes. Thus observed transformities are a measure of energy quality. Tables of solar transformity have been prepared based on previous EMERGY analysis (Odum, 1996). See sample in [Table 8.16.1](#)

*Empower* is the EMERGY used per unit time, for the United States about 8.5 E24 solar emjoules per year, a measure of the nation’s processing of real wealth. By dividing the gross economic product (\$6.5 trillion per year) the *EMERGY/money ratio* results (1.3 trillion solar emjoules per dollar). This is real wealth buying power of a dollar.

After an EMERGY evaluation is made, the solar EMERGY of each item can be divided by the *EMERGY/money ratio* to determine the *emdollars*, the buying power contributed by that item.

*Emdollars are defined as the dollars of gross economic product due to that much real wealth measured as EMERGY.*

Because it puts all forms of available energy on a common basis, EMERGY may be the correct way to evaluate useful work. If real wealth comes from work, maximizing EMERGY production and use maximizes the real wealth of an economy. Selecting alternatives to maximize empower and emdollars is a new tool for engineering design and public policy.

Many energy analysis procedures add available energy as an exergy sum. However, EMERGY evaluation recognizes that each form of energy is different in its quality and the quantity of energy of other kinds required to make it. As shown in the EMERGY evaluation example ([Table 8.16.2](#)), each energy value is multiplied by its transformity so as to convert all items to solar EMERGY.

**FIGURE 8.16.1** Energy transformation hierarchy: (a) spatial view of units, their sizes, and territories; (b) systems diagram of energy flow web; (c) web aggregated into an energy transformation chain; (d) energy flows between hierarchical levels; (e) transmittites of flows between levels.

\* Analysis of Big Brown Plant, Fairfield, Texas (Odum et al., 1987, revised).

<sup>#</sup> Solar empower in Column 5 divided by 1.3 E12 sej/\$ for U.S.A., 1995. Net EMERGY ratio = Yield/Inputs = 73.6/10.8 = 6.8

## An Example of EMERGY Evaluation, Lignite

The evaluation procedure starts with an aggregated systems diagram to relate inputs, outputs, and main processes. This is used to identify line items in an evaluation table. An example is the analysis of lignite processing at the Big Brown Mine in Fairfield, Texas. Line items for the EMERGY evaluation in Table 8.16.2 were identified from the summarizing systems diagram in Figure 8.16.2. The net EMERGY ratio relates the EMERGY yield to the EMERGY required for the processing. The net EMERGY ratio of 6.8 (Table 8.16.2) means that 6.8 times more real wealth was contributed to the economy than required in the processing. The operation contributed 5.6 million emdollars per day to the economy as lignite yield, almost 12 times more than the economic value of \$477,000 dollars per day.

## Defining Terms

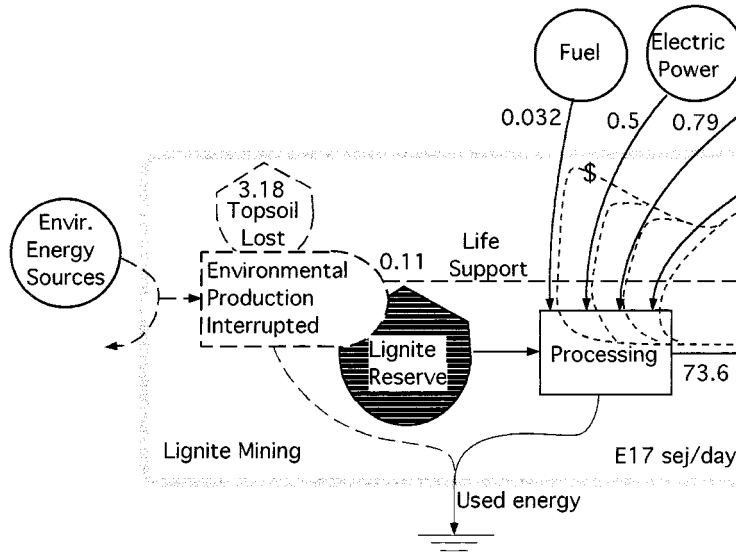

**EMERGY:** Available energy of one kind previously required directly and indirectly to make a product or service (unit: emjoules). Example: solar emjoules (abbreviation: sej).

**Transformity:** EMERGY per unit available energy (units: emjoules per joule). Example: solar emjoules per joule (abbreviation: sej/J).

**Empower:** EMERGY flow per unit time (units: emjoules per time). Example: solar emjoules per year (abbreviation: sej/yr).

**Emdollars:** EMERGY divided by EMERGY/money ratio. (abbreviation Em\$).

**Net EMERGY ratio:** Yield EMERGY/EMERGY of purchased inputs.

**FIGURE 8.16.2** Energy systems diagram and energy flows of a lignite mining operation evaluated in Table 8.16.2.

## 9.1 Introduction

---

### Air-Conditioning

*Air-conditioning* is a process that simultaneously conditions air; distributes it combined with the outdoor air to the conditioned space; and at the same time controls and maintains the required space's temperature, humidity, air movement, air cleanliness, sound level, and pressure differential within predetermined limits for the health and comfort of the occupants, for product processing, or both.

The acronym HVAC&R stands for heating, ventilating, air-conditioning, and refrigerating. The combination of these processes is equivalent to the functions performed by air-conditioning.

Because I-P units are widely used in the HVAC&R industry in the U.S., I-P units are used in this chapter. A table for converting I-P units to SI units is available in Appendix X of this handbook.

### Air-Conditioning Systems

An *air-conditioning* or *HVAC&R system* consists of components and equipment arranged in sequential order to heat or cool, humidify or dehumidify, clean and purify, attenuate objectionable equipment noise, transport the conditioned outdoor air and recirculate air to the conditioned space, and control and maintain an indoor or enclosed environment at optimum energy use.

The types of buildings which the air-conditioning system serves can be classified as:

- Institutional buildings, such as hospitals and nursing homes
- Commercial buildings, such as offices, stores, and shopping centers

- Residential buildings, including single-family and multifamily low-rise buildings of three or fewer stories above grade
- Manufacturing buildings, which manufacture and store products

### Types of Air-Conditioning Systems

In institutional, commercial, and residential buildings, air-conditioning systems are mainly for the occupants' health and comfort. They are often called *comfort air-conditioning systems*. In manufacturing buildings, air-conditioning systems are provided for product processing, or for the health and comfort of workers as well as processing, and are called *processing air-conditioning systems*.

Based on their size, construction, and operating characteristics, air-conditioning systems can be classified as the following.

*Individual Room or Individual Systems.* An individual air-conditioning system normally employs either a single, self-contained, packaged room air conditioner (installed in a window or through a wall) or separate indoor and outdoor units to serve an individual room, as shown in [Figure 9.1.1](#). “Self-contained, packaged” means factory assembled in one package and ready for use.

**FIGURE 9.1.1** An individual room air-conditioning system.

*Space-Conditioning Systems or Space Systems.* These systems have their air-conditioning—cooling, heating, and filtration—performed predominantly in or above the conditioned space, as shown in [Figure 9.1.2](#). Outdoor air is supplied by a separate outdoor ventilation system.

*Unitary Packaged Systems or Packaged Systems.* These systems are installed with either a single self-contained, factory-assembled packaged unit (PU) or two split units: an indoor air handler, normally with ductwork, and an outdoor condensing unit with refrigeration compressor(s) and condenser, as shown in [Figure 9.1.3](#). In a packaged system, air is cooled mainly by direct expansion of refrigerant in coils called DX coils and heated by gas furnace, electric heating, or a heat pump effect, which is the reverse of a refrigeration cycle.

*Central Hydronic or Central Systems.* A central system uses chilled water or hot water from a central plant to cool and heat the air at the coils in an air handling unit (AHU) as shown in [Figure 9.1.4](#). For energy transport, the heat capacity of water is about 3400 times greater than that of air. Central systems are built-up systems assembled and installed on the site.

Packaged systems are comprised of only air system, refrigeration, heating, and control systems. Both central and space-conditioning systems consist of the following.

*Air Systems.* An air system is also called an air handling system or the air side of an air-conditioning or HVAC&R system. Its function is to condition the air, distribute it, and control the indoor environment according to requirements. The primary equipment in an air system is an AHU or air handler; both of these include fan, coils, filters, dampers, humidifiers (optional), supply and return ductwork, supply outlets and return inlets, and controls.

**FIGURE 9.1.2** A space-conditioning air-conditioning system (fan-coil system).

*Water Systems.* These systems include chilled water, hot water, and condenser water systems. A water system consists of pumps, piping work, and accessories. The water system is sometimes called the water side of a central or space-conditioning system.

*Central Plant Refrigeration and Heating Systems.* The refrigeration system in the central plant of a central system is usually in the form of a chiller package with an outdoor condensing unit. The refrigeration system is also called the refrigeration side of a central system. A boiler and accessories make up the heating system in a central plant for a central system, and a direct-fired gas furnace is often the heating system in the air handler of a rooftop packaged system.

*Control Systems.* Control systems usually consist of sensors, a microprocessor-based direct digital controller (DDC), a control device, control elements, personal computer (PC), and communication network.

Based on Commercial Buildings Characteristics 1992, Energy Information Administration (EIA) of the Department of Energy of United States in 1992, for commercial buildings having a total floor area

**FIGURE 9.1.3** A packaged air-conditioning system.

**FIGURE 9.1.4a** A central air-conditioning system: schematic diagram.

of 67,876 million ft<sup>2</sup>, of which 57,041 million ft<sup>2</sup> or 84% is cooled and 61,996 million ft<sup>2</sup> or 91% is heated, the air-conditioning systems for cooling include:

Individual systems	19,239 million ft <sup>2</sup>	(25%)
Packaged systems	34,753 million ft <sup>2</sup>	(49%)
Central systems	14,048 million ft <sup>2</sup>	(26%)

Space-conditioning systems are included in central systems. Part of the cooled floor area has been counted for both individual and packaged systems. The sum of the floor areas for these three systems therefore exceeds the total cooled area of 57,041 million ft<sup>2</sup>.

FIGURE 9.1.4b A central air-conditioning system: air and control systems for a typical floor.

### Air-Conditioning Project Development and System Design

The goal of an air-conditioning/HVAC&R system is to provide a healthy and comfortable indoor environment with acceptable indoor air quality, while being energy efficient and cost effective.

ASHRAE Standard 62-1989 defines *acceptable indoor air quality* as “air in which there are no known contaminants at harmful concentrations as determined by cognizant authorities and with which a substantial majority (80% or more) of the people exposed do not express dissatisfaction.”

The basic steps in the development and use of an air-conditioning project are design, installation, commissioning, operation, and maintenance. There are two types of air-conditioning projects: *design-bid* and *design-build*. A design-bid project separates the design (engineering consultant) and installation (contractors) responsibilities. In a design-build project, the design is also done by the installation contractor. A design-build project is usually a small project or a project having insufficient time to go through normal bidding procedures.

In the building construction industry, air-conditioning or HVAC&R is one of the *mechanical services*; these also include plumbing, fire protection, and escalators.

*Air-conditioning design* is a process of selecting the optimum system, subsystem, equipment, and components from various alternatives and preparing the drawings and specifications. Haines (1994) summarized this process in four phases: gather information, develop alternatives, evaluate alternatives,

and sell the best solution. Design determines the basic operating characteristics of a system. After an air-conditioning system is designed and constructed, it is difficult and expensive to change its basic characteristics.

The foundation of a successful project is teamwork and coordination between designer, contractor, and operator and between mechanical engineer, electrical engineer, facility operator, architect, and structural engineer.

Field experience is helpful to the designer. Before beginning the design process it is advisable to visit similar projects that have operated for more than 2 years and talk with the operator to investigate actual performance.

### Mechanical Engineer's Responsibilities

The normal procedure in a design-bid construction project and the mechanical engineer's responsibilities are

1. Initiation of a project by owner or developer
2. Organizing a design team
3. Determining the design criteria and indoor environmental parameters
4. Calculation of cooling and heating loads
5. Selection of systems, subsystems, and their components
6. Preparation of schematic layouts; sizing of piping and ductwork
7. Preparation of contract documents: drawings and specifications
8. Competitive biddings by various contractors; evaluation of bids; negotiations and modifications
9. Advice on awarding of contract
10. Monitoring, supervision, and inspection of installation; reviewing shop drawings
11. Supervision of commissioning
12. Modification of drawings to the as-built condition; preparation of the operation and maintenance manual
13. Handing over to the property management for operation

### Design Documents

*Drawings* and *specifications* are legal documents of a construction contract. The designer conveys the owner's or developer's requirements to the contractor through these documents. Drawings and specifications complement each other.

Drawings should clearly and completely show, define, and present the work. Adequate plan and sectional views should be drawn. More often, isometric drawings are used to show the flow diagrams for water or the supply, return, and exhaust air.

Specifications include the legal contract between the owner and the contractor, installer, or vendor and the technical specifications, which describe in detail what kind of material and equipment should be used and how they are to be installed.

Most projects now use a format developed by the Construction Specifications Institute (CSI) called the Masterformat for Specifications. It includes 16 divisions. The 15000 Mechanical division is divided into the following:

Section No.	Title
15050	Basic Mechanical Materials and Methods
15250	Mechanical Insulation
15300	Fire Protection
15400	Plumbing
15500	Heating, Ventilating, and Air-Conditioning
15550	Heat Generation
15650	Refrigeration
15750	Heat Transfer
15850	Air Handling

Section No.	Title
15880	Air Distribution
15950	Controls
15990	Testing, Adjusting, and Balancing

Each section includes general considerations, equipment and material, and field installation. Design criteria and selected indoor environmental parameters that indicate the performance of the HVAC&R system must be clearly specified in the general consideration of Section 15500.

There are two types of specifications: the performance specification, which depends mainly on the required performance criteria, and the or-equal specification, which specifies the wanted vendor. Specifications should be written in simple, direct, and clear language without repetition.

### Computer-Aided Design and Drafting

With the wide acceptance of the PC and the availability of numerous types of engineering software, the use of *computer-aided drafting* (CAD) and *computer-aided design and drafting* (CADD) has increased greatly in recent years. According to the 1994 CADD Application and User Survey of design firms reported in *Engineering Systems* (1994[6]), “15% of the design firms now have a computer on every desk” and “Firms with high productivity reported that they perform 95% on CADD.” Word processing software is widely used to prepare specifications.

Drafting software used to reproduce architectural drawings is the foundation of CADD. Automated CAD (AutoCAD) is the leading personal computer-based drafting tool software used in architectural and engineering design firms.

In “Software Review” by Amistadi (1993), duct design was the first HVAC&R application to be integrated with CAD.

- Carrier Corp. DuctLINK and Softdesk HVAC 12.0 are the two most widely used duct design software. Both of them convert the single-line duct layout drawn with CAD to two-dimensional (2D) double-line drawings with fittings, terminals, and diffusers.
- Tags and schedules of HVAC&R equipment, ductwork, and duct fittings can be produced as well.
- DuctLINK and Softdesk can also interface with architectural, electrical, and plumbing drawings through AutoCAD software.

Software for piping system design and analysis can also be integrated with CAD. The software developed at the University of Kentucky, KYCAD/KYPIPE, is intended for the design and diagnosis of large water piping systems, has extensive hydraulic modeling capacities, and is the most widely used. Softdesk AdCADD Piping is relative new software; it is intended for drafting in 2D and 3D, linking to AutoCAD through design information databases.

Currently, software for CADD for air-conditioning and HVAC&R falls into two categories: engineering and product. The engineering category includes CAD (AutoCAD integrated with duct and piping system), load calculations and energy analysis, etc. The most widely used software for load calculations and energy analysis is Department of Energy DOE-2.1D, Trane Company’s TRACE 600, and Carrier Corporation’s softwares for load calculation, E20-II Loads.

Product categories include selection, configuration, performance, price, and maintenance schedule. Product manufacturers provide software including data and CAD drawings for their specific product.

### Codes and Standards

*Codes* are federal, state, or city laws that require the designer to perform the design without violating people’s (including occupants and the public) safety and welfare. Federal and local codes must be followed. The designer should be thoroughly familiar with relevant codes. HVAC&R design codes are definitive concerning structural and electrical safety, fire prevention and protection (particularly for gas- or oil-fired systems), environmental concerns, indoor air quality, and energy conservation.

Conformance with *ASHRAE Standards* is voluntary. However, for design criteria or performance that has not been covered in the codes, whether the ASHRAE Standard is followed or violated is the vital criterion, as was the case in a recent indoor air quality lawsuit against a designer and contractor.

For the purpose of performing an effective, energy-efficient, safe, and cost-effective air-conditioning system design, the following ASHRAE Standards should be referred to from time to time:

- ASHRAE/IES Standard 90.1-1989, Energy Efficient Design of New Buildings Except New Low-Rise Residential Buildings
- ANSI/ASHRAE Standard 62-1989, Ventilation for Acceptable Indoor Air Quality
- ANSI/ASHRAE Standard 55-1992, Thermal Environmental Conditions for Human Occupancy
- ASHRAE Standard 15-1992, Safety Code for Mechanical Refrigeration

## 9.2 Psychrometrics

### Moist Air

Above the surface of the earth is a layer of air called the *atmosphere*, or *atmospheric air*. The lower atmosphere, or homosphere, is composed of moist air, that is, a mixture of dry air and water vapor.

*Psychrometrics* is the science of studying the thermodynamic properties of moist air. It is widely used to illustrate and analyze the change in properties and the thermal characteristics of the air-conditioning process and cycles.

The composition of dry air varies slightly at different geographic locations and from time to time. The approximate composition of dry air by volume is nitrogen, 79.08%; oxygen, 20.95%; argon, 0.93%; carbon dioxide, 0.03%; other gases (e.g., neon, sulfur dioxide), 0.01%.

The amount of water vapor contained in the moist air within the temperature range 0 to 100°F changes from 0.05 to 3% by mass. The variation of water vapor has a critical influence on the characteristics of moist air.

The equation of state for an ideal gas that describes the relationship between its thermodynamic properties covered in Chapter 2 is

$$pv = RT_R \quad (9.2.1)$$

or

$$pV = mRT_R \quad (9.2.2)$$

where  $p$  = pressure of the gas, psf (1 psf = 144 psi)  
 $v$  = specific volume of the gas, ft<sup>3</sup>/lb  
 $R$  = gas constant, ftlb<sub>f</sub>/lb<sub>m</sub> °R  
 $T_R$  = absolute temperature of the gas, °R  
 $V$  = volume of the gas, ft<sup>3</sup>  
 $m$  = mass of the gas, lb

The most exact calculation of the thermodynamic properties of moist air is based on the formulations recommended by Hyland and Wexler (1983) of the U.S. National Bureau of Standards. The psychrometric charts and tables developed by ASHRAE are calculated and plotted from these formulations. According to Nelson et al. (1986), at a temperature between 0 and 100°F, enthalpy and specific volume calculations using ideal gas Equations (9.2.1) and (9.2.2) show a maximum deviation of 0.5% from the results of Hyland and Wexler's exact formulations. Therefore, ideal gas equations are used in the development and calculation of psychrometric formulations in this handbook.

Although air contaminants may seriously affect human health, they have little effect on the thermodynamic properties of moist air. For thermal analysis, moist air may be treated as a binary mixture of dry air and water vapor.

Applying Dalton's law to moist air:

$$p_{at} = p_a + p_w \quad (9.2.3)$$

where  $p_{at}$  = atmospheric pressure of the moist air, psia  
 $p_a$  = partial pressure of dry air, psia  
 $p_w$  = partial pressure of water vapor, psia

Dalton's law is summarized from the experimental results and is more accurate at low gas pressure. Dalton's law can also be extended, as the Gibbs-Dalton law, to describe the relationship of internal energy, enthalpy, and entropy of the gaseous constituents in a mixture.

## Humidity and Enthalpy

The *humidity ratio* of moist air,  $w$ , in lb/lb is defined as the ratio of the mass of the water vapor,  $m_w$  to the mass of dry air,  $m_a$ , or

$$w = m_w/m_a = 0.62198 p_w / (p_{at} - p_w) \quad (9.2.4)$$

The *relative humidity* of moist air,  $\phi$ , or RH, is defined as the ratio of the mole fraction of water vapor,  $x_w$ , to the mole fraction of saturated moist air at the same temperature and pressure,  $x_{ws}$ . Using the ideal gas equations, this relationship can be expressed as:

$$\phi = x_w/x_{ws}|_{T,p} = p_w/p_{ws}|_{T,p} \quad (9.2.5)$$

and

$$x_w = n_w / (n_a + n_w); \quad x_{ws} = n_{ws} / (n_a + n_{ws})$$

$$x_a + x_w = 1 \quad (9.2.6)$$

where  $p_{ws}$  = pressure of saturated water vapor, psia

$T$  = temperature, °F

$n_a, n_w, n_{ws}$  = number of moles of dry air, water vapor, and saturated water vapor, mol

*Degree of saturation*  $\mu$  is defined as the ratio of the humidity ratio of moist air,  $w$ , to the humidity ratio of saturated moist air,  $w_s$ , at the same temperature and pressure:

$$\mu = w/w_s|_{T,p} \quad (9.2.7)$$

The difference between  $\phi$  and  $\mu$  is small, usually less than 2%.

At constant pressure, the difference in specific enthalpy of an ideal gas, in Btu/lb, is  $\Delta h = c_p \Delta T$ . Here  $c_p$  represents the specific heat at constant pressure, in Btu/lb. For simplicity, the following assumptions are made during the calculation of the *enthalpy* of moist air:

1. At 0°F, the enthalpy of dry air is equal to zero.
2. All water vapor is vaporized at 0°F.
3. The enthalpy of saturated water vapor at 0°F is 1061 Btu/lb.
4. The unit of the enthalpy of the moist air is Btu per pound of dry air and the associated water vapor, or Btu/lb.

Then, within the temperature range 0 to 100°F, the enthalpy of the moist air can be calculated as:

$$h = c_{pd} T + w(h_{g0} + c_{ps} T)$$

$$= 0.240T + w(1061 + 0.444T) \quad (9.2.8)$$

where  $c_{pd}, c_{ps}$  = specific heat of dry air and water vapor at constant pressure, Btu/lb°F. Their mean values can be taken as 0.240 and 0.444 Btu/lb°F, respectively.

$h_{g0}$  = specific enthalpy of saturated water vapor at 0°F.

## Moist Volume, Density, Specific Heat, and Dew Point

The specific *moist volume*  $v$ , in  $\text{ft}^3/\text{lb}$ , is defined as the volume of the mixture of dry air and the associated water vapor when the mass of the dry air is exactly 1 lb:

$$v = V/m_a \quad (9.2.9)$$

where  $V$  = total volume of the moist air,  $\text{ft}^3$ . Since moist air, dry air, and water vapor occupy the same volume,

$$v = R_a T_R / p_{\text{at}} (1 + 1.6078w) \quad (9.2.10)$$

where  $R_a$  = gas constant for dry air.

*Moist air density*, often called *air density*  $\rho$ , in  $\text{lb}/\text{ft}^3$ , is defined as the ratio of the mass of dry air to the total volume of the mixture, or the reciprocal of the moist volume:

$$\rho = m_a / V = 1/v \quad (9.2.11)$$

The *sensible heat of moist air* is the thermal energy associated with the change of air temperature between two state points. In Equation (9.2.8),  $(c_{\text{pd}} + wc_{\text{ps}})T$  indicates the sensible heat of moist air, which depends on its temperature  $T$  above the datum  $0^\circ\text{F}$ . *Latent heat of moist air*, often represented by  $wh_{\text{fg}0}$ , is the thermal energy associated with the change of state of water vapor. Both of them are in  $\text{Btu}/\text{lb}$ . Within the temperature range 0 to  $100^\circ\text{F}$ , if the average humidity ratio  $w$  is taken as 0.0075  $\text{lb}/\text{lb}$ , the *specific heat of moist air*  $c_{\text{pa}}$  can be calculated as:

$$c_{\text{pa}} = c_{\text{pd}} + wc_{\text{ps}} = 0.240 + 0.0075 \times 0.444 = 0.243 \text{ Btu}/\text{lb } ^\circ\text{F} \quad (9.2.12)$$

The *dew point temperature*  $T_{\text{dew}}$ , in  $^\circ\text{F}$ , is the temperature of saturated moist air of the moist air sample having the same humidity ratio at the same atmospheric pressure. Two moist air samples of similar dew points  $T_{\text{dew}}$  at the same atmospheric pressure have the same humidity ratio  $w$  and the same partial pressure of water vapor  $p_w$ .

## Thermodynamic Wet Bulb Temperature and Wet Bulb Temperature

The *thermodynamic wet bulb temperature* of moist air,  $T^*$ , is equal to the saturated state of a moist air sample at the end of a constant-pressure, ideal adiabatic saturation process:

$$h_1 + (w_s^* - w_1)h_w^* = h_s^* \quad (9.2.13)$$

where  $h_1, h_s^*$  = enthalpy of moist air at the initial state and enthalpy of saturated air at the end of the constant-pressure, ideal adiabatic saturation process,  $\text{Btu}/\text{lb}$

$w_1, w_s^*$  = humidity ratio of moist air at the initial state and humidity ratio of saturated air at the end of the constant-pressure, ideal adiabatic saturation process,  $\text{lb}/\text{lb}$

$h_w^*$  = enthalpy of water added to the adiabatic saturation process at temperature  $T^*$ ,  $\text{Btu}/\text{lb}$

An *ideal adiabatic saturation process* is a hypothetical process in which moist air at initial temperature  $T_1$ , humidity ratio  $w_1$ , enthalpy  $h_1$ , and pressure  $p$  flows over a water surface of infinite length through a well-insulated channel. Liquid water is therefore evaporated into water vapor at the expense of the sensible heat of the moist air. The result is an increase of humidity ratio and a drop of temperature until the moist air is saturated at the thermodynamic wet bulb temperature  $T^*$  during the end of the ideal adiabatic saturation process.

The thermodynamic wet bulb temperature  $T^*$  is a unique fictitious property of moist air that depends only on its initial properties,  $T_1$ ,  $w_1$ , or  $h_1$ .

A sling-type *psychrometer*, as shown in Figure 9.2.1, is an instrument that determines the temperature, relative humidity, and thus the state of the moist air by measuring its dry bulb and wet bulb temperatures. It consists of two mercury-in-glass thermometers. The sensing bulb of one of them is dry and is called the dry bulb. Another sensing bulb is wrapped with a piece of cotton wick, one end of which dips into a water tube. This wetted sensing bulb is called the wet bulb and the temperature measured by it is called the *wet bulb temperature*  $T'$ .

**FIGURE 9.2.1** A sling psychrometer.

When unsaturated moist air flows over the surface of the wetted cotton wick, liquid water evaporates from its surface. As it absorbs sensible heat, mainly from the surrounding air, the wet bulb temperature drops. The difference between the dry and wet bulb temperatures is called *wet bulb depression* ( $T - T'$ ). Turning the handle forces the surrounding air to flow over the dry and wet bulbs at an air velocity between 300 to 600 fpm. Distilled water must be used to wet the cotton wick.

At steady state, if heat conduction along the thermometer stems is neglected and the temperature of the wetted cotton wick is equal to the wet bulb temperature of the moist air, as the sensible heat transfer from the surrounding moist air to the cotton wick exactly equals the latent heat required for evaporation, the heat and mass transfer per unit area of the wet bulb surface can be evaluated as:

$$h_c(T - T') + h_r(T_{ra} - T) = h_d(w'_s - w_1) \quad (9.2.14)$$

where  $h_c$ ,  $h_r$  = mean conductive and radiative heat transfer coefficient, Btu/hr ft<sup>2</sup>°F  
 $h_d$  = mean convective mass transfer coefficient, lb/hr ft<sup>2</sup>

- $T$  = temperature of undisturbed moist air at a distance from the wet bulb, °F  
 $T_{ra}$  = mean radiant temperature (covered later), °F  
 $w_1, w'_s$  = humidity ratio of the moist air and the saturated film at the interface of cotton wick and surrounding air, lb/lb  
 $h'_{fg}$  = latent heat of vaporization at the wet bulb temperature, Btu/lb

The humidity ratio of the moist air is given by:

$$w_1 = w'_s - K'(T - T') \left( 1 + \left\{ h_r (T_{ra} - T') / [h_c (T - T')] \right\} \right)$$

$$K' = c_{pa} Le^{0.6667} / h'_{fg} \quad (9.2.15)$$

where  $K'$  = wet bulb constant, which for a sling psychrometer = 0.00218 1/°F  
 $Le$  = Lewis number

The wet bulb temperature  $T'$  depends not only on its initial state but also on the rate of heat and mass transfer at the wet bulb. Therefore, the thermodynamic wet bulb temperature is used in ASHRAE psychrometric charts.

According to Threlkeld (1970), for a sling psychrometer whose wet bulb diameter is 1 in. and for air flowing at a velocity of 400 fpm over the wet bulb, if the dry bulb temperature is 90°F and the measured wet bulb temperature is 70°F, the difference between the measured wet bulb and the thermodynamic wet bulb  $(T' - T^*) / (T^* - T')$  is less than 1%.

## Psychrometric Charts

A *psychrometric chart* is a graphical presentation of the thermodynamic properties of moist air and various air-conditioning processes and air-conditioning cycles. A psychrometric chart also helps in calculating and analyzing the work and energy transfer of various air-conditioning processes and cycles.

Psychrometric charts currently use two kinds of basic coordinates:

1.  $h$ - $w$  charts. In  $h$ - $w$  charts, enthalpy  $h$ , representing energy, and humidity ratio  $w$ , representing mass, are the basic coordinates. Psychrometric charts published by ASHRAE and the Chartered Institution of Building Services Engineering (CIBSE) are  $h$ - $w$  charts.
2.  $T$ - $w$  charts. In  $T$ - $w$  charts, temperature  $T$  and humidity ratio  $w$  are basic coordinates. Psychrometric charts published by Carrier Corporation, the Trane Company, etc. are  $T$ - $w$  charts.

Figure 9.2.2 shows an abridged ASHRAE psychrometric chart. In the ASHRAE chart:

- A normal temperature chart has a temperature range of 32 to 120°F, a high-temperature chart 60 to 250°F, and a low-temperature chart -40 to 50°F. Since enthalpy is the basic coordinate, temperature lines are not parallel to each other. Only the 120°F line is truly vertical.
- Thermodynamic properties of moist air are affected by atmospheric pressure. The standard atmospheric pressure is 29.92 in. Hg at sea level. ASHRAE also published charts for high altitudes of 5000 ft, 24.89 in. Hg, and 7500 ft, 22.65 in. Hg. Both of them are in the normal temperature range.
- Enthalpy  $h$ -lines incline downward to the right-hand side (negative slope) at an angle of 23.5° to the horizontal line and have a range of 12 to 54 Btu/lb.
- Humidity ratio  $w$ -lines are horizontal lines. They range from 0 to 0.28 lb/lb.
- Relative humidity  $\phi$ -lines are curves of relative humidity 10%, 20%, ... 90% and a saturation curve. A saturation curve is a curve of the locus of state points of saturated moist air, that is,  $\phi = 100\%$ . On a saturation curve, temperature  $T$ , thermodynamic wet temperature bulb  $T^*$ , and dew point temperature  $T_{dew}$  have the same value.

**FIGURE 9.2.2** The abridged ASHRAE psychrometric chart and the determination of properties as in Example 9.2.1.

- Thermodynamic wet bulb  $T^*$ -lines have a negative slope slightly greater than that of the  $h$ -lines. A  $T^*$ -line meets the  $T$ -line of the same magnitude on the saturation curve.
- Moist volume  $v$ -lines have a far greater negative slope than  $h$ -lines and  $T^*$ -lines. The moist volume ranges from 12.5 to 15 ft³/lb.

Moist air has seven independent thermodynamic properties or property groups:  $h$ ,  $T$ ,  $\phi$ ,  $T^*$ ,  $p_{\text{at}}$ ,  $\rho - v$ , and  $w - p_w - T_{\text{dew}}$ . When  $p_{\text{at}}$  is given, any additional two of the independent properties determine the state of moist air on the psychrometric chart and the remaining properties.

Software using AutoCAD to construct the psychrometric chart and calculate the thermodynamic properties of moist air is available. It can also be linked to the load calculation and energy programs to analyze the characteristics of air-conditioning cycles.

Refer to Wang’s *Handbook of Air Conditioning and Refrigeration* (1993) and *ASHRAE Handbook, Fundamentals* (1993) for details of psychrometric charts and psychrometric tables that list thermodynamic properties of moist air.

**Example 9.2.1**

An air-conditioned room at sea level has an indoor design temperature of 75°F and a relative humidity of 50%. Determine the humidity ratio, enthalpy, density, dew point, and thermodynamic wet bulb temperature of the indoor air at design condition.

*Solution*

1. Since the air-conditioned room is at sea level, a psychrometric chart of standard atmospheric pressure of 14.697 psi should be used to find the required properties.
2. Plot the state point of the room air at design condition  $r$  on the psychrometric chart. First, find the room temperature 75°F on the horizontal temperature scale. Draw a line parallel to the 75°F

temperature line. This line meets the relative humidity curve of 50% at point  $r$ , which denotes the state point of room air as shown in [Figure 9.2.2](#).

3. Draw a horizontal line toward the humidity ratio scale from point  $r$ . This line meets the ordinate and thus determines the room air humidity ratio  $\phi_r = 0.0093$  lb/lb.
4. Draw a line from point  $r$  parallel to the enthalpy line. This line determines the enthalpy of room air on the enthalpy scale,  $h_r = 28.1$  Btu/lb.
5. Draw a line through point  $r$  parallel to the moist volume line. The perpendicular scale of this line indicates  $v_r = 13.67$  ft<sup>3</sup>/lb.
6. Draw a horizontal line to the left from point  $r$ . This line meets the saturation curve and determines the dew point temperature,  $T_{\text{dew}} = 55^\circ\text{F}$ .
7. Draw a line through point  $r$  parallel to the thermodynamic wet bulb line. The perpendicular scale to this line indicates that the thermodynamic wet bulb temperature  $T^* = 62.5^\circ\text{F}$ .

## 9.3 Air-Conditioning Processes and Cycles

### Air-Conditioning Processes

An *air-conditioning process* describes the change in thermodynamic properties of moist air between the initial and final stages of conditioning as well as the corresponding energy and mass transfers between the moist air and a medium, such as water, refrigerant, absorbent or adsorbent, or moist air itself. The energy balance and conservation of mass are the two principles used for the analysis and the calculation of the thermodynamic properties of the moist air.

Generally, for a single air-conditioning process, heat transfer or mass transfer is positive. However, for calculations that involve several air-conditioning processes, heat supplied to the moist air is taken as positive and heat rejected is negative.

The *sensible heat ratio* (SHR) of an air-conditioning process is defined as the ratio of the change in absolute value of sensible heat to the change in absolute value of total heat, both in Btu/hr:

$$\text{SHR} = |q_{\text{sen}}| / |q_{\text{total}}| = |q_{\text{sen}}| / (|q_{\text{sen}}| + |q_1|) \quad (9.3.1)$$

For any air-conditioning process, the sensible heat change

$$q_{\text{sen}} = 60 \dot{V}_s \rho_s c_{\text{pa}} (T_2 - T_1) = 60 \dot{m}_a c_{\text{pa}} (T_2 - T_1) \quad (9.3.2)$$

where  $\dot{V}_s$  = volume flow rate of supply air, cfm

$\rho_s$  = density of supply air, lb/ft<sup>3</sup>

$T_2, T_1$  = moist air temperature at final and initial states of an air-conditioning process, °F

and the mass flow rate of supply air

$$\dot{m}_s = \dot{V}_s \rho_s \quad (9.3.3)$$

The latent heat change is

$$q_1 \approx 60 \dot{V}_s \rho_s (w_2 - w_1) h_{\text{fg},58} = 1060 \times 60 \dot{V}_s \rho_s (w_2 - w_1) \quad (9.3.4)$$

where  $w_2, w_1$  = humidity ratio at final and initial states of an air-conditioning process, lb/lb.

In Equation (9.3.4),  $h_{\text{fg},58} \approx 1060$  Btu/lb represents the latent heat of vaporization or condensation of water at an estimated temperature of 58°F, where vaporization or condensation occurs in an air-handling unit or packaged unit. Therefore

$$\text{SHR} = \dot{m}_a c_{\text{pa}} (T_2 - T_1) / \left[ \dot{m}_a c_{\text{pa}} (T_2 - T_1) + \dot{m}_a (w_2 - w_1) h_{\text{fg},58} \right] \quad (9.3.5)$$

### Space Conditioning, Sensible Cooling, and Sensible Heating Processes

In a *space conditioning process*, heat and moisture are absorbed by the supply air at state  $s$  and then removed from the conditioned space at the state of space air  $r$  during summer, as shown by line  $sr$  in Figure 9.3.1, or heat or moisture is supplied to the space to compensate for the transmission and infiltration losses through the building envelope as shown by line  $s'r'$ . Both processes are aimed at maintaining a desirable space temperature and relative humidity.

The space cooling load  $q_{\text{tc}}$ , in Btu/hr, can be calculated as:

FIGURE 9.3.1 Supply conditioning, sensible heating, and sensible cooling processes.

$$q_{rc} = 60 \dot{m}_a (h_r - h_s) = 60 \dot{V}_s \rho_s (h_r - h_s) \tag{9.3.6}$$

where  $h_r, h_s$  = enthalpy of space air and supply air, Btu/lb.

The space sensible cooling load  $q_{rs}$ , in Btu/hr, can be calculated from Equation (9.3.2) and the space latent load  $q_{rl}$ , in Btu/hr, from Equation (9.3.1). In Equation (9.3.4),  $T_2$  should be replaced by  $T_r$  and  $T_1$  by  $T_s$ . Also in Equation (9.3.1),  $w_2$  should be replaced by  $w_r$  and  $w_1$  by  $w_s$ . The space heating load  $q_{th}$  is always a sensible load, in Btu/hr, and can be calculated as:

$$q_{th} = 60 \dot{m}_a c_{pa} (T_s - T_r) = 60 \dot{V}_s \rho_s c_{pa} (T_s - T_r) \tag{9.3.7}$$

where  $T_s, T_r$  = temperature of supply and space air, °F.

A *sensible heating process* adds heat to the moist air in order to increase its temperature; its humidity ratio remains constant, as shown by line 12 in Figure 9.3.1. A sensible heating process occurs when moist air flows over a heating coil. Heat is transferred from the hot water inside the tubes to the moist air. The rate of heat transfer from the hot water to the colder moist air is often called the heating coil load  $q_{th}$ , in Btu/hr, and is calculated from Equation (9.3.2).

A *sensible cooling process* removes heat from the moist air, resulting in a drop of its temperature; its humidity ratio remains constant, as shown by line 1'2' in Figure 9.3.1. The sensible cooling process occurs when moist air flows through a cooling coil containing chilled water at a temperature equal to or greater than the dew point of the entering moist air. The sensible cooling load can also be calculated from Equation (9.3.2).  $T_2$  is replaced by  $T_1$  and  $T_1$  by  $T_2$ .

**FIGURE 9.3.2** Humidifying and cooling and dehumidifying processes: (a) process on psychrometric chart, (b) steam humidifier, (c) air washer, and (d) water cooling or DX coil.

### Humidifying and Cooling and Dehumidifying Processes

In a *humidifying process*, water vapor is added to moist air and increases the humidity ratio of the moist air entering the humidifier if the moist air is not saturated. Large-scale humidification of moist air is usually performed by steam injection, evaporation from a water spray, atomizing water, a wetted medium, or submerged heating elements. Some details of their construction and characteristics are covered in a later section. Dry steam in a steam injection humidifying process is often supplied from the main steam line to a grid-type humidifier and injected into the moist air directly through small holes at a pressure slightly above atmospheric, as shown by line 12 in [Figure 9.3.2\(a\)](#) and (b). The humidifying capacity  $\dot{m}_{hu}$ , in lb/min, is given by:

$$\dot{m}_{hu} = \dot{V}_s \rho_s (w_{hl} - w_{he}) \tag{9.3.8}$$

where  $w_{hl}, w_{he}$  = humidity ratio of moist air leaving and entering the humidifier, lb/lb. The slight inclination at the top of line 12 is due to the high temperature of the steam. The increase in temperature of the moist air due to steam injection can be calculated as:

$$(T_2 - T_1) = w_{sm} c_{ps} T_s / (c_{pd} + w_{12} c_{ps}) \quad (9.3.9)$$

where  $T_2, T_1$  = temperature of moist air at initial and final states, °F

$w_{sm}$  = ratio of mass flow rate of injected steam to moist air,  $\dot{m}_s / \dot{m}_a$

$T_s$  = temperature of injected steam, °F

$w_{12}$  = average humidity ratio of moist air, lb/lb

An *air washer* is a device that sprays water into moist air in order to humidify, to cool and dehumidify, and to clean the air, as shown in [Figure 9.3.2\(c\)](#). When moist air flows through an air washer, the moist air is humidified and approaches saturation. This actual adiabatic saturation process approximately follows the thermodynamic wet bulb line on the psychrometric chart as shown by line 1'2'. The humidity ratio of the moist air is increased while its temperature is reduced. The cooling effect of this adiabatic saturation process is called *evaporative cooling*.

*Oversaturation* occurs when the amount of water present in the moist air  $w_{os}$ , in lb/lb, exceeds the saturated humidity ratio at thermodynamic wet bulb temperature  $w_s^*$ , as shown in [Figure 9.3.2\(a\)](#). When moist air leaves the air washer, atomizing humidifier, or centrifugal humidifier after humidification, it often contains unevaporated water droplets at state point 2',  $w_w$ , in lb/lb. Because of the fan power heat gain, duct heat gain, and other heat gains providing the latent heat of vaporization, some evaporation takes place due to the heat transfer to the water drops, and the humidity ratio increases further. Such evaporation of oversaturated drops is often a process with an increase of both humidity ratio and enthalpy of moist air. Oversaturation can be expressed as:

$$w_{os} = w_o - w_s^* = (w_{2'} + w_w) - w_s^* \quad (9.3.10)$$

where  $w_{2'}$  = humidity ratio at state point 2', lb/lb

$w_o$  = sum of  $w_{2'}$  and  $w_w$ , lb/lb

The magnitude of  $w_w$  depends mainly on the construction of the humidifier and water eliminator, if any. For an air washer,  $w_w$  may vary from 0.0002 to 0.001 lb/lb. For a pulverizing fan without an eliminator,  $w_w$  may be up to 0.00135 lb/lb.

### Cooling and Dehumidifying Process

In a cooling and dehumidifying process, both the humidity ratio and temperature of moist air decrease. Some water vapor is condensed in the form of liquid water, called a *condensate*. This process is shown by curve m cc on the psychrometric chart in [Figure 9.3.2\(a\)](#). Here m represents the entering mixture of outdoor and recirculating air and cc the conditioned air leaving the cooling coil.

Three types of heat exchangers are used in a cooling and dehumidifying process: (1) water cooling coil as shown in [Figure 9.3.2\(d\)](#); (2) direct expansion DX coil, where refrigerant evaporates directly inside the coil's tubes; and (3) air washer, in which chilled water spraying contacts condition air directly.

The temperature of chilled water entering the cooling coil or air washer  $T_{we}$ , in °F, determines whether it is a sensible cooling or a cooling and dehumidifying process. If  $T_{we}$  is smaller than the dew point of the entering air  $T_{ae}''$  in the air washer, or  $T_{we}$  makes the outer surface of the water cooling coil  $T_{s,t} < T_{ae}''$ , it is a cooling and dehumidifying process. If  $T_{we} \geq T_{ae}''$ , or  $T_{s,t} \geq T_{ae}''$ , sensible cooling occurs. The cooling coil's load or the cooling capacity of the air washer  $q_{cc}$ , in Btu/hr, is

$$q_{cc} = 60 \dot{V}_s \rho_s (h_{ae} - h_{cc}) - 60 \dot{m}_w h_w \quad (9.3.11a)$$

where  $h_{ae}, h_{cc}$  = enthalpy of moist air entering and leaving the coil or washer, Btu/lb

$\dot{m}_w$  = mass flow rate of the condensate, lb/min

$h_w$  = enthalpy of the condensate, Btu/lb

Since the thermal energy of the condensate is small compared with  $q_{cc}$ , in practical calculations the term  $60\dot{m}_w h_w$  is often neglected, and

$$q_{cc} = 60\dot{V}_s \rho_s (h_{ae} - h_{cc}) \quad (9.3.11b)$$

The sensible heat ratio of the cooling and dehumidifying process  $SHR_c$  can be calculated from

$$SHR_c = q_{cs}/q_{cc} \quad (9.3.12)$$

where  $q_{cs}$  = sensible heat removed during the cooling and dehumidifying process, Btu/hr.  $SHR_c$  is shown by the slope of the straight line joining points m and cc.

The relative humidity of moist air leaving the water cooling coil or DX coil depends mainly on the outer surface area of the coil including pipe and fins. For coils with ten or more fins per inch, if the entering moist air is around 80°F dry bulb and 68°F wet bulb, the relative humidity of air leaving the coil (off-coil) may be estimated as:

Four-row coil	90 to 95%
Six-row and eight-row coils	96 to 98%

### Two-Stream Mixing Process and Bypass Mixing Process

For a *two-stream adiabatic mixing process*, two moist air streams, 1 and 2, are mixed together adiabatically and a mixture  $m$  is formed in a mixing chamber as shown by line 1 m 2 in [Figure 9.3.3](#). Since the AHU or PU is well insulated, the heat transfer between the mixing chamber and ambient air is small and is usually neglected. Based on the principle of heat balance and conservation of mass:

$$\begin{aligned} \dot{m}_1 h_1 + \dot{m}_2 h_2 &= \dot{m}_m h_m \\ \dot{m}_1 w_1 + \dot{m}_2 w_2 &= \dot{m}_m w_m \\ \dot{m}_1 T_1 + \dot{m}_2 T_2 &= \dot{m}_m T_m \end{aligned} \quad (9.3.13)$$

In Equation (9.3.13),  $\dot{m}$  represents the mass flow rate of air, lb/min;  $h$  the enthalpy, in Btu/lb;  $w$  the humidity ratio, in lb/lb; and  $T$  the temperature, in °F. Subscripts 1 and 2 indicate air streams 1 and 2 and m the mixture; also,

$$\begin{aligned} \dot{m}_1/\dot{m}_m &= (h_2 - h_m)/(h_2 - h_1) = (w_2 - w_m)/(w_2 - w_1) \\ &= (\text{line segment } m1\ 2)/(\text{line segment } 12) \end{aligned} \quad (9.3.14)$$

Similarly,

$$\begin{aligned} \dot{m}_2/\dot{m}_m &= (h_m - h_1)/(h_2 - h_1) = (w_m - w_1)/(w_2 - w_1) \\ &= (\text{line segment } 1\ m1)/(\text{line segment } 12) \end{aligned} \quad (9.3.15)$$

Mixing point  $m$  must lie on the line that joins points 1 and 2 as shown in [Figure 9.3.3](#).

If the differences between the density of air streams 1 and 2 and the density of the mixture are neglected,

FIGURE 9.3.3 Mixing processes.

$$\begin{aligned} \dot{V}_1 h_1 + \dot{V}_2 h_2 &= \dot{V}_m h_m \\ \dot{V}_1 w_1 + \dot{V}_2 w_2 &= \dot{V}_m w_m \end{aligned} \tag{9.3.16}$$

$$\begin{aligned} \dot{V}_1 T_1 + \dot{V}_2 T_2 &= \dot{V}_m T_m \\ \dot{V}_1 + \dot{V}_2 &= \dot{V}_m \end{aligned} \tag{9.3.17}$$

In a *bypass mixing process*, a conditioned air stream is mixed with a bypass air stream that is not conditioned. The cold conditioned air is denoted by subscript cc, the heated air ch, and the bypass air by.

Equations (9.3.14) and (9.3.17) can still be used but subscript 1 should be replaced by cc or ch and subscript 2 by “by” (bypass).

Let  $K_{cc} = \dot{m}_{cc} / \dot{m}_m$  and  $K_{ch} = \dot{m}_{ch} / \dot{m}_m$ ; then the cooling coil’s load  $q_{cc}$  and heating coil’s load  $q_{ch}$ , both in Btu/hr, for a bypass mixing process are

$$q_{cc} = K_{cc} \dot{V}_s \rho_s (h_m - h_{cc}) \quad (9.3.18)$$

$$q_{ch} = K_{ch} \dot{V}_s \rho_s (h_2 - h_1)$$

In Equation (9.3.18), subscript s denotes the supply air and m the mixture air stream.

## Air-Conditioning Cycle and Operating Modes

An *air-conditioning cycle* comprises several air-conditioning processes that are connected in a sequential order. An air-conditioning cycle determines the operating performance of the air system in an air-conditioning system. The *working substance* to condition air may be chilled or hot water, refrigerant, desiccant, etc.

Each type of air system has its own air-conditioning cycle. Psychrometric analysis of an air-conditioning cycle is an important tool in determining its operating characteristics and the state of moist air at various system components, including the volume flow rate of supply air, the coil's load, and the humidifying and dehumidifying capacity.

According to the cycle performance, air-conditioning cycles can be grouped into two categories:

- *Open cycle*, in which the moist air at its end state does not resume its original state. An air-conditioning cycle with all outdoor air is an open cycle.
- *Closed cycle*, in which moist air resumes its original state at its end state. An air-conditioning cycle that conditions the mixture of recirculating and outdoor air, supplies it, recirculates part of the return air, and mixes it again with outdoor air is a closed cycle.

Based on the outdoor weather and indoor operating conditions, the operating modes of air-conditioning cycles can be classified as:

- *Summer mode*: when outdoor and indoor operating parameters are in summer conditions.
- *Winter mode*: when outdoor and indoor operating parameters are in winter conditions.
- *Air economizer mode*: when all outdoor air or an amount of outdoor air that exceeds the minimum amount of outdoor air required for the occupants is taken into the AHU or PU for cooling. The air economizer mode saves energy use for refrigeration.

*Continuous modes* operate 24 hr a day and 7 days a week. Examples are systems that serve hospital wards and refrigerated warehouses. An *intermittently operated mode* usually shuts down once or several times within a 24-hr operating cycle. Such systems serve offices, class rooms, retail stores, etc. The 24-hr day-and-night cycle of an intermittently operated system can again be divided into:

1. *Cool-down or warm-up period*. When the space is not occupied and the space air temperature is higher or lower than the predetermined value, the space air should be cooled down or warmed up before the space is occupied.
2. *Conditioning period*. The air-conditioning system is operated during the occupied period to maintain the required indoor environment.
3. *Nighttime shut-down period*. The air system or terminal is shut down or only partly operating to maintain a set-back temperature.

Summer, winter, air economizer, and continuously operating modes consist of *full-load* (design load) and part-load operations. *Part load* occurs when the system load is less than the design load. The capacity of the equipment is selected to meet summer and winter system design loads as well as system loads in all operating modes.

### Basic Air-Conditioning Cycle — Summer Mode

A *basic air-conditioning system* is a packaged system of supply air at a constant volume flow rate, serving a single zone, equipped with only a single supply/return duct. A *single zone* is a conditioned space for which a single controller is used to maintain a unique indoor operating parameter, probably indoor temperature. A *basic air-conditioning cycle* is the operating cycle of a basic air-conditioning system. Figure 9.1.3 shows a basic air-conditioning system. Figure 9.3.4 shows the basic air-conditioning cycle of this system. In summer mode at design load, recirculating air from the conditioned space, a worship hall, enters the packaged unit through the return grill at point ru. It is mixed with the required minimum amount of outdoor air at point o for acceptable indoor air quality and energy saving. The mixture *m* is then cooled and dehumidified to point cc at the DX coil, and the conditioned air is supplied to the hall through the supply fan, supply duct, and ceiling diffuser. Supply air then absorbs the sensible and latent load from the space, becoming the space air *r*. Recirculating air enters the packaged unit again and forms a closed cycle. *Return air* is the air returned from the space. Part of the return air is exhausted to balance the outdoor air intake and infiltration. The remaining part is the *recirculating air* that enters the PU or AHU.

**FIGURE 9.3.4** Basic air-conditioning cycle — summer, winter, and air economizer mode.

The summer mode operating cycle consists of the following processes:

1. Sensible heating process, represented by line *r ru*, due to the return system gain  $q_{r,s}$ , in Btu/hr, when recirculating air flows through the return duct, ceiling plenum, and return fan, if any. In this packaged system, the return system heat gain is small and neglected.
2. Adiabatic mixing process of recirculating air at point *ru* and outdoor air at point *o* in the mixing box, represented by line *ru m o*.
3. Cooling and dehumidifying process *m cc* at the DX coil whose coil load determines the cooling capacity of the system calculated from Equation (9.3.11).
4. Sensible heating process related to the supply system heat gain  $q_{s,s}$ , in Btu/hr, represented by line *cc sf s*.  $q_{s,s}$  consists of the fan power heat gain  $q_{sf}$ , line *cc sf*, and duct heat gain  $q_{sd}$ , line *sf s*, that is:

$$q_{s,s} = q_{sf} + q_{sd} = \dot{V}_s \rho_s c_{pa} \Delta T_{s,s} \quad (9.3.19)$$

It is more convenient to use the temperature rise of the supply system  $\Delta T_{s,s}$  in psychrometric analysis.

#### 5. Supply conditioning process line sr.

### Design Supply Volume Flow Rate

Design supply volume flow rate and cooling and heating capacities are primary characteristics of an air-conditioning system. Design supply volume flow rate is used to determine the size of fans, grills, outlets, air-handling units, and packaged units. For most comfort systems and many processing air-conditioning systems, *design supply volume flow rate*  $\dot{V}_{s,d}$ , in cfm, is calculated on the basis of the capacity to remove the space cooling load at summer design conditions to maintain a required space temperature  $T_s$ :

$$\dot{V}_{s,d} = q_{rc,d} / [60\rho_s(h_r - h_s)] = q_{rs,d} / [60\rho_s c_{pa}(T_r - T_s)] \quad (9.3.20)$$

where  $q_{rc,d}$ ,  $q_{rs,d}$  = design space cooling load and design sensible cooling load, Btu/hr. In Equation (9.3.20), the greater the  $q_{rs,d}$ , the higher  $\dot{V}_s$  will be. Specific heat  $c_{pa}$  is usually considered constant. Air density  $\rho_s$  may vary with the various types of air systems used. A greater  $\rho_s$  means a smaller  $\dot{V}_{s,d}$  for a given supply mass flow rate. For a given  $q_{rs,d}$ , the supply temperature differential  $\Delta T_s = (T_r - T_s)$  is an important parameter that affects  $\dot{V}_{s,d}$ . Conventionally, a 15 to 20°F  $\Delta T_s$  is used for comfort air-conditioning systems. Recently, a 28 to 34°F  $\Delta T_s$  has been adopted for cold air distribution in ice-storage central systems. When  $\Delta T_s$  has a nearly twofold increase, there is a considerable reduction in  $\dot{V}_s$  and fan energy use and saving in investment on ducts, terminals, and outlets.

The summer cooling load is often greater than the winter heating load, and this is why  $q_{rc}$  or  $q_{rs,d}$  is used to determine  $\dot{V}_{s,d}$ , except in locations where the outdoor climate is very cold.

Sometimes the supply volume flow rate may be determined from the following requirements:

- To dilute the concentration of air contaminants in the conditioned space  $C_i$ , in mg/m<sup>3</sup>, the design supply volume flow rate is

$$\dot{V}_{s,d} = 2118 \dot{m}_{par} / (C_i - C_s) \quad (9.3.21)$$

where  $C_s$  = concentration of air contaminants in supply air, mg/m<sup>3</sup>  
 $\dot{m}_{par}$  = rate of contaminant generation in the space, mg/sec

- To maintain a required space relative humidity  $\phi_r$  and a humidity ratio  $w_r$  at a specific temperature, the design supply volume flow rate is

$$\dot{V}_{s,d} = q_{rl,d} / [60\rho_s(w_r - w_s)h_{fg,58}] \quad (9.3.22)$$

where  $q_{rl,d}$  = design space latent load, Btu/hr.

- To provide a required air velocity  $v_r$ , in fpm, within the working area of a clean room, the supply volume flow rate is given by

$$\dot{V}_{s,d} = A_r v_r \quad (9.3.23a)$$

where  $A_r$  = cross-sectional area perpendicular to the air flow in the working area, ft<sup>2</sup>.

- To exceed the outdoor air requirement for acceptable air quality for occupants, the supply volume flow rate must be equal to or greater than

$$\dot{V}_s \geq n \dot{V}_{oc} \quad (9.3.23b)$$

where  $n$  = number of occupants

$\dot{V}_{oc}$  = outdoor air requirement per person, cfm/person

- To exceed the sum of the volume flow rate of exhaust air  $\dot{V}_{ex}$  and the exfiltrated or relief air  $\dot{V}_{ef}$ , both in cfm,

$$\dot{V}_s \geq \dot{V}_{ex} + \dot{V}_{ef} \quad (9.3.24)$$

The design supply volume flow rate should be the largest of any of the foregoing requirements.

### Rated Supply Volume Flow Rate

For an air system at atmospheric pressure, since the required mass flow rate of the supply air is a function of air density and remains constant along the air flow,

$$\dot{m}_a = \dot{V}_{cc} \rho_{cc} = \dot{V}_s \rho_s = \dot{V}_{sf} \rho_{sf} \quad (9.3.25)$$

$$\dot{V}_{sf} = \dot{V}_s \rho_s / \rho_{sf}$$

where  $\dot{V}_{sf}$  = volume flow rate at supply fan outlet, cfm

$\rho_{sf}$  = air density at supply fan outlet, lb/ft<sup>3</sup>

A supply fan is rated at *standard air conditions*, that is, dry air at a temperature of 70°F, an atmospheric pressure of 29.92 in. Hg (14.697 psia), and an air density of 0.075 lb/ft<sup>3</sup>. However, a fan is a constant-volume machine at a given fan size and speed; that is,  $\dot{V}_{sf} = \dot{V}_{sf,r}$ . Here  $\dot{V}_{sf,r}$  represents the rated volume flow rate of a fan at standard air conditions. Therefore,

$$\dot{V}_{sf,r} = \dot{V}_{sf} = q_{rs,d} / \left[ 60 \rho_{sf,r} c_{pa} (T_r - T_s) \right] \quad (9.3.26)$$

- For conditioned air leaving the cooling coil at  $T_{cc} = 55^\circ\text{F}$  with a relative humidity of 92% and  $T_{sf}$  of  $57^\circ\text{F}$ ,  $\rho_{sf,r} = 1/v_{sf} = 1/13.20 = 0.0758$  lb/ft<sup>3</sup>. From Equation (9.3.26):

$$\dot{V}_{sf,r} = q_{rs,d} / \left[ 60 \times 0.0758 \times 0.243 (T_r - T_s) \right] = q_{rs,d} / \left[ 1.1 (T_r - T_s) \right] \quad (9.3.26a)$$

Equation (9.3.26a) is widely used in calculating the supply volume flow rate of comfort air-conditioning systems.

- For cold air distribution,  $T_{cc} = 40^\circ\text{F}$  and  $\phi_{cc} = 98\%$ , if  $T_{sf} = 42^\circ\text{F}$ , then  $v_{sf} = 12.80$  ft<sup>3</sup>/lb, and the rated supply volume flow rate:

$$\dot{V}_{sf,r} = 12.80 q_{rs,d} / \left[ 60 \times 0.243 (T_r - T_s) \right] = q_{rs,d} / \left[ 1.14 (T_r - T_s) \right] \quad (9.3.26b)$$

- For a blow-through fan in which the fan is located upstream of the coil, if  $T_{sf} = 82^\circ\text{F}$  and  $\phi_{sf} = 43\%$ , then  $v_{sf} = 13.87$  ft<sup>3</sup>/lb, and the rated supply volume flow rate:

$$\dot{V}_{sf,r} = 13.87q_{rs,d} / [60 \times 0.243(T_r - T_s)] = q_{rs,d} / [1.05(T_r - T_s)] \tag{9.3.26c}$$

**Effect of the Altitude**

The higher the altitude, the lower the atmospheric pressure and the air density. In order to provide the required mass flow rate of supply air, a greater  $\dot{V}_{sf,r}$  is needed. For an air temperature of 70°F:

$$\dot{V}_{x,ft} = \dot{V}_{sf,r} (p_{sea} / p_{x,ft}) = \dot{V}_{sf,r} (\rho_{sea} / \rho_{x,ft}) \tag{9.3.27}$$

where  $\dot{V}_{x,ft}$  = supply volume flow rate at an altitude of  $x$  ft, cfm

$p_{sea}, p_{x,ft}$  = atmospheric pressure at sea level and an altitude of  $x$  ft, psia

$\rho_{sea}, \rho_{x,ft}$  = air density at sea level and an altitude of  $x$  ft, psia

Following are the pressure or air density ratios at various altitudes. At 2000 ft above sea level, the rated supply volume flow rate  $\dot{V}_{r,2000} = \dot{V}_{sf,r} (p_{sea} / p_{x,ft}) = 1.076 \dot{V}_{sf,r}$  cfm instead of  $\dot{V}_{sf,r}$  cfm at sea level.

Altitude, ft	$p_{at}$ , psia	$\rho$ , lb/ft <sup>3</sup>	$(p_{sea} / p_{x,ft})$
0	14.697	0.075	1.000
1000	14.19	0.0722	1.039
2000	13.58	0.0697	1.076
3000	13.20	0.0672	1.116
5000	12.23	0.0625	1.200

**Off-Coil and Supply Air Temperature**

For a given design indoor air temperature  $T_r$ , space sensible cooling load  $q_{rs}$ , and supply system heat gain  $q_{s,s}$ , a lower air off-coil temperature  $T_{cc}$  as well as supply temperature  $T_s$  means a greater supply temperature differential  $\Delta T_s$  and a lower space relative humidity  $\phi_r$  and vice versa. A greater  $\Delta T_s$  decreases the supply volume flow rate  $\dot{V}_s$  and then the fan and terminal sizes, duct sizes, and fan energy use. The result is a lower investment and energy cost.

A lower  $T_{cc}$  and a greater  $\Delta T_s$  require a lower chilled water temperature entering the coil  $T_{we}$ , a lower evaporating temperature  $T_{ev}$  in the DX coil or refrigerating plant, and therefore a greater power input to the refrigerating compressors. When an air-conditioning system serves a conditioned space of a single zone, optimum  $T_{cc}$ ,  $T_s$ , and  $T_{we}$  can be selected. For a conditioned space of multizones,  $T_{cc}$ ,  $T_s$ , and  $T_{we}$  should be selected to satisfy the lowest requirement. In practice,  $T_s$  and  $T_{we}$  are often determined according to previous experience with similar projects.

In general, the temperature rise due to the supply fan power system heat gain  $q_{sf}$  can be taken as 1 to 3°F depending on the fan total pressure. The temperature rise due to the supply duct system heat gain at design flow can be estimated as 1°F/100 ft insulated main duct length based on 1-in. thickness of duct insulation.

**Outside Surface Condensation**

The outside surface temperature of the ducts, terminals, and supply outlets  $T_{sur}$  in the ceiling plenum in contact with the return air should not be lower than the dew point of the space air  $T_r'$ , in °F. The temperature rise due to the fan power heat gain is about 2°F. According to Dorgan (1988), the temperature difference between the conditioned air inside the terminal and the outside surface of the terminal with insulation wrap is about 3°F. For a space air temperature of 75°F and a relative humidity of 50%, its dew point temperature is 55°F. If the outside surface temperature  $T_s = (T_{cc} + 2 + 3) \leq 55^\circ\text{F}$ , condensation may occur on the outside surface of the terminal. Three methods are often used to prevent condensation:

1. Increase the thickness of the insulation layer on the outside surface.
2. Adopt a supply outlet that induces more space air.

- Equip with a terminal that mixes the supply air with the space air or air from the ceiling plenum.

During the cool-down period, due to the high dew point temperature of the plenum air when the air system is started, the supply air temperature must be controlled to prevent condensation.

### Example 9.3.1

The worship hall of a church uses a package system with a basic air system. The summer space sensible cooling load is 75,000 Btu/hr with a latent load of 15,000 Btu/hr. Other design data for summer are as follows:

Outdoor summer design temperature: dry bulb 95°F and wet bulb 75°F

Summer indoor temperature: 75°F with a space relative humidity of 50%:

Temperature rise: fan power 2°F

supply duct 2°F

Relative humidity of air leaving cooling coil: 93%

Outdoor air requirement: 1800 cfm

Determine the

- Temperature of supply air at summer design conditions
- Rated volume flow rate of the supply fan
- Cooling coil load
- Possibility of condensation at the outside surface of the insulated branch duct to the supply outlet

*Solution*

- From Equation 9.3.1 the sensible heat ratio of the space conditioning line is

$$\text{SHR}_s = |q_{rs}| / (|q_{rs}| + |q_{rl}|) = 60,000 / (60,000 + 15,000) = 0.8$$

On the psychrometric chart, from given  $T_r = 75^\circ\text{F}$  and  $\phi_r = 50\%$ , plot space point r. Draw a space conditioning line sr from point r with  $\text{SHR}_s = 0.8$ .

Since  $\Delta T_{s,s} = 2 + 2 = 4^\circ\text{F}$ , move line segment cc s ( $4^\circ\text{F}$ ) up and down until point s lies on line sr and point cc lies on the  $\phi_{cc} = 93\%$  line. The state points s and cc are then determined as shown in Figure 9.3.4:

$$T_s = 57.5^\circ\text{F}, \phi_s = 82\%, \text{ and } w_s = 0.0082 \text{ lb/lb}$$

$$T_{cc} = 53.5^\circ\text{F}, \phi_{cc} = 93\%, h_{cc} = 21.8 \text{ Btu/lb}, \text{ and } w_{cc} = 0.0082 \text{ lb/lb}$$

- Since  $T_{sf} = 53.5 + 2 = 55.5^\circ\text{F}$  and  $w_{sf} = 0.0082 \text{ lb/lb}$ ,  $\rho_{sf} = 1/v_{sf} = 1/13.15 = 0.076 \text{ lb/ft}^3$ . From Equation 9.4.2, the required rated supply volume flow rate is

$$\begin{aligned} \dot{V}_{sf,r} &= q_{rs,d} / [60\rho_{sf}c_{pa}(T_r - T_s)] \\ &= 60,000 / [60 \times 0.076 \times 0.243(75 - 57.5)] = 3094 \text{ cfm} \end{aligned}$$

- Plot outdoor air state point o on the psychrometric chart from given dry bulb 95°F and wet bulb 75°F. Connect line ro. Neglect the density differences between points r, m, and o; then

$$rm/ro = 1800/3094 = 0.58$$

From the psychrometric chart, the length of line ro is 2.438 in. As shown in Figure 9.3.4, point m is then determined as:

$$T_m = 86.7^\circ\text{F}, \quad h_m = 35 \text{ Btu/lb}$$

From Equation (9.3.11), the cooling coil load is

$$q_{cc} = 60 \dot{V}_s \rho_s (h_m - h_{cc}) = 60 \times 3094 \times 0.076(35 - 21.8) = 186,234 \text{ Btu/lb}$$

4. From the psychrometric chart, since the dew point of the space air  $T_r'' = 55^\circ\text{F}$  and is equal to that of the plenum air, the outside surface temperature of the branch duct  $T_s = 53.5 + 2 + 3 = 58^\circ\text{F}$  which is higher than  $T_r'' = 55^\circ\text{F}$ . Condensation will not occur at the outside surface of the branch duct.

### Basic Air-Conditioning Cycle — Winter Mode

When the basic air-conditioning systems are operated in winter mode, their air-conditioning cycles can be classified into the following four categories:

*Cold Air Supply without Space Humidity Control.* In winter, for a fully occupied worship hall, if the heat loss is less than the space sensible cooling load, a cold air supply is required to offset the space sensible cooling load and maintain a desirable indoor environment as shown by the lower cycle in [Figure 9.3.4](#). Usually, a humidifier is not used.

The winter cycle of a cold air supply without humidity control consists of the following air-conditioning processes:

1. Adiabatic mixing process of outdoor air and recirculating air o m r.
2. Sensible heating process due to supply fan power heat gain m sf. Because of the smaller temperature difference between the air in the ceiling plenum and the supply air inside the supply duct, heat transfer through duct wall in winter can be neglected.
3. Supply conditioning line sr.

For a winter-mode basic air-conditioning cycle with a cold air supply without space humidity control, the space relative humidity depends on the space latent load, the humidity ratio of the outdoor air, and the amount of outdoor air intake. In order to determine the space humidity ratio  $w_r$ , in lb/lb, and the space relative humidity  $\phi_r$ , in %, Equations (9.3.15) and (9.3.22) should be used to give the following relationships:

$$\begin{aligned} (w_r - w_m) / (w_r - w_o) &= \dot{V}_o / \dot{V}_s \\ (w_r - w_s) &= q_{rl} / \left( 60 \dot{V}_s \rho_s h_{fg,58} \right) \\ w_s &= w_m \end{aligned} \quad (9.3.28)$$

For a cold air supply, if there is a high space sensible cooling load, the amount of outdoor air must be sufficient, and the mixture must be cold enough to satisfy the following relationships:

$$\begin{aligned} (T_r - T_s) &= q_{rs} / \left( 60 \dot{V}_s \rho_s c_{pa} \right) \\ (T_r - T_s) / (T_r - T_o) &= \dot{V}_o / \dot{V}_s \end{aligned} \quad (9.3.29)$$

The heating coil load for heating of the outdoor air can be calculated using Equation (9.3.7).

**Example 9.3.2**

For the same packaged air-conditioning system using a basic air system to serve the worship hall in a church as in Example 9.3.1, the space heating load at winter design condition is 10,000 Btu/hr and the latent load is 12,000 Btu/hr. Other winter design data are as follows:

Winter outdoor design temperature	35°F
Winter outdoor design humidity ratio	0.00035 lb/lb
Winter indoor design temperature	70°F
Temperature rise due to supply fan heat gain	2°F
Outdoor air requirement	1800 cfm

Determine (1) the space relative humidity at winter design temperature and (2) the heating coil load.

*Solution*

1. Assume that the supply air density  $\rho_{sf} = 1/v_{sf} = 1/13.0 = 0.0769$  lb/ft<sup>3</sup>, and the mass flow rate of the supply air is the same as in summer mode. Then from Equation 9.3.28 the humidity ratio difference is

$$(w_r - w_s) = q_{rl} / \left( 60 \dot{V}_{sf,r} \rho_{sf} h_{fg,58} \right) = 12,000 / (60 \times 3094 \times 0.0769 \times 1060) = 0.00079 \text{ lb/lb}$$

From Equation 9.3.29, the supply air temperature differential is

$$(T_r - T_s) = q_{rs,d} / \left( 60 \dot{V}_{sf,r} \rho_{sf} c_{pa} \right) = 10,000 / (60 \times 3094 \times 0.0769 \times 0.243) = 2.88^\circ\text{F}$$

Since  $\dot{V}_o / \dot{V}_s = 1800/3094 = 0.58$  and  $w_s = w_m$ ,

$$(w_r - w_s) / (w_r - w_o) = 0.00079 / (w_r - w_o) = \dot{V}_o / \dot{V}_s = 0.58$$

$$(w_r - w_o) = 0.00079 / 0.58 = 0.00136 \text{ lb/lb}$$

And from given information,

$$w_r = 0.00136 + w_o = 0.00136 + 0.0035 = 0.00486 \text{ lb/lb}$$

From the psychrometric chart, for  $T_r = 70^\circ\text{F}$  and  $w_r = 0.00486$  lb/lb, point r can be plotted, and  $\phi_r$  is about 32% (see Figure 9.3.4).

2. Since  $m_r/o_r = 0.58$ , point m can be determined, and from the psychrometric chart  $T_m = 50.0^\circ\text{F}$ . As  $T_s = 70 - 2.88 = 67.12^\circ\text{F}$  and  $T_{sf} = T_m + 2 = 50.0 + 2 = 52.0^\circ\text{F}$ , from Equation 9.3.7 the heating coil's load is

$$q_{ch} = 60 \dot{V}_s \rho_s c_{pa} (T_s - T_{sf}) = 60 \times 3094 \times 0.0769 \times 0.243 (67.12 - 52.0) = 52,451 \text{ Btu/hr}$$

**Warm Air Supply without Space Humidity Control**

When the sum of space heat losses is greater than the sum of the internal heat gains in winter, a warm air supply is needed. For many comfort systems such as those in offices and stores, in locations where winter is not very cold, humidification is usually not necessary. The basic air-conditioning cycle for a warm air supply without space humidity control is shown in Figure 9.3.5(a). This cycle is similar to the

**FIGURE 9.3.5** Basic air-conditioning cycle — winter modes: (a) warm air supply without space humidity control, (b) cold air supply without space humidity control, and (c) cold air supply with space humidity control. ch = air leaving heating coil, h = air leaving humidifer, and aw = air leaving air washer.

winter mode cycle of a cold air supply without space humidity control shown in Figure 9.3.4 except that the supply air temperature is higher than space temperature, that is,  $T_s > T_r$ . To prevent stratification, with the warm supply air staying at a higher level,  $(T_s - T_r) > 20^\circ\text{F}$  is not recommended.

**Warm Air Supply with Space Humidity Control**

This operating cycle (see Figure 9.3.5[b]) is often used for hospitals, nurseries, etc. or in locations where winter is very cold. The state point of supply air must be determined first by drawing a space conditioning line with known  $\text{SHR}_s$  and then from the calculated supply temperature differential  $\Delta T_s$ . The difference in humidity ratio ( $w_s - w_{ch}$ ) is the water vapor must be added at the humidifier. Humidifying capacity can be calculated from Equation 9.3.8.

**Cold Air Supply with Space Humidity Control**

This operating cycle (shown in Figure 9.3.5[c]) is widely used in industrial applications such as textile mills where a cold air supply is needed to remove machine load in winter and maintains the space relative humidity required for the manufacturing process. An outdoor air and recirculating air mixture is often used for the required cold air supply. An air washer is adopted for winter humidification.

### Air Economizer Mode

In the *air economizer* mode, as shown by the middle dotted line cycle  $o''$ -cc-sf-s-r in Figure 9.3.4, all outdoor air or an outdoor air-recirculating air mixture is used to reduce the refrigeration capacity and improve the indoor air quality during spring, fall, or winter.

When all outdoor air is admitted, it is an open cycle. Outdoor air is cooled and often dehumidified to point cc. After absorbing fan and duct heat gains, it is supplied to the conditioned space. Space air is exhausted entirely through openings, relief dampers, or relief/exhaust fans to the outside. An all-outdoor air-operating mode before the space is occupied is often called an *air purge* operation, used to dilute space air contaminants.

### Cool-Down and Warm-Up Modes

In summer, when an air system is shut down during an unoccupied period at night, the space temperature and relative humidity often tend to increase because of infiltration of hot and humid air and heat transfer through the building envelope. The air system is usually started before the space is occupied in cool-down mode to cool the space air until the space temperature falls within predetermined limits.

In winter, the air system is also started before the occupied period to warm up the space air to compensate for the nighttime space temperature setback to 55 to 60°F for energy saving or the drop of space temperature due to heat loss and infiltration.

If dilution of indoor air contaminants is not necessary, only recirculating space air is used during cool-down or warm-up periods in order to save energy.

## 9.4 Refrigerants and Refrigeration Cycles

### Refrigeration and Refrigeration Systems

*Refrigeration* is the cooling effect of the process of extracting heat from a lower temperature heat source, a substance or cooling medium, and transferring it to a higher temperature heat sink, probably atmospheric air and surface water, to maintain the temperature of the heat source below that of the surroundings.

A *refrigeration system* is a combination of components, equipment, and piping, connected in a sequential order to produce the refrigeration effect. Refrigeration systems that provide cooling for air-conditioning are classified mainly into the following categories:

1. *Vapor compression systems.* In these systems, a compressor(s) compresses the refrigerant to a higher pressure and temperature from an evaporated vapor at low pressure and temperature. The compressed refrigerant is condensed into liquid form by releasing the latent heat of condensation to the condenser water. Liquid refrigerant is then throttled to a low-pressure, low-temperature vapor, producing the refrigeration effect during evaporation. Vapor compression is often called *mechanical refrigeration*, that is, refrigeration by mechanical compression.
2. *Absorption systems.* In an absorption system, the refrigeration effect is produced by means of thermal energy input. After liquid refrigerant produces refrigeration during evaporation at very low pressure, the vapor is absorbed by an aqueous absorbent. The solution is heated by a direct-fired gas furnace or waste heat, and the refrigerant is again vaporized and then condensed into liquid form. The liquid refrigerant is throttled to a very low pressure and is ready to produce the refrigeration effect again.
3. *Gas expansion systems.* In an air or other gas expansion system, air or gas is compressed to a high pressure by compressors. It is then cooled by surface water or atmospheric air and expanded to a low pressure. Because the temperature of air or gas decreases during expansion, a refrigeration effect is produced.

### Refrigerants, Cooling Mediums, and Absorbents

A *refrigerant* is a primary working fluid used to produce refrigeration in a refrigeration system. All refrigerants extract heat at low temperature and low pressure during evaporation and reject heat at high temperature and pressure during condensation.

A *cooling medium* is a working fluid cooled by the refrigerant during evaporation to transport refrigeration from a central plant to remote cooling equipment and terminals. In a large, centralized air-conditioning system, it is more economical to pump the cooling medium to the remote locations where cooling is required. Chilled water and brine are cooling media. They are often called secondary refrigerants to distinguish them from the primary refrigerants.

A *liquid absorbent* is a working fluid used to absorb the vaporized refrigerant (water) after evaporation in an absorption refrigeration system. The solution that contains the absorbed vapor is then heated. The refrigerant vaporizes, and the solution is restored to its original concentration to absorb water vapor again.

A numbering system for refrigerants was developed for hydrocarbons and halocarbons. According to ANSI/ASHRAE Standard 34-1992, the first digit is the number of unsaturated carbon-carbon bonds in the compound. This digit is omitted if the number is zero. The second digit is the number of carbon atoms minus one. This is also omitted if the number is zero. The third digit denotes the number of hydrogen atoms plus one. The last digit indicates the number of fluorine atoms. For example, the chemical formula for refrigerant R-123 is  $\text{CHCl}_2\text{CF}_3$ . In this compound:

No unsaturated carbon-carbon bonds, first digit is     0  
 There are two carbon atoms, second digit is     2 - 1 = 1  
 There is one hydrogen atom, third digit is     1 + 1 = 2

There are three fluorine atoms, last digit is 3

To compare the relative ozone depletion of various refrigerants, an index called the *ozone depletion potential* (ODP) has been introduced. ODP is defined as the ratio of the rate of ozone depletion of 1 lb of any halocarbon to that of 1 lb of refrigerant R-11. For R-11, ODP = 1.

Similar to the ODP, halocarbon global warming potential (HGWP) is an index used to compare the global warming effect of a halocarbon refrigerant with the effect of refrigerant R-11.

## Classification of Refrigerants

Nontoxic and nonflammable synthetic chemical compounds called *halogenated hydrocarbons*, or simply *halocarbons*, were used almost exclusively in vapor compression refrigeration systems for comfort air-conditioning until 1986. Because chlorofluorocarbons (CFCs) cause ozone depletion and global warming, they must be replaced. A classification of refrigerants based on ozone depletion follows (see [Table 9.4.1](#)):

### Hydrofluorocarbons (HFCs)

HFCs contain only hydrogen, fluorine, and carbon atoms and cause no ozone depletion. HFCs group include R-134a, R-32, R-125, and R-245ca.

### HFC's Azeotropic Blends or Simply HFC's Azeotropic

An azeotropic is a mixture of multiple components of volatilities (refrigerants) that evaporate and condense as a single substance and do not change in volumetric composition or saturation temperature when they evaporate or condense at constant pressure. HFC's azeotropics are blends of refrigerant with HFCs. ASHRAE assigned numbers between 500 and 599 for azeotropic. HFC's azeotropic R-507, a blend of R-125/R-143, is the commonly used refrigerant for low-temperature vapor compression refrigeration systems.

### HFC's Near Azeotropic

A near azeotropic is a mixture of refrigerants whose characteristics are near those of an azeotropic. Because the change in volumetric composition or saturation temperature is rather small for a near azeotropic, such as, 1 to 2°F, it is thus named. ASHRAE assigned numbers between 400 and 499 for zeotropic. R-404A (R-125/R-134a/R-143a) and R-407B (R-32/R-125/R134a) are HFC's near azeotropic. R-32 is flammable; therefore, its composition is usually less than 30% in the mixture. HFC's near azeotropic are widely used for vapor compression refrigeration systems.

Zeotropic or nonazeotropic, including near azeotropic, shows a change in composition due to the difference between liquid and vapor phases, leaks, and the difference between charge and circulation. A shift in composition causes the change in evaporating and condensing temperature/pressure. The difference in dew point and bubble point during evaporation and condensation is called glide, expressed in °F. Near azeotropic has a smaller glide than zeotropic. The midpoint between the dew point and bubble point is often taken as the evaporating and condensing temperature for refrigerant blends.

### Hydrochlorofluorocarbons (HCFCs) and Their Zeotropics

HCFCs contain hydrogen, chlorine, fluorine, and carbon atoms and are not fully halogenated. HCFCs have a much shorter lifetime in the atmosphere (in decades) than CFCs and cause far less ozone depletion (ODP 0.02 to 0.1). R-22, R-123, R-124, etc. are HCFCs. HCFCs are the most widely used refrigerants today.

*HCFC's near azeotropic* and *HCFC's zeotropic* are blends of HCFCs with HFCs. They are transitional or interim refrigerants and are scheduled for a restriction in production starting in 2004.

### Inorganic Compounds

These compounds include refrigerants used before 1931, like ammonia R-717, water R-718, and air R-729. They are still in use because they do not deplete the ozone layer. Because ammonia is toxic and

TABLE 9.4.1 Properties of Commonly Used Refrigerants 40°F Evaporating and 100°F Condensing

		Chemical Formula	Molecular Mass	Ozone Depletion Potential (ODP)	Global Warming Potential (HGWP)	Evaporating Pressure, psia	Condensing Pressure, psia	Compression Ratio	Refrigeration Effect, Btu/lb

<sup>a</sup> First classification is that safety classification of the formulated composition. The second is the worst case of fractionation.

flammable, it is used in industrial applications. Inorganic compounds are assigned numbers between 700 and 799 by ASHRAE.

### **Chlorofluorocarbons, Halons, and Their Azeotropic**

CFCs contain only chlorine, fluorine, and carbon atoms. CFCs have an atmospheric lifetime of centuries and cause ozone depletion (ODP from 0.6 to 1). R-11, R-12, R-113, R-114, R-115... are all CFCs.

Halons or BFCs contain bromide, fluorine, and carbon atoms. R-13B1 and R-12B1 are BFCs. They cause very high ozone depletion (ODP for R-13B1 = 10). Until 1995, R-13B1 was used for very low temperature vapor compression refrigeration systems.

### **Phaseout of CFCs, BFCs, HCFCs, and Their Blends**

On September 16, 1987, the European Economic Community and 24 nations, including the United States, signed a document called the Montreal Protocol. It is an agreement to restrict the production and consumption of CFCs and BFCs in the 1990s because of ozone depletion.

The Clean Air Act amendments, signed into law in the United States on November 15, 1990, concern two important issues: the phaseout of CFCs and the prohibition of deliberate venting of CFCs and HCFCs.

In February 1992, President Bush called for an accelerated ban of CFCs in the United States. In late November 1992, representatives of 93 nations meeting in Copenhagen agreed to phase out CFCs beginning January 1, 1996. Restriction on the use of HCFCs will start in 2004, with a complete phaseout by 2030.

In the earlier 1990s, R-11 was widely used for centrifugal chillers, R-12 for small and medium-size vapor compression systems, R-22 for all vapor compression systems, and CFC/HCFC blend R-502 for low-temperature vapor compression systems. Because of the phaseout of CFCs and BFCs before 1996 and HCFCs in the early years of the next century, alternative refrigerants have been developed to replace them:

- R-123 (an HCFC of ODP = 0.02) to replace R-11 is a short-term replacement that causes a slight reduction in capacity and efficiency. R-245ca (ODP = 0) may be the long-term alternative to R-11.
- R-134a (an HFC with ODP = 0) to replace R-12 in broad applications. R-134a is not miscible with mineral oil; therefore, a synthetic lubricant of polyolester is used.
- R-404A (R-125/R-134a/143a) and R-407C (R-32/R-125/R-134a) are both HFCs near azeotropic of ODP = 0. They are long-term alternatives to R-22. For R-407C, the composition of R-32 in the mixture is usually less than 30% so that the blend will not be flammable. R-407C has a drop of only 1 to 2% in capacity compared with R-22.
- R-507 (R-125/R-143a), an HFC's azeotropic with ODP = 0, is a long-term alternative to R-502. Synthetic polyolester lubricant oil will be used for R-507. There is no major performance difference between R-507 and R-502. R-402A (R-22/R-125/R-290), an HCFC's near azeotropic, is a short-term immediate replacement, and drop-in of R-502 requires minimum change of existing equipment except for reset of a higher condensing pressure.

### **Required Properties of Refrigerants**

A refrigerant should not cause ozone depletion. A low global warming potential is required. Additional considerations for refrigerant selection are

1. *Safety*, including toxicity and flammability. ANSI/ASHRAE Standard 34-1992 classifies the *toxicity* of refrigerants as Class A and Class B. Class A refrigerants are of low toxicity. No toxicity was identified when their time-weighted average concentration was less than or equal to 400 ppm, to which workers can be exposed for an 8-hr workday and 40-hr work week without adverse effect. Class B refrigerants are of higher toxicity and produce evidence of toxicity.

ANSI/ASHRAE Standard 34-1982 classifies the *flammability* of refrigerants as Class 1, no flame propagation; Class 2, lower flammability; and Class 3, higher flammability.

The safety classification of refrigerants is based on the combination of toxicity and flammability: A1, A2, A3, B1, B2, and B3. R-134a and R-22 are in the A1 group, lower toxicity and nonflammable; R-123 in the B1 group, higher toxicity and nonflammable; and R-717 (ammonia) in the B2 group, higher toxicity and lower flammability.

2. *Effectiveness of refrigeration cycle.* High effectiveness is a desired property. The power consumed per ton of refrigeration produced, hp/ton or kW/ton, is an index for this assessment. Table 9.4.1 gives values for an ideal single-stage vapor compression cycle.
3. *Oil miscibility.* Refrigerant should be miscible with mineral lubricant oil because a mixture of refrigerant and oil helps to lubricate pistons and discharge valves, bearings, and other moving parts of a compressor. Oil should also be returned from the condenser and evaporator for continuous lubrication. R-22 is partially miscible. R-134a is hardly miscible with mineral oil; therefore, synthetic lubricant of polyolester will be used.
4. *Compressor displacement.* Compressor displacement per ton of refrigeration produced, in cfm/ton, directly affects the size of the positive displacement compressor and therefore its compactness. Ammonia R-717 requires the lowest compressor displacement (1.70 cfm/ton) and R-22 the second lowest (1.91 cfm/ton).
5. Desired properties:
  - Evaporating pressure  $p_{ev}$  should be higher than atmospheric. Then noncondensable gas will not leak into the system.
  - Lower condensing pressure for lighter construction of compressor, condenser, piping, etc.
  - A high thermal conductivity and therefore a high heat transfer coefficient in the evaporator and condenser.
  - Dielectric constant should be compatible with air when the refrigerant is in direct contact with motor windings in hermetic compressors.
  - An inert refrigerant that does not react chemically with material will avoid corrosion, erosion, or damage to system components. Halocarbons are compatible with all containment materials except magnesium alloys. Ammonia, in the presence of moisture, is corrosive to copper and brass.
  - Refrigerant leakage can be easily detected. Halide torch, electronic detector, and bubble detection are often used.

## Ideal Single-Stage Vapor Compression Cycle

### Refrigeration Process

A refrigeration process shows the change of the thermodynamic properties of the refrigerant and the energy and work transfer between the refrigerant and surroundings.

Energy and work transfer is expressed in British thermal units per hour, or Btu/hr. Another unit in wide use is ton of refrigeration, or ton. A ton = 12,000 Btu/hr of heat removed; i.e., 1 ton of ice melting in 24 hr = 12,000 Btu/hr.

### Refrigeration Cycles

When a refrigerant undergoes a series of processes like evaporation, compression, condensation, throttling, and expansion, absorbing heat from a low-temperature source and rejecting it to a higher temperature sink, it is said to have undergone a refrigeration cycle. If its final state is equal to its initial state, it is a *closed cycle*; if the final state does not equal the initial state, it is an *open cycle*. Vapor compression refrigeration cycles can be classified as single stage, multistage, compound, and cascade cycles.

A *pressure-enthalpy diagram* or *p-h diagram* is often used to calculate the energy transfer and to analyze the performance of a refrigeration cycle, as shown in Figure 9.4.1. In a *p-h* diagram, pressure  $p$ , in psia or psig logarithmic scale, is the ordinate, and enthalpy  $h$ , in Btu/lb, is the abscissa. The saturated liquid and saturated vapor line encloses a two-phase region in which vapor and liquid coexist. The two-phase region separates the subcooling liquid and superheated vapor regions. The constant-temperature

**FIGURE 9.4.1** Skeleton of pressure-enthalpy diagram for R-22.

line is nearly vertical in the subcooling region, horizontal in the two-phase region, and curved down sharply in the superheated region.

In the two-phase region, a given saturated pressure determines the saturated temperature and vice versa. The constant-entropy line is curved upward to the right-hand side in the superheated region. Each kind of refrigerant has its own  $p-h$  diagram.

**Refrigeration Processes in an Ideal Single-Stage Cycle**

An *ideal cycle* has isentropic compression, and pressure losses in the pipeline, valves, and other components are neglected. All refrigeration cycles covered in this section are ideal. Single stage means a single stage of compression.

There are four refrigeration processes in an ideal single-stage vapor compression cycle, as shown in Figure 9.4.2(a) and (b):

1. Isothermal evaporation process 4–1 — The refrigerant evaporates completely in the evaporator and produces refrigeration effect  $q_{rf}$ , in Btu/lb:

$$q_{rf} = (h_1 - h_4) \tag{9.4.1}$$

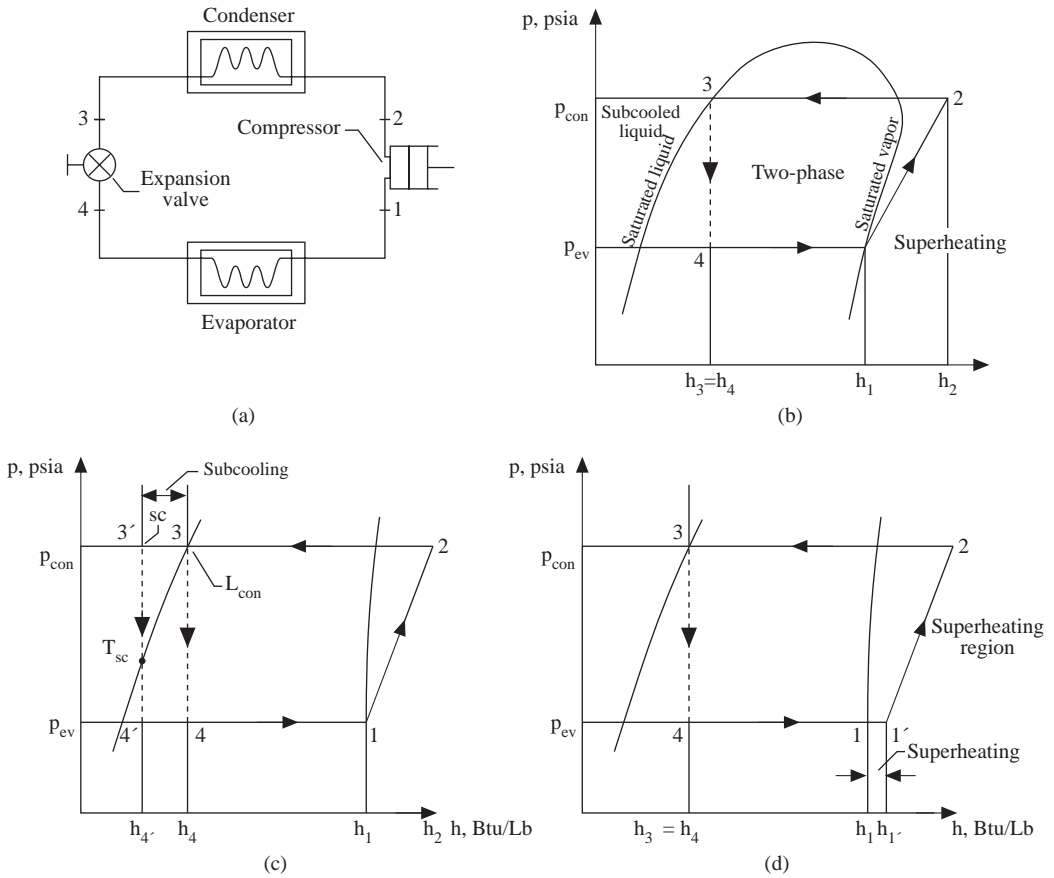

where  $h_1, h_4$  = enthalpy of refrigerant at state points 1 and 4, respectively, Btu/lb.

2. Isentropic compression process 1–2 — Vapor refrigerant is extracted by the compressor and compressed isentropically from point 1 to 2. The work input to the compressor  $W_{in}$ , in Btu/lb, is

$$W_{in} = (h_2 - h_1) \tag{9.4.2}$$

where  $h_2$  = enthalpy of refrigerant at state point 2, Btu/lb.

The greater the difference in temperature/pressure between the condensing pressure  $p_{con}$  and evaporating pressure  $p_{ev}$ , the higher will be the work input to the compressor.

**FIGURE 9.4.2** A single-stage ideal vapor compression refrigeration cycle: (a) schematic diagram, (b)  $p$ - $h$  diagram, (c) subcooling, and (d) superheating.

3. Isothermal condensation process 2–3 — Hot gaseous refrigerant discharged from the compressor is condensed in the condenser into liquid, and the latent heat of condensation is rejected to the condenser water or ambient air. The heat rejection during condensation,  $q_{2-3}$ , in Btu/lb, is

$$-q_{2-3} = (h_2 - h_3) \tag{9.4.3}$$

where  $h_3$  = enthalpy of refrigerant at state point 3, Btu/lb.

4. Throttling process 3–4 — Liquid refrigerant flows through a throttling device (e.g., an expansion valve, a capillary tube, or orifices) and its pressure is reduced to the evaporating pressure. A portion of the liquid flashes into vapor and enters the evaporator. This is the only irreversible process in the ideal cycle, usually represented by a dotted line. For a throttling process, assuming that the heat gain from the surroundings is negligible:

$$h_3 = h_4 \tag{9.4.4}$$

The mass flow rate of refrigerant  $\dot{m}_r$ , in lb/min, is

$$\dot{m}_r = q_{rc} / 60q_{rf} \tag{9.4.5}$$

where  $q_{rc}$  = refrigeration capacity of the system, Btu/hr.

The ideal single-stage vapor compression refrigeration cycle on a  $p$ - $h$  diagram is divided into two pressure regions: high pressure ( $p_{con}$ ) and low pressure ( $p_{ev}$ ).

## Coefficient of Performance of Refrigeration Cycle

The *coefficient of performance* (COP) is a dimensionless index used to indicate the performance of a thermodynamic cycle or thermal system. The magnitude of COP can be greater than 1.

- If a *refrigerator* is used to produce a refrigeration effect,  $COP_{ref}$  is

$$COP_{ref} = q_{rf} / W_{in} \quad (9.4.6)$$

- If a *heat pump* is used to produce a useful heating effect, its performance denoted by  $COP_{hp}$  is

$$COP_{hp} = q_{2-3} / W_{in} \quad (9.4.7)$$

- For a heat recovery system when both refrigeration and heating effects are produced, the  $COP_{hr}$  is denoted by the ratio of the sum of the absolute values of  $q_{rf}$  and  $q_{2-3}$  to the work input, or

$$COP_{hr} = (|q_{rf}| + |q_{2-3}|) / W_{in} \quad (9.4.8)$$

## Subcooling and Superheating

Condensed liquid is often subcooled to a temperature lower than the saturated temperature corresponding to the condensing pressure  $p_{con}$ , in psia or psig, as shown in [Figure 9.4.2\(c\)](#). *Subcooling* increases the refrigeration effect to  $q_{rf,sc}$  as shown in [Figure 9.4.2\(c\)](#):

$$q_{rf,sc} = (h_{4'} - h_1) > (h_4 - h_1) \quad (9.4.9)$$

The enthalpy of subcooled liquid refrigerant  $h_{sc}$  approximately equals the enthalpy of the saturated liquid refrigerant at subcooled temperature  $h_{s,sc}$ , both in Btu/lb:

$$h_{sc} = h_{3'} = h_{4'} = h_{l,con} - c_{pr}(T_{con} - T_{sc}) \approx h_{s,sc} \quad (9.4.10)$$

where  $h_{3'}$ ,  $h_{4'}$  = enthalpy of liquid refrigerant at state points 3' and 4' respectively, Btu/lb

$h_{l,con}$  = enthalpy of saturated liquid at condensing temperature, Btu/lb

$c_{pr}$  = specific heat of liquid refrigerant at constant pressure, Btu/lb °F

$T_{con}$  = condensing temperature or saturated temperature of liquid refrigerant at condensing pressure, °F

$T_{sc}$  = temperature of subcooled liquid refrigerant, °F

The purpose of *superheating* is to prevent liquid refrigerant flooding back into the compressor and causing slugging damage as shown in [Figure 9.4.2\(d\)](#). The degree of superheating depends mainly on the types of refrigerant feed, construction of the suction line, and type of compressor. The state point of vapor refrigerant after superheating of an ideal system must be at the evaporating pressure with a specific degree of superheat and can be plotted on a  $p$ - $h$  diagram for various refrigerants.

## Refrigeration Cycle of Two-Stage Compound Systems with a Flash Cooler

A *multistage system* employs more than one compression stage. Multistage vapor compression systems are classified as compound systems and cascade systems. A *compound system* consists of two or more

compression stages connected in series. It may have one high-stage compressor (higher pressure) and one low-stage compressor (lower pressure), several compressors connected in series, or two or more impellers connected internally in series and driven by the same motor.

The *compression ratio*  $R_{com}$  is defined as the ratio of discharge pressure  $p_{dis}$  to the suction pressure at the compressor inlet  $p_{suc}$ :

$$R_{com} = p_{dis}/p_{suc} \tag{9.4.11}$$

Compared to a single-stage system, a multistage has a smaller compression ratio and higher compression efficiency for each stage of compression, greater refrigeration effect, lower discharge temperature at the high-stage compressor, and greater flexibility. At the same time, a multistage system has a higher initial cost and more complicated construction.

The pressure between the discharge pressure of the high-stage compressor and the suction pressure of the low-stage compressor of a multistage system is called *interstage pressure*  $p_i$ , in psia. Interstage pressure for a two-stage system is usually determined so that the compression ratios are nearly equal between two stages for a higher COP. Then the interstage pressure is

$$p_i = \sqrt{(p_{con}p_{ev})} \tag{9.4.12}$$

where  $p_{con}$ ,  $p_{ev}$  = condensing and evaporating pressures, psia.

For a multistage system of  $n$  stages, then, the compression ratio of each stage is

$$R_{com} = (p_{con}/p_{suc})^{1/n} \tag{9.4.13}$$

Figure 9.4.3(a) shows a schematic diagram and Figure 9.4.3(b) the refrigeration cycle of a two-stage compound system with a flash cooler. A *flash cooler*, sometimes called an economizer, is used to subcool the liquid refrigerant to the saturated temperature corresponding to the interstage pressure by vaporizing a portion of the liquid refrigerant in the flash cooler.

Based on the principle of heat balance, the fraction of evaporated refrigerant,  $x$ , or quality of the mixture in the flash cooler is

$$x = (h_{5'} - h_8)/(h_7 - h_8) \tag{9.4.14}$$

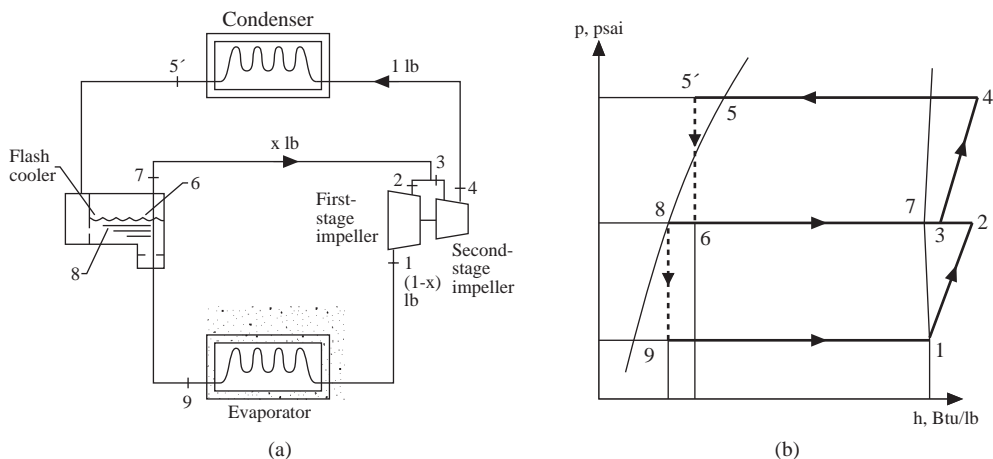

FIGURE 9.4.3 Two-stage compound system with a flash cooler: (a) schematic diagram and (b) refrigeration cycle.

where  $h_5, h_7, h_8$  = enthalpy of the refrigerant at state points 5', 7, and 8, respectively, Btu/lb. The coefficient of performance of the refrigeration cycle of a two-stage compound system with a flash cooler,  $COP_{ref}$ , is given as

$$COP_{ref} = q_{rf} / W_{in} = (1 - x)(h_1 - h_9) / [(1 - x)(h_2 - h_1) + (h_4 - h_3)] \tag{9.4.15}$$

where  $h_1, h_2, h_3, h_4, h_9$  = enthalpy of refrigerant at state points 1, 2, 3, 4, and 9, respectively, Btu/lb. The mass flow rate of refrigerant flowing through the condenser,  $\dot{m}_r$ , in lb/min, can be calculated as

$$\dot{m}_r = q_{rc} / 60q_{rf} \tag{9.4.16}$$

Because a portion of liquid refrigerant is flashed into vapor in the flash cooler and goes directly to the second-stage impeller inlet, less refrigerant is compressed in the first-stage impeller. In addition, the liquid refrigerant in the flash cooler is cooled to the saturated temperature corresponding to the interstage temperature before entering the evaporator, which significantly increases the refrigeration effect of this compound system. Two-stage compound systems with flash coolers are widely used in large central air-conditioning systems.

### Cascade System Characteristics

A *cascade system* consists of two independently operated single-stage refrigeration systems: a lower system that maintains a lower evaporating temperature and produces a refrigeration effect and a higher system that operates at a higher evaporating temperature as shown in Figure 9.4.4(a) and (b). These two separate systems are connected by a *cascade condenser* in which the heat released by the condenser in the lower system is extracted by the evaporator in the higher system.

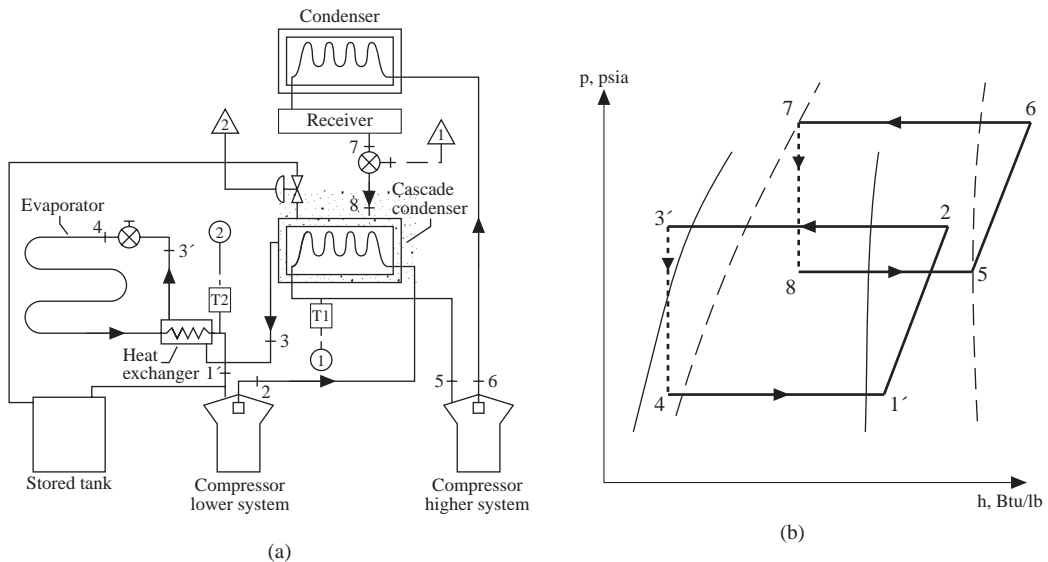

FIGURE 9.4.4 Cascade system: (a) schematic diagram and (b) refrigeration cycle.

A heat exchanger is often used between the liquid refrigerant from the condenser and the vapor refrigerant leaving the evaporator of the lower system. When the system is shut down in summer, a relief valve connected to a stored tank should be used to relieve the higher pressure of refrigerant at the higher storage temperature.

The main advantages of a cascade system compared with a compound system are that different refrigerants, oils, and equipment can be used for the lower and higher systems. Disadvantages are the overlap of the condensing temperature of the lower system and the evaporating temperature of the higher system because of the heat transfer in the cascade condenser and a more complicated system.

The refrigeration effect  $q_{\text{rf}}$  of the cascade system is

$$q_{\text{rf}} = (h_1 - h_4) \quad (9.4.17)$$

where  $h_1, h_4$  = enthalpy of the refrigerant leaving and entering the evaporator of the lower system, Btu/lb. The total work input to the compressors in both higher and lower systems  $W_{\text{in}}$ , in Btu/lb, can be calculated as

$$W_{\text{in}} = (h_2 - h_{1'}) + \dot{m}_h (h_6 - h_5) / \dot{m}_l \quad (9.4.18)$$

where  $h_2$  = enthalpy of refrigerant discharged from the compressor of the lower system  
 $h_{1'}$  = enthalpy of the vapor refrigerant leaving the heat exchanger  
 $h_6, h_5$  = enthalpy of the refrigerant leaving and entering the high-stage compressor  
 $\dot{m}_h, \dot{m}_l$  = mass flow rate of the refrigerant of the higher and lower systems, respectively

The coefficient of performance of a cascade system  $\text{COP}_{\text{ref}}$  is

$$\text{COP}_{\text{ref}} = q_{\text{rf}} / W_{\text{in}} = \dot{m}_l (h_1 - h_4) / \left[ \dot{m}_l (h_2 - h_{1'}) + \dot{m}_h (h_6 - h_5) \right] \quad (9.4.19)$$

## 9.5 Outdoor Design Conditions and Indoor Design Criteria

### Outdoor Design Conditions

In principle, the capacity of air-conditioning equipment should be selected to offset or compensate for the space load so that indoor design criteria can be maintained if the outdoor weather does not exceed the design values. Outdoor and indoor design conditions are used to calculate the design space loads. In energy use calculations, hour-by-hour outdoor climate data of a design day should be adopted instead of summer and winter design values.

*ASHRAE Handbook 1993 Fundamentals* (Chapter 24 and 27) and *Wang's Handbook of Air Conditioning and Refrigeration* (Chapter 7) both list tables of climate conditions for the U.S. and Canada based on the data from the National Climate Data Center (NCDC), U.S. Air Force, U.S. Navy, and Canadian Atmospheric Environment Service. In these tables:

- *Summer design dry bulb temperature* in a specific location  $T_{o,s}$ , in °F, is the rounded higher integral number of the statistically determined summer outdoor design dry bulb temperature  $T_{o,ss}$  so that the average number of hours of occurrence of outdoor dry bulb temperature  $T_o$  higher than  $T_{o,ss}$  during June, July, August, and September is less than 1, 2.5, or 5% of the total number of hours in these summer months (2928 hr). The data are an average of 15 years. An occurrence of less than 2.5% of 2928 hr of summer months, that is,  $0.025 \times 2928 = 73$  hr, is most widely used.
- *Summer outdoor mean coincident wet bulb temperature*  $T'_{o,s}$ , in °F, is the mean of all the wet bulb temperatures at the specific summer outdoor design dry bulb temperature  $T_{o,s}$  during the summer months.
- *Summer outdoor 2.5% design wet bulb temperature* is the design wet bulb temperature that has an average annual occurrence of  $T'_o > T'_{o,s}$  less than 73 hr. This design value is often used for evaporative cooling design.
- *Mean daily range*, in °F, is the difference between the average daily maximum and the average daily minimum temperature during the warmest month.
- In *ASHRAE Handbook 1993 Fundamentals*, *solar heat gain factors* (SHGFs), in Btu/h.ft<sup>2</sup>, are the average solar heat gain per hour during cloudless days through double-strength sheet (DSA) glass. The *maximum SHGFs* are the maximum values of SHGFs on the 21st of each month for a specific latitude.
- *Winter outdoor design dry bulb temperature*  $T_{o,w}$ , in °F, is the rounded lower integral value of the statically determined winter outdoor design temperature  $T_{o,ws}$ , so that the annual average number of hours of occurrence of outdoor temperature  $T_o > T_{o,ws}$  is equal to or exceeds 99%, or 97.5% of the total number of hours in December, January, and February (2160 hr).

A *degree day* is the difference between a base temperature and the mean daily outdoor air temperature  $T_{o,m}$  for any one day, in °F. The total numbers of heating degree days HDD65 and cooling degree days CDD65 referring to a base temperature of 65°F per annum are

$$\begin{aligned} \text{HDD65} &= \sum_{n=1} (65 - T_{o,m}) \\ \text{CDD65} &= \sum_{m=1} (T_{o,m} - 65) \end{aligned} \tag{9.5.1}$$

where  $n$  = number of days for which  $T_{o,m} < 65^\circ\text{F}$

$m$  = number of days for which  $T_{o,m} > 65^\circ\text{F}$

## Indoor Design Criteria and Thermal Comfort

*Indoor design criteria*, such as space temperature, humidity, and air cleanliness, specify the requirements for the indoor environment as well as the quality of an air-conditioning or HVAC&R project.

The human body requires energy for physical and mental activity. This energy comes from the oxidation of food. The rate of heat release from the oxidation process is called the *metabolic rate*, expressed in met (1 met = 18.46 Btu/h.ft<sup>2</sup>). The metabolic rate depends mainly on the intensity of the physical activity of the human body. Heat is released from the human body by two means: *sensible heat exchange* and *evaporative heat loss*. Experience and experiments all show that there is thermal comfort only under these conditions:

- Heat transfer from the human body to the surrounding environment causes a steady state of thermal equilibrium; that is, there is no heat storage in the body core and skin surface.
- Evaporative loss or regulatory sweating is maintained at a low level.

The physiological and environmental factors that affect the thermal comfort of the occupants in an air-conditioned space are mainly:

1. Metabolic rate  $M$  determines the amount of heat that must be released from the human body.
2. *Indoor air temperature*  $T_r$  and *mean radiant temperature*  $T_{rad}$ , both in °F. The *operating temperature*  $T_o$  is the weighted sum of  $T_r$  and  $T_{rad}$ .  $T_{rad}$  is defined as the temperature of a uniform black enclosure in which the surrounded occupant would have the same radiative heat exchange as in an actual indoor environment.  $T_r$  affects both the sensible heat exchange and evaporative losses, and  $T_{rad}$  affects only sensible heat exchange. In many indoor environments,  $T_{rad} \approx T_r$ .
3. Relative humidity of the indoor air  $\phi_r$ , in %, which is the primary factor that influences evaporative heat loss.
4. Air velocity of the indoor air  $v_r$ , in fpm, which affects the heat transfer coefficients and therefore the sensible heat exchange and evaporative loss.
5. *Clothing insulation*  $R_{cl}$ , in clo (1 clo = 0.88 h.ft<sup>2</sup>.°F/Btu), affects the sensible heat loss. Clothing insulation for occupants is typically 0.6 clo in summer and 0.8 to 1.2 clo in winter.

## Indoor Temperature, Relative Humidity, and Air Velocity

For comfort air-conditioning systems, according to ANSI/ASHRAE Standard 55-1981 and ASHRAE/IES Standard 90.1-1989, the following indoor design temperatures and air velocities apply for conditioned spaces where the occupant's activity level is 1.2 met, indoor space relative humidity is 50% (in summer only), and  $T_r = T_{rad}$ :

	Clothing insulation (clo)	Indoor temperature (°F)	Air velocity (fpm)
Winter	0.8–0.9	69–74	<30
Summer	0.5–0.6	75–78	<50

If a suit jacket is the clothing during summer for occupants, the summer indoor design temperature should be dropped to 74 to 75°F.

Regarding the indoor humidity:

1. Many comfort air-conditioning systems are not equipped with humidifiers. Winter indoor relative humidity should not be specified in such circumstances.
2. When comfort air-conditioning systems are installed with humidifiers, ASHRAE/IES Standard 90.1-1989 requires that the humidity control prevent “the use of fossil fuel or electricity to produce humidity in excess of 30% ... or to reduce relative humidity below 60%.”

3. Indoor relative humidity should not exceed 75% to avoid increasing bacterial and viral populations.
4. For air-conditioning systems that use flow rate control in the water cooling coil, space indoor relative humidity may be substantially higher in part load than at full load.

Therefore, for comfort air-conditioning systems, the recommended indoor relative humidities, in %, are

	Tolerable range	Preferred value
Summer	30–65	40–50
Winter		
With humidifier		25–30
Without humidifier		Not specified

In surgical rooms or similar health care facilities, the indoor relative humidity is often maintained at 40 to 60% year round.

### Indoor Air Quality and Outdoor Ventilation Air Requirements

According to the National Institute for Occupational Safety and Health (NIOSH), 1989, the causes of indoor air quality complaints in buildings are inadequate outdoor ventilation air, 53%; indoor contaminants, 15%; outdoor contaminants, 10%; microbial contaminants, 5%; construction and furnishings, 4%; unknown and others, 13%. For space served by air-conditioning systems using low- and medium-efficiency air filters, according to the U.S. Environmental Protection Agency (EPA) and Consumer Product Safety Commission (CPSC) publication “A Guide to Indoor Air Quality” (1988) and the field investigations reported by Bayer and Black (1988), *indoor air contaminants* may include some of the following:

1. *Total particulate concentration.* This concentration comprises particles from building materials, combustion products, mineral fibers, and synthetic fibers. In February 1989, the EPA specified the allowable indoor concentration of particles of 10  $\mu\text{m}$  and less in diameter (which penetrate deeply into lungs) as:
  - 50  $\mu\text{g}/\text{m}^3$  (0.000022 grain/ft<sup>3</sup>), 1 year
  - 150  $\mu\text{g}/\text{m}^3$  (0.000066 grain/ft<sup>3</sup>), 24 hr
 In these specifications, “1 year” means maximum allowable exposure per day over the course of a year.
2. *Formaldehyde and organic gases.* Formaldehyde is a colorless, pungent-smelling gas. It comes from pressed wood products, building materials, and combustion. Formaldehyde causes eye, nose, and throat irritation as well as coughing, fatigue, and allergic reactions. Formaldehyde may also cause cancer. Other organic gases come from building materials, carpeting, furnishings, cleaning materials, etc.
3. *Radon.* Radon, a colorless and odorless gas, is released by the decay of uranium from the soil and rock beneath buildings, well water, and building materials. Radon and its decay products travel through pores in soil and rock and infiltrate into buildings along the cracks and other openings in the basement slab and walls. Radon at high levels causes lung cancer. The EPA believes that levels in most homes can be reduced to 4 pCi/l (picocuries per liter) of air. The estimated national average is 1.5 pCi/l, and levels as high as 200 pCi/l have been found in houses.
4. *Biologicals.* These include bacteria, fungi, mold and mildew, viruses, and pollen. They may come from wet and moist walls, carpet furnishings, and poorly maintained dirty air-conditioning systems and may be transmitted by people. Some biological contaminants cause allergic reactions, and some transmit infectious diseases.

5. *Combustion products.* These include environmental tobacco smoke, nitrogen dioxide, and carbon monoxide. *Environmental tobacco* smoke from cigarettes is a discomfort factor to other persons who do not smoke, especially children. Nicotine and other tobacco smoke components cause lung cancer, heart disease, and many other diseases. *Nitrogen dioxide* and *carbon monoxide* are both combustion products from unvented kerosene and gas space heaters, woodstoves, and fireplaces. Nitrogen dioxide (NO<sub>2</sub>) causes eye, nose, and throat irritation; may impair lung function; and increases respiratory infections. Carbon monoxide (CO) causes fatigue at low concentrations; impaired vision, headache, and confusion at higher concentrations; and is fatal at very high concentrations. Houses without gas heaters and gas stoves may have CO levels varying from 0.5 to 5 parts per million (ppm).
6. *Human bioeffluents.* These include the emissions from breath including carbon dioxide exhaled from the lungs, body odors from sweating, and gases emitted as flatus.

There are three basic means of reducing the concentration of indoor air contaminants and improving indoor air quality: (1) eliminate or reduce the source of air pollution, (2) enhance the efficiency of air filtration, and (3) increase the ventilation (outdoor) air intake. Dilution of the concentrations of indoor contaminants by outdoor ventilation air is often the simple and cheapest way to improve indoor air quality. The amount of outdoor air required for metabolic oxidation is rather small.

Abridged outdoor air requirements listed in ANSI/ASHRAE Standard 62-1989 are as follows:

Applications	cfm/person
Hotels, conference rooms, offices	20
Retail stores	0.2–0.3 cfm/ft <sup>2</sup>
Classrooms, theaters, auditoriums	15
Hospital patient rooms	25

These requirements are based on the analysis of dilution of CO<sub>2</sub> as the representative human bioeffluent to an allowable indoor concentration of 1000 ppm. Field measurements of daily maximum CO<sub>2</sub> levels in office buildings reported by Persily (1993) show that most of them were within the range 400 to 820 ppm. The quality of outdoor air must meet the EPA's National Primary and Secondary Ambient Air Quality Standards, some of which is listed below:

Pollutants	Long-term concentration			Short-term concentration		
	µg/m <sup>3</sup>	ppm	Exposure	µg/m <sup>3</sup>	ppm	Exposure
Particulate	75		1 year	260		24 hr
SO <sub>2</sub>	80	0.03	1 year	365	0.14	24 hr
CO				40,000	35	1 hr
				10,000	9	8 hr
NO <sub>2</sub>	100	0.055	1 year			
Lead	1.5		3 months			

Here exposure means average period of exposure.

If unusual contaminants or unusually strong sources of contaminants are introduced into the space, or recirculated air is to replace part of the outdoor air supply for occupants, then acceptable indoor air quality is achieved by controlling known and specific contaminants. This is called an indoor air quality procedure. Refer to ANSI/ASHRAE Standard 62-1989 for details.

### Clean Rooms

Electronic, pharmaceutical, and aerospace industries and operating rooms in hospitals all need strict control of air cleanliness during manufacturing and operations. According to ASHRAE Handbook 1991 HVAC Applications, clean rooms can be classified as follows based on the particle count per ft<sup>3</sup>:

Class	Particle size	
	0.5 μm and larger	5 μm and larger
	Particle count per ft <sup>3</sup> not to exceed	
1	1	0
10	10	0
100	100	
1000	1000	
10,000	10,000	65
100,000	100,000	700

For clean rooms, space temperature is often maintained at 72 ± 2°F and space humidity at 45 ± 5%. Here, ±2°F and ±5% are allowable tolerances. Federal Standard 209B specifies that the ventilation (outdoor air) rate should be 5 to 20% of the supply air.

**Space Pressure Differential**

Most air-conditioning systems are designed to maintain a slightly higher pressure than the surroundings, a positive pressure, to prevent or reduce infiltration and untreated air entering the space directly. For laboratories, restrooms, or workshops where toxic, hazardous, or objectional gases or contaminants are produced, a slightly lower pressure than the surroundings, a negative pressure, should be maintained to prevent or reduce the diffusion of these contaminants' exfiltrate to the surrounding area.

For comfort air-conditioning systems, the recommended pressure differential between the indoor and outdoor air is 0.02 to 0.05 in. WG. WG indicates the pressure at the bottom of a top-opened water column of specific inches of height; 1 in. WG = 0.03612 psig.

For clean rooms, Federal Standard No. 209B, Clean Rooms and Work Stations Requirements (1973), specifies that the minimum positive pressure between the clean room and any adjacent area with lower cleanliness requirements should be 0.05 in. WG with all entryways closed. When the entryways are open, an outward flow of air is to be maintained to prevent migration of contaminants into the clean room. In comfort systems, the space pressure differential is usually not specified in the design documents.

**Sound Levels**

Noise is any unwanted sound. In air-conditioning systems, noise should be attenuated or masked with another less objectionable sound.

*Sound power* is the capability to radiate power from a sound source excited by an energy input. The intensity of sound power is the output from a sound source expressed in watts (W). Due to the wide variation of sound output at a range of 10<sup>20</sup> to 1, it is more convenient to use a logarithmic expression to define a *sound power level*  $L_w$ , in dB:

$$L_w = 10\log(w/10^{-12} \text{ W}) \text{ re } 1 \text{ pW} \tag{9.5.2}$$

where  $w$  = sound source power output, W.

The human ear and microphones are sound pressure sensitive. Similarly to the sound power level, the *sound pressure level*  $L_p$ , in dB, is defined as:

$$L_p = 20\log(p/2 \times 10^{-5} \text{ Pa}) \text{ re } 20 \text{ μPa} \tag{9.5.3}$$

where  $p$  = sound pressure, Pa.

The sound power level of any sound source is a fixed output. It cannot be measured directly; it can only be calculated from the measured sound pressure level. The sound pressure level at any one point is affected by the distance from the source and the characteristics of the surroundings.

Human ears can hear frequencies from 20 Hz to 20 kHz. For convenience in analysis, sound frequencies are often subdivided into eight octave bands. An *octave* is a frequency band in which the frequency of the upper limit of the octave is double the frequency of the lower limit. An octave band is represented by its center frequency, such as 63, 125, 250, 500, 1000, 2000, 4000, and 8000 Hz. On 1000 Hz the octave band has a higher limit of 1400 Hz and a lower limit of 710 Hz. Human ears do not respond in the same way to low frequencies as to high frequencies.

The object of noise control in an air conditioned space is to provide background sound low enough that it does not interfere with the acoustical requirements of the occupants. The distribution of background sound should be balanced over a broad range of frequencies, that is, without whistle, hum, rumble, and beats.

The most widely used criteria for sound control are the noise criteria NC curves. The shape of NC curves is similar to the equal-loudness contour representing the response of the human ear. NC curves also intend to indicate the permissible sound pressure level of broad-band noise at various octave bands rated by a single NC curve. NC curves are practical and widely used.

Other criteria used are room criteria RC curves and A-weighted sound level, dBA. RC curves are similar to NC curves except that the shape of the RC curves is a close approximation to a balanced, bland-sounding spectrum. The A-weighted sound level is a single value and simulates the response of the human ear to sound at low sound pressure levels.

The following are abridged indoor design criteria, NC or RC range, listed in *ASHRAE Handbook 1987 Systems and Applications*:

Type of area	Recommended NC or RC range (dB)
Hotel guest rooms	30–35
Office	
Private	30–35
Conference	25–30
Open	30–35
Computer equipment	40–45
Hospital, private	25–30
Churches	25–30
Movie theaters	30–35

For industrial factories, if the machine noise in a period of 8 hr exceeds 90 dBA, Occupational Safety and Health Administration Standard Part 1910.95 requires the occupants to use personal protection equipment. If the period is shorter, the dBA level can be slightly higher. Refer to this standard for details.

## 9.6 Load Calculations

### Space Loads

#### Space, Room, and Zone

*Space* indicates a volume or a site without partitions, or a partitioned room or a group of rooms. A *room* is an enclosed or partitioned space that is considered as a single load. An air-conditioned room does not always have an individual zone control system. A *zone* is a space of a single room or group of rooms having similar loads and operating characteristics. An air-conditioned zone is always installed with an individual control system. A typical floor in a building may be treated as a single zone space, or a *multizone space* of perimeter, interior, east, west, south, north, ... zones.

Space and equipment loads can be classified as:

1. *Space heat gain*  $q_{es}$ , in Btu/hr, is the rate of heat transfer entering a conditioned space from an external heat source or heat releases to the conditioned space from an internal source. The rate of sensible heat entering the space is called *sensible heat gain*  $q_{es}$ , whereas the rate of latent heat entering the space is called *latent heat gain*  $q_{el}$ . In most load calculations, the time interval is often 1 hr, and therefore  $q_{es}$ ,  $q_{es}$ , and  $q_{el}$  are all expressed in Btu/hr.
2. *Space cooling load* or simply *cooling load*  $q_{rc}$ , also in Btu/hr, is the rate at which heat must be removed from a conditioned space to maintain a constant space temperature and an acceptable relative humidity. The sensible heat removed is called *sensible cooling load*  $q_{rs}$ , and the latent heat removed is called *latent cooling load*  $q_{rl}$ , both in Btu/hr.
3. *Space heat extraction rate*  $q_{ex}$ , in Btu/hr, is the rate at which heat is removed from the conditioned space. When the space air temperature is constant,  $q_{ex} = q_{rc}$ .
4. *Space heating load*  $q_{th}$ , in Btu/hr, is the rate at which heat must be added to the conditioned space to maintain a constant temperature.
5. *Coil load*  $q_c$ , in Btu/hr, is the rate of heat transfer at the coil. The cooling *coil load*  $q_{cc}$  is the rate of heat removal from the conditioned air by the chilled water or refrigerant inside the coil. The *heating coil load*  $q_{ch}$  is the rate of heat energy addition to the conditioned air by the hot water, steam, or electric elements inside the coil.
6. *Refrigeration load*  $q_{rl}$ , in Btu/hr, is the rate at which heat is extracted by the evaporated refrigerant at the evaporator. For packaged systems using a DX coil,  $q_{rl} = q_{cc}$ . For central systems:

$$q_{rl} = q_{cc} + q_{pi} + q_{pu} + q_{s,t} \quad (9.6.1)$$

where  $q_{pi}$  = chilled water piping heat gain, Btu/hr  
 $q_{pu}$  = pump power heat gain, Btu/hr  
 $q_{s,t}$  = storage tank heat gain, if any, Btu/hr

Heat gains  $q_{pi}$  and  $q_{pu}$  are usually about 5 to 10% of the cooling coil load  $q_{cc}$ .

#### Convective Heat and Radiative Heat

Heat enters a space and transfer to the space air from either an external source or an internal source is mainly in the form of *convective heat* and *radiative heat* transfer.

Consider radiative heat transfer, such as solar radiation striking the outer surface of a concrete slab as shown in [Figure 9.6.1\(a\) and \(b\)](#). Most of the radiative heat is absorbed by the slab. Only a small fraction is reflected. After the heat is absorbed, the outer surface temperature of the slab rises. If the slab and space air are in thermal equilibrium before the absorption of radiative heat, heat is convected from the outer surface of the slab to the space air as well as radiated to other surfaces. At the same time, heat is conducted from the outer surface to the inner part of the slab and stored there when the temperature of the inner part of the slab is lower than that of its outer surface. Heat convected from the outer surface of the concrete slab to the space air within a time interval forms the sensible cooling load.

**FIGURE 9.6.1** Solar heat gain from west window and its corresponding space cooling load for a night shutdown air system: (a) convective and radiative heat transfer and (b) heat gain and cooling load curves.

The sensible heat gain entering the conditioned space does not equal the sensible cooling load during the same time interval because of the stored heat in the building envelope. Only the convective heat becomes cooling load instantaneously. The sum of the convective heats from the outer surfaces, including the outer surfaces of the internal heat gains in a conditioned space, becomes cooling load. This phenomenon results in a smaller cooling load than heat gain, as shown in [Figure 9.6.1\(a\) and \(b\)](#). According to *ASHRAE Handbook 1993 Fundamentals*, the percentages of convective and radiative components of the sensible heat gains are as follows:

Sensible heat gains	Convective (%)	Radiative (%)
Solar radiation with internal shading	42	58
Fluorescent lights	50	50
Occupants	67	33
External wall, inner surface	40	60

### Load Profile, Peak Load, and Block Load

A *load profile* shows the variation of space, zone, floor, or building load in a certain time period, such as a 24-hr day-and-night cycle. In a load profile, load is always plotted against time. The load profile depends on the outdoor climate as well as the space operating characteristics.

*Peak load* is the maximum cooling load in a load profile. *Block load* is the sum of the zone loads and floor loads at a specific time. The sum of the zone peak loads in a typical floor does not equal the block load of that floor because the zone peak loads may all not appear at the same time.

### Moisture Transfer in Building Envelope

Moisture transfer takes place along two paths:

1. Moisture migrates in the building envelope in both liquid and vapor form. It is mainly liquid if the relative humidity of the ambient air exceeds 50%. Liquid flow is induced by capillary flow and moisture content gradient. Vapor diffusion is induced by vapor pressure gradients. *Moisture content* is defined as the ratio of the mass of moisture contained in a solid to the mass of bone-dry solid. During the migration, the moisture content and the vapor pressure are in equilibrium at a specific temperature and location.
2. Air leakage and its associated water vapor infiltrate or exfiltrate through the cracks, holes, and gaps between joints because of poor construction of the building envelope. The driving potential of this air leakage and associated water vapor is the pressure differential across the building envelope. If the insulating material is of open-cell structure, air leakage and associated water vapor may penetrate the perforated insulating board through cracks and gaps. Condensation, even freezing, will occur inside the perforated insulation board if the temperature of the board is lower than the dew point of the leaked air or the freezing point of the water.

In most comfort air-conditioning systems, usually only the space temperature is controlled within limits. A slight variation of the space relative humidity during the operation of the air system is often acceptable. Therefore, the store effect of moisture is ignored except in conditioned spaces where both temperature and relative humidity need to be controlled or in a hot and humid area where the air system is operated at night shutdown mode. In most cases, latent heat gain is considered equal to latent cooling load instantaneously. For details refer to Wang's *Handbook of Air Conditioning and Refrigeration* (1993), Chapters 6 and 7.

### Cooling Load Calculation Methodology

Basic considerations include the following:

- It is assumed that equations of heat transfer for cooling load calculation within a time interval are linear. It is also assumed that the superposition principle holds. When a number of changes occur simultaneously in the conditioned space, they will proceed as if independent of each other. The total change is the sum of the responses caused by the individual changes.
- Space load calculations are often performed by computer-aided design (CAD), with market-available software like DOE-2.1D, TRACE-600, and Carrier E20-II Loads.
- Peak load calculations evaluate the maximum load to size and select the equipment. The energy analysis program compares the total energy use in a certain period with various alternatives in order to determine the optimum one.
- The methodology of various cooling load calculations is mainly due to their differences in the conversion of space radiative heat gains into space cooling loads. Convective heat, latent heat, and sensible heat gains from infiltration are all equal to cooling loads instantaneously.
- Space cooling load is used to calculate the supply volume flow rate and to determine the size of the air system, ducts, terminals, and diffusers. The coil load is used to determine the size of the

cooling coil and the refrigeration system. Space cooling load is a component of the cooling coil load.

### The Rigorous Approach

The rigorous approach to the calculation of the space cooling load consists of (1) finding the inside surface temperatures of the building structures that enclose the conditioned space due to heat balance at time  $t$  and (2) calculating the sum of the convective heats transferred from these surfaces as well as from the occupants, lights, appliances, and equipment in the conditioned space at time  $t$ .

The inside surface temperature of each surface  $T_{i,t}$ , in °F, can be found from the following simultaneous heat balance equations:

$$q_{i,t} = \left[ h_{ci}(T_{r,t} - T_{i,t}) + \sum_{j=1}^m g_{ij}(T_{j,t} - T_{i,t}) \right] A_i + S_{i,t} + L_{i,t} + P_{i,t} + E_{i,t} \quad (9.6.2)$$

where  $h_{ci}$  = convective heat transfer coefficient, Btu/hr.ft<sup>2</sup>.°F  
 $g_{ij}$  = radiative heat transfer factor between inside surface  $i$  and inside surface  $j$ , Btu/hr.ft<sup>2</sup>.°F  
 $T_{r,t}$  = space air temperature at time  $t$ , °F  
 $T_{i,t}$ ,  $T_{j,t}$  = average temperature of inside surfaces  $i$  and  $j$  at time  $t$ , °F  
 $A_i$  = area of inside surface  $i$ , ft<sup>2</sup>  
 $S_{i,t}$ ,  $L_{i,t}$ ,  $P_{i,t}$ ,  $E_{i,t}$  = solar radiation transmitted through windows and radiative heat from lights, occupants, and equipment absorbed by inside surface  $i$  at time  $t$ , Btu/hr

In Equation (9.6.2),  $q_{i,t}$  in Btu/hr, is the conductive heat that comes to surface  $i$  at time  $t$  because of the temperature excitation on the outer opposite surface of  $i$ . This conductive heat can be found by solving the partial differential equations or by numerical solutions. The number of inside surfaces  $i$  is usually equal to 6, and surface  $i$  is different from  $j$  so that radiative exchange can proceed.  $q_{i,t}$  could also be expressed in Btu/min or even Btu/sec.

The space sensible cooling load  $q_{rs}$ , in Btu/hr, is the sum of the convective heat from the inside surfaces, including the convective heat from the inner window glass due to the absorbed solar radiation and the infiltration:

$$q_{rs} = \left[ \sum_{i=1}^6 h_{ci}(T_{i,t} - T_{r,t}) \right] A_i + 60 \dot{V}_{if} \rho_o c_{pa} (T_{o,t} - T_{r,t}) + S_{c,t} + L_{c,t} + P_{c,t} + E_{c,t} \quad (9.6.3)$$

where  $\dot{V}_{if}$  = volume flow rate of infiltrated air, cfm  
 $\rho_o$  = air density of outdoor air, lb/ft<sup>3</sup>  
 $c_{pa}$  = specific heat of moist air, Btu/lb.°F  
 $T_{o,t}$  = temperature of outdoor air at time  $t$ , °F  
 $S_{c,t}$ ,  $L_{c,t}$ ,  $P_{c,t}$ ,  $E_{c,t}$  = heat convected from the windows, lights, occupants, and equipment, Btu/hr

Equations (9.6.2) and (9.6.3), and partial differential equations to determine conductive heat  $q_{i,t}$  must be solved simultaneously. Using a rigorous approach to find the space cooling load requires numerous computer calculations. It is laborious and time consuming. The rigorous approach is impractical and is suitable for research work only.

### Transfer Function Method (TFM)

The *transfer function* of a system relates its output in Laplace transform  $Y$  to its input in Laplace transform  $G$  by a ratio  $K$ , that is,

$$K = Y/G = (v_0 + v_1 z^{-1} + v_2 z^{-2} + \dots) / (1 + w_1 z^{-1} + w_2 z^{-2} + \dots) \quad (9.6.4)$$

$$z = e^{s\Delta}$$

where  $\Delta$  = time interval.

In Equation (9.6.4),  $K$ ,  $Y$ , and  $G$  are all expressed in  $z$ -transforms of the time series function. Coefficients  $v_n$  and  $w_n$  are called *transfer function coefficients*, or weighting factors. *Weighting factors* are used to weight the importance of the effect of current and previous heat gains as well as the previous space sensible cooling load on the current space sensible cooling load  $q_{rs,t}$ . Then, the output  $q_{rs,t}$  can be related to the input, the space sensible heat gain  $q_{es,t}$  through  $q_{rs,t} = Kq_{es,t}$ .

Mitalas and Stevenson (1967) and others developed a method for determining the transfer function coefficients of a zone of given geometry and details of the calculated space heat gains and the previously known space sensible cooling load through rigorous computation or through tests and experiments. In DOE 2.1A (1981) software for custom weighting factors (tailor made according to a specific parametric zone) is also provided. Sowell (1988) and Spitler et al. (1993) expanded the application of TFM to zones with various parameters: zone geometry, different types of walls, roof, floor, ceilings, building material, and mass locations. Mass of construction is divided into light construction, 30 lb/ft<sup>2</sup> of floor area; medium construction, 70 lb/ft<sup>2</sup>; and heavy construction, 130 lb/ft<sup>2</sup>. Data are summarized into groups and listed in tabular form for user's convenience.

### **Cooling Load Temperature Difference/Solar Cooling Load Factor/Cooling Load Factor (CLTD/SCL/CLF) Method**

The *CLTD/SCL/CLF method* is a one-step simplification of the transfer function method. The space cooling load is calculated directly by multiplying the heat gain  $q_e$  with CLTD, SCL, or CLF instead of first finding the space heat gains and then converting into space cooling loads through the room transfer function. In the CLTD/SCL/CLF method, the calculation of heat gains is the same as in the transfer function method.

The CLTD/SCL/CLF method was introduced by Rudoy and Duran (1975). McQuiston and Spitler (1992) recommended a new SCL factor. In 1993 they also developed the CLTD and CLF data for different zone geometries and constructions.

### **Finite Difference Method**

Since the development of powerful personal computers, the finite difference or numerical solution method can be used to solve transient simultaneous heat and moisture transfer in space cooling load calculations. Wong and Wang (1990) emphasized the influence of moisture stored in the building structure on the cool-down load during the night shut-down operating mode in locations where the summer outdoor climate is hot and humid. The finite difference method is simple and clear in concept as well as more direct in computation than the transfer function method. Refer to Wang's *Handbook of Air Conditioning and Refrigeration* for details.

### **Total Equivalent Temperature Differential/Time Averaging (TETD/TA) Method**

In this method, the heat gains transmitted through external walls and roofs are calculated from the Fourier series solution of one-dimensional transient heat conduction. The conversion of space heat gains to space cooling loads takes place by (1) averaging the radiative heat gains to the current and successive hours according to the mass of the building structure and experience and (2) adding the instantaneous convective fraction and the allocated radiative fraction in that time period. The TETD/TA method is simpler and more subjective than the TFM.

### **Conduction Heat Gains**

Following are the principles and procedures for the calculation of space heat gains and their conversion to space cooling loads by the TFM. TFM is the method adopted by software DOE-2.1D and is also one

of the computing programs adopted in TRACE 600. Refer to *ASHRAE Handbook 1993 Fundamentals*, Chapters 26 and 27, for detail data and tables.

### Surface Heat Transfer Coefficients

*ASHRAE Handbook 1993 Fundamentals* adopts a constant *outdoor heat transfer coefficient*  $h_o = 3.0$  Btu/hr.ft<sup>2</sup>.°F and a constant *inside heat transfer coefficient*  $h_i = 1.46$  Btu/hr.ft<sup>2</sup>.°F during cooling load calculations. However, many software programs use the following empirical formula (*TRACE 600 Engineering Manual*):

$$h_{o,t} = 2.00 + 0.27v_{\text{wind},t} \quad (9.6.5)$$

where  $h_{o,t} = h_o$  at time  $t$ , Btu/hr.ft<sup>2</sup>.°F  
 $v_{\text{wind},t}$  = wind velocity at time  $t$ , ft/sec

Coefficient  $h_i$  may be around 2.1 Btu/hr.ft<sup>2</sup>.°F when the space air system is operating, and  $h_i$  drops to only about 1.4 Btu/hr.ft<sup>2</sup>.°F when the air system is shut down. The *R value*, expressed in hr.ft<sup>2</sup>.°F/Btu, is defined as the reciprocal of the overall heat transfer coefficient *U* value, in Btu/hr.ft<sup>2</sup>.°F. The *R* value is different from the thermal resistance  $R^*$ , since  $R^* = 1/UA$ , which is expressed in hr.°F/Btu.

*Sol-air temperature*  $T_{\text{sol}}$  is a fictitious outdoor air temperature that gives the rate of heat entering the outer surface of walls and roofs due to the combined effect of incident solar radiation, radiative heat exchange with the sky vault and surroundings, and convective heat exchange with the outdoor air.  $T_{\text{sol}}$ , in °F, is calculated as

$$T_{\text{sol}} = T_o + \alpha I_t / h_o - \epsilon \Delta R / h_o \quad (9.6.6)$$

where  $T_o$  = outdoor air temperature, °F  
 $\alpha$  = absorptance of incident solar radiation on outer surface  
 $\epsilon$  = hemispherical emittance of outer surface, assumed equal to 1  
 $I_t$  = total intensity of solar radiation including diffuse radiation, Btu/hr.ft<sup>2</sup>

Tabulated sol-air temperatures that have been calculated and listed in *ASHRAE Handbook 1993 Fundamentals* are based on the following: if  $\epsilon = 1$  and  $h_o = 3$  Btu/hr.ft<sup>2</sup>.°F,  $\Delta R/h_o$  is  $-7^\circ\text{F}$  for horizontal surfaces and  $0^\circ\text{F}$  for vertical surfaces, assuming that the long-wave radiation from the surroundings compensates for the loss to the sky vault.

### External Wall and Roof

The sensible heat gain through a wall or roof at time  $t$ ,  $q_{e,t}$ , in Btu/hr, can be calculated by using the sol-air temperature at time  $t-n\delta$ ,  $T_{\text{sol},t-n\delta}$ , in °F, as the outdoor air temperature and a constant indoor space air temperature  $T_r$ , in °F, as

$$q_{e,t} = A \left[ \sum_{n=0} b_n T_{\text{sol},t-n\delta} - \sum_{n=1} d_n (q_{e,t-n\delta} / A) \right] - T_r \sum_{n=0} c_n \quad (9.6.7)$$

where  $A$  = surface area of wall or roof, ft<sup>2</sup>  
 $q_{e,t-n\delta}$  = heat gain through wall or roof at time  $t-n\delta$ , Btu/hr  
 $n$  = number of terms in summation

In Equation (9.6.7),  $b_n$ ,  $c_n$ , and  $d_n$  are *conduction transfer function* coefficients.

### Ceiling, Floor, and Partition Wall

If the variation of the temperature of the adjacent space  $T_{aj}$ , in °F, is small compared with the differential  $(T_{aj} - T_r)$ , or even when  $T_{aj}$  is constant, the heat gain to the conditioned space through ceiling, floor, and partition wall  $q_{aj,t}$ , in Btu/hr, is

$$q_{aj,t} = UA(T_{aj} - T_r) \quad (9.6.8)$$

where  $U$  = overall heat transfer coefficient of the ceiling, floor, and partition (Btu/hr.ft<sup>2</sup>.°F).

### Heat Gain through Window Glass

*Shading Devices.* There are two types of shading devices: indoor shading devices and outdoor shading devices. *Indoor shading devices* increase the reflectance of incident radiation. *Venetian blinds* and *draperies* are the most widely used indoor shading devices. Most horizontal venetian blinds are made of plastic, aluminum, or rigid woven cloth slats spaced 1 to 2 in. apart. Vertical venetian blinds with wider slats are also used. *Draperies* are made of fabrics of cotton, rayon, or synthetic fibers. They are usually loosely hung, wider than the window, often pleated, and can be drawn open and closed as needed. Draperies also increase thermal resistance in winter.

*External shading devices* include overhangs, side fins, louvers, and pattern grilles. They reduce the sunlit area of the window glass effectively and therefore decrease the solar heat gain. External shading devices are less flexible and are difficult to maintain.

*Shading Coefficient (SC).* The shading coefficient is an index indicating the glazing characteristics and the associated indoor shading device to admit solar heat gain. SC of a specific window glass and shading device assembly at a summer design solar intensity and outdoor and indoor temperatures can be calculated as

$$SC = \frac{\text{solar heat gain of specific type of window glass assembly}}{\text{solar heat gain of reference (DSA) glass}} \quad (9.6.9)$$

*Double-strength sheet glass (DSA)* has been adopted as the reference glass with a transmittance of  $\tau = 0.86$ , reflectance  $\rho = 0.08$ , and absorptance  $\alpha = 0.06$ .

*Solar Heat Gain Factors (SHGFs).* SHGFs, in Btu/hr.ft<sup>2</sup>, are the average solar heat gains during cloudless days through DSA glass.  $SHGF_{max}$  is the maximum value of SHGF on the 21st day of each month for a specific latitude as listed in *ASHRAE Handbook 1993 Fundamentals*. At high elevations and on very clear days, the actual SHGF may be 15% higher.

*Heat Gain through Window Glass.* There are two kinds of heat gain through window glass: heat gain due to the solar radiation transmitted and absorbed by the window glass,  $q_{es,t}$ , and conduction heat gain due to the outdoor and indoor temperature difference,  $q_{ec,t}$ , both in Btu/hr:

$$q_{es,t} = (A_s \times SHGF \times SC) + (A_{sh} \times SHGF_{sh} \times SC) \quad (9.6.10)$$

where  $A_s$ ,  $A_{sh}$  = sunlit and shaded areas of the glass (ft<sup>2</sup>).

In Equation (9.6.10),  $SHGF_{sh}$  represents the SHGF of the shaded area of the glass having only diffuse radiation. Generally, the SHGF of solar radiation incident on glass facing north without direct radiation can be considered as  $SHGF_{sh}$ . Because the mass of window glass is small, its heat storage effect is often neglected; then the conduction heat gain at time  $t$  is

$$q_{ec,t} = U_g (A_s + A_{sh}) (T_{o,t} - T_r) \quad (9.6.11)$$

where  $U_g$  = overall heat transfer coefficient of window glass, Btu/hr.ft<sup>2</sup>.°F  
 $T_{o,t}$  = outdoor air temperature at time  $t$ , °F

The inward heat transfer due to the solar radiation absorbed by the glass and the conduction heat transfer due to the outdoor and indoor temperature difference is actually combined. It is simple and more convenient if they are calculated separately.

## Internal Heat Gains

*Internal heat gains* are heat released from the internal sources.

### People

The sensible heat gain and latent heat gain per person,  $q_{es,t}$  and  $q_{el,t}$ , both in Btu/hr, are given as

$$\begin{aligned} q_{es,t} &= N_t q_{os} \\ q_{el,t} &= N_t q_{ol} \end{aligned} \quad (9.6.12)$$

where  $N_t$  = number of occupants in the conditioned space at time  $t$ .

Heat gains  $q_{os}$  and  $q_{ol}$  depend on the occupant's metabolic level, whether the occupant is an adult or a child, male or female, and the space temperature. For a male adult seated and doing very light work, such as system design by computer in an office of space temperature 75°F,  $q_{os}$  and  $q_{ol}$  are both about 240 Btu/hr.

### Lights

Heat gain in the conditioned space because of the electric lights,  $q_{e,li}$ , in Btu/hr, is calculated as

$$q_{e,li} = \sum_{n=1} \left[ 3.413 W_{li} N_{li} F_{ul} F_{al} (1 - F_{lp}) \right] = 3.413 W_{lA} A_n \quad (9.6.13)$$

where  $W_{li}$  = watt input to each lamp, W

$W_{lA}$  = lighting power density, W/ft<sup>2</sup>

$A_n$  = floor area of conditioned space, ft<sup>2</sup>

$N_{li}, n$  = number of lamps (each type) and number of types of electric lamp

$F_{al}, F_{ul}$  = use factor of electric lights and allowance factor for ballast loss, usually taken as 1.2

$F_{lp}$  = heat gain carried away by the return air to plenum or by exhaust device; it varies from 0.2 to 0.5

### Machines and Appliances

The sensible and latent heat gains in the conditioned space from machines and appliances,  $q_{e,ap}$  and  $q_{l,ap}$ , both in Btu/hr, can be calculated as

$$\begin{aligned} q_{e,ap} &= 3.413 W_{ap} F_{ua} F_{load} F_{ra} = q_{is} F_{ua} F_{ra} \\ q_{l,ap} &= q_{il} F_{ua} \end{aligned} \quad (9.6.14)$$

where  $W_{ap}$  = rated power input to the motor of the machines and appliances, W

$F_{ua}$  = use factor of machine and appliance

$F_{load}$  = ratio of actual load to the rated power

$F_{ra}$  = radiation reduction factor because of the front shield of the appliance

$q_{is}, q_{il}$  = sensible and latent heat input to the appliance, Btu/hr

## Infiltration

*Infiltration* is the uncontrolled inward flow of unconditioned outdoor air through cracks and openings on the building envelope because of the pressure difference across the envelope. The pressure difference is probably caused by wind pressure, stack effect due to outdoor–indoor temperature difference, and the operation of an air system(s).

Today new commercial buildings have their external windows well sealed. If a positive pressure is maintained in the conditioned space when the air system is operating, infiltration is normally considered as zero.

When the air system is shut down, or for hotels, motels, and high-rise residential buildings, ASHRAE/IES Standard 90.1-1989 specifies an infiltration of 0.038cfm/ft<sup>2</sup> of gross area of the external wall, 0.15 air change per hour (ach) for the perimeter zone.

When exterior windows are not well sealed, the outdoor wind velocity is high at winter design conditions, or there is a door exposed to the outdoors directly, an infiltration rate of 0.15 to 0.4 ach for perimeter zone should be considered.

When the volume flow rate of infiltration is determined, the sensible heat gain due to infiltration  $q_{s,if}$  and latent heat gain due to infiltration  $q_{l,if}$ , in Btu/hr, are

$$q_{s,if} = 60 \dot{V}_{if} \rho_o c_{pa} (T_o - T_r) \quad (9.6.15)$$

$$q_{l,if} = 60 \times 1060 \dot{V}_{if} \rho_o (w_o - w_r)$$

where  $\dot{V}_{if}$  = volume flow rate of infiltration, cfm  
 $\rho_o$  = air density of outdoor air, lb/ft<sup>3</sup>  
 $c_{pa}$  = specific heat of moist air, 0.243 Btu/lb.°F  
 $w_o, w_r$  = humidity ratio of outdoor and space air, lb/lb  
 $h_{fg,58}$  = latent heat of vaporization, 1060 Btu/lb

Infiltration enters the space directly and mixes with space air. It becomes space cooling load instantaneously. Ventilation air is often taken at the AHU or PU and becomes sensible and latent coil load components.

## Conversion of Heat Gains into Cooling Load by TFM

The space sensible cooling load  $q_{rs,t}$ , in Btu/hr, is calculated as

$$q_{rs,t} = q_{s-e,t} + q_{s-c,t} \quad (9.6.16)$$

where  $q_{s-e,t}$  = space sensible cooling load converted from heat gains having radiative and convective components, Btu/hr  
 $q_{s-c,t}$  = space sensible cooling load from convective heat gains, Btu/hr

Based on Equation (9.6.4), space sensible cooling load  $q_{s-e,t}$  can be calculated as

$$q_{s-e,t} = \sum_{i=1} (v_o q_{e,t} + v_1 q_{e,t-\delta} + v_2 q_{e,t-2\delta} + \dots) - (w_1 q_{r,t-\delta} + w_2 q_{r,t-2\delta} + \dots) \quad (9.6.17)$$

where  $q_{e,t}, q_{e,t-\delta}, q_{e,t-2\delta}$  = space sensible heat gains having both radiative and convective heats at time  $t, t-\delta,$  and  $t-2\delta$ , Btu/hr

$q_{r,t-\delta}, q_{r,t-2\delta}$  = space sensible cooling load at time  $t-\delta,$  and  $t-2\delta$ , Btu/hr

In Equation (9.6.17),  $v_n$  and  $w_n$  are called *room transfer function coefficients* (RTFs). RTF is affected by parameters like zone geometry; wall, roof, and window construction; internal shades; zone location; types of building envelope; and air supply density. Refer to RTF tables in *ASHRAE Handbook 1993 Fundamentals*, Chapter 26, for details.

Space sensible cooling load from convective heat gains can be calculated as

$$q_{s-c,t} = \sum_{k=1} q_{ec,t} \quad (9.6.18)$$

where  $q_{ec,t}$  = each of  $k$  space sensible heat gains that have convective heat gains only (Btu/hr). Space latent cooling load at time  $t$ ,  $q_{rl,t}$  in Btu/hr, can be calculated as

$$q_{rl,t} = \sum_{m=1} q_{el,t} \quad (9.6.19)$$

where  $q_{el,t}$  = each of  $m$  space latent heat gains (Btu/hr).

### Space Air Temperature and Heat Extraction Rate

At equilibrium, the space sensible heat extraction rate at time  $t$ ,  $q_{xs,t}$ , is approximately equal to the space sensible cooling load,  $q_{rs,t}$ , when zero offset proportional plus integral or proportional-integral-derivative control mode is used. During the cool-down period, the sensible heat extraction rate of the cooling coil or DX coil at time  $t$ ,  $q_{xs,t}$ , or the sensible cooling coil load, in Btu/hr, is greater than the space sensible cooling load at time  $t$  and the space temperature  $T_r$ , in °F then drops gradually. According to *ASHRAE Handbook 1993 Fundamentals*, the relationship between the space temperature  $T_r$  and the sensible heat extraction rate  $q_{xs,t}$  can be expressed as

$$\sum_{i=0}^1 p_i (q_{xs,t} - q_{rs,t-i\delta}) = \sum_{i=0}^2 g_i (T_r - T_{r,t-i\delta}) \quad (9.6.20)$$

where  $q_{rs,t-i\delta}$  = space sensible cooling load calculated on the basis of constant space air temperature  $T_r$ , Btu/hr

$T_{r,t-i\delta}$  = space temperature at time  $t-i\delta$

In Equation (9.6.20),  $p_i$ ,  $g_i$  are called *space air transfer function coefficients*. Space air temperature  $T_r$  can be considered an average reference temperature within a time interval.

### Cooling Coil Load

*Cooling coil load*  $q_{cc}$ , in Btu/hr, can be calculated from Equation (9.3.11). The sensible and latent cooling coil loads can then be calculated as

$$q_{cs} = 60 \dot{V}_s \rho_s c_{pa} (T_m - T_{cc}) \quad (9.6.21)$$

$$q_{cl} = 60 \dot{V}_s \rho_s (w_m - w_{cc})$$

where  $q_{cs}$ ,  $q_{cl}$  = sensible and latent cooling coil load, Btu/hr

$T_m$ ,  $T_{cc}$  = air temperature of the mixture and leaving the cooling coil, °F

$w_m$ ,  $w_{cc}$  = humidity ratio of the air mixture and air leaving the cooling coil, lb/lb

## Heating Load

The *space heating load* or simply *heating load* is always the possible maximum heat energy that must be added to the conditioned space at winter design conditions to maintain the indoor design temperature. It is used to size and select the heating equipment. In heating load calculations, solar heat gain, internal heat gains, and the heat storage effect of the building envelope are usually neglected for reliability and simplicity.

Normally, space heating load  $q_{th}$ , in Btu/hr, can be calculated as

$$q_{th} = q_{trans} + q_{if,s} + q_{ma} + q_{hu}$$

$$= \left[ \left( \sum_{n=1} AU \right) + 60 \dot{V}_{if} \rho_o c_{pa} \dot{m}_m c_m \right] (T_r - T_o) + \dot{m}_w h_{fg,58} \quad (9.6.22)$$

where  $A$  = area of the external walls, roofs, glasses, and floors, ft<sup>2</sup>

$U$  = overall heat transfer coefficient of the walls, roofs, glasses, and floors, Btu/hr.ft<sup>2</sup>.°F

$c_m, \dot{m}_m$  = specific heat and mass flow rate of the cold product entering the space per hour, Btu/lb.°F and lb/hr

$\dot{m}_w$  = mass flow rate of water evaporated for humidification, lb/hr

$h_{fg,58}$  = latent heat of vaporization at 58°F, 1060 Btu/lb

In Equation 9.88,  $q_{trans}$  indicates the *transmission loss* through walls, roofs, glasses, and floors,  $q_{if,s}$  the *sensible infiltration heat loss*,  $q_{ma}$  the heat required to heat the cold product that enters the conditioned space, and  $q_{hu}$  the heat required to raise the space air temperature when water droplets from a space humidifier are evaporated in the conditioned space. For details, refer to *ASHRAE Handbook 1993 Fundamentals*.

## 9.7 Air Handling Units and Packaged Units

### Terminals and Air Handling Units

A *terminal unit*, or *terminal*, is a device or equipment installed directly in or above the conditioned space to cool, heat, filter, and mix outdoor air with recirculating air. Fan-coil units, VAV boxes, fan-powered VAV boxes, etc. are all terminals.

An *air handling unit* (AHU) handles and conditions the air, controls it to a required state, and provides motive force to transport it. An AHU is the primary equipment of the air system in a central air-conditioning system. The basic components of an AHU include a supply fan with a fan motor, a water cooling coil, filters, a mixing box except in a makeup AHU unit, dampers, controls, and an outer casing. A return or relief fan, heating coil(s), and humidifier are optional depending on requirements. The supply volume flow rate of AHUs varies from 2000 to about 60,000 cfm.

AHUs are classified into the followings groups according to their structure and location.

### Horizontal or Vertical Units

*Horizontal AHUs* have their fan, coils, and filters installed at the same level as shown in Figure 9.7.1(a). They need more space and are usually for large units. In *vertical units*, as shown in Figure 9.7.1(b), the supply fan is installed at a level higher than coils and filters. They are often comparatively smaller than horizontal units.

**FIGURE 9.7.1** Type of air handling units: (a) horizontal draw-through unit, (b) vertical draw-through unit, and (c) multizone blow-through unit.

### Draw-Through or Blow-Through Units

In a *draw-through unit*, as shown in Figure 9.7.1(a), the supply fan is located downstream of the coils. Air is evenly distributed over the coil section, and the fan discharge can easily be connected to a supply duct of nearly the same air velocity. In a *blow-through unit*, as shown in Figure 9.7.1(c), the supply fan

is located upstream of the coils. It usually has hot and cold decks with discharge dampers connected to warm and cold ducts, respectively.

### Factory-Fabricated and Field Built-Up Units

*Factory-fabricated units* are standard in construction and layout, low in cost, of higher quality, and fast in installation. *Field built-up units* or *custom-built units* are more flexible in construction, layout, and dimensions than factory-built standardized units.

### Rooftop and Indoor Units

A *rooftop AHU*, sometimes called a penthouse unit, is installed on the roof and will be completely weatherproof. An *indoor AHU* is usually located in a fan room or ceiling and hung like small AHU units.

### Make-Up Air and Recirculating Units

A *make-up AHU*, also called a primary-air unit, is used to condition outdoor air entirely. It is a once-through unit. There is no return air and mixing box. *Recirculating units* can have 100% outdoor air intake or mixing of outdoor air and recirculating air.

## Packaged Units

A *packaged unit* (PU) is a self-contained air conditioner. It conditions the air and provides it with motive force and is equipped with its own heating and cooling sources. The packaged unit is the primary equipment in a packaged air-conditioning system and is always equipped with a DX coil for cooling, unlike an AHU. R-22, R-134a, and others are used as refrigerants in packaged units. The portion that handles air in a packaged unit is called an *air handler* to distinguish it from an AHU. Like an AHU, an indoor air handler has an indoor fan, a DX coil (indoor coil), filters, dampers, and controls. Packaged units can be classified according to their place of installation: rooftop, indoor, and split packaged units.

### Rooftop Packaged Units

A *rooftop packaged unit* is mounted on the roof of the conditioned space as shown in [Figure 9.7.2](#). From the types of heating/cooling sources provided, rooftop units can be subdivided into:

- Gas/electric rooftop packaged unit, in which heating is provided by gas furnace and cooling by electric power-driven compressors.
- Electric/electric rooftop packaged unit, in which electric heating and electric power-driven compressors provide heating and cooling.
- Rooftop packaged heat pump, in which both heating and cooling are provided by the same refrigeration system using a four-way reversing valve (heat pump) in which the refrigeration flow changes when cooling mode is changed to heating mode and vice versa. Auxiliary electric heating is provided if necessary.

Rooftop packaged units are single packaged units. Their cooling capacity may vary from 3 to 220 tons with a corresponding volume flow rate of 1200 to 80,000 cfm. Rooftop packaged units are the most widely used packaged units.

### Indoor Packaged Units

An *indoor packaged unit* is also a single packaged and factory-fabricated unit. It is usually installed in a fan room or a machinery room. A small or medium-sized indoor packaged unit could be floor mounted directly inside the conditioned space with or without ductwork. The cooling capacity of an indoor packaged unit may vary from 3 to 100 tons and volume flow rate from 1200 to 40,000 cfm.

Indoor packaged units are also subdivided into:

- Indoor packaged cooling units

**FIGURE 9.7.2** A cut view of a rooftop package unit. (Source: Mammoth, Inc. Reprinted by permission.)

- Indoor packaged cooling/heating units, in which heating may be provided from a hot water heating coil, a steam heating coil, and electric heating
- Indoor packaged heat pumps

Indoor packaged units have either an air-cooled condenser on the rooftop or a shell-and-tube or double-tube water-cooled condenser inside the unit.

### Split Packaged Units

A *split packaged unit* consists of two separate pieces of equipment: an indoor air handler and an outdoor condensing unit. The indoor air handler is often installed in the fan room. Small air handlers can be ceiling hung. The condensing unit is usually located outdoors, on a rooftop or podium or on the ground.

A split packaged unit has its compressors and condenser in its outdoor condensing unit, whereas an indoor packaged unit usually has its compressors indoors. The cooling capacity of split packaged units varies from 3 to 75 tons and the volume flow rate from 1200 to 30,000 cfm.

### Rating Conditions and Minimum Performance

Air Conditioning and Refrigeration Institute (ARI) Standards and ASHRAE/IES Standard 90.1-1989 specified the following rating indices:

- Energy efficiency ratio (EER) is the ratio of equipment cooling capacity, in Btu/hr, to the electric input, in W, under rating conditions.
- SEER is the seasonal EER, or EER during the normal annual usage period.
- IPLV is the integrated part-load value. It is the summarized single index of part-load efficiency of PUs based on weighted operations at several load conditions.
- HSPF is the heating seasonal performance factor. It is the total heating output of a heat pump during its annual usage period for heating, in Btu, divided by the total electric energy input to the heat pump during the same period, in watt-hours.

According to ARI standards, the minimum performance for air-cooled, electrically operated single packaged units is

	$q_{rc}$ (Btu/hr)	$T_o$ (°F)	EER	$T_o$ (°F)	IPLV
Air-cooled	<65,000	95	9.5		
	$65,000 \leq q_{rc} < 135,000$	95	8.9	80	8.3
	$135,000 \leq q_{rc} < 760,000$		8.5		7.5

For water- and evaporatively cooled packaged units including heat pumps, refer to ASHRAE/IES Standard 90.1-1989 and also ARI Standards.

## Coils

### Coils, Fins, and Water Circuits

*Coils* are indirect contact heat exchangers. Heat transfer or heat and mass transfer takes place between conditioned air flowing over the coil and water, refrigerant, steam, or brine inside the coil for cooling, heating, dehumidifying, or cooling/dehumidifying. Chilled water, brine, and refrigerants that are used to cool and dehumidify the air are called *coolants*. Coils consist of tubes and external fins arranged in rows along the air flow to increase the contact surface area. Tubes are usually made of copper; in steam coils they are sometimes made of steel or even stainless steel. Copper tubes are staggered in 2, 3, 4, 6, 8, or up to 10 rows.

*Fins* are extended surfaces often called *secondary surfaces* to distinguish them from the *primary surfaces*, which are the outer surfaces of the tubes. Fins are often made from aluminum, with a thickness  $F_t = 0.005$  to  $0.008$  in., typically  $0.006$  in. Copper, steel, or sometimes stainless steel fins are also used. Fins are often in the form of continuous plate fins, corrugated plate fins to increase heat transfer, crimped spiral or smooth spiral fins that may be extruded from the aluminum tubes, and spine pipes, which are shaved from the parent aluminum tubes. Corrugated plate fins are most widely used.

*Fin spacing*  $S_f$  is the distance between two fins. *Fin density* is often expressed in fins per inch and usually varies from 8 to 18 fins/in.

In a water cooling coil, *water circuits* or *tube feeds* determine the number of water flow passages. The greater the finned width, the higher the number of water circuits and water flow passages.

### Direct Expansion (DX) Coil

In a *direct expansion coil*, the refrigerant, R-22, R-134a, or others, is evaporated and expanded directly inside the tubes to cool and dehumidify the air as shown in Figure 9.7.3(a). Refrigerant is fed to a distributor and is then evenly distributed to various copper tube circuits typically 0.375 in. in diameter. Fin density is usually 12 to 18 fins/in. and a four-row DX coil is often used. On the inner surface of the copper tubes, microfins, typically at 60 fins/in. and a height of 0.008 in., are widely used to enhance the boiling heat transfer.

Air and refrigerant flow is often arranged in a combination of counterflow and cross flow and the discharge header is often located on the air-entering side. Refrigerant distribution and loading in various circuits are critical to the coil's performance. Vaporized vapor refrigerant is superheated 10 to 20°F in order to prevent any liquid refrigerant from flooding back to the reciprocating compressors and damaging them. Finally, the vapor refrigerant is discharged to the suction line through the header.

For comfort air-conditioning systems, the evaporating temperature of refrigerant  $T_{ev}$  inside the tubes of a DX coil is usually between 37 and 50°F. At such a temperature, the surface temperature of the coil is often lower than the dew point of the entering air. Condensation occurs at the coil's outside surface, and the coil becomes a wet coil. A condensate *drain pan* is necessary for each vertically banked DX coil, and a trap should be installed to overcome the negative pressure difference between the air in the coil section and the ambient air.

Face velocity of the DX coil  $v_a$ , in fpm, is closely related to the blow-off of the water droplets of the condensate, the heat transfer coefficients, the air-side pressure drop, and the size of the air system. For corrugated fins, the upper limit is 600 fpm, with an air-side pressure drop of 0.20 to 0.30 in. WG/row.

**FIGURE 9.7.3** Types of coils: (a) direct expansion coil, (b) water cooling coil, (c) water heating coil, and (d) steam heating coil.

A large DX coil is often divided into two refrigerant sections, each with its own expansion valve, distributor, and discharge header.

For a packaged unit of a specific model, size, face velocity and condition of entering air and outdoor air, the DX coil’s cooling capacities in nominal tons, number of rows, and fin density are all fixed values.

**Water Cooling Coils — Dry-Wet Coils**

In a water cooling coil, chilled water at a temperature of 40 to 50°F, brine, or glycol-water at a temperature of 34 to 40°F during cold air distribution enters the coil. The temperature of chilled water, brine, or glycol-water is usually raised 12 to 24°F before it leaves the water cooling coil.

The water tubes are usually copper tubes of 1/2 to 5/8 in. diameter with a tube wall thickness of 0.01 to 0.02 in. They are spaced at a center-to-center distance of 0.75 to 1.25 in. longitudinally and 1 to 1.5

in. transversely. These tubes may be staggered in 2, 3, 4, 6, 8, or 10 rows. Chilled water coils are often operated at a pressure of 175 to 300 psig.

As in a DX coil, the air flow and water flow are in a combination of counterflow and cross flow. The outer surface of a chilled water cooling coil at the air entering side  $T_{se}$  is often greater than the dew point of the entering air  $T_{ae}''$ , or  $T_{se} > T_{ae}''$ . The outer surface temperature of coil at the air leaving side  $T_{sl}$  may be smaller than  $T_{ae}''$ , or  $T_{sl} < T_{ae}''$ . Then the water cooling coil becomes a dry–wet coil with part of the dry surface on the air entering side and part of the wet surface on the air leaving side. A *dry–wet boundary* divides the dry and wet surfaces. At the boundary, the tube outer surface temperature  $T_{sb} = T_{ae}''$  as shown in Figure 9.7.3(b). A condensate drain pan is necessary for a dry–wet coil.

A water cooling coil is selected from the manufacturer's selection program or from its catalog at (1) a dry and wet bulb of entering air, such as 80°F dry bulb and 67°F wet bulb; (2) an entering water temperature, such as 44 or 45°F; (3) a water temperature rise between 10 and 24°F; and (4) a coil face velocity between 400 and 600 fpm. The number of rows and fins per inch is varied to meet the required sensible and cooling coil load, in Btu/hr.

### Water Cooling Coil–Dry Coil

When the temperature of chilled water entering the water cooling coil  $T_{we} \geq T_{ae}''$ , condensation will not occur on the outer surface of the coil. This coil becomes a sensible cooling–dry coil, and the humidity ratio of the conditioned air  $w_a$  remains constant during the sensible cooling process.

The construction of a sensible cooling–dry coil, such as material, tube diameter, number of rows, fin density, and fin thickness, is similar to that of a dry–wet coil except that a dry coil always has a poorer surface heat transfer coefficient than a wet coil, and therefore a greater coil surface area is needed; the maximum face velocity of a dry coil can be raised to  $v_a \leq 800$  fpm; and the coil's outer surface is less polluted. The effectiveness of a dry coil  $\epsilon_{dry}$  is usually 0.55 to 0.7.

### Water Heating Coil

The construction of a water heating coil is similar to that of a water cooling coil except that in water heating coils hot water is supplied instead of chilled water and there are usually fewer rows, only 2, 3, and 4 rows, than in water cooling coils. Hot water pressure in water heating coils is often rated at 175 to 300 psig at a temperature up to 250°F. Figure 9.7.3(c) shows a water heating coil.

### Steam Heating Coil

In a steam heating coil, latent heat of condensation is released when steam is condensed into liquid to heat the air flowing over the coil, as shown in Figure 9.7.3(d). Steam enters at one end of the coil, and the condensate comes out from the opposite end. For more even distribution, a baffle plate is often installed after the steam inlet. Steam heating coils are usually made of copper, steel, or sometimes stainless steel.

For a steam coil, the coil core inside the casing should expand or contract freely. The coil core is also pitched toward the outlet to facilitate condensate drainage. Steam heating coils are generally rated at 100 to 200 psig at 400°F.

### Coil Accessories and Servicing

*Coil accessories* include air vents, drain valves, isolation valves, pressure relief valves, flow metering valves, balancing valves, thermometers, pressure gauge taps, condensate drain taps, and even distribution baffles. They are employed depending on the size of the system and operating and servicing requirements.

*Coil cleanliness* is important for proper operation. If a medium-efficiency air filter is installed upstream of the coil, dirt accumulation is often not a problem. If a low-efficiency filter is employed, dirt accumulation may block the air passage and significantly increase the pressure drop across the coil. Coils should normally be inspected and cleaned every 3 months in urban areas when low-efficiency filters are used. Drain pans should be cleaned every month to prevent buildup of bacteria and microorganisms.

## Coil Freeze-Up Protection

Improper mixing of outdoor air and recirculating air in the mixing box of an AHU or PU may cause coil freeze-up when the outdoor air temperature is below 32°F. Outdoor air should be guided by a baffle plate and flow in an opposite direction to the recirculating air stream so that they can be thoroughly mixed without stratification.

Run the chilled water pump for the idle coil with a water velocity of 2.5 ft/sec, so that the cooling coil will not freeze when the air temperature drops to 32°F. A better method is to drain the water completely. For a hot water coil, it is better to reset the hot water temperature at part-load operation instead of running the system intermittently. A steam heating coil with inner distributor tubes and outer finned heating tubes provides better protection against freeze-up.

## Air Filters

### Air Cleaning and Filtration

*Air cleaning* is the process of removing airborne particles from the air. Air cleaning can be classified into air filtration and industrial air cleaning. Industrial air cleaning involves the removal of dust and gaseous contaminants from manufacturing processes as well as from the space air, exhaust air, and flue gas for air pollution control. In this section, only air filtration is covered.

*Air filtration* involves the removal of airborne particles presented in the conditioned air. Most of the airborne particles removed by air filtration are smaller than 1  $\mu\text{m}$ , and the concentration of these particles in the airstream seldom exceeds 2  $\text{mg}/\text{m}^3$ . The purpose of air filtration is to benefit the health and comfort of the occupants as well as meet the cleanliness requirements of the working area in industrial buildings.

An *air filter* is a kind of air cleaner that is installed in AHUs, PUs, and other equipment to filter the conditioned air by inertial impaction or interception and to diffuse and settle fine dust particles on the fibrous medium. The filter medium is the fabricated material that performs air filtration.

Operating performance of air filters is indicated by their:

- *Efficiency* or effectiveness of dust removal
- *Dust holding capacity*  $m_{\text{dust}}$ , which is the amount of dust held in the air filter, in grains/ft<sup>2</sup>
- *Initial pressure drop* when the filter is clean  $\Delta p_{\text{fi}}$  and *final pressure drop*  $\Delta p_{\text{ff}}$  when the filter's  $m_{\text{dust}}$  is maximum, both in in. WG
- *Service life*, which is the operating period between  $\Delta p_{\text{fi}}$  and  $\Delta p_{\text{ff}}$

Air filters in AHUs and PUs can be classified into low-, medium-, and high-efficiency filters and carbon activated filters.

### Test Methods

The performance of air filters is usually tested in a test unit that consists of a fan, a test duct, the tested filter, two samplers, a vacuum pump, and other instruments. Three test methods with their own test dusts and procedures are used for the testing of low-, medium-, and high-efficiency air filters.

The *weight arrestance test* is used for low-efficiency air filters to assess their ability to remove coarse dusts. Standard synthetic dusts that are considerably coarser than atmospheric dust are fed to the test unit. By measuring the weight of dust fed and the weight gain due to the dust collected on the membrane of the sampler after the tested filter, the arrestance can be calculated.

The *atmospheric dust spot efficiency test* is used for medium-efficiency air filters to assess their ability to remove atmospheric dusts. *Atmospheric dusts* are dusts contained in the outdoor air, the outdoor atmosphere. Approximately 99% of atmospheric dusts are dust particles  $<0.3 \mu\text{m}$  that make up 10% of the total weight; 0.1% of atmospheric dusts is particles  $>1 \mu\text{m}$  that make up 70% of the total weight.

Untreated atmospheric dusts are fed to the test unit. Air samples taken before and after the tested filter are drawn through from identical fiber filter-paper targets. By measuring the light transmission of these discolored white filter papers, the efficiency of the filter can be calculated. Similar atmospheric

dust spot test procedures have been specified by American Filter Institute (AFI), ASHRAE Standard 52.1, and former National Bureau of Standards (NBS).

The *DOP penetration and efficiency test* or simply *DOP test* is used to assess high-efficiency filters removing dusts particles of  $0.18\ \mu\text{m}$ . According to U.S. Military Standard MIL-STD-282 (1956), a smoke cloud of uniform dioctyl phthalate (DOP) droplets  $0.18\ \mu\text{m}$  in diameter, generated from the condensation of the DOP vapor, is fed to the test unit. By measuring the concentration of these particles in the air stream upstream and downstream of the tested filter using an electronic particle counter or laser spectrometer, the penetration and efficiency of the air filter can be calculated.

### Low-Efficiency Air Filters

ASHRAE weight arrestance for low-efficiency filters is between 60 and 95%, and ASHRAE dust spot efficiency for low-efficiency filters is less than 20%. These filters are usually in panels as shown in Figure 9.7.4(a). Their framework is typically  $20 \times 20$  in. or  $24 \times 24$  in. Their thickness varies from 1 to 4 in.

**FIGURE 9.7.4** Various types of air filters: (a) low efficiency, (b) medium efficiency, (c) HEPA and ULPA filters, and (d) activated carbon filter.

For low-efficiency filters, the filter media are often made of materials such as

- Corrugated wire mesh and screen strips coated with oil, which act as adhesives to enhance dust removal. Detergents may be used to wash off dusts so that the filter media can be cleaned and reused — they are therefore called *viscous and reusable*.
- Synthetic fibers (nylon, terylene) and polyurethane foam can be washed, cleaned, and reused if required — *dry and reusable*.

- Glass fiber mats with fiber diameter greater than 10  $\mu\text{m}$ . The filter medium is discarded when its final pressure drop is reached — *dry and disposable*. The face velocity of the panel filter is usually between 300 and 600 fpm. The initial pressure drop varies from 0.05 to 0.25 in. WG and the final pressure drop from 0.2 to 0.5 in. WG.

### Medium-Efficiency Air Filters

These air filters have an ASHRAE dust spot efficiency usually between 20 and 95%. Filter media of medium-efficiency filters are usually made of glass fiber mat with a fiber diameter of 10 to 1  $\mu\text{m}$  using nylon fibers to join them together. They are usually dry and disposable. In addition:

- As the dust spot efficiency increases, the diameter of glass fibers is reduced, and they are placed closer together.
- Extended surfaces, such as pleated mats or bags, are used to increase the surface area of the medium as shown in [Figure 9.7.4\(b\)](#). Air velocity through the medium is 6 to 90 fpm. Face velocity of the air filter is about 500 fpm to match the face velocity of the coil in AHUs and PUs.
- Initial pressure drop varies from 0.20 to 0.60 in. WG and final pressure drop from 0.50 to 1.20 in. WG.

### High-Efficiency Particulate Air (HEPA) Filters and Ultra-Low-Penetration Air (ULPA) Filters

*HEPA filters* have a DOP test efficiency of 99.97% for dust particles  $\geq 0.3 \mu\text{m}$  in diameter. *ULPA filters* have a DOP test efficiency of 99.999% for dust particles  $\geq 0.12 \mu\text{m}$  in diameter.

A typical HEPA filter, shown in [Figure 9.7.4\(d\)](#), has dimensions of  $24 \times 24 \times 11.5$  in. Its filter media are made of glass fibers of submicrometer diameter in the form of pleated paper mats. The medium is dry and disposable. The surface area of the HEPA filter may be 50 times its face area, and its rated face velocity varies from 190 to 390 fpm, normally at a pressure drop of 0.50 to 1.35 in. WG for clean filters. The final pressure drop is 0.8 to 2 in. WG. Sealing of the filter pack within its frame and sealing between the frame and the gaskets are critical factors that affect the penetration and efficiency of the HEPA filter.

An ULPA filter is similar to a HEPA filter in construction and filter media. Both its sealing and filter media are more efficient than those of a HEPA filter.

To extend the service life of HEPA filters and ULPA filters, both should be protected by a medium-efficiency filter, or a low-efficiency and a medium-efficiency filter in the sequence low–medium just before the HEPA or ULPA filters. HEPA and ULPA filters are widely used in clean rooms and clean spaces.

### Activated Carbon Filters

These filters are widely used to remove objectional odors and irritating gaseous airborne particulates, typically 0.003 to 0.006  $\mu\text{m}$  in size, from the air stream by adsorption. *Adsorption* is physical condensation of gas or vapor on the surface of an activated substance like activated carbon. Activated substances are extremely porous. One pound of activated carbon contains 5,000,000  $\text{ft}^2$  of internal surface.

Activated carbon in the form of granules or pellets is made of coal, coconut shells, or petroleum residues and is placed in trays to form activated carbon beds as shown in [Figure 9.7.4\(d\)](#). A typical carbon tray is  $23 \times 23 \times 5/8$  in. thick. Low-efficiency prefilters are used for protection. When air flows through the carbon beds at a face velocity of 375 to 500 fpm, the corresponding pressure drop is 0.2 to 0.3 in. WG.

### Humidifiers

A *humidifier* adds moisture to the air. Air is humidified by: (1) heating the liquid to evaporate it; (2) atomizing the liquid water into minute droplets by mechanical means, compressed air, or ultrasonic vibration to create a larger area for evaporation; (3) forcing air to flow through a wetted element in

which water evaporates; and (4) injecting steam into air directly before it is supplied to the conditioned space.

For comfort air-conditioning systems, a steam humidifier with a separator as shown in Figure 9.7.5(a) is widely used. Steam is supplied to a jacketed distribution manifold. It enters a separating chamber with its condensate. Steam then flows through a control valve, throttles to a pressure slightly above atmospheric, and enters a dry chamber. Due to the high temperature in the surrounding separating chamber, the steam is superheated. Dry steam is then discharged into the ambient air stream through the orifices on the inner steam discharge tubes.

**FIGURE 9.7.5** Steam grid humidifier (a) and air washer (b).

For an air system of cold air supply with humidity control during winter mode operation, an air washer is economical for large-capacity humidification in many industrial applications.

An air washer is a humidifier, a cooler, a dehumidifier, and an air cleaner. An air washer usually has an outer casing, two banks of spraying nozzles, one bank of guide baffles at the entrance, one bank of eliminators at the exit, a water tank, a circulating pump, a water filter, and other accessories as shown in Figure 9.7.5(b). Outer casing, baffles, and eliminators are often made of plastics or sometimes stainless steel. Spraying nozzles are usually made of brass or nylon, with an orifice diameter of 1/16 to 3/16 in., a smaller orifice for humidification, and a larger orifice for cooling and dehumidification. An eccentric inlet connected to the discharge chamber of the spraying nozzle gives centrifugal force to the water stream and atomizes the spraying water. Water is supplied to the spraying nozzle at a pressure of 15 to 30 psig. The distance between two spraying banks is 3 to 4.5 ft, and the total length of the air water from 4 to 7 ft. The air velocity inside an air washer is usually 500 to 800 fpm.

**Selection of AHUs and PUs**

- The size of an AHU is usually selected so that the face velocity of its coil is 600 fpm or less in order to prevent entrained condensate droplets. The cooling and heating capacities of an AHU can be varied by using coils of different numbers of rows and fin densities. The size of a PU is determined by its cooling capacity. Normally, the volume flow rate per ton of cooling capacity in PUs is 350 to 400 cfm. In most packaged units whose supply fans have belt drives, the fan speed can be selected so that the volume flow rate is varied and external pressure is met.
- ASHRAE/IES Standard 90.1-1989 specifies that the selected equipment capacity may exceed the design load only when it is the smallest size needed to meet the load. Selected equipment in a size larger always means a waste of energy and investment.
- To improve the indoor air quality, save energy, and prevent smudging and discoloring building interiors, a medium-efficiency filter of dust spot efficiency  $\geq 50\%$  and an air economizer are preferable for large AHUs and PUs.

## 9.8 Refrigeration Components and Evaporative Coolers

### Refrigeration Compressors

A *refrigeration compressor* is the heart of a vapor compression system. It raises the pressure of refrigerant so that it can be condensed into liquid, throttled, and evaporated into vapor to produce the refrigeration effect. It also provides the motive force to circulate the refrigerant through condenser, expansion valve, and evaporator.

According to the compression process, refrigeration compressors can be divided into *positive displacement* and *nonpositive displacement* compressors. A positive displacement compressor increases the pressure of the refrigerant by reducing the internal volume of the compression chamber. Reciprocating, scroll, rotary, and screw compressors are all positive displacement compressors. The centrifugal compressor is the only type of nonpositive displacement refrigeration compressor widely used in refrigeration systems today.

Based on the sealing of the refrigerant, refrigeration compressors can be classified as

- *Hermetic compressors*, in which the motor and the compressor are sealed or welded in the same housing to minimize leakage of refrigerant and to cool the motor windings by using suction vapor
- *Semihhermetic compressors*, in which motor and compressor are enclosed in the same housing but are accessible from the cylinder head for repair and maintenance
- *Open compressors*, in which compressor and motor are enclosed in two separate housings

Refrigeration compressors are often driven by motor directly or by gear train.

### Performance Indices

*Volumetric efficiency*  $\eta_v$  of a refrigeration compressor is defined as

$$\eta_v = \dot{V}_{a,v} / \dot{V}_p \quad (9.8.1)$$

where  $\dot{V}_{a,v}$  = actual induced volume of the suction vapor at suction pressure, cfm  
 $\dot{V}_p$  = calculated displacement of the compressor, cfm

*Isentropic efficiency*  $\eta_{isen}$ , *compression efficiency*  $\eta_{cp}$ , *compressor efficiency*  $\eta_{com}$ , and *mechanical efficiency*  $\eta_{mec}$  are defined as

$$\begin{aligned} \eta_{isen} &= (h_2 - h_1) / (h'_2 - h_1) = \eta_{cp} \eta_{mec} = \eta_{com} \\ \eta_{cp} &= W_{sen} / W_v \\ \eta_{mec} &= W_v / W_{com} \end{aligned} \quad (9.8.2)$$

where  $h_1, h_2, h'_2$  = enthalpy of the suction vapor, ideal discharged hot gas, and actual discharged hot gas, respectively, Btu/lb

$W_{isen}, W_v, W_{com}$  = isentropic work =  $(h_2 - h_1)$ , work delivered to the vapor refrigerant, and work delivered to the compressor shaft, Btu/lb

The actual power input to the compressor  $P_{com}$ , in hp, can be calculated as

$$\begin{aligned} P_{com} &= \dot{m}_r (h_2 - h_1) / (42.41 \eta_{isen} \eta_{mo}) \\ \dot{m}_r &= \dot{V}_p \eta_v \rho_{suc} \\ \eta_{mo} &= P_{com} / P_{mo} \end{aligned} \quad (9.8.3)$$

where  $\dot{m}_r$  = mass flow rate of refrigerant, lb/min  
 $\rho_{\text{suc}}$  = density of suction vapor, lb/ft<sup>3</sup>  
 $P_{\text{mo}}$  = power input to the compressor motor, hp

*Power consumption*, kW/ton refrigeration, is an energy index used in the HVAC&R industry in addition to EER and COP.

Currently used refrigeration compressors are reciprocating, scroll, screw, rotary, and centrifugal compressors.

### Reciprocating Compressors

In a reciprocating compressor, as shown in [Figure 9.8.1\(a\)](#), a crankshaft connected to the motor shaft drives 2, 3, 4, or 6 single-acting pistons moving reciprocally in the cylinders via a connecting rod.

The refrigeration capacity of a reciprocating compressor is a fraction of a ton to about 200 tons. Refrigerants R-22 and R-134a are widely used in comfort and processing systems and sometimes R-717 in industrial applications. The maximum compression ratio  $R_{\text{com}}$  for a single-stage reciprocating compressor is about 7. Volumetric efficiency  $\eta_v$  drops from 0.92 to 0.65 when  $R_{\text{com}}$  is raised from 1 to 6. Capacity control of reciprocating compressor including: on-off and cylinder unloader in which discharge gas is in short cut and return to the suction chamber.

Although reciprocating compressors are still widely used today in small and medium-sized refrigeration systems, they have little room for significant improvement and will be gradually replaced by scroll and screw compressors.

### Scroll Compressors

A scroll compressor consists of two identical spiral scrolls assembled opposite to each other, as shown in [Figure 9.8.1\(b\)](#). One of the scrolls is fixed, and the other moves in an orbit around the motor shaft whose amplitude equals the radius of the orbit. The two scrolls are in contact at several points and therefore form a series of pockets.

Vapor refrigerant enters the space between two scrolls through lateral openings. The lateral openings are then sealed and the formation of the two trapped vapor pockets indicates the end of the suction process. The vapor is compressed and the discharge process begins when the trapped gaseous pockets open to the discharge port. Compressed hot gas is then discharged through this opening to the discharge line. In a scroll compressor, the scrolls touch each other with sufficient force to form a seal but not enough to cause wear.

The upper limit of the refrigeration capacity of currently manufactured scroll compressors is 60 tons. A scroll compressor has  $\eta_v > 95\%$  at  $R_{\text{com}} = 4$  and  $\eta_{\text{isen}} = 80\%$ . A scroll compressor also has only about half as many parts as a reciprocating compressor at the same refrigeration capacity. Few components result in higher reliability and efficiency. Power input to the scroll compressor is about 5 to 10% less than to the reciprocating compressor. A scroll compressor also operates more smoothly and is quieter.

### Rotary Compressors

Small rotary compressors for room air conditioners and refrigerators have a capacity up to 4 tons. There are two types of rotary compressors: rolling piston and rotating vane. A typical rolling piston rotary compressor is shown in [Figure 9.8.1\(c\)](#). A rolling piston mounted on an eccentric shaft is kept in contact with a fixed vane that slides in a slot. Vapor refrigerant enters the compression chamber and is compressed by the eccentric motion of the roller. When the rolling piston contacts the top housing, hot gas is squeezed out from the discharge valve.

### Screw Compressors

These are also called *helical rotary compressors*. Screw compressors can be classified into single-screw compressors, in which there is a single helical rotor and two star wheels, and twin-screw compressors. Twin-screw compressors are widely used.

**FIGURE 9.8.1** Various types of refrigeration compressors: (a) reciprocating, (b) scroll, (c) rotary, (d) twin-screw, and (e) centrifugal.

A typical twin-screw compressor, as shown in [Figure 9.8.1\(d\)](#) consists of a four-lobe male rotor and a six-lobe female rotor, a housing with suction and discharge ports, and a sliding valve to adjust the

capacity during part load. Normally, the male rotor is the driver. Twin-screw compressors are often direct driven and of hermetic type.

Vapor refrigerant is extracted into the interlobe space when the lobes are separated at the suction port. During the successive rotations of the rotor, the volume of the trapped vapor is compressed. When the interlobe space is in contact with the discharge port, the compressed hot gas discharges through the outlet. Oil injection effectively cools the rotors and results in a lower discharge temperature. Oil also provides a sealing effect and lubrication. A small clearance of 0.0005 in. as well as the oil sealing minimizes leakage of the refrigerant.

The refrigeration capacity of twin-screw compressors is 50 to 1500 tons. The compression ratio of a twin-screw compressor can be up to 20:1. R-22 and R-134a are the most widely used refrigerants in comfort systems. In a typical twin-screw compressor,  $\eta_v$  decreases from 0.92 to 0.87 and  $\eta_{isen}$  drops from 0.82 to 0.67 when  $R_{com}$  increases from 2 to 10. Continuous and stepless capacity control is provided by moving a sliding valve toward the discharge port, which opens a shortcut recirculating passage to the suction port.

Twin-screw compressors are more efficient than reciprocating compressors. The low noise and vibration of the twin-screw compressor together with its positive displacement compression results in more applications today.

### Centrifugal Compressors

A *centrifugal compressor* is a turbomachine and is similar to a centrifugal fan. A hermetic centrifugal compressor has an outer casing with one, two, or even three impellers internally connected in series and is driven by a motor directly or by a gear train. At the entrance to the first-stage impeller are inlet guide vanes positioned at a specific opening to adjust refrigerant flow and therefore the capacity of the centrifugal compressor.

Figure 9.8.1(e) shows a two-stage hermetic centrifugal compressor. The total pressure rise in a centrifugal compressor, often called head lift, in psi, is due to the conversion of the velocity pressure into static pressure. Although the compression ratio  $R_{com}$  of a single-stage centrifugal compressor using R-123 and R-22 seldom exceeds 4, two or three impellers connected in series satisfy most of the requirements in comfort systems.

Because of the high head lift to raise the evaporating pressure to condensing pressure, the discharge velocity at the exit of the second-stage impeller approaches the acoustic velocity of saturated vapor  $v_{ac}$  of R-123, 420 ft/sec at atmospheric pressure and a temperature of 80°F. Centrifugal compressors need high peripheral velocity and rotating speeds (up to 50,000 rpm) to produce such a discharge velocity. It is not economical to manufacture small centrifugal compressors. The available refrigeration capacity for centrifugal compressors ranges from 100 to 10,000 tons. Centrifugal compressors have higher volume flow per unit refrigeration capacity output than positive displacement compressors. Centrifugal compressors are efficient and reliable. Their volumetric efficiency almost equals 1. At design conditions, their  $\eta_{isen}$  may reach 0.83, and it drops to 0.6 during part-load operation. They are the most widely used refrigeration compressors in large air-conditioning systems.

### Refrigeration Condensers

A *refrigeration condenser* or simply a *condenser* is a heat exchanger in which hot gaseous refrigerant is condensed into liquid and the latent heat of condensation is rejected to the atmospheric air, surface water, or well water. In a condenser, hot gas is first desuperheated, then condensed into liquid, and finally subcooled.

The capacity of a condenser is rated by its *total heat rejection*  $Q_{rej}$ , in Btu/hr, which is defined as the total heat removed from the condenser during desuperheating, condensation, and subcooling. For a refrigeration system using a hermetic compressor,  $Q_{rej}$  can be calculated as

$$\dot{Q}_{\text{rej}} = U_{\text{con}} A_{\text{con}} \Delta T_m = 60 \dot{m}_r (h_2 - h'_3) = q_{\text{rl}} + (2545 P_{\text{com}}) / \eta_{\text{mo}} \quad (9.8.4)$$

where  $U_{\text{con}}$  = overall heat transfer coefficient across the tube wall in the condenser, Btu/hr.ft<sup>2</sup>.°F  
 $A_{\text{con}}$  = condensing area in the condenser, ft<sup>2</sup>  
 $\Delta T_m$  = logarithmic temperature difference, °F  
 $\dot{m}_r$  = mass flow rate of refrigerant, lb/min  
 $h_2, h'_3$  = enthalpy of suction vapor refrigerant and hot gas, Btu/lb  
 $q_{\text{rl}}$  = refrigeration load at the evaporator, Btu/hr

A factor that relates  $\dot{Q}_{\text{rej}}$  and  $q_{\text{rl}}$  is the *heat rejection factor*  $F_{\text{rej}}$ , which is defined as the ratio of total heat rejection to the refrigeration load, or

$$F_{\text{rej}} = \dot{Q}_{\text{rej}} / q_{\text{rl}} = 1 + (2545 P_{\text{com}}) / (q_{\text{rl}} \eta_{\text{mo}}) \quad (9.8.5)$$

*Fouling factor*  $R_f$ , in hr.ft<sup>2</sup>.°F/Btu, is defined as the additional resistance caused by a dirty film of scale, rust, or other deposits on the surface of the tube. ARI Standard 550-88 specifies the following for evaporators and condensers:

Field fouling allowance	0.00025 hr.ft <sup>2</sup> .°F/Btu
New evaporators and condensers	0

According to the cooling process used during condensation, refrigeration condensers can be classified as air-cooled, water-cooled, and evaporative-cooled condensers.

### Air-Cooled Condensers

In an *air-cooled condenser*, air is used to absorb the latent heat of condensation released during desuperheating, condensation, and subcooling.

An air-cooled condenser consists of a condenser coil, a subcooling coil, condenser fans, dampers, and controls as shown in Figure 9.8.2(a). There are refrigeration circuits in the condensing coil. Condensing coils are usually made of copper tubes and aluminum fins. The diameter of the tubes is 1/4 to 3/4 in., typically 3/8 in., and the fin density is 8 to 20 fins/in. On the inner surface of the copper tubes, microfins, typically 60 fins/in. with a height of 0.008 in., are used. A condensing coil usually has only two to three rows due to the low pressure drop of the propeller-type condenser fans. A subcooling coil is located at a lower level and is connected to the condensing coil.

Hot gas from the compressor enters the condensing coil from the top. When the condensate increases, part of the condensing area can be used as a subcooling area. A receiver is necessary only when the liquid refrigerant cannot all be stored in the condensing and subcooling coils during the shut-down period in winter.

Cooling air is drawn through the coils by a condenser fan(s) for even distribution. Condenser fans are often propeller fans for their low pressure and large volume flow rate. A damper(s) may be installed to adjust the volume flow of cooling air.

In air-cooled condensers, the volume flow of cooling air per unit of total heat rejection  $\dot{V}_{\text{ca}} / \dot{Q}_{\text{u.rej}}$  is 600 to 1200 cfm/ton of refrigeration capacity at the evaporator, and the optimum value is about 900 cfm/ton. The corresponding cooling air temperature difference — cooling air leaving temperature minus outdoor temperature ( $T_{\text{ca,l}} - T_o$ ) — is around 13°F.

The condenser temperature difference (CTD) for an air-cooled condenser is defined as the difference between the saturated condensing temperature corresponding to the pressure at the inlet and the air intake temperature, or ( $T_{\text{con,i}} - T_o$ ). Air-cooled condensers are rated at a specific CTD, depending on the evaporating temperature of the refrigeration system  $T_{\text{ev}}$  in which the air-cooled condenser is installed. For a refrigeration system having a lower  $T_{\text{ev}}$ , it is more economical to equip a larger condenser with a smaller CTD. For a comfort air-conditioning system having a  $T_{\text{ev}}$  of 45°F, CTD = 20 to 30°F.

**FIGURE 9.8.2** Various types of refrigeration condensers: (a) air-cooled, (b) shell-and-tube water-cooled, and (c) evaporative cooled.

A higher condensing temperature  $T_{\text{con}}$ , a higher condensing pressure  $p_{\text{con}}$ , and a higher compressor power input may be due to an undersized air-cooled condenser, lack of cooling air or low  $\dot{V}_{\text{ca}}/Q_{\text{u,rej}}$  value, a high entering cooling air temperature at the roof, a dirty condensing coil, warm air circulation because of insufficient clearance between the condenser and the wall, or a combination of these. The clearance should not be less than the width of the condensing coil.

If  $p_{\text{con}}$  drops below a certain value because of a lower outdoor temperature, the expansion valve in a reciprocating vapor compression system may not operate properly. At a low ambient temperature  $T_o$ , the following controls are often used:

- Duty cycling, turning the condenser fans on and off until all of them are shut down, to reduce cooling air volume flow
- Modulating the air dampers to reduce the volume flow
- Reducing the fan speed

Some manufacturers' catalogs start low ambient control at  $T_o = 65^\circ\text{F}$  and some specify a minimum operating temperature at  $T_o = 0^\circ\text{F}$ .

### Water-Cooled Condensers

In a *water-cooled condenser*, latent heat of condensation released from the refrigerant during condensation is extracted by water. This cooling water, often called condenser water, is taken directly from river, lake, sea, underground well water or a cooling tower.

Two types of water-cooled condensers are widely used for air-conditioning and refrigeration: double-tube condensers and horizontal shell-and-tube condensers.

A *double-tube condenser* consists of two tubes, one inside the other. Condenser water is pumped through the inner tube and refrigerant flows within the space between the inner and outer tubes in a counterflow arrangement. Because of its limited condensing area, the double-tube condenser is used only in small refrigeration systems.

A horizontal *shell-and-tube water-cooled condenser* using halocarbon refrigerant usually has an outer shell in which copper tubes typically 5/8 to 3/4 in. in diameter are fixed in position by tube sheets as shown in [Figure 9.8.2\(b\)](#). Integral external fins of 19 to 35 fins/in. and a height of 0.006 in. and spiral internal grooves are used for copper tubes to increase both the external and the inner surface area and their heat transfer coefficients.

Hot gas from the compressor enters the top inlet and is distributed along the baffle to fill the shell. Hot gas is then desuperheated, condensed, subcooled into liquid, and discharged into the liquid line at the bottom outlet. Usually one sixth of the volume is filled with subcooled liquid refrigerant. Subcooling depends on the entering temperature of condenser water  $T_{\text{ce}}$ , in  $^\circ\text{F}$ , and usually varies between 2 and  $8^\circ\text{F}$ .

Condenser water enters the condenser from the bottom for effective subcooling. After extracting heat from the gaseous refrigerant, condenser water is discharged at a higher level. Two-pass or three-pass water flow arrangements are usually used in shell-and-tube water-cooled condensers. The two-pass arrangement means that water flows from one end to the opposite end and returns to the original end. Two-pass is the standard setup. In a shell-and-tube water-cooled condenser, the condensing temperature  $T_{\text{con}}$  depends mainly on the entering temperature of condenser water  $T_{\text{ce}}$ , the condenser area, the fouling factor, and the configuration of the copper tube.

### Evaporative Condenser

An *evaporative condenser* uses the evaporation of water spray on the outer surface of the condensing tubes to remove the latent heat of condensation of refrigerant during condensation.

An evaporative condenser consists of a condensing coil, a subcooling coil, a water spray, an induced draft or sometimes forced draft fan, a circulating water pump, a water eliminator, a water basin, an outer casing, and controls as shown in [Figure 9.8.2\(c\)](#). The condensing coil is usually made of bare copper, steel, or sometimes stainless steel tubing.

Water is sprayed over the outside surface of the tubing. The evaporation of a fraction of condenser water from the saturated air film removes the sensible and latent heat rejected by the refrigerant. The wetted outer surface heat transfer coefficient  $h_{\text{wet}}$  is about four or five times greater than the dry surface heat transfer coefficient  $h_o$ , in Btu/hr.ft<sup>2</sup>.°F. The rest of the spray falls and is collected by the basin. Air enters from the inlet just above the basin. It flows through the condensing coil at a face velocity of 400 to 700 fpm, the water spray bank, and the eliminator. After air absorbs the evaporated water vapor, it is extracted by the fan and discharged at the top outlet. The water circulation rate is about 1.6 to 2 gpm/ton, which is far less than that of the cooling tower.

An evaporative condenser is actually a combination of a water-cooled condenser and a cooling tower. It is usually located on the rooftop and should be as near the compressor as possible. Clean tube surface and good maintenance are critical factors for evaporative condensers. An evaporative condenser also needs low ambient control similar as in an air-cooled condenser.

### Comparison of Air-Cooled, Water-Cooled, and Evaporative Condensers

An air-cooled condenser has the highest condensing temperature  $T_{\text{con}}$  and therefore the highest compressor power input. For an outdoor dry bulb temperature of 90°F and a wet bulb temperature of 78°F, a typical air-cooled condenser has  $T_{\text{con}} = 110^\circ\text{F}$ . An evaporative condenser has the lowest  $T_{\text{con}}$  and is most energy efficient. At the same outdoor dry and wet bulb temperatures, its  $T_{\text{con}}$  may be equal to 95°F, even lower than that of a water-cooled condenser incorporating with a cooling tower, whose  $T_{\text{con}}$  may be equal to 100°F. An evaporative condenser also consumes less water and pump power. The drawback of evaporative condensers is that the rejected heat from the interior zone is difficult to recover and use as winter heating for perimeter zones and more maintenance is required.

### Evaporators and Refrigerant Flow Control Devices

An *evaporator* is a heat exchanger in which the liquid refrigerant is vaporized and extracts heat from the surrounding air, chilled water, brine, or other substance to produce a refrigeration effect.

Evaporators used in air-conditioning can be classified according to the combination of the medium to be cooled and the type of refrigerant feed, as the following.

*Direct expansion DX coils* are air coolers, and the refrigerant is fed according to its degree of superheat after vaporization. DX coils were covered earlier.

*Direct expansion ice makers* or *liquid overfeed ice makers* are such that liquid refrigerant is forced through the copper tubes or the hollow inner part of a plate heat exchanger and vaporized. The refrigeration effect freezes the water in the glycol-water that flows over the outside surface of the tubes or the plate heat exchanger. In direct expansion ice makers, liquid refrigerant completely vaporizes inside the copper tubes, and the superheated vapor is extracted by the compressor. In liquid overfeed ice makers, liquid refrigerant floods and wets the inner surface of the copper tubes or the hollow plate heat exchanger. Only part of the liquid refrigerant is vaporized. The rest is returned to a receiver and pumped to the copper tubes or plate heat exchanger again at a circulation rate two to several times greater than the evaporation rate.

*Flooded shell-and-tube liquid coolers*, or simply *flooded liquid coolers*, are such that refrigerant floods and wets all the boiling surfaces and results in high heat transfer coefficients. A flooded shell-and-tube liquid cooler is similar in construction to a shell-and-tube water-cooled condenser, except that its liquid refrigeration inlet is at the bottom and the vapor outlet is at the top. Water velocity inside the copper tubes is usually between 4 and 12 ft/sec and the water-side pressure normally drops below 10 psi. Flooded liquid coolers can provide larger evaporating surface area and need minimal space. They are widely used in large central air-conditioning systems.

Currently used refrigerant flow control devices include thermostatic expansion valves, float valves, multiple orifices, and capillary tubes.

A *thermostatic expansion valve* throttles the refrigerant pressure from condensing to evaporating pressure and at the same time regulates the rate of refrigerant feed according to the degree of superheat

of the vapor at the evaporator's exit. A thermostatic expansion valve is usually installed just prior to the refrigerant distributor in DX coils and direct-expansion ice makers.

A thermostatic expansion valve consists of a valve body, a valve pin, a spring, a diaphragm, and a sensing bulb near the outlet of the DX coil, as shown in Figure 9.7.3(a). The sensing bulb is connected to the upper part of the diaphragm by a connecting tube.

When the liquid refrigerant passes through the opening of the thermostatic expansion valve, its pressure is reduced to the evaporating pressure. Liquid and a small fraction of vaporized refrigerant then flow through the distributor and enter various refrigerant circuits. If the refrigeration load of the DX coil increases, more liquid refrigerant evaporizes. This increases the degree of superheat of the leaving vapor at the outlet and the temperature of the sensing bulb. A higher bulb temperature exerts a higher saturated pressure on the top of the diaphragm. The valve pin then moves downward and widens the opening. More liquid refrigerant is allowed to enter the DX coil to match the increase of refrigeration load. If the refrigeration load drops, the degree of superheat at the outlet and the temperature of the sensing bulb both drop, and the valve opening is narrower. The refrigeration feed decreases accordingly. The degree of superheat is usually 10 to 20°F. Its value can also be adjusted manually by varying the spring tension.

A *float valve* is a valve in which a float is used to regulate the valve opening to maintain a specific liquid refrigerant level. A lower liquid level causes a lower valve pin and therefore a wider opening and vice versa.

In a centrifugal refrigeration system, two or more orifice plates, *multiple orifices*, are sometimes installed in the liquid line between the condenser and the flash cooler and between the flash cooler and the flooded liquid cooler to throttle their pressure as well as to regulate the refrigerant feed.

A *capillary tube*, sometimes called a *restrictor tube*, is a fixed length of small-diameter tubing installed between the condenser and the evaporator to throttle the refrigerant pressure from  $p_{\text{con}}$  to  $p_{\text{ev}}$  and to meter the refrigerant flow to the evaporator. Capillary tubes are usually made of copper. The inside diameter  $D_{\text{cap}}$  is 0.05 to 0.06 in. and the length  $L_{\text{cap}}$  from an inch to several feet. There is a trend to use short capillary tubes of  $L_{\text{cap}}/D_{\text{cap}}$  between 3 and 20. Capillary tubes are especially suitable for a heat pump system in which the refrigerant flow may be reversed.

## Evaporative Coolers

An evaporative cooling system is an air-conditioning system in which air is cooled evaporatively. It consists of evaporative coolers, fan(s), filters, dampers, controls, and others. A mixing box is optional. An evaporative cooler could be a stand-alone cooler or installed in an air system as a component. There are three types of evaporative coolers: (1) direct evaporative coolers, (2) indirect evaporative coolers, and (3) indirect–direct evaporative coolers.

### Direct Evaporative Cooler

In a *direct evaporative cooler*, the air stream to be cooled directly contacts the water spray or wetted medium as shown in Figure 9.8.3(a). Evaporative pads made of wooden fibers with necessary treatment at a thickness of 2 in., rigid and corrugated plastics, impregnated cellulose, or fiber glass all dripping with water are wetted mediums.

The direct evaporation process 12 takes place along the thermodynamic wet bulb line on the psychrometric chart. Saturation effectiveness  $\epsilon_{\text{sat}}$  is an index that assesses the performance of a direct evaporative cooler:

$$\epsilon_{\text{sat}} = (T_{\text{ae}} - T_{\text{al}}) / (T_{\text{ae}} - T_{\text{ae}}^*) \quad (9.8.6)$$

where  $T$ ,  $T^*$  = temperature and thermodynamic wet bulb temperature of air stream, °F. Subscript ae indicates the entering air and al the leaving air.  $\epsilon_{\text{sat}}$  usually varies between 0.75 and 0.95 at a water–air ratio of 0.1 to 0.4.

FIGURE 9.8.3 Types of evaporative coolers: (a) direct, (b) indirect, and (c) indirect–direct.

### Indirect Evaporative Coolers

In an *indirect evaporative cooler*, the cooled-air stream to be cooled is separated from a wetted surface by a flat plate or tube wall as shown in Figure 9.8.3(b). A wet-air stream flows over the wetted surface so that liquid water is evaporated and extracts heat from the cooled-air stream through the flat plate or tube wall. The cooled-air stream is in contact with the wetted surface indirectly.

The core part of an indirect evaporative cooler is a plate heat exchanger. It is made of thin polyvinyl chloride plates 0.01 in. thick and spaced from 0.08 to 0.12 in. apart to form horizontal passages for cooled air and vertical passages for wet air and water. As in a direct evaporative cooler, there are also fan(s), water sprays, circulating pump, air intake, dampers, controls, etc.

An indirect evaporative cooling process is represented by a horizontal line on a psychrometric chart, which shows that humidity ratio remains constant. If the space air is extracted and used as the wet air intake, the wet air will be exhausted at point x at nearly saturated state.

The performance of an indirect evaporative cooler can be assessed by its performance factor  $e_{in}$ , which is calculated as:

$$e_{\text{in}} = (T_{\text{ca,e}} - T_{\text{ca,l}}) / (T_{\text{ca,e}} - T_{\text{s,a}}) \quad (9.8.7)$$

where  $T_{\text{ca,e}}$ ,  $T_{\text{ca,l}}$  = temperature of cooled air entering and leaving the indirect evaporative cooler, °F, and  $T_{\text{s,a}}$  = temperature of the saturated air film on the wet air side and is about 3°F higher than the wet bulb temperature of the entering air, °F.

An indirect evaporative cooler could be so energy efficient as to provide evaporative cooling with an EER up to 50 instead of 9 to 12 for a reciprocating compression refrigeration system.

*Direct–Indirect Evaporative Cooler.* A direct–indirect evaporative cooler is a two-stage evaporating cooler, as shown in [Figure 9.8.3\(c\)](#), in which the first-stage indirect evaporative cooler is connected in series with a second-stage direct evaporative cooler for the purpose of increasing the evaporating effect.

*Operating Characteristics.* The saturation effectiveness  $\epsilon_{\text{sat}}$  and performance factor  $e_{\text{in}}$  are both closely related to the air velocity flowing through the air passages. For a direct evaporative cooler, face velocity is usually less than 600 fpm to reduce drift carryover. For an indirect evaporative cooler, face velocity  $v_s$  is usually between 400 to 1000 fpm. A higher  $v_s$  results at a greater air-side pressure drop.

Scofield et al. (1984) reported the performance of an indirect–direct evaporative cooler in Denver, Colorado. Outdoor air enters the indirect cooler at a dry bulb of 93°F and a wet bulb of 67.5° and was evaporatively cooled to 67.5°F dry bulb and 49.8°F wet bulb with an  $e_{\text{in}} = 0.76$  as shown in [Figure 9.8.3\(c\)](#). In the direct cooler, conditioned air was further cooled to a dry bulb of 53.5°F and the wet bulb remained at 49.8°F at a saturation effectiveness  $\epsilon_{\text{sat}} = 0.8$ .

In locations where outdoor wet bulb  $T'_o \leq 60^\circ\text{F}$ , a direct evaporative can often provide an indoor environment of 78°F and a relative humidity of 60%. In locations  $T'_o \leq 68^\circ\text{F}$ , an indirect–direct evaporative cooler can maintain a comfortable indoor environment. In locations  $T'_o \geq 72^\circ\text{F}$ , an evaporative cooler with a supplementary vapor compression refrigeration may be cost effective. Because the installation cost of an indirect–direct cooler is higher than that of refrigeration, cost analysis is required to select the right choice. Evaporative coolers are not suitable for dehumidification except in locations where  $T'_o \leq 60^\circ\text{F}$ .

## 9.9 Water Systems

### Types of Water Systems

In central and space conditioning air-conditioning systems, water that links the central plant and the air handling units or terminals, that extracts condensing heat, or that provides evaporative cooling may be classified as

- *Chilled water system*, in which chilled water is first cooled in the centrifugal, screw, and reciprocating chillers in a central plant. Chilled water is then used as a cooling medium to cool the air in the cooling coils in AHUs and terminals.
- *Evaporative-cooled water system*, used to cool air directly or indirectly in evaporative coolers.
- *Hot water system*, in which hot water is heated in the boiler and then used to heat the air through heating coils in AHUs, terminals, or space finned-tube heaters.
- *Dual-temperature water system*, in which chilled water and hot water are supplied to and returned from the coils in AHUs and terminals through separate or common main and branch pipes. Using common main and branch pipes requires a lengthy changeover from chilled water to hot water or vice versa for a period of several hours.
- *Condenser water system*, which is a kind of cooling water system used to extract the latent heat of condensation from the condensing refrigerant in a water-cooled condenser and heat of absorption from the absorber.

Water systems can also be classified according to their operating characteristics.

### Closed System

In a closed system, water forms a closed loop for water conservation and energy saving when it flows through the coils, chillers, boilers, heaters, or other heat exchangers and water is not exposed to the atmosphere.

### Open System

In an open system, water is exposed to the atmosphere.

### Once-Through System

In a once-through system, water flows through a heat exchanger(s) only once without recirculation.

## Basics

### Volume Flow and Temperature Difference

The rate of heat transfer between water and air or water and refrigerant when water flows through a heat exchanger  $q_w$ , in Btu/hr, can be calculated as

$$q_w = 500 \dot{V}_{\text{gal}} (T_{\text{wl}} - T_{\text{we}}) = 500 \dot{V}_{\text{gal}} \Delta T_w \quad (9.9.1)$$

where  $\dot{V}_{\text{gal}}$  = volume flow rate of water, gpm  
 $T_{\text{wl}}, T_{\text{we}}$  = temperature of water leaving and entering the heat exchanger, °F  
 $\Delta T_w$  = temperature rise or drop of water when it flows through a heat exchanger, °F

The temperature of chilled water leaving the water chiller  $T_{\text{el}}$  should not be lower than 38°F in order to prevent freezing in the evaporator. Otherwise, brine or glycol-water should be used. The  $T_{\text{el}}$  of chilled water entering the coil  $T_{\text{we}}$  and the temperature difference of chilled water leaving and entering the coil  $\Delta T_w$  directly affect the temperature of air leaving the cooling coil  $T_{\text{ce}}$ . The lower  $T_{\text{we}}$ , the higher will be the compressor power input. The smaller  $\Delta T_w$ , the greater will be the water volume flow rate, the pipe

size, and the pump power. For chilled water in conventional comfort systems,  $T_{we}$  is usually 40 to 45°F and  $\Delta T_w$  12 to 24°F. Only in cold air distribution,  $T_{we}$  may drop to 34°F. For a cooling capacity of 1 ton refrigeration, a  $\Delta T_w$  of 12°F requires a  $\dot{V}_{gal} = 2$  gpm.

For hot water heating systems in buildings, hot water often leaves the boiler and enters the heating coil or heaters at a temperature  $T_{we}$  of 190 to 200°F. It returns at 150 to 180°F. For dual-temperature systems, hot water is usually supplied at 100 to 150°F and returns at a  $\Delta T_w$  of 20 to 40°F.

### Pressure Drop

Usually the pressure drop of water in pipes due to friction for HVAC&R systems,  $H_f$ , is in the range 0.75 ft/100 ft length of pipe to 4 ft/100 ft. A pressure loss of 2.5 ft/100 ft is most often used. ASHRAE/IES Standard 90.1-1989 specifies that water piping systems should be designed at a pressure loss of no more than 4.0 ft/100 ft. Figure 9.9.1(a), (b), and (c) shows the friction charts for steel, copper, and plastic pipes for closed water systems.

### Water Piping

The piping materials of various water systems for HVAC&R are as follows:

Chilled water	Black and galvanized steel
Hot water	Black steel, hard copper
Condenser water	Black steel, galvanized ductile iron, polyvinyl chloride (PVC)

The pipe thickness varies from Schedule 10, a light wall pipe, to Schedule 160, a very heavy wall pipe. Schedule 40 is the standard thickness for a pipe of up to 10 in. diameter. For copper tubing, type K is the heaviest, and type L is generally used as the standard for pressure copper tubes.

Steel pipes of small diameter are often joined by threaded cast-iron fittings. Steel pipes of diameter 2 in. and over, welded joints, and bolted flanges are often used.

In a water system, the maximum allowable working pressure for steel and copper pipes at 250°F varies from 125 to 400 psig, depending on the pipe wall thickness. Not only pipes, but also their joints and fittings should be considered.

During temperature changes, pipes expand and contract. Both operating and shut-down periods should be taken into consideration. Bends like U-, Z-, and L-bends, loops, and sometimes packed expansion joints, bellows, or flexible metal hose mechanical joints are used.

ASHRAE/IES Standard 90.1-1989 specifies that for chilled water between 40 to 55°F, the minimum thickness of the external pipe insulation varies from 0.5 to 1 in. depending on the pipe diameter. For chilled water temperature below 40°F, the minimum thickness varies from 1 to 1.5 in. For hot water temperatures not exceeding 200°F, the minimum thickness varies from 0.5 to 1.5 in. depending on the pipe diameter and the hot water temperature.

### Corrosion, Impurities, and Water Treatments

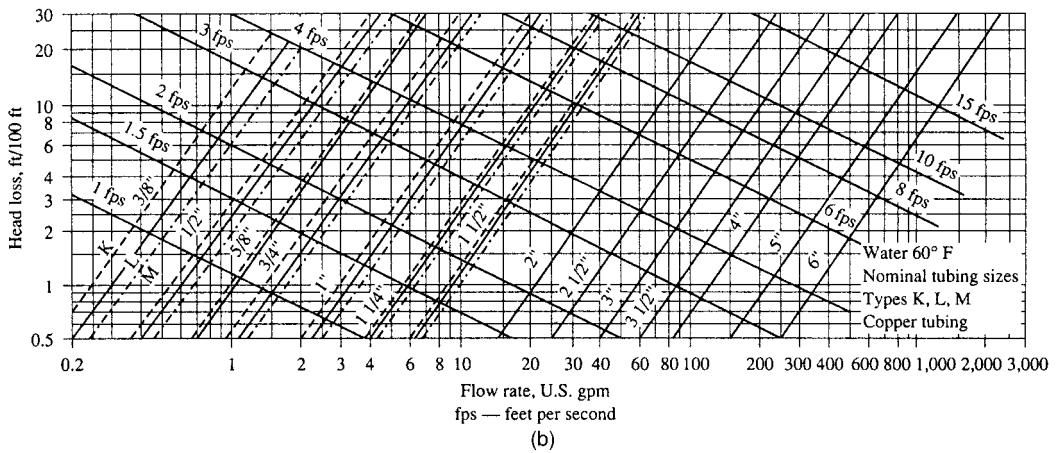

*Corrosion* is a destructive process caused by a chemical or electrochemical reaction on metal or alloy. In water systems, dissolved *impurities* cause corrosion and scale and the growth of microorganisms like algae, bacteria, and fungi. *Scale* is the deposit formed on a metal surface by precipitation of the insoluble constituents. In addition to the dissolved solids, unpurified water may contain suspended solids.

Currently used chemicals include crystal modifiers to change the crystal formation of scale and sequestering chemicals. Growth of bacteria, algae, and fungi is usually treated by biocides to prevent the formation of an insulating layer resulting in lower heat transfer as well as restricted water flow. Chlorine and its compounds are effective and widely used. Blow-down is an effective process in water treatment and should be considered as important as chemical treatments.

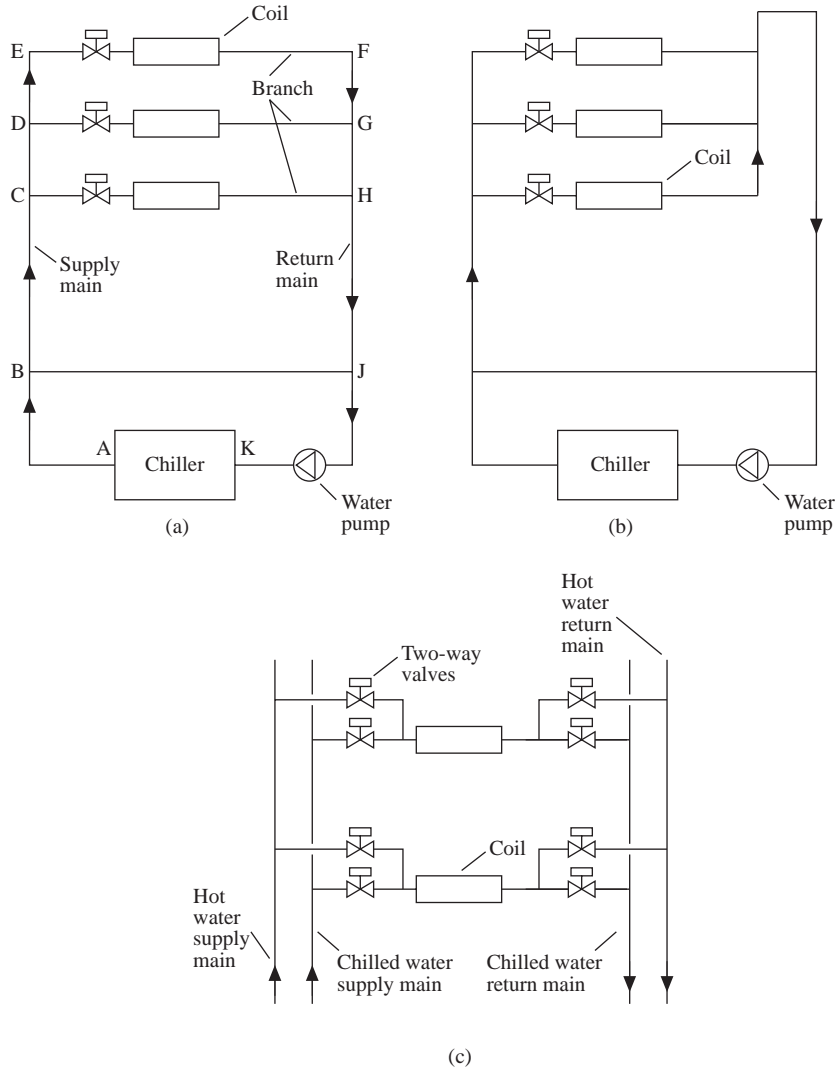

### Piping Arrangements

*Main and Branch Pipes.* In a piping circuit as shown in Figure 9.9.2(a), chilled water from a chiller or hot water from a boiler is often supplied to a *main pipe* and then distributed to *branch pipes* that

**FIGURE 9.9.1** Friction chart for water in pipes: (a) steel pipe (schedule 40), (b) copper tubing, and (c) plastic pipe (schedule 80). (Source: ASHRAE Handbook 1993 Fundamentals. Reprinted with permission.)

**FIGURE 9.9.2** Piping arrangements: (a) two-pipe direct return system, (b) two-pipe reverse system, and (c) four-pipe system.

connect to coils and heat exchangers. Chilled or hot water from the coils and heat exchangers is accumulated by the return main pipe through return branch pipes and then returned to the chiller or boiler.

*Constant Flow and Variable Flow.* In a constant-flow water system, the volume flow rate at any cross-sectional plane of the supply and return mains remains constant during the entire operating period. In a variable-flow water system, the volume flow rate varies when the system load changes during the operating period.

*Direct Return and Reverse Return.* In a *direct return* system, the water supplies to and returns from various coils through various piping circuits. ABCHJKA, ... ABCDEFHJKA are not equal in length, as shown in [Figure 9.9.2\(a\)](#). Water flow must be adjusted and balanced by using balance valves to provide required design flow rates at design conditions. In a *reverse-return* system, as shown in [Figure 9.9.2\(b\)](#), the piping lengths for various piping circuits including the branch and coil are almost equal. Water flow rates to various coils are easier to balance.

*Two-Pipe or Four-Pipe.* In a dual-temperature water system, the piping from the chiller or boiler to the coils can be either a *two-pipe* system with a supply main and return main as shown in Figure 9.9.2(a) or (b) or a *four-pipe* system with a chilled water supply main, a hot water supply main, a chilled water return main, and a hot water return main as shown in Figure 9.9.2(c). The two-pipe system needs a changeover from chilled to hot water and vice versa. A four-pipe system is more expensive to install.

## Plant-Building Loop

### System Description

The chillers/boilers in a central plant are often located in the basement, machinery room, or on the rooftop of the building. Generally, a fairly constant-volume water flow is required in the evaporator to protect it from freezing at part load. ASHRAE/IES Standard 90.1-1989 specifies that water systems using control valves to modulate the coil load must be designed for variable flow for energy savings.

Current chilled water systems or dual-temperature water systems often adopt a *plant-building loop* that consists of two piping loops as shown in Figure 9.9.3(a) for reliable and energy-efficient operation:

*Plant Loop.* A plant loop ABJK is comprised of chiller(s)/boiler(s); plant chilled/hot water pump(s) usually of split-case, double suction, or end suction type; a diaphragm expansion tank to allow water expansion and contraction during water temperature changes; an air separator to purge dissolved air from water; corresponding piping and fittings; and control systems. The plant loop is operated at constant flow.

*Building Loop.* A building loop BCDEFGHJB contains coils; building circulating water pumps, often variable-speed pumps, one being a standby pump; corresponding pipes and fittings; and control systems. A differential pressure transmitter is often installed at the farthest end from the building pump between the supply and return mains. The building loop is operated at variable flow.

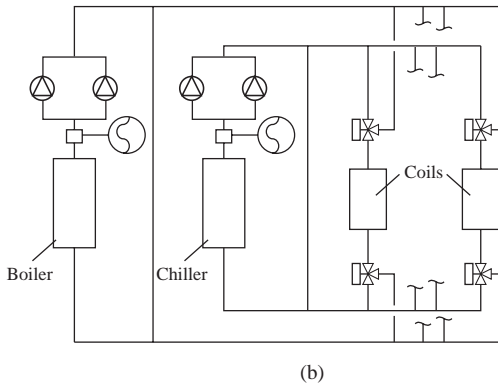

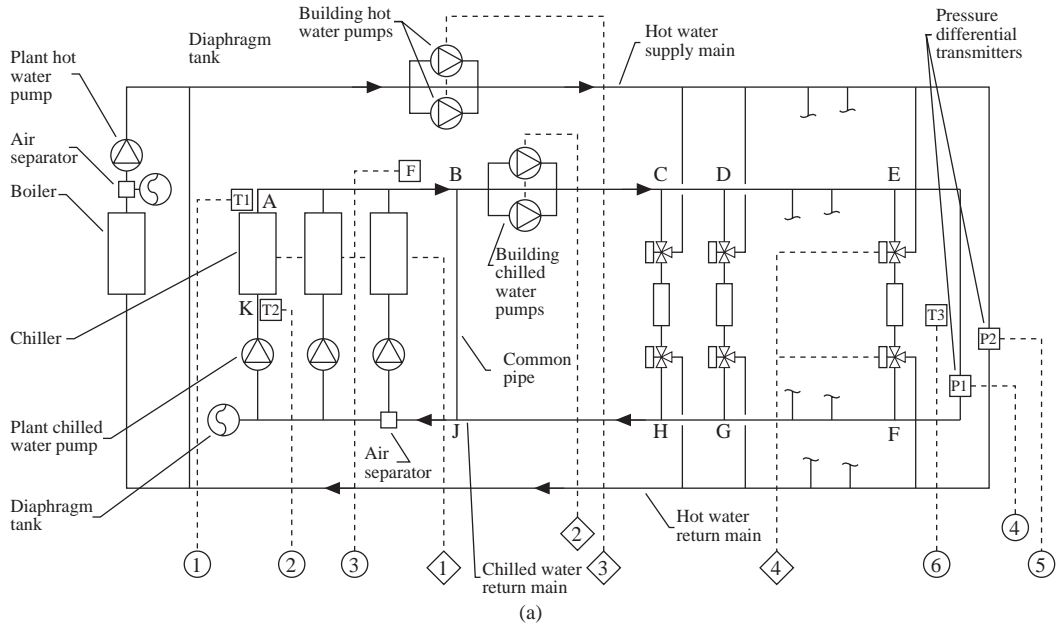

A short common pipe connects these two loops and combines them into a plant-building loop combination. It is also called a *primary-secondary loop*, with the plant loop the primary loop and the building loop the secondary loop. The location of the pump in a water system should be arranged so that the pressure at any point in the system is greater than atmospheric pressure to prevent air leaking into the system.

### Operating Characteristics

In a dual-temperature water system, when the coil load  $q_{cc}$ , in Btu/hr, drops, two-way valves close to a smaller opening. The pressure drop across the coils then increases. As soon as the increase of the pressure differential is sensed by the transmitter, a DDC controller reduces the flow rate of the variable-speed pump to match the reduction of the coil load during part load. The pressure differential transmitter functions similarly to a duct static pressure sensor in a VAV system.

Since the plant loop is at constant flow, excess chilled water bypasses the building loop and flows back to the chiller(s) through the common pipe. When the reduction of coil loads in the building loop is equal to or greater than the refrigeration capacity of a single chiller, the DDC controller will shut down a chiller and its associated chilled water pump. The operating characteristics of the hot water in a dual-temperature water system are similar to those in a chilled water system.

Due to the coil's heat transfer characteristics, the reduction of a certain fraction of the design sensible cooling coil load  $q_{cs,d}$  does not equal the reduction of the same fraction of design water volume flow  $\dot{V}_{w,d}$  (Figure 9.9.3[c]). Roughly, a  $0.7 q_{cs,d}$  needs only a  $0.45 \dot{V}_{w,d}$ , and the temperature difference  $\Delta T_w = (T_{wl} - T_{we})$  will be about 150% of that at the design condition. When an equal-percentage contour two-way control valve is used, the valve stem displacement of the cooling coil's two-way valve is approximately linearly proportional to the sensible cooling coil's load change.

**FIGURE 9.9.3** A dual-temperature water system: (a) plant-building loop, (b) single-loop, (c) design sensible load and design volume flow relationship, and (d) variable-speed building pump curves.

### Comparison of a Single-Loop and a Plant-Building Loop

Compared with a single-loop water system as shown in [Figure 9.9.3\(b\)](#) that has only a single-stage water pump(s), the plant-building loop:

- Provides variable flow at the building loop and thus saves pump power at reduced flow during part load.
- Separates plant and building loops and makes design, operation, maintenance, and control simpler and more stable as stated in Carlson (1968). The pressure drop across the two-way control valve is considerably reduced as the control valve is only a component of the building loop.

### Plant-Distribution-Building Loop

In universities, medical centers, and airports, buildings are often scattered from the central plant. A campus-type chilled water system using a plant-distribution-building loop is often reliable in operation, requires less maintenance, has minimal environmental impact, and sometimes provides energy cost savings.

In a plant-distribution-building loop, plant loop water is combined with many building loops through a distribution loop as shown in [Figure 9.9.4\(a\)](#). The water flow in the plant loop is constant, whereas in both distribution and building loops it is variable. Chilled water often leaves the chiller at a temperature of 40 to 42°F. It is extracted by the distribution pumps and forced into the distribution supply main. At the entrance of each building, chilled water is again extracted by the building pumps and supplied to the cooling coils in AHUs and fan-coil units. From the coils, chilled water is returned through the building return main and the distribution return main and enters the chillers at a temperature around 60°F at design volume flow. System performances of the plant and building loops in a plant-distribution-building loop are similar to those in a plant-building loop.

A campus-type central plant may transport several thousand gallons of chilled water to many buildings, and the farthest building may be several thousand feet away from the central plant. A smaller pressure gradient and end pressure differential between distribution supply and return mains,  $\Delta H_{s,d}$ , save energy. Meanwhile, a larger diameter of pipes is needed. For a distribution loop, a pressure drop of 0.5 to 1 ft head loss per 100 ft of piping length may be used. A low pressure differential may be offset at the control valves without affecting the normal operation of the coils. Usually, direct return is used for distribution loops.

Using a two-way distribution from the central plant with two separate supply and return loops often reduces the main pipe length and diameter.

A differential pressure transmitter may be located at the farthest end of the distribution mains. As the pressure loss in the building loop is taken care of by the variable-speed building pump(s), a set point of 5 ft WG pressure differential across the supply and return mains seems appropriate.

Chilled water and hot water distribution pipes are often mounted in underground accessible tunnels or trenches. They are well insulated except when chilled water return temperature  $T_{ret} > 55^\circ\text{F}$ . Under such circumstances, the return main may not be insulated, depending on local conditions and cost analysis.

Many retrofits of campus-type chilled water systems required an existing refrigeration plant(s) and a new developed plant(s) connected to the same plant-distribution-building loop. A stand-alone DDC panel is often used to optimize the turning on and off of the chillers in the existing and developed plants according to the system loads and available sources (chillers).

**FIGURE 9.9.4** A chilled water system using a plant-distribution-building loop: (a) schematic diagram and (b) pressure gradient for distribution loop.

## 9.10 Heating Systems

### Types of Heating Systems

According to EIA Commercial Buildings Characteristics 1992, for the 57.8 billion ft<sup>2</sup> of heated commercial buildings in the United States in 1992, the following types of heating systems were used:

Warm air heating systems using warm air furnace	27%
Hot water heating systems using boilers	33%
Heat pumps	13%
District heating	8%
Individual space heaters and others heaters	19%

Modera (1989) reported that nearly 50% of U.S. residential houses are using warm air heating systems with direct-fired warm air furnaces.

### Warm Air Furnaces

A *warm air furnace* is a device in which gaseous or liquid fuel is directly fired or electric resistance heaters are used to heat the warm supply air. Natural gas, liquefied petroleum gas (LPG), oil, electric energy, or occasionally wood may be used as the fuel or energy input. Among these, natural gas is most widely used. In a warm air furnace, the warm air flow could be *upflow*, in which the warm air is discharged at the top, as shown in Figure 9.10.1(a) and (b); *downflow*, with the warm air discharged at the bottom; or *horizontal flow*, with the warm air discharged horizontally.

**FIGURE 9.10.1** Upflow warm air gas furnace: (a) a natural-vent gas furnace and (b) a power-vent high-efficiency gas furnace.

**Natural Vent Combustion Systems.** There are two types of combustion systems in a natural gas-fired warm air furnace: natural vent or power vent combustion systems. In a *natural vent* or *atmospheric vent* combustion system, the buoyancy of the combustion products carries the flue gas flowing through the heat exchanger and draft hood, discharging from the chimney or vent pipe. The gas burner is an

*atmospheric burner.* In an atmospheric burner, air is extracted for combustion by the suction effect of the high-velocity discharged gas and the buoyance effect of the combustion air. An atmospheric burner can be either an in-shot or an up-shot burner or multiple ports. Atmospheric burners are simple, require only a minimal draft of air, and need sufficient gas pressure for normal functioning.

Two types of ignition have been used in burners: standing pilot and spark ignition. In *standing pilot ignition*, the small pilot flame is monitored by a sensor and the gas supply is shut off if the flame is extinguished. *Spark ignition* fires intermittently only when ignition is required. It saves gas fuel if the furnace is not operating.

In a natural vent combustion system, the heat exchanger is often made from cold-rolled steel or aluminized steel in the shape of a clamshell or S. A fan or blower is always used to force the recirculating air flowing over the heat exchanger and distribute the heated air to the conditioned space. A low-efficiency disposable air filter is often located upstream of the fan to remove dust from the recirculating air. A draft hood is also installed to connect the flue gas exit at the top of the heat exchanger to a vent pipe or chimney. A relief air opening is employed to guarantee that the pressure at the flue gas exit is atmospheric and operates safely even if the chimney is blocked. The outer casing of the furnace is generally made of heavy-gauge steel with access panels.

*Power Vent Combustion Systems.* In a *power vent* combustion system, either a forced draft fan is used to supply the combustion air or an induced draft fan is used to induce the flue gas to the vent pipe or chimney. A power vent is often used for a large gas furnace or a high-efficiency gas furnace with condensing heat exchangers.

Gas burners in a power vent system are called *power burners*. The gas supply to the power burner is controlled by a pressure regulator and a gas valve to control the firing rate. Intermittent spark ignition and *hot surface ignition* that ignites the main burners directly are often used.

Usually, there are two heat exchangers in a power vent combustion system: a primary heat exchanger and a secondary or condensing heat exchanger. The primary heat exchanger constitutes the heating surface of the combustion chamber. When the water vapor in the flue gas is condensed by indirect contact with the recirculating air, part of the latent heat of condensation released is absorbed by the air. Thus the furnace efficiency is increased in the *secondary or condensing heat exchanger*. Both primary and secondary heat exchangers are made from corrosion-resistant steel. A fan is also used to force the recirculating air to flow over the heat exchangers and to distribute the heated air to the conditioned space.

Most natural gas furnaces can use LPG. LPG needs a pressure of 10 in. WG at the manifold, compared with 3 to 4 in. for natural gas. It also needs more primary air for gas burners. Oil furnaces are usually of forced draft and installed with pressure-atomizing burners. The oil pressure and the orifice size of the injection nozzle control the firing rate.

*Furnace Performance Indices.* The performance of a gas-fired furnace is usually assessed by the following indices:

- Thermal efficiency  $E_t$ , in percent, is the ratio of the energy output of heated air or water to the fuel energy input during specific test periods using the same units:

$$E_t = 100(\text{fuel energy output})/(\text{fuel energy input}) \quad (9.10.1)$$

- Annual fuel utilization efficiency (AFUE), in percent, is the ratio of the annual output energy from heated air or water to the annual input energy using the same units:

$$\text{AFUE} = (100 \text{ annual output energy})/(\text{annual input energy}) \quad (9.10.2)$$

- Steady-state efficiency (SSE) is the efficiency of a given furnace according to an ANSI test procedure, in percent:

$$SSE = 100(\text{fuel input} - \text{fuel loss})/(\text{fuel input}) \quad (9.10.3)$$

Jakob et al. (1986) and Locklin et al. (1987), in a report on ASHRAE Special Project SP43, gave the following performance indices based on a nighttime setback period of 8 hr with a setback temperature of 10°F:

Description	AFUE (%)	SSE (%)
Natural vent		
Pilot ignition	64.5	77
Intermittent ignition	69	77
Intermittent ignition plus vent damper	78	77
Power vent		
Noncondensing	81.5	82.5
Condensing	92.5	93

ASHRAE/IES Standard 90.1-1989 specifies a minimum AFUE of 78% for both gas-fired and oil-fired furnaces of heating capacity <225,000 Btu/hr. For a gas-fired warm air furnace  $\geq 225,000$  Btu/hr at maximum rating capacity (steady state) the minimum  $E_t$  is 80%, and at minimum rating capacity,  $E_t$  is 78%.

*Operation and Control.* Gas is usually brought from the main to the pressure regulator, where its pressure is reduced to 3.5 in. WG. Gas then flows through a valve and mixes with the necessary amount of outside primary air. The mixture mixes again with the ambient secondary air and is burned. The combustion products flow through the heat exchanger(s) due either to natural draft or power vent by a fan. The flue gas is then vented to the outside atmosphere through a vent pipe or chimney.

Recirculating air is pulled from the conditioned space through the return duct and is mixed with the outdoor air. The mixture is forced through the heat exchanger(s) by a fan and is then heated and distributed to the conditioned space. The fan is often started 1 min after the burner is fired in order to prevent a cold air supply.

At part-load operation, the reduction of the heating capacity of the warm air furnace is usually controlled by the gas valve and the ignition device. For small furnaces, the gas valve is often operated at on-off control. For large furnaces, a two-stage gas valve operates the furnace at 100, 50, and 0% heating capacity as required.

*Low NO<sub>x</sub> Emissions.* NO<sub>x</sub> means nitrogen oxides NO and NO<sub>2</sub>. They are combustion products in the flue gas and become air pollutants with other emissions like SO<sub>2</sub> and CO when they are discharged to the atmosphere. NO<sub>x</sub> cause ozone depletion as well as smog.

Southern California regulations required that NO<sub>x</sub> emissions should be 30 ppm or less for gas-fired warm air furnaces and boilers. Many gas burner manufactures use induced flue gas recirculation to cool the burner's flame, a cyclonic-type burner to create a swirling high-velocity flame, and other technologies to reduce NO<sub>x</sub> and other emissions while retaining high furnace and boiler efficiencies.

## Hot Water Boilers

*Types of Hot Water Boilers.* A hot water boiler is an enclosed pressure vessel used as a heat source for space heating in which water is heated to a required temperature and pressure without evaporation. Hot water boilers are fabricated according to American Society of Mechanical Engineers (ASME) codes for boilers and pressure vessels. Boilers are generally rated on the basis of their gross output delivered at the boiler's outlet. Hot water boilers are available in standard sizes from 50 to 50,000 MBtu/hr (1 MBtu/hr = 1000 Btu/hr).

According to EIA Characteristics of Commercial Buildings (1991), the percentages of floor area served by different kinds of fuel used in hot water and steam boilers in 1989 in the United States are gas-fired, 69%; oil-fired, 19%; electric, 7%; others, 5%.

Hot water boilers can be classified as *low-pressure boilers*, whose working pressure does not exceed 160 psig and working temperature is 250°F or less, and *medium-* and *high-pressure boilers*, whose working pressure is above 160 psig and working temperature above 250°F. Most of the hot water boilers are low-pressure boilers except those in campus-type or district water heating systems.

Based on their construction and material, hot water boilers can be classified as fire tube boilers, water tube boilers, cast iron sectional boilers, and electric boilers. Water tube boilers are used mainly to generate steam. Cast iron sectional boilers consist of many vertical inverted U-shaped cast iron hollow sections. They are lower in efficiency and used mainly for residential and small commercial buildings. Electric boilers are limited in applications because of their higher energy cost in many locations in the United States.

*Scotch Marine Boiler.* In a *fire tube* hot water boiler, the combustion chamber and flue gas passages are in tubes. These tubes are enclosed by an outer shell filled with water. A recently developed fire tube model is the modified Scotch Marine packaged boiler, which is a compact, efficient, and popular hot water boiler used today.

A *Scotch Marine* boiler, as shown in [Figure 9.10.2](#), consists of a gas, oil, or gas/oil burner, a mechanical forced-draft fan, a combustion chamber, fire tubes, flue gas vent, outer shell, and corresponding control system. A packaged boiler is a one-piece factory-assembled boiler.

This figure is not available.

**FIGURE 9.10.2** A Scotch Marine packaged boiler.

Gas or oil and air are measured, mixed, and injected into the combustion chamber in which they are initially ignited by an ignition device. The mixture burns and the combustion process is sustained when there is a high enough temperature in the combustion chamber. Because the number of fire tubes decreases continuously in the second, third, and fourth passes due to the volume contraction at lower flue gas temperatures, the gas velocity and heat transfer coefficients are maintained at reasonably high values.

Return water enters the side of the boiler. It sinks to the bottom, rises again after heating, and then discharges at the top outlet.

The dew point of the flue gas is often 130°F. If the temperature of the return water in a *condensing boiler* is below 125°F, it can be used as a condensing cooling medium to condense the water vapor contained in the flue gas. Latent heat of condensation of water vapor can then be recovered. Corrosion in the condensing heat exchanger and the flue gas passage should be avoided.

The *chimney*, or *stack*, is the vertical pipe or structure used to discharge flue gas, which usually has a temperature rise of 300 to 400°F above the ambient temperature. The chimney or stack should be extended to a certain height above adjacent buildings according to local codes.

*Operation and Safety Controls.* During part-load operation, reduction of heating capacity is achieved by sensing the temperature of return water and controlling the firing rate of the gas burners in on-off, high-low-off, or modulating modes.

For gas burners, two pressure sensors are often provided to maintain the gas pressure within a narrow range. For modulating controls, the ratio of maximum to minimum input is called the *turn-down* ratio. The minimum input is usually 5 to 25% of the maximum input, that is, a turn-down ratio of 20:1 to 4:1. The boiler should be shut off if the input is less than the minimum.

Pressure and temperature relief valves should be installed in each boiler. An additional high limit control is often equipped to shut down the boiler in case the sensed water pressure or temperature exceeds the predetermined limits. A flame detector is often used to monitor the flame and an airflow sensor to verify the combustion airflow. As soon as the flame is extinguished or the combustion airflow is not sensed, the fuel valve closes and the boiler is shut down. ASHRAE/IES Standard 90.1-1989 specifies that gas-fired boilers should have a minimum AFUE of 80%.

### Low-Pressure Warm Air Heating Systems

A *low-pressure warm air heating system* is often equipped with an upflow gas-fired furnace having a furnace heat capacity  $Q_f$  to air flow  $\dot{V}_a$  ratio,  $Q_f/\dot{V}_a$ , of 50 to 70 Btu/hr.cfm and a temperature rise immediately after the furnace of 50 to 70°F. The external pressure loss of the supply and return duct system is usually not higher than 0.5 in. WG. The supply temperature differential ( $T_s - T_r$ ) is often 20 to 35°F. The heating system is often integrated with a cooling system, forming a heating/cooling system.

Low-pressure warm air heating systems usually have a heating capacity not exceeding 100,000 Btu/hr. They are often used in residences and sometimes in small commercial buildings.

*System Characteristics.* A low-pressure warm air heating system is equipped with either supply and return ducts or a supply duct and a return plenum. Recirculating air is then returned from living, dining, bed, and study rooms to the return plenum through door undercuts in case the doors are closed.

The location of the furnace has a significant effect on the efficiency of the heating system. According to Locklin et al. (1987), if the gas furnace of a low-pressure warm air heating system is installed in a closet and its supply duct is mounted inside the conditioned space, its system efficiency may be 20% higher than that of installations whose furnace and supply duct are in the attic or basement.

When a low-pressure warm air heating system is operating, the supply duct leakage in the attic or basement raises its pressure to a positive value and promotes exfiltration. Return duct leakage extracts the ambient air, lowers the attic or basement pressure to a negative value, and induces infiltration. Gammage et al. (1986) reported that both types of leakage increase the whole house infiltration to 0.78 ach when the low-pressure warm air heating system is operating. The infiltration rate is only 0.44 ach when the low-pressure warm air heating system is shut off.

If the supply temperature differential  $\Delta T_s = (T_s - T_r)$  exceeds 30°F, or if there is a high ceiling, thermal stratification may form in the conditioned space. Greater supply volume flow rates and suitable locations of the supply and return outlets may reduce thermal stratification and vertical temperature difference.

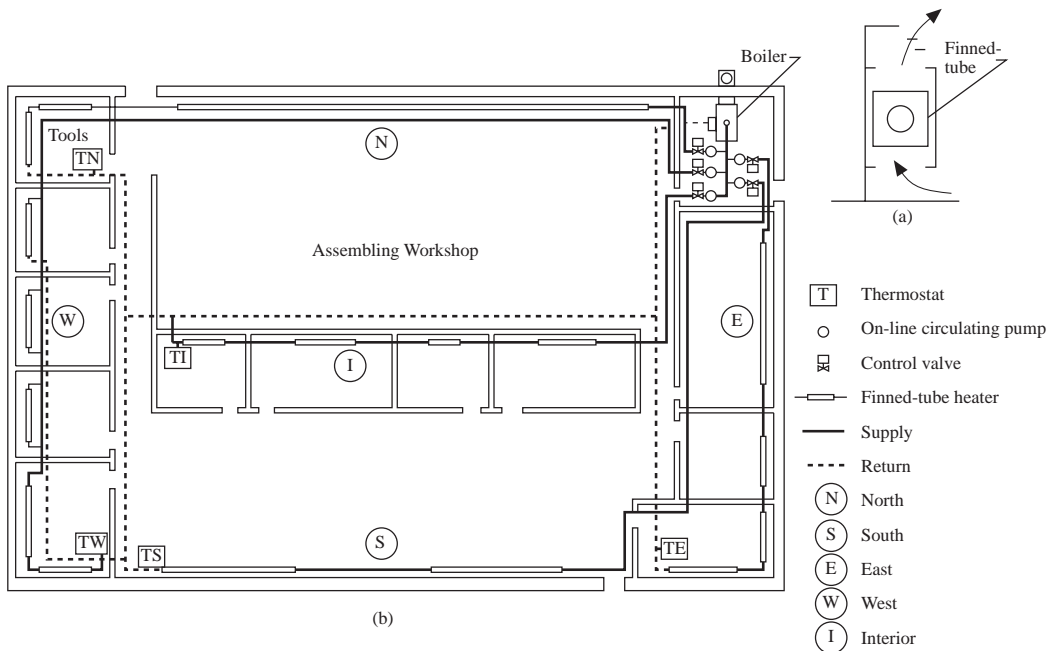

**Part-Load Operation and Control.** For a low-pressure warm air heating system, a space thermostat is often used to control the gas valve of the furnace operated in on-off or high-low-off mode. The proportion of on and off times in an operating cycle can be varied to meet the change of space heating load. The time period of an on-off operating cycle is usually 5 to 15 min.

A warm-air heating system that has an external pressure higher than 0.5 in. WG is often integrated with a cooling system and becomes a part of an air-conditioning system.

**Low-Temperature Hot Water Heating System Using Fin-Tube Heaters**

In a *low-temperature hot water heating system*, the operating temperature is 250°F or less with a maximum working pressure not exceeding 150 psig, usually less than 30 psig. Low-temperature hot water heating systems are widely used for space heating in residences and commercial buildings.

**Fin-Tube Heaters.** A *fin-tube heater* is a device installed directly inside the conditioned space to add heat to the space through radiant and convective heat transfer. A fin-tube heater consists of a finned-tube element and an outer casing as shown in Figure 9.10.3(a). The tubes are often made of copper and steel. Copper tubes are generally 0.75, 1, and 1.25 in. in diameter and steel tubes 1.25 and 2 in. in diameter. The fins are usually made of aluminum for copper tubes and of steel for steel tubes. Fin density may vary from 24 to 60 fins per foot. A fin heater may have a maximum length of 12 ft. The outer casing of a finned-tube heater always has a bottom inlet and top outlet for better convection.

**FIGURE 9.10.3** A two-pipe individual-loop low-temperature hot water heating system: (a) finned-tube heater and (b) piping layout.

The most widely used finned-tube heater is the *baseboard heater*, which is often mounted on cold walls at a level 7 to 10 in. from the floor. It is usually 3 in. deep and has one fin-tube row. A wall finned-tube heater has a greater height. A convector has a cabinet-type enclosure and is often installed under the windowsill.

*Two-Pipe Individual-Loop Systems.* Current low-temperature hot water heating systems using finned-tube heaters are often equipped with zone controls. Zone controls can avoid overheating rooms facing south and underheating rooms facing north because of the effects of solar radiation.

Figure 9.10.3(b) shows the piping layout of a *two-pipe individual-loop system* that is widely used in low-temperature hot water heating systems. Two-pipe means that there are a supply main and a return main pipe instead of one common main for both supply and return. Individual-loop means that there is an individual loop for each control zone. Several finned-tube heaters in a large room can be connected in series, while finned-tube heaters in several small rooms can be connected in reverse return arrangement.

The sizing of low-temperature hot water pipes is usually based on a pressure drop of 1 to 3 ft per 100 ft of pipe length. For a small low-temperature hot water heating system, an open-type expansion tank is often used. A diaphragm tank is often used for a large system. On-line circulating pumps with low head are often used.

*Part Load and Control.* Usually a hot water sensor located at the exit of the hot water boiler is used to control the firing rate of the boiler at part-load operation. Its set point is usually reset according to the outdoor temperature. Zone control is provided by sensing the return hot water temperature from each individual loop or zone and then varying the water volume flow rate supplied to that zone by modulating the speed of each corresponding on-line circulating pump or its control valve. For hot water heating systems using multiple boilers, on and off for each specific boiler depend not only on the heating demand, but also on minimizing the energy cost.

## Infrared Heating

*Infrared heating* is a process that uses radiant heat transfer from a gas-fired or electrically heated high-temperature device to provide space heating on a localized area for the health and comfort of the occupants or to maintain a suitable indoor environment for a manufacturing process.

An *infrared heater* is a device used to provide infrared heating. Heat radiates from an infrared heater in the form of electromagnetic waves and scatters in all directions. Most infrared heaters have reflectors to focus the radiant beam onto a localized area. Therefore, they are often called *beam radiant heaters*. Infrared heaters are widely used in high-ceiling supermarkets, factories, warehouses, gymnasiums, skating rinks, and outdoor loading docks.

*Gas Infrared Heaters.* Infrared heaters can be divided into two categories: gas and electric infrared heaters. *Gas infrared heaters* are again divided into porous matrix gas infrared heaters and indirect gas infrared heaters. In a *porous matrix gas infrared heater*, a gas and air mixture is supplied and distributed evenly through a porous ceramic, a stainless steel panel, or a metallic screen, which is exposed to the ambient air and backed by a reflector. Combustion takes place at the exposed surface with a maximum temperature of about 1600°F. An indirect infrared heater consists of a burner, a radiating tube, and a reflector. Combustion takes place inside the radiating tube at a temperature not exceeding 1200°F.

Gas infrared heaters are usually vented and have a small conversion efficiency. Only 10 to 20% of the input energy of an open combustion gas infrared heater is radiated in the form of infrared radiant energy. Usually 4 cfm of combustion air is required for 1000 Btu/hr gas input. A thermostat often controls a gas valve in on–off mode. For standing pilot ignition, a sensor and a controller are used to cut off the gas supply if the flame is extinguished.

*Electric Infrared Heaters.* An *electric infrared heater* is usually made of nickel–chromium wire or tungsten filaments mounted inside an electrically insulated metal tube or quartz tube with or without inert gas. The heater also contains a reflector that directs the radiant beam to the localized area requiring heating. Nickel–chromium wires often operate at a temperature of 1200 to 1800°F. A thermostat is also used to switch on or cut off the electric current. An electric infrared heater has a far higher conversion efficiency and is cleaner and more easily managed.
