The carbon content selected has a great effect on the mechanical properties of cast plain-carbon steel as does the heat treatment selected (see the article "Steel Castings" in the Section "Carbon and Alloy Steels" in this Handbook). Section size also affects properties, as properties depend on the cooling rate during solidification, and heavy sections solidify more slowly than thin sections.

Carbon steels generally are melted in electric arc furnaces; melting practice is discussed in the article "Melting Methods" in this Section. While melting generally follows the melt practice used in steel mills, tapping temperatures must be higher to assure that the molten metal will fill the mold. Another difference between the melt practice used in steel mills and that used in foundries is that steel poured in the foundry is always fully deoxidized.

Because plain carbon steels solidify with a fairly small mushy region, they are prone to the formation of centerline porosity, and risers used with them pipe deeply. Centerline shrink can be cured by tapering the casting section, with the small end of the taper away from the riser. The size of the riser can be reduced with the use of exothermic riser sleeves that keep the riser liquid while it provides feed metal for the casting. Carbon steels are especially sensitive to reoxidation inclusions formed during pouring and mold filling. These inclusions tend to float to the top of the solidifying casting and are often found during machining operations in a layer just beneath the cope surface of the casting. They can be controlled by the use of filters in the runner system, by counter-gravity casting techniques, or a combination of both.

## Alloy Steels

Steels are alloyed to obtain specific properties, such as corrosion resistance; improved properties at high or low temperatures; or to produce a specific response to heat treatment. Alloyed steels may be either "low-alloy" or "high-alloy," depending on the amounts of alloying elements they contain. While standard designations for wrought and cast grades of alloy steels refer to the same amounts of alloying elements, alloy steels differ from wrought compositions in that they will normally contain 0.30 to 0.65% Si and 0.50 to 1.00% Mn unless otherwise specified. Alloy steels have lower melting points than carbon steels of the same carbon content and solidify in a somewhat more mushy manner; this can be compensated for in riser design. Melting and deoxidation practices for low-alloy steels are the same as those for plain carbon steel. Depending on the alloying element, alloying may be carried out in the original charge (if the element is not oxidized during the refining step), at the end of the melt just before tapping, or in the ladle. Low-alloy steels are generally melted in arc furnaces, but high-alloy steels may be melted in induction furnaces. Vacuum melting is rarely used for alloy steels, but these steels may be vacuum degassed.

An important consideration in low-alloy steels is the control of the response of the microstructure to cooling rate during solidification and heat treatment. Since the surface of the casting cools much faster than the interior, it may have a different microstructure than the interior, a situation that may decrease casting properties. The principal method of hardening carbon and low-alloy steels is to quench the steel from the austenitizing temperature and then temper the steel to produce the desired microstructure. However, steels vary in their response to quench rate, depending on their composition. Figure 18 schematically shows the cooling curves for the center and surface of a steel section superimposed on the continuous cooling transformation diagram. The curve labeled "50% martensite" intersects the pearlite area briefly, showing that half the mass is transformed to pearlite, and the remainder is transformed to martensite. By adding the proper alloying elements, the entire casting can be made to transform to pearlite, avoiding formation to martensite.

**Fig. 18** Difference in cooling rates at the surface and center of a steel casting and the resulting microstructures obtained

Low-alloy steels contain up to 8% alloying elements. They generally fall into the following families:

- *Carbon-manganese steels*, containing 0.20 to 0.50% carbon and 1.00 to 1.90% manganese. These steels have excellent properties that are obtained with a simple normalizing heat treatment.
- *Manganese-molybdenum steels*, which have higher hardenability than carbon steels and better properties at elevated temperatures. These steels contain 0.20 to 0.50% C and are available in two grades, one containing 1.0 to 1.30% Mn and 0.10 to 0.30% Mo, and another containing 1.35 to 1.75% Mn and 0.25 to 0.55% Mo.
- *Manganese-nickel-chromium-molybdenum steels* that are used because their high hardenability makes it possible to produce castings having sections up to 125 mm (5 in.) thick with a fully tempered martensitic structure.
- *Nickel steels*, which contain up to 4% Ni and have high mechanical properties.
- *Nickel-chromium-molybdenum steels*, which are used when high hardenability and elevated temperature properties are desired.

As the composition of the steel varies, its response to cooling rate also varies, which, as noted, is a primary reason for alloying. This response to the effect of cooling rate also influences the weldability of alloy steels. As the alloying content increases, it is necessary to slow the cooling rate to avoid formation of martensite. This is done by preheating and sometimes postheating the weld zone.

High-alloy steels include stainless steels used for corrosion and heat resistance and high-manganese (austenitic) steels used for wear resistance. Foundry practice for stainless steels is similar to that for carbon and low-alloys steels. Compositions and properties of cast stainless steels can be found in the Section "Stainless Steels" in this Handbook.

High manganese steels are most commonly produced in electric arc furnaces using a basic melting practice. They are also induction melted. Typical charge materials include carbon and manganese steel scrap, high-carbon ferromanganese, ferrosilicon, and silicon-manganese. Alloying elements such as chromium, molybdenum, and vanadium are usually added as ferroalloys, while elements such as nickel are used in a nearly pure metallic state. Deoxidation of the steel is accomplished with aluminum prior to pouring. In the case of most castings, the pouring temperature is regulated to less than 1470 °C (2680 °F) to prevent an excessively coarse grain size and minimize chemical segregation and other related casting defects. In casting high manganese steels, care must be taken in selecting mold and core coatings, as these steels react with silica sands and other refractories to produce MnO, a highly fluid liquid oxide which causes severe metal penetration. As a result, sand castings are produced with olivine rather than silica sand to prevent mold-metal reaction. Compositions and properties of high manganese steel castings can be found in the article "Wear-Resistant Austenitic Manganese Steels" contained in the Section "Carbon and Alloys Steels" in this Handbook.

## ***Aluminum Alloys***

ALUMINUM CASTINGS are primarily used because of their light weight and corrosion resistance. There are a wide variety of aluminum alloys, developed for both properties and the casting method employed. Foundry alloys may be divided into two groups: those most suitable for gravity casting by any process and those used in pressure die casting. A finer distinction is made between alloys suitable for permanent mold application and those for other gravity processes. In general, the most alloy-versatile processes (that is, those in which the largest number of alloys can be used) are those in which the mold collapse accompanies pouring and solidification. The least forgiving processes, which require special consideration in alloy selection, are more rigid or permanent mold processes. The least alloy-versatile casting process based on process requirements is pressure die casting, in which more than the usual measures of castability apply. The process demands a high level of fluidity, hot strength, hot tear resistance, and die soldering resistance. Chemical compositions of aluminum casting alloys are given in the Section "Aluminum and Aluminum Alloys" in this Handbook (see Table 2 in the article "Chemical Compositions and International Designations"). Aluminum alloys are cast in all casting processes, including green sand, dry sand, composite mold, plaster mold, investment casting, permanent mold, counter-gravity low-pressure casting, and pressure die casting.

## **Melting and Metal Treatment**

Aluminum and aluminum alloys can be melted in a variety of ways. In routine use are coreless and channel induction furnaces, crucible and open-hearth reverberatory furnaces (fired by natural gas or fuel oil), and electric resistance and

electric radiation furnaces. The nature of the furnace charge may range from prealloyed ingot of high quality to charges made up exclusively from low-grade scrap. However, even under optimum melting pouring conditions, molten aluminum is susceptible to three types of degradation:

- With time at temperature, adsorption of hydrogen results in increased dissolved hydrogen in the melt.
- With time at temperature, oxidation of the melt occurs.
- Loss of alloying elements

**Dissolved Hydrogen.** Hydrogen is easily adsorbed by molten aluminum. Unfortunately, the solubility of hydrogen in molten aluminum alloys is substantially greater than in solid aluminum (Fig. 1). When the aluminum alloy solidifies, hydrogen is driven out of solution, exaggerating and enlarging shrinkage porosity, with accompanying loss in mechanical properties (Fig. 2). Sources of hydrogen may include wet charges and damp melting tools, but the primary source of hydrogen is ambient humidity. Because little can be done to prevent hydrogen pickup during melting, hydrogen must be removed from the melt before pouring. The most common method used is bubbling dry nitrogen or argon through the melt. Rotary degassing units, as described and illustrated in the article "Melting Methods" in this Section (see Fig. 17 of that article), are particularly effective. These units may be inserted into melting crucibles for use. The use of chlorine gas is especially effective in removing hydrogen; however, environmental and safety considerations generally preclude its use in production.

Fig. 1 Solubility of hydrogen in aluminum at 1 atm hydrogen pressure

**Fig. 2 Ultimate tensile strength versus hydrogen porosity for sand cast bars of three aluminum alloys**

Measurement of the amount of hydrogen dissolved in the melt has historically been done using a reduced pressure test in which a sample of molten aluminum is poured into a small steel cup and allowed to solidify in a vacuum chamber. Solidification is observed; the degree of evolution of bubbles during solidification indicates the amount of hydrogen present. Subsequent sectioning of the solidified sample and inspection of the size of the pores formed is also used. Unfortunately, these methods are inaccurate and are heavily influenced by the presence in the melt of oxide particles that act as nuclei for the hydrogen bubbles. The preferred way to test for dissolved hydrogen is to use instruments specifically designed to show hydrogen by liquid extraction techniques.

**Oxidation of the Melt.** Aluminum forms a very stable oxide that forms instantaneously on the surface of the melt. The rate of oxidation increases with temperature and the presence of certain alloying elements, such as magnesium and beryllium. While the oxide film that forms on the surface of an aluminum melt is self-limiting if the surface of the melt is not disturbed, any turbulence will mix the oxide film into the bulk of the melt and create a fresh surface for the formation of more oxide. The oxide films and oxide inclusions that result are especially detrimental to the performance of aluminum castings. Turbulence may be induced during alloying operations, molten metal transfer, or pouring and mold filling.

Oxide particles in the melt serve as nuclei for the formation of shrinkage and gas porosity. In the absence of oxide inclusions, porosity and microporosity are substantially reduced. This is an especially important consideration in aluminum casting alloys, as they often have very large liquidus-to-solidus spreads and freeze in a mushy manner making feeding very difficult.

Oxide films in the casting form planes of weakness that nucleate failure under load. Much of the scatter in mechanical properties of cast aluminum alloys results directly from the presence of these films. When they are absent, the scatter is reduced, and the reproducibility of casting properties surpasses that of forgings. The films are not normally visible during radiographic inspection and must be prevented rather than found and repaired.

Oxides are controlled by using covering fluxes during melting. These fluxes are usually magnesium chloride salts, and they float on the melt surface. They must be removed from the surface of the melt periodically. Suspended oxide inclusions are removed from large melters by passing the melt through a filter bed. In smaller operations, the oxides are removed by placing filters in the gating system.

Prevention of the formation of oxide films in the casting requires that the metal enter the mold cavity in a non-turbulent manner. As this is not possible using gravity pouring methods for most castings, because the head height of sprues accelerates the metal to speeds where turbulent flow takes place, counter-gravity or liquid-level mold filling techniques must be used. While filters slow the velocity of the metal, they rarely slow it enough to prevent oxidation. Mold cavities must be filled from the bottom, and the sequence in which different levels in the casting fill must be carefully planned to avoid "waterfalling," the dropping of liquid metal from a higher to a lower level in the mold, and the resulting oxidation of newly created metal surface. By filling the mold from the bottom, the oxide layer on the top of the liquid metal will rise to the top of the cope surface and flow into top risers where it will not harm the casting.

**Loss of Alloying Elements.** Many aluminum casting alloys contain elements such as magnesium that react with oxygen over time. If molten metal is held too long, these elements will be lost, and the chemical composition of the resulting casting will not be within specification. Other alloying elements, such as zinc, may have low vapor pressures and evaporate from the surface of the bath.

## Structure Control

Aluminum alloy melts are commonly treated to produce the desired metallurgical microstructure during solidification. Both nucleation of the primary dendrites and the form of the eutectic are controlled.

**Dendrite Arm Spacing.** In all commercial processes, solidification takes place through the formation of dendrites in the liquid solution (see the article "Solidification of Metals and Alloys" in this Section). The cells contained within the dendrite structure correspond to the dimensions separating the arms of primary dendrites and are controlled for a given composition exclusively by solidification rate. Dendrite cell sizes on the order of 25  $\mu\text{m}$  produce optimum mechanical properties in aluminum castings.

**Grain Structure.** A fine, equiaxed structure is normally preferred in aluminum alloys, as such a structure improves feeding, the response to heat treatment, and mechanical properties. Grain refinement is accomplished through the addition of small amounts of master alloys (grain refiners) of titanium (containing 3 to 10% Ti) or titanium and boron (containing 0.2 to 1% boron and titanium-to-boron ratios of from 5 to 50). The effect is dramatic, as shown in Fig. 3. Care must be taken in using these grain refiners to avoid excessive superheating of the melt. In addition, because titanium oxidizes easily, the metal must be poured soon after grain refinement treatment, or the titanium will no longer be available to act as a grain refiner.

**Fig. 3** As-cast Al-7Si ingots showing the effects of grain refinement. (a) No grain refiner. (b) Grain refined. Both etched using Poulton's etch; both 2×

**Refinement of Hypoeutectic Alloys.** Many sand and permanent mold aluminum-silicon alloys are hypoeutectic and benefit from refinement or "modification" of the silicon eutectic phase. This is done by adding small amounts of sodium, strontium, calcium, or antimony to the melt prior to pouring. These elements reduce the size of the eutectic silicon plates that form, decrease their interlamellar spacing, and change their morphology (Fig. 4). This change in silicon morphology improves casting properties. Silicon, strontium, and calcium are compatible, meaning that they can be mixed, an important consideration when charges may be made up from purchased scrap. Antimony, however, is not compatible with the other modifiers, and must be kept out of melts containing them.

**Fig. 4** Varying degrees of aluminum-silicon eutectic modification ranging from unmodified (A) to well modified

(F)

The use of strontium and sodium is usually accompanied by an increase in hydrogen content of the melt. Inert gas degassing treatments must be used in this case. Because the silicon eutectic can also be modified by rapid cooling rates, foundries that pour thin-section castings (that solidify rapidly) often do not add modifiers to their melts. When using modifiers, the phosphorus content of the melt must be kept below 5 ppm in hypoeutectic alloys.

**Refinement of Hypereutectic Alloys.** In hypereutectic aluminum-silicon alloys, phosphorous, in the form of phosphor-copper or phosphorous pentachloride, changes the distribution and morphology of the silicon phase (Fig. 5). In refining hypereutectic melts, the bath temperature should be kept to a minimum, and impurities that react with phosphorous should be removed prior to modification treatment. Phosphorus refinement substantially improves mechanical properties and castability of hypereutectic alloys.

**Fig. 5** Effect of phosphorus refinement on the microstructure of Al-22Si-1Ni-1Cu alloy. (a) Unrefined. (b) Phosphorus-refined. (c) Refined and fluxed. All 100×

## Sand Casting and Permanent Mold Alloys

**Alloy Compositions.** Although a great many aluminum casting alloys have been developed, only a few are used widely. These are the hypoeutectic aluminum-silicon alloys containing small amounts of magnesium and/or copper. Table 1 lists compositions of common aluminum-silicon alloys. Copper is also used in some alloys as the major alloying constituent. The most popular alloy, A356.0, used for most automotive and general purpose castings, contains 6.5 to 7.5% Si and 0.25 to 0.45% Mg. A variation of this alloy, used for aircraft castings, increases the magnesium content to 0.55 to 0.60% while reducing the level of residual elements allowed in the alloy.

**Table 1 Compositions of common aluminum-silicon alloys**

Alloy	Product <sup>(a)</sup>	Nominal composition <sup>(b)</sup> , %				
		Cu	Mg	Mn	Si	Others
<b>355.0</b>	S, P	1.2	0.50	0.50 max	5.0	0.15Ti
<b>A356.0</b>	S, P	...	0.35	0.35 max	7.0	...
<b>A357.0</b>	S, P	...	0.60	0.03 max	7.0	0.15Ti, 0.04Be

<b>380.0</b>	D	3.5	...	0.50 max	8.5	...
<b>390.0</b>	D	4.5	0.60	0.10 max	17.0	...
<b>413.0</b>	D	...	...	0.35 max	12.0	...
<b>B443.0</b>	S, P	...	...	0.50 max	5.2	...

(a) S, sand casting; P, permanent mold casting; D, die casting.

(b) All compositions contain balance of aluminum.

**Eliminating Microporosity.** A major problem in the manufacture of aluminum alloy castings is elimination of microporosity. These alloys have large mushy zones (liquidus-to-solidus spreads) and, because of the high heat of fusion of aluminum, tend to solidify more slowly than iron castings. Delivery of feed metal to areas where shrinkage is occurring in the casting is difficult, as the feed metal must wind its way through the growing dendrites. When the mesh of dendrites becomes coherent, which occurs when the casting is less than 50% solid, movement of liquid metal through the dendrite mesh becomes extremely difficult and microporosity results. Pore size is increased by the presence of hydrogen gas coming out of solution, which is why it is important to thoroughly degas the metal before pouring. However, as the shrinkage pores nucleate heterogeneously on inclusions, the number of pores can be significantly reduced by eliminating the presence of oxide inclusions and oxide films in the casting. This is accomplished by avoiding the introduction of oxygen during melting, carefully removing the oxide skin that forms spontaneously on the surface of the melt, using ceramic filters in the mold, and filling the mold using counter-gravity techniques.

The most effective way to eliminate porosity in aluminum alloy castings is to decrease the length of the mushy zone through which the feed metal must travel during solidification. This is done by establishing very high thermal gradients in the casting by arranging metal chills and risers in the mold strategically and insulating the risers. Castings made using this practice are often referred to as "premium quality castings." Alloys commonly considered premium by definition and specifications are 201.0, C355.0, A206.0, A356.0, 224.0, A357.0, 249.0, 358.0, and 354.0. Unfortunately, the high heat of fusion of these alloys limits the section size over which it is possible to establish effective thermal gradients. For this reason, few aluminum castings are made in sections heavier than 25 mm (1 in.). Complete elimination of microporosity in aluminum castings is generally not possible, unless the castings are hot isostatically pressed after casting. It should be

pointed out that the techniques used to control microporosity generally reduce it to a level where it has little effect on static and dynamic properties.

**Melt Practice.** Degassing, addition of grain refiner and addition of the eutectic modifier are carried out during melting. Avoiding oxide formation is a major concern in melting and pouring. Molten metal transfer from melting furnace to pouring ladle must be done with minimum turbulence. When gravity pouring is used to fill the mold, it is essential to position the pouring ladle as close to the pour cup as possible, in no case more than 25 mm (1 inch) above the cup. Turbulence must be avoided in the flowing stream. As in the casting of ferrous metals, venting the mold is important to assure that the mold fills evenly.

**Permanent molding** is often used to make aluminum alloy castings. In this case the thermal gradients may be established by using the metal mold as the chill and placing resin-bonded sand inserts in the mold to slow solidification in that area. Permanent molding is widely used in the automobile industry.

**Heat Treatment.** Aluminum casting alloys develop their properties as a result of heat treatment. The heat treatments used are generally solution heat treatment, quenching, and aging. The aging treatment employed can be varied to control specific properties to a desired specification. In solution heat treatment, the casting is heated into the single-phase zone on the phase diagram but generally not above the eutectic temperature (Fig. 6). To obtain the maximum advantage from solutionizing treatments, there must be as little segregation in the cast structure as possible, as heavily segregated castings contain pockets of segregated alloying elements that melt at temperatures below the solutionizing temperature. These areas melt during heat treatment but do not re-solidify with the proper structure, thereby substantially decreasing casting properties. Segregation is avoided by using rapid solidification rates and restricting the amount of low-melting point elements in the alloy composition. As most permanent mold and sand castings are solidified at as high a rate as can be obtained to minimize the formation of microporosity, segregation is rarely a problem.

**Fig. 6** Portion of aluminum-copper binary phase diagram. Temperature ranges for annealing, precipitation heat treating, and solution heat treating are indicated.

Castings are held at the solutionizing temperature long enough to dissolve the alloying elements into the matrix. The amount of time required varies with the alloy, section size, and solutionizing temperature; higher temperatures require less time. The time also varies with section thickness; thicker sections take longer to reach the solutionizing temperature. No special atmosphere controls are needed for aluminum heat treatment. However, control of the furnace temperature in all parts of the furnace is essential to avoid overheating and the possibility of melting interdendritic regions where some microsegregation exists.

After solution heat treatment, the castings are quenched to retain the alloying element in supersaturated solution. The quenchant used is normally water held near its boiling point. Although better properties are obtained when castings are

quenched into room temperature or refrigerated water, quenching often distorts castings, and the degree of distortion increases as the quenchant temperature decreases. Distortion occurs because different parts of the casting cool at different rates, depending on their surface area-to-volume ratio (as in solidification) and, more importantly, on whether or not bubbles of steam form on the surface in the quenching medium, thereby insulating that section of the casting and slowing its cooling rate. Distortion results from the stresses set up as the casting contracts during cooling and when sections of the casting cool at rates different from that of neighboring sections, thus contracting at different rates. The key to minimizing quench distortion is to obtain uniform cooling over all parts of the casting. One quenching method that does this is quenching into a fluidized bed of small refractory particles.

After the castings are quenched, they are heated to an intermediate temperature to precipitate the supersaturated phases that strengthen the casting and give it its properties. The properties developed depend on the alloy, the temperature selected, and the time the casting is held at the aging temperature. Castings are air cooled after aging. Aluminum castings may be annealed to remove residual stresses; however, annealing destroys the effects of the aging treatment.

## Die Casting Alloys

**Alloy Compositions.** Alloys used in sand casting are rarely used in pressure die casting. This is because the steel die material is soluble in molten aluminum. Therefore, iron is added to die casting alloys in amounts above 0.7%, which stops dissolution of the die in the alloy. Low-iron alloys solder to the die, and the castings cannot be removed from the die easily. (The problem is avoided in permanent mold castings by applying a refractory coating to the surface of the mold.) The most commonly used die casting alloys contain 7.5 to 9.5% Si, 1.3 to 2% Fe, 3 to 4% Cu, and 0.5% Mn. Of these, Alloy 380 listed in Table 1 and its variations predominate. Magnesium is not added to die casting alloys because it oxidizes during the shot and forms inclusions in the casting.

The addition of iron, unfortunately, lowers casting ductility. In addition, iron reacts with other alloying elements to form insoluble intermetallic compounds in the melt. These intermetallics have the beneficial effect of increasing alloy strength, particularly at higher temperatures. However, these insoluble compounds can build up in melting and holding furnaces and transfer launders, creating a sludge that, if inadvertently included in the metal used for a casting, produces hard and brittle inclusions in the casting. Die casters are familiar with composition limits that prevent sludge formation. A common rule is that iron content plus two times manganese content plus three times chromium content should not exceed the sum of 1.7%. This limit is arbitrary and inexact; it is often assigned values from 1.5 through 1.9%, and it is subject to the specific composition and actual minimum process temperature.

**Melt practice** for die casting alloys differs from that for sand and permanent mold alloys, primarily because the high velocities under which the metal enters the die in this casting process often trap air in the casting. Because of this, properties of die castings are not expected to be as high as those of sand and permanent mold castings. Therefore degassing, grain refinement, and eutectic modification are traditionally not done in preparing die casting melts. However, the development of vertical squeeze casting and slow-fill techniques that eliminate the entrapment of air into the casting are now permitting die casters to make use of melt preparation methods that eliminate gas and inclusions and lead to much higher properties in die castings than those obtainable before. The vertical squeeze casting process is described and illustrated in the article "Molding Methods" in this Section (Fig. 22).

**Heat Treatment.** Because of the entrapped air in conventional die castings, these alloys are not heat treated (the air expands during heating, forming blisters on the surface of the casting). However, as castings made by the vertical squeeze casting method are generally free of entrapped air, they may be heat treated to develop a variety of useful properties.

## Copper Alloys

COPPER is alloyed with other elements because pure copper is extremely difficult to cast and prone to surface cracking, porosity problems, and the formation of internal cavities. The casting characteristics of copper can be improved by the addition of small amounts of elements including beryllium, silicon, nickel, tin, zinc, chromium, and silver. When casting copper alloys, the lowest possible pouring temperature needed to suit the size and form of the solid metal should be adopted to encourage as small a grain size as possible as well as to create a minimum of turbulence of the metal during pouring. Recommended pouring temperatures for copper foundry alloys are listed in Table 2.

Table 2 Pouring temperatures of copper alloys

Alloy type	UNS No.	Light castings		Heavy castings

## Types of Copper Alloys

Copper alloys (brass and bronze) for the foundry industry are grouped into three classifications, depending on the spread between their liquidus and solidus temperatures (i.e., their freezing range or the size of the mushy zone during solidification). As the mushy zone increases, so does the difficulty of making sound castings. Table 2 categorizes the three groups of copper casting alloys. Compositions and properties of these alloys can be found in the Section "Copper and Copper Alloys" in this Handbook.

**Group I alloys** have a narrow freezing range, that is, a range of 50 °C (90 °F) between the liquidus and solidus.

**Group II alloys** are those that have an intermediate freezing range, that is, a freezing range of 50 to 110 °C (90 to 200 °F) between the liquidus and the solidus.

**Group III alloys** have a wide freezing range of well over 110 °C (200 °F), even up to 170 °C (300 °F).

## Melting and Casting Practice

Copper-base alloys are melted in oil- and gas-fired crucible and open flame furnaces as well as electric induction furnaces. Both core type and coreless induction melters are widely used. Copper alloys are poured into many types of molds such as green sand, shell, investment, plaster, permanent mold (mold washes are employed), resin-bonded sand, centrifugal, and die. Melting and casting practice varies depending on the alloy group.

**In the Group I alloys**, pure copper and chromium copper are particularly prone to picking up hydrogen gas during melting and are normally melted under a flux to avoid oxidation and gas pickup. Alloys containing substantial amounts of zinc are subject to "flaring," the volatilizing of zinc from the melt. The zinc vapor instantly reacts with oxygen in the atmosphere, forming zinc oxide, a white powder that is easily visible to the melter. Aluminum additions help control flaring. These alloys do not require fluxing, and zinc additions are often added just before pouring to compensate for losses due to flaring. Aluminum bronzes and nickel bronzes dissolve gas easily and therefore must be melted under a flux in an oxidizing atmosphere (i.e., if a fuel-fired furnace is used for melting, the flame must be controlled so that the furnace atmosphere is oxidizing, not reducing). No fluxes are needed for white brasses.

**In the Group II alloys**, beryllium coppers require no fluxes. However, beryllium is toxic, so care must be exercised to capture all fumes from the furnace. Silicon brasses and bronzes do not normally require a flux and do not pick up gas unless superheated to excessively high temperatures. Copper-nickel alloys are susceptible to hydrogen pickup and therefore are melted as quickly as possible, deoxidized, and poured; fluxing is not necessary if the charge is cleaned before melting.

**Group III alloys** should be deoxidized before pouring. Because of the large mushy zone (large freezing range), it has been found that chilling or the establishment of a steep thermal gradient in the mold is necessary to produce sound castings. With these alloys, cover fluxes are seldom used.

Leaded red and yellow brasses were used widely for plumbing components. Lead is added to these alloys to assure pressure tightness. However, concern over the toxicity of lead has resulted in regulations which forbid its presence in municipal water supplies. In addition, disposal of sand from foundries pouring lead-containing alloys is strictly regulated (lead vaporizes during pouring and condenses on the sand grains). For this reason a new series of plumbing alloys known as SeBilloys have been developed. These alloys contain selenium in the range of 0.25 to 1.2% and bismuth in the range of 0.5 to 2.5% in place of lead. These alloys have both casting and mechanical properties similar to the alloys they replace.

## Zinc Alloys

DIE CASTING is the process most often used for shaping zinc alloys although gravity casting (sand and permanent mold) is also employed. Some zinc castings have also been produced by the semisolid casting process.

## Types of Zinc Alloys

Zinc foundry alloys are classified as either hypoeutectic or hypereutectic. The hypoeutectic alloys contain less aluminum (close to 4% Al) and 0.25 to 1.25% Cu. These alloys are die cast. Included in this group are Alloy No. 3, Alloy No. 5, and Alloy No. 7. The hypereutectic alloys have higher aluminum contents (5.0% up to 28% Al), copper contents up to 2%, and can be die cast, sand cast, or cast in permanent molds. Included in this group are ZA-8, ZA-12, and ZA-27. Compositions and properties of these alloys are given in the article "Zinc and Zinc Alloys" in this Handbook.

## Melting and Casting Practice

**Melting.** Most melting is carried out using cast iron crucibles in fuel-fired furnaces. Gas-fired immersion tube furnaces (in which the gases burn in metal tubes that are inserted in the bath) are also popular. Fluxing is not needed when clean ingot is used but may be required when foundry returns are used. Because zinc oxidizes easily, any activity that mixes oxygen into the melt, such as excessive stirring or turbulent metal transfer, should be avoided. Excessive melting and holding temperatures will oxidize the melt and lead to zinc flaring and will require adjustment of melt chemistry before pouring. Lead, cadmium, and tin levels must be held below 0.004% (or less in some alloys) to prevent die cast parts from swelling or cracking in service.

**Die Casting.** Zinc alloys are most commonly die cast using hot chamber machines, although cold chamber machines are used for casting some hypereutectic alloys (ZA-12 and ZA-27). These die casting machines are easily automated and have high production rates. Because zinc has a low melting temperature, hot-work tools steels are not necessary for die materials though recommended for high volume parts. The optimum die temperature for zinc die castings is generally between 160 and 245 °C (325 to 475 °F), although higher temperatures are recommended when a hardware finish is specified for the part. Die temperature should be controlled to within 5 °C (9 °F).

**Sand Casting.** The ZA alloys, especially ZA-12 and ZA-27, are being used increasingly in gravity sand casting operations. The wide freezing range of the ZA-27 alloy (~109 °C, or 200 °F) means that control of solidification is especially important for this alloy. The use of chills or patterns that promote directional solidification is recommended.

**Permanent mold casting** is done using both metallic and machined graphite molds. Cast iron or steel is commonly used for metallic permanent molds. The use of graphite molds permits as-cast tolerances similar to those obtained in die casting.

## Magnesium Alloys

---

MAGNESIUM ALLOY CASTINGS can be produced by nearly all of the conventional casting methods, namely, sand, permanent and semipermanent mold, shell, investment, and die casting. The choice of a casting process for a particular part depends on factors such as configuration of the proposed design, the application, properties required, and the total number of castings required. However, because magnesium reacts violently with moisture and with the oxygen in the air, a number of precautions must be taken when melting, pouring, and heat treating magnesium alloy castings.

## Types of Foundry Alloys

Foundry alloys vary with the type of molding method used. Three systems of magnesium alloys are used for high-pressure die casting: magnesium-aluminum-zinc-manganese (AZ), magnesium-aluminum-manganese (AM), and magnesium-aluminum-silicon-manganese (AS). Systems used for sand and permanent mold castings include: magnesium-aluminum-manganese with and without zinc (AM and AZ), magnesium-zirconium (K), magnesium-zinc-zirconium with and without rare earths (ZK, ZE, and EZ), magnesium-thorium-zirconium with and without zinc (HK, HZ, and ZH), magnesium-silver-zirconium with rare earths or thorium (QE and QH), magnesium-yttrium-rare earth-zirconium (WE), and magnesium-zinc-copper-manganese (ZC). Compositions and properties of these alloys are listed in the Section "Magnesium and Magnesium Alloys" in this Handbook.

The AZ family of alloys is grain refined by the addition of pellets of hexachlorethane to the melt before pouring. The zirconium content of Mg-Zr alloys acts as its own grain refiner.

## Melting and Casting Practice

**Melting.** Magnesium is usually melted in a steel crucible in a fuel-fired or electric resistance furnace. Because molten magnesium burns in air, it is essential to exclude air and oxygen from the surface of the melt. If a flux is used, a small quantity of flux (about 1.5% of the total charge weight) is placed in the crucible before it is charged, and the crucible is preheated to a dull red heat. The charge, which must be thoroughly cleaned to prevent sand or oxide phases from entering the melt (where they would react with the metal) and preheated to drive off all moisture, is then progressively fed into the crucible. The object is to maintain a steadily advancing level of liquid alloy in the crucible, with no splashing as charge ingots are added. More flux is sprinkled on the surface of the melt during this process, whenever bare metal is seen by the melter. The fluxes are proprietary mixes developed for use with specific alloys. The flux must be removed from the melt surface prior to pouring, and a sulfur/boric acid powder is sprinkled on the surface of the stream during pouring to prevent formation of magnesium oxide, which, if uncontrolled, will result in a magnesium fire.

In the fluxless technique, widely used in die casting, an air/sulfur hexafluoride or air/carbon dioxide/sulfur hexafluoride ( $\leq 2\% \text{ SF}_6$ ) is fed to the surface of the melt and protects the molten surface during pouring. In sand casting practice, the amount of  $\text{SF}_6$  is generally increased, and the carrier gas may be entirely carbon dioxide.

**Sand Casting.** Successful production of sand castings became possible only when the means for preventing metal/mold reactions were developed. This was achieved by the additions of suitable inhibitors to the sand mix used in the manufacture of the mold and the cores. These inhibitors include boric acid, sulfur, potassium fluoborate, and ammonium fluosilicate, and they are added in an amount equal to that of the moisture content of the sand. Diethylene glycol is often added to the sand mix to decrease the amount of moisture needed in the sand mix. Because large quantities of gas are generated during pouring, the sand must have high permeability, which implies the use of a fairly coarse sand grain size and extensive venting of the casting and the gating systems. Inhibitors must be added to core mixes to prevent reaction with the cores. The amount of inhibitor to add to the sand mix increases as the size of the casting increases and its cooling rate decreases, because inhibitors often volatilize during cooling of the casting. It is absolutely essential to add sufficient inhibitor to sand molds and cores to prevent mold explosions that can occur at any time until the casting is solid if the inhibitor content is too low.

**Die casting** is a particularly attractive process for magnesium. Because it has a lower heat of fusion than aluminum, casting cycles can be up to four times faster, and die wear is significantly reduced. Molten metal systems can be isolated from the atmosphere in fluxless melting. Because molten magnesium does not attack iron and steel, hot chamber machines may be used. Dies are operated in the temperature range of  $260^\circ\text{C} \pm 14^\circ\text{C}$  ( $500^\circ\text{F} \pm 25^\circ\text{F}$ ).

**Gating and Riser Practice.** An unpressurized gating system is used, and it is important that the metal enter the casting cavity from the bottom and fill the cavity progressively. Waterfalling (the dropping of metal from one level in the mold to a lower level during mold filling) must be avoided. Turbulence must also be minimized during pouring. Screens and filters are usually placed in the gating system to trap inclusions. Risers are often insulated to increase their feeding efficiency.

**Castings are finished** using standard techniques. Refractory media, not steel shot, is used in blast cleaning the castings. A protective atmosphere must be used during heat treating.

## Superalloys

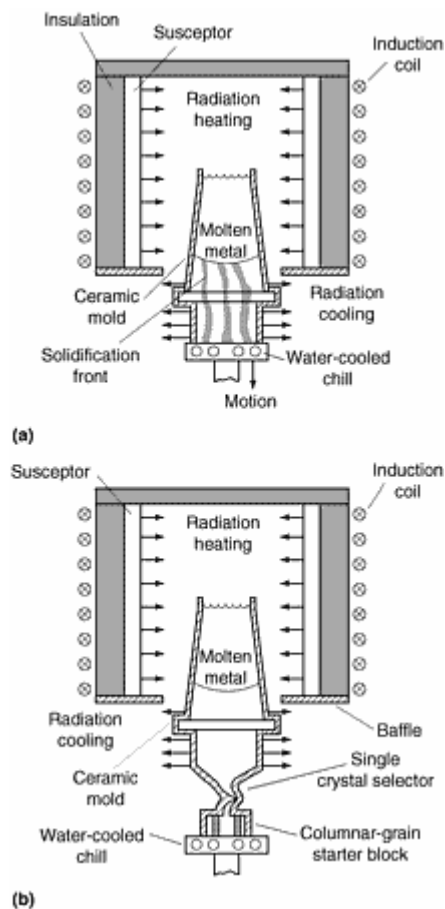

SUPERALLOYS are primarily nickel-base alloys containing substantial quantities of chromium, cobalt, refractory elements such as molybdenum and tungsten, and up to 7% Ti plus Al. Superalloys are inherently non-machinable and, as many are too brittle to forge, must be cast. They have a wide liquidus-to-solidus spread and are difficult to feed. They are primarily produced by investment casting and are most widely used in the gas turbine engine industry. The complex metallurgy of the superalloys as well as their compositions and properties are described in the article "Superalloys" in this Handbook.

## Melting and Casting Practice

**Vacuum Melting.** Because of the high aluminum and titanium contents of the melt and the stringent requirements for casting cleanliness, these alloys are vacuum induction melted from prealloyed charges. Magnesia crucibles are most often used. Usually only enough metal is melted for one mold. Multiple-chamber vacuum furnaces are used. The melt chamber is kept at melt pressure of around  $10^{-3}$  torr continuously. The charge is placed in a charge lock that is evacuated, and when the pressure in the charge lock is equal to that of the melting furnace, a mechanical device places the charge in the induction melting furnace. When the charge is melted, the mold is placed in the mold lock (generally located beneath the melting chamber) and the mold lock is evacuated. When the pressure in the mold lock reaches the pressure in the melting chamber, a valve between the chambers opens and the mold is raised into the melting chamber, where it is poured. The mold and solidifying metal are then retracted into the mold chamber, and the melting sequence can begin again, making maximum use of the facility.

**Pouring.** Because melting, pouring, and solidification take place in a vacuum, superalloys may be poured at very high pouring rates, around 50 kg/s (110 lb/s). These high pouring rates are frequently necessary to fill the thin sections often encountered in gas turbine hardware. Filling of thin sections is also made easier by preheating the molds to temperatures above 900 °C (1650 °F).

**Directional Solidification.** Because gas turbine blades are primarily stressed in one direction, it was realized that their performance could be improved if there were no grain boundaries perpendicular to the principal stress axis of the blade. This led to the development of the directional solidification process. In this process the investment mold is left open at its bottom, which is placed on a water-cooled copper plate prior to pouring. The mold is raised into the melt chamber that also contains a mold heater that is typically an induction-heated graphite susceptor. The mold is heated to a temperature above the melting point of the superalloy and filled with metal. The solid nucleates on the copper chill, and the grains begin to grow into the molten metal. Because the growth of nickel-base alloy grains during solidification is easiest in the [001] direction, those grains which have their [001] directions most nearly perpendicular to the chill plate will grow most easily. The mold is then withdrawn slowly from the heater (Fig. 7a). This removal causes the grains to grow from the bottom of the mold to the top of the mold and the resulting casting structure to consist of parallel grains running the length of the casting.

**Fig. 7** Schematics showing (a) the directional solidification process and (b) the single-crystal solidification

## process for casting of superalloys

**Single Crystal Casting.** After the development of directional solidification, it was realized that the elevated temperature capability of superalloys could be increased if grain boundaries, which melt at lower temperatures than the grains themselves, could be eliminated so that the resulting casting would be a single grain or a single crystal. This can be accomplished using the directional solidification process, arranging the solidification so that only a single grain is allowed to grow throughout the mold. Grain selection is accomplished either by seeding the mold (placing a solid seed at the bottom of the mold prior to pouring), or by the use of grain selectors (Fig. 7b). In the grain selector section of the mold, which is nearest the chill, the mold is arranged so that only the grain that is most favorably oriented with respect to the chill is able to grow from the chill plate into the casting cavity. The selector can be either a helix or a series of right angle segments. Grain selectors are easier for the foundry to use than seeds; the use of seeds is generally restricted to castings where the desired grain orientation is different from that of the direction of easy growth.

## *Titanium Alloys*

TITANIUM AND ITS ALLOYS are attractive because they have the strength of steel but weigh only 60% as much as steel. However, the high reactivity of titanium, especially in the molten state, presents a special challenge to the foundry. For example, titanium reacts violently with silica and has a fairly high solubility for most other refractories (including oxides, carbides, and nitrides). As a result, titanium alloys cannot be melted in refractory crucibles, and they dissolve or react with all refractory molds.

## Foundry Alloys

All production titanium castings to date are based on traditional wrought product compositions. As is the case with wrought alloys, Ti-6Al-4V is also the most popular casting alloy. More detailed information on titanium castings can be found in the Section "Titanium and Titanium Alloys" in this Handbook.

## Melting and Casting Practice

**Melting.** Foundries generally use vacuum arc remelting (skull melting) or a vacuum induction melting technique in which a magnetic field is arranged to partially levitate the melt and keep it from touching the sides of the metal crucible.

**Rammed Graphite Molding.** Large heavy-section titanium castings can be made in rammed graphite molds. These molds are made using finely divided graphite as the molding aggregate, bound by a mixture of pitch, syrup, and starch. The molding material is rammed around the pattern in the same manner used in conventional green sand molding, and the mold is baked and fired to develop its strength.

**Investment casting** is used to produce most titanium aerospace and sporting equipment castings. Titanium investment casting differs from traditional ferrous investment casting only in the composition of the first two dipcoats and stuccos. Because silica reacts with molten titanium, the silica content of these first two coats must be minimized, and the refractory used in the dips and stuccos is selected from materials that are thermodynamically more stable than titanium dioxide. Investment cast molds may be preheated but are not normally preheated to temperatures as high as those used in nickel-base superalloys, to minimize the mold reaction.

In spite of these precautions, there will be a reaction between the molten metal and the mold that results in a layer of increased oxygen content on the surface of the casting. This layer, which varies in thickness up to as much as 1.5 mm (0.06 in.) depending on how long the casting took to solidify in the section, stabilizes the alpha phase of titanium and is known as the "alpha case." It is removed by chemical milling on those castings where its presence could lead to premature failure. Stock is deliberately added to patterns to compensate for the material that will be removed.

Because of the necessity of minimizing the amount of alpha case formed, titanium castings are usually solidified as rapidly as possible. This means that feeding is difficult and titanium castings often contain unacceptable amounts of porosity. For this reason, most titanium castings intended for high integrity applications are hot isostatically pressed as part of the standard finishing procedure.

## ***Cast Metal-Matrix Composites***

METAL-MATRIX COMPOSITES (MMCs) offer unique properties that may have advantages in certain applications. Both particulate-reinforced MMCs and fiber-reinforced MMCs can be produced by casting methods. Additional information on the processing and properties of MMCs can be found in the Section "Special-Purpose Materials" in this Handbook.

### **Casting MMCs**

**For particulate-reinforced composites**, the reinforcing phase is dispersed in the melt by stirring, injection, or ultrasonic agitation. The reinforcing phase is generally non-wetting and usually differs in density from the matrix metal, which may cause the particles to float or sink in the melt. However, if the particles are in suspension, the resulting molten metal/particle slurry can be poured just as any casting alloy can be poured. Fluidity may be affected by the volume fraction of particles and the pouring temperature. Solidification rates are usually high enough that the particles are engulfed during solidification, not pushed ahead of the advancing solid interface. Typical uses for particulate MMCs are in automobile pistons (aluminum alloy/silicon carbide reinforcement) and in applications where high wear resistance is essential.

**Fiber-reinforced composites** are made by vacuum infiltration, pressure casting, or a combination of both. The object is to force the liquid into a mold cavity into which the fiber reinforcement has been preplaced. Care must be taken that the fibers do not freeze the molten alloy prematurely. It is common to treat the surface of the fibers to improve their wettability to the alloy being infiltrated. Aluminum, magnesium, copper, and superalloys have been used as matrix materials for these castings. Fiber reinforcements include boron, graphite, silicon carbide, and refractory metals.

# **Casting Design and Quality Assurance**

Thomas S. Piwonka, The University of Alabama

## **Introduction**

DESIGNING A COMPONENT as a casting requires special consideration be given to how the part will solidify. In addition to the general guidelines given in this article, design manuals are available from foundries and metalcasting trade and professional societies.

## **Design Considerations**

Castings offer the designer cost advantages over other manufacturing methods for most components, especially those having complex geometries. Casting properties are usually isotropic, and castings may be designed for function rather than ease of assembly, like built-up structures. Fillet radii are usually generous, decreasing stress concentration factors. Converting a built-up assembly to a casting usually is accompanied by a decrease in part count, assembly time and inventory, and weight. With the development of rapid prototyping, expensive tooling is not necessary, and parts can be delivered within days after the order is placed.

**Design and Properties.** Designers face a number of challenges in the design of castings. Static property data often found in handbooks may consist of "typical values," which obscure a crucial fact: casting properties are determined during solidification and subsequent heat treatment. This determination means properties will vary depending on how quickly the casting solidifies and how the casting is heat treated.

Component design is usually approached with the assumption that the material is uniform and isotropic and that there is an inherent small and random scatter in properties. In castings, properties will be uniform in specific casting sections from casting to casting, provided the casting variables are constant for each casting. However, they may vary in a predictable manner from point to point within the casting.

Designers frequently use handbook data in designing components. Very often, this data is developed using the Gaussian statistics. As previously noted, such data can be misleading if it is not corrected to reflect differences in cooling rate from section to section within a casting. The Gaussian statistics are appropriate for those materials that are truly ductile (those that have a tensile elongation over 8 to 10%). Many casting alloys, however, even when discontinuity-free, have elongations of only 5 to 10%. Indeed, this is often the reason these alloys are commonly cast: their low ductilities make them hard to form by forging or machining. Use of the Gaussian statistics to determine design allowables in these alloys is incorrect and can lead to "casting factors" that cause significant overdesign, waste of material, and weight penalties. Casting factors are arbitrary increases in casting section thickness applied to compensate for perceived lack of reproducibility of casting properties.

Reproducibility of properties produced by a process is most important for the designer, as the components designed must behave according to the design. Reliability is often evaluated using the Weibull statistics. The Weibull statistics consider the probability of the existence of a discontinuity that would cause failure. This is particularly appropriate for the design of low ductility materials. In analyzing data using Weibull statistics, one evaluates the value of the Weibull modulus. The higher the Weibull modulus, the more reliable the material (i.e., the higher the Weibull modulus, the less the variation in property within a given section of the component).

**General Design Rules.** The most important principle of good casting design is that casting sections should freeze progressively, allowing the riser to supply liquid metal to feed shrinkage occurring during solidification. There are a number of excellent summaries of principles of good casting design (for example, the *Steel Castings Handbook*, jointly published by the Steel Founders' Society of America and ASM International) and a comprehensive booklet has been published on design of premium quality aluminum alloy castings (*Design and Procurement of High-Strength Structural Aluminum Castings*, published by the American Foundrymen's Society, Inc.). This publication also includes general information on the specification and process of approving foundry sources, which is applicable to castings made from any metal.

Designing for progressive solidification requires tapering walls so they freeze from one end to the other; (Fig. 1) and avoiding situations where two heavy sections are separated by a thin section (this is a poor design because metal must feed one heavy section through the thin section and, when the thin section freezes before the heavy section, the flow path will be cut off and shrinkage may form in the heavy section).

**Fig. 1** Redesign of castings to provide progressive solidification through the use of tapered walls. (a) Elbow design. (b) Valve fitting design

Junctions also concentrate heat, leading to areas in the casting where heat is retained. These areas solidify more slowly than others, thus having a coarser structure and different properties from other sections, and solidify after the rest of the casting has solidified, so shrinkage cannot be fed. Minimizing the concentration of heat in junctions therefore aids in improving casting properties. Examples of this are shown in Fig. 2.

(a)

(b)

**Fig. 2 Redesign of a casting to minimize heat concentration. (a) Design has numerous hot spots (X-junctions) that will cause the casting to distort. (b) Improved design using Y junctions**

Concave corners concentrate heat, so they freeze later and more slowly than straight sections, while convex corners lose heat faster and freeze sooner and more quickly than straight sections. In designing a casting, the designer should use properties from test bars that have solidified at the actual cooling rate in that section of the casting. This cooling rate can be determined by instrumenting a casting and measuring the cooling rate in various sections or by simulating its solidification using a commercial solidification simulation program.

The hollow spaces in castings are formed by cores, refractory shapes placed in the molds and around which the casting freezes. These cores are later removed from the casting, usually by thermal or mechanical means. However, each core requires tooling to form and time for placement in the mold. Casting designs that minimize cores are preferable for minimizing costs. Some examples are given in Fig. 3.

(a)

(b)

(c)

**Fig. 3 Redesign of castings to eliminate cores. (a) Casting redesigned to eliminate outside cores. (b) Simplification of a base plate design to eliminate a core. (c) Redesign of a bracket to eliminate a core and to**

## decrease stress problems

The casting must solidify toward the riser in order to be sound, and gates must be located so the mold fills from the bottom to the top so that oxide films that form are swept to the top surface of the casting or into risers where they will not affect casting properties. Gate and riser locations must be accessible for easy removal to minimize processing costs. The position of gate and riser contacts also may add costs if placed where subsequent machining will be required to remove gate stubs or riser pads in the finished component.

**Casting Design Summary.** Casting design influences the way the castings solidify, and hence, the properties that are obtained. Many collections of casting data in handbooks overlook the effect of cooling rate on casting performance, and, as a result, do not provide adequate information for designers. Designers are therefore encouraged to work with foundries to develop databases of reliable mechanical property data that reflect the effect of cooling rates of the alloy and the sections the designer intends to use. This is particularly important for areas of the casting where stress concentrations are likely; use of a solidification simulation program (see following discussion) should assure that these areas are not also areas of slow solidification.

Designers should also be aware that different casting alloys have different levels of "castability," meaning that development of reliable casting properties may be more difficult in some alloys than others. Specification of a casting alloy solely on the results of test bar data (test bars are easy to cast and often do not reflect casting problems encountered in actual castings) without consulting the metalcaster can lead to high casting costs as the foundry compensates for castability difficulties with the alloy.

The designer must begin the design of a casting with an understanding of what properties are desired and required throughout the cast component. Flaw sizes must be kept below the critical level, and the designer should determine what that level is. Critical flaw sizes will vary according to location in the casting; that information should be reflected in specifications that also vary by location, in order to minimize manufacturing costs.

## Casting Tolerances

Casting tolerances depend on the alloy being poured, the size of the casting, and the molding method used. Generally speaking, casting dimensional accuracy increases as one moves to the right in Fig. 4 and as the casting dimensions decrease. However, there is significant overlap between processes.

**Fig. 4** General relationship between dimensional accuracy and casting process

Casting design also affects tolerances. Critical dimensions should not cross parting lines in molds or injection or core dies. Stresses that arise from unequal contraction of parts of the casting as it cools from solidification temperatures, as well as those that result from heat treating, can distort castings so they no longer conform to design dimensions. This also affects tolerances and may lead to extra costs to straighten castings. Solidification stresses are caused by shrinkage during casting solidification when different sections of the casting solidify at different times and rates. Because casting solidification rates depend on the casting design, the designer should consider the effect of the component design on casting distortion. Some examples are given in Fig. 5.

**Fig. 5** Designing castings to prevent distortion caused by mold restraint. The original design, shown in top and front views in (a), was altered to three possible preventative designs, as follows. (b) Preferred method incorporating a tie bar. (c) Less effective method than that shown in (b). (d) Open cavity created in the molding media to relieve restraint upon flanges during casting solidification by allowing solid sand mass to collapse during shrinkage and minimize restraint. Dimensions given in inches

## Solidification Simulation Programs

Since the cast structure controls the heat treated structure and the final structure controls the properties of the component, the designer must be able to predict the effect of the design on the structure of the final part. This is done today by using solidification simulation models. Most progressive foundries today use simulation models in engineering the casting process. Designers are encouraged to work with foundries and have them run solidification models on their designs in a concurrent design process to engineer castings that perform satisfactorily and are reasonably priced.

Solidification simulation models have been extensively developed over the last 20 years, and today there are a large variety to choose from. The more elementary models are based on Chvorinov's law and operate by comparing surface area to volume ratios of adjoining casting sections to predict the order in which the sections solidify (i.e., whether or not solidification will be progressive and shrinkage eliminated). Those models are satisfactory for predicting whether macroporosity will form on solidification; some models are effective at predicting the location of microporosity also.

Advanced models use finite element or finite difference methods to predict how the casting fills, and, from those results, establish the temperature of each point in the mold and each point in the liquid metal at the start of solidification. This produces a more accurate picture of the way the casting solidifies than is possible with models that consider only the surface area to volume ratio of adjacent casting sections. These models also are capable of predicting the grain size and structure and, from that information, are now being used to predict casting properties that result from a specific casting design and choice of casting process parameters. Some solidification models are capable of predicting distortion that will occur during casting and heat treatment and can be used to minimize residual stresses. Some commercial packages include expert systems to help orient the casting in the mold to minimize casting defects and to suggest gating and risering schemes.

Finite element and finite difference models represent the actual physical processes taking place during solidification. As such, they are inherently more accurate than models depending on statistics or heuristics (expert systems). However,

statistical and expert system models can often serve as the starting point for a physics-based model. As the models are merely a tool for the foundryman to use in improving castings, no metalcaster should be intimidated by the physics or mathematics used to make up the model. Commercial models can be run by trained foundrymen with all educational backgrounds if they are interested in learning the instructions.

These models are a powerful tool for concurrent engineering of cast components. The designer, working with the foundry, can see the way the casting will solidify before the casting is poured. If problem areas are found with the design, it can be altered and the new design simulated. This iteration can be repeated until a satisfactory design is developed. When these simulations are combined with rapid prototyping methods, expedited delivery of cast components can be achieved.

## **Rapid Prototyping**

Rapid prototyping (RP) is the use of a number of computer-aided design, layer-based processes to build temporary tooling for a manufacturing process. In casting, RP can be used to produce plastic or wax patterns for investment casting, actual investment casting molds, patterns for sand casting, and direct production of resin-bonded sand cores and molds. This means that a user of castings can obtain prototype quantities of parts from temporary tooling and that modifications can be made in the design before hard tooling is built.

All RP processes are based on the ability of a computer to slice a part into many parallel thin sections. The foundry's computer receives a data file of the geometry of the part from the customer and processes the solid model into sections. Based on these sections, the RP machine can then build up a pattern or a mold or core box by either fusing a pattern or mold material following directions from the computer or by cutting material that is glued together by a suitable adhesive to form the pattern or mold. The cutting or fusing is generally done using a laser guided by the computer program.

The materials used for prototype tools usually last for only a few parts. Tolerances of these prototype tools and patterns are generally acceptable for prototype evaluation, although not quite as good as hard tooling tolerances. However, they may be entirely acceptable for an application when only a few castings will ever be made. Time from part design to casting has been cut to as little as 48 h using RP processes, and the technique is especially valuable when bringing a new product or assembly to market. It should be noted that the most advanced of the RP devices combine solidification modeling programs with the RP process to automatically design gating and risering that will produce a satisfactory casting.

## **Quality Assurance in the Foundry**

Consistent production of quality castings requires that the foundry exercise a high degree of control over a complex process. Casting dimensions are affected by the molding system, the pattern, the gating, the cores (aggregate, binder, coremaking method, and the way they are placed), and the pouring parameters. Freedom from inclusions in the casting depends on the melting, gating, and molding systems. Soundness and grain size control depend on gating and risering, casting design, melt practice, and melt treatment. Casting surface quality depends on mold and core materials and additives, mold surface coating, casting design, and pouring temperature.

Because of the large number of variables, foundries exercise continuous process control at a number of points in the casting process. Much of the information gathered is kept in the form of control charts that are analyzed using the tools of statistical process control. Control charts are routinely kept on molding variables (mold hardness, moisture content, sand temperature and compactability for green sand, slurry viscosity, temperature, plate weight for investment castings, etc.), metal composition (carbon equivalent, chill, and degree of nodularity for ductile iron and gas content and pouring temperature for aluminum alloys), and casting dimensions. These charts are used to plot trends in product attributes, giving the metalcaster warning when a process requires corrective action.

While traditional nondestructive testing methods (magnetic and fluorescent particle, radiographic, ultrasonic, and dimensional inspections) are routinely used either for 100% inspection or on a sampling basis, foundries prefer to apply statistical process control to the manufacturing process. As a result of the application of statistical process control and the acceptance by many foundries of the principals embodied in the ISO 9000 certification, metalcasting quality equals or exceeds that of other manufacturing processes.

# Forming of Sheet, Strip, and Plate

## Presses and Auxiliary Equipment for Forming Sheet Metal

THE PRESSES described in this article are mechanically or hydraulically powered machines used for producing parts from sheet metal. Power presses can be classified according to the following characteristics: source of power, type of frame, method of actuation of slides, and number of slides in action. Presses in any of these classes are available in a range of capacities (tonnage or bed area), although the range is not necessarily the same for all types of presses. Characteristics of 18 types of presses are summarized in Table 1.

### Table 1 Characteristics of 18 types of presses

## JIC Identification System

The Joint Industry Conference (JIC), a committee of press builders and large-press users formed some years ago, set guidelines for uniformity with respect to nomenclature, bed and ram sizes, force ranges, and symbols for presses (Fig. 1). Although the JIC is no longer in existence, most press builders adhere to the standards either completely or in part. Under the JIC press classification system with respect to the number of slides, the first letter in the designation is S for single-action, D for double-action, and T for triple-action presses. Most press builders place the JIC markings in a prominent position on the fronts of the presses.

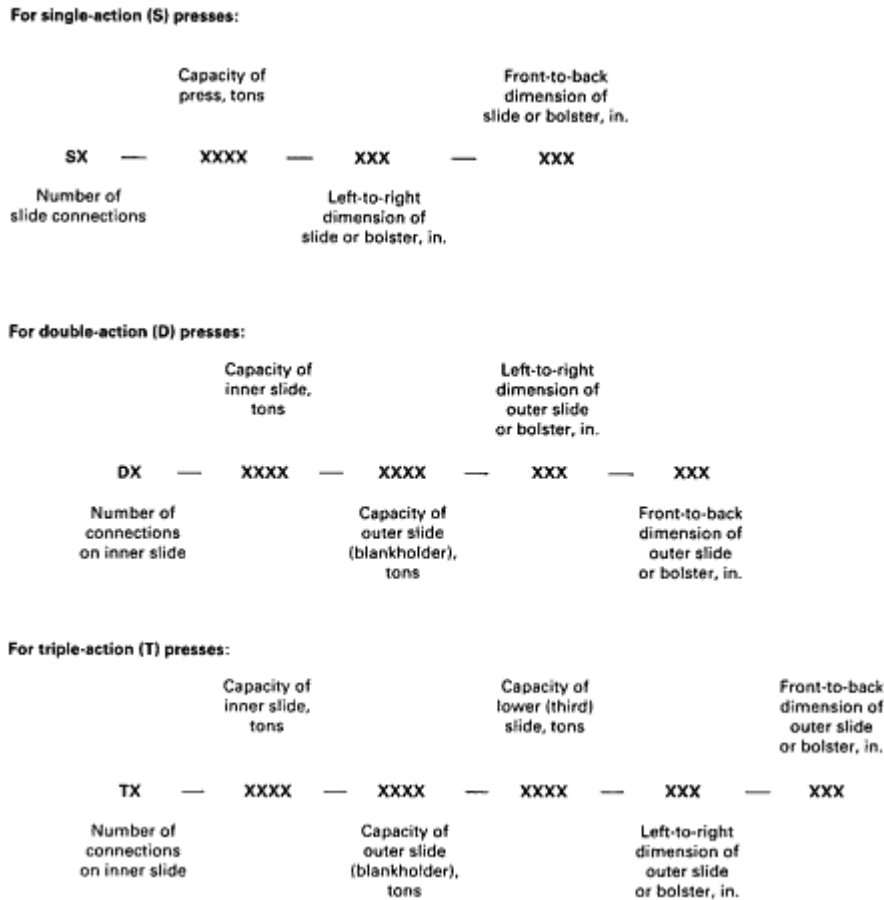

Fig. 1 Designations used for press identification under the JIC classification system

## Source of Power

Power presses for sheet metal forming can be driven either hydraulically or mechanically. The performance characteristics and other operational features of hydraulic and mechanical presses are compared in Table 2.

**Table 2 Comparison of characteristics of mechanical and hydraulic presses**

Force	Capacity	Stroke length	Slide speed	Control	Preferred uses
<b>Mechanical</b>					
<b>Varies depending on slide position</b>	Practical maximum of ~54 MN (6000 tonf)	Limited	Higher than hydraulic, and can be varied. Highest at midstroke	Full stroke is usually required before reversal.	Preferred for operations requiring maximum pressure near the bottom of the stroke. Preferred for cutting operations such as blanking and piercing, and for relatively shallow forming and drawing (depths to about 102 mm, or 4 in.). Good for high-production applications and progressive and transfer die operations
<b>Hydraulic</b>					
<b>Relatively constant (does not depend on slide position)</b>	445 MN (50,000 tonf) or more	Capable of long (2.5 m, or 100 in.) strokes	Slower pressing speeds, with rapid advance and retraction. Speed is uniform throughout the stroke.	Adjustable; slide can be reversed at any position.	Good for operations requiring steady pressure throughout the stroke. Preferred for deep drawing, die tryout, flexible-die forming, drawing of irregular-shape parts, straightening, operations requiring high and variable forces, and operations requiring variable or partial strokes

**Mechanical Presses.** In most mechanical presses, a flywheel is the major source of energy applied to the slides by cranks, gears, eccentrics, or linkages during the working part of the stroke. The flywheel runs continuously, engaged by the clutch only when a press stroke is needed. In some very large mechanical presses, the drive motor is directly connected to the press shaft, thus eliminating the need for a flywheel and a clutch.

Two basic types of drives, gear and nongear, are used to transfer the rotational force of the flywheel to the main shaft of the press (Fig. 2).

Fig. 2 Four types of drive-and-clutch arrangements for mechanical presses

**Hydraulic Presses.** Hydrostatic pressure against one or more pistons provides the power for a hydraulic press. Most hydraulic presses have a variable-volume, variable-pressure, concentric-piston pump to provide a fast slide opening and closing speed. It also provides a slow working speed at high forming pressure. The principal components of a typical hydraulic press, shown in Fig. 3, include a bolster plate attached to the bed to support the dies and to guide the pressure pins between the die cushion and the pressure pad. The capacity of a hydraulic press depends on the diameter of the hydraulic pistons and on the rated maximum hydraulic pressure, which is a function of the pump pressure and related mechanisms. Hydraulic presses with capacities up to 445 MN (50,000 tonf) have been built, but most are less than 133 MN (15,000 tonf). The typical hydraulic press is rated at 900 kN to 9 MN (100 to 1000 tonf). Gap-frame presses are rated at 345 to 4350 kN (5 to 50 tonf).

Fig. 3 Principal components of a double-action hydraulic press with a die cushion

Hydraulic press slides, or platens, are actuated by numerous combinations of hydraulic drives. Hydraulic presses usually have a longer stroke than mechanical presses, and force can be constant throughout the stroke. Hydraulic presses have an adjustable stroke for one or more slides. Accumulators or large-volume pumps can provide fast motion for a slide to open and close. High-pressure pumps provide the working force at a slower speed.

Usually all slides are operated by one pumping system. The relation of each action to the others, interaction, and timing all depend on the controls.

## Press Selection

Proper press selection is essential for successful and economical operation. The purchase of a press represents a substantial capital investment, and return on investment depends upon how well the press performs the job required. No general-purpose press exists that can provide maximum productivity and economy for all applications. Compromises usually require the use of a press for more than one job. Consideration should include both present and future production requirements. Important factors influencing the selection of a press include size, force, energy, and speed requirements. The press must be capable of exerting force in the amount, location, and direction, as well as for the length of time, needed to perform the specified operations. Other necessary considerations include the size and geometry of the workpieces, the workpiece material, operations to be performed, number of workpieces to be produced, production rate needed, accuracy and finish requirements, equipment costs, and other factors.

**Size, Force, and Energy Requirements.** Bed and slide areas of the press must be large enough to accommodate the dies to be used and provide adequate space for die changing and maintenance. Space is required around the dies for accessories such as keepers, pads, cam return springs, and gages; space is also needed for attaching the dies to the press. Shut height of the press, with adjustment, also must be suitable for the dies.

For higher-speed operation, presses should be selected with the shortest stroke possible, thus increasing productivity. Stroke requirements, however, depend upon the height of the parts to be produced. Blanking requires short strokes, but some forming and drawing operations require long strokes, especially for ejection of parts.

Size and type of press to be selected also depend upon the method and direction of feeding, the size of sheet, coil stock, blank, or workpiece to be formed, the type of operation, and the strength and other characteristics of the material being formed. Material or workpiece handling and die accessibility generally determine whether the press should be of gap-frame or straight-side construction, and whether it should be inclined or inclinable. Physical size of a press can be misleading with respect to its capacity. Presses having the same force rating can vary considerably in size depending upon differences in length of stroke, pressing speed, and number of strokes per minute.

The force required to perform the desired operations determines press capacity, expressed in tons or kilonewtons (kN). The position on the stroke at which the force is required and the length of stroke must be considered.

Energy or work (force  $\times$  distance), expressed in inch-tons or joules (J), varies with the operation. Blanking and punching require the force to be exerted over only a short distance; drawing, forming, and other operations require force application over a longer distance. The major source is the flywheel. The energy available increases with the square of the flywheel speed.

Possible problems are minimized by selecting a press that has the proper frame capacity, drive motor rating, flywheel energy, and clutch torque capacity.

**Speed Requirements.** Press speed is relative, varying with the point of reference. Fast speeds are generally desirable, but limited by the operations performed, the distances above stroke bottoms where the forces must be applied, and the stroke lengths. High speed, however, is not necessarily the most efficient or productive. Size and configuration of the workpiece, the material from which it is made, die life, maintenance costs, and other factors must be considered to determine the highest production rate at the lowest cost per workpiece. A lower speed may be more economical because of possible longer production runs with less downtime.

Simple blanking and shallow forming operations, however, can be performed at high speeds. Mechanical presses have been built that operate to 2000 strokes/min with 25 mm (1 in.) stroke, but applications at this maximum speed are rare. Speeds of 600 to 1400 strokes/min are more common for blanking, and thick materials are often blanked at much slower

speeds. For drawing operations, contact velocities are critical with respect to the workpiece material, and presses are generally operated at slide speeds from 10 to 300 strokes/min, with the slower speed for longer stroke drawing operations.

**Mechanical Versus Hydraulic Presses.** Mechanical presses are the most frequently used for the blanking, forming, and drawing of sheet metal, but hydraulic presses are being used increasingly. For some applications, hydraulic presses offer certain advantages, and in some cases, they are the only machines that can be used. For example, very high force requirements can only be met with hydraulic presses (Table 2).

## Slide Actuation in Mechanical Presses

Rotary motion of the motor shaft on a mechanical press is converted into reciprocating motion of the slides by a crankshaft, eccentric shaft, eccentric-gear drive, knuckle lever drive, rocker arm drive, or toggle mechanism, each of which is discussed below and illustrated in Fig. 4.

Fig. 4 Operating principles of various drive systems for mechanical presses

**Crankshafts.** The most common mechanical drive for presses with capacities up to 2.7 MN (300 tonf) is the crankshaft drive.

**Eccentric Shafts.** Similar to crankshafts, the eccentric completely fills the space between the supporting bearings of the press crown, thereby eliminating the deflection commonly caused by the unsupported portion where the crank cheeks normally would be. Eccentric drives often are used in high-speed, short-stroke, straight-side presses with progressive dies.

**Eccentric-gear drives** are used almost universally for large, straight-side presses that operate at speeds under 50 strokes/min. In place of a crankshaft, an eccentric is built as an integral part of the press drive gear. The eccentric gear permits strokes to as long as 1.3 m (50 in.). However, long strokes usually reduce speeds to only 8 to 16 strokes/min. With the eccentric as part of the gear, accuracy and alignment of the gears determine accuracy of alignment of the slide.

**Knuckle Lever Drives.** Combining the motions of a crank and knuckle lever to drive the press slide, this drive is limited to operations such as coining or embossing.

**Rocker arm drives** apply crank or eccentric motion to a rocker arm connected to the press slide. In this mechanism, the linkage is driven by an eccentric gear and a connecting rod. The rocker arm drive is a variation of the knuckle lever drive. However, a press with rocker arm drive is not limited to coining operations; it can also be used for drawing or forming operations.

**Toggle mechanisms** are the most widely used means of providing the second action in double-action mechanical presses. The toggles operate an outer slide, which clamps the blank against the die, while the punch, operated by the inner slide directly from the crankshaft, performs the draw operation.

## Number of Slides

Mechanical (and hydraulic) presses have one, two, or three slides and are referred to as single, double, or triple-action presses. Each slide can be moved in a separately controlled motion. A single-action press has one reciprocating slide (tool carrier) acting against a fixed bed. Presses of this type, which are the most widely used, are used for many different metal-stamping operations, including blanking, embossing, coining, and drawing.

**A double-action press** has two slides moving in the same direction against a fixed bed. These slides are generally referred to as the outer (blankholder) slide and the inner (draw) slide. The blankholder slide is a hollow rectangle, while the inner slide is a solid rectangle that reciprocates within the blankholder.

**A triple-action press** has three moving slides: two slides moving in the same direction as in a double-action press and a third, or lower, slide moving upward through the fixed bed opposite in direction to the blankholder and inner slides. This permits reverse drawing, forming, or beading operations against the inner slide while both upper actions are dwelling.

Cycle time for a triple-action press is necessarily longer than for a double-action press because of the time required for the third action.

## Auxiliary Equipment

Most primary press operations are automated, allowing equipment for feeding and unloading to be used for fairly short runs. Hand feeding, with its attendant hazards, is often confined to secondary operations on partly completed workpieces. Goals for planning automated operations should include:

- Maximum safety to the operator and to the equipment
- High or nearly continuous production
- Improved quality of the product and minimum scrap
- Reduction in cost of the finished parts

The shape and position of the part before and after each operation must be carefully studied to determine whether design changes, such as adding tabs or extra stock to the blank, will facilitate handling.

Automatic handling equipment can be divided into the following categories: feeding equipment, unloading equipment, and transfer equipment.

Coil-handling equipment moves coiled stock to the press area and uncoils it with a minimum of damage to the stock and minimum danger to the tools and operator. Reliable coil handling is important, because coil stock is increasingly used to supply material to presses. Other auxiliary equipment includes lubricant applicators, stock straighteners, and levelers.

## Selection of Die Materials for Sheet Metal Forming

---

THE USEFUL PERFORMANCE of a forming die is measured in terms of its wear. Total wear is affected primarily by the length of the production run and the severity of the forming operation. Hence, production quantity and forming

severity are the most important factors in selecting die materials for forming. The metal being formed, its thickness, and the finish and dimensional tolerances required in the part are also influential factors.

## Die Materials

Recommended die materials range from plastics for low reduction of simple to moderate parts, up to the most wear-resistant surface hardened tool steels. Parts of even greater severity, or those run in quantities larger than one million, may require dies or inserts of cemented carbide. Table 3 lists the variety of die materials for press forming operations.

**Table 3 Tool materials commonly used for press forming dies**

Material	Nominal composition
Tool steels	
<b>W1</b>	Fe-1.0C
<b>S1</b>	Fe-0.50C-1.5Cr-2.5W
<b>O1</b>	Fe-0.9C-1Mn-0.5Cr-0.5Mo
<b>A2</b>	Fe-1C-5Cr-1Mo
<b>A4</b>	Fe-1C-2Mn-1Cr-1Mo
<b>D2</b>	Fe-1.5C-12Cr-1Mo-1V
<b>D3</b>	Fe-2.25C-12Cr
<b>D5</b>	Fe-1.5C-12Cr-1Mo-3Co
<b>D7</b>	Fe-2.35C-12Cr-1Mo-4V
<b>M2</b>	Fe-0.8C-4Cr-5Mo-6W-2V
<b>M4</b>	Fe-1.3C-4Cr-4.5Mo-5.5W-4V
<b>Vanadis 4<sup>(a)</sup></b>	Fe-1.5C-8Cr-4V-1.5Mo
<b>Vanadis 10<sup>(a)</sup></b>	Fe-2.9C-8Cr-9.8V-1.5Mo
<b>CPM 10V<sup>(a)</sup></b>	Fe-2.45C-5Cr-9.75V-1.3Mo
Other ferrous alloys	
<b>Hot-rolled low-carbon steel</b>	Fe-0.10 to 0.20C
<b>Unalloyed cast iron, 185 to 225 HB</b>	Fe-3C-1.6Si-0.7Mn
<b>Alloy cast iron, 200 to 250 HB</b>	Fe-3C-1.6Si-0.4Cr-0.4Mo
<b>Cast high-carbon steel, 185 to 225 HB</b>	Fe-0.75C
<b>Cast alloy steel, 200 to 235 HB</b>	Fe-0.45C-1.1Cr-0.4Mo
<b>4140 alloy steel</b>	Fe-0.4C-0.6Mn-0.3Si-1Cr-0.2Mo
<b>4140 modified</b>	Fe-0.4C-1.2Cr-0.2Mo-1Al
Nonferrous alloys	
<b>Zinc alloy (UNS Z35543)</b>	Zn-4Al-3Cu-0.06Mg
<b>Aluminum bronze (UNS C62500), 270 to 300 HB</b>	Cu-13Al-4Fe
Nonmetals	
<b>Polyester-glass</b>	50% polyester, 50% glass in the form of cloth, strand, or chopped fibers
<b>Epoxy-glass</b>	50% epoxy, 50% glass as above
<b>Polyester-metal</b>	Polyester reinforced with metal powder
<b>Epoxy-metal</b>	Epoxy reinforced with metal powder
<b>Nylon-metal</b>	Polyamide reinforced with metal powder
<b>Polyester or epoxy-glass-metal</b>	Polyester or epoxy with both glass and metal as above

(a) P/M tool steels

A brief review of tool materials for various forming operations is given below. More detailed information on selection of tool and die materials for press forming, deep drawing, spinning, shearing, and slitting, as well as other forming processes, can be found in the *ASM Specialty Handbook: Tool Materials*.

**Cast iron** is a useful die material for forming parts larger than about 300 mm (12 in.). Its performance makes it suitable for use in medium production runs or short runs of large parts. When cast iron is used with inserts, it will produce greater quantities. Cast iron should have predominantly fine pearlite with no massive carbides and a minimum of ferrite. Graphite should be of type A distribution with a preferred flake size 4 to 5.

**The zinc alloy** recommended for some sheet forming dies (Table 3) has high pattern fidelity when cast, but requires very accurate shrink patterns to minimize hand labor in finishing. It is economical only for die components at least 300 mm (12 in.) long, and is most economical in dies about 900 mm (36 in.). One of its principal values is for complicated

dies that would require intricate machining and hand tooling if made of cast iron, but which can be cast more closely with zinc. In tensile strength, compressive strength, and hardness, zinc tooling alloys are inferior to other metals used in die construction.

**Steels.** Hot-rolled mild steel plate with carbon content from 0.10 to 0.20% is in major use as a die material for short-run forming of small parts. This type of steel is not recommended without surface hardening except for quantities of less than 10,000 parts. In addition, hot-rolled mild steel can be used for dies where straightening facilities are available for correcting distortion induced by heat treatment.

Several medium-carbon alloy steels such as 4140 are available in plate form and are useful for some types of forming dies. Such steels are generally used for lower production runs.

Cast steel is used for forming parts larger than 300 mm (12 in.) long where the shape of the part makes a casting more feasible than wrought stock. Plain carbon steel (0.65 to 0.85% C) and alloy cast steel (Fe-0.45C-1.1Cr-0.4Mo) are two commonly used compositions. Cast steel is more costly and more difficult to machine than cast iron and is more likely to gall. However, it is tougher than cast iron. One important advantage of cast steel, particularly the plain carbon grade, is its weldability. It can be rewelded with steel or hardfaced with tool steel, aluminum bronze, or other wear-resistant hardfacing alloy. Because of its resistance to galling, it is less desirable for dies used for forming carbon and stainless steels than for aluminum and copper alloys. Cast steel is also useful for restrike, flanging, and other types of dies that are less likely to gall or pick up metal from the sheet.

**Tool steels**, often nitrided, are used for long production runs (100,000 to one million parts) and for tooling applications requiring long wear life and good toughness. As shown in Table 3, a wide variety of wrought and powder metallurgy grades are used.

**Aluminum bronzes** are available in a wide range of hardness from 120 to 340 HRB. These alloys have excellent resistance to galling and are desirable for dies where best finish is required on carbon or stainless steel parts.

**Cemented Carbides.** For long production runs, inserts of sintered tungsten carbide (WC-10Co) are widely used, especially for deep-drawing dies. In dies of about 200 mm (8 in.) or less for continuous production of over one million pieces, cemented carbides have proved to be the most economical die material. Such dies have maintained size in drawing 60% reductions of more than 500,000 pieces and have made as many as one million parts with reductions greater than 40% when the steel to be drawn is surface treated with zinc phosphate and soap. However, cemented carbides are not superior to tool steels (such as D2) in complex deep drawing operations, such as those with reductions greater than 40% which combine drawing with coining or stretching.

**Plastics.** Even more than with other tooling materials, the quality and economy of plastic tooling improves with shop experience and volume. Polyester, epoxy, phenolic resin, and nylon have been used. Plastic dies of longest life are constructed so that the wearing surface is faced with glass cloth that has had most of the plastic material forced out under pressure before and during curing. Plastics are most economical when a model is available as a pattern for the lay-up of the plastic-impregnated glass cloth facing, which is backed up with chopped glass fibers impregnated with 50% resin. The strength (70 to 275 MPa, or 10 to 40 ksi), and, in particular, the hardness of plastics are inferior to those of metallic die materials. In some instances, the problem of obtaining the required strength in a plastic die must be solved by extra work in designing or developing; but in many cases the regions of high pressure are confined to local areas, which, if anticipated, are strengthened with metal inserts.

## **Selection and Use of Lubricants in Forming Sheet Metal**

LUBRICANTS AND LUBRICATION are relatively inexpensive, yet important and often indispensable for efficient forming of quality parts. In general, the specific characteristics of the surfaces of both the sheet and the dies are critical in the selection of sheet metal lubrication. As such they provide the boundaries between which the lubricant must operate. These surfaces are complex. The chemistry of the surface is not the same as the bulk chemistry of the sheet or tools. The lubricant interacts with an oxide layer of varying complexity; various contaminants may infiltrate the oxide layer (such as oils, gases, acids, and rust preventives); and the surface may be carburized or decarburized, nitrided, or subjected to some other surface treatment, or coated with a polymer or phosphate. Many other surface-chemistry variations are possible. Furthermore, the surface may have residual compressive or tensile stresses from prior processing. The fine structure of the

metal surface also may vary with prior history and be quite different from that of the bulk material. The surface roughness also varies in many geometrically significant ways. Interposed between these nonhomogeneous surfaces is a lubricating film that may be quite complex in structure, activity, and wetting ability.

The complexity of the lubricant/metal interface fundamentally affects the lubricant performance by preventing galling or wear of the tooling, as well as tearing, scratching, or imperfect forming to desired dimensions of the sheet metal.

## Lubrication Mechanisms

In sheet metal forming, several different lubrication regimes have been identified (Fig. 5).

**Fig. 5** Three lubrication regimes experienced in sheet metal forming. (a) Thick-film lubrication. (b) Thin-film lubrication. (c) Boundary lubrication

**Thick-film (hydrodynamic) lubrication** (Fig. 5a) is the occurrence of a thick film of lubricant between tool and workpiece that completely prevents the metal-to-metal contact.

**Thin-Film (Quasi-Hydrodynamic) Lubrication.** The film between tool and workpiece is thinner, and some metal-to-metal contact takes place (Fig. 5b). This regime occurs in bar and wire drawing and less frequently in sheet metal forming.

**Boundary lubrication** (Fig. 5c) is typified by metal surfaces separated by a lubricant film only a few molecules thick, with considerable metal-to-metal contact between asperities of the two surfaces. In most forming operations, because of the high pressures and low speeds involved, lubrication is of the boundary type.

## Lubricant Forms

The three principle fluids (water, oil, and synthetic fluid) that comprise the primary ingredients of sheet metal forming lubricants are combined with additives to achieve the desired operating characteristics. Table 4 lists the relative effectiveness of four types of lubricants for various functions. Some of the more important additives include emulsifiers, extreme-pressure (EP) additives, thickeners, solid lubricants (e.g., graphite and molybdenum disulfide), antifoaming agents, corrosion inhibitors, and antimicrobial agents.

**Table 4 Relative effectiveness of different types of lubricants for various functions**

Function	Relative effectiveness <sup>(a)</sup>			
	Compounded oil	Oil-in-water emulsion	Semisynthetic solution	Synthetic solution
Provide lubrication at high pressure (boundary lubrication)	1	2	3	4
Reduce heat from plastic deformation (heat transfer)	5	2	2	1
Provide cushion between workpiece and die to reduce adhesion and pickup (film thickness)	1	2	3	4
Reduce friction between die and workpiece and, thus, heat	1	2	2	1
Reduce wear and galling between tool and workpiece (chemical surface activity)	4	3	2	1
Flushing action to prevent buildup of scale and dirt (fluid flow)	5	4	3	2
Protect surface characteristics; nonstaining	5	2	2	1
Minimize processing costs, welding, cleaning, and painting	5	2	2	1
Minimize environmental effect, air contamination, and water recovery	5	2	2	1

(a)

1, most effective; 5, least effective

## Lubricant Selection

Selection of an appropriate lubricant for a specific sheet metal forming operation depends on a number of diverse criteria that must be successfully satisfied:

- Effect of lubricant on the the forming operation (effect on both tool wear and part tolerance and finish)
- Application method and efficiency thereof
- Maintenance of lubricant performance, taking into account problems of recirculation, testing, and disposal
- Corrosion of tooling, machine, and finished parts
- Cleaning
- Welding, painting, or coating of the work material
- Worker response
- Supplier support
- Toxicity and health
- Cost, including cost of lubricant and its effect on overall product cost

Unlike bulk deformation processes such as forging, the temperature increase in sheet metal forming is generally low unless the complexity of deformation and/or the strength of the material is very high. Generally, except in the case of ironing, sheet metal forming involves little or no thickness change. Deformation is generally biaxial in the plane of the sheet. However, there can be considerable relative motion between tool and workpiece. Further, the area of tool contact is often large. Surface finish and part tolerance depend on tool geometry and finish, speed and temperature of deformation, the combination of forming steps required, and the choice and application of lubricant. The type of metal, complexity of part shape, part tolerance, and surface finish specifications all influence the choice of lubricant. Table 5 lists recommended lubricants for various work metals.

**Table 5 Lubricants for forming of specific sheet materials**

Metal or alloy	Recommended lubricants for:	
	<b>Cold forming</b>	<b>Hot forming</b>
<b>Aluminum alloys</b>	Synthetic solutions, emulsions, lanolin suspensions, water suspensions, soap solutions, mineral oil plus fatty oils	Graphite suspension
<b>Copper alloys</b>	Emulsions plus fatty oils, mineral oils plus fatty oils, soap suspensions, water suspensions, tallow suspensions synthetic solutions	Pigmented pastes, graphite suspensions
<b>Magnesium alloys</b>	Solvent plus fatty compounds, mineral oils plus fatty compounds	Graphite plus molybdenum disulfide, soap plus water, tallow plus graphite
<b>Nickel, nickel-base alloys</b>	Emulsions, mineral oils plus EP additives, water plus chlorine additives, conversion coatings plus soap	Graphite suspension, molybdenum disulfide suspension, resin coating plus salts
<b>Refractory metals and alloys</b>	Copper plating	Molybdenum disulfide, graphite suspension
<b>Carbon and low-alloy steels</b>	Emulsions, soap pastes, water, fatty oils plus mineral oils, polymers, conversion coating plus soap, molybdenum disulfide or graphite in grease, synthetic solutions	Graphite suspension
<b>Stainless steels</b>	Fatty oils plus mineral oil, water, polymers, conversion coating plus soap, mineral oil plus EP additives, pigmented soaps	Graphite suspension
<b>Titanium, titanium alloys</b>	Water, pigmented soaps, polymers, conversion coating plus soap	Graphite and molybdenum disulfide suspension

The relationship of many process variables influence the choice of lubricant. These include speed of operation; tool geometry; number and severity of each forming operation; worker exposure to lubricant; fluid makeup; circulation, recycling, and disposal; and the effect of the lubricant film on subsequent operations such as welding, cleaning, and plating. A simple recommendation based on material, tooling, and process may prove to be far from optimum; many other factors can influence lubricant choice. The following discussions for specific materials are guidelines to provide some background in lubricant selection.

### ***Lubricants for Forming Carbon and Alloy Steels***

A wide range of lubricants is available for forming steel sheet. The speed of operation and resulting temperature, as well as thickness of stock and complexity of shape, influence lubricant choice. Oil, solvent, and water-base fluids, as well as pastes and gels, may be effective, depending on operating conditions.

**Blanking and Piercing.** Straight oil, compound oil, or emulsions with sulfur, chlorine, and/or fatty esters are used for most operations. Solutions may be used when the operation is less severe.

**Multislide Forming.** Light compounded oils and water-base emulsions and solutions with chlorine and fatty additives are used successfully. Care must be taken to prevent buildup on the dies and corrosion of machine or formed parts when water-base lubricants are used.

**Deep Drawing.** Progressive and multiple-die sets are being used more and more frequently, and thus carry-through of the lubricant becomes more and more important. Multiple-die lubrication sites to provide die lubrication at succeeding stations may be an alternative to ensure adequate lubrication. Compounded oils and emulsions or pastes are used successfully. Chlorinated compounds and fatty esters are commonly chosen additives. Soap-base lubricants are also applied frequently and successfully.

**Spinning.** Both lubrication and cooling are important effects provided by appropriate lubricant choices. Water-base emulsions and solutions containing chlorinated or sulfochlorinated additives and/or fatty esters are used. Nonpigmented water-base pastes are also effective.

**Roll Forming.** Water-base emulsions and solutions have been used to form both bare and coated steel. For galvanized steel, white rust can be a problem if water-base lubricants are used and not properly applied and removed. Solvent-base fluids are often preferred, particularly to reduce residue. Light oils also may be used, both compounded and uncompounded with chlorinated compounds, soaps, or fatty esters.

### ***Lubricants for Forming Stainless Steels***

In general, stainless steels are more difficult to form than carbon or low-alloy steels because of their higher strength. Chemically reactive lubricants containing sulfur or chlorine must be chosen carefully. Formed parts should be furnace treated after removal of the lubricant film. Sometimes this step may be avoided if high-molecular-weight polymers or complex fats are used in lubricant formulation.

**Blanking and Piercing.** Solutions and emulsions containing sulfur and/or chlorine are particularly effective for lighter-gage material. Oils compounded with sulfur and/or chlorine are effective in heavier-gage material.

**Multiple-Slide Forming.** Oil and water-base fluids are successfully used. Recently, solutions with complex esters and fatty compounds have been used to eliminate parts cleaning before use.

**Deep Drawing.** Because of the high work-hardening characteristics of some stainless steels and attendant high die pressure and temperatures, oils with EP additives such as sulfur, chlorine, and phosphorus are most often the lubricants selected. Pigmented and nonpigmented pastes are often used with or without EP additives.

**Roll Forming.** Thin-gage sheet may be formed by application of solvent-base as well as water-base fluids at the roller. Thicker material and/or more complex shapes, on the other hand, require oils or emulsions compounded with fatty oils, EP additives, and soaps.

### ***Lubricants for Forming Heat-Resistant Alloys***

In general, heat-resistant alloys (complex iron, nickel, and cobalt-base materials) as a class use lubricants that are suitable for stainless steel. Cobalt-base alloys are particularly difficult to form into sheet because of their high strength and relative inertness. Care must be taken to avoid embrittlement by sulfur diffusion in nickel-base alloys. Pigmented lubricants are difficult to remove after forming, and this may discourage their use.

**Blanking and Piercing.** Soap-base oils and emulsions are used with and without chlorinated additives. Wax and polymer additives may be used if the blanking step is complex.

**Spinning.** Chlorinated additives in an oil base as well as in emulsions containing fatty esters are effective. Soap-base pastes are also often chosen for application.

### ***Lubricants for Forming Refractory Metals and Alloys***

Materials such as molybdenum, tungsten, tantalum, niobium, and their alloys are often warm or hot formed. Forming is most successful, however, at room temperature using metal coatings with application of an auxiliary lubricant.

**Drawing.** Fluorinated complex polymers are used to form tantalum; graphite in fat has been used for forming niobium. Both metals may be formed at room temperature.

**Spinning.** Molybdenum disulfide in oil or graphite in a soap-base paste is used to spin niobium at room temperatures.

### ***Lubricants for Forming Aluminum and Aluminum Alloys***

Aluminum and aluminum alloy sheet may be stained or corroded through the improper choice of lubricant. Aluminum oxides build up during forming and may necessitate cleaning of parts and equipment. The lubricant may contribute to undesirable buildup. Lubricant chemistry differs from the chemistry used in formulating lubricants for steel and refractory metals or high-temperature alloys.

**Blanking and Piercing.** Oils or compounded oils of light viscosity are used. Compounding additions of fatty esters and chlorinated compounds are frequently chosen. Fatty compounded emulsions, as well as soap-base solutions, are also effective. Oxides may be deposited, however, with some compounded oils and emulsions.

**Roll Forming.** Solvent-base lubricants containing fatty esters as well as emulsions and solutions are frequently used lubricants. Light viscosity oils also may be used; however, oxides may build up on the rolls. Soap-base lubricants are used with care taken to prevent soap deposits.

**Deep Drawing.** Viscosity and lubricity are critical attributes of lubricants. Water-base fluids may be used if appropriate fatty additives and/or soap additives are used to provide the required barrier and lubricity. Oils of varying viscosity or dry soap films may be used for more difficult draws. Pastes that are soap- and fat-base have been applied successfully. Progressive draws involving multiple steps should provide frequent lubrication at more than one station.

**Spinning.** Waxes and soaps are effective. Colloidal graphite suspended in an oil carrier also is used successfully. Cleaning can be difficult depending on the severity of the spinning operation.

### ***Lubricants for Forming Copper and Copper Alloys***

These metals can stain or corrode during forming. Lubricants must be formulated to prevent both from taking place.

**Multislide Forming.** Soap and fat-containing oil and/or water-base lubricants are effective. Solvent-base lubricants containing a fatty ester or an inhibited chlorine-containing compound may be used.

**Roll Forming.** All classes of lubricants using fatty compounds and/or soap-base additives are used successfully in water, oil, or solvent fluids.

**Deep Drawing.** Depending on severity of draw, oil or water-base lubricants in fluid or paste form may be effective. Soap and fatty compounds, as well as inhibited chlorine-containing compounds, are commonly used additives.

### ***Lubricants for Forming Magnesium Alloys***

Magnesium alloys are most often formed warm or hot. Forming at these elevated temperatures is not normally required for other metals of industrial importance.

**Drawing.** At temperatures to approximately 120 °C (250 °F), soap-base lubricants, fatty esters, polymer additives in oil and water, and pastes formulated with chlorinated additives are successful lubricant systems. At temperatures in excess of 120 °C (250 °F), the choice of lubricant is restricted to synthetic fluids formulated with soap, fatty esters, and/or chlorinated compounds. Above 230 °C (450 °F), graphite and/or molybdenum disulfide in various carriers are preferred.

**Spinning.** At elevated temperatures, the synthetic fluids compounded with graphite and/or molybdenum disulfide are applied. Water carriers for the solid lubricants may be preferred to reduce smoke and the possibility of fire.

### ***Lubricants for Forming Nickel and Nickel-Base Alloys***

These metals are difficult to wet with lubricants; thus heavy-duty lubricants with exceptional film-priming characteristics are necessary for effective lubrication. On the other hand, lubricants containing sulfur, chlorine, or solid additives such as zinc oxide or lead carbonate can, if not removed from the nickel surface, cause embrittlement of the metal.

**Shearing, Blanking, and Piercing.** Oils incorporating sulfur or chlorine-containing additives may be used. Water-base lubricants of similar composition may be applied if they are removed as soon as possible after forming to prevent embrittlement. Fatty esters and polymers are frequently used as components of formulated lubricants.

**Deep Drawing.** Soap-base pastes as well as oils with fatty esters, amides, and/or sulfur and chlorine additives have been used. Emulsions fortified with amides and polymers also have been formulated and applied.

**Spinning.** Pigmented pastes and chlorinated wax in oils are successful lubricants. Plain waxes and soaps are frequently important components of these lubricants.

### ***Lubricants for Forming Titanium Alloys***

Titanium alloys gall because of the affinity of the metal for die materials. Notch sensitivity and embrittlement may also lead to splitting or cracking of formed parts. Cold and warm forming with suitable films can prevent metal-to-metal contact. Frequently, overlays of steel sheet or plastic sheet are used with an auxiliary lubricant.

**Deep Drawing.** Overlays are often used with oil-base lubricants formulated with chlorinated waxes. Oxidized or phosphated coatings are successful in relatively severe drawing operations at elevated temperatures. Graphite and/or molybdenum disulfide in oil may be used.

**Roll Forming.** Oils compounded with sulfurized or chlorinated fats are used. Oil or water-soluble polymers may also be added. Chlorinated waxes, high-molecular-weight waxes, or polymers soluble in oil may be effective for relatively moderate deformation.

**Spinning.** Colloidal graphite and/or molybdenum disulfide blended in oil may be used at temperatures up to approximately 205 °C (400 °F), in addition to chlorinated wax and/or sulfurized fat in oil. At higher temperatures, fillers such as bentonite or mica with graphite and/or molybdenum disulfide formulated into a grease are used successfully.

## Blanking of Low-Carbon Steel

A BLANK is a shape cut from flat or performed stock. Ordinarily, a blank serves as a starting workpiece for a formed part; less often, it is the end product. This article will discuss the production of blanks from low-carbon steel (such as 1008 and 1010) sheet and strip in dies in a mechanical or hydraulic press.

**Fig. 7** Use of a parting punch to make blanks not having mating adjacent surfaces

**Blanking.** Also called punching, blanking is used to cut a complete outline of a workpiece in a single press stroke. Because a scrap skeleton is usually produced, blanking involves some material waste. However, blanking is usually the fastest and most economical way to make flat parts, particularly in large quantities.

**Piercing.** Also called punching or perforating, piercing (with a flat-end punch), is similar to blanking except that the punched-out (blanked) slug is the waste and the surrounding metal is the workpiece. (See "Piercing of Low-Carbon Steel" in this article.)

**Notching.** In notching, the individual punch removes a piece of metal from the edge of the blank or strip (Fig. 8).

**Fig. 8** Notched work illustrating the use of notching for freeing metal (a) before drawing and (b) before forming and for (c) removing excess metal before forming

## Die Clearance

The terms clearance, die clearance, and punch-to-die clearance are used synonymously to refer to the space between punch and die. Clearance is important for the reliable operation of the blanking equipment, the quality and type of cut edges, and the life of the punch and die.

**Relief** in a blanking die (Fig. 9) is the taper provided to allow the severed blank to fall free. The relief angle may range from  $\frac{1}{2}^\circ$  to  $2^\circ$  from the vertical wall of the die opening. Relief is sometimes called draft or angular clearance. In some dies, the relief may start at the top of the die surface and have a taper of only 0.002 mm/mm (0.002 in./in.) per side. Some dies have a straight, vertical wear land between the top of the die and the relief.

Fig. 9 Relief in a blanking die

## Piercing of Low-Carbon Steel

PIERCING is the process of cutting holes in sheet metal, generally by removing a slug of metal, with a punch and die. Piercing is similar to blanking, except that in piercing the work metal that surrounds the piercing punch is the workpiece and the punched-out slug is scrap, while in blanking the workpiece is punched out.

Ordinarily, piercing is the fastest method of producing holes in steel sheet or strip. Generally, it is the most economical method for medium-to-high production. Pierced holes can be almost any size and shape; elongated holes are usually called slots. The accuracy of conventional tool steel or carbide dies provides pierced holes with a degree of quality and accuracy that is satisfactory for a wide variety of applications.

## Characteristics of Pierced Holes

Pierced holes are different from through holes produced by drilling or other machining methods. A properly drilled or otherwise machined through hole has a straight sidewall for the full thickness of the work metal, with a high degree of accuracy in size, roundness, and straightness. The sidewall of a pierced hole is generally straight and smooth for only a portion of the thickness, beginning near the punch end of the hole; the rest of the wall is broken out in an irregular cone beyond the straight portion of the hole, producing fracture, break-out, or die break (see Fig. 10).

Fig. 10 Characteristics of a pierced hole. Curvature and angles are exaggerated for emphasis.

Piercing typically begins as a cut that produces a burnished surface on the hole wall and some rollover (a curved surface caused by deformation of the workpiece before cutting begins) as shown in Fig. 10. The punch completes its stroke by breaking and tearing away the metal that was not cut during the beginning of the piercing operation.

## **Selection of Die Clearance**

Clearance, or the space between the punch and the sidewall of the die, affects the reliability of piercing equipment, the characteristics of the cut edges, and the life of the punch and die. Published recommendations for clearances have varied widely, with most suggesting a clearance per side of 3 to 12.5% of the stock thickness for steel.

Establishment of the clearance to be used for a given piercing or blanking operation is influenced by the required characteristics of the cut edge of the hole or blank and by the thickness and the properties of the work metal. Larger clearances prolong tool life. An optimal clearance can be defined as the largest clearance that will produce a hole or blank having the required characteristics of the cut edge in a given material and thickness. Because of differences in cut-edge requirements and in the effect of tool life on overall cost, clearance practices vary among plants and for different applications.

## **Presses**

Presses used in piercing are the same as those used in other pressworking operations. Open-back gap-frame presses of the fixed upright, fixed inclined, or inclinable type are common. The stock can be fed from the side with minimal interference from the press frame, and the parts can be removed from the front by the operator or ejected out the back by gravity or air jets.

## **Tools**

A typical piercing die consists of upper and lower die shoes, to which punch and die retainers are attached; punches and die buttons; and a spring-actuated guided stripper (Fig. 11). Small workpieces are generally pierced in compound dies that blank and pierce in the same stroke. Piercing is also done in the stations of a progressive die or a transfer die. Any of these dies can be constructed as multiple dies, in which two or more workpieces are pierced at each stroke of the press.

**Fig. 11** Layout of a typical piercing die, and three types of punches used

Figure 11 shows the three types of punches used for piercing: conventional, standard quill, and telescoping-sleeve quill. Conventional punches are generally available with a standard maximum shank diameter of 25 mm (1 in.). They can be used to pierce round, square, oblong, or rectangular holes with size and shape not exceeding 25 mm (1 in.) in diameter or a size and shape that can be machined or ground on the end of the shank.

### Fine-Edge Blanking and Piercing

FINE-EDGE BLANKING (also known as fine blanking) produces precise blanks in a single operation with smoother edges and closer tolerances than possible with conventional blanking. In fine-edge blanking, a V-shaped impingement ring (Fig. 12) is forced into the stock to lock it tightly against the die. The ring also forces the work metal to flow toward the punch, so that the part can be extruded out of the strip without fracture or die break. Die clearance is extremely small, and punch speed is much slower than in conventional blanking.

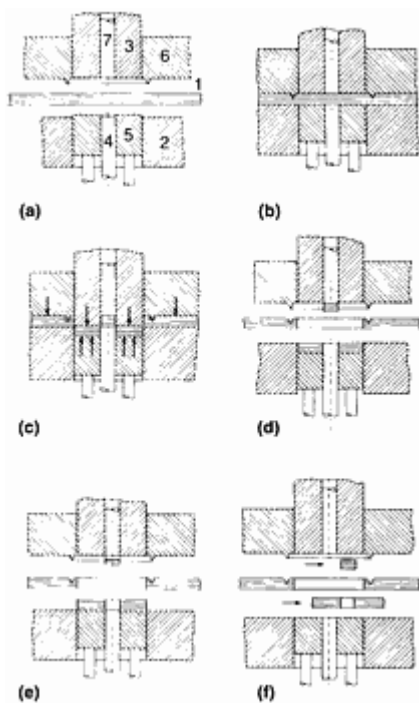

**Fig. 12 Typical tooling setup for fine-edge blanking a simple shape**

Fine-edge piercing is performed either separately or at the same time as fine-edge blanking. In piercing small holes, an impingement ring may not be needed.

No further finishing or machining is necessary to obtain blank or hole edges comparable to machined edges, or to those that are conventionally blanked or pierced and then shaved. A quick touch-up on an abrasive belt or a short treatment in a vibratory finisher may be used to remove the small burr on the blank. Specially designed single-operation or compound blanking and piercing dies are generally used for the process.

## Comparison with Conventional Blanking

Fine-edge blanking and piercing (Fig. 13) are actually more akin to cold extrusion than to a cutting operation. They are similar to conventional blanking using a compound die but with several important differences. First, fine-edge blanking and piercing use the V-shaped impingement ring. Second, they involve the independent control of the three forces acting on the workpiece (clamping, counterpressure, and blanking) obtained through the use of a triple-action press.

**Fig. 13 The fine-edge blanking process. (a)** Work material is fed into the die. 1, work material; 2, die plate; 3, punch; 4, piercing punch; 5, ejector/counterpunch; 6, impingement ring; 7, slug ejector. (b) The die closes, and the V-shaped impingement ring is embedded into the work material. (c) The part is blanked. The

impingement ring maintains pressure while blanking pressure and counterpressure are exerted against the part. (d) Slugs are ejected from the top down. (e) Part is ejected from the bottom up by reversing counterpressure. (f) Parts and slugs are removed from the die area.

The very small clearance between punch and die is another difference between fine-edge blanking and conventional blanking. Combined with correspondingly tighter tolerances on both punch and die and the fact that the punch enters the die only a slight amount if at all, this feature prevents cracking of the workpiece and results in smooth blanked and pierced edges.

## Process Capabilities

Holes with diameters as small as 50% of stock thickness can be pierced in low-carbon steel. In high-carbon steel, the smallest hole diameter is about 75% of stock thickness. Holes can be spaced as close to each other, or to the edge of the blank, as 50 to 70% of stock thickness. Total tolerances obtainable are 0.013 mm (0.0005 in.) on hole diameter and for accuracy of blank outline; 0.025 mm (0.001 in.) on hole location with respect to a datum surface; and 0.025 mm (0.001 in.) on flatness.

No die break shows on the sheared surface of the hole. Blank edges may be rough for a few thousandths of an inch of thickness on the burr side of the part when the width of the part is about twice the stock thickness or less. Finish on the sheared edge is governed by the condition of the die edge and the land within the die. Parts fine-edge blanked from stainless steel will have a surface finish of 0.8  $\mu\text{m}$  (32  $\mu\text{in.}$ ) or better. Smooth edges also are produced on spheroidize-annealed steel parts. Burr formation increases rapidly during a run, necessitating frequent grinding of the cutting elements.

Chamfers can be coined around holes and on edges. Forming near the cut edge, or forming offset parts with a bend angle up to 30° is possible under restricted conditions. Metals up to 3.18 mm ( $\frac{1}{8}$  in.) thick having a tensile strength of 586 to 793 MPa (85 to 115 ksi) are easily blanked. Parts up to 13 mm ( $\frac{1}{2}$  in.) thick can be blanked if press capacity is available. Material thicker than 3.18 mm ( $\frac{1}{8}$  in.), especially steel having a carbon content of 0.25% or more, requires an impingement ring on the die so that the corners on the part will not break down. The edges of parts made of 1018 steel work harden as much as 7 to 12 points HRC during blanking. The cutting speed for fine-edge blanking is 7.6 to 15.2 mm/s (0.3 to 0.6 in./s).

## Work Materials

**Carbon and Alloy Steels.** The easiest materials to fine-edge blank are low-carbon steels (<0.25% C). Thin parts, however, have been fine-edge blanked from plain carbon steels containing up to about 0.95% C. Alloy steels can be fine-edge blanked only in the fully annealed, spheroidized condition.

**Stainless Steels.** Austenitic stainless steels, such as AISI types 301 to 304 and 316, can be fine-edge blanked in the fully annealed condition. These materials, as well as the ferritic type 430 and martensitic type 416 (both fully annealed), have good blanked edges but cause higher tool wear than do plain carbon steels.

**Aluminum.** Most aluminum alloys, with the exception of alloy 2024, can be fine-edge blanked in the O (annealed) temper. Wrought alloys of the 1xxx, 3xxx, and 5xxx series can be fine-edge blanked in the H (strain hardened) temper with excellent results. In thinner gages, alloys 6061 and 7075 can be fine-edge blanked in the T3 or T4 condition.

**Copper.** Copper alloys are easily fine-edge blanked. The most workable alloys, such as alloy C27400 (yellow brass, 63%) can be fine-edge blanked even in the full hard condition. Other brasses, such as C26000 (cartridge brass, 70%) and C26800 (yellow brass, 66%) can be worked in the annealed, quarter-hard or half-hard condition. Beryllium copper alloys can be fine-edge blanked in the annealed condition, as can pure copper, soft bronzes, Monel alloys, nickel-silvers, silvers, and gold.

---

## Tools

The design of tools for fine-edge blanking is based on the shape of the part, the method of making the die, the required load, and the extremely small punch-to-die clearance. The considerable loading and required accuracy dictate that the press tools be sturdy and well supported to prevent deflection. The small clearance presupposes precise alignment of the punch and die.

**Design.** A basic tool consists of three functional components: the die, the punch, and back-pressure components. To produce high-quality blanks, the punch-to-die clearance must be uniform along the entire profile and must be suitable for the thickness and strength of the work metal. Clearance varies between 0.005 and 0.01 mm (0.0002 and 0.0004 in.).

Some diemakers put a small radius on the cutting edge of the die. This causes a slight bell-mouth condition, which produces a burnishing action as the blank is pushed into the die, improving the edge finish.

## Blanking and Piercing of Electrical Steel Sheet

ELECTRICAL STEELS are used for various static and rotating electrical devices. They are magnetically soft materials; that is, they are not permanent magnets but have properties that make them useful in electrical applications. Most of the parts produced from electrical steels must be laminated. A lamination consists of flat blanked sheets of a particular shape that are stacked to a given height and fastened together by riveting, bolting, or welding. Electrical steel sheet is available in coils or cut-to-length. For most applications, stock thickness ranges from 29 to 24 gage (0.343 to 0.607 mm, or 0.0135 to 0.0239 in.).

Flat laminations are blanked and pierced from electrical sheet. Laminations can range in diameter from less than 25 mm to 1.3 m (1 to 50 in.) or more (Fig. 14a). Others (Fig. 14b) can range in length from less than 25 to 305 mm (1 to 12 in.) or more.

**Fig. 14** Typical laminations blanked and pierced from electrical sheet. (a) Laminations for rotating electrical machinery are blanked and pierced in single-station dies (Fig. 15) or progressive dies (Fig. 16). Slots can also be made in precut blanks, one at a time, with notching dies. (b) Typical laminations blanked and pierced from

electrical sheet for application in units other than rotating machines. Dimensions given in inches

Material used for electrical sheet can be classified in the following order with respect to decreasing ease of blanking, piercing, and notching: conventional flat-rolled low-carbon steels such as 1008, nonoriented silicon steels, and oriented silicon steels.

## Presses

A general-purpose punch press in good mechanical condition is acceptable for stamping laminations, but large-volume production of laminations by progressive-die methods requires the use of high-productivity presses.

## Dies

Single-station and progressive dies are both used for making laminations.

**Single-Station Dies.** Each single-station die performs one operation, and a set of dies for a lamination can be mounted in one press or in different presses. Simple laminations (Fig. 14) are usually produced in one operation. More complex parts may require several operations. Figure 15 shows a typical sequence for the production of stator and rotor laminations in four operations.

**Fig. 15** Sequence of operations for producing stator and rotor laminations using single-station dies. Operation 1, stock blanked and pierced; operation 2, stator lamination notched; operation 3, rotor lamination separated from stator lamination; operation 4, rotor lamination notched. Compare with Fig. 16.

Single-station dies can be used for punching any lamination, regardless of size, composition, shape or quality requirements. However, because production with single-station dies is relatively slow, the cost per piece is high for mass production.

**Progressive Dies.** Laminations can be produced in large quantities at a lower cost in progressive dies. Progressive dies perform a series of operations at two or more die stations during each stroke of the press. Each working, or active, station in the die performs one or more operations. The work material progresses through successive stations until a completed part is produced (Fig. 16). Idle stations, in which no work is performed, are added to provide strength to the die, to facilitate material travel through the die, to simplify construction, or to increase flexibility for die changes.

**Fig. 16** Blanking and piercing sequence for rotor and stator laminations in a five-station progressive die. Two pilot punches were used at each station. Station 1, pierce pilot holes, rotor slots, and rotor-shaft hole; station 2, pierce stator rivet holes and blank rotor; station 3, pierce stator slots; station 4, idle; station 5, blank stator. Compare with Fig. 15.

## Press Bending of Low-Carbon Steel

PUNCH PRESSES are used for bending, flanging, and hemming low-carbon steel when production quantities are large, when close tolerances must be met, or when the parts are relatively small. Press brakes are ordinarily used for small lots, uncritical work, and long parts.

To estimate the press capacity needed for bending in V-dies, the bending load in tons can be computed from:

$$L = \frac{lt^2kS}{s}$$

where  $L$  is press load, in tons;  $l$  is length of bend (parallel to bend axis), in inches;  $t$  is work-metal thickness, in inches;  $k$  is a die-opening factor (varying from 1.2 for a die opening of  $16t$  to 1.33 for a die opening of  $8t$ );  $S$  is tensile strength of the work metal, in tons per square inch; and  $s$  is width of die opening, in inches.

For U-dies, the constant  $k$  should be twice the values shown above.

## Bendability and Selection of Steels

Temper of the metal affects bendability. Figure 17 shows the types of bends for which the standard AISI tempers of cold-rolled carbon steel strip are suited. Stock of No. 1 temper is not recommended for bending, except to large radii. Stock of No. 2 temper can be bent  $90^\circ$  over a radius equal to strip thickness, perpendicular to the rolling direction. Stock of No. 3 temper can be bent  $90^\circ$  over a radius equal to strip thickness, parallel to the rolling direction; it can also be bent  $180^\circ$  around a strip of the same thickness when the bend is perpendicular to the rolling direction. Stock of No. 4 or No. 5 temper can be bent  $180^\circ$  flat on itself in any direction. The No. 5 temper stock may develop stretcher strains and should not be used if these markings are objectionable.

**Fig. 17** The most severe bend that can be tolerated by each of the standard tempers of cold-rolled carbon steel strip. Stock of No. 1 (hard) temper is sometimes used for bending to large radii; each lot should be checked for suitability, unless furnished for specified end use by prior agreement. Hardnesses shown are for steel containing 0.25% C (max) in the three hardest tempers and 0.15% C (max) in the No. 4 and 5 tempers. Hardness for No. 1 temper applies to thicknesses of 1.8 mm (0.070 in.) and greater; for thinner sheet, hardness would be a minimum of 90 HRB.

**Minimum Bend Radius.** Carbon content, quality, and temper of some grades of carbon steel strip and sheet determine minimum bend radius. This is especially true of hot-rolled steel, for which a change from commercial quality to drawing quality reduces minimum bend radius by 33 to 50%. Low-carbon steels of commercial quality are suitable for 90 and 180° bends.

Alloy composition also determines minimum bend radii for common grades of carbon and low-alloy steels. High-strength low-alloy steels, because of their higher yield strength and lower ductility, are more difficult to bend than plain carbon steels--requiring more power, greater bend radii, more die clearance, and greater allowance for springback. It may be necessary to remove shear burrs and to smooth corners in the area of the bend. Whenever possible, the axis of the bend should be across the direction of rolling. If the bend axis must be parallel with the rolling direction, it may be necessary to use cross-rolled material, depending on the severity of the bend.

**Effect of Edge Condition on Minimum Bend Radius.** For low-carbon steel, the condition of the edge perpendicular to the bend axis has little effect on the minimum bend radius. Steels that are susceptible to work hardening or hardening by heating during gas or electric-arc cutting may crack during bending because of edge condition. For these steels, burrs and hardened edge metal in the bend area should be removed to prevent fracture. Edges can be prepared for bending by grinding parallel with the surface of the sheet and removing sharp corners in the bend area by radiusing or chamfering.

If the burr side is on the inside of the bend, cracking is less likely during bending. This is important on parts with small bend radii in comparison with the metal thickness and on parts with metal thickness greater than 1.6 mm ( $\frac{1}{16}$  in.), because fractures are likely to start from stress-raising irregularities in the burr edge if it is on the outside of the bend.

**Effect of Metal Thickness on Minimum Bend Radius.** Minimum bend radii are generally expressed in multiples or fractions of the thickness of the work metal. On parts that require a minimum flange width or a minimum width of flat on the flange, stock thickness will limit both of these dimensions. If thickness is not critical in the design, the use of thinner stock can make the bending of small radii and narrow flanges feasible.

Hot bending is necessary when the product shapes are too complex or when bend radii are too small for cold forming. The high-strength low-alloy steels can be successfully hot bent at temperatures as low as 650 °C (1200 °F); however, when maximum bendability is needed, temperatures of 845 to 900 °C (1550 to 1650 °F) are recommended. Cooling in still air from these temperatures returns the material nearly to the as-rolled mechanical properties.

## Die Construction

The same types of bending dies as those used in press brakes can generally be used in presses. However, there are major differences:

- Because presses ordinarily are not long and narrow like press brakes, more consideration must be given to clearance for removing the finished workpiece when the press is open, as well as clearance for the legs of the bend when the piece is being formed. The bed dimensions of a press also limit the size of workpiece that can be bent.
- Presses cycle rapidly, and shut height is not as easy to change; therefore, fewer pieces are bent in air. More frequently, pieces are formed by bottoming the dies. This has the advantage of decreasing springback.
- Presses are usually used for workpieces less than 610 mm (2 ft) long, and press brakes for pieces longer than 610 mm (2 ft). However, the automotive industry bends very large sheet metal structural members on large presses.

**V-dies** are composed of a V-block for a die and a wedge-shaped punch (Fig. 18a). The width of the opening in the V is ordinarily at least eight times the stock thickness. In bending, the workpiece is laid over the V in the die, and the punch descends to press the workpiece into the V to form the bend.

**Fig. 18** Bending in a V-die and a wiping die

**Wiping Dies.** In the wiping die, Fig. 18(b), a pressure pad that is either spring loaded or attached to a fluid cylinder clamps the workpiece to the die before the punch makes contact. The punch descends and wipes one side of the workpiece over the edge of the die. The bend radius is on the edge of the die.

**Interchangeable V-Dies.** To produce various sizes of V-bends in a punch press, four different sizes of punches can be mounted into the punch holder, which is attached to the press slide. In operation, the groove in the die that gives the needed bend is aligned with the punch, and the die is then fastened to the bolster plate on the press bed. Adjustable side and end stops can be used to position the blanks for bending.

**U-Bending Dies.** U-shaped pieces can be bent in a die. The width of the U is adjustable by means of spacers and by changing the width of the knockout. Punches can be mounted in the press with a holder similar to that for a V-die and can be provided to the proper width and shape to make either a U or a channel shape.

**Rotary-bending dies** (Fig. 19) are used to make bends or twists in bars or strip. They rely on cam action to rotate the workpiece. The strip metal is twisted 90° to make a connecting link. The punch is made in two major parts: a hollow cylinder that is solidly mounted to the ram, and inside it, a solid cylinder that is free to rotate. In the inner cylinder, a 90° helical cam groove in its cylindrical surface engages a hardened pin in the outer cylinder.

**Fig. 19** Rotary bending die used for 90° twisting of strip metal. Die is shown in closed position; inner cylinder has rotated to give workpiece a 90° twist. The auxiliary cam prevents rotation of the inner cylinder until it is free of workpiece.

When the ram descends, a slot in the face of the inner cylinder engages the end of the workpiece. After the inner cylinder bottoms, as the ram continues to move down, the spring compresses, moving the outer cylinder down over the inner cylinder. The action of the pin in the groove makes the inner cylinder rotate, giving the workpiece a 90° twist.

## Lubrication

Lubrication is less important for most bending operations than for other types of forming. In many bending operations, no lubricant is used; in others, the mill oil remaining on the stock or a light mineral oil applied before forming is sufficient to prevent galling.

Exceptions to this practice are hole flanging, compression and stretch flanging, and severe bending in which wiping, ironing, or drawing of the work metal may call for more effective lubrication.

## Press-Brake Forming

IN PRESS-BRAKE FORMING, the workpiece is placed over an open die. It is then pressed down into the die by a punch actuated by the ram portion of a machine called a press brake. The process is most widely used to form relatively long, narrow parts that are not adaptable to press forming and for applications in which production quantities are too small to warrant the tooling cost for contour roll forming.

Simple V-bends or more intricate shapes can be formed in a press brake. Operations such as blanking, piercing, lancing, shearing, straightening, embossing, beading, wiring, flattening, corrugating, and flanging can be formed in a press brake.

press-brake forming, as in other forming processes, when a bend is made, the metal on the inside of the bend is compressed or shrunk, and that on the outside of the bend is stretched. The applied forces create a strain gradient across the thickness of the work metal in the area of die contact. Tensile strain occurs in the outer fiber, and compressive strain in the inner fiber; both decrease in magnitude toward the neutral axis.

The setup and tooling for press-brake forming are relatively simple (Fig. 20). The distance the punch enters the die determines the bend angle and is controlled by the shut height of the machine. The span width of the die, or the width of the die opening, affects the force needed to bend the workpiece. The minimum width is determined by the thickness of the work and sometimes by the punch-nose radius. After the tools have been set up and the shut height has been adjusted, the press brake is cycled, and the work metal is bent to the desired angle around the nose radius of the punch.

**Fig. 20** Typical setup for press-brake forming in a die with a vertical opening.  $B$ , punch radius;  $s$ , span width;  $r$ , die radius;  $t$ , metal thickness

## Applicability

Press-brake forming is most widely used for producing shapes from ferrous and nonferrous metal sheet and plate. Although sheet or plate 6.4 mm ( $\frac{1}{4}$  in.) thick or less is most commonly formed in a press brake, metals up to 25 mm (1 in.) thick have often been used.

**Workpiece Dimensions.** The length of plate or sheet that can be bent is limited only by the size of the press brake. For example, a 5350 kN (600 tonf) press brake can bend a 3 m (10 ft) length of 19 mm ( $\frac{3}{4}$  in.) thick low-carbon steel plate to a  $90^\circ$  angle, with an inside radius of the bend equal to stock thickness. If the included angle of the bend is greater than  $90^\circ$ , if the bend radius is larger than stock thickness, or if the length of bend is less than the bed length, a press of correspondingly lower capacity can be used.

**Work Metals.** Press-brake forming is applicable to any metal that can be formed by other methods, such as press forming and roll forming. Low-carbon steels, high-strength low-alloy steels, stainless steels, aluminum alloys, and copper alloys are commonly formed in press brakes. High-carbon steels and titanium alloys are less frequently formed in a press brake, because they are more difficult to form.

## Press Brakes

The primary advantages of press brakes are versatility, the ease and speed with which they can be changed over to a new setup, and low tooling costs. A press brake is basically a slow-speed punch press that has a long, relatively narrow bed and a ram mounted between end housings (Fig. 21). Rams are actuated mechanically or hydraulically.

**Fig. 21** Principal components of a mechanical press brake

**Mechanical Press Brakes.** The ram of a mechanical press brake is actuated by a crank or an eccentric through a gear train with a clutch and a flywheel. The gear train is usually designed to provide fast movement of the ram. Shut height (the distance between ram and bed at the bottom of the stroke) is adjustable by means of a screw (usually powered) in the pitman, or link, at each end of the ram. The length of the ram stroke, however, is constant.

**Hydraulic Press Brakes.** The ram of a hydraulic press brake is actuated by two double-acting cylinders, one at each end of the ram. Force supplied by the hydraulic mechanism will not exceed the press rating; therefore, it is almost impossible to overload a hydraulic press brake. (When thicker metal is inadvertently used, the ram stalls.) Therefore, frames can be lighter and less costly than those for mechanical press brakes, which are subject to overloading.

**Hybrid Press Brake.** The hydraulic-mechanical hybrid consists of a mechanical press brake driven by a rotary hydraulic motor. Containing a vane that rotates  $270^\circ$  between stops, the rotary hydraulic motor has replaced the piston used in a hydraulic cylinder. As it moves between the two stops, the motor propels the eccentric shaft through the complete cycle, driving the ram to the stroke bottom and back to the top. The hybrid press brake combines the best features of both mechanical and hydraulic press brakes. It offers the same accuracy and operating speeds obtainable with the mechanical press brake while providing the adjustable length and controllability of the hydraulic press brake.

## Dies and Punches

V-bending dies and their corresponding punches (Fig. 22a-d) are the tools most commonly used in press-brake forming. The width of the die opening is usually a minimum of eight times the thickness of the work metal ( $8t$ ). The nose radius of the punch should not be less than  $1t$  for bending low-carbon steel, and it must be increased as the formability of the work metal decreases. The radius of the V-bending die must be greater than the nose radius of the punch by an amount equal to or somewhat greater than the stock thickness to allow the punch to bottom.

**Fig. 22** Dies and punches most commonly used in press-brake forming. (a)  $90^\circ$  V-bending. (b) Offset bending. (c) Radiused  $90^\circ$  bending. (d) Acute-angle bending. (e) Flattening, for three types of hems. (f) Combination bending and flattening. (g) Gooseneck punch for multiple bends. (h) Special clearance punch for multiple bends

**Offset Dies.** Punch and die combinations like the one shown in Fig. 22(b) are often used to produce offset bends. Because an offset bend requires about four times as much force as a  $90^\circ$  V-bend, offset bending is usually restricted to relatively light-gage metal (3.2 mm, or  $\frac{1}{8}$  in., or less). The depth of offset ( $h$  in Fig. 22b) should be a minimum of six times the work metal thickness to provide stability at the bends.

**Radius forming** is done with a  $90^\circ$  die and a punch, each having a large radius (Fig. 22c). When the punch is at the bottom position, the inside radius of bend in the workpiece conforms to the radius of the punch over a part of the curve.

The harder the punch bottoms, the more closely the work metal wraps around the punch nose, resulting in a smaller radius of bend and less springback. Uniformity of bend angle depends greatly on the uniformity of the work metal thickness.

**Acute angles** are formed by the die and punch (Fig. 22d). The air-bending technique, which used a die deep enough so the workpiece does not bottom out on the die, is often used to produce acute angles.

**Flattening dies**, shown in Fig. 22(e), are used to produce three types of hems after the metal has been formed into an acute angle. A combination die produces an acute angle on one workpiece and a hem on another, so that a piece is started and a piece completed with each stroke of the press brake.

**Gooseneck punches** (Fig. 22g) and narrow-body or special clearance punches (Fig. 22h) are used to form workpieces to shapes that prevent the use of punches having conventional width.

## Selection of Tool Material

Selection of tool material for punches and dies used in press brakes depends on the composition of the work metal, the shape of the workpiece (severity of forming), and the quantity to be produced. The tool material used for press-brake bending and forming ranges from hardwood to cemented carbide, although the use of carbide has usually been confined to inserts at high-wear areas. Hardwood and carbide represent the rare extremes; hardwood is suitable only for making a few simple bends in the most formable work metal, and cemented carbide would be considered only for making severe bends in a less-formable work metal (such as high-strength low-alloy steel) in high production. Most dies and punches used for simple V-bending operations are made from low-carbon steel (such as 1020) or gray iron. Both of these materials are inexpensive and give acceptable tool life in mild service.

## Press Forming of Low-Carbon Steel

PRESS FORMING shapes the workpiece with a punch and die. The applied forces may be tensile, compressive, bending, shearing, or various combinations of these. In some applications, the metal requires appreciable stretching in order to retain the shape of the formed part.

## Presses

Restriking, coining, and embossing are usually done in presses with more available force capacity than that needed for simple forming of similarly sized areas, because in these operations the metal is confined while being forced into plastic flow. Progressive dies are used in presses with enough force capacity to meet the total demands of the various stations.

**Transfer Presses.** In transfer machines (eyelet machines), the mechanism for moving the workpiece from station to station is a part of the machine to which suitable transfer fingers are attached. Transfer presses are generally long-bed straight-side presses. The transfer mechanism as a part of the press is actuated by the main press drive or is powered separately. A dial feed is a transfer mechanism that moves the workpiece from die to die in a circular path rather than in a straight line. Transfer press technology has progressed to the point at which large automotive outer body panels can be formed in transfer presses.

**Multiple-slide machines** are designed for automatic, complete production of a variety of small formed parts. In these units flat stock is fed into a straightener and then a feed mechanism. It then progresses through one or more presses incorporated in the multiple-slide machine for operations such as piercing, notching, and bending--often in a progressive die. The feed mechanism then moves the metal into the multiple-slide forming area, where it is first severed by a cutoff mechanism to predetermined lengths. The piece is usually formed around a center post by four sets of tools mounted 90° apart around the forming post. Finally, the part is stripped off the center post and dropped through a hole in the bed.

## Speed of Forming

Speed of forming has little effect on the formability of steels used for simple bending or flanging or for moderate stretching. The maximum velocity of the punch when it contacts the blank in conventional press forming is usually not greater than about 1 m/s (200 ft/min). However, the steels used for most parts that involve local stretching of more than

20% in forming move considerably over the face of the punch or flow appreciably over the blankholder. The flow of the metal in such operations is controlled by frictional forces so sensitive to speed that the steel often stretches to failure before moving against the frictional forces, provided the punch velocity exceeds a critical value, which differs for each steel and die combination. A maximum punch velocity of 0.2 m/s (40 ft/min) is recommended; high punch speeds also shorten tool life.

## Lubrication

The lubricant used usually has little effect on the grade of steel selected to form a given part. The main purposes of a lubricant are to prevent die galling and die wear and to reduce the friction over critical areas, thus allowing proper flow of metal and possibly a reduction in severity class. The selection of the optimal lubricant for a given part is complex and depends on part geometry and the forming process used.

In progressive dies, a light oil sprayed on the strip as it enters the die is often enough to keep the stock lubricated through all stages. The oil is generally applied to the stock between the feeding device and the die.

## Dies

Dies for press forming low-carbon steel are made from a wide range of materials, including plastics, cast irons, tool steels, and cemented carbides. Severity of forming, number of parts to be produced, workpiece shape, work metal hardness, specified surface condition, and tolerances affect selection of the die material.

Low-carbon steel can be formed by any of the several types of dies described in this section. Workpiece size and shape, production volume, tolerances, and available presses are the major factors that determine the most suitable type of die for a specific application.

**Single-operation dies** perform one operation at a time and are individually loaded and unloaded. They are usually set up in a press, and the operation is performed on a specific lot size. The die is then removed from the press, and the next die in the sequence is set up. For continuous production, a line of presses--each operating a single die--can produce finished pieces from raw stock without interruption for change in setup. Occasionally, more than one die is set up in a press at a time, and the parts are moved manually from one die to the next.

**Compound dies** are one-station dies in which more than one operation is done on a workpiece in one press stroke without relocating the workpiece in the die. The operations must be such that they do not weaken the die elements or restrict other operations. The operations generally are successive in the course of the press stroke, rather than simultaneous. Typical combinations of operations include: cutting a blank from a strip and then forming, lancing and forming a tab or louver, and forming a flange and embossing a stiffening bead.

When a die is used for blanking and forming a part, holes often can be pierced in the bottom with the same die. When pierced holes are required in a flange, piercing should be done after the flange has been formed; otherwise, the hole (and perhaps the edge of the flange) can distort. The combination of lancing and forming is common. Continued travel of the lancing punch does the forming. Flanging can be combined with forming or embossing if no metal flow is necessary after the flange has been formed.

Several operations can be performed successively on a workpiece in a press using two or more compound or single-operation dies. The parts can be transferred manually from die to die, eliminating storage and transfer between presses. High-capacity, large-bed press can be used most efficiently for several operations during each press stroke.

**Progressive dies** contain two or more cavities, or die stations. One or more operations are done on the workpiece at each die station. As the outline of the workpiece is developed in the trimming or forming stations, connecting tabs link the workpiece to the strip until the workpiece reaches the last station, where it is cut off and ejected from the die. Pilot holes that are engaged by pilot pins in the die keep the workpieces aligned and properly spaced as they progress through the die.

Although a progressive die runs more slowly than a single-operation die or a compound die for similar work, overall production is usually higher because the die is operated more continuously. Dies are used to perform an almost endless variety of operations on one piece. Operations that can be combined in a progressive die include notching, piercing, coining, embossing, lancing, forming, cupping, drawing, and trimming.

**Transfer dies** are similar to progressive dies except that the workpieces are not attached to a strip but are mechanically moved from station to station. A blank is automatically fed into the first station and moved to the next at each press stroke. The first station can be a blanking die, which cuts a blank from manually or automatically fed stock during each press stroke.

## Press Forming of High-Carbon Steel

HIGH-CARBON STEEL strip (including spring steel and tool steel) is blanked, pierced, and formed to make a variety of parts. The practices, precautions, presses, and tools used in making high-carbon steel parts are comparable to those used for producing similar parts of low-carbon steel. There are differences, however: more force is required for high-carbon steel because of its higher strength; greater clearance between the punch and die is necessary in blanking and piercing; and more wear-resistant tool material may be required before acceptable tool life can be obtained.

## Blanking and Piercing

The most important difference between the blanking and piercing of high-carbon and of low-carbon steel is that greater clearance between punch and die is required for high-carbon steels. Although the complexity of the workpiece and the total quantity to be blanked are more significant factors than work metal composition in the selection of tool material, the hardness of the work metal is nevertheless significant. Carbide dies are often used for large quantities. Die life in blanking and piercing of high-carbon steel varies with different applications, depending greatly on the dimensional accuracy that must be maintained and the burr height that can be tolerated on the blanked parts.

## Forming Pretempered Steel

Mild forming of high-carbon steel in the quenched-and-tempered (pretempered) condition (usually 47 to 55 HRC) is common practice. The severity of forming that can be done without cracking of the work metal depends mainly on thickness. When metal is no more than about 0.38 mm (0.015 in.) thick, relatively severe bends without fracturing the work metal are possible. However, as metal thickness increases, the amount of forming of pretempered steel decreases rapidly.

## Forming Annealed Steel

Moderately severe forming is possible with cold-rolled stock that has not been quenched and tempered and on high-carbon steel that has been spheroidize-annealed. These materials usually are hardened and tempered after forming to improve spring properties. Table 6 shows the effect of carbon content of steel on bendability and demonstrates the major importance of sheet thickness.

**Table 6 Typical effects of carbon content and sheet thickness on minimum bend radius of annealed steels**

Thickness of sheet		Minimum bend radius

## Press Forming of Coated Steel

COATED STEEL sheet or strip is formed in the same presses as those used for forming uncoated steel. Forming procedures, however, sometimes must be modified, depending on the type of coating. During processing, scratching or breaking of the coating (sometimes only marring of the surface) must be avoided because these defects could cause rejection of the finished part.

## Effect of Coating Process on Substrate Formability

Coated steels can be categorized according to the formability of the substrate. However, the method used to apply the coating can affect the metallurgical structure of the substrate and can therefore affect its properties.

The most prevalent coated steel that is currently in use is zinc-coated (galvanized) steel. Steel can be galvanized by hot dipping or electrogalvanizing.

**Hot-Dip Galvanizing.** Hot-dip galvanized steel is produced by one of two basic processes, depending on the properties required. A low-temperature process (455 to 480 °C, or 850 to 900 °F) is used when the steel is pre-annealed to achieve a soft, ductile structure and good formability. Higher temperatures (675 to 870 °C, or 1250 to 1600 °F) are used for in-line annealing (that is, the steel substrate is annealed as the hot dip coating is applied). Because of the short duration of the in-line annealing process, steels processed by this method are less formable than steels that are coated at lower temperature. Depending on carbon content, steels coated by the high-temperature hot-dip process may require post-annealing to enhance formability. Low-carbon steels often require post-annealing to restore full formability; extra-low-carbon steels (0.01% C) normally do not require post-annealing.

**Electrogalvanizing.** Coated at temperatures at or near ambient, the properties of electrogalvanized steel sheet are nearly identical to those of uncoated cold-rolled steel.

## Galvanized Steels

The formability of galvanized steels is reduced to some extent by the brittle iron-zinc alloy layer that is produced between the metallic zinc and the steel base during hot-dip galvanizing. The thickness of the alloy layer depends on the temperature-time cycle in galvanizing, but it is also affected by the percentage of other metals, especially lead and aluminum, in the molten-zinc bath. The decrease in formability is usually in direct proportion to the thickness of the iron-zinc alloy layer. Modern hot-dip galvanizing processes use special thermal cycles and low-lead low-aluminum coating materials to minimize formation of the iron-zinc alloy layer.

In deep drawing, the beneficial effects of the free-zinc layer on the surface of the work metal outweigh the adverse effect of the alloy layer, often permitting greater reductions and greater draw depths than with similar uncoated steel. The layer of soft metallic zinc prevents galling during forming by eliminating direct contact between the steel substrate and the punch.

Formability is also influenced by other factors; chiefly, the initial properties of the steel base; the amount of mechanical work before or after galvanizing; and the response of the steel to the heating cycle for galvanizing, to supplementary heat treatments, and to aging. These factors often have a greater effect on the formability of galvanized steel than the galvanized coating does.

**Tools** for forming zinc-coated steel parts are conventional, made of cast iron and standard tool steels. However, parts formed of commercial quality (CQ) continuous-annealed steel or of steel over 1.52 mm (0.060 in.) thick require more compensation for springback than conventional box-annealed steel and uncoated steel, which have lower yield strengths and hardnesses. Post-heat-treated continuous-annealed and box-annealed drawing quality (DQ) galvanized steels require the same tooling as uncoated steels in most forming operations.

## Aluminum-Coated Steels

Moderately severe forming is possible with hot-dip aluminum-coated (aluminized) steel. The same dies and pressworking practices used for uncoated steel are applicable to aluminum-coated stock. Drawing compounds are recommended for forming and drawing operations. Requirements for corrosion resistance in service often limit the permissible severity of forming. Hairline cracks that develop in the aluminum coating lead to lower service life at high temperature or in atmospheric exposure.

## Tin-Coated and Terne-Coated Steels

The steels to which tin and terne coatings are applied vary in composition for different products and among different manufacturers, but are generally low-carbon grades similar to 1008 or 1010. Nearly all of the common forming methods are used on tin-coated and terne-coated low-carbon steel. Spinning is not ordinarily performed on these materials because of the likelihood of excessively thinning or fusing the coatings. The thickness of tin on electroplated mill products ordinarily ranges from 0.4 to 2.3  $\mu\text{m}$  (15 to 90  $\mu\text{in.}$ ) per side. Hot-dip products have coating thicknesses of 1.7 to 3.8  $\mu\text{m}$  (66 to 150  $\mu\text{in.}$ ) per side.

The behavior of terneplate in forming is generally the same as that of tin plate. Because of its high lead content, terneplate is toxic and therefore not suitable for food containers, but it is formed into containers for gasoline and paint. Terneplate is used in formed products such as roofing, doorframes, and automotive parts because of its excellent resistance to atmospheric corrosion and its low cost.

## Nickel-Plated and Chromium-Plated Steels

Press forming and roll forming are sometimes performed on steel that has been electroplated in the coil with decorative copper-nickel or copper-nickel-chromium. More often, however, parts are formed to final shape before electroplating with these materials.

Conventional lubricants can be used to press form this material, particularly in high-volume production. Sometimes, however, no lubricant is used in making decorative parts. Instead, surface contact between the work metal and tools is prevented by the use of strippable plastic coatings or adhesive-backed paper on the work metal, or of loose paper between the work metal and the punch or the die. These materials protect the decorative finish on the preplated steel, prevent galling, and reduce friction for forming. They can also be removed from the completed parts without harming the finish.

## Forming of Steel Strip in Multiple-Slide Machines

MULTIPLE-SLIDE FORMING is a process in which the workpiece is progressively formed in a combination of units that can be used in various ways for the automated fabrication of a large variety of simple and intricately shaped parts from coil stock or wire. Operations such as straightening, feeding, trimming, blanking, embossing, coining, lettering, forming to shape, and ejecting can all be done in one cycle of a multiple-slide machine. Forming is generally limited to bending operations, but the four slides and center post permit the fabrication of very complex parts. Deep drawing is generally not done in the forming or press stations of a multiple-slide machine.

## Applicability

Multiple-slide forming is used to produce shapes from coiled strip or wire. The maximum size of workpiece that can be formed from strip metal in a multiple-slide machine is 203 mm (8 in.) wide by 685 mm (27 in.) long. Parts made from wire up to 1015 mm (40 in.) long (or longer if a special machine is used) and up to 9.5 mm ( $\frac{3}{8}$  in.) in diameter can be formed automatically from coil stock.

If the work metal is comparatively thin and the bending is not severe, tempered strip material can be formed. Plated or coated materials can be formed, but it is usually better to coat after forming because it is difficult to avoid marring coated surfaces during forming. However, nonmetallic inserts at appropriate points in the straightener, feeder, and forming tools can be used to reduce tool marks.

Springback must be considered in bending materials such as stainless steel, phosphor bronze, certain grades of brass and beryllium copper, or high-carbon steel. Adjustments can be made in the forming tools to provide the amount of overbending required for the accuracy of the finished work.

More than one piece can be made in each cycle of a multiple-slide machine. For example, a part that had been made in seven conventional press operations was replanned for the multiple-slide production of four pieces per cycle at 200 cycles per minute.

## Multiple-Slide Machines

Multiple-slide machines are made in a range of sizes, all similar in construction and principle. The larger machines have a longer die space, which allows more die stations to be used in the manufacture of complicated components. Generally, the number of strokes per minute decreases and the horsepower increases as the machine size increases.

The four forming slides of a typical multiple-slide machine are generally sufficient for ordinary part-forming needs. However, complex parts can be formed at two or three levels around the center post, thus doubling or tripling the number of forming positions available.

Figure 23 shows a plan view of the main units of a medium-size multiple-slide machine. In a typical machine, four shafts (A, B, C, and D) mounted to a flat-top bed plate are driven at equal speed through spur gearing (E) by an electric motor. Each of the four shafts is fitted with a positive-action cam (F) that drives a slide (G) on which the forming tools can be secured. In the center of the machine is a vertical post (H) into which the center post or former is fixed and around which the work material is bent. The formed workpiece is removed from the center post by a stripper mechanism, which usually consists of a hardened steel plate surrounding the center post and secured to a vertical rod operated by a cam (F) on the right-hand shaft to give up-and-down motion to the stripper.

**Fig. 23** Plan view of a multiple-slide machine showing major components. A to D, integrated shafts; E, spur gearing; F, positive-action cam; G, slide; H, vertical post; J, bell crank; K and R, cams; L, stock straightener; M, automatic gripper in feed slide; N, links; O, adjustable crank; P, stationary gripper with cam-operated jaws; Q, horizontal press with dies; R, cam. See text for description of operation.

To the left side of the machine proper is a stock straightener (L), shown in working position with strip stock passing through it. Intermittent feeding of the work metal is accomplished by an automatic gripper in the feed slide (M) and an

adjustable crank (O), which is attached to a shaft (C). A separate gripper (P) is provided with cam-operated jaws, which grip the strip on the return stroke of the feed slide to prevent backward motion of the strip.

The work metal strip, fed through the machine in a vertical plane (on edge), passes horizontally through dies in a horizontal press (Q). A short, powerful stroke is given to the horizontal press slide by a cam on the front shaft (D) (see Fig. 23).

## Deep Drawing

DRAWING is a process in which sheet metal is formed into round or square cup-shape parts. The work metal is placed over a shaped die and pressed into the die with a punch (Fig. 24). The term deep drawing implies that some drawing-in of the flange metal occurs and that the formed parts are deeper than those that could be obtained by simply stretching the metal over a die. Clearance between the male punch and the female die is closely controlled to minimize the free span so that there is no wrinkling of the sidewall. This clearance is sufficient to prevent ironing of the metal being drawn into the sidewall in the deep-drawing process. If ironing of the walls is to be part of the process, it is done in operations subsequent to deep drawing.

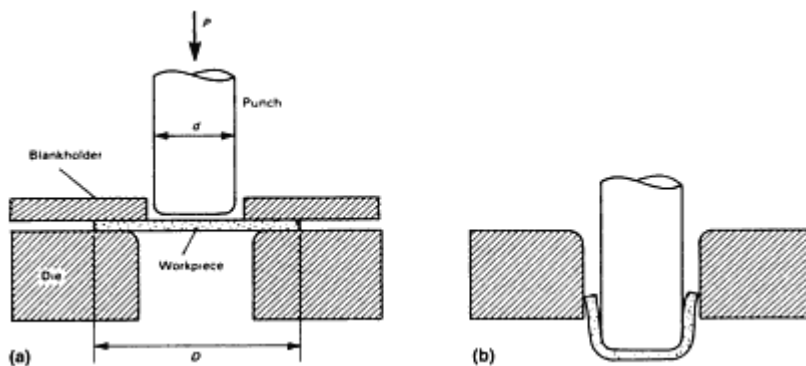

Fig. 24 Deep drawing of a cylindrical cup. (a) Before drawing. (b) After drawing.

Suitable radii in the punch bottom to side edge, as well as the approach to the die opening, are necessary to allow the metal sheet to be formed without tearing. In most deep-drawing operations, the part has a solid bottom to form a container and a retained flange that is trimmed later in the processing. In some cases, the cup shape is fully drawn into the female die cavity, and a straight-wall cup shape is ejected through the die opening. To control the flange area and to prevent wrinkling, a hold-down force is applied to the blank to keep it in contact with the upper surface of the die. A suitable subpress or a double-action press is required. Presses can be either hydraulic or mechanical devices, but hydraulic presses are preferred because of better control of the rate of punch travel.

## Fundamentals of Drawing

A flat blank is formed into a cup by forcing a punch against the center portion of a blank that rests on the die ring. The progressive stages of metal flow in drawing a cup from a flat blank are shown schematically in Fig. 25. During the first stage, the punch contacts the blank (Fig. 25a), and metal section 1 is bent and wrapped around the punch nose (Fig. 25b). Simultaneously and in sequence, the outer sections of the blank (2 and 3 in Fig. 25) move radially toward the center of the blank until the remainder of the blank has bent around the punch nose and a straight-wall cup is formed (Fig. 25c and d). During drawing, the center of the blank (punch area, Fig. 25a) is essentially unchanged as it forms the bottom of the drawn cup. The areas that become the sidewall of the cup (1, 2, and 3, Fig. 25) change from the shape of annular segments to longer parallel-side cylindrical elements as they are drawn over the die radius. Metal can flow until all the metal has been drawn over the die radius, or a flange can be retained.

**Fig. 25** Progression of metal flow in drawing a cup from a flat blank

A blankholder is used in a draw die to prevent the formation of wrinkles as compressive action rearranges the metal from flange to sidewall. Wrinkling starts because of some lack of uniformity in the movement or because of the resistance to movement in the cross section of the metal.

## Drawability

The drawability of a metal depends on two factors: the ability of the material in the flange region to flow easily in the plane of the sheet under shear, and the ability of the sidewall material to resist deformation in the thickness direction. Taking both of these factors into account, it is desirable in drawing operations to maximize material flow in the plane of the sheet and to maximize resistance to materials flow in a direction perpendicular to the plane of the sheet. Low flow strength in the plane of the sheet is of little value if the work material also has low flow strength in the thickness direction.

The flow strength of sheet metal in the thickness direction is difficult to measure, but the plastic strain ratio  $r$  compares strengths in the plane and thickness direction by determining true strains in these directions in a tension test. A high  $r$  value is the measure of a material with good deep-drawing characteristics. Table 7 lists  $r$  values for carbon steel sheet in various conditions. Equations for determining the plastic strain ratio can be found in the Section "Design Considerations and Materials Selection" in this Handbook (see the discussion of formability in the article "Factors in Materials Selection").

**Table 7** Typical mechanical properties of low-carbon sheet steels

Quality level	Tensile strength		Yield strength		Elongation, % in 50 mm (2 in.)	Plastic-strain ratio, $r$	Strain-hardening exponent, $n$	Hardness, HRB
	MPa	ksi	MPa	ksi				
Hot rolled								
Commercial quality	358	52	234	34	35	1.0	0.18	58
Drawing quality	345	50	220	32	39	1.0	0.19	52
Drawing quality, aluminum killed	358	52	234	34	38	1.0	0.19	54
Cold rolled, box annealed								
Commercial quality	331	48	234	34	36	1.2	0.20	50
Drawing quality	317	46	207	30	40	1.2	0.21	42
Drawing quality, aluminum killed	303	44	193	28	42	1.5	0.22	42

Drawability can also be expressed in terms of a limiting draw ratio or percentage of reduction based on results of Swift cup testing. The limiting draw ratio is the ratio of the diameter  $D$  of the largest blank that can be successfully drawn to the diameter of the punch  $d$ :

$$\text{LDR} = \frac{D}{d}$$

Percentage of reduction would then be defined as:

$$\text{Percentage of reduction} = \frac{100 (D - d)}{D}$$

Additional information on formability testing can be found in the Section "Mechanical, Wear, and Corrosion Testing" in this Handbook.

**Earing** in deep-drawn parts is related to planar anisotropy. The sheet metal therefore may be stronger in one direction than in other directions in the plane of the sheet. This causes ears to form on the drawn part even when a circular blank is used. In practice, enough extra metal is left on the drawn cup so that the ears can be trimmed.

## Presses

Sheet metal is drawn in either hydraulic or mechanical presses. Double-action presses are required for most deep drawing because a more uniform blank holding force can be maintained for the entire stroke than is possible with a spring-loaded blankholder. Double-action hydraulic presses with a die cushion are often preferred for deep drawing because of their constant drawing speed, stroke adjustment, and uniformity of clamping pressure. Regardless of the source of power for the slides, double-action straight-side presses with die cushions are best for deep drawing. Straight-side presses provide a wide choice of tonnage capacity, bed size, stroke, and shut height.

Drawing force requirements, die space, and length of stroke are the most important considerations in selecting a press for deep drawing. The condition of the crankshaft, connection bearings, and gibs is also a factor in press selection.

## Dies

**Single-action dies** (Fig. 26a) are the simplest of all drawing dies and have only a punch and a die. A nest or locator is provided to position the blank. The drawn part is pushed through the die and stripped from the punch by the counterbore in the bottom of the die. The rim of the cup expands slightly to make this possible. Single-action dies can be used only when the forming limit permits cupping without the use of a blankholder.

Fig. 26 Components of three types of simple dies shown in a setup used for drawing a round cup. See text for

discussion.

**Double-action dies** have a blankholder, permitting greater reductions and the drawing of flanged parts (Fig. 26b). In this design, the die is mounted on the lower shoe; the punch is attached to the inner, or punch slide; and the blankholder is attached to the outer slide. The pressure pad is used to hold the blank firmly against the punch nose during the drawing operation and to lift the drawn cup from the die. If a die cushion is not available, springs or air or hydraulic cylinders can be used; however, they are less effective than a die cushion, especially for deep draws.

An inverted double-action die (Fig. 26c) is used in single-action presses. In this design, the punch is mounted on the lower shoe, the die on the upper shoe. A die cushion can supply the blank-holding force, or springs or air or hydraulic cylinders are incorporated into the die to supply the necessary blank-holding force. The drawn cup is removed from the die on the upstroke of the ram when the pin-like extension of the knockout strikes a stationary knockout bar attached to the press frame.

**Compound Dies.** When the initial cost is warranted by production demands, it is practical to combine several operations in a single die. Blanking and drawing operations are commonly placed in compound dies. With compound dies, workpieces can be produced several times as fast as by the simple dies.

**Progressive Dies.** The initial cost and length of bed needed for progressive dies usually limit their application to relatively small workpieces.

**Multiple Dies.** In conjunction with transfer mechanisms, multiple dies are often used instead of progressive dies for mass producing larger parts. Multiple dies and transfer mechanisms are practical for a wider range of workpiece sizes than progressive dies are.

## Die and Punch Materials

The material used for dies and punches for drawing sheet metal depends on work metal composition, workpiece size, severity of the draw, quantity of parts to be drawn, and tolerances and surface finish specified for the drawn workpieces. To meet the wide range of requirements, punch and die materials include polyester, epoxy, phenolic, or nylon resins; highly alloyed tool steels with nitrided surfaces; and cemented carbides.

## Lubrication

Lubricants are used in most drawing operations. They range from ordinary machine oil to pigmented compounds. Selection of lubricant is primarily based on the ability to prevent galling, wrinkling, or tearing during deep drawing. It is also influenced by ease of application and removal, corrosivity, and other factors.

Lubricants used in drawing steel (Table 8) are selected according to severity of draw or the percentage of reduction from blank to cup diameter. Zinc phosphate conversion coating of the steel to be drawn is helpful for any drawing operation, and the importance of phosphate coating increases as the severity of the draw increases.

**Table 8 Lubricants commonly used for the drawing of low-carbon steel**

Type or composition of lubricant	Ease of removal by:		Protection against rusting
	Water-base cleaners	Degreasers or solvents	
Water-base lubricants			
Low severity (10% or less)			
Water emulsion of 5-20% general-purpose soluble oil or wax	Very good	Good	Fair
Moderate severity (11-20%)			
Water solution of 5-20% soap	Very good	Very poor	Fair
Water emulsion of heavy-duty soluble oil (contains sulfurized or chlorinated additives)	Very good	Good	Fair
High severity (21-40%)			
Soap-fat paste, diluted with water (may contain wax)	Fair	Poor	Fair
Water emulsion of heavy-duty soluble oil (contains a high concentration of sulfurized or chlorinated additives)	Very good	Good	Fair to poor
Maximum severity (>40%)			
Pigmented soap-fat paste, diluted with water	Poor	Very poor	Good
Dry soap or wax (applied from water solution or dispersion); may contain soluble filler such as borax	Good	Very poor	Good
Oil-base lubricants			
Low severity (10% or less)			
Mill oil, residual	Good	Very good	Fair
Mineral oil	Good	Very good	Fair
Vanishing oil	Removal not required		. . .
Moderate severity (11-20%)			
Mineral oil plus 10-30% fatty oil	Good	Very good	Fair
Mineral oil plus 2-20% sulfurized or chlorinated oil (extreme-pressure oil)	Good to fair	Good	Fair to poor
High severity (21-40%)			
Fatty oil	Fair	Fair	Fair
Mineral oil plus 5-50% of:			
Nonemulsifiable chlorinated oil	Poor	Good	Very poor
Emulsifiable chlorinated oil	Good	Good	Very poor
Concentrated phosphated oil	Fair	Fair	Fair
Maximum severity (>40%)			
Blend of pigmented soap-fat paste with mineral oil	Poor	Poor	Fair
Concentrated sulfochlorinated oil (may contain some fatty oil):			
Nonemulsifiable	Very poor	Fair	Poor
Emulsifiable	Good	Fair	Poor
Concentrated chlorinated oil:			
Nonemulsifiable	Very poor	Fair	Very poor
Emulsifiable	Good	Fair	Very poor

Severity is indicated by the percentage of reduction in diameter in drawing a cylindrical shell.

## Direct Redrawing

In direct redrawing in a single-action die, the drawn cup is slipped over the punch and is loaded in the die (Fig. 27). At first, the bottom of the cup is wrapped around the punch nose without reducing the diameter of the cylindrical section. The sidewall section then enters the die and is gradually reduced to its final diameter. Metal flow takes place as the cup is drawn into the die so that the wall of the redrawn shell is parallel to, and deeper than, the wall of the cup at the start of the redraw. At the beginning of redrawing, the cup must be supported and guided by a recess in the die or by a blankholder to prevent it from tipping, which would result in an uneven shell.

Fig. 27 Direct and reverse redrawing in single-action and double-action dies

In a single-action redraw, the metal must be thick enough to withstand the compressive forces set up in reducing the cup diameter without wrinkling. Wrinkling can be prevented by the use of an internal blankholder and a double-action press, which usually permits a shell to be formed in fewer operations than by single-action drawing without the use of a blankholder.

## Reverse Redrawing

In reverse redrawing, the cupped workpiece is placed over a reversing ring and redrawn in the direction opposite to that used for drawing the initial cup. Reverse redrawing can be done with or without a blankholder (Fig. 27). The blankholder serves the same purposes as in direct redrawing. Reverse redrawing can be performed in a progressive die as well as in single-stage dies if the operations are divided to distribute the work and to reduce the severity of each stage.

Advantages of reverse drawing as compared with direct redrawing include:

- Metal can be drawn and redrawn in one stroke of a triple-action hydraulic press, or of a double-action mechanical press with a die cushion, which can eliminate the need for a second press.
- Greater reductions per redraw are possible with reverse redrawing.
- One or more intermediate annealing operations can often be eliminated by using the reverse technique.
- Better distribution of metal can be obtained in a complex shape.

In borderline applications, annealing is required between redraws in direct redrawing, but is not needed in reverse redrawing.

The disadvantages of reverse drawing are:

- The technique is not practical for work metal thicker than 6.4 mm ( $\frac{1}{4}$  in.).
- Reverse redrawing requires a longer stroke than direct redrawing.

Usually, metals that can be direct redrawn can be reverse redrawn. All of the carbon and low-alloy steels, austenitic and ferritic stainless steels, aluminum alloys, and copper alloys can be reverse redrawn.

Reverse redrawing requires more closely controlled processing than direct redrawing. The blanks should be free from nicks and scratches, especially at the edges.

The restraint in reverse redrawing must be uniform and low. For low friction, polished dies and effective lubrication of the work are needed. Friction also is affected by hold-down pressure and by the shape of the reversing ring. Radii of tools should be as large as practical--ten times the thickness of the work metal if possible.

## Stretch Forming

STRETCH FORMING involves forming sheet, bars, and rolled or extruded sections over a form block of the required shape while the workpiece is held in tension. The work metal is often stretched just beyond its yield point (generally 2 to 4% total elongation) to retain permanently the contour of the form block.

The four methods of stretch forming are: stretch draw forming (Fig. 28a and b); stretch wrapping, also called rotary stretch forming (Fig. 28c); compression forming (Fig. 28d); and radial draw forming (Fig. 28e).

Fig. 28 Fundamentals of the techniques involved in the four methods of stretch forming

## Applicability

Almost any shape that can be produced by other sheet-forming methods can be produced by stretch forming. Drawn shapes that involve metal flow, particularly straight cylindrical shells, and details that result from compression operations such as coining and embossing, cannot be made. However, some embossing is done by the mating-die method of stretch draw forming.

Stretch forming is used to form aerospace parts from steel, nickel, aluminum, and titanium alloys and other heat-resistant and refractory metals. Some of these parts are difficult or impossible to form by other methods.

Stretch forming is also used to shape automotive body panels, both inner and outer, and frame members that could be formed by other processes but at higher cost. Architectural shapes and aerospace forms that call for compound curves, reverse bends, twists, and bends in two or more planes are also produced by stretch forming.

## Machines and Accessories

Stretch wrapping, compression forming, and radial-draw forming use rotary tables on which are mounted the form block, a ram gripping and tensioning or wiping device, and a mechanically or hydraulically actuated table gripper (Fig. 28c-e). In stretch wrapping, the workpiece is pulled from one end, wrapping the metal around the form block. In compression

forming, a wiper shoe presses the workpiece against the form block. Radial-draw forming combines both pulling and pressing of the metal. Machines used for these operations have capacities to 8900 kN (1000 tonf).

Stretch draw forming is done in three types of machines. In one type, the form block is mounted on a hydraulic cylinder and is pushed into the blank, which is held in tension by a pair of pivoting grippers. In another type, the form block is fixed to the table and a pair of grippers actuated by slides or a hydraulic cylinder draws the blank around it. The third type of machine is a single-action hydraulic press equipped with a two-piece mating die. Grippers pull the blank over the lower die, then the upper die descends to produce the workpiece (Fig. 28b). The hydraulic presses ordinarily used in stretch draw forming have capacities of 1800 to 7100 kN (200 to 800 tonf).

**Accessory Equipment.** Grippers and wiping shoes or rollers are made to conform to the rolled or extruded shape that is to be stretch formed. Jaws used for gripping sheet in stretch draw forming can be segmented or contoured to apply equal stretch to all parts of the sheet as it is formed.

## Spinning

SPINNING forms sheet metal or tubing into seamless hollow cylinders, cones, hemispheres, or other circular shapes by a combination of rotation and force. (Tube spinning is discussed in the following article "Forming of Bars, Tubes, and Wire.") The technique falls into two categories: manual spinning and power spinning.

Any metal that can be cold formed by other methods can be spun. Most spinning takes place without heating the workpiece; sometimes the metal is preheated to increase ductility or to allow thicker sections to be spun.

### Manual Spinning

Manual spinning involves no appreciable thinning of the work metal. The operation requires a lathe and it consists of pressing a tool against a circular metal blank that is rotated by the headstock. The blank is usually forced over a mandrel of a predetermined shape, but simple shapes can be spun without a mandrel. Various mechanical devices are used to increase the force that can be applied to the workpiece.

Manual spinning is used to form flanges, rolled rims, cups, cones, and double-curved surfaces of revolution (such as bells). Products include light reflectors, tank ends, covers, housings, shields, components for musical instruments, and aircraft and aerospace components (often with mechanical assistance for increased force).

The practical maximum thickness of low-carbon steel that can be spun without mechanical assistance is 3.2 mm ( $\frac{1}{8}$  in.). At this thickness, the diameter can be as great as 1.8 m (72 in.). Diameters can be greater when the sheet steel is thinner, but the maximum practical diameter is often limited by the availability of equipment. The upper limit of thickness increases as work metal ductility increases or as strength decreases. For example, the manual spinning of aluminum as thick as 6.4 mm ( $\frac{1}{4}$  in.) is feasible

### Equipment for Manual Spinning

A typical tool and workpiece setup for manual spinning is shown in Fig. 29(a). A mandrel is mounted on the headstock of a lathe. A circular blank (workpiece) is clamped to the mandrel by a follower block attached to the tailstock of the lathe. The blank is rotated by the headstock, while a friction-type spinning tool is manually pressed against the blank, forcing the blank over the preshaped mandrel. The tool is mounted on a tool rest by a support pin (fulcrum). The operator presses the tool against the blank by pivoting it around the support pin. The tool rest permits the tool to be moved to different positions.

**Fig. 29** Manual spinning in a lathe. (a) Setup using a simple hand tool, applied like a pry bar. (b) Setup using scissorlike levers and a roller spinning tool

Figure 29(b) shows a more complex setup for manual spinning. Here, the spinning tools are rollers which are mounted in the fork sections of long levers. The roller is pressed against the workpiece by manipulating the scissor-like levers.

## Power Spinning

Power spinning is also known as shear spinning, because in this method metal is intentionally thinned by shear forces as high as 3.5 MN (400 tonf). Power spinning is used in two broad areas of application: cone spinning and tube spinning. Virtually all ductile metals can be processed by power spinning. Products range from small hardware items made in large quantities (metal tumblers, for example) to large components for aerospace applications in unit or low-volume production.

Blanks as large as 6 m (240 in.) in diameter have been successfully power spun. Plate stock up to 25 mm (1 in.) thick can be power spun without heat. When heated, blanks as thick as 140 mm ( $5\frac{1}{2}$  in.) can be spun. Conical and curvilinear shapes are most commonly produced from flat (or preformed) blanks by power spinning.

## Machines for Power Spinning

Most power spinning requires machines specially built for the purpose. The primary components of such a machine are shown in Fig. 30. Power spinning machines are usually described by capacity: the diameter and length (in inches) of the largest workpiece that can be spun and the amount of force that can be applied to the work. It is also common practice to specify that the machine can spin a given thickness of metal at a 50% reduction in thickness in one pass.

**Fig. 30 Schematic illustration of power spinning in a vertical machine**

The capacity of spinning machines, which may be horizontal or vertical, ranges from  $455 \times 380$  mm ( $18 \times 15$  in.) at 18 kN (4000 lbf) to machines capable of spinning workpieces as large as 6 m (240 in.) in diameter  $\times$  6 m ( $240 \frac{1}{2}$  in.) long. Force on the work can be as great as 3.5 MN (400 tonf). Machines have been built that spin steel 140 mm ( $5 \frac{1}{2}$  in.) thick.

Machines for power spinning can be automated to various degrees. Automatic spinning machines are available with computer numerical controls (CNC) to automatically perform the spinning operation.

## Rubber-Pad Forming

RUBBER-PAD FORMING, also known as flexible-die forming, uses two tool halves: a rubber pad or a flexible diaphragm (or bladder), and one solid tool half to form a part to final shape. The solid tool half usually is similar to the punch in a conventional die, but it can be the die cavity. The rubber acts somewhat like hydraulic fluid in exerting nearly equal pressure on all workpiece surfaces as it is pressed around the form block.

Rubber-pad forming is used on moderately shallow, recessed parts with simple flanges and relatively simple configurations. Form block height is usually less than 100 mm (3.9 in.). The production rates are relatively high, with cycle times averaging 1 min or less.

Flexible-die forming methods fall into three groups: rubber-pad forming, fluid-cell forming, and fluid forming. Specific processes falling into these three categories are described below.

## Rubber-Pad Forming

The Guerin process is synonymous with the term rubber-pad forming. Other processes, which are essentially modified/improved version of the Guerin process, include the Marform process, the trapped-rubber process, and the ASEA Quintus rubber-pad process.

### *Guerin Process*

The Guerin process is the oldest and most basic of the production rubber-pad forming processes. Its advantages are simplicity of equipment, adaptation to small-lot production, and ease of changeover.

Some metals that are commonly formed by this process are listed in Table 9. Titanium can be formed only if the workpiece and the form block are both heated. The resulting deterioration of the rubber pad often makes the process too costly compared with forming by conventional dies.

**Table 9 Metals commonly formed by the Guerin process**

Metal	Maximum thickness <sup>(a)</sup>	
	mm	in.
Mild forming		
<b>Aluminum alloys</b>		
<b>2024-O, 7075-W</b>	4.7	0.187
<b>2024-T4</b>	1.6	0.064
<b>Austenitic stainless steels</b>		
<b>Annealed</b>	1.3	0.050 <sup>(b)</sup>
<b>Quarter hard</b>	0.8	0.032 <sup>(c)</sup>
<b>Titanium alloys</b>	1.0	0.040 <sup>(d)</sup>
Stretch flanging		
<b>Aluminum alloy 2024-T4</b>	1.6	0.064
<b>Austenitic stainless steels</b>		
<b>Annealed</b>	1.3	0.050

- (a) Typical; varies with type of equipment and part design.
- (b) Up to 2.0 mm (0.078 in.) when compression dams are used.
- (c) Only very mild forming.
- (d) When heated to 315 °C (600 °F)

**Presses.** Almost any hydraulic press can be used for the Guerin process. For maximum forming capability, the force capacity of the press and the area of the rubber pad must be suitable for the operation under consideration. The rubber pad is generally about the same size as the press ram, but it can be smaller.

**Tools.** The principal tools are the rubber pad and the form block, or punch (Fig. 31). The rubber pad is relatively soft (about Durometer A 60 to 75) and usually three times as deep as the part to be formed. The pad can consist of a solid block of rubber, or of laminated slabs cemented together and held in a retainer.

**Fig. 31 Tooling and setup for rubber-pad forming by the Guerin process. Dimensions given in inches**

**Procedure.** The rubber-pad retainer is fixed to the upper ram of the press; the platen, containing the form block, is placed on the bed of the press. A blank is placed on the form block and is held in position by two or more locating pins. The pins must be mounted rigidly in the form block so that the rubber will not drive them down into the pinhole or push them out of position. The pins must be no higher than necessary to hold the blank, or they will puncture the rubber pad. In some applications, nests can be used to locate the blank during forming.

As the ram descends, the rubber presses the blank around the form block, thus forming the workpiece. The rubber-pad retainer fits closely around the platen, forming an enclosure that traps the rubber as pressure is applied. The pressure produced in the Guerin process is ordinarily 6.9 to 48 MPa (1 to 7 ksi). The pressure can be increased by reducing the size

of the platen. Pressures as high as 140 MPa (20 ksi) have been developed through the use of small platens in high-capacity presses.

### ***Marform Process***

This process was developed to apply the inexpensive tooling of the Guerin process to the deep drawing and forming of wrinkle-free shrink flanges. A blankholder plate and a hydraulic cylinder with a pressure-regulating valve are used with a thick rubber pad and a form block similar to those used in the Guerin process. The blank is gripped between the blankholder and the rubber pad. The pressure-regulating valve controls the pressure applied to the blank while it is being drawn over the form block.

For a soft aluminum alloy blank, the diameter can usually be reduced 57%, with reductions as high as 72%. A shell depth equal to the shell diameter is normal when the minimum stock thickness is 1% of the cup diameter. Depths up to three times shell diameter have been reached with multiple-operation forming. The minimum cup diameter is 38 mm ( $1\frac{1}{2}$  in.).

Foil as thin as 0.038 mm (0.0015 in.) can be formed by placing the blank between two aluminum blanks about 0.76 mm (0.030 in.) thick and forming the three pieces as a unit. The inner and outer shells are discarded.

**Presses.** The Marform process is best suited to a single-action hydraulic press in which pressure and speed of operation can be varied and controlled.

**Tools.** The rubber pad used in Marforming is similar to that used in the Guerin process. It is normally  $1\frac{1}{2}$  to 2 times as thick as the total depth of the part, including trim allowance.

### ***Drop Hammer Forming with Trapped Rubber***

Similar to the Guerin process for forming shallow workpieces, the trapped-rubber process uses a drop hammer in place of the hydraulic press; the primary differences are faster forming speed and the impact force of the hammer.

### ***ASEA Quintus Rubber-Pad Press***

ASEA presses, generally designed with force capacities of 50 to 500 MN (5600 to 56,000 tonf), are constructed of wire-wound frames and have separate guiding columns. By winding the press frames with prestressed wire, only compressional stresses are present in the large castings or forgings of the yokes and columns, even when subjected to maximum forming pressure. Therefore, when the press is loaded, the frame remains in slight compression, and the major structural components never operate in the tensile mode.

The press is equipped with a forged-steel rubber-pad retainer with a replaceable insert to allow for forming at higher pressures. Although the maximum tool height is sacrificed by using these high-pressure inserts, cutting the work area in half doubles the maximum forming pressure of the press when needed.

Standard table sizes range from  $0.7 \times 1.0$  m ( $28 \times 39$  in.) to  $2 \times 3$  m ( $79 \times 118$  in.). Difficult-to-form materials such as titanium, along with the die, can be heated outside the press by an infrared heater; blanks can also be heated by conduction from the table through the heat transferred through the die (Fig. 32).

**Fig. 32** Schematic of ASEA Quintus rubber-pad press with provision for heating difficult-to-form materials using infrared heater or heating elements contained in feed table

## Fluid-Cell Process

Initially developed as the Verson-Wheelon process, this process uses a fluid cell (a flexible bladder, rather than a rubber pad) backed up by hydraulic fluid to exert a uniform pressure directly on the form block positioned on the press table. This process can be classified in terms of the presses used (as for Verson-Wheelon and ASEA Quintus) or as a specialized method (such as the Demarest process) for producing cylindrical and conical parts. The Verson-Wheelon press has cylindrical press housings of laminated, prestressed steel that serve as pressure chambers. The ASEA Quintus press has a forged steel cylinder that is wound with high strength steel wire to create a prestressed press frame with extremely good fatigue properties.

Fluid-cell forming can be used for recessed parts that are beyond the capabilities of rubber-pad forming, for all flange configurations (including C-shaped flanges), and for complex parts with reentrant features and intricate joggles. Maximum form block height is 425 mm (16.7 in.), and typical cycle time is 1 to 2 min.

### *Verson-Wheelon Process*

The Verson-Wheelon process was developed from the Guerin process. It uses higher pressure and is primarily designed for forming shallow parts, using a rubber pad as either the die or punch. A flexible hydraulic fluid cell forces an auxiliary rubber pad to follow the contour of the form block and to exert a nearly uniform pressure at all points.

The distribution of pressure on the sides of the form block permits the forming of wider flanges than with the Guerin process. In addition, shrink flanges, joggles, and beads and ribs in flanges and web surfaces can be formed in one operation to rather sharp detail in aluminum, low-carbon steel, stainless steel, heat-resistant alloys, and titanium.

**Presses.** The Verson-Wheelon press has a horizontal cylindrical steel housing, the roof of which contains a hydraulic fluid cell (Fig. 33). Fluid-cell bladders can be of neoprene or polyurethane composition. Hydraulic fluid is pumped into the cell, causing it to inflate or expand. The expansion creates the force needed to cause the rubber of the work pad to flow downward, over and around the form block and the metal to be formed.

**Fig. 33** Principal components of the Vernon-Wheelon process

Below the chamber containing the rubber pad and the hydraulic fluid cell is a passage, extending the length of the press, that is wide and high enough to accommodate a sliding table containing form blocks. At each end of the passage is a sliding table that is moved into position for forming.

Vernon-Wheelon presses are available with forming pressures ranging from 35 to 140 MPa (5 to 20 ksi) and force capacities of 22 to 730 MN (2500 to 82,000 tonf). Sliding tables range in size from 508 × 1270 mm (20 × 50 in.) to 1270 × 4170 mm (50 × 164 in.). The larger machine can form parts having flange widths up to 238 mm (9 <sup>3</sup>/<sub>8</sub> in.).

### ***Demarest Process***

This technique uses an expanding or bulging rubber punch (Fig. 34). It is suitable for cylindrical, somewhat spherical, and conical parts. The punch, equipped with a hydraulic cell, is placed inside the workpiece, which is in turn placed inside the die. Hydraulic pressure expands the punch. After forming, the punch is contracted and removed.

**Fig. 34** Forming of a fuel-tank section from a blank using the Demarest process

### ***ASEA Quintus Fluid Cell Process***

This is another variation of the Guerin process for deeper and more complex parts. It uses a flexible rubber diaphragm backed up by oil as either the male or female tool half. The pressurized diaphragm forces the blanks to assume the shape of the solid-tool halves. The high, uniform, hydrostatic pressure forms shallow- to medium-depth parts with complex shapes to final shape, practically eliminating the subsequent hand forming usually required to apply the Guerin process.

**Presses.** ASEA Quintus fluid cell presses are available with maximum forming pressures ranging from 100 to 200 MPa (14 to 29 ksi) and force capacities up to 1400 MN (157,000 tonf). The forming tables range in size from 700 × 2000 mm (27.5 × 78.7 in.) to 2000 × 5000 mm (78.7 × 196.8 in.). The large presses can accommodate tools as high as 425 mm (16.7 in.) and consequently form parts as deep or flanges as wide as 425 mm (16.7 in.).

## Fluid Forming

In contrast to conventional two-die forming, which produces local stress concentrations in a workpiece, fluid forming (previously classified as rubber-diaphragm forming) is a flexible-die technique that inhibits thinning and crack initiation due to the uniformly distributed pressure. In fluid forming, a rubber diaphragm serves as both the blankholder and a flexible-die member. Fluid forming differs from the rubber-pad and fluid-cell processes in that the forming pressure can be controlled as a function of the draw depth of the part.

Fluid forming was initially known as the *Hydroform* process. The process can use a Verson Hydroform press in which a hydraulic pump delivers fluid under pressure into the pressure-dome cavity. The punch containing the die is driven upward into the cavity against the resistance provided by the fluid, and the workpiece is formed. Fluid forming is intended for punch, cavity, hydroblock, or expansion forming of deep-recessed parts. Cycle time is 15 to 20 s for most parts.

### Verson Hydroform Process

This process differs from those previously described in that the die cavity is not completely filled with rubber, but with hydraulic fluid retained by a 64 mm ( $2\frac{1}{2}$  in.) thick cup-shaped rubber diaphragm. This cavity is termed the pressure dome (Fig. 35). A replaceable wear sheet is cemented to the lower surface of the diaphragm. This method allows more severe draws than in conventional draw dies because the oil pressure against the diaphragm causes the metal to be held tightly against the sides as well as against the top of the punch.

Fig. 35 Fluid-cell forming in a Hydroform press

Reductions in blank diameter of 60 to 70% are common for a first draw. When redrawing is necessary, reductions can reach 40%. Low-carbon steel, stainless steel, and aluminum in thicknesses from 0.25 to 1.65 mm (0.010 to 0.065 in.) are commonly formed. Parts made of heat-resistant alloys and copper alloys are also formed by this process.

### SAAB Rubber-Diaphragm Method

In this variation, hydraulic fluid is used behind a comparatively thin rubber pad or diaphragm. A hydraulic piston compresses the fluid against the rubber and forces the blank into the die (Fig. 36).

**Fig. 36** Principals of SAAB rubber-diaphragm (fluid forming) method. The air vents keep trapped air from causing blisters on the workpiece.

### ***ASEA Quintus Fluid Forming Press***

This is a vertical press with a circular fluid form unit containing the rubber diaphragm and pressure medium. These modular fluid form units serve the same function as the units used in the ASEA Quintus deep-drawing fluid forming press described below. The rigid tool half may be a male block, a cavity die, or an expansion die situated in a movable tool holder. Blanks are loaded onto the tool holder prior to shuttling the holder into the press for the 10 to 50 s forming cycle required to produce the part.

### ***ASEA Quintus Deep-Drawing Technique***

A variation of the SAAB rubber-diaphragm method, ASEA Quintus deep-drawing fluid forming uses two telescopic rams: an outer ram to control dome pressure and an inner ram to regulate the length of the punch draw. Because domes are interchangeable, the user can select a dome of optimal size. Maximum forging pressure can also be increased with smaller domes.

## **Three-Roll Forming**

THREE-ROLL FORMING is used to form plate, sheet, bars, beams, angles, or pipe into various shapes (Fig. 37) by passing the work metal between three properly spaced rolls. Any metal that can be cold formed by other processes can be formed in a three-roll machine.

**Fig. 37** Typical shapes produced from flat stock by three-roll forming

## Machines

There are two types of three-roll forming machines: the pinch-roll type and the pyramid-roll type. The rolls on most three-roll machines are positioned horizontally; a few vertical machines are used, primarily in shipyards. An advantage of vertical machines in forming scaly plate is that loose scale is less likely to become embedded in the work metal. Vertical rolls, however, handle wide sections that require careful support to avoid skewness in rolling with difficulty. Most vertical machines have short rolls for fast unloading and are used for bending narrow plate, bars, and structural sections.

**Conventional pinch-type machines** have the roll arrangement shown in Fig. 38. For rolling flat stock up to about 25 mm (1 in.) thick, each roll is of the same diameter. However, on larger machines, the top rolls are sometimes smaller to maintain approximately the same surface speed on both the inside and outside surfaces of the plate being formed. These heavier machines are also supplied with a slip-friction drive on the front roll to permit slip, because of the differential in surface speed of the rolls. Therefore, as work metal thickness increases, the diameter of the top roll is decreased in relation to the diameter of the lower rolls. In general, the smallest cylinder that can be rolled under optimal conditions is 50 mm (2 in.) larger in diameter than the top roll of a pinch-type machine.

**Fig. 38** End view of a cylindrical workpiece being rolled in a conventional pinch-type machine. Note large flat area on leading end, and smaller flat area on trailing end.

**Shoe-Type Pinch-Roll Machines.** One important modification of the three-roll pinch-type machine is the shoe-type machine, which uses the pinch principle with a forming shoe (Fig. 39). Because of the relationship of the two front rolls and the forming shoe to the workpiece, the flat area becomes barely discernible compared with the length of flat area obtained when rolling in a conventional machine (without preforming). This machine is used to manufacture transformer cases and small tanks, such as jackets for hot water tanks.

**Fig. 39** End view of a cylindrical workpiece being rolled in a shoe-type machine with two powered rolls

**In pyramid-type machines** (Fig. 40) the bottom rolls are of equal diameter, but about 50% smaller than the top roll. The bottom rolls are gear driven and are normally fixed; each roll is supported by two smaller rolls. The top roll is adjustable vertically to control the diameter of the cylinder formed. The top roll, which rotates freely, depends on friction with the work metal for rotation. Backup rolls are not used on the top roll.

**Fig. 40** Arrangement of rolls in a pyramid-type machine. (a) Entrance of flat workpiece and shape of a nearly finished workpiece, including the flat areas on the leading and trailing ends. (b) Similar, except that the workpiece was prebent to minimize the flat areas on the ends.

As shown in Fig. 40, the work metal is placed on the bottom rolls while the top roll is raised. The top roll is then lowered to contact and bend the work metal a predetermined amount, depending on the diameter of the workpiece to be formed. On a pyramid-type machine, the minimum workpiece diameter is rarely less than 150 mm (6 in.) greater than the top roll. However, more power is required to form sheet or plate into cylinders of minimum diameter than to form cylinders substantially larger than the top roll.

## Rolls

Rolls for three-roll forming machines are machined from steel forgings having a carbon content of 0.40 to 0.50% and a hardness of 160 to 210 HRB. Plain carbon steel such as 1045 has often been used; when greater strength is needed, rolls are forged from an alloy steel such as 4340.

## Contour Roll Forming

CONTOUR ROLL FORMING (also known as roll forming or cold roll forming) is a continuous process for forming metal from sheet, strip, or coiled stock into shapes of uniform cross section by feeding the stock through a series of roll stations equipped with contoured rolls (sometimes called roller dies). With two or more rolls per station, most contour roll forming is done by working the stock progressively in two or more stations until the finished shape is produced.

The process is suited for large quantities and long lengths to close tolerances and involves a minimum of handling. Auxiliary operations, such as notching, slotting, punching, embossing, curving, and coiling, can be combined with contour roll forming.

Contour roll forming is used for parts that were previously manufactured by extrusion processes. This use is limited, however, to parts that can be redesigned to have a constant wall thickness. Industries that use roll-formed products include the automotive; building; office furniture; home appliance and home product; medical; railcar; aircraft; and heating, ventilation, and air conditioning (HVAC) industries.

Contour roll forming can be divided into two broad categories: a process using precut lengths of work metal (precut or cut-to-length method), and a process that uses coil stock that is trimmed to size after forming (post-cut method).

## Work Materials

Any material that can withstand bending to the desired radius can be contour roll formed. Thicknesses of 0.13 to 19 mm (0.005 to  $\frac{3}{4}$  in.) and material widths of 3.2 to 1830 mm ( $\frac{1}{8}$  to 72 in.) can be used. Length of the formed part is limited only by the length that can be handled conveniently after forming.

In some cases, multiple sections can be formed from a single strip; in other cases, several strips can be fed simultaneously into the machine and combined after forming to produce a composite section. Contour roll forming is almost always

performed at room temperature; however, some materials, such as certain titanium alloys, must be formed at elevated temperatures. This is done on specially designed machines.

## Machines

The machine most commonly used has a number of individual units, each of which is actually a dual-spindle roll-forming machine mounted on a suitable baseplate to make a multiple-unit machine. The flexibility of this construction permits the user to purchase enough units for immediate needs only.

Roll forming machines can be classified according to the method by which the spindles are supported in the unit. Generally, two types exist: inboard (or overhung spindle) machines and outboard machines.

**Inboard machines** (Fig. 41) have spindle shafts supported on one end that are 25 to 38 mm (1 to  $1\frac{1}{2}$  in.) in diameter and up to 102 mm (4 in.) in length. They are used for forming light-gage moldings, weather strips, and other simple shapes. Material thickness is limited to about 1 mm (0.040 in.), and the top roll shaft is generally geared directly to the bottom shaft. This direct-mesh gearing permits only a small amount of roll redressing (no more than the thickness of the material being formed) on the top and bottom rolls. Tooling changeover is faster on this machine than on the outboard machine.

Fig. 41 Overhung-spindle machine (one roll station) for contour roll forming

**Outboard machines** (Fig. 42) have housings supporting both ends of the spindle shafts. The outboard housing is generally adjustable along the spindles, permitting shortening of the distance between the supports to accommodate the roll forming of small shapes of heavy-gage material. This also permits the machine to be used as an inboard machine when desired. Outboard machines can be readily designed to accommodate any width of material by making the spindle lengths suit the material width and then mounting the individual units and spindles on a baseplate of suitable width. This type of machine is built with spindle sizes ranging from 38 to 102 mm ( $1\frac{1}{2}$  to 4 in.) diameter and with width capacities up to 1830 mm (72 in.).

Fig. 42 Universal contour roll forming machine, with outboard support for roll shafts (rolls not shown)

## Tooling

Tooling used in roll forming includes the forming rolls and the dies for punching and cutting off the material. Tube mills require some additional tooling to weld, size, and straighten the tubes as they are produced on the machine.

**Forming Rolls.** The rolls actually form the material as it moves through the machine. Several factors must be considered when designing the rolls to form a particular part. These include the number of required passes, the material width, the "flower" design, the roll design parameters, and the roll material. Flower is the name given to the progressive section contours, starting with the flat material and ending with the desired section profile.

**Roll Materials.** The materials that are most commonly used for contour rolls are: low-carbon steel, turned and polished but not hardened; gray iron (such as class 30), turned and polished but not hardened; low-alloy tool steel (such as O1 or L6), hardened to 60 to 63 HRC and sometimes chromium plated; high-carbon high-chromium tool steel (such as D2), hardened to 60 to 63 HRC and sometimes chromium plated; and bronze (usually aluminum bronze).

## Drop Hammer Forming

DROP HAMMER FORMING is a process for producing shapes by the progressive deformation of sheet metal in matched dies under the repetitive blows of a gravity drop hammer or a power drop hammer. Configurations most commonly formed by the process include shallow, smoothly contoured, double-curvature parts; shallow-beaded parts; and parts with irregular and comparatively deep recesses. Small quantities of cup-shape and box-shape parts, curved sections, and contoured flanged parts also are formed.

## Advantages and Limitations

The main advantages of drop hammer forming are: (a) low cost for limited production; (b) relatively low tooling costs; (c) dies that can be cast from low-melting alloys and that are relatively simple to make; (d) short delivery time of product because of simplicity of toolmaking; and (e) the possibility of combining coining with forming.

Against these advantages, the following limitations must be weighed: (a) probability of forming wrinkles; (b) need for skilled operators, specially trained for this process; (c) restriction to relatively shallow parts with generous radii; (d) restriction to relatively thin sheet, from about 0.61 to 1.6 mm (0.024 to 0.064 in.) (thicker sheet can be formed only if the parts are shallow and have generous radii).

Drop hammer forming is not a precision forming method; tolerances of less than 0.8 to 1.6 mm ( $\frac{1}{32}$  to  $\frac{1}{16}$  in.) are not practical.

## Hammers for Forming

Gravity drop hammers and power drop hammers are comparable to a single-action press. However, they can be used to do the work of a press equipped with double-action dies through the use of rubber pads, beads in the die surfaces, draw rings, and other auxiliary equipment.

Because they can be controlled more accurately and because their blows can be varied in intensity and speed, power drop hammers, particularly the air-actuated types, have virtually replaced gravity drop hammers. A typical air drop hammer, equipped for drop hammer forming, is shown in Fig. 43.

Fig. 43 Air-actuated power drop hammer equipped for drop hammer forming

## Tooling

In general, a tool set consists of a die that conforms to the outside shape of the desired part, and a punch that conforms to the inside contour (see Fig. 43).

**Tool Materials.** Dies are cast from zinc alloy (3.5% Cu, 4% Al, and 0.04% Mg), aluminum alloy, beryllium copper, ductile iron, or steel. The wide use of zinc alloy as a die material stems from the ease of casting it close to the final shape desired. Its low melting point (381 °C, or 717 °F) also is advantageous. All dies, regardless of die material, are polished.

Punches usually are made of lead or a low-melting alloy, although zinc or a reinforced plastic also may be used. The sharpness of the contours to be formed, the production quantity, and the accuracy desired primarily govern the choice of punch material. As a punch material, lead has the advantage of not having to be cast accurately to shape, because it deforms to assume the shape of the die during the first forming trial with a blank.

## Lubricants

Lubricants are used in drop hammer forming to facilitate deformation by reducing friction and minimizing galling and sticking, and to preserve or improve surface finish. Selection of a lubricant depends primarily on type of work metal, forming temperature, severity of forming, and subsequent processing. Recommendations for lubricants used with steels and aluminum, magnesium, and titanium alloys are given in the section "Selection and Use of Lubricants in Forming Sheet Metal" in this article.

## Explosive Forming

EXPLOSIVE FORMING changes the shape of a metal blank or preform by the instantaneous high pressure that results from the detonation of an explosive. This discussion deals only with the explosives generally termed high explosives, and not with so-called low explosives. Metal tubing up to 1.4 m (54 in.) in diameter in lengths up to 4.6 m (15 ft) is formed using this process. Tubing with diameters of 1.4 m (54 in.) or less can be as long as 9.1 m (30 ft). Typical domes constructed of 6- to 12-piece gore sections fabricated from explosively formed metal can measure up to 6.1 m (20 ft) in diameter. The process has been used to fabricate gore sections for a 12 m (40 ft) diameter dome.

## Confined and Unconfined Systems

Systems used for explosive-forming operations are generally classified as either confined or unconfined.

Confined systems (Fig. 44) use a die, in two or more pieces, that completely encloses the workpiece. The closed system has distinct advantages for forming thin stock to close tolerances. It has been used for close-tolerance sizing of thin-wall tubing. However, confined systems are generally used only for comparatively small workpieces because economic feasibility decreases as the size of the workpiece increases.

Fig. 44 Confined system for explosive forming

In an unconfined system (Fig. 45) the shock wave from the explosive charge takes the place of the punch in conventional forming. A single-element die is used with a blank held over it, and the explosive charge is suspended over the blank at a predetermined distance (the standoff distance). The complete assembly can be immersed in a tank of water, or a plastic bag filled with water can be placed over the blank.

Fig. 45 Unconfined system for explosive forming

## Equipment

The primary equipment for explosive forming in an unconfined system consists of a water tank, a crane, a vacuum pump, and a detonator control (firing) box.

**The water tank** must withstand the repeated impacts of the explosive shock without rupturing. Many tanks are large enough to reduce the shocks reaching the walls from centrally placed charges.

**A crane** is usually needed to move material around the facility, as well as in and out of the water tank. Ideally, the crane should be air operated to avoid electric power lines within the firing area.

**A vacuum pump** may be needed for explosive-forming operations in which parts are formed under water. If the firing area is to be maintained with a minimum of electric lines, an entire pump operating on water pressure will work satisfactorily. A mechanical pump driven by an electric motor can be used; the vacuum lines are brought into the firing area from a remote pumping site. An electrically driven mechanical pump is preferred over a venturi pump for its considerably greater capacity and is economy.

**Detonation Circuit.** Under ideal conditions, the firing box for the electric blasting caps in the only electric device that should be permitted in the area where explosives are handled. A firing box should be constructed on the fail-safe principle so that any malfunction will immediately cause the circuit to be disarmed.

## Die Systems and Materials

Basic differences between tooling for explosive forming and for conventional forming arise from the type of loading that the die material must withstand. In explosive forming, high-impact loads transmit shock waves through the metal that cause unusual stress patterns within the die materials. Therefore, corners should be eliminated where possible. Shock loading causes the die to fracture along lines from the corners, rather than through the thinnest section, as in static fracture (Fig. 46).

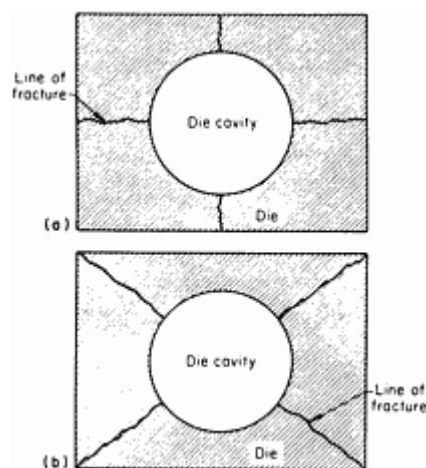

Fig. 46 Modes of fracture of a rectangular die under (a) static load and (b) shock load

**Die Materials.** Solid dies made from heat-treated alloy steel maintain contour, surface finish, and dimensional accuracy for a relatively long time. To avoid brittle fracture under overloads, a maximum hardness of 50 HRC is desirable.

## Electromagnetic Forming

ELECTROMAGNETIC FORMING (EMF) is widely used to both join and shape metals and other materials rapidly and precisely, and without the heat effects and tool marks associated with other techniques. Also known as magnetic pulse forming, EMF uses the direct application of a pressure created in an intense, transient magnetic field. Without mechanical contact, a metal workpiece is formed by the passage of a pulse of electric current through a forming coil.

The major application of EMF is the single-step assembly of metal parts to each other or to other components, although it is also used to shape metal parts. Within the transportation industry, for example, one automotive producer assembles aluminum driveshafts without welding to save a significant amount of weight in light trucks and vans in order to meet requirements for reduced energy consumption. Using the EMF process allows the joining of an impact-extruded aluminum yoke to a seamless tube without creating the heat-affected zone associated with welding.

EMF also is used to expand, compress, or form tubular shapes. It is occasionally used to form flat sheet, and it is often used to combine several forming and assembly operations into a single step. In the automotive industry, EMF is used by all three major U.S. manufacturers and several foreign producers to assemble components such as air conditioner accumulators, high-pressure hoses, shock absorber dust covers, rubber boots on constant velocity (CV) joints, oil cooler heat exchangers, steering wheels, gasoline fill tubes, and accessory motor packages.

## Process Description

In its simplest form, EMF uses a capacitor bank, a forming coil, a field shaper, and an electrically conductive workpiece to create intense magnetic fields to do useful work. This very intense magnetic field, produced by the discharge of a bank of capacitors into a forming coil, lasts only a few microseconds. The resulting eddy current that are induced in the conductive workpiece that is placed close to the coil interact with the magnetic field to cause mutual repulsion between the workpiece and the forming coil. The force of this repulsion is sufficient to cause permanent deformation.

**The basic circuit** (Fig. 47) used for electromagnetic compression forming of a tubular workpiece consists of a forming coil, an energy-storage capacitor, switches, and a power supply of nearly constant current to charge the capacitor. Figure 47(a) shows the flux-density pattern of the magnetic field produced by discharging the capacitor through the forming coil in the absence of an electrically conductive workpiece. The evenly spaced flux lines indicate a uniform flux density within the coil. Figure 47(b) shows the change in field pattern that results when the capacitor is discharged through a forming coil in which a tubular workpiece of highly conductive metal has been inserted. The magnetic field is distorted and the flux density intensified (flux lines are more closely spaced) by confinement to the small annular space between the coil and the workpiece.

**Fig. 47** Basic circuit and magnetic field patterns for electromagnetic compression forming of a tubular workpiece. (a) Field pattern in absence of workpiece. (b) Field pattern with workpiece in forming coil. (c) Field pattern when field shaper is used. A, high pressure; B, low pressure.

Field shapers, which are massive current-carrying conductors inductively coupled to the forming coil, concentrate the magnetic field at the point at which forming is desired. This technique most efficiently uses stored energy to produce high

local forming pressures in desired areas. Field shapers also allow the use of a standard forming coil for a variety of applications. The field shaper, which is simpler to make, can be tailored to the specific part to be formed.

Figure 47(c) illustrates the use of a field shaper to concentrate the force in certain regions of the workpiece. This technique not only produces high local forming pressures in desired areas, but also lengthens the life of the forming coil by preventing high pressures on weaker parts of the coil.

**Forming Methods.** Electromagnetic forming can usually be applied to three forming methods: compression, expansion, and contour forming. As shown in Fig. 48(a), a tubular workpiece is compressed by an external coil, usually against a grooved or suitably contoured insert, plug, tube, or fitting inside the workpiece. The tubular workpiece is expanded by an internal coil (Fig. 48b), usually against a collar or other component surrounding the workpiece. Flat stock is almost always contour-formed against a die (Fig. 48c).

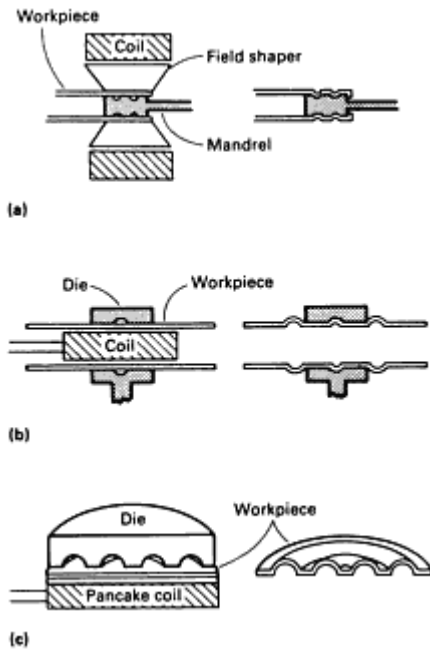

Fig. 48 Three basic methods of EMF. (a) Compression. (b) Expansion. (c) Contour forming

## Superplastic Forming (SPF)

SUPERPLASTICITY refers to the ability of certain metals to develop extremely high tensile elongations at elevated temperatures and under controlled rates of deformation. The tensile ductility of superplastic metals typically ranges from 200 to 1000% elongation, but ductilities in excess of 5000% have been reported. Elongations of this magnitude are one to two orders greater than those observed for conventional metals and alloys, and they are more characteristic of plastics than metals.

Because the capabilities and limitations of sheet metal fabrication are most often determined by the tensile ductility limits, significant advantages potentially are available for forming such materials, provided the high-ductility characteristics observed in the tensile test can be used in production forming processes.

## Superplastic Alloys

There are several different types of superplasticity in terms of the microstructural mechanisms and deformation conditions, including the following: micrograin superplasticity, transformation superplasticity, and internal stress superplasticity. At this time, only the micrograin superplasticity is of importance in the fabrication of parts. For micrograin superplasticity, the high ductilities are observed under the following conditions:

- Very fine grain size material (approximately 10  $\mu\text{m}$ , or 400  $\mu\text{in.}$ )
- Relatively high temperature (greater than about one-half the absolute melting point)
- A controlled strain rate, usually 0.0001 to 0.01  $\text{s}^{-1}$

Because of these requirements, only a limited number of commercial alloys are superplastic. These include Zn-22Al and the titanium and aluminum alloys listed in Table 10. Other alloys, including some ferrous alloys (e.g., hypereutectoid high-carbon steels), exhibit superplastic behavior, but very few of these have been produced commercially.

**Table 10 Superplastic properties of aluminum and titanium alloys**

Alloy	Test temperature		Strain rate, s <sup>-1</sup>	Strain rate sensitivity, <i>m</i> <sup>(a)</sup>	Elongation, %
	°C	°F			
Aluminum					
Statically recrystallized					
Al-33Cu	400-500	752-930	8 × 10 <sup>-4</sup>	0.8	400-1000

- (a) The strain rate sensitivity exponent  $m$  indicates the rate of change of flow stress with strain rate. It is defined by  $m = \Delta \ln \sigma / \Delta \ln \dot{\epsilon}$  where  $\sigma$  is the flow stress and  $\dot{\epsilon}$  is the strain rate

## Superplastic Forming Processes

**Blow forming and vacuum forming** are basically the same process (sometimes called stretch forming) in that a gas pressure differential is imposed on the superplastic diaphragm, causing the material to form into the die configuration. In vacuum forming, the applied pressure is limited to atmospheric pressure (100 kPa, or 15 psi), and the forming rate and capability are therefore limited. With blow forming, additional pressure is applied from a gas pressure reservoir, and the only limitations are related to the pressure rating of the system and the pressure of the gas source. A maximum pressure of 690 to 3400 kPa (100 psi to 500 psi) is typically used in this process.

In blow forming (Fig. 49) the dies and sheet material are normally maintained at the forming temperature, and the gas pressure is imposed over the sheet, causing the sheet to form into the lower die; the gas within the lower die chamber is

simply vented to atmosphere. The lower die chamber also can be held under vacuum, or a back pressure can be imposed to suppress cavitation if necessary.

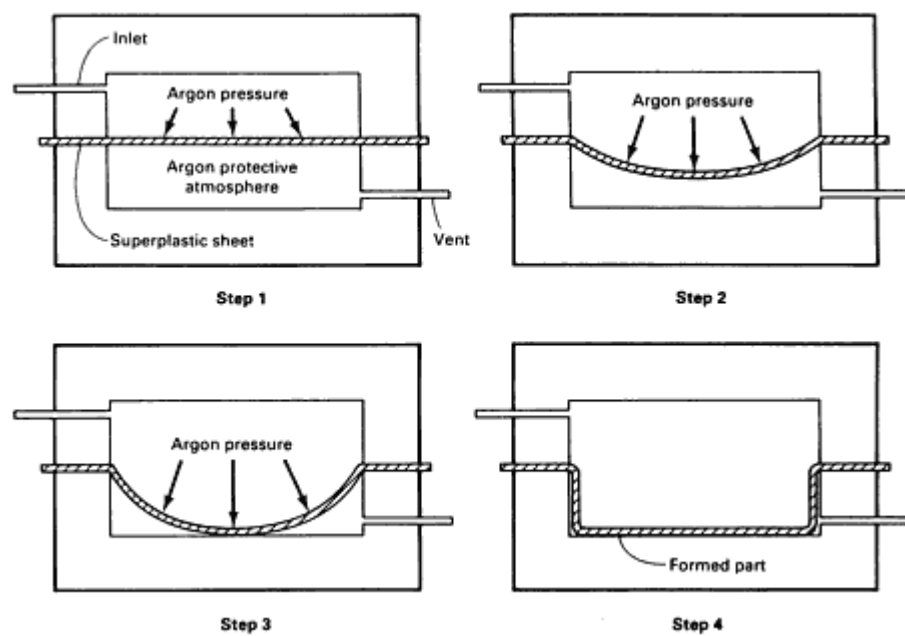

Fig. 49 Schematic of the blow forming technique for superplastic forming

The periphery of the sheet is held in a fixed position and does not "draw-in," as would be the case in typical deep-drawing processes. It is common to use a raised land (seal bead) machined into the tooling around the periphery (Fig. 50) to secure the sheet from slippage and draw-in and to form an airtight seal to prevent leakage of the forming gas. Therefore, the sheet alloy stretches into the die cavity, and all of the material used to form the part comes from the sheet overlying the die cavity. This thins the sheet considerably for complex and deep-drawn parts; it also can create significant gradients in the thickness in the finished part.

Fig. 50 Various sealing methods that have been used around the sheet to provide a pressure seal suitable for containing the gas pressure during forming. Sections (a) and (b) utilize seal beads machined into the tooling, and (c) shows the use of a superplastic frame used as a soft gasket.

This process is used to fabricate structural and ornamental parts from titanium, aluminum, and other metals. For titanium alloys, forming is carried out at about 900 °C (1650 °F). Large, complex parts can be formed by this method; it has the advantage of no moving die components (that is, no double-acting mechanisms) and does not require mated dies. Multiple parts can be formed in a single process cycle, thus increasing the production rate for some parts.

**Thermoforming** has been adapted from plastics technology for forming superplastic metals. These methods sometimes use a moving or adjustable die member in conjunction with gas pressure or vacuum. Figure 51 shows two variations of thermoforming methods. In one variation, an undersize male die punch is used to stretch-form the superplastic sheet, followed by application of gas pressure to force the sheet material against the configurational die to complete the shaping operation. In another method, the first step involves blowing a bubble in the sheet away from the tool. The male tool is then moved into the bubble, and the pressure is reversed to cause the bubble to conform to the shape of the tool.

**Fig. 51** Examples of thermoforming methods used for superplastic forming. (a) Plug-assisted forming into a female die cavity. (b) Snap-back forming over a male die that is moved up into the sheet

Two additional alternative methods use a movable die member to aid in prestretching the sheet material before gas pressure is applied (Fig. 52). In this case, the gas pressure is applied from the same side of the sheet as the moving die. These techniques provide ways of producing different shapes of parts and are effective for controlling the thinning characteristics of the finished part.

**Fig. 52** Thermoforming methods that use gas pressure and movable tools to produce parts from superplastic alloys. (a) Female forming. (b) Male forming

**SPF/DB Processes.** Joining methods, such as diffusion bonding (DB), can be combined with superplastic forming; these processes are generally referred to as SPF/DB. Although diffusion bonding is not a sheet metal process, it complements and enhances superplastic forming to such an extent that the two processes must be discussed together.

SPF/DB evolved as a natural combination because the process temperature requirements of both are similar. The low flow properties characteristic of the superplastic alloys aid the DB pressure requirements. Many superplastic alloys can be diffusion bonded under pressures in the same low range as that used for SPF processing (that is, approximately 2100 to 3400 kPa, or 300 to 500 psi). The SPF method most used with SPF/DB is blow forming.

SPF/DB includes several variations:

- Forming of a single sheet onto preplaced details, followed by diffusion bonding (Fig. 53)
- Diffusion bonding two sheets at selected locations, followed by the forming of one or both into a die (Fig. 54). The reverse sequence can be used.
- Diffusion bonding of three or more sheets at selected locations under gas pressure, followed by expansion under internal gas pressure, which forms the outer two sheets into a die. In the process, the center sheet(s) is (are) stretched into a core configuration (Fig. 55).

Fig. 53 Cross section of the SPF process combined with diffusion bonding (SPF/DB). The process shown utilizes pre-placed details to which the superplastic sheet is bonded.

Fig. 54 Operations required for joining two sheets of superplastic alloy using the SPF/DB process

Fig. 55 Operations required for joining three sheets of superplastic alloy using the SPF/DB process

A variation of the above method uses a minimum of four sheets to make a sandwich panel. As the skin sheets are expanded, the inner two sheets are bonded to define the core structure; finally the core is expanded to bond with the external sheets and to complete formation of the sandwich structure (Fig. 56).

Fig. 56 Example of a four-sheet SPF/DB process in which the outer sheets are formed first and the center sheets are then formed and bonded to the outer two sheets.

## Forming Equipment and Tooling

The forming of superplastic sheet materials involves methods that are different from those used in other forming processes. The environmental conditions, the equipment, and tooling are different.

**Forming Equipment.** For blow forming and vacuum forming, the forming tools must be constrained to counteract the forming gas pressure. In addition, a seal is needed at the interface between the sheet and the tool around the periphery to prevent loss of the gas pressure.

Hydraulic presses and mechanical clamping systems have been used. The hydraulic press can be loaded and unloaded fairly rapidly, but it requires a significant capital investment. The mechanical clamping systems are much less expensive, but are more cumbersome to load and unload. Recently, robotic systems have been coupled with a hydraulic press to aid the loading and unloading. This system is especially beneficial for high-temperature SPF of titanium alloys.

The hydraulic presses used include both single-action and multiple-action systems. The single-action press applies constraining pressure only. The multiple-action press can also move dies into the forming sheet and effectively aid in the control of the thinning gradients.

**Tooling Materials.** The tooling used in SPF is heated to the forming temperature and subjected to internal gas pressure and pressing clamping loads. The internal gas pressure is typically less than 3400 kPa (500 psi), which usually is not the critical design factor for SPF tools. More important are the clamping loads and thermal stresses encountered during heat-up and cool-down and the environmental conditions. Thermal stresses can cause permanent distortions in the die; this is controlled by selecting a material with high strength and creep resistance at the forming temperature. Slow heating and cooling of the tooling can reduce the thermal stresses. Materials with a low coefficient of thermal expansion and those that do not undergo a phase transformation during heating and cooling are preferred for high-temperature SPF. Various metals and alloys, graphite, and ceramics have been used as tool materials.

## Hammers and Presses for Forging

FORGING MACHINES fall into three categories according to their method of operation. Mechanical forging presses are classified as *stroke-restricted machines*; the ability of mechanical presses to deform the work is determined by the length of the press stroke and the available force at various stroke positions. Hydraulic presses are *force-restricted machines* because their ability to deform the material depends on the maximum force rating of the press. *Energy-restricted machines*, including hammers and high-energy-rate forging machines, deform the workpiece by the kinetic energy of the hammer ram. Screw-type presses, although similar in construction to mechanical and hydraulic presses, are classified as energy-restricted machines.

Some of these machines can be used for many forging processes, such as open-die forging and impression-die (or closed-die) forging. Others are restricted to specific processes.

## Hammers

Forging processes using hammers are the most versatile and the least expensive of all forging processes. Hammers are used primarily in hot forging and coining. Basically, the two types of hammers are gravity drop and power drop, with several variations of each type. In hammer forging, the workpiece, usually a heated bar, billet, bloom, or ingot, is placed on the lower die and struck by the upper die and ram, causing it to deform plastically with each successive blow. Although all hammers operate on the principle of high impact, designs vary, depending on the method of actuation. Table 1 compares the capacities of various types of hammers.

**Table 1 Capacities of various types of forging hammers**

Type of hammer	Ram weight		Maximum blow energy		Impact speed		Number of blows per minute
	kg	lb	kJ	ft · lb	m/s	ft/s	
<b>Board drop</b>	45-3,400	100-7,500	47.5	35,000	3-4.5	10-15	45-60
<b>Air or steam lift</b>	225-7,250	500-16,000	122	90,000	3.7-4.9	12-16	60
<b>Electrohydraulic drop</b>	450-9,980	1,000-22,000	108.5	80,000	3-4.5	10-15	50-75
<b>Power drop</b>	680-31,750	1,500-70,000	1,153	850,000	4.5-9	15-30	60-100

## Gravity-Drop Hammers

The main components of a gravity-drop hammer are the anvil or base, supporting columns that contain the ram guides, and a device that returns the ram to its starting position. The energy that deforms the workpiece is derived from the downward drop of the ram. The height of the fall and the weight of the ram determine the force of the blow.

**Board-drop hammers** (Fig. 1) are widely used, especially for producing forgings weighing no more than a few pounds. In the board-drop hammer, the ram is lifted by one or more boards keyed to it and passed between two friction rolls at the top of the hammer. The boards are rolled upward and then mechanically released, permitting the ram to drop from the desired height. Power for lifting the ram is supplied by one or more motors. The hammers have falling weights, or rated sizes, of 180 to 4500 kg (400 to 10,000 lb); standard sizes range from 450 to 2250 kg (1000 to 5000 lb), in increments of approximately 225 and 455 kg (500 and 1000 lb). The height of fall of the ram varies with hammer size, ranging from approximately 900 mm (35 in.) for a 180 kg (400 lb) hammer to approximately 2 m (75 in.) for a 3400 kg (7500 lb) hammer. The height of fall, and thus the striking force, of the hammer is approximately constant for a given setting and cannot be altered without stopping the machine and adjusting the length of stroke. Anvils on board-drop hammers are 20 to 25 times as heavy as the rams.

Fig. 1 Principal components of a board-drop hammer

**The air-lift, gravity-drop hammer** is similar to the board drop hammer in that the forging force is derived from the weight of the falling ram assembly and upper die. It differs in that the ram is raised by air, steam, or hydraulic power. The size of an air-lift hammer generally ranges from approximately 225 to 4500 kg (500 to 10,000 lb). Maximum forging-weight capabilities for drop hammers and board hammers are comparable.

**Hydraulic-Lift, Gravity-Drop Hammers.** During recent years two significant innovations have been introduced in hammer designs. The first is the electrohydraulic gravity-drop hammer in which the ram is lifted with oil pressure against an air cushion. The compressed air slows down the upstroke of the ram and contributes to its acceleration during the downstroke blow. Thus, the electrohydraulic drop hammer also has a minor power-hammer action. The size of a typical hydraulic-lift hammer is about the same as for air-lift equipment.

The second innovation is the use of electronic blow-energy control. This allows the user to program the drop height of the ram for each blow. As a result, the operator can set automatically the number and intensity of blows in each die cavity. Electronic blow control increases the efficiency of the hammer operations and decreases the noise and vibration associated with unnecessarily strong hammer blows.

### ***Power-Drop Hammers***

In a power-drop hammer, the ram is accelerated during the downstroke by air, steam, or hydraulic pressure. This equipment is used almost exclusively for impression or closed-die forging.

The steam or air-powered drop hammer (Fig. 2) is the most powerful machine in general use for the production of impression-die forgings by impact pressure. A heavy anvil block supports two frame members that accurately guide a vertically moving ram; the frame also supports a cylinder that, through a piston and piston rod, motivates the ram. In its lower face, the ram carries an upper die, which contains one part of the impression that shapes the forging. The lower die, which contains the remainder of the impression, is keyed into an anvil cap firmly wedged in place on the anvil. The motion of the piston is controlled by a valve, which admits steam, air, or hydraulic oil to the upper or lower side of the piston. The valve usually is controlled electronically. Most modern power-drop hammers are equipped with programmable electronic blow control to adjust the intensity of each blow.

**Fig. 2** Principal components of a power-drop hammer with foot control to regulate the force of the blow

Power-drop hammers are rated by the weight of the striking mass, not including the upper die. Hammer ratings commonly range from approximately 450 to 32,000 kg (1000 to 70,000 lb). The striking velocity by the downward pressure on the piston sometimes exceeds 7.5 m/s (25 ft/s).

Rating of hammers by the weight of the striking mass is not correct, although it has been common practice. Realistically, hammers should be rated by the maximum energy, in joules or foot-pounds, that the ram can impart to the hot metal during a single blow at the maximum energy setting of the hammer controls. The useful energy supplied to the forged metal by the hammer ram depends on (a) the hammer design (weight of the ram and the pressure on the top of the piston), (b) the ratio of the anvil weight versus the ram weight, and (c) the hammer foundation design.

Power-drop hammers are suitable for the production of large forgings. (Forgings commonly produced in power-drop hammers range in weight from 50 lb to several tons.) An important advantage is that the striking intensity is entirely under the control of the operator or is preset by the electronic blow-control system. Consequently, auxiliary impressions in the dies can be used to preform the billet to a shape that will best fill the finishing impressions in the dies. This helps create proper grain flow, soundness, and less scrap, with minimum die wear. When adequate preliminary impressions

cannot be incorporated in the same set of die blocks, two or more hammers are used to produce adequate shaping or blocking to an intermediate shape before the final die is used.

The greater striking forces developed with power-drop hammers give rise to several disadvantages. As much as 15 to 25% (and, in hard finishing blows, up to 80%) of the kinetic energy of the ram is dissipated in the anvil block and foundation, and therefore does not contribute to deformation of the workpiece. This loss of energy is most critical when finishing blows are struck and the actual deformation per stroke is relatively slight. The transmitted energy imposes a high stress on the anvil block and can even break it. The transmitted energy also develops violent, and potentially damaging, shocks in the surrounding floor area. This necessitates the need for shock absorbing materials, such as timber or iron felt, in anvil-block foundations, adding appreciably to foundation cost.

**Die-Forger Hammers.** Similar in operation to power-drop hammers, die-forger hammers have a shorter stroke and faster striking rate. Typically, these hammers can deliver approximately 5.5 to 90 kJ (4000 to 66,000 ft · lb) of energy per blow. Pressurized air energizes the blow.

**Counterblow Hammers.** Another variation of the power-drop hammer, the counterblow hammer develops striking force by the movement of two rams, simultaneously approaching from opposite directions and meeting at a midway point. Some hammers are air or hydraulically actuated; others incorporate a combination of mechanical-hydraulic, steam-hydraulic, air-hydraulic, or mechanical-air activation.

In the steam-hydraulic actuating system (Fig. 3) steam is admitted to the upper cylinder and drives the upper ram downward. Simultaneously, pistons connected to the upper ram act through a hydraulic linkage to force the lower ram upward. Because the weight of the lower ram and piston assembly is greater than that of the upper assembly, the rams retract automatically after the blow. Retraction speed is increased by steam pressure acting upward on the piston. Through proper design relative to weights (including tooling and workpiece) and hydraulics (slower lower-assembly velocities), the kinetic energy of the upper and lower assemblies can be balanced at impact.

**Fig. 3** Essential components of a vertical counterblow hammer with a steam-hydraulic actuating system

The rams of a counterblow hammer are capable of striking repeated blows; they develop combined velocities of 5 to 6 m/s (6 to 20 ft/s). Compared to single-action hammers, vibration of impact is reduced, and approximately the full energy of each blow is delivered to the workpiece, without loss to an anvil. As a result, the wear of moving hammer parts is minimized, contributing to longer operating life. At the time of impact, forces are canceled out, and no energy is lost to foundations. In fact the large inertia blocks and foundations of conventional power-drop hammers are not required.

A horizontal counterblow hammer has two opposing, die-carrying rams that are moved horizontally by compressed air. Heated stock is positioned automatically at each die impression by a present pattern of accurately timed movements of a stock-handling device. A 90° rotation of stock can be programmed between blows.

## High-Energy-Rate Forging Machines

High-energy-rate forging (HERF) machines are high speed hammers. They can be grouped into three basic designs: ram-and-inner-frame, two-ram, and controlled-energy-flow. Each differs in engineering and operating features, but all are essentially very high-velocity, single-blow hammers that require less moving weight than conventional hammers to achieve the same impact energy per blow. All the designs use counterblow principles to minimize foundation requirements and energy losses. All the designs use inert high-pressure gas controlled by a quick release mechanism for rapid acceleration of the ram. The machine frame is not required to resist the forging forces in any of the designs.

**Ram-and-Inner-Frame Machines.** The frames for these machines (Fig. 4a) consist of two units: an inner or working frame connected to a firing chamber and an outer or guiding frame within which the inner frame is free to move vertically. As the trigger-gas seal opens, high-pressure gas from the firing chamber acts on the top face of the piston and forces the ram and upper die downward. Reaction to the downward acceleration of the ram raises the inner frame and lower die.

**Fig. 4** Three types of machines for high-energy-rate forging. (a) Ram-and-inner-frame machine. (b) Two-ram machine. (c) Controlled-energy-flow machine. Triggering and expansion of gas in the firing chamber cause the upper and lower rams to move toward each other at high velocity. An outer frame provides close guiding surfaces for the rams. See text for descriptions of the mechanics of operation.

The machine is made ready for the next blow by hydraulic jacks that elevate the ram until the trigger-gas seal between the upper surface of the firing chamber and the ram piston is reestablished. Venting of the seal gas, and gas pressure on the lower lip of the piston, then hold the ram in the elevated position.

This type of machine is produced in several sizes, ranging in capacity from 17 to 745 kJ (12,500 to 550,000 ft · lb) of impact energy.

**Two-Ram Machines.** In a two-ram machine (Fig. 4b), the counterblow is achieved by means of an upper ram and a lower ram. An outer frame (not shown) guides the two rams vertically. Vertical movement of the trigger permits high-pressure gas to enter the lower chamber and the space beneath the drive piston. This forces the drive piston, rod, lower ram, and lower die upward. The reaction to this force drives the floating piston, cylinder, upper ram, and upper die downward. The rods provide relative guidance between the moving upper and lower assemblies.

After the blow, hydraulic fluid enters the cylinder, returning the upper and lower rams to their starting positions. The gas is recompressed by the floating pistons, and the gas seals at the lower edges of the drive pistons are reestablished. When the trigger is closed, the hydraulic pressure is released, the high-pressure gas in the lower chamber expands through the

drive-piston ports and forces the floating pistons up, and the machine is ready for the next blow. These machines are made in several sizes; the largest is rated at 407 kg (300,000 ft · lb) of impact energy.

**Controlled-energy-flow forging machines** (Fig. 4c) are counterblow machines with separately adjustable gas cylinders and separate rams for the upper and lower dies; however, they do not rely on self reacting principles. The lower ram has a hydraulically actuated vertical adjustment cylinder so that various stroke lengths can be preset.

The trigger, although pneumatically operated, is a massive mechanical latch that returns and holds the rams through mechanical support of the upper ram and hydraulic connection with the lower ram. This arrangement assures simultaneous release of the two rams. Controlled-energy-flow forging machines have been made in two sizes, with ratings of 99 and 542 kJ (73,000 and 400,000 ft · lb) of maximum impact energy.

**Applicability.** High-energy-rate forging machines basically are limited to fully symmetrical or concentric forgings such as wheels and gears or for coining applications where little metal movement but high die forces are required. The practical use of these machines has been limited and is expected to remain so. Parts that can be forged in high-energy-rate forging machines also can be forged in counterblow hammers or mechanical presses. High-velocity impact during the forging blow reduces die life and increases machine maintenance requirements. Therefore, lower-intensity-stroke machines, for example, hammers and presses, are more economical to use in most applications. Cases where the extremely high-forging rate imparts unusual properties and microstructures to the forged materials may be exceptions.

### ***Open-Die Forging Hammers***

Open-die forging hammers, commonly known as general forging hammers, are used to make a large percentage of open-die forgings. In size, they range from small hammers rated at approximately 11 to 23 kg (25 to 50 lb) to hammers with ratings as high as 11,000 kg (24,000 lb). A general forging hammer is operated by steam or compressed air, usually at pressures of 690 to 825 kPa (100 to 120 psi) for steam and 620 to 690 kPa (90 to 100 psi) for compressed air. These conditions are similar to those of the power-drop hammer used for closed-die forging.

Smaller hammers--those rated at less than approximately 455 kg (1000 lb)--are usually found in repair or maintenance departments of manufacturing plants, where they are used to forge repair parts, to dress tools, and to shape many items needed by maintenance departments. These small hammers are not considered part of a forge shop.

There are two basic differences between power-drop hammers used for closed-die forging and those used for open-die forging. First, a modern power-drop hammer has blow-energy control to assist the operator in setting the intensity of each blow. In hammers for closed-die forging, the hammer stroke is limited by the upper die surface contacting the surface of the lower die face. In open-die forging, the upper and lower dies do not make contact; stroke-position control is provided through control of the air or steam valve that actuates the hammer piston.

The second difference between closed-die and open-die forging hammers is that the anvil of an open-die hammer is separate and independent of the hammer frame that contains the striking ram and the top die. Separation of the anvil from the frame allows the anvil to give way under a heavy blow or series of blows, without disturbing the frame. The anvil can rest on oak timbers, which absorb the hammering shock.

Open-die hammers are made either with a single frame (often termed C-frame or single-arch hammers) or with a double frame (often called double-arch hammers). Double-frame general forging hammers (Fig. 5) usually come in rated sizes from 2720 to 10,900 kg (6000 to 24,000 lb), although larger hammers have been built.

Fig. 5 Double-frame power hammer used for open-die forging

## Mechanical Presses

A massive, rotating flywheel imparts the energy to drive the ram into the workpiece in a mechanical press. Driven by a motor and controlled by an air clutch, a full-eccentric drive shaft provides a constant-length stroke to a vertically operating ram. The ram carries the top (or moving) die, whereas the bottom (or stationary) die is clamped to the die seat of the main frame. The ram stroke is shorter than that of a forging hammer or a hydraulic press. Ram speed is greatest at the center of the stroke, but force is greatest at the bottom of the stroke.

Because of the short stroke, mechanical presses are best suited for low profile forgings. Capacities of these forging presses are rated on the maximum force they can apply and range from approximately 3 to 140 MN (300 to 16,000 tonf).

Knuckle-joint mechanical presses are operated by an eccentric shaft or by a crankshaft. The knuckle mechanism increases available forging force but reduces ram-stroke length. Thus, knuckle-joint presses are used primarily for flash trimming, coining, or sizing.

Mechanical forging presses are similar to eccentric-shaft, straight-side, single-action presses used for forming sheet metal. In detail, however, mechanical forging presses are considerably different from mechanical presses that are used for forming sheet. Forging presses are built stronger than presses for forming sheet metal. Forging presses deliver their maximum force within 3.2 mm ( $\frac{1}{8}$  in.) of the end of the stroke because maximum pressure is required to form the flash. In addition, the slide velocity in a forging press is faster than that of a sheet-metal deep drawing press.

The character of the blow in a forging press resembles that of an upsetting machine, thus combining some features of hammers and upsetters. Mechanical forging presses use drive mechanisms similar to those of upsetters, although an upsetter generally is a horizontal machine.

Mechanical forging presses provide higher production rates than forging hammers. Stroking rates vary from approximately 30 strokes per minute, for a 140 MN (16,000 tonf) press, to approximately 100 strokes per minute, for a 4500 kN (500 tonf) press. Because the impact is less in presses than in hammers, dies can be less massive, thus requiring less tool steel to make the dies. Cast dies can be used. Also because presses deliver a less severe impact blow, dies can be

operated at higher hardness, which prolongs die life. In addition, presses generate less noise and vibration than hammers. Presses require less operator skill than is required for hammers, they are easier to automate, and they can produce more precise parts.

However, initial cost of mechanical forging presses is up to three times the cost of a hammer to produce the same forging. A press delivers consecutive strokes of equal force and therefore, is less suitable for preliminary shaping operations such as fullering or rolling.

## Hydraulic Presses

Hydraulic presses (Fig. 6) are used for both open-die and impression-die (closed-die) forging. The ram is driven by hydraulic cylinders and pistons, which are part of a high-pressure hydraulic or hydropneumatic system. Because pressing speeds can be controlled accurately, these presses are advantageous for producing close-tolerance, precision forgings.

**Fig. 6** Components of a four-post hydraulic press for closed-die forging

For precision forging, presses can be equipped with a hydraulic control circuit that produces a rapid advance stroke, followed by preselected first and second pressing speeds. Many other process variables can be controlled including pullout speed, force, dwell times, and ejection.

Hydraulic presses are equipped with either direct drives or accumulator drives. Direct-driven presses use a hydraulic pump to feed oil under pressure into the cylinder of the press continuously during the stroke. Thus, the pump capacity determines the maximum available press speed and press load. In accumulator-driven presses, a water emulsion, the working medium, is stored in an accumulator under nitrogen pressure. When the press stroke is initiated, the pressurized water emulsion is fed into the press cylinder. During the press stroke, the water emulsion expands and loses some of its initial pressure. In automatic programmed forging operations, direct drive offers the advantage of very close control of ram speed and ram position.

Capacities of hydraulic presses range from 1.8 to 125 MN (200 to 14,000 tonf) for open-die presses and 4.5 to 640 MN (500 to 72,000 tonf) for impression-die presses.

With hydraulic presses, pressure can be changed at any point in the stroke by adjusting the pressure control valve. Rates of deformation can be controlled and varied during the stroke, if required. This is especially important in forging of metals that rupture if subjected to high deformation rates. Parts can be forged using split dies to create offset flanges, projections, back draft, and other design features that are extremely difficult, if not impossible, to incorporate in hammer forgings.

When excessive heat transfer (from the hot workpiece to the dies) is not a problem, or can be eliminated, the gentle squeezing action of a hydraulic press results in lower maintenance cost and increased die life because of less shock compared with other types of forging equipment. Maximum press load can be limited to protect the tooling.

One disadvantage of a hydraulic press is that the initial cost is higher than that of a mechanical press of equivalent capacity. In addition, the action of a hydraulic press is slower than that of a mechanical press. The slower action produces longer contact between the dies and the workpiece, which allows time for heat transfer from the hot workpiece to the dies. This reduces die life, particularly when forging high-temperature materials such as steel, titanium, and nickel alloys.

## Screw Presses

Machines in this category use energy from a flywheel to turn a screw that drives the ram. Screw presses are used for precision-forging, steam-turbine, and jet-engine compressor blades; diesel-engine crankshafts; and gearlike parts. The process, when economical, can be used for open- and impression-die forging and precision forging of brass and aluminum parts.

### Drive Systems

The screw press uses a friction, gear, electric, or hydraulic drive to accelerate the flywheel and the screw assembly, and it converts the angular kinetic energy into the linear energy of the slide or ram (Fig. 7).

**Fig. 7** Two basic designs of screw presses. (a) Friction-drive press. (b) Direct-electric-drive press

**In the friction-drive press** (Fig. 7a), the driving disks, mounted on a horizontal shaft, are rotated continuously. For a downstroke, one of the driving disks is pressed against the flywheel by a servomotor. The flywheel, which is connected to the screw either positively or by a friction slip clutch, is accelerated by this driving disk through friction. The flywheel energy and the ram speed continue to increase until the ram hits the workpiece. Thus, the forming load is built up and

transmitted through the slide, the screw, and the bed to the press frame. When the entire energy in the flywheel is used in deforming the workpiece and elastically deflecting the press, the flywheel, the screw, and the slide stop. At this moment, the servomotor activates the horizontal shaft and presses the upstroke driving disk wheel against the flywheel. Thus, the flywheel and the screw are accelerated in the reverse direction, and the slide is lifted to its top position.

**In the direct-electric-drive press** (Fig. 7b), a reversible electric motor is built directly on the screw and on the frame, above the flywheel. The screw is threaded into the ram or slide and does not move vertically. To reverse the direction of flywheel rotation, the electric motor is reversed after each downstroke and upstroke.

**Other Drive Systems.** In addition to friction and direct-electric drives, several other types of mechanical, electric, and hydraulic drives are commonly used in screw presses. A relatively new screw press drive (Fig. 8) uses a flywheel similar to that used to initiate the stroke of an eccentric mechanical forging press. Upon engagement of the clutch, the screw is accelerated rapidly and reaches the speed of the flywheel. As a result, the ram moves downward. The downstroke charges a hydropneumatic lift cylinder system. The downstroke is terminated in either of two ways: by controlling the ram position with a position switch, or by controlling the maximum load on the ram by disengaging the clutch and the flywheel from the screw when the preset forming load is reached. The ram is then lifted by the lift-up cylinders, releasing the elastic energy stored in the press frame, the screw, and the lift-up cylinders. At the end of the upstroke, the ram is stopped and held in position by a hydraulic brake.

**Fig. 8** Screw press drive combining the characteristics of mechanical and screw presses. (a) Flywheel. (b) Air-operated clutch. (c) Screw. (d) Ram. (e) Lift-up cylinders

This press provides a high and nearly constant ram speed throughout the stroke with full press load at any position of the stroke. Other advantages include high deformation energy, overload protection, and short contact time between the workpiece and the tools.

This drive system is limited in that only two levels of energy are available, high and low. Furthermore, because force is controlled through slippage of the clutch, application of power is not predictable. The large amount of energy available can create material flow problems.

### ***Capacities and Speed***

Screw presses usually are rated by the diameter of the screw. Screw diameters range from 100 to 635 mm (4 to 25 in.). These sizes translate to nominal forces of 1.4 to 35.6 MN (160 to 4000 tonf). Direct electric-drive screw presses have

been built with 600 mm (24 in.) diameter screws, or 37.3 MN (4190 tonf) of nominal force capacity. Hydraulically driven screw presses have hard-on-hard blow capacities up to 310 MN (35,000 tonf).

Press speed in strokes per minute depends largely on the energy required by the specific forming process and on the capacity of the drive mechanism to accelerate the screw and the flywheel. In general, however, the production rate of a screw press is lower than that of a mechanical press, especially in automated high-volume operations. Small screw presses operate up to 40 to 50 strokes per minute, while larger presses operate at approximately 12 to 16 strokes per minute.

## Multiple-Ram Presses

Hollow, flashless forgings for valve bodies, hydraulic cylinders, seamless tubes, and a variety of pressure vessels can be produced in a hydraulic press with multiple rams. The rams converge on the workpiece in vertical and horizontal planes, alternately or in combination, and fill the die by displacement of metal outward from a central cavity developed by one or more of the punches (Fig. 9).

**Fig. 9** Examples of multiple-ram forgings. Displacement of metal can take place from vertical, horizontal, and combined vertical and horizontal planes. Dimensions given in inches.

Piercing holes in a forging at an angle to the normal direction of forging force can save considerable material and machining time required to generate the holes. In addition to versatility provided by multiple rams, these presses can be used for forward or reverse extrusion. Lack of flash at the parting line decreases stress-corrosion cracking in forging alloys susceptible to this type of failure. Multidirectional hot working, characteristic of this process, decreases adverse directional effects on mechanical properties.

## Die Design and Materials

THE TECHNOLOGY in this section applies in general to the design of dies, terminology, and materials selection for dies for the most common hot-forging processes--particularly those using vertical presses, hammers, and horizontal forging machines (upsetters). More specific details are given in the next section, which discusses each of the primary forging processes.

## Designing Parts for Forging

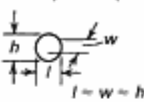

Metal flow in forging is greatly influenced by part or die geometry. Often, several operations (preforming or blocking) are needed to achieve gradual flow of the metal from an initially simple shape (cylinder or round-cornered, square billet) into the more complex shape of the final forging. Generally, spherical and blocklike shapes are the easiest to forge in impression or closed dies. Parts with long, thin sections or projections (webs and ribs) are more difficult to forge because they have more surface area per unit volume. The shape of the final forging determines process variables including friction, temperature changes in the dies, and pressure required to fill the die cavities. The surface-to-volume ratio of a forging is directly related to the difficulty of producing the forging.

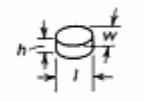

The ease of forging complex shapes depends on the relative proportions of vertical and horizontal projections on the part. For example, parts (c) and (d) in Fig. 10 require not only higher forging loads, but also at least one more forging operation than parts (a) and (b) to ensure die filling.

**Fig. 10** Rectangular shape and three modifications, showing increasing forging difficulty (from a to d) with increasing rib height and decreasing web thickness

Most forgings can be classified into three main groups (Fig. 11). For the first group, the so-called "compact shapes," the three major dimensions (length,  $l$ ; width,  $w$ ; and height,  $h$ ) are approximately equal. Few parts fall into this group. In the second group, "disk shapes," two of the three dimensions (length,  $l$ , and width,  $w$ ) are approximately equal and greater than the height,  $h$ . All round forgings belong to this group, which includes approximately 30% of all commonly used forgings. The third group consists of long shapes for which one major dimension is significantly greater than the other two ( $l > w \geq h$ ). These three basic groups are further divided into subgroups depending on the presence and type of elements subsidiary to the basic shape.

Shape class 1 Compact shape  Spherical and cubical	Sub-group	101	102	103	104
	Shape group	No subsidiary elements	Unilateral subsidiary elements	Rotational subsidiary elements	Unilateral subsidiary elements
					

Shape class 2 Disk shape  Parts with circular, square and similar contours; cross piece with short arms, upset heads, and long shapes (flanges, valves, etc.)	Sub-group	No subsidiary elements	With hub	With hub and hole	With rim	With rim and hub
	Shape group					
	21 Disk shape with unilateral element	211 	212 	213 	214 	215 
	22 Disk shape with bilateral element	...	222 	223 	224 	225 

Shape class 3 Oblong shape  Parts with pronounced longitudinal axis  Length groups 1. Short $l > 3w$ 2. Average $l = 3 \text{ to } 8w$ 3. Long $l = 8 \text{ to } 16w$ 4. Very long $l = 16w$  Length group numbers added behind bar, for example, 334/2	Sub-group	No subsidiary elements	Subsidiary elements parallel to axis of principal shape	With open or closed fork element	With subsidiary elements asymmetrical to axis of principal shape	With two or more subsidiary elements of similar size
	Shape group					
	31 Principal shape element with straight axis	311 	312 	313 	314 	315 
	32 Longitudinal axis of principal shape element curved in one plane	321 	322 	323 	324 	325 
	33 Long axis of principal shape element curved in several planes	331 	332 	333 	334 	335 

Fig. 11 Classification of forging shapes

This "shape classification" can be useful for estimating costs and predicting preforming steps. However, this method is not entirely quantitative and requires subjective evaluation based on past experience.

### Parting Line

The parting line is the line along the forging at which the dies meet. It can be in a single plane, curved, or irregular. The shape and location of the parting line determine die cost, draft requirements, grain flow, and trimming procedures.

In most forgings, the parting line is at the largest cross section of the part because it is easier to spread metal by forging action than to force it into deep die impressions. If the largest cross section coincides with a flat side of a forging, the

parting line could be located along the edges of the flat section, thus placing the entire impression in one die half. This reduces die costs because one die is simply a flat surface. This also prevents mismatch between upper and lower dies and allows forging flash to be trimmed readily.

When a die set with one flat die cannot be used, the parting line should be positioned to provide for location of the preform in the finished impression of the forging die and the finished forging in the trimming die.

Because part of the metal flow is toward the parting line during forging, the location of the parting line affects the grain-flow characteristics of a forged piece. For good internal-flow patterns in, for example, a forging having a vertical wall adjacent to a bottom web section, a parting line on the outer side of the wall should be either adjacent to the web section and near the bottom of the wall, or at the top of the wall. A parting line at any point above the center of the bottom web but below the top of the wall can disrupt the grain flow and cause defects in the forging.

Because the dies move only in a straight line, and because the forging must be removed from the die without damage either to the impression or to the forging, die impressions usually can have no undercuts. Frequently, the forging can be inclined with respect to the forging plane to overcome the effect of an undercut. In press forging, "split dies," confined in a holder during forging and opened up for removal of the forged part, allow forging parts with undercuts and complex shapes.

### ***Locks and Counterlocks***

Many forgings require a parting line that is not flat and, correspondingly, die parting surfaces that are neither planar nor perpendicular to the direction of the forging force. Dies that have a change in the plane of their mating surfaces, and that, therefore, mesh ("lock") in a vertical direction when closed, are called locked dies.

In forging with locked dies, side or end thrust is frequently a problem. A strong lateral thrust during forging can cause mismatch of the dies or breakage of the forging equipment.

To eliminate or control side thrust, forgings can be inclined, rotated, or otherwise placed in the dies to balance the lateral forces (Fig. 12c). Flash can be used to cushion the shock and help absorb the lateral forces. For large production quantities of parts small enough to be forged in multiple-part dies, the impressions can be arranged so the side thrusts cancel each other.

**Fig. 12** Locked and counterlocked dies. Locked dies (a) with no means of counteracting side thrust, (b) with counterlock, and (c) requiring no counterlock because the forging has been rotated to minimize side thrust.

Generally, alignment between the upper and lower die impressions can be maintained with proper placement of the impression in the die, using clearance between the guides on the hammer or press to absorb side thrust. When these techniques will not work, side thrust can be counteracted by machining mating projections and recesses, or counterlocks, into the parting surfaces of the dies.

Counterlocks can be relatively simple. A pin lock, consisting of a round or square peglike section with its mating section, may be all that is required to control mismatch. Two such sections, or sections at each corner of the die, may be necessary. A simple raised section with a mating countersunk section running the width and the length of the die can control side and end match. Counterlocks of these types should not be used in long production runs.

Counterlocks in high-production dies should be carefully designed and constructed. The height of the counterlock usually is equal to, or slightly greater than, the depth of the locking portion of the die. The thickness of the counterlock should be at least 1.5 times the height to provide adequate strength to resist side thrust. Adequate lubrication of the sliding surfaces is difficult to maintain because of the temperature of the die and the heat radiated from the workpiece. Therefore, the surfaces of the counterlock wear rapidly and need frequent reworking. Because of the cost of constructing and maintaining counterlocks, they should be used only if a forging cannot be produced more economically without them.

### ***Size of the Die Block***

The size of the die block is determined by the width of the finished "platter," including allowance for flash and gutters and allowance for the preforming impressions and for sprues and gates for the blocker and finisher impressions. ("Platter" is defined as the entire workpiece on which the forging equipment performs work, including the flash, sprue, tonghold, and as many forgings as are made at one time.)

The impressions in a block should be spaced in such a way that the size of the die face is suitable for the size of the hammer, that flash cannot flow from one impression to another, and that the forging is not pinched in preform impressions that are too narrow. Die pressures vary with different work metals and workpiece shapes. A larger die block usually is needed as die pressure is increased.

When standard forged alloy steel rams are used in gravity-drop hammers, the minimum area of the upper die face recommended by one manufacturer is 30% of the ram area for 225 to 1135 kg (500 to 2500 lb) hammers, 35% for 1360 to 2270 kg (3000 to 5000 lb) hammers and 40% for hammers with capacities of 2720 kg (6000 lb) or more. The weight of the upper die should be 25 to 30% of the falling weight. Heavier dies are not recommended for regular practice. For power-drop hammers, the area of the die face should be 50% of the ram area for 455 to 1360 kg (1000 to 3000 lb) hammers, 60% for 1815 to 3630 kg (4000 to 8000 lb) hammers and 70% for hammers with capacities of 4535 kg (10,000 lb) or more.

The minimum shut height of the dies should be at least 50 mm (2 in.) greater than the shut height of the hammer or press. The height of the die block determines the maximum impression depth because adequate die material must remain between the bottom of the impression and the bottom face of the die block to provide strength to the die.

Relatively small "die inserts" usually are used in mechanical presses. This saves expensive die material and the machining required on large die blocks. The dies are set in recesses in holders fastened to the ram and bed of the press. The dies are held in the recesses by clamps, and screws extending through the holders into the recesses provide for adjustment of die position and hold the die in position.

In modern press-forging operations, quick die-change mechanisms are available. Thus, die inserts can be held by hydraulic clamps that hold or release very quickly. Another method is to set up the inserts in an extra die holder outside the press and to change the entire die holder before starting a new production run.

### ***Draft***

Draft, or taper, is added to straight sidewalls of a forging to permit easier removal from the die impression. Forgings having round or oval cross sections or slanted sidewalls form their own draft. Forgings having straight sidewalls, such as square or rectangular sections, can be forged by parting them across the diagonal and tilting the impression in the die so that the parting line is parallel to the forging plane. Another method is to place the parting line at an angle to the forging plane and to machine a straight-wall cavity and a counterlock in each die.

The draft used in die impressions normally varies from 3 to 7° for external walls of the forged surfaces that surround holes or recesses having angles ranging from 5 to 10°. More draft is used on walls surrounding recesses to prevent forging sticking in the die as a result of natural shrinkage of the metal as it cools.

### ***Flash Allowance***

Flash, or excess metal extruded from the finisher impression during forging, acts as a cushion for impact blows and as a pressure-relief valve for the almost incompressible work metal. Also, it restricts the outward flow of the metal so that thin ribs and bosses can be filled in the upper die. The finisher impression generally includes a provision for flash. Figure 13 shows a typical arrangement (flash clearance, flash land, and gutter).

**Fig. 13** Section through a forging, die finisher impression showing flash clearance, flash land, and gutter

A small amount of flash clearance in the dies, with an excess volume of work metal in the impression, requires much greater forging load or extra hammer blows to bring the forging to size. This creates excessive wear on the flash land, produces extreme pressures within the impression, and can cause dies to break.

Conversely, if the flash clearance is too great, work metal needed to fill the impression flows out through the flash land, and the forging is not properly filled. A balanced condition is needed, with just enough volume of metal to ensure that the flash clearance provided will force the work metal to fill the impression properly without causing excess wear and pressure.

The volume, the complexity, and the height-to-weight ratio of the forging, as well as the type of work metal, have an effect on flash thickness. General practice has been to use smaller flash clearance for small forgings than for large forgings. The amount of clearance varies from a minimum of approximately 0.51 mm (0.020 in.) up to a maximum of approximately 9.52 mm (0.375 in.) for forgings weighing up to 90 kg (200 lb). Approximately 3% of the maximum forging thickness is a reasonable guide for flash clearance.

The amount of excess work metal extruded from the impression can be too great to permit complete closing of the dies. To ensure complete closing, a gutter is provided for the excess metal after it has passed through the flash land.

### ***Locating Impressions***

The preform and finisher impressions should be positioned across the die block so the forging force is as near the center of the striking force (ram) as possible. This will minimize tipping of the ram, reduce wear on the ram guides, and help to maintain the thickness dimensions of the forging. When the forging is transferred manually to each impression, the impression for the operation requiring the greatest forging force (usually, the finisher) is placed at the center of the die block, and the remaining impressions are distributed as nearly equally as possible on each side of the die block.

Symmetrical forgings usually have their centerline along the front-to-back centerline of the die block. For asymmetrical forgings, the center of gravity can be used as a reference for positioning the preform and finisher impressions in the die block.

The center of gravity of a forging does not necessarily correspond to the center of the forging force because of the influence of thin sections on the forging force. Because the increase in force is not always directly proportional to the decrease in thickness, both the flash and the location of the thin sections must be considered when locating the impressions in a die block. Evenly distributed flash has little effect on an out-of-balance condition; very thin sections have a marked effect. Often it is necessary to make some calculations in order to determine the center of loading of the finisher impression.

### ***Die Inserts***

Die inserts are used for economy in production of some forgings. In general, they prolong the life of the die block into which they fit. Inserts can decrease production costs when several can be made for the cost of producing one solid die. The time required for changeover or replacement of inserts is brief because a second set of inserts can be made while the

first set is being used. Finally, more forgings can be made accurately in a die with inserts than in a solid die because steel of higher alloy content and greater hardness can be used in inserts than would be safe or economical to use in solid dies.

Some commercial drop-hammer forge shops rarely use die inserts. However, nearly all press shops use die inserts.

Inserts can contain the impression of only the portion of a forging subjected to greatest wear, or they can contain the impression of a whole forging. An example of the first type of insert is the plug-type insert used for forging deep cavities. Examples of the second type include master-block inserts that permit forging of a variety of shallow parts in a single die block and inserts for replacement of impressions that wear the most rapidly in multiple-impression dies.

**A plug-type insert** (Fig. 14) is usually a projection in the center of the die to forge a hub or cup, for example. In some impressions, the plug may not be in the center, and more than one plug can be used in a single impression. Although plugs are used in either shallow or deep impressions, the need is usually greater in deep impressions.

**Fig. 14** Use of a plug-type insert in combination with a nearly complete insert in the lower die block for making a forging of extreme severity. For forging this workpiece (an automotive axle housing), shown in cross section, an H12 tool steel plug in the upper die block is used in combination with a nearly complete H12 insert in the lower die block.

Plug inserts can be made either from prehardened die steel at a higher hardness than the main part of the die or, for longer life, from one of the hot-work tool steels. For extremely high wear resistance, the plug can be hardfaced.

**Full inserts** are generally used for shallow forgings. The insert can be of high hardness with less danger of breakage because it has the softer block as a backing. With only the insert made from a higher alloy steel, die costs are low. Changes in die designs are less costly when inserts are used; also, the same die block, or master block, can be used for slightly different forgings by changing inserts (Fig. 15a).

**Fig. 15** Two types of die inserts used in hammer forging. (a) Full insert and master block for use in forging of gear blanks in hammers. (b) Multiple-impression insert for use when wear is excessive on one or more impressions. Such an insert is usually secured by a key.

Another application for an insert is in multiple-impression dies in which the impressions wear at different rates. Inserts are used for only the impressions that wear most rapidly. In the multiple-impression die, Fig. 15(b), the blocker and finisher impressions are in the same insert.

This technique is not necessarily limited to shallow impressions. If the insert contains a single impression, the impression can be of any practical depth. However, if it contains several impressions, the impression depth is limited to approximately 64 mm ( $2\frac{1}{2}$  in.) or less. Width of the insert must be considered; sufficient wall thickness must be allowed between the edge of the impression and the edge of the insert so the die-block walls are not weakened too greatly.

## Die Steels

Prehardened and tempered tool steel die blocks are available in a range of compositions and hardnesses. Tool steels are also available for small die blocks, die inserts, and trimming tools. Prehardened die-block steels are usually purchased on a basis of hardness.

Hot-work die steels are commonly used for hot-forging dies subjected to temperatures ranging from 315 to 650 °C (600 to 1200 °F). These materials contain chromium, tungsten, and in some cases vanadium or molybdenum or both. These alloying elements induce deep hardening characteristics and resistance to abrasion and softening. These steels are usually hardened by quenching in air or molten salt baths. The chromium-base steels (Table 2) contain approximately 5% Cr. High molybdenum content gives these materials resistance to softening; vanadium increases resistance to abrasion and softening. Tungsten improves toughness and hot hardness; tungsten-containing steels, however, are not resistant to thermal shock and cannot be cooled intermittently with water. The tungsten-base, hot-work die steels contain 9 to 18% W, 2 to 12% Cr, and sometimes small amounts of vanadium. The high tungsten content provides resistance to softening at high temperatures while maintaining adequate toughness, but it also makes water cooling of these steels impossible. Low-alloy proprietary steels are also used frequently as die materials for hot forging. Steels with ASM designations 6G, 6F2, and 6F3 have good toughness and shock resistance with good resistance to abrasion and heat checking. These steels are tempered at lower temperatures (usually 450 to 500 °C, or 840 to 930 °F); therefore, they are more suited for applications that do not result in high die surface temperatures (for example, die holders for hot forging or hammer die blocks).

**Table 2** Compositions of tool and die materials for hot forging

**Selection Factors.** Die steels are selected according to their ability to harden uniformly, to resist the abrasive action of the hot metal during forging, to withstand high pressure and heavy shock loads, and to resist cracking and checking caused by heat. Process variables to consider when selecting a die steel include shape, size, and weight of the forging; the metal to be forged; forging temperature; production quantity; and the forging equipment to be used.

Further variables in die material selection are cost of the die steel; how the die will be machined (before or after hardening); and forging tolerances (including those specified for draft angles). Typically, the selection also will be determined by previous experience with similar applications and the availability of machining equipment.

Additional information on properties and selection of die steels can be found in the Section "Tool Steels" in this Volume. Another excellent information source for die material selection is the *Tool Materials, ASM Specialty Handbook*, 1995. This Volume provides material selection guidelines for individual forging (hot and cold) and forming operations.

## **Computer-Aided Design and Computer-Aided Manufacture of Forging Dies**

Computer analysis is well suited to the design of forging dies. Three-dimensional computer models can simulate metal flow through the die cavities and assist in establishing the best die design. Computer-aided design (CAD) and computer-aided manufacture (CAM) techniques are increasingly used in the forging industry. Once the computer determines the detailed dimensions of the die, it can translate them into instructions for numerically controlled machining of the final tooling. Software designed for die design provides a database reference for draft angles, flash dimensioning, and even control of the forging operation.

Software now can perform analyses based on sections through the workpiece. The computer can be used to predict forging load, stress concentrations in the die, elastic deformation of the die material, and metal flow of the workpiece. With little effort, these variables can be observed for alternative designs. Flash dimensions can be selected, and initial estimates of blocker or preform sections can be evaluated.

Once the die is created on the computer to the designer's satisfaction, the software presents a geometric database to be used to write numerical control instructions for milling the die. More information on computer modeling for forging is available in *Forming and Forging*, Volume 14, *ASM Handbook* (see the Section "Computer-Aided Process Design for Bulk Forming," in this Volume).

## **Forging Processes**

THIS SECTION reviews specific characteristics of the most common forging processes. Process limitations, advantages, and disadvantages are discussed.

### **Open-Die Forging**

Open-die forging--sometimes known as hand, smith, hammer, and flat-die forging--is a process in which the metal workpiece is not confined by dies. The process is typically associated with large parts, although parts can weigh from a few pounds to 150 tons. Probably 80% of all parts forged in open dies weigh between 30 and 1000 lb each.

Open-die forging progressively works the starting stock into the final shape, most commonly between flat-faced dies. This process can be selected when the forging is too large to be produced in closed dies. All forgeable metals can be forged in open dies.

### ***Shapes Produced***

Highly skilled hammer and press operators, with the aid of various auxiliary tools, can produce relatively complex shapes in open dies. However, because forging of complex shapes is time consuming and expensive, such forgings are produced only under unusual circumstances.

Most open-die forgings are rounds, squares, rectangles, hexagons, and octagons forged from billet stock, either to develop mechanical properties that are superior to those of rolled bars or to provide these shapes in compositions for which the

shapes are not readily available as rolled products. Hubs that have a small diameter adjacent to a large diameter can be produced in small quantities by open-die forging.

Open-die forging is used to produce spindles, pinion gears, and rotors that are shaft-like parts with their major or functional diameters either in the center or at one end with one or more smaller diameters extending from one or both sides of the major diameter in shaft-like extensions. Forged and pierced blanks, prior to conversion to rolled rings, are open-die forged. Various basic shapes can be developed between open dies with the aid of "loose" tooling.

### ***Hammers and Presses***

The principles of operation of hammers and presses are discussed in the Section, "Hammers and Presses for Forging." However, open-die forging requires control of the stroke, the position and the speed of the ram, to obtain acceptable precision and quality in the forged part. Therefore, in general, only air or oil-driven power hammers and hydraulic presses are suitable for open-die forging. Modern open-die forging installations use direct-driven hydraulic presses with pulldown frame design and with quick die-changing mechanisms. In this type of press, the cylinder crosshead, which is located below floor level, is rigidly connected to the press columns. This assembly is movable and well guided. The center of gravity of this press is low, with high stiffness.

Direct-driven hydraulic presses offer better control of ram speed and ram position. In modern installations this feature is very significant because the press is usually integrated with a manipulator. The stroke position of the press and the motions of the manipulator are computer controlled. As a result, the entire open-die forging operation can be programmed for given initial and final stock shape and workpiece material.

### ***Dies***

Most open-die forgings are produced in a pair of flat dies--one attached to the hammer or to the press ram and the other attached to the anvil. Swage dies (curved), V-dies, and V-die and flat-die combinations are also used (Fig. 16). Occasionally, a combination of a flat die and a swage die is used. Dies are attached to platens and rams or are held on the anvil manually with handles.

**Fig. 16** Four types of die sets commonly used in open-die forging

**Steels used for dies** for open-die forging are often the same as those used for impression dies in closed-die forging--for example, 6G or 6F2 die-block steels (compositions of these steels can be found in Table 2). Alloy steels such as 4150 give satisfactory results for small dies. Some forgers prefer a higher carbon steel and use a 0.70% carbon, 4300 grade (such as 4370, although this is not a standard steel).

The hardness of dies for open-die forging is generally lower than the hardness of impression dies for closed-die forging. For 6G or 6F2, the usual hardness range is 302 to 331 HB. Dies made of 4150 or a similar alloy steel are usually heat treated to 277 to 321 HB.

**Parallelism.** If the faces of a set of dies mounted in a hammer or press are not parallel, the deviation creates a taper on the forgings that may be out of tolerance. Tolerances for parallelism vary to some extent with the size of the dies. Fairly large dies (dies 965 by 510 mm, or 38 by 20 in., for example) should be parallel within 1.6 mm ( $\frac{1}{16}$  in.) front to back and side to side. For smaller dies, closer parallelism can be maintained.

**Life of dies** for open-die forging is longer than that of impression dies for closed-die forging. Because of the wide variety of forgings produced on the same open dies, life is usually expressed in production hours rather than in number of forgings. It is not unusual for dies to operate in a hammer for 600 h before they require redressing. Dies are usually designed to permit eight to ten redressings, which is equivalent to 4800 to 6000 h total life.

### ***Auxiliary Tools***

To assist in forging production, mandrels, saddle supports, sizing blocks (spacers), ring tools, bolsters, fullers, punches, drifts (expansion tools), and a wide variety of special tools (for producing special shapes) are used. Because most auxiliary tools are exposed to heat, they are usually made from the same steels as the dies.

## **Closed-Die Forging in Hammers and Presses**

Closed-die forging, often referred to as impression-die forging, accounts for the bulk of commercial forging production. As the name implies, two or more dies containing impressions of the part shape are brought together causing the workpiece to plastically deform with the metal flow restricted by the die contours.

The forging stock, generally round or square bar, is cut to length to provide the volume of metal needed to fill the die cavity, in addition to an allowance for flash and sometimes for a projection for holding the forging. The flash allowance is, in effect, a relief valve for the extreme pressure produced in closed dies. Flash also acts as a brake to slow the outward flow of metal in order to permit complete filling of the desired configuration.

Most closed-die forging is performed at elevated temperatures and is known as hot forging. Both the forging stock and the die are preheated prior to forging. Various types of electric and fuel-fired furnaces are used for heating the forging stock, as well as resistance and induction heating. Die heating is discussed in the section "Die Heating."

Also in the closed-die category are cold forging and warm forging processes. Cold forging processes technically include such categories as coining, which is covered in the section "Coining." Cold forgings, produced at about room temperature are generally symmetrical and typically weigh less than 11 kg (25 lb). Because of their extreme dimensional precision and fine surface finish they often need little or no further machining. Production rates are very high with long die life.

In warm forging, technically and metallurgically similar to cold forging, the workpiece is heated to "a few" hundred degrees above room temperature, but well below hot-forging temperatures. Warm forging may be selected over cold forging for higher carbon grades of steel or to eliminate subsequent annealing.

### ***Capabilities of the Process***

Closed-die forging is used for both low-volume or high-volume production. In addition to producing final, or nearly final, metal shapes, closed-die forging controls grain-flow direction, often improving mechanical properties in the longitudinal direction of the workpiece.

**Size of forgings** produced in closed, impression dies can range from a few ounces to several tons. The maximum size that can be produced is limited only by the equipment that is available for handling and for forging. Steel forgings weighing as much as 25,400 kg (56,000 lb) have been closed-die forged. Typically, however, more than 70% of the closed-die forgings produced weigh 0.9 kg (2 lb) or less.

**Shapes.** Complex nonsymmetrical shapes that require a minimum number of operations for completion are suitable for closed-die forging. In addition, the process can be used in combination with other processes to produce parts having greater complexity or closer tolerances than are possible by forging alone. Cold coining and the assembly of two or more closed-die forgings by welding are examples of other processes that can extend the useful range of closed-die forging.

**Forging Materials.** Materials selected for closed-die forgings must satisfy two basic requirements. First, the material strength (or flow stress) must be low to hold die pressures to within the capabilities of practical die materials and constructions. Also, the forgeability of the material (its ability to deform without failure) must be equal to the amount of deformation required in the die. A comparison of the forgeability of various metals and alloys can be found in the article "Forging of Specific Metals and Alloys" later in this Section.

## ***Classification of Closed-Die Forgings***

Closed-die forgings are generally classified as blocker-type, conventional, and close-tolerance.

**Blocker-type forgings** are produced with generous allowance for finishing. These forgings are produced in relatively inexpensive dies, but their weight and dimensions are somewhat greater than those of counterpart conventional closed-die forgings. Often blocker-type forgings are specified when only a small number of forgings are required and the cost of machining parts to final shape is not excessive.

Blocker-type forgings can be produced in metal die blocks containing cavities of simple shape, or with stops and gages that the forging producer has in stock. These are called "loose" tools because they are not attached to the ram or anvil but are held in position on a bottom flat die by a handle. Loose tooling can be used to produce a variety of simple shapes, on short notice, without the cost of dies.

Because they lack the detail and the dimensional accuracy of forgings completed in finisher dies by conventional closed-die forging methods, forgings produced in loose tooling usually require substantially more machining to provide a finished part. Figure 17 shows specific examples.

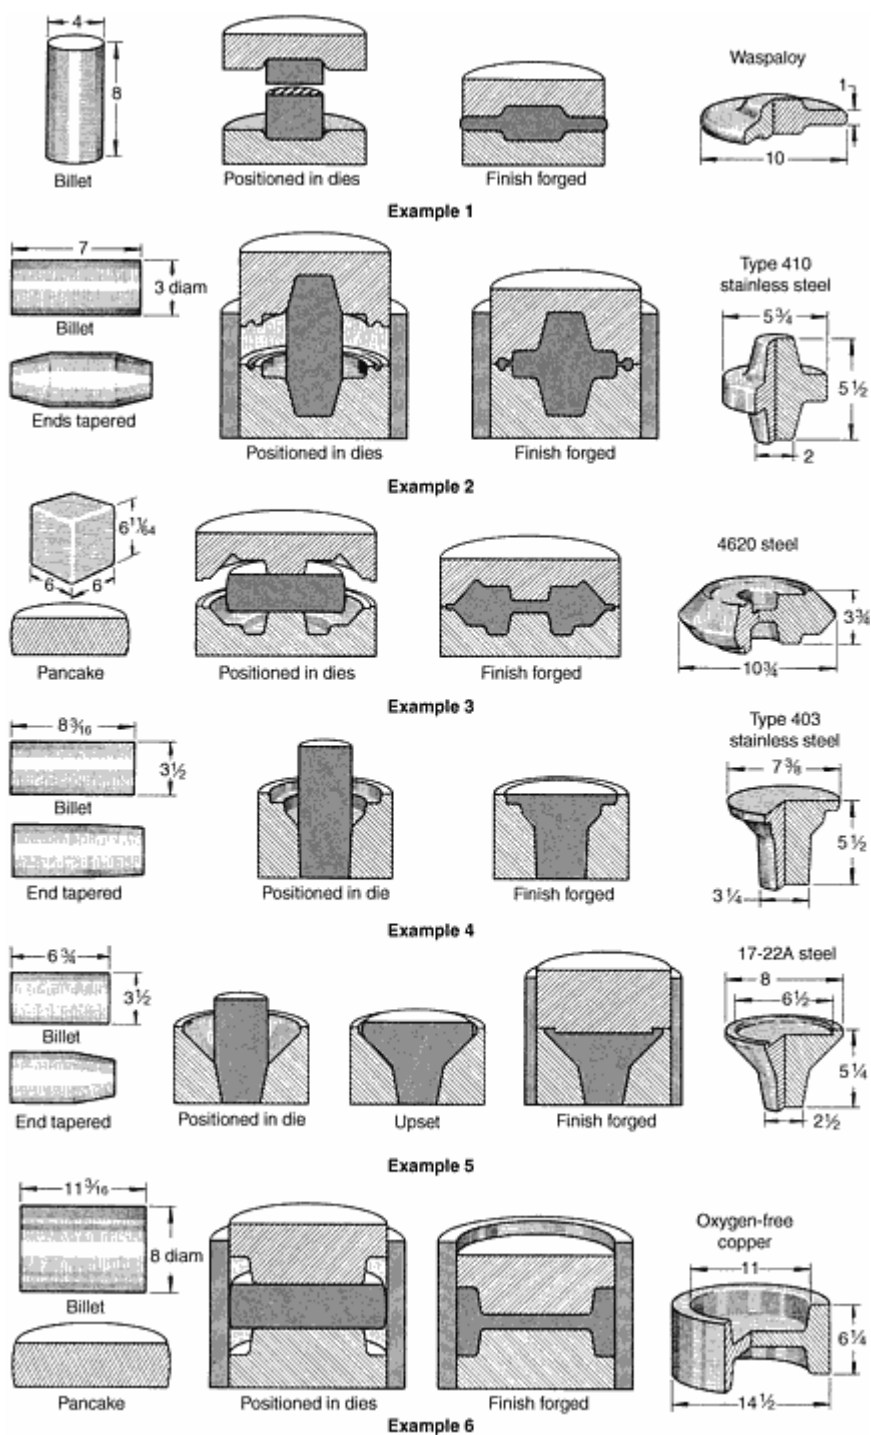

Fig. 17 Production of six blocker-type forgings with loose tooling in hammers. Dimensions are in inches.

**Conventional closed-die forgings** are the most common. They can be complex in shape with tolerances that fall within the broad range of general forging practice. Because they are made closer to the shape and dimensions of the final part than blocker-type forgings, they are lighter with more detail.

**Close-tolerance forgings**, obviously, are held to tighter dimensional tolerances than conventional forgings. Little or no machining is required after forging because close-tolerance forgings are made with less draft and with thinner walls, webs, and ribs. These forgings cost more and require higher forging pressures per unit of plan area than conventional forgings. However, the higher forging cost is sometimes justified by a reduction in machining cost. Additional information on close-tolerance forgings can be found in the subsection "Precision Forging."

**Die Impressions.** Several different types of can be used in a forging die, each type being designed to serve a specific function. In a forging sequence that incorporates several types of impressions, each impression should be considered for the specific function that it is to perform, both by itself and in relation to the preceding and succeeding impressions. In particular, the design of each impression should provide for location of the workpiece in the succeeding die impression.

**Finishers.** The finisher impression gives the final overall shape to the workpiece. In this impression excess metal is forced out into the flash. Despite its name, the finisher impression is not necessarily the last step in the production of a forging. Bending or hot coining sometimes follows to produce the final shape or dimensions to the forged part after it has passed through the finisher impression and the trimming die.

**Preforming or Roughing.** In any form of hammer forging, parts usually are preformed or roughed by one or a sequence of preliminary steps in impressions called fullers, edgers, rollers, flatteners, benders, splatters, and blockers (Fig. 18). Blockers are also used in press forging.

**Fig. 18** Typical multiple-impression hammer dies for closed-die forging

**Fullers.** This die impression is used to reduce the cross section and to lengthen a portion of the forging stock. In longitudinal cross section, the fuller is usually elliptical or oval, to obtain optimum metal flow without producing laps, folds, or cold shuts. (Reducing and lengthening forging stock between flat portions of die surfaces is called drawing, rather than fullering.) Fullers are used in combination with edgers or rollers, or as the only impression prior to the blocker or finisher.

Because fullering usually is the first step in the forging sequence and generally uses the least amount of forging load, the fuller is almost always placed on the extreme edge of the die (Fig. 18a).

**Edgers.** Used to redistribute and proportion stock for heavy sections to be further shaped in blocker or finisher impressions, the action of the edger is opposite to that of the fuller. A forged connecting rod, for example, is first reduced in a fuller to prepare the slender central part of the rod and then worked in an edger to proportion the ends for the boss and crank shapes.

The edger impression can be open at the side of the die block, Fig. 18(a), or confined, (Fig. 18b). An edger is sometimes used in combination with a bender in a single die impression to reduce the number of forging blows necessary to produce a forging.

**Rollers** round the stock (for example, from a square billet to a round bar) or redistribute the mass prior to the next impression. The stock usually is rotated, and two or more blows are needed to roller the stock.

The operation of a roller impression is similar to that of an edger, but the metal is partially confined on all sides, with shapes in the top and bottom dies resembling a pair of shallow bowls. Because of the cost of sinking the die impressions, rolling is more expensive than edging when both operations require the same number of blows.

**Flatteners** widen the work metal so it more nearly covers the next impression or, with a 90° rotation, to reduce the width to within the dimensions of the next impression. The flattener station can be either a flat area on the face of the die or an impression in the die to give the exact size required.

**Benders.** A portion of the die can be used to bend the stock, generally along its longitudinal axis, in two or more planes. There are two basic designs of bender impressions: free flow and trapped stock.

In bending with a free-flow bender, Fig. 18(b), one end or both ends of the forging are free to move into the bender. A single bend is usually made. This type of bending can cause folds or small wrinkles on the inside of the bend.

The trapped-stock bender usually creates multiple bends. In trapped-stock bending, the stock is gripped at both ends as the blow is struck and the stock in between is bent. Because the metal is held at both ends, it usually is stretched during bending. There is a slight reduction in cross-sectional area in the bend, and the work metal is less likely to wrinkle or fold than in a free-flow bender.

Stock that is to be bent may require preforming by fullering, edging, or rolling. Bulges of extra material can be provided at the bends to prevent formation of kinks or folds in free-flow bending. This is particularly necessary for sharp bends. The bent preform usually is rotated 90° as it is placed in the next impression.

**Splitters.** In making "forked" forgings, part of the work metal is split to conform more closely to the subsequent blocker impression. In splitting, the stock is forced outward from its longitudinal axis by the action of the splitter. Generous radii should be used to prevent formation of cold shuts, laps, and folds.

**Blockers.** The blocker impression is used in both hammer and press forging. The blocker immediately precedes the finisher impression to refine the shape of the metal. Usually, the blocker omits those details that restrict metal flow in finishing. A blocker may be a streamlined model of the finisher. Streamlining helps the metal to flow around radii, reducing the possibility of cold shuts or other defects.

Sometimes, the blocker impression is made by duplicating the finisher impression in the die block and then rounding it off as required for smooth flow of metal. Preferred, however, is to make the blocker impression slightly narrower and deeper than the finisher impression with a volume that is equal to, or only slightly greater than, that of the finisher. This minimizes die wear at the parting line in the finisher impression.

For parts that include deep holes or bosses, the blocker can be a gathering operation. It can sink a volume of metal to one side of the forging, which then can be forced through to the other side in the finisher impression to fill a high boss.

Blocker impressions are also used to reduce wear on the finisher cavity. Therefore, a blocker is often included in the series of dies for long forging runs, or in production of close-tolerance forgings, to prolong the life of the finisher impression.

## ***Process Variables***

Flashing design, die preheating, and trimming are several characteristics of closed-die forging that must be considered.

**Flash.** Forging pressures are determined in part by flash thickness and flash-land width (Fig. 19). Essentially, forging pressure increases with decreasing flash thickness and increasing flash-land width. These variables control restriction, frictional forces, and metal temperatures at the flash gap.

**Fig. 19** Metal flow and load-stroke curve in closed-die forging. (a) Upsetting. (b) Filling. (c) End. (d) Load-stroke curve

During a typical forging press stroke, loads are relatively low until the more difficult details in the die are partly filled and the metal reaches the flash opening. At this point, two conditions must be fulfilled: a sufficient volume of metal must be trapped within the confines of the die to fill the remaining cavities and extrusion of metal through the narrowing gap of the flash opening must be more difficult than filling of the more intricate detail in the die.

As the dies continue to close, the load increases sharply until the die cavity is filled completely. Ideally, at this point, the cavity pressure provided by the flash geometry should be just sufficient to fill the entire cavity, and the forging should be completed. A cavity can be filled with various flash geometries provided that there is always a sufficient supply of material in the die. In general, the flash thickness should increase with increasing forging weight, while the ratio of flash width to flash thickness ( $w/t$ ) decreases to a limiting value.

**Die Heating.** Dies should be heated to at least 120 °C (250 °F), and preferably to 205 to 315 °C (400 to 600 °F), before forging begins. "Warmers" (pieces of hot metal) placed between the die faces, or torches, are used. Dies can be heated in ovens before set up in the hammer or press. Temperature-indicating crayons can be used to measure surface temperature. Cold dies can break when a hot billet is placed on them.

**Trimming.** Several processes are used to trim flash after forging. The method used will depend on the production quantity and size of the parts. Trimming can sometimes eliminate a machining operation.

For small quantities or for large forgings, hand grinding, sawing, or machining can be used to remove the flash. In large quantities, most forgings are die trimmed.

Cold trimming usually refers to die trimming below 150 °C (300 °F). This method, often used, especially for small forgings, can be done at any time; it need not be a part of the forging sequence. No reheating of the forgings is needed. Another advantage is that the trimming blades can be adjusted to shear the flash to a smooth surface that does not require machining.

Almost all of the common forging alloys can be cold trimmed. Some may require annealing or other heat treatment after forging before they can be cold trimmed. As a rule of thumb, a forging can be cold trimmed if, after forging, its tensile strength does not exceed 690 MPa (100 ksi) or hardness not over 207 HB.

Cold trimming may require great press capacity, however. Thus, hot trimming may be selected. Hot trimming is done as low as 150 °C, or 300 °F (for nonferrous alloys), and as high as 980 °C (1800 °F) or above for steels and other ferrous alloys.

### ***Friction and Lubrication in Forging***

In forging, friction greatly influences metal flow, pressure distribution, and load and energy requirements. In addition to lubrication effects, the effects of die chilling or heat transfer from the hot material to colder dies must be considered. For example, for a given lubricant, friction data obtained from hydraulic press forging cannot be used for mechanical press or hammer forging even if die and billet temperatures are comparable.

In forging, the ideal lubricant is expected to:

- Reduce sliding friction between the dies and the forging in order to reduce pressure requirements, to fill the die cavity, and to control metal flow
- Act as a parting agent and prevent local welding and subsequent damage to the die and workpiece surfaces
- Possess insulating properties so as to reduce heat losses from the workpiece and to minimize temperature fluctuations on the die surface
- Cover the die surface uniformly so that local lubricant breakdown and uneven metal flow are prevented
- Be nonabrasive and noncorrosive so as to prevent erosion of the die surface
- Be free of residues that would accumulate in deep impressions
- Develop a balanced gas pressure to assist quick release of the forging from the die cavity; this characteristic is particularly important in hammer forging, in which ejectors are not used
- Be free of polluting or poisonous components and not produce smoke upon application to the dies

No single lubricant can fulfill all of the requirements listed above; therefore, a compromise must be made for each specific application.

Various types of lubricants are used, and they can be applied by swabbing or spraying. The simplest is a high flash point oil swabbed onto the dies. Colloidal graphite suspensions in either oil or water are frequently used. Synthetic lubricants can be employed for light forging operations. The water-base and synthetic lubricants are extensively used primarily because of cleanliness.

## Hot Upset Forging

Hot upset forging (also called hot heading, hot upsetting, or machine forging) is essentially a process for enlarging and reshaping some of the cross-sectional area of a bar, tube, or other uniform, usually round, section. Basically, the heated forging stock is held between grooved dies while pressure is applied to the end of the stock in the direction of its axis by a heading tool. The tool spreads (upsets) the end by metal displacement (Fig. 20).

**Fig. 20** Basic types of upsetter heading tools and dies, showing the extent to which stock is supported. (a) Unsupported working stock. (b) Stock supported in die impression. (c) Stock supported in heading tool recess. (d) Stock supported in heading tool recess and die impression

## ***Applicability***

Although hot upsetting originally was restricted to single-blow heading of parts such as bolts, present-day machines and tooling permit the use of multiple-pass dies that can produce complex shapes accurately and economically. The process now is widely used for producing finished forgings ranging in complexity from simple headed bolts or flanged shafts to wrench sockets that require simultaneous upsetting and piercing. Parts requiring center (not at bar end) or offset shaping also can be upset.

In many instances, hot upsetting is used to prepare stock for subsequent hammer or press forging. Occasionally, hot upsetting is also used as a finishing operation following hammer or press forging, such as in making crankshafts.

Because the transverse action of the moving die and longitudinal action of the heading tool can forge in both directions, either separately or simultaneously, hot upset forging is not limited to simple gripping and heading operations. The die motion can be used for swaging, bending, shearing, slitting, and trimming. In addition to upsetting, heading tools are used for punching, internal displacement, extrusion, trimming, and bending.

In upset forging, the working stock usually is confined in the die cavities during forging. The upsetting action creates pressure, similar to hydrostatic pressure, which causes the stock to fill the die impressions completely. Thus, a wide variety of shapes can be forged and removed from the dies by this process.

**Work Material and Size.** Although most forgings produced by hot upsetting are of carbon or alloy steel, the process can be used for shaping any forgeable metal. The size or weight of workpiece that can be hot upset is limited only by the capabilities of available equipment; forgings ranging in weight from less than an ounce to several hundred pounds can be produced by this method.

## ***Upset Forging Equipment***

A typical machine for hot upset forging is mechanically operated from a main shaft with an eccentric drive that operates a main slide, or header slide, horizontally. The action of the header slide is similar to that of the ram in a mechanical press. Power is supplied to a machine flywheel by an electric motor. A flywheel clutch provides for "stop motion" operation, placing movement of the slides under operator control.

Forging takes place in three die elements: two gripper dies (one stationary and one moved by the die slide), which have matching faces with horizontal grooves to grip the forging stock and hold it by friction, and a heading tool, or "header," which is carried by the header slide in the plane of the work faces of the gripper dies and aligns with the grooves in these dies (Fig. 21). The travel of the moving die is designated as the "die opening," and its timed relation to the movement of the header slide is such that the dies close during the early part of the header-slide stroke. The part of the forward header-slide stroke that takes place after the dies are closed is known as the "stock gather," and the amount that the returning header slide travels before the moving die starts to open is called the "hold on," or the "hold."

**Fig. 21 Basic actions of the gripper dies and heading tools of an upsetter**

The die opening determines the maximum diameter of upset that can be formed on a given machine, transferred between the dies and withdrawn through the throat, without pushing the workpiece forward and lifting it out over the top. The diameter of the stock, rather than the stock gather, determines the amount of stock that can be upset; the stock gather, however, has an important bearing on the depth to which internal displacement can be carried. The height of the die determines the number of progressive operations that can be accommodated in one set of dies.

Although some forgings are produced by a single stroke of the ram, most shapes require more than one pass to complete. The upsetter dies may incorporate several different impressions or "stations." The stock is moved from one impression (or station) to the next in sequence, to give the forging a final shape. Each move constitutes a "pass." Three or more passes are commonly used to complete the upset, and if flash removal (trimming) is a part of the forging operation, another pass is added.

Piercing and shearing passes can also be incorporated in the dies. In single-blow, solid-die machines, the gripper dies are replaced by a shear arm and shear blade. A long heated bar of forging stock is placed in a slot and pushed against a stop. As the machine is actuated, either automatically or by means of a foot pedal, a motion similar to that of a conventional upsetter occurs, except that, instead of the dies closing, a section of the bar is sheared off. While the shear slide is moving, a cam actuates a transfer arm, which moves until it contacts the stock. The stock, now positioned between the shear blade and the transfer arm, is moved into proper position between the punch and the die. As the punch advances and contacts the stock, the shear blade and the transfer arm move apart. The punch continues its advance, and the forging is produced in a single blow. Ejector pins push the forging from the die, and it drops onto an underground conveyor. Another heated bar of forging stock is pushed against the stop, and the cycle is repeated.

### ***Tool Materials***

For short runs, solid dies are made of lower-alloy steels such as 4340, 6G, or 6F3. For runs of approximately 1000 pieces, higher-alloy hot work steels are commonly used for small dies or inserts in large dies. Two important advantages in the use of punch and die inserts are that they can be replaced when worn out and that, in many applications, two or more different parts can be forged with a master block by changing inserts.

### ***Die Cooling and Lubrication***

Normal practice is to keep dies below 205 °C (400 °F) during forging. In some low-production operations, no coolant is required to keep dies below this temperature. In most applications, however, a water spray (sometimes containing a small amount of salt or graphite) is used as a coolant.

Die lubrication slows production and is not widely used in upsetting of steel. Because of the die action in upsetting, parts are less likely to stick than in hammer or press forging. In deep punching and piercing, however, sticking may be encountered, thus requiring a lubricant. An oil-graphite spray is effective and can simultaneously provide adequate cooling. A recirculated suspension of alumina in water is used in some high-production operations.

## Roll Forging

Roll forging (also known as hot forge rolling) is a process for reducing the cross-sectional area of heated bars or billets by passing them between two driven rolls that rotate in opposite directions and have one or more matching grooves in each roll. The principle involved in reducing the cross-sectional area of the work metal in roll forging is essentially the same as that employed in rolling mills to reduce billets to bars.

### *Applications*

Any metal that can be forged by other methods can be roll forged. Heating times and temperatures are the same as those used in the forging of metals in open or closed dies.

Roll forging can be used either as the sole or main operation in producing a shape. Generally this involves the shaping of long, thin, usually tapered parts. Typical examples are airplane propeller-blade half sections, tapered axle shafts, tapered leaf springs, table-knife blades, hand shovels and spades, various agricultural tools (such as pitchforks), and tradesman's tools (such as chisels and trowels). Roll forging is sometimes followed by the upsetting of one end of the workpiece to form a flange, as in the forging of axle shafts.

Roll forging also is used as a preliminary operation to save material and number of hits in subsequent forging in closed dies. Applications in this case include preliminary shaping of stock prior to forging in impression dies in either a press or hammer, thus eliminating a fullering or blocking operation. Crankshafts, connecting rods, and other automotive parts are typical products that are first roll forged from billets to preform stock and then finish forged in a press.

### *Equipment for Roll Forging*

In machines for roll forging (often called forge rolls, reducer rolls, back rolls, or gap rolls), the driving motor is mounted at the top of the main housing (Fig. 22). The motor drives a large flywheel by means of V-belts. In turn, the flywheel drives the roll shafts, to which the roll dies are attached, through a system of gears. Forging rolls are available in numerous sizes and have the capacity to roll blanks up to 127 mm (5 in.) thick and 1020 mm (40 in.) long.

**Fig. 22** Roll-forging machine with outboard housing

Roll dies are bolted to the roll shafts, which rotate in opposite directions during operation. Roll dies (or their effective forging portion) usually occupy about one-half the total circumference; therefore, at least some forging action takes place during half of the revolution. Machines can be operated continuously or stopped between passes, as required. In the roll forging of long tapered workpieces, the more common practice is to operate the machine intermittently.

## Roll Dies

Roll dies are of three types: flat back, semicylindrical, and fully cylindrical. Each type is shown in Fig. 23(a).

Fig. 23 (a) Dies used in roll forging. (b) Overhang-type roll forger that utilizes fully cylindrical dies

**Flat-back dies** are primarily used for short-length reductions. They are bolted to the roll shafts and can be easily changed.

**Semicylindrical dies** are well suited to the forging of medium-length workpieces. Most are true half cylinders ( $180^\circ$ ), although some (particularly in large sizes) may encompass up to  $220^\circ$  of a circle to provide sufficient periphery for the specific application. When each die section is no more than  $180^\circ$ , the dies can be made by first machining the flat surfaces of the half rounds for assembly, clamping the half rounds together, and then boring and finishing.

**Fully cylindrical dies** are used to forge long members, sometimes in an overhang-type machine (Fig. 23b). They are built up with rings, with a cutaway portion just large enough to feed in the forging stock. Fully cylindrical dies are sometimes more efficient than semicylindrical or flat-back dies because of the larger periphery available for the forging action. However, one disadvantage of fully cylindrical dies is that the small opening prevents continuous operation; consequently, motion must be controlled by a clutch and a brake.

**Steels for roll dies** do not differ greatly from those used for dies in hammer, press, and upset forging. However, because roll dies are subjected to less impact than dies in other types of forging, they can be made of die steels that are somewhat higher in carbon content, which is helpful in prolonging die life.

## High-Energy-Rate Forging

High-energy-rate forging (HERF), sometimes called high-velocity forging, is a closed-die, hot- or cold-forging process in which the stored energy of high-pressure gas is used to accelerate a ram to unusually high velocities to deform the

workpiece. Ideally, the final configuration of the forging is developed in one blow or, at most, a few blows. In HERF, the velocity of the ram, rather than its mass, generates the major forging force. The maximum impact velocity of HERF machines is approximately three to four times that of conventional drop hammers. Typically, the ram velocity at impact in the HERF machine is in the range of 5 to 22 m/s (16 to 72 ft/s); ram velocities range from 4.5 to 9.1 m/s (15 to 30 ft/s) for a power-drop hammer and from 3.6 to 5.5 m/s (12 to 18 ft/s) for a gravity-drop hammer.

High-energy-rate machines can be used to hot forge parts of the same general shapes as those produced with conventional hammers and presses. However, the work metal must be capable of undergoing extremely rapid deformation rates as it fills the die cavity without rupturing it. In HERF, the high ram velocities forge parts with thin webs, high-rib, height-to-width ratios, and small draft angles to profiles sufficiently accurate that machining allowance can sometimes be as little as 0.500 mm (0.0197 in.). Even parts made of difficult-to-forge metals can be formed close to finished dimensions in a few blows and often without reheating.

### ***Process Advantages and Limitations***

**Advantages.** When evaluating high-energy-rate forging in relation to conventional forging, both the machine advantages and process advantages, as a result of the high velocities, must be considered. The machine advantages are beyond dispute. For a given forming capacity, high-speed machines are much smaller than conventional forging machines, and they require much less installation/foundation and therefore a lower capital investment. These advantages arise because the principle used in these machines involves the conversion of the kinetic energy of a ram/platen into forming work. Kinetic energy is proportional to the square of the impact velocity; therefore, a threefold increase in impact speed produces a nine-fold increase in forming energy. High-energy-rate forging machines are typically one-ninth the bulk and weight of equivalent slow-speed machines. Although the finished forging is generally made in one high-speed blow, some machines can be fired two or three times before the work metal has cooled below the forging temperature.

The process advantages are not as obvious as the machine advantages and depend on the particular application under consideration. In general, with HERF, complex parts can be forged in one blow from a billet or a preform. Many metals that are difficult to forge by other methods can be successfully forged by HERF.

Dimensional accuracy, surface detail, and, often, surface finish are better with HERF than other techniques. Draft allowances, both internal and external, can be reduced or, in some applications, eliminated. Forgings are made to size or with a minimum of machining allowance. Reduced machining lowers the induced mechanical stress and minimizes the cutting of end grain, which improves the stress-corrosion resistance of some metals, notably aluminum.

Deep, thin sections can be HERFed because the rapidity of the blow provides little time for heat transfer to the die walls. Severe deformation possible with HERF provides a high degree of grain refinement in some metals.

**Limitations.** The process, however, does have several limitations. Sharp corners and small radii cannot be forged without causing undue wear. The process is generally limited to symmetrical parts, although some asymmetrical parts can be forged from preformed billets. High-energy-rate forging part size is limited to approximately 11 to 12 kg (24 to 26 lb) for carbon steel forgings and to lesser weights for forgings made of stainless steel or heat-resistant alloys.

The production rate is about the same as in hammer or hydraulic press forging but is slower than in mechanical press forging. However, dies must be carefully designed and fabricated in order to withstand the high impact; compressive prestressing of the die inserts by a shrink ring is a common practice.

### ***High-Energy-Rate Forging Equipment and Production Rates***

As described earlier, the three basic types of HERF machines are ram-and-inner-frame, two-ram, and controlled-energy-flow (counterblow) (refer to Fig. 4 and related text). The cycle time for a HERF machine is 12 to 20 s per piece, or a production rate of 180 to 300 parts per hour. Therefore, HERF machines can make parts to close profiles at production rates often comparable to those of drop-hammer and hydraulic presses. Adaptation of automatic transfer equipment to high-energy-rate forging further increases the production rates to levels competitive with manually operated mechanical presses. The machines are readily adaptable to automatic loading and unloading equipment. However, high-production runs or multiple runs of similar parts are needed to justify the cost of automatic handling equipment.

### ***Dies***

Closed dies and flash-and-gutter impression dies are used in HERF. The closed dies restrict the flow of metal and force it to fill the cavity completely; they are recommended because they require less material in the billet and permit closer dimensional control of the forging. Flash-and-gutter impression dies are generally used for thicker parts with more liberal dimensional tolerances.

As in conventional hammer forging, the force of the ram should be completely expended in deforming the workpiece. Impact between the upper and lower tools is potentially destructive. It can be avoided by control of processing conditions that significantly influence metal plasticity (such as temperature, volume, and die temperature and lubrication) and in some cases by selective placement of a protective ring around the upper die.

### ***HERF Processing***

Like conventional forging, HERF is performed over a broad range of temperatures, depending on the specific part, the material, and the design requirements. Three categories of HERF are hot forging, cold forging, and warm forging.

**Hot Forging.** Under the most favorable conditions, hot HERF is used to forge parts that cannot be forged with conventional machines. Complex parts and components with thin sections have been produced; webs and ribs 3.18 mm (0.125 in.) thick and central ribs 4.76 mm (0.1875 in.) thick are technically feasible. However with pneumatic-hydraulic HERF machines, such results can often be obtained only at the expense of die life in view of their long dwell times.

**Cold HERF** at high speeds improves die lubrication, which lowers the fictional forces, which in turn improves metal flow and surface finish of the components. The process is practically adiabatic; therefore, with soft materials, such as aluminum and copper, some softening occurs. Forging forces and pressures are generally higher than those obtained at conventional speeds, although energy requirements may well be lower.

**Warm HERF**, in comparison to hot HERF, is free of scale and therefore produces better surface quality, high precision, and improved tool life. In relation to cold HERF, the process significantly lowers tool loads, permitting a wider range of both component sizes and available materials to be forged without appreciable deterioration in component material properties.

### ***Metals HERFed***

Metals best suited to HERF are those that withstand very high deformation rates without rupturing. High-energy-rate forging is particularly suited to alloys that require high forging temperatures and pressures, especially when thin webs or unusual design features are required. Low-carbon steels, refractory metals, and nickel alloys that have broad forging temperature ranges can be forged. Metals with low ductility under rapid deformation rates, such as magnesium and beryllium alloys, cannot be forged by high-velocity methods.

Heating that is caused by rapid deformation, if excessive, may cause incipient melting and serious rupturing when forging to large reductions. The metals affected in this manner include high-carbon steels, high-strength aluminum alloys, and nickel-base, heat-resistant alloys. Increased temperatures during forging can cause  $\beta$ -embrittlement in some titanium alloys.

## **Ring Rolling**

Ring rolling is used to manufacture seamless annular forgings that are accurately dimensioned and have circumferential grain flow. Ring rolling usually requires less input material than alternative forging methods, and it is applicable to production in any quantity.

**Operating Principles.** In ring rolling (Fig. 24), a heated doughnut-shaped blank, preformed on a press or forging hammer, is placed over a mandrel of slightly smaller diameter than the hole in the blank. The roll gap between the mandrel (undriven) and a larger diameter driven main roll is progressively reduced. Friction between the main roll and the ring causes the ring to rotate, and the ring in turn rotates the bearing-mounted mandrel. As the radial cross section of the ring decreases, circumferential extrusion occurs in the direction of ring rotation, and the ring diameter grows. The work rolls can be plain, producing uniformly rectangular ring cross sections or may have grooves or flanges to produce contoured ring cross sections. Ring height is controlled either by main roll shape or by the use of axial rolls set diametrically across the ring from the mandrel and main roll pass.

Fig. 24 Operational principles of a horizontal ringrolling mill

**Products and Applications.** Annular components can be ring rolled from any forgeable material. The configuration can range from very flat washer-shaped rings to long sleeve-type rings. Typical materials include carbon and low-alloy steels, copper, brass, aluminum and titanium alloys, and high-strength nickel and cobalt-base alloys, which are very difficult to form. Applications for seamless rolled rings include antifriction bearing races, gear rims, slewing rings, railroad wheel bearings, commutator rings, rotating and nonrotating rings for jet engines and other aerospace applications, nuclear reactor components, bevel ring gears, flanges of all kinds (including weld-neck flanges), sheaves, wheels, valve bodies, food-processing dies, and chain master links.

**Sizes.** About 90% of all rolled rings have outside diameters in the range from 240 to 980 mm (9.5 to 38.6 in.), heights (lengths) ranging from 70 to 210 mm (2.75 to 8.25 in.), and wall thicknesses between 16 and 48 mm (0.63 and 1.9 in.). A significant number of rings, however, are rolled outside the previously mentioned parameters, and it is not unusual to find outside diameters ranging from 75 mm to 8 m (3 in. to 26.25 ft), heights from 15 mm to 2 m (0.6 in. to 6.5 ft), and weights from 0.4 to 82,000 kg (0.9 to 181,000 lb).

## Rotary Swaging of Bars and Tubes

Rotary swaging is used to reduce the cross-sectional area or otherwise change the shape of bars, tubes, or wires by repeated radial blows with two or more dies. The work is elongated as the cross-sectional area is reduced. The workpiece (starting blank) is usually round, square, or otherwise symmetrical in cross section, although other forms, such as rectangles, can be swaged.

Most swaged parts are round, the simplest being formed by reduction in diameter. However, swaging can also produce straight and compound tapers, contours on the inside diameter of tubing, and can change round to square or other shapes.

**Applicability.** Swaging can reduce tubes up to 355 mm (14 in.) in initial diameter and bars up to 100 mm (4 in.) in initial diameter. Hardness, tensile strength, and reduction in area of the work metal have the most significant effect on swageability. Type and homogeneity of microstructure also influence the ease of swaging and the degree to which a metal can be swaged.

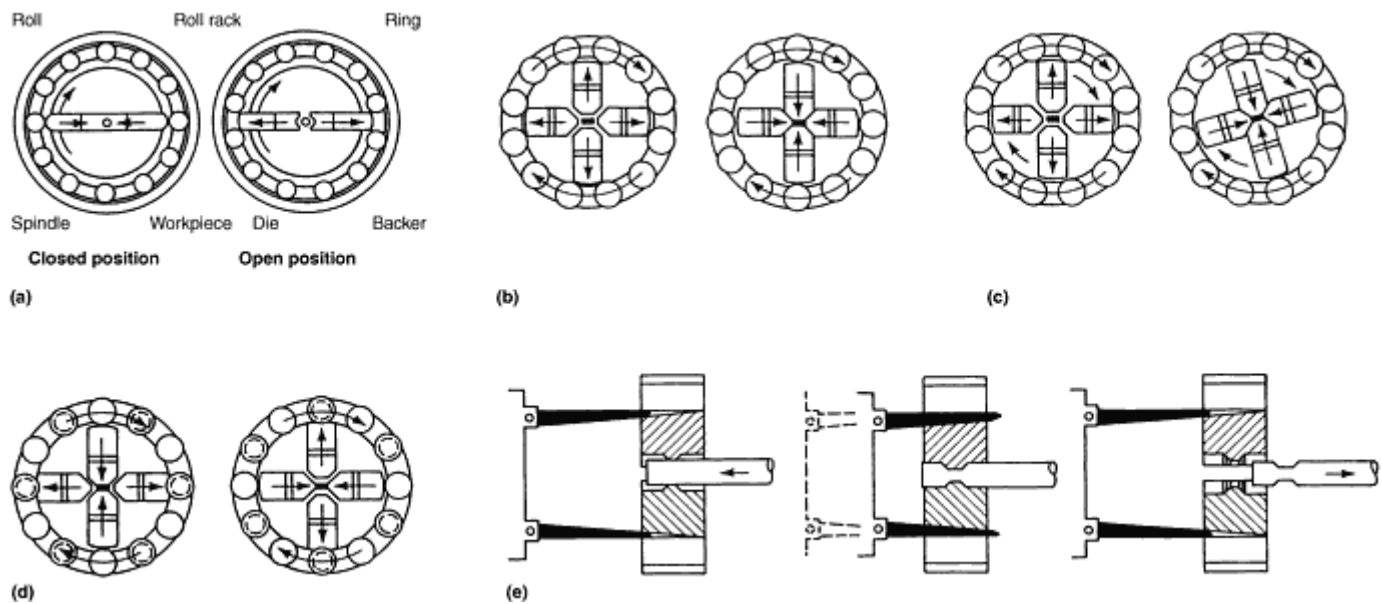

**Work Metals.** Of the plain carbon steels, those with a carbon content of 0.20% or less are the most swageable. These grades can be reduced up to 70% in a cross-sectional area by swaging. As carbon content or alloy content is increased, swageability is decreased. Alloying elements such as manganese, nickel, chromium, and tungsten increase work metal strength and therefore decrease the ability of the metal to flow. Free-machining additives such as sulfur, lead, and phosphorus cause discontinuities in structure that result in splitting or crumbling of the work metal during swaging.

**Metal flow** during rotary swaging is not confined to one direction. Metal also moves opposite to the direction feed. The action of the metal moving against the direction of feed is termed "feedback." It results from slippage of the workpiece in the die taper when it is too steep.

Unless resisted, the workpiece rotates as the dies close. The speed of rotation is that of the roller cage. If rotation is permitted, swaging occurs in only one position on the workpiece, causing ovaling, flash, and sticking of the workpiece in the die. Resistance to rotation is manual when the swager is hand fed; mechanical means are used with automatic feeds.

**Swaging Equipment.** Rotary swaging machines are classified as standard rotary, stationary-spindle, creeping-spindle, alternate-blow, and die-closing (Fig. 25). All these machines are equipped with dies that open and close rapidly to provide the impact action that shapes the workpiece. Swagers allow the work to be fed into the taper entrance of the swaging dies.

The amount of diameter reduction per pass is limited by the design of the entrance taper of the dies or the area reduction capability of the machine. The results are expressed in terms of diameter reduction or area reduction.

**Fig. 25 Principle machine concepts for rotary swaging.** (a) The standard rotary swager is a mechanical hammer that delivers blows (impact swaging) at high frequency, thus changing the shape of a workpiece by metal flow. This machine is used for straight reducing of stock diameter or for tapering round workpieces. (b) With stationary-spindle swagers, the spindle, dies, and work remain stationary while the head and roll rack rotate. These machines are used for swaging shapes other than round. (c) Creeping-spindle swaging employs the principles of both standard and stationary-spindle swaging. The spindle and dies are mounted on a shaft that rotates slowly inside the rapidly rotating roller cage, thus permitting more accurately controlled reciprocation of the dies. (d) Alternate-blow swaging is accomplished by recessing alternate rolls; when two opposing rollers hammer the dies, the rolls 90° away do not. (e) Die-closing swagers are essentially the same as standard rotary swagers. However, die-closing swagers feature a reciprocating wedge mechanism that forces closure of the taper back dies.

## Radial Forging

Radial forging is performed with four-hammer machines (Fig. 26). The technology of the four-hammer forging machine differs from that of all other hot-forming methods. Conventional presses and hammers, or even rolling mills, use only two tools per forming operation. In the radial forging machine, however, a workpiece is formed at the same time by four hammers arranged in one plane, with maximum forging forces per die of up to 30 MN (3400 tonf). The free spreading that occurs between the two contacting tools in all conventional forging methods is eliminated. A radial press contacts the circumference of the workpiece equally and puts the entire surface of the workpiece under compressive stresses. These compressive stresses prevent the formation of surface cracks during the forging process and improve existing defects.

**Fig. 26** Cross section of four-hammer radial forging machine with mechanical drive. (a) Eccentric shaft. (b) Sliding block. (c) Connecting rod. (d) Adjustment housing. (e) Adjusting screw. (f) Hydraulic overload protection. (g) Hammer adjustment drive shafts

Radial forging is sometimes confused in the literature with rotary (orbital) forging. In the rotary forging process described in "Rotary Forging," the axis of the upper die is tilted at a slight angle with respect to the axis of the lower die, and one or both dies rotate.

**Current applications** include bars with round, square, or rectangular cross section starting from ingots or blooms; stepped solid shafts and axles for locomotives, railroad cars, and trucks; stepped hollow shafts for components in the automotive and aircraft industries; preforms for turbine shafts or for subsequent closed-die forging; thick-wall tubes forged over a water-cooled mandrel; necks and bottoms of steel bottles; and couplings and tool joints.

**Process advantages** include high production rates (approximately four times greater rates for low-alloy steel products than for hammer or press forging; high-alloy steel production is six times higher), low energy consumption, and close tolerances (machining allowances are approximately 33% of the usual allowances on conventional forged products).

**Equipment and Process.** The four-hammer radial forging machine is basically a short-stroke mechanical press. The stroke of the forging connecting rods is initiated through eccentric shafts. The eccentric shafts are supported in housings that allow adjustment of the stroke position of the four forging connecting rods. One or two electric motors drive the eccentric shafts through a drive gear, which simultaneously controls the synchronization of the four eccentric shafts. The forging connecting rods can be changed in their stroke position either in unison or in pairs so that round, square, or rectangular cross sections can be forged.

Depending on its application, the part-handling system of the machine can be equipped with either one or two workpiece manipulators, which differ widely from conventional forging manipulators. In contrast to press or hammer forging, the workpiece axis in radial forging is always maintained on the forging machine centerline, regardless of the diameter. The manipulator moves only in the longitudinal direction. For exact guidance, the chuck head slides on a machine bed. During the forging of round cross sections, the chuck head rotates the workpiece in cycle with the forging hammers; that is, the rotary movement stops while the hammers are in contact with the workpiece. The rotary movement of the chuck-head spindle is synchronized with the hammer blows, eliminating twisting of the workpiece. The indexing positions of the chuck-head spindle required for forging squares, rectangles, or hexagons can be set automatically. The entire forging process, including loading and unloading, can be performed automatically by computer numerical control (CNC).

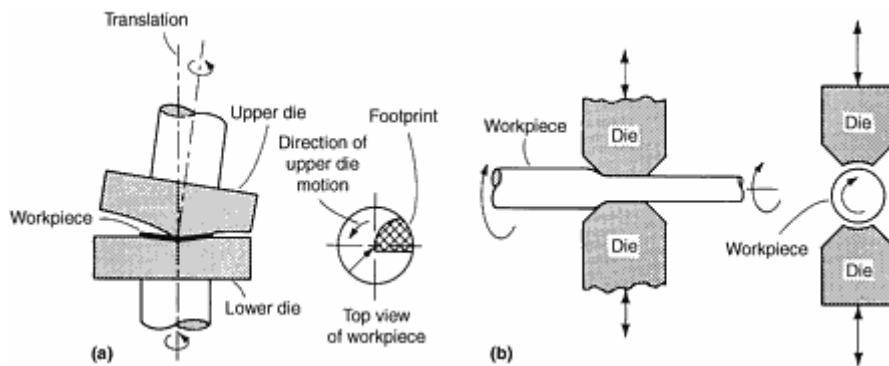

In radial forging, temperature of the workpiece increases with the deformation rate and the forming resistance of the material. The higher the forming resistance, the higher the temperature increase at each pass. Therefore, the temperature loss of the workpiece (because of heat radiation) can be compensated for by preselecting the deformation rate, forming

the workpiece in temperature ranges with the highest material ductility. In practical terms, this means that all forming can be done in one heat from the ingot to finished bar steel, regardless of the alloy. Chamber furnaces, pit furnaces, and hearth-type furnaces can therefore be replaced by continuously operating furnaces.

Equipment for mandrel forging is available in different designs for the hot and cold forging of tubular workpieces. Long tubes with cylindrical bores are forged over a short mandrel, while short tubes are forged over a long mandrel. During hot forging, the mandrel is water cooled while in contact with the workpiece. Tungsten carbide mandrels are often used in cold forging for improved mandrel life.

## Rotary Forging

Rotary forging, or orbital forging, is a two-die forging process that deforms only a small portion of the workpiece at a time in a continuous manner. Unfortunately, the term rotary forging is sometimes used to describe the process that is more commonly referred to as radial forging, causing some confusion in terminology. Figure 27 illustrates the differences between the two processes. As described in the section "Radial Forging," radial forging is a hot- or cold-forming process that uses two or more radially moving anvils or dies to produce solid or tubular components with constant or varying cross sections along their lengths.

**Fig. 27** Differences between rotary and radial forging. (a) In rotary forging, the upper die, tilted with respect to the lower die, rotates around the workpiece. The tilt angle and shape of the upper die result in only a small area of contact (footprint) between the workpiece and the upper die at any given time. Because the footprint is typically only about one-fifth the workpiece surface area, rotary forging requires considerably less force than conventional forging. (b) In radial forging, the workpiece is fed between the dies, which are given a rapid periodic motion as the workpiece rotates. In this manner, the forging force acts on only a small portion of the workpiece at any one time.

In rotary forging (Fig. 27a), the axis of the upper die is tilted at a slight angle with respect to the axis of the lower die, causing the forging force to be applied to only a small area of the workpiece. As one die rotates relative to the other, the contact area between die and workpiece, termed the "footprint," continually progresses through the workpiece, gradually deforming it until a final shape is formed. The tilt angle between the two dies determines the amount of forging force applied to the workpiece. A larger tilt angle results in a smaller footprint; consequently, a smaller amount of force is required to complete the same amount of deformation as compared to a larger contact area. Tilt angles are commonly about 1 to 2°. The larger the tilt angle, however, the more difficult the machine design and maintenance problems are because the drive and bearing system for the tilted die is subjected to large lateral loads and is more difficult to maintain. In addition, a larger tilt angle causes greater frame deflection within the forge, making it difficult to maintain a consistently high level of precision.

**Process Advantages.** The primary advantage of rotary forging is in the low axial force required to form a part. Because only a small area of the die is in contact with the workpiece at any given time, rotary forging requires as little as one-tenth the force required by conventional forging techniques. The smaller forging forces reduce machine and die deformation and die-workpiece friction. This low level of equipment wear makes rotary forging a precision production process that can be used to form intricate parts to a high degree of accuracy.

The average cycle time for a moderately complex part is 10 to 15 s, which is a relatively short time of deformation from preform to final part. A cycle time in the range of 10 to 15 s yields approximately 300 pieces per hour. The resulting piece is also virtually flash free. Therefore, rotary forging results in a much shorter operation from start to finish.

Tooling costs for rotary forging are often lower than those for conventional forging. The smaller forging forces allow many parts to be cold forged that would conventionally require hot forging, resulting in decreased die wear and greater ease in handling parts after forging.

**Machines.** Rotary forgers can be broadly classified into two groups. In rotating-die forgers, both dies rotate around their own axis, but neither die rocks or precesses about the axis of the other die. In rocking-die, or orbital forgers, the upper die rocks across the face of the lower die in a variety of fashions. The most common form is where the upper die orbits in a circular pattern about the axis of the lower die. In this case, the upper die can also either rotate or remain stationary in relation to its own axis. Other examples of rocking-die motion include the rocking of the upper die across the workpiece in a straight, spiral, or planetary pattern.

**Applications.** Rotary forging is generally considered to be a substitute for conventional drop-hammer or press forging. In addition, rotary forging produces parts that would otherwise have to be completely machined because of their shape or dimensions. Currently, approximately one-quarter to one-third of all parts that are either hammer or press forged could be formed on a rotary forge.

Parts made by rotary forging include gears, flanges, hubs, cams, rings, and tapered rollers, as well as thin disks and flat shapes. These parts are axially symmetric and are formed by using an orbital die motion. More complex parts can be forged through the use of such rocking-die motions as straight-line, planetary, and spiral. Straight-line die motion is most commonly used to produce asymmetric pieces, such as T-flanges.

Rotary forging is especially effective in forging parts that have high diameter-to-thickness ratios. Thin disks and large flanges are ideally suited to this process because of the ability of rotary forging to produce a higher ratio of lateral deformation per given downward force than conventional forging. There is also very little friction between the dies. Therefore, the lateral movement of workpiece material in rotary forging is as much as 30% more than that in impact forging.

Rotary forging is also used to produce intricate features on workpiece surfaces. Parts such as gears, hubs, and hexagonal shapes have traditionally been difficult to produce by conventional forging because die-workpiece friction made it difficult to fill tight spots properly on the dies.

**Work Materials.** Any material, ferrous or nonferrous, that has adequate ductility and cold-forming qualities can be rotary forged. These materials include carbon and alloy steels, stainless steels, brass, and aluminum alloys. In the past, cold-forged production parts were primarily steels with a Rockwell C hardness in the mid 30s or lower. Generally, harder materials should be annealed before forging or should be warm forged.

Warm rotary forging is used for materials with Rockwell C hardness greater than the mid 30s or when an unusually large amount of lateral movement in the workpiece is required. Materials are heated to a point below their recrystallization temperature; for steels, this is generally in the range of 650 to 800 °C (1200 to 1470 °F). Because the working temperature is below the recrystallization temperature, the inherent structure and properties of the metal are preserved.

Warm rotary forging increases forgeability, compared to cold rotary forging. However, some disadvantages are inherent in higher temperature forging. The work-hardening effects on the material that are associated with cold working are not as prominent, even though the working temperature is below the recrystallization temperature. In addition, as with any forging process, higher working temperatures result in increased die wear. Dies not only wear at a faster rate but also must be fabricated from more durable, more expensive materials.

## **Isothermal and Hot-Die Forging**

Hot-die and isothermal forging are special categories of forging processes in which the die temperatures are significantly higher than those used in conventional hot-forging processes. This has the advantage of reducing die chill, thereby producing near-net and/or net shape parts. Therefore, these processes are also referred to as near-net shape, forging processes. These techniques are primarily used for manufacturing airframe structures and jet-engine components made of titanium and nickel-base alloys, but they have also been used in steel transmission gears and other components.

## ***Isothermal Forging***

In isothermal forging, the dies are maintained at the same temperature as the forging stock. This eliminates the die chill completely and maintains the stock at a constant temperature throughout the forging cycle. The process uses extremely slow strain rates, thus taking advantage of the strain-rate sensitivity of flow stress for certain alloys.

## ***Hot-Die Forging***

Hot-die forging is characterized by die temperatures higher than those in conventional forging, but lower than those in isothermal forging. Typical die temperatures in hot-die forging are 110 to 225 °C (200 to 400 °F) lower than the temperature of the stock. When compared with isothermal forging, lower die temperature allows wider selection of die materials, but the ability to produce very thin and complex geometries is compromised.

## ***Process Advantages***

The principal criterion for selecting these processes in production is the economic advantage offered because of reduced input material and/or reduced machining. Therefore, they are primarily used for expensive and difficult-to-machine alloys such as titanium and nickel-base alloys.

**Reduced Material Costs.** These near-net shape processes allow the forging to be designed with smaller corner and fillet radii, a smaller draft angle, and a smaller forging envelope. These design features reduce the additional material incorporated to protect the finished part geometry and therefore reduce the weight of the forging considerably. For costly alloys, the reduction in input weight amounts to a significant cost savings. Figure 28 shows an example of this weight reduction for production of titanium alloy forgings.

**Fig. 28** Comparison of raw material saved in the production of a Ti-6Al-4V structural forging that was hot-die forged versus a conventionally forged part (see cross-sectional areas and legend)

**Reduced Machining.** Because near-net shape forgings are produced close to end use weight and configuration, less material removal is required during machining when compared with conventional forgings. In most cases, no machining is required, or only finish machining cuts are required to produce the final part. The elimination of complex machining can sometimes justify the use of these processes even for less expensive alloys, as in the case of steel gears forged with net tooth geometry.

**Uniformity of Product.** The final product produced by isothermal and hot-die forging has more uniform properties because of lower or nonexistent thermal gradients within the forging.

## ***Process Description***

In conventional forging operations, the dies are heated to 95 to 205 °C (200 to 400 °F) for hammer operations and to 95 to 425 °C (200 to 800 °F) for press operations. These temperatures are significantly lower than the 760 to 980 °C (1400 to

1800 °F) stock temperature for titanium and the 980 to 1205 °C (1800 to 2200 °F) stock temperature for nickel-base alloys and steels. In addition, these operations are performed at relatively high speeds, resulting in high strain rates. Typical strain rates range to 50 mm/mm per min (50 in./in. per min) for hydraulic presses, 700 mm/mm per min (700 in./in. per min) for screw presses, and exceed 12,000 mm/mm per min (12,000 in./in. per min) for hammers.

For titanium and nickel-base alloys, the flow stress in general is highly sensitive to both temperature and strain rate. Therefore, conventional forging for these alloys is characterized by high resistance to deformation, high forging loads, multiple forging operations, and sometimes cracking.

The isothermal forging and hot-die forging processes overcome some of these limitations by increasing the die temperature close to the temperature of the forging stock. The die temperatures are maintained at these high levels through continuous heating of the dies during the forge operation using induction heating, gas-fired infrared heating, resistance heating, and so on. The heating arrangement is combined with the press so that heat can be provided to the dies during the forging operation. Another heating arrangement uses gas-fired infrared heaters.

### ***Forging Alloys***

Alloys forged using these processes include titanium alloys, such as Ti-6Al-4V, Ti-6Al-2Sn-4Zr-2Mo, and Ti-10V-2Fe-3Al, and superalloys, such as Alloy 100, Alloy 95, Alloy 718 (UNS07718), and WASPALOY (Precision Rings, Inc., Indianapolis, IN). In the case of superalloys such as Alloy 100, the working temperature range is so small that the isothermal and hot-die methods are the only feasible forging processes currently available. In addition, at specific temperatures and strain rates, Alloy 100 exhibits superplasticity. When forged within this temperature range and strain rate range, the alloy can be deformed to large strains at low loads and to fairly complex geometries.

### ***Forging Parameters***

The same factors that affect conventional forging processes also affect near-net shape processes. However, because of tighter forging designs and the requirements for strict uniformity and consistency, stringent controls on parameters such as forge temperature, strain rate, preform microstructure, forging pressure, and dwell time are all important in deciding the degree of dimensional sophistication and the resultant microstructure of the finished part.

In general, lower strain rates and increased dwell time increase the potential degree of shape complexity and shape sophistication of the forging, but could influence microstructure due to exposure to high temperatures for long periods of time during and after deformation. In addition, very low strain rates cannot be used in hot-die forging because of the potential decrease in the stock temperature. Preform microstructure has a direct influence on the flow stress and superplasticity of the material, sometimes requiring extruded billet with fine-grain structure as the starting material. Some of the alloys that are forged achieve their final mechanical properties by thermomechanical processing; in this case, the selection of the forge temperature and the amount of deformation are controlled by property requirements.

### ***Die Materials***

Conventional hot-work die steels do not have adequate strength or resistance to creep and oxidation at near-net shape temperatures. Therefore, expensive nickel-base superalloys or molybdenum alloys (e.g., TZM) must be used. Dies are machined by electrical discharge machining. When TZM is used as a die material, a special atmospheric control with either vacuum or inert gases is necessary because of the tendency of molybdenum alloys to oxidize severely at temperatures greater than 425 °C (800 °F).

### ***Precision Forging***

Precision forging does not specify a distinct forging process but rather describes a philosophical approach to forging. The goal of this approach is to produce a net shape, or at least a near-net shape, in the as-forged condition. "Net" indicates that no subsequent machining or finishing of a forged surface is required. Thus, a net shape forging requires no further work on any of the forged surfaces, although secondary operations may be required to produce minor holes, threads, and other such details. A near-net shape forging can be either one in which some but not all of the surfaces are net or one in which the surfaces require only minimal machining or finishing. Precision forging is sometimes described as close-tolerance forging to emphasize the goal of achieving, solely through the forging operation, the dimensional and surface finish tolerances required in the finished part.

Usually, precision forging indicates a hot or warm closed-die forging process that has been upgraded to achieve greater process control. Traditionally, hot forging has not been regarded as a precision process. Due to difficulties in producing close tolerances and acceptable surface finish, hot forgings have traditionally been designed with a generous machining allowance sometimes 3 mm ( $\frac{1}{8}$  in.) or more. The motivation for precision forging is the elimination, or at least the reduction, of the costs associated with this machining allowance. These costs include not only the labor and indirect costs of the machining and finishing operations but also the cost of the excess raw material that is lost during machining (Fig. 28).

The material cost savings may not be as obvious as the savings obtained by eliminating machining operations. Material costs are a significant fraction (often more than half) of the total cost of a forging. The weight of a traditional forging is often more than twice the weight of the finished part after machining. Given a geometry that is amenable to precision forging, tolerances of  $\pm 0.25$  mm ( $\pm 0.010$  in.) typically can be held. In many cases, significantly better tolerances have been demonstrated. Forged surfaces have finishes of  $3.20 \mu\text{m}$  ( $125 \mu\text{in.}$ ) root mean square (rms) or better.

**Forging processes** discussed under separate headings in this article that are likely to qualify as "precision forging" include close-tolerance, closed-die forgings, warm high-energy-rate forging, radial forging, rotary forging, and hot-die and isothermal forging. Cold-forging processes, such as cold heading and cold extrusion (see the following sections) are traditionally precision processes. Similarly, powder forging processes are also classified as precision forging. Powder forging is described in the Section "Ferrous Powder Metallurgy Materials" in this Volume.

**Work metals** commonly precision forged include carbon and alloy steels, stainless steels, copper alloys, aluminum alloys, titanium alloys, and nickel-base superalloys. Figure 29 compares precision aluminum forging design characteristics with those of conventional aluminum closed-die forging. Precision aluminum forgings are produced with very thin ribs and webs; sharp corner and fillet radii; undercuts, backdraft, and/or contours; and frequently, multiple parting planes that may optimize grain flow characteristics. Similar improvements are possible in other precision forged metals.

Fig. 29 Cross sections of precision (a) and conventional (b) forgings

## Cold Forging

Cold forging is a very general term that covers processes such as coining/sizing, extrusion, and heading/upsetting. The most widely accepted definition of a cold-forging process is the forming or forging of a bulk material at room temperature. What should be emphasized is that in cold forging, no heating (of either the forging stock or the dies) is required for the actual forming operation.

### Coining

Coining is a closed-die forging operation, usually performed cold, in which all surfaces of the workpiece are confined or restrained, resulting in a well-defined imprint of the die on the workpiece. It is also a restriking operation, called sizing, that is used to sharpen or change a radius or profile.

**Preliminary Workpiece Preparation.** Full contact between the blank and die surfaces, which is necessary for coining, usually requires some preliminary metal redistribution by other processes, such as forging or extrusion, because only a small amount of metal redistribution can take place in the coining dies in single-station coining. In progressive-die operations, coining is preceded by other operations such as blanking, drawing, piercing, and bending. Coining is often the final operation in a progressive-die sequence, although blanking or trimming, or both, frequently follow coining.

**Development of Detail in the Workpiece.** In coining dies, the prepared blank is loaded above the compressive yield strength and is held in this condition during coining. Dwell time under load is important for the development of dimensions in sizing and embossing; it is also necessary for the reproduction of fine detail, as in engraving.

**Trimming.** Flash that develops during coining and any hangers used to carry the blank through coining, especially in progressive-die coining, must be trimmed from the piece.

**Applicability.** In coining, the surface of the workpiece copies the surface detail in the dies with dimensional accuracy that is seldom obtained by any other process. It is because of this that the process is used for coin minting.

Decorative items, such as patterned tableware, medallions, and metal buttons are also produced by coining. When articles with a design and a polished surface are required, coining is the only practical production method to use. Also, coining is well suited to the manufacture of extremely small items, such as interlocking-fastener elements. Many automotive components are sized by coining. Sizing is usually done on semifinished products and provides significant savings in material and labor costs relative to machining.

**Workpiece Size.** Practical limits on workpiece size are mainly imposed by available press capacities and properties of the die material. For example, work metal with a compressive yield strength of 690 MPa (100 ksi) loaded in a press of 22 MN (2500 tonf) capacity can be coined in a maximum surface area of 0.032 m<sup>2</sup> (50 in.<sup>2</sup>). As the yield strength increases, the area that can be coined using the same press decreases proportionately. However, an increase in strength of the workpiece must be limited so that plastic failure of the die does not occur.

**Coining Equipment.** In coining, the workpiece is squeezed between the dies so that the entire surface area is simultaneously loaded above the yield strength. To achieve metal deformation, the load determined from the compressive yield strength must be increased three to five times. Because of the area loading requirement and the great stress needed to ensure metal movement, press loading for coining is very severe, frequently approaching the capacity of the equipment used, with consequent danger of overloading.

Some coining equipment, such as drop hammers, cannot be readily overloaded, but presses (especially mechanical presses) can be severely overloaded. This is most likely to happen if more than one blank is fed to the coining dies at a time. Such overloading can break the press and the dies, and it will certainly shorten the life of the dies. Coining can be performed in any type of press that has the required capacity.

Drop hammers and knuckle-type and eccentric-driven mechanical presses are extensively used in coining. High-speed hydraulic presses also are well adapted for coining, especially when progressive dies are used. Large-capacity hydraulic presses are ideal for coining and sizing operations on large workpieces. Conversely, when it is feasible to coin large numbers of small, connected parts, as in a continuous strip of work metal, roll coining is the most economical method.

**Die Materials.** Tool steels for dies for striking high-quality coins and medals are selected for machinability, hardenability, distortion in hardening, hardness, wear resistance, and toughness. In dies used for decorative coining, materials that can be through hardened to produce a combination of good wear resistance, high hardness, and high toughness are preferred.

A smooth, polished background surface on the die is required for striking proof-type coins and medals. Massive undissolved carbides or nonmetallic inclusions make it more difficult to obtain this smooth background.

**Work Materials.** Steels that are most easily coined include carbon and alloy grades with carbon content up to approximately 0.30%. Malleable iron castings are frequently sized by coining. Stainless steels of types 301, 302, 304,

305, 410, and 430 are preferred for coining. Free-machining type 303Se (selenium-bearing) is sometimes coined. Types 301, 302, and 430 are used in coining of spoons and forks. Type 305 coins well but is not widely used because of cost. Stainless steels are preferred in the soft annealed condition, in the hardness range of 75 to 85 HRB.

Copper, silver, gold, and their alloys have excellent coinability and are widely used in coin and medallion manufacture. The pure metals are sufficiently soft and coinable to allow extreme deformation in coining, but even after such deformation they are too soft to wear well. As a consequence, important coining metals are prepared by alloying; thus, a relatively wide range of hardness is obtainable.

### ***Cold Heading***

Cold heading is a cold-forging process in which the force developed by one or more strokes (blows) of a heading tool is used to upset (displace) the metal in a portion of a wire or rod blank in order to form a section of different contour or, more commonly, of larger cross section than the original. The process is widely used to produce a variety of small- and medium-sized hardware items, such as bolts and rivets. Cold heading, however, is not limited to the cold deformation of the ends of a workpiece nor to conventional upsetting; metal displacement can be imposed at any point, or at several points, along the length of the workpiece and may incorporate extrusion in addition to upsetting. In cold heading, the cross-sectional area of the initial material is increased as the height of the workpiece is decreased. Advantages of the process over machining of the same parts from suitable bar stock include:

- Almost no waste material
- Increased tensile strength from cold working
- Controlled grain flow

**Suitable Work Metals.** Most cold heading is done on low-carbon steel wire with hardness ranging from Rockwell B 75 to 87. This is the type of material for which most machines are rated. Copper, aluminum, stainless steel, and some nickel alloys are also cold headed. Titanium, beryllium, magnesium, and refractory metals are less formable at room temperature and are likely to crack when cold headed; these metals are sometimes warm headed.

**Rating Formability.** Metals and alloys are rated for cold heading on the basis of the length of stock, in terms of diameter, that can be successfully upset. Equipped with flat-end punches, most cold-heading machines can upset to approximately two diameters of low-carbon steel wire per stroke. If the unsupported length is increased beyond approximately two diameters, the stock is likely to fold onto itself, as shown in Fig. 30. For more formable metals, such as copper and some copper alloys, the length of upset per stroke may be up to four diameters. Punches and dies can, however, be designed to increase the headable length of any work metal. For example, with a coning punch (Fig. 31) or a bulbing punch, it is possible to head as much as six diameters of low-carbon steel stock in two strokes.

**Fig. 30** Typical folding effect with a flat-end punch when heading low-carbon steel wire with unsupported length of more than two diameters

**Fig. 31** Use of a coning punch in the first blow of a two-blow heading operation, which enables a low-carbon steel workpiece to be upset to a length of up to six diameters in two strokes

**Machines.** Standard cold headers are classified according to whether the dies open and close to admit the work metal or are solid, and according to the number of strokes (blows) the machine imparts to the workpiece during each cycle. The die in a single-stroke machine has one mating punch; in a double-stroke machine, the die has two punches. The two punches usually reciprocate so that each contacts the workpiece during a machine cycle.

**Tools** used in cold heading consist principally of punches or hammers and dies. The dies can be made as one piece (solid dies) or as two pieces (open dies), as shown in Fig. 32.

**Fig. 32** Solid (one-piece) and open (two-piece) cold heading dies. (a) Solid die. (b) Open dies

Solid dies (known also as closed dies) consist of a cylinder of metal with a hole through the center (Fig. 32a). Solid dies can be made entirely from one material or may be made with the center portion surrounding the hole as an insert of a different material.

Open dies (also called two-piece dies) consist of two blocks with matching grooves in their faces (Fig. 32b). When the grooves in the blocks are put together, they match to form a die hole as in a solid die. The die blocks have as many as eight grooves on various faces, so that as one wears, the block can be turned to make use of a new groove.

**Tool Materials.** The shock loads imposed upon cold heading tools must be considered in selecting tool materials. For optimum tool life it is essential that both punches and dies have hard surfaces (preferably Rockwell C 60 or higher). However, with the exception of tools for cold heading of hard materials, the interior portions of the tools must be softer (Rockwell C 40 to 50, and sometimes as low as Rockwell C 35 for larger tools) or breakage is likely.

To meet these conditions, shallow-hardening tool steel such as W1 or W2 is used extensively for punches and open dies and for solid dies made without inserts.

**Lubrication.** Although some of the more ductile metals can be successfully cold headed to moderate severity without a lubricant, most metals to be cold headed are lubricated to prevent galling of the work metal or the dies, sticking in the dies, and excessive die wear.

Lubricants used include lime coating, phosphate coating, stearates and oils, and plating with softer metals such as copper, tin, or cadmium.

The ultimate in lubrication for steel to be cold headed is a coating of zinc phosphate with stearate soap--the same as is used for cold extrusion of steel.

### **Cold Extrusion**

Cold extrusion is so called because the slug or preform enters the die at room temperature or at a temperature appreciably below the recrystallization temperature. Any subsequent rise in temperature, which may amount to several hundred degrees Fahrenheit, is caused by the thermomechanical effects of plastic deformation and friction. Cold extrusion involves backward or forward, or combined backward-and-forward, displacement of metal by plastic flow under steady, though not uniform, pressure. Backward displacement from a closed die is in the direction opposite to punch travel, as shown in Fig. 33(a). Workpieces are often cup-shaped and have wall thickness equal to the clearance between the punch

and die. In forward extrusion, the work metal is forced in the direction of the punch travel, as shown in Fig. 33(b). Sometimes these two basic methods of extrusion are combined so that some of the work metal flows backward and some forward, as shown in Fig. 33(c).

**Fig. 33** Displacement of metal in cold extrusion. (a) Backward. (b) Forward. (c) Combined backward and forward

**Metals Cold Extruded.** Aluminum and aluminum alloys, copper and copper alloys, low-carbon and medium-carbon steels, modified carbon steels, low-alloy steels, and stainless steels are the metals most commonly cold extruded. This listing is in the order of decreasing extrudability.

**Extrusion ratio  $R$**  is determined by dividing the original area undergoing deformation by the final deformed area of the workpiece:

$$R = \frac{A_0}{A_f}$$

Because volume remains constant during extrusion, the extrusion ratio can also be estimated by increase in length. An extrusion ratio of 4 to 1 indicates that the length has increased by approximately a factor of four.

The metal being extruded has a large effect on the maximum ratio that is practical. Some typical approximate maximum extrusion ratios are 40 for aluminum alloy 1100, 5 for 1018 steel, and 3.5 for type 305 stainless steel and similar austenitic grades.

Extrusion pressure increases with extrusion ratio. Figure 34 shows that extrusion ratio has a larger effect on ram pressure in the forward extrusion of carbon steel than either carbon content or type of annealing treatment. Figure 35 illustrates the effect of tensile strength on extrudability in terms of ram pressure for both the backward and forward extrusion of low-carbon and medium-carbon steels of the 1000, 1100, and 1500 series at different extrusion ratios.

**Fig. 34** Effect of carbon content, type of annealing treatment, and extrusion ratio on maximum ram pressure in forward extrusion of the carbon steel part shown from the preformed slug shown

**Fig. 35** Effect of tensile strength of steel being extruded on ram pressure required for backward and forward extrusion at different ratios

**Presses and Headers.** Hydraulic presses, mechanical presses, special knuckle-joint presses for cold extrusion, special cold forging machines, and cold heading machines are employed for cold extrusion. Most presses used for cold extrusion are essentially the same as those used for sheet metal forming.

Most cold extrusion operations are performed on mechanical presses or cold heading machines. Of the two, mechanical presses are used more often because of their adaptability to other types of operations. Mechanical presses are generally less costly and are capable of higher speeds than are hydraulic presses of similar capacity.

The ram pressure that must be borne during the stroke is a function of the workpiece strength (as affected by composition, state of cold work, anneal, etc.) and the extrusion ratio, as shown in Fig. 34 and 35.

**Tooling.** The components of a typical tool assembly used for backward extrusion of steel parts are identified in Fig. 36. There is considerable variation in tooling practice and in the design details of tool-assembly components.

**Fig. 36** Nomenclature of tools comprising a typical setup for backward extrusion

**Tool Materials.** Compressive strength of the punch and tensile strength of the die are important considerations when selecting material for cold extrusion tools. Because the die is invariably prestressed in compression by the pressure of the inner and outer shrink rings, the principal requirement for a satisfactory die is a combination of tensile yield strength and prestressing that will prevent failure. Punches must have enough compressive strength to resist upsetting without being hazardously brittle. Thus, almost without exception, and particularly for extruding steel, the primary tools in contact with the workpiece must be made of steels that will harden through the section in the sizes involved. (This is notably different from cold heading tools, for which a hard case and soft core are usually desired.) Among the relatively few exceptions are small dies made of a water-hardening tool steel and bore quenched. As the bore hardens, the remainder of the die cools and shrinks, placing the bore in compression.

The degree of strength required for the tools is influenced by workpiece shape, composition and hardness of the metal being extruded, and production requirements.

**Preparation of Slugs.** Despite the loss of metal, sawing and cutting off in a machine, such as an automatic bar machine, are widely used methods of producing slugs. The advantages of these methods include dimensional accuracy, freedom from distortion, and minimal work hardening. Shearing is an economical means of producing slugs. Variation in the sizes of the slugs is a major disadvantage of shearing. If slugs are allowed to vary in size, die design must allow for the escape of excess metal in the form of flash. An alternative to die adjustment in some applications is to compensate for the distortion and other discrepancies in sheared slugs by coining the slugs to desired dimensions.

**Lubricants for Steel.** In most instances, the starting metal surface is given a conversion coating such as zinc phosphate to facilitate lubrication. A soap lubricant gives best results. Slugs are immersed in a dilute (45 to 120 kg/m<sup>3</sup>, or 16 oz/gal) soap solution at 60 to 90 °C (145 to 190 °F) for three to five minutes. Some soaps are formulated to react chemically with a zinc phosphate coating, resulting in a layer of water-insoluble metal soap (zinc stearate) on the surfaces of the slugs. This coating has a high degree of lubricity and maintains a film between the work metal and tools at the high pressures and temperatures developed during extrusion.

Other soap lubricants, such as high-titer sodium tallow soaps, with or without filler additives, can be used effectively for mild extrusion of steel. This type of lubricant is absorbed by a phosphate coating, rather than reacting with it.

Although the lubricant obtained by reaction of soap and zinc phosphate is best for extruding steel, its use demands precautions. If soap builds up in the dies, workpieces will not completely fill out. Best practice is to vent all dies so that the soap can escape and also to keep a coating of mineral seal oil (applied as an air-oil mist) on the dies to prevent adherence of the soap.

When steel extrusions are produced directly from coiled wire (similar to cold heading), the usual practice is to coat the coils with zinc phosphate. This practice, however, has one deficiency; because only the outside diameter of the work metal is coated, the sheared ends are uncoated at the time of extrusion. This deficiency is partly compensated for by constantly flooding the work with sulfochlorinated oil.

**Lubricants for Aluminum.** Aluminum and aluminum alloys can be successfully extruded with lubricants such as high-viscosity oil, grease, wax, tallow, and sodium-tallow soap. Zinc stearate, applied by dry tumbling, is an excellent lubricant for extruding aluminum.

The lubricant should be applied to clean metal surfaces, free from foreign oil, grease, and dirt. Preliminary etching of the surfaces increases the effectiveness of the lubricant.

For the most difficult aluminum extrusions (less extrudable alloys or greater severity, or both), the slugs should be given a phosphate-treatment followed by application of a soap that reacts with the surface to form a lubricating layer similar to that formed when extruding steel.

**Impact extrusion**, often simply called impacting, is similar to backward, forward, and combination extrusion except that faster speeds, shorter strokes, and shallower dies are employed. Cold impacting is used extensively for the easy extrusion of nonferrous metals having low melting points and good ductility, such as lead, tin, zinc, aluminum, copper, and alloys of these metals.

## Hot Extrusion

Hot extrusion involves pushing a heated billet of metal through a die. The temperature at which extrusion is performed depends on the material being extruded (Table 3). The extruded product can be hollow or solid, and the cross section can vary from a simple round to a complicated shape. Direct (forward) extrusion, wherein the metal is forced under pressure through a die opening of the desired cross-sectional area and shape, is most widely employed. The die is located in the end of the cylinder opposite the ram. In the less-used indirect (backward) extrusion process, the die is mounted on a hollow ram and is pushed through the metal instead of the metal being pushed through the die. The principal differences between direct and indirect extrusion are illustrated in Fig. 33.

**Table 3 Typical billet temperatures for hot extrusion**

Material	Billet temperature	
	°C	°F
Lead alloys	90-260	200-500
Magnesium alloys	340-430	650-800
Aluminum alloys	340-510	650-950
Copper alloys	650-1100	1200-2000
Titanium alloys	870-1040	1600-1900
Nickel alloys	1100-1260	2000-2300

## Process Variations

The three basic types of hot extrusion are nonlubricated, lubricated, and hydrostatic (Fig. 37).

**Fig. 37** Schematics of the (a) nonlubricated, (b) lubricated, and (c) hydrostatic extrusion processes

**Nonlubricated Hot Extrusion.** As the name implies, this extrusion method uses no lubrication on the billet, container, and die, and it can produce very complex sections, with mirror surface finishes and close dimensional tolerances. Generally, aluminum alloys are extruded without lubrication.

**In lubricated hot extrusion,** a suitable lubricant (usually ground or powdered glass or grease) is placed between the extruded billet and the die. The choice between grease and glass lubricants is based mainly on extrusion temperature. Below 1000 °C (1830 °F), grease lubricants are used; above this temperature glass is employed. Steels, titanium alloys, nickel alloys, and copper alloys require a lubricant during extrusion.

**In hydrostatic extrusion,** a fluid film present between the billet and die exerts pressure on the deforming billet. The hydrostatic extrusion process is primarily used when conventional lubrication is inadequate—for example, in the extrusion of brittle alloys (including beryllium and TZM molybdenum), composites, or clad materials. For all practical purposes, hydrostatic extrusion can be considered an extension of the lubricated hot extrusion process.

### ***Presses and Tooling for Hot Extrusion***

Horizontal and vertical presses are used for hot extrusion. Horizontal presses are the most common (Fig. 38). Most modern extrusion presses are driven hydraulically, but mechanical drives are used in some applications, such as the production of small tubes. Two basic types of hydraulic drives are available: direct and accumulator. In the past, accumulator presses were the most widely used, but today direct-drive presses are used more extensively.

**Fig. 38** Schematic of a horizontal extrusion press showing a hydraulically powered ram forcing the heated billet through the die

**The container,** which receives the hot billet to be extruded, is a heated cylinder that is almost always fitted with a liner. The liner must resist the abrasive action of the billet during extrusion and should maintain relatively high hardness at elevated temperatures. The container and liner should be made of materials with high fracture toughness and good resistance to low-cycle fatigue.

**The ram,** also referred to as the stem, operates within the liner and transmits pressure from the press cylinder to the billet. The ram must sustain high cyclic compressive loading. The material used for the ram should have good resistance to upsetting, work hardening, thermal shock, and rapidly applied stress.

**The dummy block** is a block of steel that is inserted between the ram and the billet to absorb the heat and erosion that otherwise would be imposed directly on the ram. The dummy block should resist indentation by the billet at temperatures approaching the billet temperature.

**The die or die assembly** is the area through which the billet is pushed to form the extruded bar or shape. A die assembly typically consists of the following component parts (see Fig. 39):

- A die, which is usually a circular steel block with a cut pattern of the transverse section of the shape to

be produced

- A die ring (die holder), which is a steel ring located in front of the container that contains the die and the backer
- A die backer, which is a circular steel block placed behind an extrusion die for support. The hole in the backer is slightly larger than the hole in the die to allow for clearance of the extrusion.
- One or more bolsters, which are circular steel blocks used adjacent to the backer to reinforce the die and backer against billet pressure
- A tool carrier (die slide or housing)

The die itself must have high toughness combined with resistance to wear and softening at elevated temperatures. The other components of the die assembly should be high in both strength and toughness.

Fig. 39 Typical extrusion die assembly, showing relative positions of components in a tool carrier

**The mandrel** is a rod used to produce the cavity in a hollow shape while it is being extruded. Mandrels should be high in hot hardness, abrasion resistance, fracture toughness, and yield strength.

**Press Operation.** With the ram retracted, a hot billet or slug is placed in the container. A dummy block is inserted between the ram and billet; then the hot billet is pushed into the container liner and advanced under high pressure against the die. The metal is squeezed through the die opening, assuming the desired shape, and is severed from the remaining stub by sawing or shearing.

# Powder Metallurgy

*Erhard Klar, Consultant*

## Introduction

POWDER METALLURGY (P/M) is a small but important branch of metallurgy that comprises the manufacture of metal powders and articles from powders through forming and sintering. In its most basic and widely used form, it consists of pressing a powder to the desired shape, followed by heating at an elevated temperature below its melting point.

The beginning of modern P/M is attributed to Wollaston (Ref 1) who, early in the 19th century, described a press-sinter forging technique for making fully dense platinum, a metal which, at that time, could not be melted because of its high melting point. Early in the 20th century, high melting point metals like tungsten and molybdenum were formed by P/M processing into articles for the electrical industry.

Powder metallurgy processing was also used for the manufacture of composite electrical contacts. Cemented carbides and porous bronze bearings followed in the 1920s, friction materials in the 1930s, and several refractory metals and so-called structural parts in the 1940s. The latter application evolved parallel to the growth of the automotive industry, and, to the present day, overall use of powder metallurgy in fully industrialized countries is strongly dependent on the automotive industry (Fig. 1).

**Fig. 1 Powder metallurgy parts markets for North America, 1995. Source: Metal Powder Industries Federation**

In the 1950s and 1960s the structural parts segment of the P/M industry expanded toward higher and full density processes and products. This led to increasing competition of the P/M industry with wrought metals. Examples of this evolution include powder forged steels, hot isostatically pressed tool steels, nickel-base superalloys, and high specific stiffness aluminum aircraft alloys

Although early uses were based on the ability of P/M to form articles of high melting point metals without melting and, later, to produce unique structures such as porous oil-impregnated bearings and composite materials, the success of the structural parts segment of P/M is largely based on economic advantages. These include energy efficient, environmentally acceptable, and nearly scrap-free mass production of parts by pressing and sintering, often without any subsequent machining or other secondary treatments.

Powder metallurgy is a dynamic technology. Advances in powder making, new processing equipment, and new P/M processes continue to emerge. Over the years, many variants of the basic compaction and sintering process have been developed. In addition to new and stronger alloys, the high and full density processes (i.e., warm compaction, hot isostatic pressing, powder forging, powder injection molding, powder rolling, and powder extrusion) combined with excellent control of microstructure and the innate capability of P/M to produce composite materials, allow the manufacture of conventional and unique materials possessing a wide property spectrum of the highest quality.

In spite of the many attractive attributes of P/M, there are limitations. The basic and economic press-and-sinter technique, employing mechanical and hydraulic presses for the compaction of the powders, has shape and size limitations. Because

of the generally higher cost of powders in comparison to ingots and the high cost of tooling, presses, and sintering furnaces, the manufacture of large part numbers, at least 1,000 to 10,000, is usually essential if competition with alternate manufacturing processes, such as machining, die and investment casting, die forging, fine blanking, and stamping, is to be successful.

This explains the preferred use of P/M in industries requiring large part numbers, especially the automotive industry. Manufacturing processes ("freeform powder molding") that allow for the production of small lot sizes of P/M components without resorting to expensive hand tooling are under development (Ref 2).

Figure 2 shows total metal powder shipments of iron, copper and copper alloys, and stainless steel powders in North America back to their initial uses. The high initial growth rate of iron powders slowed down to a more sustainable annual rate of approximately  $3\frac{1}{2}\%$  around 1970, a rate only moderately higher than the U.S. gross domestic product. This is related in part to the still increasing usage of P/M parts in the automobile. The compound annual growth rate of stainless steel powders and parts is still around 5%. This is attributed to improvements in the corrosion resistance of sintered stainless steels and their uses in more demanding applications such as in antilock brake system (ABS) sensor rings and automobile exhaust system components. The growth rate of copper powders, because their consumption was recorded in the 1940s and 1950s, exhibits a stagnant consumption over the past 50+ years. This is attributed largely to the relatively high cost and price volatility of copper and its partial or full substitution with less expensive materials such as iron and plastics.

**Fig. 2 Powder production in North America. Source: Metal Powder Industries Federation**

In the following, some basic P/M terms are briefly explained, and after a discussion of powder properties, an overview of general and individual powder production processes is presented. Consolidation of powders by pressing and sintering as well as high density methods are treated similarly. Emphasized are distinguishing features of powders, their manufacturing processes, compacting processes, and consolidated part properties. This information forms a basis for selecting the optimum P/M approach in the design of a product. Actual properties of P/M parts are found in the Sections dealing with the individual alloy product classes in this Handbook.

For more details, refer to *Powder Metal Technologies and Applications*, Volume 7, *ASM Handbook*, 1998; to general textbooks on P/M (Ref 3 and 4); and to the Selected References listed at the conclusion of this Section.

## P/M Definitions

Definitions of key powder metallurgy terms, which are used in the following sections, are given here. Additional terms related to P/M technology can be found in the "Glossary of Metallurgical and Metalworking Terms" in this Handbook.

- **activated sintering**
  - A sintering process in which the rate of sintering is increased, for example by addition of a substance to the powder
- **apparent density**
  - The weight of a unit volume of powder. It is related to particle shape; the more irregular the shape of a powder particle, the lower the apparent density.
- **cold isostatic pressing**
  - The densification of a material under isostatic pressure conditions at room temperature using a flexible mold and a high pressure hydrostatic pressure in a hydraulic chamber
- **compressibility**
  - A measure of the ability of a powder to densify under pressure
- **cross contamination**
  - Contamination of a material with material of a different (chemical) composition as a result of the (sequential) manufacture of different materials using the same processing equipment
- **dimensional change**
  - The shrinkage or growth of a part as a result of sintering
- **double-action pressing**
  - Method by which a powder is pressed in a die between two punches moving from opposite directions into the die cavity
- **flow rate**
  - The time required for a powder sample of standard weight to flow through an orifice in a standard instrument according to a specified procedure
- **green part**
  - The pressed part
- **green strength**
  - A measure of the ability of a green (i.e., pressed) compact to maintain size and shape during handling prior to sintering
- **hot isostatic pressing**
  - A process combining temperature and high pressure gas to densify a material into a net-shape component using a pressure-tight outer envelope
- **metal injecting molding**
  - A process in which a mixture of a metal powder and plastic binder is injection molded
- **powder forging**
  - Hot densification by forging of an unsintered, presintered, or sintered preform made from powder (also known as P/M forging or known as P/M hot forming)
- **powder metallurgy**
  - The branch of metallurgy related to the manufacture of metal powders and articles fabricated from powders by the application of forming and sintering processes
- **preform**
  - A compact blank intended to be subjected to deformation and densification involving change of shape.
- **premix**
  - A lubricated powder mixture ready for compaction

- **prior particle boundaries**
  - Precipitates present on the surfaces of powder particles, or precipitates forming on the surfaces during processing. These boundaries are usually visible by metallography and responsible for low ductility and deterioration of other properties of parts made from such powders.
- **punch**
  - Part of a die or compacting tool set that is used to transmit pressure to the powder in the die cavity
- **single-action pressing**
  - Method by which a powder is pressed in a stationary die between one moving and one fixed punch
- **sintering**
  - The bonding of neighboring particles in a mass of powder (as in a compact) by heating
- **withdrawal process**
  - Operation by which a die descends over a fixed lower punch to free the compact

## Powder Characteristics

For a powder to be suitable to P/M processing, it must possess powder properties that are tailored to the particular compacting and sintering process used, and it must provide the end or performance properties required in the finished P/M part. It must also be cost effective and, increasingly, powder specifications are becoming stricter and narrower in the interest of improving quality and consistency of P/M parts. The most significant fundamental powder characteristics include particle size, particle size distribution, particle shape, and purity of a powder. Engineering-type powder properties such as apparent density, flow rate, green strength, and compressibility depend on several of the fundamental powder properties in a more complex way. Quantitative relationships between the two types of properties are still of an empirical nature.

**Particle Size.** Powders suitable for conventional P/M processing are typically called -80 mesh powders, that is, powders with an upper particle size of approximately 177  $\mu\text{m}$ . This upper particle size limit arises from the need of porous sintered parts to have a surface texture that is pleasing to the eye and to assure adequate mechanical properties. Also, many powders are mixtures of several components that alloy with each other during sintering by solid-state diffusion. In the presence of large particles, the sintering times of such systems would be unacceptably long.

The lower end of the particle size spectrum of typical P/M powders is approximately 1  $\mu\text{m}$ . Most P/M powders have -325 mesh (<44  $\mu\text{m}$ ) fractions not exceeding 30 to 40%. These requirements are dictated by the need of a powder to flow freely, or by gravity, from a storage hopper to the die in an automated compacting press. With decreasing particle size, increasing amounts of fines (-325 mesh), and with more irregular particle shapes, powder flowability deteriorates. Moderate amounts of fines also provide for a good balance between sintering activity and shrinkage during sintering. In contrast to injection molding, which uses fine powders for rapid sintering and maximum densification (shrinkage), conventional pressing and sintering seeks to minimize shrinkage in the interest of maintaining dimensional tolerances.

**Particle Size Distribution.** In between these limits of coarse and fine, most P/M powders have particle size distributions consisting of more or less evenly weighted intermediate size powder fractions in accordance with the particulars of a powder production process. For most P/M uses the actual numbers of these fractions are of lesser importance than their consistency from powder lot to powder lot.

**Lubricants.** Powders used in the press-and-sinter process typically contain  $\frac{1}{2}$  to  $1\frac{1}{2}$  % of an admixed lubricant with a function that is to reduce friction during pressing, thereby facilitating compacting and ejection and lengthening the useful life of a compaction die. Widely used lubricants include stearic acid, synthetic waxes, zinc stearate, lithium stearate, and mixtures of these. The addition of a lubricant to a powder affects many of its engineering properties, including powder flow, apparent density, green strength, and compressibility. Lubricant optimization usually consists of identifying, empirically, composition and amount of lubricant providing the smallest loss of green strength for a given reduction in friction. Lubricants volatilize and decompose during sintering.

**Coarse and Fine Powders.** Some P/M processes employ finer or coarser powders than those used in conventional pressing and sintering. Powder injection molding (PIM) works best using powders with particle sizes up to approximately 20  $\mu\text{m}$ . The small powder particles, with high specific surface areas, provide the increased driving force for shrinkage during sintering to achieve nearly full density required in this process. The problem of powder flow is solved by compounding the fine powder with the organic binder into a coarser-grained, flowable powder.

Powders containing particles exceeding 177  $\mu\text{m}$  are sometimes used in powder forging, hot isostatic pressing, and powder extrusion. These processes typically produce fully dense materials, and, therefore, some of the restrictions that apply to porous materials do not apply.

**Particle Shape.** Another important distinction of metal powders relates to particle shape, or more broadly, particle morphology. Particle shape often reveals the process by which a powder was manufactured. Particle morphology greatly affects flow, apparent density, compressibility, and sintering characteristics of a powder. In the basic press-and-sinter process a powder needs to possess sufficient green strength to permit safe handling of the green compact prior to sintering. Spherically shaped powders have the lowest green strength characteristics and for that reason are generally not usable for room temperature die compaction. Conversely, such powders are often preferred in other P/M processes (i.e., hot isostatic pressing, powder extrusion, and powder injection molding) because of their higher packing and filling densities and their lower oxygen contents.

For thin or fragile parts, high green strength powders are preferred. Copper powders used in P/M friction products are an example where green strength has been driven to an extreme and where special powder manufacturing processes have been developed. Here, the need for high green strength derives from the fragile shape of some friction parts and the presence of other materials for which copper forms the supporting matrix. The more irregular the shape of the copper particles, the less copper is required to form a coherent matrix for holding the other components. The preferred friction grade copper powders are of small particle size, high specific surface area, and high purity. All three properties contribute to high green strength. These requirements explain why copper powders produced by hydrometallurgy, electrolysis, and oxide reduction are suitable for high green strength applications, whereas atomized copper powders are not. The inability of these powders to flow is not important because the copper powder is mixed with several other powders that are coarse enough so that the final powder mixture flows, or special powder dispensers are used to facilitate uniform die filling, even though the powders are not free flowing.

**Compressibility and Green Strength.** Since its beginning in the 1940s, the structural parts industry has placed great emphasis on the compressibility of a powder. A more compressible powder can be compacted to a higher density and, consequently, permits the manufacture of parts possessing higher mechanical properties, or a more compressible powder permits the use of a smaller and less expensive compaction press. Figure 3 shows typical compressibility curves for aluminum, copper, and iron powders. Maximizing compressibility is of particular importance for relatively hard powders that require high compaction pressures such as iron, tool steel, and stainless steel powders. Both compressibility and green strength of these powders improve by decreasing their hardness through minimizing the concentration of interstitials (carbon, nitrogen, and oxygen), through the removal of work hardening by annealing and by assuring, through proper heat treatment, the absence of any hard phases. Figure 4 shows the large negative effects of residual carbon in iron powder on compressibility and green strength. It is equally important for stainless steel powders.

Fig. 3 Compressibility curves for various metal powders. Source: Ref 5

Fig. 4 Effect of residual carbon content on compressibility and green strength of water-atomized high carbon iron. Pressed at 550 MPa (40 tsi) with 1% zinc stearate admixed. Symbols represent experimental data points. Source: Ref 5

In terms of morphological powder characteristics, a compromise must be sought between compressibility and green strength as the factors that improve compressibility have the opposite effect on green strength. The correct and optimum balance for high compressibility is to tailor the morphological characteristics of a powder so that green strength is just sufficient for the intended use. Compressibility increases and green strength decreases with decreasing surface area and increasing particle size of a powder. This explains why the highest compressibility iron powders available today are atomized powders of very low interstitial contents, of high apparent density with nonporous solid particles, and with moderate amounts (approximately 20%) of fines (-325 mesh). The detrimental effect of sponge powders, possessing

internal particle pores, on compressibility is illustrated in Fig. 5(a). Figure 5(b) shows the positive effect of particle porosity on green strength. Typical green strength curves for a low-alloy steel powder are shown in Fig. 6.

**Fig. 5** Effect of particle porosity on (a) green density and (b) green strength of solid and porous iron powders. Powders were pressed at 414 MPa (30 tsi) using die wall lubrication. The figures in parentheses in (a) signify specific surface areas (as measured by the gas adsorption method) and average intraparticle pore sizes of powders. Source: Ref 5

**Fig. 6** Effect of admixed lubricant on green strength of water-atomized 4600 low-alloy steel powder. Source: Ref 5

**Powder Cleanliness.** Powder cleanliness in P/M has become of increasing importance during the past 30 years. It generally refers to the presence of foreign, unreducible oxides and metallic trace impurities. It also includes the presence of foreign nonmetallic material arising from cross contamination. Soluble trace impurities reduce the electrical and thermal conductivities of copper; unreducible oxides can interfere with sintering and seriously impair the dynamic mechanical properties of high density parts, even at very low concentrations. For P/M products made by pressing and sintering, the density is typically below approximately 92% of theoretical. At such densities, the pores of a part usually overshadow the effect of oxidic impurities as stress raisers. It is for this reason that sponge iron powders with their larger amounts of unreducible oxides continue to be used successfully in the manufacture of low and medium density parts, whereas with the appearance of high and full density P/M processes, special "forging grade" iron powders were developed that contain only minimal amounts (and of small particle size) of unreducible inclusions. Figure 7 illustrates the large effect of oxide inclusions upon the toughness of a fully dense 4340 steel. Tool steel, and even more so superalloy powders, are produced with still greater care in order to minimize defects in the consolidated products.

**Fig. 7** Effect of oxide inclusions on impact toughness of fully dense 4340 steel processed by hot forging. (The smaller inclusions are more detrimental at a given concentration because their number is larger.) Source: Ref 4

Special analytical methods are used to guarantee the cleanliness of a powder. Examples include wet analysis, emission or flame spectroscopy, atomic absorption, x-ray diffraction, and x-ray fluorescence. Some of these methods are described in the Section "Materials Characterizations" in this Handbook.

## Powder Production Processes

Metal powders are used in many other industries outside of powder metallurgy. The high capital cost of metal powder production and its sensitivity to economics of scale makes it mandatory for a powder producer to manufacture a wide range of powders of a given composition. Each powder manufacturing process has typical characteristics and limitations with respect to particle size, particle shape, microstructure, chemistry, and cost. Over the years, atomization has steadily gained in significance on account of its flexibility and cleanliness. This was at the expense of some ore derived, electrolytic and some hydrometallurgically-produced powders, due to technical, economic, and/or ecological factors.

Judicious selection of a powder is critical in P/M processing. Powder selected for optimal performance allows for smooth and efficient processing. Generally speaking, powders today are cleaner and have more uniform particle size distributions and particle shape and permit the production of superior and more consistent P/M products.

In the following sections the major mechanical, chemical, electrochemical and atomizing processes are briefly described.

**Mechanical Processes.** Mechanical-based powder production processes have low energy efficiency, and their commercial use today is therefore limited to brittle materials such as electrolytic iron chips, carbonized iron scarf, master alloys, and certain oxidation-sensitive and reactive materials. It is also used to produce metallic flake powders and in the manufacture of mechanically alloyed materials. The latter employs intense milling of multicomponent powders for the production of advanced dispersion strengthened materials. Milling is also employed for the manufacture of cemented carbides where intense mixing and good dispersion of the hardmetal and the binders are important.

In the so-called coldstream process, a relatively coarse powder is carried in a high-velocity, compressed gas onto a target. Adiabatic cooling of the compressed gas cools and embrittles the metal so that it disintegrates upon impact. This process is used to pulverize hard and abrasive materials, such as tungsten carbide, tool steels, and beryllium. The process is simple and produces a relatively oxide-free powder.

Crushing and milling are widely employed intermediate unit operations for converting sintered powder cakes into powder. Widely used mills include jaw crushers, ball mills, and hammer mills. For milling to fine powders, high energy mills (attritors and vibrating mills) and surface active milling additives can be used.

The particle shape of powders made by mechanical processing ranges from angular to irregular. Figure 8 shows a scanning electron micrograph of an electrolytic iron powder made by the milling of a brittle electrodeposited sheet. Figure 9 shows angular shaped copper particles made by hammer milling a sintercake of oxide-reduced copper. Figure 10 shows the effect of attritor milling on the particle shape of spherical (gas atomized) Ti-6Al-4V particles.

**Atomization.** The mechanical disintegration of a melt, known as atomization, has become the most flexible and important method for producing metal powders for P/M use. There are several variants of this method (Fig. 11), but atomization with high pressure water or gas are the two most common. The use of centrifugal force to break up a liquid metal stream is known as centrifugal atomization; atomization into a vacuum as vacuum, or soluble-gas, atomization; and

the use of ultrasonic energy to effect break up as ultrasonic atomization. Figure 12 shows a schematic of a typical water atomization process, including melting facility, atomizing chamber, and powder drying equipment.

Fig. 11 Schematic of atomization processes. Source: Ref 5

Fig. 12 Water atomization setup. Source: Ref 5

Common to all atomization methods is the rapid quenching of the liquid particles at rates from  $10^3$  to  $10^8$  °C/s, depending on the particular atomizing process and particle size. The particle size of a water atomized powder is mainly controlled by the pressure of the water, which can be as low as 2.77 to 3.46 MPa (400 to 500 psi) units for a coarse or shotted powder, and as high as 20.7 MPa (3000 psi) for a very fine powder of a high melting point metal. The pressure range for gas atomized powders is smaller and narrower, typically from 0.69 to 2.77 MPa (100 to 400 psi).

The particle shape of gas atomized powders is usually spherical. Deviation from spherical can be attributed to oxidation during atomization in an oxidizing environment and/or to atomizing close to the melting point of the metal.

The particle shape of a water atomized powder is of great technical significance as it has a marked effect upon apparent density, green strength, and compressibility. The most important parameters that control the particle shape of a water atomized powder include the atomizing temperature (i.e., the temperature of the liquid metal), the cooling rate during atomization, the design of the atomizing nozzle system, and the degree of oxidation occurring during atomization. So-called dual atomization employs superimposed jets of gas and water and extends the control of both particle size and particle shape.

Some P/M processes require the use of powders of relatively narrow particle size distributions. With a good gas or water atomization system, it is possible to produce powders where two-thirds of the mass of the particle size distribution have a particle size range with a size ratio of less than four. Powders made by centrifugal atomization (spinning disk, rotating electrode) can have even narrower particle size distributions because of the uniform centrifugal force acting upon a thin and uniform sheet of liquid metal, plus the near absence of particle collisions (Fig. 13).

**Fig. 13** Scanning electron micrograph of plasma rotating electrode processed René 95 powder particles. Approximately 70 $\times$ . Source: Ref 5

The oxides formed during water atomization are distributed mainly on the surfaces of the individual particles. As shown in Fig. 14, these oxides, in alloys, consist predominantly of elements that are of small atomic size, which diffuse and oxidize rapidly. In superalloys, these oxides are difficult to remove; it is for this reason that superalloy powders are produced exclusively by inert gas atomization methods, which limits the oxygen contents to that of the liquid melt prior to atomization. Water atomized tool steels and stainless steels are examples where surface oxides (silicon oxides in stainless steels) are reduced during sintering at high temperature in a low dew point furnace atmosphere (or by carbon in vacuum sintered tool steels), which accounts for their widespread use. For iron and copper powders the oxides formed during atomization are reduced during powder annealing or during sintering.

**Fig. 14 Auger composition-depth profile of argon-atomized nickel-base superalloy powder. Source: Ref 5**

In one commercial process for the production of iron powder, a high carbon iron melt is water atomized in the presence of air. This results in the partial oxidation of iron. In a subsequent heat treatment, carbon reacts with oxygen to form a protective atmosphere of CO and a low carbon content compressible iron powder.

The rapid quench rates attainable with atomization are related to the so-called dendrite arm spacing of the microstructures of the powders, as shown for aluminum alloys in Fig. 15. Glassy or amorphous particles can be found in the fine fractions because of the higher cooling rates of fine powders. Rapid quenching reduces segregation, refines the microstructure, and extends the solubility of a metal, with benefits in hot formability, fatigue and impact strength, and electrical and magnetic properties. In alloys that form precipitates on cooling, such precipitates generally are uniform in size and small compared to those in ingots of the same composition. Figure 16 shows such a comparison of microstructures for T15 high-speed tool steel. The benefits of these differences, improved formability and toughness, have led to the increasing use of P/M tool steels. Low alloy steels and superalloys are other examples where rapid cooling benefits have been exploited for two or three decades. New alloys continue to be developed, often in combination with consolidation to full density.

**Fig. 15 Dendrite arm spacing versus cooling rate for aluminum alloys. Source: Ref 5**

**Fig. 16 Microstructures of T15 tool steel. (a) Wrought. (b) Powder metallurgy processed. Source: Ref 5**

**Chemical Processes.** After atomization, next in importance are chemical processes of powder production for P/M uses. These include reduction of oxides, precipitation from solution or from a gas, thermal decomposition, chemical embrittlement, hydride decomposition, and thermit reactions. The most widely used processes within this category include oxide reduction, precipitation from solution, and thermal decomposition.

**Oxide Reduction.** This method of powder manufacture is widely used for the production of iron, copper, tungsten, and molybdenum powders from their oxides. Such powders are also known as sponge powders because of the presence of

pores within the individual particles (Fig. 17). Most commercial processes of oxide reduction employ stationary-type reduction in belt furnaces. The reducing gas composition required for successful reduction depends on the particular metal oxide and the reduction temperature. The reduced oxide is actually a porous cake that must be ground to powder; sometimes the ground powder is annealed to further remove oxygen and/or carbon and to render it soft. The choice of reducing media (hydrogen, carbon monoxide, or carbon), raw material quality and size, and reduction conditions (temperature, bed depth, etc.) permits the manufacture of powders with a broad range of characteristics. Reduction temperature is perhaps the most critical process variable. Low reduction temperatures result in powders possessing fine pores, large specific surface areas, low apparent densities, and high green strength. High reduction temperatures ( $>0.6 T$ ) produce large intraparticle pores and small specific surface area powders with good compressibility.

**Fig. 17** Sponge iron particles. (a) Cross section. (b) Scanning electron micrograph. Both  $180\times$ . Source: Ref 5

The most important commercial process for oxide-reduced iron powder, the Höganäs process, is based on the direct reduction of a high-purity magnetite ore. Beneficiation and magnetic separation reduce the level of silicon dioxide to approximately 0.2%. Because of this, the powder is mainly used in low and medium density P/M applications where the deleterious effects of oxide inclusions are overshadowed by the effect of pores.

Oxide reduced powders of high purity made from high purity oxides include iron, copper, tungsten, and molybdenum. Oxide-reduced powders, because of their superior green strength characteristics, are often preferred in applications where green strength is important (i.e., friction parts) and where compressibility is of lesser importance. Sponge powders, as a result of their porous structure and larger surface area, shrink more than atomized powders during sintering, and they are sometimes added to atomized powders to modify and/or adjust the shrinkage characteristics of a powder.

**Precipitation from Solution.** Production of metal powders by hydrometallurgical processing is based on leaching an ore or ore concentrate, followed by precipitating the metal from the leach solution by electrolysis, cementation, or chemical reduction. In the Sherritt-Gordon process, copper, nickel, and cobalt are separated and precipitated from salt solutions by reduction with hydrogen. Hydrogen pressure, solution pH, and solution temperature must be controlled for successful reduction and differ for different metals. Through the use of additives and control of nucleation, powders with a wide range of particle sizes, particle density, and particle shape may be produced.

Through co-precipitation or successive precipitation of different metals, alloyed and composite powders can be produced.

**Thermal Decomposition.** Of the group of thermally decomposed powders, those produced by thermal decomposition of carbonyls are the most important. Both iron and nickel are produced by decomposition of their carbonyls.

Carbonyls are obtained by passing carbon monoxide over sponge metal at specific temperatures and pressures. Powder is produced by boiling the carbonyls in heated vessels at atmospheric pressure. The powder can be milled and annealed in hydrogen. The chemical purity of the powder can be high (over 99.5%) with the principal impurities being carbon, nitrogen, and oxygen. Particle size can be controlled very closely. Iron carbonyl powder is usually spherical in shape and less than  $10\text{ }\mu\text{m}$  in diameter. Nickel carbonyl powder is usually available as a fine spiky, a fine filamentary, and fine or coarse, high density powder.

**Electrochemical Processes.** Copper, iron, manganese, and silver are the main metals produced commercially by electrodeposition. Depending on the electrochemical polarization characteristics of a metal, it can be deposited as a

loosely adhering, powdery deposit on the cathode, or as a smooth, dense, and brittle deposit, which subsequently is milled into powder. In metals where the deposition potential varies little with current density, such as copper, silver, zinc, and cadmium, powdery deposits form. Iron, nickel, manganese, and cobalt require a large change in cathode potential for a small change in current density. These deposits are dense. Their brittleness can be controlled to some extent by proper adjustment of the electrolytic cell conditions.

The singularly outstanding quality of electrolytic powders is high purity. Before the advent of atomized powders, electrolytic iron and copper powders were widely used in the manufacture of electrical and magnetic P/M parts and also for high density parts because the high purity of the metals provided superior electrical, magnetic, or high compressibility characteristics. The relatively high purity of atomized powders has bridged this gap to a considerable extent. In addition, the high processing cost of electrolytic powders, in part related to environmental factors, has widened the cost differential between electrolytic and other types of metal powders.

Particle shape and size of loosely deposited electrolytic powders depends on the electrolytic cell conditions and can be additionally controlled through the use of addition agents to the electrolyte. Subsequent annealing can be used to stabilize the powders against oxidation and to broaden the range of powder characteristics. Commercial electrolytic copper powders have particle shapes from dendritic to equiaxed irregular and apparent densities from less than 1 g/cm<sup>3</sup> to over 3 g/cm<sup>3</sup>. The particle shape of electrolytic iron powder, as a result of milling, is irregular and flaky, with fairly rough surfaces. Table 1 compares chemical and physical properties of typical compacting-grade iron powders made by electrolysis, oxide reduction, and atomization.

**Table 1 Chemical and physical properties of compacting-grade iron powder**

Constituent or property	Electrolytic	Reduced	Atomized
Chemical analysis, %			
<b>Total iron</b>	99.61	98.80	99.15
<b>Insolubles</b>	0.02	0.10	0.17

## Powder Treatments

Most powders receive one or more treatments prior to compaction. These treatments are tailored to the use of a powder and may include particle size distribution adjustment through screening and/or air classifying, annealing for the purpose

of improving compacting properties, lubricant addition for compacting grade powders, mixing of different powders for premixes, and blending of powders and powder mixes to homogenize their various components. These treatments are usually performed by the powder producer. The quality of these treatments can greatly affect the uniformity and consistency of sintered part properties. With increasing emphasis on zero-defect manufacture, the treatments have received more attention in recent years.

**Classifying/Screening.** Many powder production processes yield relatively broad particle size distributions, and because of the many manufacturing variables, the distributions and average particle sizes may exhibit marked lot-to-lot variations, which contribute to the variation of important powder and sintered part properties. Classifying and screening are used to render the particle size distributions of powders more uniform with well-defined, upper particle size limits. Powder producers often manufacture series of powders that differ only in particle size distribution. Such powders exhibit "graded" differences in dimensional change during sintering. For filter manufacture, classifying and screening is used to generate narrowly sized powder fractions for controlled pore size in filters and flow restrictors.

**Powder Mixtures and Segregation of Powders.** Most P/M metal powders are multicomponent systems and, therefore, are subject to segregation. Segregation is even possible in a one-component metal powder if, for instance, coarse and fine powder particles "demix" as a result of vibration. The opportunity for powder segregation exists in processes such as shipping and filling of hoppers and compaction dies, where individual components, on account of differences in particle size, shape, density, surface roughness, and other properties, exhibit different flow rates.

The most widely used P/M compacting grade powders are mixtures of iron with graphite, copper, nickel, and/or molybdenum. The preferred use of powder mixtures rather than of prealloyed powders is related to several factors. The most important factor is that elemental powder mixtures generally possess significantly higher compressibilities than their prealloyed counterparts. Secondly, powder mixtures are usually less expensive than prealloyed powders. And thirdly, powder mixtures more often can be formulated to provide transient liquid phases during sintering, which can reduce sintering times and improve mechanical properties.

In most powder mixtures, the base powder typically comprises 90% or more of the powder mixture. As the other components are present in only small amounts, and their alloying effects are powerful, it is very important that they are uniformly distributed and that the homogeneity of the powder is preserved during shipping of the powders and during handling at the parts producer's site until compaction is completed. Without such precautions, the properties of the sintered parts are not optimal and the standard deviation, that is, the scatter of the properties, can be quite large.

**Stabilization of Multicomponent Powder Mixtures.** Because of the wide use of powder mixtures and their sensitivity toward demixing, much work has been done toward the stabilization of powder mixtures.

**Stabilizers.** A powder mixture is optimally mixed if its components approach a random (statistical) distribution that is free of agglomeration (Fig. 18). The quality of mixing can be measured by the number of particle contacts (in green compacts) between identical or different powder components as illustrated in Fig. 19 for iron-copper mixtures, or by the chemical analysis of appropriate samples taken from the powder mixture.

**Fig. 18** Schematic representation of particle patterns in a powder mixture. (a) Ordered. (b) Agglomerated. (c)

Statistical (random) distribution. (d) Demixed or segregated. Source: Ref 6

**Fig. 19** Effect of stabilizer on iron-iron contact formation in binary iron-copper system. Source: Ref 6

Blenders and mixers that rely mainly on gravity (tumblers) are suitable for powders that mix readily. More intense mixing is accomplished with low-shear, agitated-type blenders that use ribbons, slow-speed paddles, screw-type augers, or other means of motion. Figure 20 illustrates how spherical powders mix quite readily, but also are subject to demixing or overblending. Consequently, mixing should be stopped once a near-random distribution has been achieved. The variability coefficient in Fig. 20 represents the standard deviation of the measured degree of mixing divided by the average value of the measured property. The quality of the mixture improves with decreasing variability coefficient.

**Fig. 20** Effect of particle size and shape of components of 90%Fe-10%Cu mixtures on degree of blending. Quality of blending improves as variability coefficient decreases. Particle size and shape for components: (a) Cu, 200 to 300  $\mu\text{m}$ ; Fe,  $<63 \mu\text{m}$  of spherical particle shape. (b) Cu, 200 to 315  $\mu\text{m}$ ; Fe, 100 to 200  $\mu\text{m}$  of spherical particle shape. (c) Cu, 200 to 315  $\mu\text{m}$ ; Fe,  $<63 \mu\text{m}$  of irregular particle shape. (d) Cu, 200 to 315  $\mu\text{m}$ ; Fe, 100 to 200  $\mu\text{m}$  of irregular particle shape. Source: Ref 6

Demixing is often caused by the accumulation of electric charges, which often can be dissipated by the addition of a small amount of water. Surfactants and stabilizers are sometimes used to improve the flow of materials. They consist of wetting liquids and oils that have no negative effects on the sintering process. Figure 21 shows the beneficial effect of oleic acid (dissolved in benzene) for 90%Fe-10%Al mixtures. In this example, the best mixture results from the addition of the optimized amount of a stabilizer after eight minutes of mixing, when the mixture has approached a random distribution (curved).

**Fig. 21** Effect of stabilizer on degree of blending of 90%Fe-10%Al mixtures. Particle size for both components: 100 to 200  $\mu\text{m}$ . Stabilizer: benzeneloleic acid. (a) Without stabilizer. (b) With 1.0% stabilizer. (c) 1.0% stabilizer added after 8 min of blending. (d) 3% stabilizer added after 8 min of blending. Source: Ref 6

**Diffusion-Bonded Powders.** In a diffusion-bonded powder, a powder mixture is heated in a reducing atmosphere to yield a sintered powder cake, which, after grinding, produces a powder that consists of agglomerates of the components of the powder. The process is controlled so that the degree of alloying between the different components is only small. This retains much of the desirable high compressibility characteristics of the original elemental powder mixture and minimizes or eliminates the demixing tendency of such a powder. As a bonus, green strength is usually increased.

**Binder-Treated Powders.** In recent years powder producers have developed proprietary binders, which are used in small amounts to bond fine graphite onto the coarser iron particles. Such powders reduce the dusting of a powder and improve the uniformity of several important engineering properties of the sintered parts because of the more uniform concentration of carbon in the final parts.

**Prealloyed Powders.** In spite of the widespread use of powder mixtures, the use of prealloyed powders in the structural parts industry has been increasing. In the low alloy steel segment, nickel, molybdenum, and manganese are used as alloying elements to provide greater hardenability than is possible with admixed copper or nickel. Admixed nickel requires economically prohibitive sintering times (even at high sintering temperatures) for complete alloying. Higher alloyed powders, such as stainless steels, tool steels, and superalloys, are all prealloyed powders. The requirement of complete alloying in these alloy classes makes the elemental powder approach impractical. The problem of low compressibility, that is, low green density and/or low green strength, is solved by high temperature and liquid phase sintering and through the use of special consolidation methods such as hot isostatic pressing and extrusion.

**Annealing.** Although the term annealing refers to a heat treatment that renders a metal soft by the removal of strain, in P/M the term is used more broadly and includes the softening of a powder by the removal of interstitials, particularly carbon, nitrogen, and oxygen. Powders that have been work hardened through milling, powders that contain residual amounts of carbon, oxygen, or nitrogen, and powders that contain objectionable surface oxide films are most often subjected to this type of annealing. Examples include sponge and atomized iron powders, carbonyl and electrolytic iron powders, tool steel powders, and ferritic stainless steel powders. In most cases, annealing is performed in a reducing atmosphere that not only protects the powder against oxidation, but also removes surface and interior oxides. Annealing improves the compressibility and green strength of a powder due to the softening of the metal. Frequently, annealing also produces slightly agglomerated powders with lower apparent densities and further increases in green strength.

**Lubrication.** Compacting grade metal powders are lubricated to facilitate part ejection from the die and to minimize die wear. Lubricants can strongly affect compacting and sintering properties of a powder. For this reason, powder producers try to optimize amount, composition, and structure of a lubricant to not only reduce friction during powder compaction, but also to protect the powder against oxidation, to obtain consistent apparent density and powder flowability, proper dimensional change during sintering, and maximum and consistent mechanical properties of the sintered parts. Widely used lubricants are zinc stearate, stearic acid, lithium stearate, and synthetic waxes. Typical lubricant concentrations vary

between 0.5 and 1.5 wt%. Although a lubricant largely evaporates and/or decomposes in the preheating zone of a sintering furnace, interactions and reactions with the metal powder can have critical consequences. Potential problems range from lubricant segregation, burnout, and blistering to carbonization and lubricant residue interference. Lubricant performance also depends on part density and metal powder composition and particle size.

Lithium stearate is widely used in stainless steel powders because of its beneficial effect on compressibility. Lithium stearate and zinc stearate mixtures are used in brass and nickel silver powders to produce stainfree parts. Synthetic waxes, with their low moisture and ash contents, are widely used for high density parts, where ash residues are objectionable. Multicomponent lubricants permit the powder producer to adjust or influence the packing, pressing, and sintering characteristics of a powder. Figures 22, 23, 24, and 25 illustrate various effects of lubricants.

**Fig. 22** The apparent density of a lubricated water atomized stainless steel powder as function of mixing time. The plot shows the apparent density versus the amount of lubricant. The conditions were 60 vol% fill in a double cone mixer rotating at 50 RPM, lithium stearate ranging from 0.5 to 1.0 wt%. Source: Ref 4

**Fig. 23** The effect of powder lubrication on the flow time as measured by the Hall flowmeter. The experimental conditions correspond to those reported in Fig. 22. Source: Ref 4

**Fig. 24** The effect of powder lubrication on the green properties of pressed sponge iron. The green density is shown as a function of the amount of zinc stearate for three compaction pressures. Source: Ref 4

**Fig. 25** The effect of the amount of zinc stearate on the ejection force (the force necessary to remove the compact from the die after pressing) of a compact. Source: Ref 4

The use of die wall rather than admixed powder lubrication is still in the development stage.

## Powder Consolidation

The techniques for forming and shaping metal powders are diverse and continue to evolve. This is directly related to the wide range of densities used in P/M products: from very low-density metallic forms to low- and medium-density filters and self-lubricating bearings, and high- and full-density structural parts. In the most widely employed technique, powders are compacted into green parts at room temperature and then sintered. There are, however, P/M techniques that use no compacting step and others that combine forming and sintering in one operation. Regardless of the density of the final part, the general requirement of a sintered part is that there is good metallurgical bonding between powder particles and that the presence of any defects (that is, pores, inclusions, original particle boundaries, etc.) is controlled in a manner that guarantees specified performance properties. The density of a part is, of course, a very fundamental property, and apart from some unique products such as filters and porous self-lubricating bearings where porosity itself is of functional importance, the highest economically feasible density is usually sought in order to obtain the highest possible strength properties. Broadly speaking, increasing density is synonymous with increasing cost of a P/M part; however, the relationship is not strictly linear in that it shows abrupt changes when the consolidation technique changes (Table 2).

**Table 2** Approximate costs of steel P/M parts produced by various methods

Condition	Density range, g/cm <sup>3</sup>	1997 selling price <sup>(a)</sup> , \$/lb
<b>Pressed and sintered</b>	6.0-7.1	2.45-2.70

---	------	-----------

- (a) These numbers are only averages; smaller parts are more expensive and larger parts less expensive per pound.

Figure 26 shows schematically the dependence of sintered density and of several mechanical properties on sintering temperature. Conventional pressing and sintering with maximum densities around 90 to 92%, and up to approximately 95% for double pressed parts, can achieve impressive relative strength values. However, ductility, and more so dynamic strength properties such as impact and fatigue strength, are relatively low because these properties, unlike ultimate tensile strength, depend more upon the morphology of the pores (both size and shape) and approach their maximum values at full density in an exponential fashion. As the so-called high and full density techniques are more expensive than conventional pressing and sintering, it is therefore imperative in the design of a new part first to identify the requirements of the intended application. To select the least expensive P/M technique for the manufacture of a part requires a broad and detailed understanding of the various P/M processes and is best done in consultation with a P/M parts manufacturer. There are many examples where wrought parts have been replaced by porous P/M parts of much lower ductility that yielded satisfactory performance. Size, shape, surface finish, mechanical and physical properties, dimensional tolerance requirements, as well as quantity and cost restrictions enter into the decision-making process for selecting the proper consolidation method. Tables 3 and 4 compare several of these characteristics for various P/M processes.

### ***Conventional Pressing and Sintering***

Conventional compaction and sintering is the most widely employed technique for producing P/M parts. Figure 27 shows the processing steps.

**Fig. 27** General steps in the P/M process. Source: Ref 7

**Compaction of Powders.** As a metal powder deforms during compaction, its hardness increases (work hardening), and its rate of densification decreases with increasing compaction pressure, as shown in Fig. 28. Cold welding and interlocking of particles provides compact green strength. Densities above 90% of theoretical are difficult to attain for many metal powders because of the increasing work hardening. High compressibility powders are, therefore, preferred in systems that require high compacting pressures, such as iron, stainless steel, and tool steel powders. Typical and maximum compaction pressures employed in the industry for these powders are in the range of 550 to 827 MPa (40 to 60 tsi).

**Fig. 28** Key steps during compaction and effect of compacting pressure on green density. Source: Ref 4

Density increases up to approximately 95% of theoretical can be obtained by repressing after sintering. The attainment of a high density by sintering at a high temperature and/or for a long period of time usually requires repressing of the sintered part in order to restore acceptable dimensional tolerances.

In the most common compaction technique, double action compaction pressure is applied along one vertical axis, from both top and bottom, as shown in Fig. 29. The punches provide compression forces while the die provides lateral support to the powders. To press parts of identical weight, it is important that the apparent density of a powder and its flow and packing properties are constant.

**Fig. 29** Tool motions during a powder compaction cycle, showing the sequence of powder fill, pressing, and ejection. Source: Ref 4

In spite of the use of lubricants, residual friction between die walls and powder and within the powder itself and the nonisotropic application of pressure result in nonuniform density throughout the part. Figure 30 shows the density distribution (lines of constant density in  $\text{g/cm}^3$ ) of a cylinder pressed from nickel powder from only one direction, at a pressure of 690 MPa (100 ksi). The low density near the bottom of the compact explains the widespread use of double action compaction. The density differences (and the implicit variations in stresses and contact geometries) are the main reason why compacts, upon sintering, do not shrink uniformly and why sintering of such compacts is, therefore, performed under conditions that result in only small dimensional changes. With substantial shrinkage, dimensional tolerances deteriorate rapidly and require sizing.

**Fig. 30** Density distribution in a cylindrical nickel powder compact. Source: Ref 5

**Design Limitations.** The vertical compaction motion and the requirement that a part be automatically ejected from the die impose size and shape limitations. Additional limitations arise from the necessity that die components resist fracture and that the flow of powder into the die must be possible for uniform density. Generally, the wall thickness of a part is not less than 1.5 mm (0.060 in.). A maximum length-to-wall thickness ratio of 8 to 1 ensures reasonable density uniformity. Simple steps or level changes not exceeding 15% of the overall part height can be formed by face contours in the punches. This requires a draft of at least 5° for proper ejection.

Spherical parts require a flat area around a major diameter to allow the punch to terminate in a flat section (Fig. 31). Parts that must fit into ball sockets are repressed after sintering to remove the flats. Through holes in the pressing direction are produced with core rods extending through the punches.

**Fig. 31** Proper design of spherical shapes in P/M parts. Source: Ref 7

Chamfers are preferred rather than radii on part edges to prevent burrs. Figures 32 and 33 show examples of unacceptable, acceptable, and preferred design features.

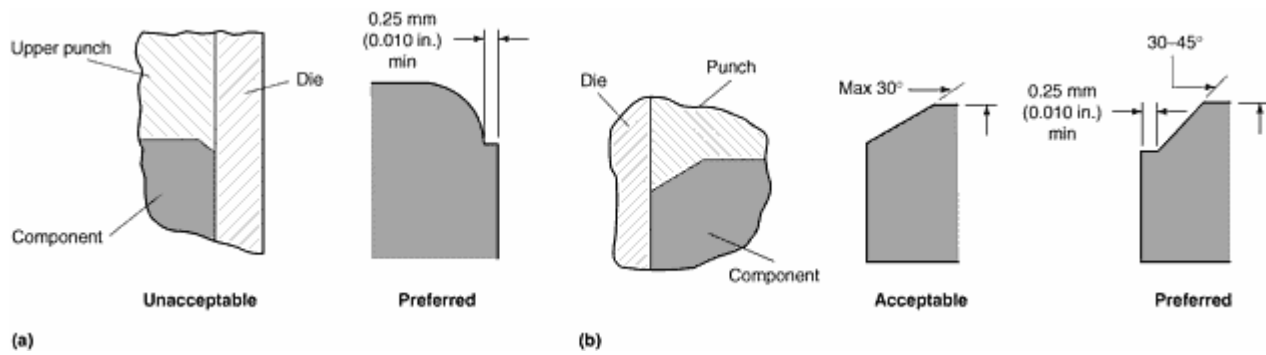

Fig. 32 Chamfer (a) and edge radii (b) design features. Source: Ref 7

Fig. 33 Examples of undesirable design features and preferred alternatives for P/M parts. Source: Ref 7

Reference 8 provides more details on designing for P/M. The limitations of shape complexity in the conventional press and sinter technique can be overcome in part by so-called multiple part assembly through sinter bonding, brazing, or welding.

With a large press ( $\sim 1000$  tons capacity) and a high compressibility powder, commercially produced parts can weigh around 2 kg (4.4 lb), with a compaction area of approximately  $160 \text{ cm}^2$  ( $62.99 \text{ in}^2$ ), and a part thickness of approximately 75 mm (2.96 in.) although larger and heavier parts have been produced on conventional equipment.

Springback of a part, that is, expansion after ejection from the die as a result of the release of elastic stresses, must be included in die design. Springback is usually less than 0.3% of the die dimension.

Dies are typically made from tool steel or cemented carbide. The latter are used in high volume production.

Powder metallurgy parts are classified by their complexity in terms of the number of their so-called levels or thicknesses and pressing directions (single or double action). Multiple level parts are the most difficult to press as each level requires separate punches for independent motion in order to minimize density differences between the various levels, (Fig. 34). Figure 35 illustrates the capabilities of the P/M press and sinter process in terms of the four compaction classes.

Fig. 34 The multiple tool components needed to compact a two-level gear. Source: Ref 4

**Fig. 35** Collection of P/M components demonstrating the variety of possible shapes and the four compaction classes. (a) Class 1. (b) Class 2. (c) Class 3. (d) Class 4. Courtesy of Randall M. German, The Pennsylvania State University

**P/M presses** can be of the hydraulic, mechanical, pneumatic, rotary, or isostatic type. Hydraulic presses have press capacities from less than 100 tons (896 kN to over 2000 tons, or 17,920 kN). Ejection of a pressed part from the die may be by the lower punches or by the so-called withdrawal type tooling. Rotary presses are cam-operated, high-speed presses. They are used for compacting small parts and can produce small bearings at rates of several 100 per min. Small mechanical presses (up to approximately 20 tons, or 179 kN) can produce parts up to approximately 100 per min, larger presses (>100 tons, or 896 kN) can produce up to approximately 25 parts per min.

Hydraulic presses are controlled by compacting load, and mechanical presses are controlled by compact dimensions. If, therefore, the apparent density of a powder fluctuates toward a higher value, a hydraulically pressed part is bound to be of slightly larger height, while a mechanically pressed part will have a slightly higher density. Herein lies the importance of uniform apparent density of a powder lot to assure uniform parts for the entire powder lot. Hydraulic presses are slower than mechanical presses, but they allow more uniform densities and more independent controls.

Complex shapes involving undercuts or large length-to-diameter ratios can be formed by cold isostatic pressing. Using this process, a flexible mold is filled with powder and pressurized isostatically (at ambient temperature), using a fluid such as oil or water. Compacting pressures ranging from 210 to 410 MPa (30 to 60 ksi) are most commonly employed, although pressures as high as 1400 MPa (200 ksi) have been used.

**Sintering.** Sintering is the process through which the particle contacts achieved during compaction grow (Fig. 36) and the physical and mechanical properties of a part are developed. Frequently, it is accompanied by shrinkage of the part. Sintering can also involve alloying and homogenization of mixed powder parts, often accompanied by growth.

**Fig. 36** Scanning electron micrographs of the neck formation due to sintering. The spheres ( $33\ \mu\text{m}$  diam) were sintered at  $1030\ ^\circ\text{C}$  for 30 min in vacuum. Courtesy of Randall M. German, The Pennsylvania State University

Sintering is performed at temperatures around  $\frac{2}{3}$  of the absolute melting point of the material, typically for 20 to 60 min and under a protective atmosphere. Widely used furnace atmospheres include endothermic gas, exothermic gas, dissociated ammonia, hydrogen, hydrogen-nitrogen mixtures, and vacuum. The main function of the atmosphere is to protect a part from oxidation or nitridation, as might occur when heating in air. Frequently, however, critical aspects of a sintering atmosphere also include reducing and carbonizing power and capability for efficient removal of the lubricant. Some sintering furnaces contain so-called rapid burn-off zones for rapid and efficient removal of the lubricant. This usually entails an atmosphere with a higher oxidation potential, that is, a higher concentration of gases such as steam and carbon dioxide.

Steel parts with defined levels of carbon require that the furnace atmosphere has the correct concentration of carbonizing components, that is,  $\text{CO}$ ,  $\text{CH}_4$ , and  $\text{C}_3\text{H}_8$ , in order to assure the correct carbon level and its uniform distribution throughout the part. Endothermic atmospheres (mixtures of hydrogen, nitrogen, and carbon monoxide) are used for this purpose.

For some materials, the sintering process must be carefully controlled for developing optimum properties. The following are examples:

- Aluminum alloys are most widely sintered in very low dew point nitrogen
- Tool steels are sintered in a very narrow temperature range to achieve densification through liquid phase sintering without excessive grain growth and carbide coarsening.
- For best corrosion resistance, stainless steels are preferably sintered at high temperature ( $1180$  to  $1290\ ^\circ\text{C}$ , or  $2250$  to  $2350\ ^\circ\text{F}$ ) in low dew point hydrogen or under vacuum, followed by rapid cooling. Sintering in dissociated ammonia increases strength, but corrosion resistance is only modest because of the formation of chromium nitrides and attendant sensitization. Furthermore, the chloride corrosion resistance of sintered stainless steels goes through a minimum at a density of approximately  $7.0\ \text{g/cm}^3$ , as a result of crevice corrosion due to the presence of pores. Corrosion resistance in acids improves steadily with increasing density.
- Soft magnetic steels are sintered at high temperatures in low dew point hydrogen to reduce their interstitials (carbon, nitrogen, and oxygen) and to maximize the magnetic properties.

The majority of parts require at least some reducing gases in the furnace atmosphere because of the ever present surface oxides on most metal powders, which, without their removal, would interfere with sintering.

As the sintering process is driven mainly by the surface energy of the powder particles, it is evident that a fine powder sinters more rapidly than a coarse powder. This is the reason why metal injection molding (MIM) employs very fine powders,  $5$  to  $20\ \mu\text{m}$ , which under normal sintering conditions shrink to nearly full density.

Sintering theory describes the evolution of the pore structure in terms of solid state atomic transport (diffusion) events. Theoretical approaches are useful for estimating the effects of the many process variables. In the early stage of sintering, bonds form at the particle contacts. During intermediate stage sintering, in the density range of approximately 70 to 92% of theoretical, the rate of sintering decreases, grain growth occurs, and pores become isolated. In the final stage, spherical and isolated pores shrink only slowly by vacancy diffusion to grain boundaries.

In liquid phase sintering, a liquid coexists with the solid phase during part or the entire sintering process. The presence of the liquid, through a solution-precipitation process, enables more rapid sintering and much faster densification than is typical for a solid state system. Thus, with a liquid phase sintering system, it is possible to achieve a high sintered density without the use of a fine powder. Commercially, widely used liquid phase sintering systems include bronze (for porous bearings), copper steels, tool steels, cemented carbides, iron-phosphorous and tungsten-nickel.

In activated sintering, a small amount of an additive is used to improve the diffusion rate during sintering. Examples include palladium added to tungsten and hydrogen chloride added to hydrogen atmospheres for sintering iron compacts.

Apart from the development of strength during sintering, a critical property is the control of dimensional change. In the press and sinter technique, the sintering cycle with its many variants is usually controlled to produce close to zero dimensional change. Shrinkage is usually less than 2.5%. This results in dimensional tolerances of approximately +0.07 to 0.10% for 1 in. diameter parts. The tolerances in the axial directions are approximately +0.5% for a 1 in. long part. Sizing can be used to further improve dimensional tolerances. Further improvements by P/M equipment manufacturers and powder producers also will result in further improvements of this important property. Liquid phase sintering typically produces more distortion and liquid phase sintered parts, even when shrinkage is absent, which are often sized to improve the final tolerances of a part.

**Sintering Furnaces.** Structural parts are typically sintered in continuous belt, pusher, or walking beam furnaces. For economic reasons, batch-type furnaces are often used for refractory metal powder parts and their alloys as well as for cemented carbide compacts. Vacuum furnaces can be used for all of the above. Still other furnaces are used for hot pressing, hot extrusion, and hot forging. Some refractory materials are sintered by directly passing electrical current through them.

Belt furnaces operate up to approximately 1177 °C (2150 °F). They are widely used for sintering the bulk of structural parts. Pusher and walking beam furnaces are operated at temperatures up to approximately 1371 °C (2500 °F), and vacuum furnaces up to 3000 °C (5432 °F). The various heating elements used in these furnaces (nichrome, kanthal, silicon carbide, molybdenum, and graphite) determine the maximum operating temperatures and the atmospheres (reducing, oxidizing, carbonizing, and inert) under which they are used. Most furnaces are designed to contain a preheat and delubrication zone, a hot zone, and a cooling zone, as shown schematically in Fig. 37.

**Fig. 37** The sequence of operations occurring in a sintering furnace. The lower diagram shows the time-temperature profile typical of metal powder sintering. Source: Ref 4

**Warm Compaction.** In warm compaction both powder and die are heated under a protective atmosphere and the compacted. This process produces parts with densities up to approximately 95% of theoretical, that is, similar to those

obtained by double pressing, but at a lower cost. Green strength is also significantly higher so that parts can be machined in the green condition.

## Full Density Processes

Commercial full density processes include powder forging (P/F), metal injection molding (MIM), hot isostatic pressing (HIP), roll compacting, hot pressing, extrusion, and spray forming. In these processes, porosity is eliminated and physical and mechanical properties are improved to the level of wrought materials and sometimes beyond.

Strengthening a part through alloying additions is less limited in the full density processes than it is in the press and sinter process. In the latter, high compressibility is important to achieve high pressed densities. In P/F, MIM, and HIP, the compressibility of a powder plays only a minor role. It is for this reason that the press and sinter process often employs powder mixtures and relies on alloying during sintering, while the full density processes in general prefer the harder prealloyed powders.

Several of the full density processes offer complex shape capability and attractive advantages regarding material utilization, energy efficiency, and precision, in comparison to conventional wrought materials. These advantages are, however, obtained through the use of more expensive processing. High or full density alone is not sufficient to achieve superior properties. Most full density processes use "clean" powders, and any nonreducible surface oxides are limited to very small amounts and, if present, are broken up and homogeneously distributed through shear deformation. Fully dense P/M materials can exceed the properties of wrought materials of the same composition through control of the microstructure, that is, control of various defects, homogeneity of structure, and the smaller grain size typical of most P/M materials. It is, therefore, important to determine the properties needed in a given application and then select the most economic process that can achieve the desired properties. Full dense processing is currently used to manufacture high fatigue strength structural parts for automotive uses; superalloy components; high-temperature, light-weight composites; wear resistant materials; cutting tools; permanent magnets; and dispersion-strengthened copper.

Figure 38 compares schematically some of the options of high and full density processing with respect to density, part size, and level of performance. The range of properties for a given density (cross-hatched area) arises from alloying and heat treatment effects, as well as from morphological differences. Tables 3 and 4 compare several performance and other properties of the major full density processes.

**Fig. 38** Three of the variables that influence the selection of a powder metallurgy processing method: component size, density, and performance (as a percentage of that of a wrought material). That behavior corresponds to ferrous based P/M systems formed from coarse powder, but is representative of many powder metallurgy materials. The symbols are press and sinter, P/S; press, sinter, and repress, reP; press, sinter, and forge, P/S + F; cold isostatically press and sinter, CIP + S; hot isostatically press, HIP; hot isostatically press and forge, HIP + F. Source: Ref 4

**Powder Forging.** In P/F a so-called preform, made by conventional pressing and sintering of a forging grade powder, is forged by a simple blow in a confined die at an elevated temperature (800 to 1200 °C, or 1450 to 2200 °F, for ferrous parts). In hot upsetting, the preform undergoes a significant amount of lateral material flow; in hot repressing, material flow is mainly in the direction of pressing. Hot upsetting with its large amount of shear stresses is effective in breaking up

powder particle oxide films, which improves metallurgical bonding between particle interfaces and enhances dynamic mechanical properties. Weight distribution within the preform is carefully controlled to obtain full density without tool breakage. Although P/F involves less handling, fewer dies and processing steps, and produces less scrap than conventional forging of cast materials, it is presently primarily used for the high volume production of automotive parts. This is attributed to the high cost for developing preforms and maintaining forging tools and automated production systems. In hot upsetting, the design of the preform is critical in that densification and shaping through the application of a uniaxial force occur simultaneously and must occur without bulging and cracking of the preform. Forging windows (computer-aided design) describe the amounts of fracture-free permissible straining.

Figure 39 shows a few of the many possible operating layouts of a powder forging process line. For the forging steps, the heated preform is removed from the furnace, usually by a robotic manipulator, and located in the die cavity for forging at high pressure (690 to 965 MPa, or 100 to 140 ksi). The preform can also be coated with graphite to minimize its oxidation during reheating and transfer to the forging die.

Fig. 39 A powder forging process line. Source: Ref 9

**Metal Injection Molding.** In MIM, a uniform mixture of metal powder and binder is injected into a mold (Fig. 40), the binder is removed, and the part sintered to more or less full density. This process permits the manufacture of very complex metallic shapes with less expensive forming equipment than the equipment used in the press and sinter process. The powders suitable for MIM are, however, very fine with an average particle size of less than approximately  $20\text{ }\mu\text{m}$ , and they can cost over twice as much as the coarser powders used in the conventional press and sinter process. The high surface area of the fine powders provide the surface energy necessary to achieve full densification during sintering. Widely used powders include carbonyl iron and nickel powders and other fine and more or less spherically shaped powders made by other processes. Near spherically shaped powders provide desirable high packing densities. The large amount of binder used in MIM, up to 40%, must be removed carefully through solvent or capillary extraction and/or through thermal debinding. The large amount of shrinkage (20% linear) taking place during sintering is mainly isotropic, and therefore dimensional tolerances, although somewhat inferior to pressed and sintered parts, are acceptable.

Fig. 40 Schematic of the metal injection molding process. Source: Ref 4

Metal injection molding is mostly used for the manufacture of relatively small parts, usually less than  $\frac{1}{4}$  lb, of complex geometries. Typical products include rechargeable batteries, orthodontic brackets, capacitors, filters, and catalytic substrates.

Forming methods that use similar metal powders and binders similar to MIM include various types of slip casting, extrusion, and freeze drying.

**Hot Isostatic Pressing.** In HIP, or "hipping," a powder is filled into a gas-tight metal or ceramic container and then heated and vacuum degassed to remove volatile contaminants. This is followed by further heating and pressurizing with gas (Ar or N<sub>2</sub>) in a HIP vessel. Temperatures up to 2200 °C (4000 °F) and pressures up to 200 MPa (30 ksi) are in use. Because of the isotropic pressure, the consolidated powder is in the shape of the original container except for the smaller size. The container can be stripped from the consolidated part by machining or by chemical dissolution. Hot isostatic pressing allows the production of large parts with very good shape complexity but modest dimensional tolerances and low production rate. The dimensional tolerances are over an order of magnitude inferior to conventional die compaction and to P/F. For these reasons, HIP is mainly used for the consolidation of expensive metals, preferably of large size, such as superalloys, titanium, stainless and tool steels, and composites.

Hot isostatic pressing is also applied to P/M materials with densities over 92%. In this case, no container is necessary because at such densities there exists no open porosity. Cemented carbides, wear materials, and titanium implants are manufactured this way.

Because of the hydrostatic stresses in HIP, powder consolidation occurs with only little shear on the particle surfaces. This mandates the use of very clean and oxide-free powders.

**Roll Compaction.** In roll compaction or powder rolling, conventional rolling technology is employed to compact a powder at room temperature into a porous (60 to 90% of theoretical) strip. The powder is gravity fed into the gap of two rolls. The flexible green strip enters a sintering furnace followed by hot rolls to complete densification to theoretical

density. Roll compaction of powders is used in the manufacture of high purity metals, soft magnetic alloys, composite, and other specialty materials.

**Hot pressing** can be performed in a rigid die using uniaxial pressure, similar to die compaction. A protective atmosphere protects the powder from becoming oxidized. Alternatively, the powder can be encapsulated in a container. Graphite, refractory metals, or ceramics can be used as die materials. Hot pressing is a slow process because of the large thermal mass of the tooling. Typical maximums for temperature and pressure are 2200 °C (4000 °F) and 50 MPa (7.3 ksi). Hot pressing under vacuum minimizes contamination. Hot pressing is used industrially for the manufacture of diamond tool and friction materials and beryllium.

**Extrusion.** In extrusion, a powder is typically canned, degassed, and then extruded at elevated temperature (over two-thirds of the absolute melting point of the material). For full densification and crack-free extrusion, reduction rates greater than ten are used. Temperature is the main control variable to achieve good product quality and acceptable tooling life. The high level of shear present in powder extrusion is very effective in breaking up prior particle boundaries of highly alloyed metals. This results in superior microstructures and superior mechanical properties.

Extrusion is used commercially for the manufacture of stainless steel tubing, oxide-dispersion strengthened metals, composites, and other specialty materials.

**Spray Forming.** In spray forming, inert gas atomized powder is directed onto a substrate. With proper process control, the atomized droplets reach the substrate surface in semisolid condition and splat deform to full or nearly full density. Rapid heat extraction results in minimal segregation in even complex alloys and in very good homogeneity. Deposition rates of up to 2 kg/s are possible. Spray forming is currently being applied to nickel, copper, and aluminum alloys.

## Secondary Operations

Sometimes sintered parts require special treatments, known as secondary and/or finishing operations, to meet final application requirements. They include heat treatments, joining, repressing and sizing, machining, and various kinds of surface treatments. The presence of residual porosity requires special precautions in some of these processes.

**Heat treatments** serve to increase the surface hardness of a part to improve wear resistance or to increase the hardness of the entire part to improve strength. Powder metallurgy parts with residual porosity are heat treated in carburizing and nitriding gases or in noncorrosive liquids (quench oils). Porosity in P/M parts increases the depth of carburization (Fig. 41). Therefore, parts to be case carburized should have a density of at least 7.2 g/cm<sup>3</sup> to avoid penetration of the carbonizing gas into the part interior. Lower density parts are sometimes copper infiltrated to meet that requirement.

**Fig. 41** Hardness, in terms of the Vickers hardness number, versus depth below the surface for three P/M steels following vacuum carburization at 925 °C (1695 °F). The higher the porosity the deeper the carbon penetration because of permeation through the open pore network. Below approximately 8% porosity, the carburization process is largely by solid-state diffusion. Source: Ref 4

The hardenability of P/M parts is reduced due to the presence of pores, which reduce thermal conductivity and cooling rate. This is illustrated in Fig. 42 for two porosity levels. Although manganese and chromium significantly improve hardenability, their use is limited to very low dew point atmospheres, which prevent the oxidation of these elements.

**Fig. 42** Hardenability, as measured by Jominy end-quench hardness traces, for two porosity levels in sintered steel. The lower porosity gives better heat conduction with concomitantly greater depth of a high hardness. Source: Ref 4

Porous steel parts can be steam treated to improve wear and corrosion resistance and to provide low-pressure, leak tightness. The treatment is performed at low temperature in superheated steam. The steam oxidizes the surface pores, which close through formation of an adherent layer of bluish to black iron oxide ( $\text{Fe}_3\text{O}_4$ ).

**Joining.** At low porosity levels (<8%), P/M parts can be joined similar to wrought materials. At densities of 80 to 90%, joining techniques based on fusion (welding and brazing) are successful provided the amount of melt is kept low. For lower densities, special brazing alloys have been developed, which minimizes the amount of filler metal penetrating the pore space of a part.

Copper infiltration can be used to sinter, infiltrate, and braze an assembly of several green parts in a simple operation.

**Repressing and Sizing.** Pressed and sintered parts can be repressed to increase their density and mechanical properties, or just sized to reduce their dimensional variations. Figure 43 illustrates repressing for 316L stainless steel. The latter is commonly done with bronze bearings to eliminate so-called hourglassing distortion.

**Fig. 43** Effect of repressing pressure on porosity of 316L stainless steel parts pressed from 4 to 8 tonnes/cm<sup>2</sup> and presintered for 15 min at 1050 °C (1920 °F). Source: Ref 10

**Machining.** Powder metallurgy can be machined to add features not possible with uniaxial pressing, that is, threads, undercuts, and horizontal holes, or to improve dimensions and surface roughness. The presence of pores reduces the heat conductivity of a part leading to heat erosion; it also causes interrupted cutting, which imposes cyclic stresses on the tool, thereby reducing its fatigue life. Copper infiltration and resin impregnation are used successfully for improving the machinability of porous P/M parts.

Powder metallurgy parts requiring machining are often pressed with machinability enhancing additives, such as MnS, MoS<sub>2</sub>, Pb, Te, and Sn.

**Surface Treatments.** Examples of surface treatments used for P/M parts include deburring, plating, polishing, sealing, and shot peening.

Dry or wet tumbling or vibrating P/M parts with or without an abrasive medium removes their surface flashes and burrs that were formed in the pressing operation. Cleaning or washing is often combined with deburring to remove surface contaminants.

Powder metallurgy parts with densities above 83% can be mechanically plated in a tumbling barrel using glass beads, water, and the metal plating powder. Parts with densities above approximately 94% can be electroplated. In lower density parts the pores are closed by impregnation or, if applicable, through burnishing, buffing, or steam treating.

Shot peening is used to improve the fatigue life of P/M parts. The repeated impacts of small diameter shot generate cold worked surfaces with compressive residual stresses.

# Principles and Procedures of Fractography

## Introduction

FRACTOGRAPHY is the term coined in 1944 to describe the science of studying fracture surfaces, although fractures and fracture surfaces had been examined and studied for centuries as part of the science of metallurgy. The two chief metallurgical benefits of fractography are that it is a useful tool in failure analysis and it provides a means of correlating the influence of microstructure on the fracture mode of the material.

Study of the characteristics of fracture surfaces by optical (light-microscope) fractography is widely practiced, particularly when a low magnification of the fracture surface is adequate. This study can be accomplished with relatively simple equipment by personnel with moderate training.

## Preparation and Preservation of Fracture Specimens

FRACTURE SURFACES are fragile and subject to mechanical and environmental damage that can destroy microstructural features. Consequently, fracture specimens must be carefully handled during all stages of analysis.

## Care and Handling of Fractures

Fracture interpretation is a function of the fracture surface condition. Because the fracture surface contains a wealth of information, it is important to understand the types of damage that can obscure or obliterate fracture features and obstruct interpretation. These types of damage are usually classified as chemical and mechanical damage. Chemical or mechanical damage of the fracture surface can occur during or after the fracture event. If damage occurs during the fracture event, very little can usually be done to minimize it. However, proper handling and care of fractures can minimize damage that can occur after the fracture.

**Chemical damage** of the fracture surface that occurs after the fracture event is the result of environmental conditions present after the fracture. Any environment that is aggressive to the base metal will cause the fracture surface to be chemically damaged. Humid air is considered to be aggressive to most iron-base alloys and will cause oxidation to occur on steel fracture surfaces in a brief period of time. Touching a fracture surface with the fingers will introduce moisture and salts that may chemically attack the fracture surface.

Chemical damage to a fracture can be prevented in a number of ways, and each laboratory has its preferred method. Because the identification of foreign material present on a fracture surface may be important in the overall interpretation of the cause of fracture, many laboratories prefer not to use corrosion-preventive coatings on fractures. If analysis of foreign material on the fracture surface will not be required (for example, in analysis of laboratory-produced fractures), a satisfactory method of preserving the fracture and preventing it from corroding is to apply a coating. When in the field, the fracture can be coated with oil or a good grade of fresh axle grease.

**Mechanical damage** may arise from several sources, including simply permitting the fracture surface to strike other objects. This can occur during the fracture event (as is often observed in fatigue failures) or in removing a fractured piece from its surroundings or transporting it from one place to another. There is also a tendency for people to put the mating halves of the fracture together; this should be avoided, particularly in view of the microscopic features examined in microfractography. Subtle fracture-surface details are easily damaged.

## Cleaning of Metal Fractures

Numerous cleaning procedures have been developed, each suited for a particular metal or the preference of a particular laboratory. Most fractured parts that have undergone extensive exposure to corrosive environmental conditions will typically require some cleaning. The most common techniques for cleaning fracture surfaces, in order of increasing aggressiveness, are:

- Dry air blast or soft organic-fiber brush (artist's brush) cleaning
- Replica stripping
- Organic-solvent cleaning
- Water-base detergent cleaning assisted by ultrasonic agitation
- Cathodic cleaning
- Chemical-etch cleaning

The mildest, least aggressive cleaning procedure should be tried first, and the results should be monitored with a stereo binocular microscope. If residue is still left on the fracture surface, more aggressive cleaning procedures should be implemented in order of increasing aggressiveness.

Because identification of foreign material present on a fracture may be important, many laboratories examine the original fracture surface before and after cleaning. Wire brushes, grinding wheels, rust removing pastes, or similar methods should never be used for cleaning fracture surfaces.

## **Sectioning of Fractures**

It is frequently necessary to remove the portion containing a fracture from the total part (because the total part is to be repaired) or to reduce the size of the specimen to be examined to a size that is convenient to handle.

For large parts, a common method of specimen removal is flame cutting. The cutting must be done at a sufficient distance from the fracture so that the microstructure of the metal underlying the fracture surface is not altered by the heat of the flame and so that none of the molten metal from flame cutting is deposited on the fracture surface.

Saw cutting and cutoff-wheel cutting can be used for parts in a wide range of sizes. Dry cutting is preferable, because coolants may corrode the fracture or may wash away foreign matter from the fracture. A coolant may be required, however, if a dry cut cannot be made at a sufficient distance from the fracture to avoid heat damage.

Often the fracture can be sectioned by hand with a hacksaw. Temperature and corrosion can be kept to a minimum using this method.

## **Opening of Secondary Cracks**

When the primary fracture has been damaged or corroded to a degree that obscures information, it is desirable to open any secondary cracks to expose their fracture surfaces for examination and study. These cracks may provide more information than the primary fracture. If rather tightly closed, they may have been protected from corrosive conditions, and if they have existed for less time than the primary fracture, they may have corroded less. Also, primary cracks that have not propagated to total fracture may have to be opened.

In opening these types of cracks for examination, care must be exercised to prevent damage, primarily mechanical, to the fracture surface. This can usually be accomplished if opening is done such that the two faces of the fracture are moved in opposite directions, normal to the fracture plane. A saw cut can usually be made from the back of the fractured part to a point near the tip of the crack, using extreme care to avoid actually reaching the crack tip. This saw cut will reduce the amount of solid metal that must be broken. Final breaking of the specimen can be done by:

- Clamping the two sides of the fractured part in a tensile-testing machine, if the shape permits, and pulling
- Placing the specimen in a vise and bending one half away from the other half by striking it with a hammer in a way that will avoid damaging the crack surfaces
- Gripping the halves of the fracture in pliers or vise grips and bending or pulling them apart

## **Effect of Nondestructive Inspection**

Many of the so-called nondestructive inspection methods are not entirely nondestructive. The liquid penetrants used for crack detection may corrode fractures in some metals, and they certainly will deposit foreign compounds on the fracture surfaces--both of which could lead to misinterpretation of the nature of the fracture.

Even magnetic-particle inspection, which is often used to locate cracks in ferrous parts, may affect later examination. For example, arcing that may occur across tight cracks can affect their fracture surfaces.

## Photography of Fractured Parts and Fracture Surfaces

PHOTOGRAPHY of a fracture surface should be preceded by a detailed and thorough examination of the specimen in the as-received condition to determine which features are most important, which aspects are extraneous (such as dirt or postfracture mechanical damage), and whether special treatment of the surface will be required. This scrutiny should begin with unassisted visual examination, continue with inspection with a hand-held magnifier (and with a penlight if helpful), and perhaps include study with a low-power stereomicroscope. Observations made in these surveys should be recorded for future review and determination of the probable causes of fracture. A list should be made of the features deserving photography, with the magnification that will probably be required.

The next step should be general photography of the entire fractured part and of the broken pieces, to record their size and condition and to show how the fracture is related to the components of the part.

## Setups for Photography of Fractured Parts

If possible, it is preferable to bring the parts or assemblies into the laboratory for photographing, where factors such as lighting can be carefully controlled. For larger parts, background paper, which is available in white or in colors and in rolls of various widths, can be used to provide an uncluttered background.

A workable setup for photographing specimens and small parts is with a view camera mounted vertically on an enlarger (or equivalent) stand. The longest-focal-length lens that will conveniently give the desired magnification to fill the image area should be chosen. Simple basic setups that should be satisfactory for photographing specimens and most small parts are shown in Fig. 1.

**Fig. 1** Basic setups and lighting used to photograph fracture specimens and small parts. (a) General arrangement of camera, light source with diffuser, and specimen. Size and angle of the beam of light should be adjusted to give the best display of texture. A reflecting mirror or white card can be used to fill in shadows. (b) Placing the specimen on a raised glass plate will throw the shadow beyond the view range of the camera and provide a shadowless background. (c) If the magnification desired requires the close approach of the camera to the specimen, a horizontal light beam reflected by a small mirror positioned near the camera lens will provide

the proper angle of illumination.

## Cameras

The camera selected for photographing fractured parts and fracture surfaces should be the one that will do the best job for the major part of the work of the laboratory. There is no one ideal camera.

**Microscope Systems.** Low-magnification stereo and monocular microscopes with attached cameras are suitable for photography of fracture surfaces. In general, these types of microscopes will cover a much smaller field than is obtainable with the single photographic objective lens. Some systems permit the eyepiece on the microscope to be removed to increase the size of the field.

Whereas view camera systems have practical magnification limits of 15 to 20 diameters, much higher magnifications can be obtained with a microscope, the magnification being limited primarily by the diminishing depth of field at higher powers.

## Lighting Techniques

For indoor photography, the usual technique for illumination of a part is to place one light to one side of and above the camera to light the part at a  $45^\circ$  angle, and a second light to the other side, at about camera level, as a fill light. At times, a third light is placed slightly behind the part for backlighting.

Lighting is very critical in photography. The specimen should be placed on a background which will not detract from the resolution of the fracture surface. For basic lighting, one spotlight is suggested. The light is then raised or lowered, and the beam adjusted from flood to spot, to find the quality of lighting desired. Generally, the flatter the fracture surface, the lower the light should be. The effects of the angle of lighting are illustrated in Fig. 2. The angle of the incident light is much more important than its intensity.

**Fig. 2** Light fractographs showing effect of angle of incident light in delineating texture of a fracture surface of an unnotched laboratory tensile-test specimen of 4340 steel. The microstructure was tempered martensite. As the angle of illumination approaches  $90^\circ$ , the surface becomes featureless. The precise optimum angle of obliquity depends on the nature of the fracture markings.  $7\times$

A spotlight beam without a diffuser, or a bare bulb with a small filament, will provide high-contrast lighting. If desired, the light can be diffused by placing a piece of tracing paper between the light source and the specimen.

## Film

There are a number of film types that have been used with macrophotographic large-format view cameras, both the traditional wet processed films and instant (Polaroid, Polaroid Corporation, Cambridge, MA) films. Today, increased use is being made of digital, "filmless" photography, and this trend is expected to increase. Historically, wet-processed black and white and color films have been used to document fractures and other failed components. Their advantages are ease of reproduction, highest quality of images, and a wide selection of film types and formats. Their disadvantage centers

around the need for a darkroom (practical only for large companies) or a commercial laboratory to process the film and make prints. This is labor-intensive but does produce the highest quality images.

Traditional wet-processed panchromatic films, available through a number of sources, such as the Eastman Kodak Co. (Rochester, NY) are available in a vast range of types, formats, and sizes. Black and white films that are particularly well suited for macrophotography include, but are not limited to: Kodak EKTAPAN (ISO 100, daylight or tungsten, very fine grain,  $4 \times 5$ ,  $5 \times 7$ , or  $8 \times 10$  in. negatives), PLUS-X Pan Professional film (ISO 125, extremely fine grained,  $4 \times 5$ ,  $5 \times 7$ , and  $8 \times 10$  in. negatives), T-MAX 100 Professional film (ISO 100, extremely fine grained,  $4 \times 5$ ,  $5 \times 7$ ,  $8 \times 10$ , and  $11 \times 14$  in. negatives), and TRI-X Pan Professional film (ISO 320, fine grained,  $2.25 \times 3.25$ ,  $4 \times 5$ ,  $5 \times 7$ , and  $8 \times 10$  in. negatives). Many of these films are also available in 35 mm format, which is frequently used in photomacrography.

Since the 1960s, Polaroid instant films have become widely used in metallographic laboratories due chiefly to the increased speed of obtaining prints and the reduction in manpower to produce them. Today, there are a host of panchromatic film sizes and types available. Most commonly, metallographers use  $4 \times 5$  in. sheet or pack films. Other common sizes are  $3.25 \times 4.25$  in. and  $8 \times 10$  in. Type 52, a fine-grained black and white print film that must be coated, is the most commonly used  $4 \times 5$  in. sheet film. Its ISO speed is 400, and it has a good contrast range. However, if multiple prints are required, additional prints must be made. Only with type 55 is a negative produced. This film has an ISO speed of 50, and it is fine grained with a wide contrast range. Type 52 can be obtained in film packs, as type 552, also at 400 ISO. There is a similar coaterless  $4 \times 5$  in. film available as type 53 in individual sheets or as type 553 in film packs. It has an ISO speed of 800, and the images are nearly as good as with types 52 or 55 films. There are also higher speed black and white films that are used mainly in low-light-level situations. These are types 57 ( $4 \times 5$  in. sheet) and type 667 ( $3.25 \times 4.25$  in. film packs) with an ISO speed of 3000. Neither require coating.

Any copies made photographically should be made at the aperture providing the best resolution at  $1\times$ . The setting will typically be  $i/22$ . Original exposures using Polaroid type 55 P-N (50 ISO film speed) will be eight times longer than with type 52 but will produce a high-quality negative. For an optimum-quality negative, the exposure giving the best quality Polaroid print should be doubled. The 55 P-N negative material has finer grain and higher resolution than the 125 ISO speed black and white film commonly used in 35 mm cameras.

For color work, which is sometimes required to document colored features on fractures or other specimens (e.g., corrosion products), there are a variety of wet-processed color films in a variety of formats. Both color negative films and color reversal films are available, the former are more popular for macrophotography. Popular color negative films for macrophotography include, but are not limited to: Kodak Pro 100 film (ISO 100, fine grained,  $4 \times 5$  and  $8 \times 10$  in. negatives), Pro 100T film (ISO 100, 64, or 40 (depending upon exposure time), tungsten balanced, fine grained,  $4 \times 5$ ,  $5 \times 7$ , and  $8 \times 10$  in. negatives), and VERICOLOR III Professional film (ISO 160, daylight or flash,  $4 \times 5$ ,  $5 \times 7$ , and  $8 \times 10$  in. negatives). There is a similar line of film products in the Ektachrome line (Eastman Kodak Co., Rochester, NY) that uses the E-6 process rather than the C-41 process. Also, most of these films are available in the 35 mm format.

In the instant film category, a number of color films are used regularly. Polacolor 64T (tungsten) is available in both  $4 \times 5$  in. individual sheets and as  $3.25 \times 4.25$  in. film packs. The film is balanced to use with tungsten lamps (3000 K), which are often used for indoor lighting and with metallographs. This film handles reciprocity losses very well. The other films are balanced for daylight and include types 59 ( $4 \times 5$  in. sheets, ISO 80), type 559 ( $4 \times 5$  in. film pack, ISO 80), type 669 ( $3.25 \times 4.25$  in. film packs, ISO 80), and type 809 ( $8 \times 10$  in. sheets, ISO 80). A comprehensive treatment of film selection, light filtration, processing, and printing is provided in ASTM E 883 ("Standard Practice for Reflected-Light Photomicrography").

Digital photography requires a suitable camera, generally a charge-coupled device (CCO) type, either color or black and white (the latter has better resolution as a function of cost), a computer and frame grabber (unless a digital camera is used), appropriate software and storage devices, and a suitable printer. This approach has many merits, such as ease of storage and retrieval of images, flexibility in image size, ease of reproducing images, ability to annotate images with text and arrows, and elimination of cutting and gluing prints into reports. Digital photography is not necessarily faster than instant photography, and the initial equipment cost is not trivial. For laboratories that do considerable photomacrography, however, this approach has many virtues. On the down side, it is expensive to keep systems technologically up to date, the cost of a high-quality printer is substantial, and the cost per print (for high-quality prints) can vary substantially depending upon the paper required by the printer. A number of metallographic supply houses now offer turnkey systems for digital photomacrography and photomicroscopy.

## Stereo Views

Stereo-pair photographs of fracture surfaces provide a means of viewing the fracture contours in simulated three dimensions. The basic technique for preparing such photographs entails taking two pictures of a subject area, the second from an angle slightly different from the first. The photographs are then examined under a visual condition in which, for example, the viewer's left eye focuses on the first picture and his right eye focuses on the second. Stereo viewers are available, and in most cases are necessary, to ease the task of viewing stereo pairs. The effect is to convince the brain that the eyes are indeed seeing a three-dimensional scene. If the angular displacement between the two pictures is appropriate (an included angle of  $12^\circ$  or  $14^\circ$  is desirable), the illusion is very vivid.

Stereo images by light microscopy have been used only to a limited extent because of the restricted depth of field. They provide a useful means of studying fractures at magnifications generally not greater than  $200\times$ .

Stereo-pair photographs can be taken using a single-lens camera, if it is provided with a mount that will pivot about a horizontal axis through the subject. After the subject is properly aligned beneath the camera with the mount vertical, the camera is swung to an angle of  $6^\circ$  to  $7^\circ$  from vertical and an exposure is made. The second exposure is made with the camera at the same angle as for the first exposure, but swung to the other side of the vertical, or zero, position.

With the stereomicroscope shown in Fig. 3, it is possible to observe the voids that are a part of ductile dimpled fracture, and, in brittle fractures, cleavage facets and some of the river marks can be discerned. It is most useful for preliminary examination of fracture surfaces, leaving final documentation of fine details for scanning electron microscopy.

**Fig. 3** Optical stereomicroscope with camera box partly removed for direct viewing. The light source is two 40 watt incandescent tubes above the specimen.

An example of a light-microscope stereo pair is shown in Fig. 4. The subject is a fracture surface in a low-carbon steel casting that cracked along prior austenite grain boundaries during a straightening operation. The bold relief contours of the columnar fracture are evident when viewed in stereo.

**Fig. 4** Stereo view of a fracture surface of cast experimental low-carbon steel. The smooth columnar contours in the lower portions of the photographs were the result of cracking along prior austenite grain boundaries during straightening. The upper portions of the photographs also show intergranular fracture, but along ferrite grain junctions, produced by impact in the laboratory to expose the original crack surface. Light fractograph (stereo pair). 3×

If a tool such as a parallax bar is used, quantitative measurements of topographic depths and elevations can be obtained.

### **Fractographic Features Revealed by Light Microscopy**

THE MACROSCOPIC APPEARANCE of a fracture surface has often been used to appraise the degree of ductility and of toughness present in a metal. According to the concepts of fracture mechanics, toughness is the critical material property associated with overload or rapid fracture. The fracture surface contains vestigial marks that indicate the amounts of high-energy (ductile, or tough) and low-energy (brittle) crack extension that produced the fracture.

### **Tensile-Fracture Surface Marks in Unnotched Specimens**

Tensile-fracture surface marks have been classified into three zones by configuration: the fibrous zone, the radial zone, and the shear-lip zone. This shear-lip zone is the highest-energy portion of the fracture. The relative amount of shear lip provides an indicator of the toughness of the material. The three zones are shown in Fig. 5. Fractures consisting solely of one zone occur only under conditions of extreme ductility or brittleness.

**Fig. 5** Tensile-fracture surface marks. (a) Schematic representation of zones within a typical tensile fracture of an unnotched cylindrical specimen. The surfaces of the fibrous and radial zones are usually normal to the tensile axis, as shown. The shear-lip surface is always at about  $45^\circ$  to the tensile axis. (b) Fracture surface of a 4340 steel tensile specimen showing fibrous zone (A), radial zone (B), and shear lip (C).  $3\times$

## Fatigue Marks

The formation of cracks under conditions of repeated or cyclic stress has been denoted as fatigue cracking. Zones of crack propagation on fatigue fractures exhibit several types of surface marks, such as beach marks, striations, and ratchet marks.

**Beach Marks.** The term "beach mark" describes the macroscopic features present on the fracture surface as illustrated in Fig. 6. Beach marks indicate a local region of variation in crack-growth rate. Such beach marks may, but do not always, indicate fatigue as the mode of cracking. Stress-corrosion fractures may also show beach marks.

**Fig. 6** Fatigue-fracture surface of an AISI 1050 shaft (35 HRC) subjected to rotating bending. Numerous ratchet marks (small shiny areas at surface) indicate that fatigue cracks were initiated at many locations along a sharp snap-ring groove. The eccentric pattern of oval beachmarks indicates that the load on the shaft was not balanced. The final rupture area is near the left (low stress) side, where there may have been no fatigue action.

The presence of beach marks is fortuitous, at least for the investigator, because beach marks permit the origin to be easily determined and provide the analyst with other information concerning the manner of loading, the relative magnitude of the stresses, and the importance of stress concentration (see Fig. 6).

**Striations.** The term "striation" refers to a "line" on the fracture surface indicating the position of a crack front after an increment of crack propagation has occurred. Each increment of propagation is due to a cycle of stress, i.e., a cyclic load. The distance between striations indicates the advance of the crack front during each succeeding cycle. Fatigue striations are not readily resolvable with the light microscope and are best viewed using a scanning electron microscope (see the section "Interpretation of Scanning-Electron Microscope Fractographs" ).

**Ratchet marks** are macroscopic features that may be seen on fatigue fractures in shafts and flat leaf springs, and they may also occur in ductile fractures in overtorqued fasteners. In fatigue fractures, ratchet marks are the result of multiple fatigue-crack origins, each producing a separate fatigue-crack zone (Fig. 6). As two approaching cracks meet, a small step is formed. The small steps are the ratchet marks.

Although ratchet marks are most apparent on the peripheries of fractures in shafts, the stepped appearance is characteristic whenever fatigue cracks emanate from several origins and subsequently meet to form one principal crack front.

## Discontinuities

Fractures originate from a broad variety of discontinuities within the metal structure, such as laps and seams from primary metal forming, shrinkage and gas cavities in cast structures, hot tears, inclusions, segregation of impurities, and imperfections in welds. Many of these features are illustrated in the section "Discontinuities Leading to Fracture" in the article "Use of Fractography for Failure Analysis."

## Interpretation of Optical Fractographs

A RUDIMENTARY KNOWLEDGE of how to "read" a fracture surface must be gained so that meaningful fractographs can be taken from which to describe the fracture process. Fractography can provide information about the conditions of stress, the effects of temperature and chemical environment, and the origin of the fracture and how the crack progressed to final rupture.

## States of Stress

Information regarding the stresses that caused a fracture can be learned from a casual examination of the fractured part.

In many types of fracture, the general plane of fracture is perpendicular to the maximum principal tensile stress. These types, called group I fractures in the following discussion, include cleavage and other brittle fractures, ductile fractures (also called microvoid coalescence and dimpled rupture) under plane-strain conditions (in thick sections), fatigue fractures (at least in the intermediate stages), and stress-corrosion cracks.

Other types of fracture propagate along planes of maximum shear stress. These types, called group II fractures here, include ductile fractures under plane stress (that is, in thin sections or near free surfaces), shear fractures, and the very early stages of fatigue fractures in pure or relatively impurity-free metals. In a ductile material, the shear stresses cause considerable deformation prior to fracture, although the deformation is not always obvious because the shape of the part is not changed except for flow on the surface. Figure 7(a) is a photograph showing deformation in a fractured shaft. Torsional single-overload fractures (group II) of a ductile material usually occur on the transverse shear plane, straight across the cylinder, and exhibit a telltale swirled appearance (Fig. 7b). The final-fracture area will be at the center of the bar. A brittle material in pure torsion will fracture in a plane perpendicular to the tensile-stress component, which is 45° to

the specimen axis (group I fracture). A spiral-type fracture is one characteristic of this type of loading and material and can be demonstrated by twisting a piece of chalk to fracture (Fig. 8). The elastic-stress distribution in pure torsion is maximum at the surface and zero at the center. Thus, fracture normally originates at the highest-stressed region (the surface) in pure torsion. Longitudinal torsional fractures are sometimes observed (for example, Fig. 9) because longitudinal planes have the same magnitude of shear stress as transverse planes, and longitudinal planes usually have lower toughness, due to the shape and distribution of inclusions.

**Fig. 7** Splined shaft of 6118 steel that fractured from a single torsional overload. (a) Photograph ( $\sim 2\times$ ) of the shaft showing the deformation of the splines in the region of fracture, which would not occur if the fracture were caused by fatigue. The shaft, 28 mm ( $1\frac{3}{32}$  in.) in diameter, was made of 6118 steel and had a hardness of 23 HRC. Being made of a ductile metal, it was twisted in pure torsion with a single overload, yielding the fracture on the transverse shear plane shown in (b). (b) Fracture surface of the shaft, showing the rotary deformation characteristic of a single-torsion-overload fracture in a ductile metal. If there is a combined bending component, the region of final, fast fracture will be offset from the center of the section. This type of fracture should not be confused with one resulting from rotating-bending fatigue, which does not have the gross distortion seen here. Light fractograph.  $2\times$

**Fig. 8** Torsional brittle fracture of chalk. Fracture follows the  $45^\circ$  direction of maximum tensile stress.

**Fig. 9** A torsional-fatigue fracture in an induction-hardened 1037 steel shaft 25 mm (1 in.) in diameter that finally fractured in longitudinal shear. No clear point of origin is visible because the surfaces rubbed as the crack propagated. Light fractograph.  $\sim 0.95\times$

## Crack Origins

An interest in the exact location of the point of origin of a fracture derives from the importance of determining what initiated the fracture. The initial examination of a fracture is concerned with the recognition of all features that may point to the crack origin.

**Gross Aspects of Fractures.** Some indications of crack-propagation direction can be seen by examination of the gross aspects of a broken part. They relate to the order in which events occurred, sometimes called "fracture sequencing." The fragments of a fractured structure can be reassembled in approximate juxtaposition, without allowing the fracture surfaces to touch, and then the telltale indications should be sought.

First, a fast-running crack in sheet or plate will frequently branch as it propagates but will almost never join another crack to continue as a single crack. Second, if a running crack joins a pre-existing fracture, it will usually meet it at approximately a  $90^\circ$  angle, not at a shallow angle. Third, it is almost impossible for an intersecting crack to cross and propagate beyond a pre-existing fracture. These considerations lead to the following useful guidelines concerning crack origins:

- The direction to the crack origin is always opposite to that of crack branching, as shown in Fig. 10.
- If a crack meets another at about  $90^\circ$ , it occurred later and the origin should not be sought in it but in the earlier crack. This is known as the T-junction method of crack-origin location (Fig. 11).

**Fig. 10** Schematic representation of the information conveyed by crack branching with regard to the location of the crack origin

**Fig. 11** Schematic representation of the T-junction method of determining which fracture surface to search to locate the crack origin. Because B does not cross A but meets it at about  $90^\circ$ , B occurred later and cannot contain the crack origin.

The initial section of fracture (containing the crack origin) transfers its original load to adjoining sections, in all probability overstressing them. If these sections do not contain imperfections, succeeding fractures (assuming a normally ductile material) will be preceded by a certain amount of plastic deformation.

Fibrous marks, tear ridges, and beach marks can also indicate the location of a crack origin. Chevron markings also can be used. Where the curvature of such marks is slight, the origin is generally on the concave side of the crack-front curve.

In general, the region of crack initiation will be flat and will lack any free-surface shear-lip zone. The shear-lip zone appears only at some distance from the origin and becomes larger as the distance increases (see Fig. 12).

**Fig. 12** Fracture in a welded pressure vessel of 4340 steel displaying a flat origin at the top with a shear lip beginning on either side of it. The shear lip increases in width with increasing distance from the origin. The radial marks below the origin and the chevron patterns to the left and right also indicate the directions of fracture. Light fractograph. 6×

**Location of Origins in Impact-Overload Fractures.** Figure 13 shows the fracture of a 12% Cr steel bar that was notched and then struck with a hammer. Two blows were necessary to complete the fracture. The fracture marks are radial. They may be traced downward to a common intersection. Also present are crack arrests, one at A and a second at B, where fracture progress came to a complete halt before the second blow was struck. The arrest marks are parallel to the crack front, and lines drawn normal to them should intersect at or near the origin. The contours of the final fracture marks, at C and D, also point to the general location of the beginning of fracture.

**Fig. 13** Locating the origin in an impact fracture, produced by two hammer blows, in a notched bar of 12% Cr steel. Fracture origin can be found in three ways: by tracing the radial marks in the lower portion of the fracture to their point of convergence (the arrows on the curved lines indicate the direction of crack propagation); by drawing normals to the crack-arrest fronts labeled A and B; and by projecting the tangents to the final radial marks at C and D toward the bottom. The crack came to a full stop at B with the first hammer blow and resumed motion at the second hammer blow. Light fractograph. 3×

## Fracture Progress

Many types of fractures, including most service fractures, occur by a sequence involving crack initiation, subcritical crack propagation (due to ductile crack extension, fatigue, corrosion fatigue, stress-corrosion cracking or hydrogen embrittlement), and fast fracture, which occurs when the remaining cross section can no longer support the applied load. The fracture processes leave telltale marks on the fracture surfaces, which enable a trained investigator to locate the initiation sites, to discern the propagation direction and crack-front shape, and to distinguish the fast-fracture zone. This information can lead to an understanding of the stress levels and conditions leading to fracture

## Fracture Changes During Crack Propagation

Several influences may affect the growth of a crack, causing it to progress thereafter by a mechanism of fracture different from that in effect when cracking started. These influences include local differences in microstructure; changes in stress-intensity factor,  $K$ ; changes in chemical or thermal environment; differences in stress state.

**Changes Caused by Local Differences in Structure.** Microstructure exerts a pronounced influence on local fracture appearance. The presence of two or more types of microstructure may result in different fracture mechanisms being involved and a different fracture appearance. A simple example is a fracture in a chilled white iron part. Fracture is by cleavage through the chilled zone and is fibrous in the pearlitic zone.

Another structure difference is that of case and core in carburized, flame-hardened, and induction-hardened parts. The difference in properties between such structures can cause a crack to proceed by quite different fracture mechanisms in adjacent regions.

**Changes Caused by Altered Environments.** A fracture-mechanism change as a result of different chemical and stress environmental conditions is shown in Fig. 14. A corrodent generated small pits below a layer of chromium plate and provided the environment for the growth of stress-corrosion cracks, which originated at the pits. The stress may have been residual or applied. As the stress-corrosion cracks grew, the stress intensity at the crack tip increased for the applied cyclic loads. At some critical level of environment and cyclic-stress intensity, the fracture mechanism changed to one of fatigue. The fatigue cracks propagated until the critical crack-tip stress-intensity values were reached, and then unstable fracture occurred in an essentially ductile manner.

**Fig. 14** Changes in fracture mechanism and appearance that were caused by changes in chemical and stress environment for a chromium-plated aluminum alloy 7079-T6 forging. Small corrosion pits formed beneath the layer of chromium plate, as at A, and generated stress-corrosion cracks B. Growth of these cracks altered the stress intensity at the crack tips, leading to propagation of fatigue cracks C. Final, fast fracture D occurred when the critical crack-tip stress-intensity value was reached. Light fractograph.  $5.7\times$

## Interpretation of Scanning-Electron Microscope Fractographs

AT LOW MAGNIFICATIONS, the features in scanning electron microscope (SEM) fractographs strongly resemble the aspects of the fracture apparent to the naked eye; but at high magnifications, more detail is visible which needs to be categorized and interpreted if the fractograph is to be related to the micromechanisms of fracture that were active.

It is important to realize that microscopic features of fractures ordinarily differ widely within a small area. The principal categories of fracture features (or fracture modes) are as follows:

- Cleavage features (tongues, microtwins, and location of cleavage-crack origins)
- Quasicleavage features
- Dimples from microvoid coalescence
- Tear ridges
- Fatigue striations

- Separated-grain facets (intergranular fracture)
- Mixed fracture features, including binary combinations of cleavage features, dimples, tears, fatigue striations, and intergranular-fracture features
- Features of fractures resulting from chemical and thermal environments

## Transgranular Cleavage Features

In cleavage fracture, the fracture path follows a transgranular plane that is usually a well-defined crystallographic plane. This plane of fracture is one of the  $\{100\}$  planes in most body-centered-cubic metals. Cleavage fracture is produced, usually at low temperature, under a condition of high triaxial stress--that is, at the root of a notch--or at a high deformation rate, as, for example, by impact loading, or as a result of environmental factors.

Figure 15 provides three views, at increasing magnification, of an area in an impact fracture exhibiting features that are typical of cleavage. It is apparent that the fracture plane changes orientation from grain to grain. As a result, the average grain size can be measured on the fractograph and related to grain-size measurements on a metallographic section. The change of orientation from grain to grain leads to a branching of the crack along different planes and to a very chaotic overall appearance of the fracture surface. At higher magnification, many features typical of cleavage can be identified. In Fig. 15(b), the evidence of change in orientation between grain A and grain B is particularly clear because of the river patterns that begin in grain B at the interface. The river patterns, which represent steps between different local cleavage facets of the same general cleavage plane, are well defined.

**Fig. 15** Cleavage fracture in a notched impact specimen of hot-rolled 1040 steel broken at  $-196^{\circ}\text{C}$  ( $-321^{\circ}\text{F}$ ), shown at three magnifications. The specimen was tilted in the scanning electron microscope at an angle of  $40^{\circ}$  to the electron beam. The cleavage planes followed by the crack show various alignments, as influenced by the orientations of the individual grains. Grain A, at the center in fractograph (a), shows two sets of tongues (see arrowheads in fractograph b) as the result of local cleavage along the  $\{112\}$  planes of microtwins created by plastic deformation at the tip of the main crack on  $\{100\}$  planes. Grain B and many other facets show the cleavage steps of river patterns. The junctions of the steps point in the direction of crack propagation from grain A through grain B, at an angle of about  $22^{\circ}$  to the horizontal plane. The details of these forks are clear in fractograph (c).

## Quasicleavage Features

In steels that have been quenched to form martensite and then tempered to precipitate a fine network of carbide particles, the size and orientation of the available cleavage planes within a grain of prior austenite may be poorly defined. True cleavage planes have been replaced by smaller, ill-defined cleavage facets, which usually are initiated at carbide particles or large inclusions. The small cleavage facets have been referred to as quasicleavage planes, because, although they look like cleavage planes with river patterns radiating from the initiation sites, until recently they have not been clearly identified as crystallographic planes. Quasicleavage features tend to be more rounded, indicating a somewhat higher energy absorption than that of true cleavage.

Quasicleavage facets on a fracture surface of a quenched and tempered 4340 steel specimen broken by impact at  $-196^{\circ}\text{C}$  ( $-321^{\circ}\text{F}$ ) are shown in Fig. 16. The poorly defined cleavage facets are connected by tear ridges and shallow dimples.

**Fig. 16** Quasicleavage in the surface of an impact fracture in a specimen of 4340 steel. The same area is shown in both fractographs, but at different magnifications. The small cleavage facets in martensite platelets contain river patterns and are separated by tear ridges. Shallow dimples, marked by arrowheads, are also visible. Direction of crack propagation is from bottom to top in each fractograph. The specimen was heat treated for 1 h at 843 °C (1550 °F), oil quenched, and tempered for 1 h at 427 °C (800 °F). Fracture was by Charpy impact at -196 °C (-321 °F).

Quasicleavage, or cleavage in complex microstructures, is more difficult to identify than the cleavage found in low-carbon steel made up of ferrite and pearlite. When identification is uncertain, it is essential to relate the fracture features to the microstructure, including the prior austenite grain size, the martensite plate size, and the distribution, size, spacing, and volume fraction of fine carbide particles precipitated during tempering.

### Dimples Formed by Microvoid Coalescence

If the temperature of fracture is raised from very low (for example, liquid-nitrogen temperature) to higher levels, the fracture mechanism changes from brittle or cleavage fracture to ductile fracture by microvoid initiation, growth, and coalescence. At low magnification, the fracture surface may exhibit both fibrous and cleavage regions. Fibrous regions are usually observed near the free surface in a shear-lip zone or at the origin of fracture at the center of a smooth (unnotched) tensile specimen. Cleavage regions are typically observed in the surfaces of flat, plane-strain fractures and in regions of high crack velocity. However, at high magnification, the fibrous-fracture region, and also the cleavage region, may show successive fracture mechanisms--that is, the fracture features may include both cleavage facets and dimples. Both dimples and cleavage facets are visible in the Charpy impact fracture shown in Fig. 17. An overall view of the region of transition between ductile and cleavage fracture is shown in Fig. 17(a). The upper portion of the fracture surface in this view is a result of cleavage, and the lower portion is a result of fracture by microvoid coalescence. The cleavage facets in Fig. 17(a) and 17(b) are at a considerable distance from the notch, which is below the region shown in the fractograph. In the intermediate-magnification view of the region of microvoid coalescence (Fig. 17c), facet A cannot be positively identified as a cleavage-fracture feature; it could be the result of a fracture along a grain boundary, or even possibly a microvoid surface that has stretched. Around this facet is a region of ductile fracture, which originated at the interface between the matrix and a carbide particle (in the deep dimple).

**Fig. 17** Dimples and cleavage facets exhibited in three aspects of a Charpy impact fracture at room temperature in a specimen of hot-rolled 1040 steel, tilted in the scanning electron microscope at an angle of

30° to the electron beam. The machined notch of the specimen was below the region shown in (a). The overall direction of crack propagation was upward. Although equiaxed dimples pre-dominate, certain grain orientations near the top of (a) were unfavorable for ductile fracture by microvoid coalescence and local cleavage occurred, as shown in detail in (b), which is a higher-magnification view of the outlined area in (a). Fractograph (c), a higher-magnification view of the region at the center of (a), shows a deep dimple, which initiated the local ductile fracture immediately surrounding it. The smooth surface at A shows no river patterns and should not be identified as a cleavage facet; it could be a grain-boundary surface, or perhaps a region of stretching.

## Tearing

Tearing designates a mechanism of local fracture that is often found at a discontinuity in the crack advance by another fracture mechanism. It occurs when small regions or ligaments fracture by plastic flow or necking. Tearing is frequently observed when small unbroken areas remain behind the main crack front. The occurrence of tearing is accompanied by the formation of tear ridges, which are typically sharp and thus produce bright contrast in the SEM image. Tearing may also produce flat-topped, featureless areas having some of the characteristics of local glide-plane decohesion, similar to facet A in Fig. 17(c).

## Fatigue Striations

The advantages offered by the use of the SEM include:

- Easier identification and evaluation of the origin of the fatigue fracture, whether near a free surface, at an edge, or at the bottom of a notch or a groove
- Better differentiation between stages I and II of fatigue-fracture progress by viewing the overall fracture at low magnification not obtainable with a transmission electron microscope
- Estimates of crack-growth rates, which are used in fracture mechanics evaluation of loads or for estimation of total number of cycles to failure
- Simpler quantitative analysis of fracture surfaces to determine which portions of fracture surfaces resulted from microvoid coalescence, from intergranular separation, and from cleavage fracture.

The main disadvantage of scanning electron microscopy for the investigation of fatigue fractures is that fatigue striations are not as sharply defined as with transmission electron microscopy. This lack of resolution occurs because a striation represents only a small surface displacement, which often fades out in the electron image. By shadowing the fracture surface with a gold-palladium film 10 nm (0.4  $\mu$ in.) thick, it is possible to enhance striation contrast markedly. Striation spacings as small as 25 nm (1.0  $\mu$ in.) have been measured in aluminum alloys with the SEM. With scanning electron microscopes that have resolutions better than 10 nm, spacings as small as 10 nm can be resolved.

It is desirable to reveal as much as possible of the surface details within all secondary cracks associated with fatigue-crack branching. This can best be achieved with the specimen oriented with the crack-propagation direction pointing toward the secondary-electron collector to gain maximum penetration of the primary electron beam into the depth of the secondary cracks.

The SEM fractographs in Fig. 18 and 19 show some of the characteristic features of fatigue-fracture surfaces.

**Fig. 18** Transition from stage I to stage II of a fatigue fracture in a coarse-grain specimen of aluminum alloy 2024-T3. The transition from stage I (upper left) to stage II is well defined. The presence of (Fe,Si)-rich inclusions did not affect the fracture path markedly. The inclusions, which were fractured, range from 5 to 25  $\mu$ m (200 to 1000  $\mu$ in.) in diameter. The stage II area shows a large number of approximately parallel fatigue patches containing very fine fatigue striations that are not resolved at this magnification.

**Fig. 19** Fatigue fracture in type 304 stainless steel tested at room temperature. The vertical secondary cracks in (a) are grain-boundary separations. The well-defined striations in (b) resulted from the planar slip characteristic of stainless steels.

## Intergranular Fracture

Intergranular fracture (or decohesive rupture) is simply described as grain-boundary separation. It can occur by catastrophic brittle separation, or by separation plus microvoid coalescence on the interfaces of grains. Such fractures are regarded as the result of a severe reduction in grain-boundary energy by a Gibbsian (thermodynamic) adsorption mechanism. In its simplest form, segregation of metallic or gas-metal impurities can alter the grain-boundary free energy. Furthermore, grain-boundary energy can vary over a temperature range, leading to brittle-ductile fracture transitions and thermally induced brittle or ductile fractures. Variations in segregation at grain boundaries can also lead to mixed mechanisms of fracture, characterized by the appearance of dimpled areas in an intergranular fracture. Intergranular brittle fracture in the absence of an aggressive environment may be the result of segregation of a thermally activated impurity, which allows the grains to separate along smooth interfacial planes. Typical examples of fractures involving grain-boundary segregation are shown for tungsten, iridium, and a tungsten-rhenium alloy in Fig. 20.

**Fig. 20** Intergranular brittle fractures in tungsten, iridium, and a tungsten-3 wt% rhenium alloy. (a) Sintered tungsten rod drawn to 1.5 mm (0.060 in.) diam, recrystallized for 100 h at  $10^{-6}$  torr and 2600 °C (4712 °F), and fractured in tension. (b) Iridium sheet annealed for 50 h in purified helium at 1700 °C (3092 °F) and broken by bending. (c) Tungsten-3 wt% rhenium alloy that was prepared in the same manner as the sintered tungsten rod in fractograph (a). Microvoids ("bubbles") at grain boundaries resulted from segregation of potassium (an impurity).

## Features Indicative of Mixed Mechanisms of Fracture

A fracture that occurs by operation of two or more intermingled mechanisms of fracture is generally labeled a "mixed-mode" fracture. This is not to be confused with the successive operation of different fracture mechanisms, which can be analyzed sequentially and therefore require no special discussion. The occurrence of fracture by mixed mechanisms often indicates that the usual factors that determine the operative mechanism, such as state of stress, loading history, microstructure, and environment, favor both mechanisms; and that the local fracture mechanism is determined by a combination of deviations in these factors and the influence of secondary variables, such as local grain orientation.

The reasons for mixed mechanisms of fracture are as diverse as the fractures in which they have been observed. However, it is useful to identify the individual fracture mechanisms that contribute to such mixtures and to establish the circumstances that can lead to their individual occurrence. These circumstances establish limits. The occurrence of mixed mechanisms of fracture usually indicates that interacting influences have caused the fracture to depart from either limiting mechanism.

Mixed fracture mechanisms can result from quite different causes, and caution must be exercised in inferring the cause of fracture from the fracture features alone.

## Features of Fractures Resulting from Chemical and Thermal Environments

For a specific metal or alloy, certain fracture mechanisms, such as cleavage, microvoid coalescence, fatigue, and intergranular separation, are often associated with particular environmental and stress states. The accumulation of experience with such fractures arising from known states of environment and stress makes it possible to ascertain, with the aid of fractography, the causes of fractures occurring under unknown service conditions. Some instances in which environment caused a specific fracture response that can be characterized through electron-microscope fractography are illustrated in Fig. 21 and 22.

Fig. 21 Intermingled cleavage facets and dimples in two views of a stress-corrosion fracture in a step-cooled two-phase Ti-6Al-2Sn-4Zr-6Mo alloy exposed to a  $3\frac{1}{2}\%$  NaCl aqueous solution. Cleavage facets formed in the alpha phase, and poorly developed dimples, such as at the sites marked A, formed in the beta phase.

Fig. 22 Intergranular fracture in copper alloy C71500 (copper nickel, 30%) that became embrittled by grain-boundary oxidation during extended exposure to high-temperature steam in a heat exchanger. Crack penetration (which was cyclic, as intergranular layers of oxide formed, broke and reformed) produced fine striations that could be mistaken for fatigue striations.

# Guide to Nondestructive Testing and Inspection Methods

## Introduction

NONDESTRUCTIVE TESTING (NDT) and inspection techniques commonly used to detect and evaluate flaws (irregularities or discontinuities) or leaks in engineering systems are reviewed in this Section. Of the many different NDT techniques used in industry, liquid penetrant and magnetic particle testing account for about one-half of all NDT, ultrasonics and x-ray methods about another third, eddy current testing about 10%, and all other methods for only about 2% (Ref 1). It should be noted that the techniques reviewed in this Section are by no means all of the NDT techniques utilized. They do represent, however, the most commonly employed methods. Table 1 is a simplified breakdown of the complexity and relative requirements of the five most frequently used NDT techniques. Table 2 compares common NDT methods. Additional information on the various types of NDT methods can be obtained from the American Society for

**Table 1 The relative uses and merits of various nondestructive testing methods**

	Test method				
	Ultrasonics	X-ray	Eddy current	Magnetic particle	Liquid penetrant
<b>Capital cost</b>	Medium to high	High	Low to medium	Medium	Low
<b>Consumable cost</b>	Very low	High	Low	Medium	Medium
<b>Time of results</b>	Immediate	Delayed	Immediate	Short delay	Short delay
<b>Effect of geometry</b>	Important	Important	Important	Not too important	Not too important
<b>Access problems</b>	Important	Important	Important	Important	Important
<b>Type of defect</b>	Internal	Most	External	External	Surface breaking
<b>Relative sensitivity</b>	High	Medium	High	Low	Low
<b>Formal record</b>	Expensive	Standard	Expensive	Unusual	Unusual
<b>Operator skill</b>	High	High	Medium	Low	Low
<b>Operator training</b>	Important	Important	Important	Important	
<b>Training needs</b>	High	High	Medium	Low	Low
<b>Portability of equipment</b>	High	Low	High to medium	High to medium	High
<b>Dependent on material composition</b>	Very	Quite	Very	Magnetic only	Little
<b>Ability to automate</b>	Good	Fair	Good	Fair	Fair
<b>Capabilities</b>	Thickness gaging; some composition testing	Thickness gaging	Thickness gaging; grade sorting	Defects only	Defects only

Source: Ref 1

**Table 2 Comparison of some nondestructive testing methods**

Method	Characteristics detected	Advantages	Limitations	Example of use
<b>Ultrasonics</b>	Changes in acoustic impedance caused by cracks, nonbonds, inclusions, or interfaces	Can penetrate thick materials; excellent for crack detection; can be automated	Normally requires coupling to material either by contact to surface or immersion in a fluid such as water. Surface needs to be smooth.	Adhesive assemblies for bond integrity; laminations; hydrogen cracking
<b>Radiography</b>	Changes in density from voids, inclusions, material variations; placement of internal parts	Can be used to inspect wide range of materials and thicknesses; versatile; film provides record of inspection	Radiation safety requires precautions; expensive; detection of cracks can be difficult unless perpendicular to x-ray film.	Pipeline welds for penetration, inclusions, and voids; internal defects in castings
<b>Visual optical</b>	Surface characteristics such as finish, scratches, cracks, or color; strain in transparent materials; corrosion	Often convenient; can be automated	Can be applied only to surfaces, through surface openings, or to transparent material	Paper, wood, or metal for surface finish and uniformity
<b>Eddy current</b>	Changes in electrical conductivity caused by material variations, cracks, voids, or inclusions	Readily automated; moderate cost	Limited to electrically conducting materials; limited penetration depth	Heat exchanger tubes for wall thinning and cracks
<b>Liquid penetrant</b>	Surface openings due to cracks, porosity, seams, or folds	Inexpensive, easy to use, readily portable, sensitive to small surface flaws	Flaw must be open to surface. Not useful on porous materials or rough surfaces	Turbine blades for surface cracks or porosity; grinding cracks
<b>Magnetic particles</b>	Leakage magnetic flux caused by surface or near-surface cracks, voids, inclusions, or material or geometry changes	Inexpensive or moderate cost, sensitive both to surface and near-surface flaws	Limited to ferromagnetic material; surface preparation and post-inspection demagnetization may be required	Railroad wheels for cracks; large castings

## Important Definitions

The terms "nondestructive testing," or NDT, and "nondestructive inspection," or NDI, are considered synonymous. They both refer to a process or procedure, such as ultrasonic or radiographic inspection, for determining the quality or characteristics of a material, part, or assembly, without permanently altering the subject or its properties. All NDT or NDI methods are used to find internal anomalies (flaws) in a structure without degrading its properties or impairing its serviceability. The term "flaw" is a general term that is used to imply any irregularity, imperfection, or discontinuity contained in a material, part, or assembly. A flaw that has been evaluated as rejectionable is usually termed a "defect." The quantitative analysis of NDT/NDI findings to determine whether the material, part, or assembly will be acceptable for its function, despite the presence of flaws, is called "nondestructive evaluation," or NDE. With NDE, a flaw can be classified by its size, shape, type, and location, allowing the investigator to determine whether or not the flaw(s) is acceptable. Damage tolerant design approaches are based on the philosophy of ensuring safe operation in the presence of flaws (Ref 2, 3).

## Uses of NDT

Although flaw detection is usually considered the most important aspect of NDT, there are also other important application areas for these methods. These include leak detection, metrology, structure or microstructure characterization, stress/strain response determination, and rapid identification of metals and alloys. Each of these is briefly described in the following paragraphs; references to direct the reader to more detailed information are also supplied.

**Leak Detection and Evaluation.** Because many objects must withstand pressure, the nondestructive determination of leakage is extremely important. The NDT area known as leak detection utilizes many techniques, as described in the article "Leak Testing" in this Section. Each technique has a specific range of applications, and a particular leak detection technique should be selected only after careful consideration.

**Metrology.** The measurement of dimensions, referred to as "metrology," is one of the most widely used NDT activities, although it is not considered with other conventional NDT activities, such as flaw detection. In recent years, conventional tools for metrology, such as micrometer calipers, vernier calipers, and dial gages, have been supplemented with modern high-technology metrology tools, such as laser inspection, coordinate measuring machines, and machine vision and robotic inspection systems (Ref 4, 5, 6).

The selection of a metrology system is highly dependent on the specific requirements of a given application. Standard reference works on the topic should be consulted for conventional metrology. In addition, other NDE methods, such as eddy current, ultrasonic, optical holography, and speckle metrology, often find application in the field of metrology.

**Structure or Microstructure Characterization.** Another interesting area of NDT is microstructural characterization, which can be done in situ without damaging the object by using replication microscopy. This is widely used to assess the condition of power plant and petrochemical metallic components on a large scale (Ref 7), or by using conventional optical microscopy techniques with portable equipment, including polishing, etching, and microscopic equipment. In addition, it is possible to characterize the microstructure through the correlation with some type of NDT information. For example, the transmission of ultrasonic energy has been correlated with the microstructure of gray cast iron.

Microstructure can often be characterized by determining physical or mechanical properties with NDT techniques because there is usually a correlation among microstructure, properties, and NDT response. Characterizing microstructure from NDT responses is a relatively recent area of NDT application, and new developments are occurring frequently.

**Stress/Strain and Dynamic Response Determination.** The local strain at a specific location in an object under a specific set of loading conditions can be determined by using strain sensing methods such as photoelastic coatings, brittle coatings, or strain gages (Ref 8). If the stress-strain behavior of the material is known, these strain values can be converted into stress values.

Residual stresses in materials can be nondestructively measured by a variety of methods, including x-ray diffraction (Ref 9), ultrasonics (Ref 10), and electromagnetics (Ref 11, 12). With the x-ray diffraction technique, the interatomic planar distance is measured, and the corresponding stress is calculated. The penetration depth of x-rays is of the order of only 10  $\mu\text{m}$  (400  $\mu\text{in.}$ ) in metals. Therefore, the technique is limited to measurements of surface stresses. Its use has been generally limited to the laboratory because of the lack of field-usable equipment and concern with radiation safety.

With ultrasonic techniques, the velocity of the ultrasonic waves in materials is measured and related to stress. These techniques rely on a small velocity change caused by the presence of stress, which is known as the acoustoelastic effect. In principle, ultrasonic techniques can be used to measure bulk as well as surface stresses. Because of the difficulty in differentiating stress effects from the effect of material texture, practical ultrasonic applications have not yet materialized.

With electromagnetic techniques, one or more of the magnetic properties of a material (such as permeability, magnetostriction, hysteresis, coercive force, or magnetic domain wall motion during magnetization) are sensed and correlated to stress. These techniques rely on the change in magnetic properties of the material caused by stress; this is known as the magnetoelastic effect. These techniques, therefore, apply only to ferromagnetic materials, such as steel.

**Rapid Identification of Metals and Alloys.** Quality assurance during the fabrication of hardware, subassemblies, and assemblies sometimes requires a reliable system of rapid identification of metals and alloys. Because various metals may become mixed during storage or use, and because lengths of strip, sheet, plate, billets, bars, wire, and fabricated products may have lost their identifying marks, some means of sorting mixed lots is necessary. The best method of identifying such items is by quantitative chemical analysis. However, chemical or spectrographic analyses require extensive, time-consuming procedures and expensive equipment that may not be fully utilized. Also, a complete chemical analysis often may be unnecessary.

Common methods of rapid identification of metals include techniques involving the magnetic properties and weight of the metal, spark testing (of ferrous alloys), and chemical spot testing. Each of these methods is discussed in Ref 13. Spark testing is also described in the Section "Recycling and Life-Cycle Analysis" in this Handbook.

## Leak Testing

### Introduction

LEAK TESTING is used to determine the rate at which a liquid or gas penetrates from inside a "tight" component or assembly to the outside, or vice versa. Penetration occurs as a result of a pressure differential between the two regions, or of permeation of a somewhat extended barrier. The term "leak" commonly refers to an actual discontinuity or passage through which a fluid flows or permeates.

**Types of Leaks.** Two basic types of leaks are real leaks and virtual leaks. A real leak essentially is a localized leak; that is, a discrete passage through which fluid can flow (crudely, a hole). Such a leak can take the form of a tube, a crack, an orifice, and so on. A system also can leak through permeation of a somewhat extended barrier; this type of real leak is called a distributed leak. A gas can flow through a solid having no holes large enough to permit more than a small fraction of the gas to flow through any one hole. This process involves diffusion through the solid and also can involve various surface phenomena such as absorption, dissociation, migration, and desorption of gas molecules. Virtual leaks are leaks that involve the gradual desorption of gases from surfaces and components within a vacuum system. It is not uncommon for a vacuum system to have both real leaks and virtual leaks at the same time.

### Leak Testing of Fluid Systems at Pressure

Leak-testing methods are classified according to the pressure and fluid (gas or liquid) in the system. Table 1 lists the common fluid-system leak-testing methods and the methods used in leak testing of vacuum systems.

**Table 1 Pressure and vacuum system leak-testing methods**

Gas systems at pressure	
• Direct sensing by:	○ Acoustic methods
	○ Bubble testing
	○ Flow detection
• Gas detection by:	○ Smell
	○ Chemical reaction
	○ Halogen gas
	○ Sulfur hexafluoride
	○ Combustible gas
	○ Thermal-conductivity gages

<ul style="list-style-type: none"> <li>○ Infrared gas analyzers</li> <li>○ Mass spectrometry</li> <li>○ Radioisotope count</li> <li>○ Ionization gages</li> <li>○ Gas chromatography</li> </ul> <ul style="list-style-type: none"> <li>• Quantity-loss determination by: <ul style="list-style-type: none"> <li>○ Weighing</li> <li>○ Gaging differential pressure</li> </ul> </li> <li>• </li> </ul>
<p><b>Liquid systems at pressure</b></p> <ul style="list-style-type: none"> <li>• Unaided visual methods</li> <li>• Aided visual methods</li> <li>• Surface wetting</li> <li>• Weight loss</li> <li>• Water-soluble paper with aluminum foil</li> </ul>
<p><b>Vacuum systems</b></p> <ul style="list-style-type: none"> <li>• Manometers</li> <li>• Halogen gas</li> <li>• Mass spectrometry</li> <li>• Ionization gages</li> <li>• Thermal-conductivity gages</li> <li>• Gas chromatography</li> </ul>

Leak detection by monitoring changes in pressure of the internal fluid often is used when leak-detection equipment is not immediately available. Generally, detection can be accomplished using instruments that are already installed in the system.

### ***Acoustic Methods***

Turbulent flow of a pressurized gas through a leak produces sound of both sonic and ultrasonic frequencies. If the leak is large, it probably can be detected with the ear. This is an economical and fast method to find gross leaks. Sonic emissions also are detected using such instruments as stethoscopes and microphones that have a limited ability to locate and determine the approximate size of a leak. Electronic transducers enhance detection sensitivity.

### ***Bubble Testing***

A simple method used to leak test small vessels pressurized with any gas is to submerge them in a liquid and observe for bubbles. If the test vessel is sealed at atmospheric pressure, a pressure differential can be obtained by pumping a partial vacuum over the liquid and by heating the liquid. The sensitivity of this test is increased by reducing (a) the pressure above the liquid, (b) the liquid density, (c) the depth of immersion in the liquid, and (d) the surface tension of the liquid.

### ***Specific-Gas Detectors***

Many available types of leak detectors react to either a specific gas or a group of gases that have some specific physical and/or chemical property in common.

**Sulfur hexafluoride detectors** operate on the principle of electron-capture detectors, used widely in the field of gas chromatography. The sensing chamber of a sulfur hexafluoride detector consists of a cylindrical cell, which has a centrally mounted insulated probe. The inner wall of the cell is coated with a radioactive element (300 millicuries of tritium). Low-energy electrons emitted by the tritium are collected on the central probe by means of a polarizing voltage maintained between the probe and the cell wall. The resulting electric current is amplified and displayed on a conventional meter. The display meter is a taut band-suspension microammeter reading 0 to 50, and response time of the instruments one second. Leak-rate sensitivity is  $10^{-8}$  mL/s.

**Mass-Spectrometer Testing.** A mass spectrometer basically is a device to sort charged particles. The sample gas enters the analyzer where its molecules are bombarded by a stream of electrons emitted by a filament. The bombarded molecules lose an electron and become positively charged ions, which are electrostatically accelerated to a high velocity. Because the analyzer lies in a magnetic field perpendicular to the ion path, the ions travel distinct, curved paths according to their mass. The radii of these paths are determined by ion mass, the magnitude of initial acceleration, and the strength of the magnetic field. With a constant magnetic field, any group of ions having the same mass can be made to travel the specific radius necessary to strike the ion collector. The positive charge of the ion is imparted to the target, or collector, and the resulting current flow is proportional to the quantity of the ions of that particular mass.

### ***Application of Specific-Gas Detectors***

The proper method for using a specific-gas detector is based on the function of the leak detector, the fluid that is leaking, and the type of vessel being tested. One of the best methods of using a leak detector is discussed below.

**Probing.** Probes, which will react to a number of gases, can be used in either of two ways: the probe mode and the monitoring of an enclosure placed around the pressurized item.

In the probe mode, the external surface of the pressurized vessel is scanned either with a portable detector having a short probe attached, or with a long probe connected to a stationary leak detector by flexible tubing (Fig. 1). In general, the connection of a long probe to a stationary detector reduces sensitivity because of the slow release of absorbed gases in the probe tubing, which results in a high background reading. Because a correspondingly longer time is required for the gas to flow up the tube to the sensing element, it is difficult to pinpoint the location of the leak.

**Fig. 1** Schematic showing connection of a long probe by a flexible hose to a stationary leak detector to scan the external surface of a pressurized vessel

In the monitoring of an enclosure placed around the pressurized item, the item is enclosed in a plastic bag and the accumulation of tracer gas in the bag is monitored by a leak detector connected to the bag by a short probe.

**Back pressuring** is a method of pressurized testing that typically is used with small, hermetically sealed electronic components such as integrated circuits, relays, and transistors. In this method, the test unit is placed in a pressurized container filled with a tracer gas and is kept there for a time to allow tracer gas to flow into the unit through any leaks that exist.

In using back pressuring, care must be taken to ensure that the leaking components contain tracer gas. Therefore, it is important that the time between back pressuring and leak testing be suitably controlled. For example, in a test specification for transistors, the transistors were subjected to helium pressure of 100 psi for 16 h, air washed for 4 min, and then leak tested within 3 h. If more than 3 h elapsed before leak testing, the transistors were pressurized again.

Because leaks generally are expected to be quite small, very sensitive tracer-detector combinations must be used. The tracer gas typically used is helium or krypton 85, and detection is by use of a helium mass spectrometer or a nuclear-radiation detector, respectively. Absolute values of the size of the leak sometimes are difficult to determine with back pressuring, because of (a) adsorption and absorption of the tracer gases and (b) different detector-response times for different leak directions.

## **Visual Inspection**

### **Introduction**

VISUAL INSPECTION is a nondestructive testing technique that provides a means to detect and examine a variety of surface flaws, such as corrosion, contamination, surface finish, and surface discontinuities. Visual inspection is the most widely used method for detecting and examining surface cracks.

Visual inspection methods range from examination with the naked eye to the use of interference microscopes to measure the depth of scratches in the finish of finely polished and lapped surfaces. Equipment used to aid visual inspection includes:

- Flexible and rigid borescopes to illuminate and observe internal, closed, and otherwise inaccessible areas
- Image sensors for remote sensing and to develop permanent visual records in the form of photographs, videotapes, and computer-enhanced images
- Magnifying systems to evaluate surface finish, surface shapes (profile and contour gaging), and surface microstructures
- Dye and fluorescent penetrants and magnetic particles to enhance the observation of surface cracks (and sometimes near-surface conditions in the case of magnetic-particle inspection)

### **Borescopes**

A borescope (Fig. 1) is a long, tubular optical device that illuminates and allows the inspection of surfaces inside narrow tubes and difficult-to-reach chambers. The tube, which can be rigid or flexible with a wide variety of lengths and diameters, provides the necessary optical connection between the viewing end and an objective lens at the distant, or distal, tip of the borescope. Three ways to achieve the optical connection are:

- A rigid tube with a series of relay lenses
- A tube (normally flexible, but also rigid) with a bundle of optical fibers
- A tube (normally flexible) with wiring that carries the image signal from a charge-coupled device (CCD) imaging sensor at the distal tip

**Fig. 1** Three typical designs of borescopes. (a) Rigid borescope with a lamp at the distal end. (b) Flexible fiberscope with a light source. (c) Rigid borescope with a light guide bundle in the shaft.

These three basic tube designs can have either fixed or adjustable focusing of the objective lens at the distal tip. The distal tip also has prisms and mirrors that define the direction and field of view (see Fig. 2). Generally, a fiber optic light guide and a lamp producing white light is used in the illumination system, although ultraviolet light can be used to inspect surfaces treated with liquid fluorescent penetrants. Light-emitting diodes at the distal tip are sometimes used for illumination in videoscopes with working lengths greater than 15 m (50 ft).

**Fig. 2 Typical directions and field of view with rigid borescopes**

### ***Rigid Borescopes***

Rigid borescopes generally are limited to use in applications with a straight-line path between the observer and the area to be observed. The sizes range from 0.15 to 30 m (0.5 to 100 ft) long and 0.9 to 70 mm (0.035 to 2.75 in.) in diameter. Magnification usually is 3 to 4×, but magnifying power up to 50× is available. The illumination system is either an incandescent lamp located at the distal end (Fig. 1a) or a light guide bundle made of optical fibers (Fig. 1c), which conduct light from an external source.

Rigid borescopes typically have a series of achromatic relay lenses in the optical tube. The borescopes generally have a 55° field of view, although the field of view can range from 10 to 90°. Some rigid borescopes have orbital scan (Fig. 1c), which involves the rotation of the optical shaft for scanning purposes. The amount of rotation can vary from 120 to 370°. Some rigid borescopes also have movable prisms at the tip for scanning. The illumination system can be either a distal lamp or a light guide bundle, and the various features may include orbital scan, various viewing heads, and adjustable focusing of the objective lens.

**Miniboreoscopes.** Instead of conventional relay lenses, miniboreoscopes have either a single image-relaying rod or quartz fiber in the optical tube. Miniboreoscopes are 110 and 170 mm (4.3 and 6.7 in.) long, and range from 0.9 to 2.7 mm (0.035 to 0.105 in.) in diameter. High magnification (up to 30×) can be achieved at minimal focal lengths, and an adjustable focus is not required because the scope has an infinite depth of field. Miniboreoscopes use an integral light guide bundle.

**Hybrid borescopes** use rod lenses combined with convex lenses to relay the image. A larger light guide bundle is used, which provides higher illumination and a larger image with a higher degree of contrast.

Hybrid borescopes are up to 990 mm (39 in.) long, and 5.5 to 12 mm (0.216 to 0.47 in.) in diameter. All hybrid borescopes have adjustable focusing of the objective lens and a 370° rotation for orbital scan.

**Extendable borescopes** allow the user to construct a longer borescopic tube by joining extension tubes. The borescopes are available with either a fiber-optic light guide or an incandescent lamp at the distal end. Extendable borescopes with an integral lamp have a maximum length of approximately 30 m (100 ft). Maximum length of scopes with a light guide bundle is about 8 m (26 ft), which allows smaller tube diameters (as small as 8 mm, or 0.3 in.). Interchangeable viewing heads are also available. Extendable borescopes do not have adjustable focusing of the objective lens.

**Rigid chamberscopes** allow more rapid inspection of larger chambers. Chamberscopes have variable magnification (zoom), a lamp at the distal tip, and a scanning mirror, which allows the user to observe in different directions. The higher illumination and greater magnification of chamberscopes allow the inspection of surfaces as far as 910 mm (36 in.) away from the distal tip of the scope.

**Mirror sheaths** convert a direct-viewing borescope into a side-viewing scope. A mirror sheath is designed to fit over the tip of the scope, and, therefore, reflects an image from the side of the scope. Side, forward-oblique, and retrospective viewing heads provide better resolution and a higher degree of image contrast. A mirror sheath also produces an inverse image and can produce unwanted reflections from the shaft.

**Scanning.** In addition to the orbital scan feature described previously, some rigid borescopes have the ability to scan longitudinally along the axis of the shaft. This is accomplished using a movable prism with a control at the handle. Typically, the prism can shift the direction of view through an arc of 120°.

### ***Flexible Borescopes***

Flexible borescopes are used primarily in applications that do not have a straight passageway to the point of observation. Two types of flexible borescopes are flexible fiberscopes and videoscopes with a CCD image sensor at the distal tip.

**Flexible Fiberscopes.** A typical fiberscope (Fig. 1b) consists of a light guide bundle, an image guide bundle, an objective lens, interchangeable viewing heads, and remote controls for articulation of the distal tip. Fiberscopes are available in diameters from 1.4 to 13 mm (0.055 to 0.5 in.) and ranging up to 12 m (40 ft) long. Special quartz fiberscopes are available in lengths up to 90 m (300 ft).

Fibers in the image guide must be precisely aligned so they are in an identical relative position to each other at their terminations for proper image resolution. Fiber diameter also is a factor in obtaining good image resolution. With smaller diameter fibers, a brighter image with better resolution can be obtained because more fibers can be packed in the image guide. Higher resolution makes it possible to use an objective lens with a wider field of view and also to magnify the image at the eyepiece. This allows better viewing of objects at the periphery of the image.

The interchangeable distal tips provide various directions and fields of view on a single fiberscope. However, because the tip can be articulated for scanning purposes, distal tips with either a forward or side viewing direction usually are sufficient. Fields of view are typically 40 to 60°, although they can range from 10 to 120°. Most fiberscopes provide adjustable focusing of the objective lens.

**Videoscopes with CCD probes** involve the electronic transmission of color or black and white images to a video monitor. The distal end of electronic videoscopes contains a CCD chip. The objective lens focuses the image of an object on the surface of the CCD chip, converting light to electrons, which are stored in each picture element, or pixel, of the CCD device. Thus, the image of the object is stored on the CCD device.

Videoscopes with CCD probes produce images having spatial resolutions of the order of those described in Fig. 3. Resolution depends on the object-to-lens distance and the fields of view, factors that affect the degree of magnification. Generally, videoscopes produce higher resolution than fiberscopes.

(a)

(b)

(c)

**Fig. 3** Typical resolution of charge-coupled device videoscopes with a (a) 90° field of view, (b) 60° field of view, and (c) 30° field of view

Another advantage of videoscopes is their longer working length. With a given amount of illumination at the distal tip, videoscopes can return an image over a greater length than fiberscopes. Videoscopes help reduce eye fatigue. Also, there is no honeycomb pattern or irregular picture distortion as with some fiberscopes, the electronic form of the image signal allows digital image enhancement and the potential for integration with automatic inspection systems, and the display allows the generation of reticles on the viewing screen for point-to-point measurements.

### ***Special Features***

**Measuring borescopes and fiberscopes** contain a movable cursor that allows measurements during viewing. When the object under measurement is in focus, the movable cursor provides a reference for dimensional measurements in the optical plane of the object. This capability eliminates the need to know the object-to-lens distance when determining magnification factors.

**Working channels** are used in borescopes and fiberscopes to pass working devices, such as measuring instruments, retrieval devices, and hooks to help insert thin, flexible fiberscopes, to the distal tip.

## ***Selection***

Factors that influence the choice of a flexible or rigid borescope for use in a specific application include focusing, illumination, magnification, working length, direction of view, and environment.

**Focusing and Resolution.** In general, the optical quality of a rigid borescope improves as the size of the lens increases. Therefore, a borescope with the largest possible diameter should be used. For fiberscopes, the resolution is dependent on the alignment accuracy and fiber diameter in the image bundle. Smaller-diameter fibers provide more resolution and edge contrast when combined with good geometrical alignment of the fibers.

**Illumination.** The required intensity of the light source is determined by the reflectivity of the surface, the area of surface to be illuminated, and the transmission losses over the length of the scope. At working lengths greater than 6 m (20 ft), rigid borescopes with a lamp at the distal end provide the greatest amount of illumination over the widest area. Fiber-optic illumination in scopes with working lengths less than 6 m (20 ft) is always brighter and is suitable for heat-sensitive applications because filters can remove infrared frequencies.

**Magnification and field of view** are interrelated; field of view decreases as magnification increases. The precise relationship between magnification and field of view is specified by the manufacturer.

The degree of magnification in a particular application is determined by the field of view and the distance from the objective lens to the object. The magnification increases when either the field of view or the lens-to-object distance decreases.

**Working length** can sometimes dictate the use of a particular type of scope. For example, a rigid borescope with a long working length might be limited by the need for additional supports. In general, videoscopes allow a longer working length than fiberscopes.

**Direction of View.** Flexible fiberscopes and videoscopes, because of their articulating tip, are often adequate with either a side or forward viewing tip.

Circumferential and panoramic heads are designed to inspect tubing and other cylindrical structures. A centrally located mirror permits right-angle viewing of an area just scanned by the panoramic view.

The forward viewing head permits the inspection of the area directly ahead of the viewing head. It is commonly used when examining facing walls or the bottoms of blind holes and cavities.

Forward-oblique heads bend the viewing direction at an angle to the borescope axis, permitting the inspection of corners at the end of a bored hole. The retrospective viewing head bends the cone of view at a retrospective angle to the borescope axis, providing a view of the area just passed by the advancing borescope. It is especially suited to inspecting the inside neck of cylinders and bottles.

**Environment.** Flexible and rigid borescopes can be manufactured to withstand a variety of environments. Although most flexible and rigid borescopes can operate at temperatures ranging from -34 to 66 °C (-30 to 150 °F), specially designed scopes can be used at temperatures to 1925 °C (3500 °F). Scopes can also be manufactured for use in liquid media.

Special scopes are required for use at pressures above ambient and in atmospheres exposed to radiation. Scopes used in a gaseous environment should be made explosion proof.

## ***Applications***

The principal use of borescopes is in equipment maintenance programs, where they can help reduce or eliminate the need for costly teardowns. Some types of equipment, such as turbines, have access ports that are specifically designed for borescopes. Borescopes provide a means to check in-service defects in various equipment, such as automotive components (Fig. 4), turbines, and process piping.

**Fig. 4** In-service defects as seen through a borescope designed for automotive servicing. (a) Carbon on valves. (b) Broken transmission gear tooth. (c) Differential gear wear.

## Optical Sensors

Visible light, which can be detected by the human eye and with optical sensors, has some advantages over inspection methods based on nuclear, microwave, and ultrasound radiation. For example, one of the advantages of visible light is the capability of tightly focusing the probing beam on the inspected surface. High spatial resolution can result from this sharp focusing, which is useful in gaging and profiling applications.

Different types of image sensors used in visual inspection include:

- Vidicon or plumbicon television tubes
- Secondary electron-coupled (SEC) vidicons
- Image orthicons and image isocons
- Charge-coupled device sensors
- Holographic plates (see the article "Holography" in this Section)

Television cameras with vidicon tubes are useful at higher light levels (approximately  $0.2 \text{ lm/m}^2$ , or  $10^{-2} \text{ ftc}$ ), while orthicons, isocons, and SEC vidicons are useful at lower light levels.

Charge-coupled devices are suitable for use in many different information-processing applications, including image sensing in television-camera technology. Charge-coupled devices offer an advantage over vacuum-tube image sensors because of the reliability of their solid-state technology, their operation at low voltage and low power dissipation, extensive dynamic range, visible and near-infrared response, and geometric reproducibility of image location. Image enhancement (or visual feedback into robotic systems) typically involves the use of CCDs as the optical sensor or the use of television signals that are converted into digital form.

Optical sensors are also used in inspection applications that do not involve imaging. However, in some applications, incoherent light sources are very effective in nonimaging inspection applications using optical sensors.

## Magnifying Systems

Magnifying systems are used in visual reference gaging. When tolerances are too tight to judge by eye alone, optical comparators or toolmakers' microscopes are used to achieve magnifications ranging from 5 to 500 $\times$ .

**A toolmakers' microscope** consists of a microscope mounted on a base that carries an adjustable stage, a stage transport mechanism, and supplementary lighting. Various objective lenses provide magnifications ranging from 10 to 200 $\times$ .

**Optical comparators** are magnifying devices that project the silhouette of small parts onto a large projection screen. The magnified silhouette is then compared against an optical comparator chart, which is a magnified outline drawing of the workpiece being gaged. Optical comparators are available with magnifications ranging from 5 to 500 $\times$ .

Parts with recessed contours can also be successfully gaged on optical comparators using a pantograph. One arm of the pantograph is a stylus that traces the recessed contour of the part, and the other arm carries a follower that is visible in the light path. As the stylus moves, the follower projects a contour on the screen.

# Liquid-Penetrant Inspection

## Introduction

LIQUID-PENETRANT INSPECTION is a nondestructive method used to find discontinuities that are open to the surface of solid, essentially nonporous materials. Indications of flaws can be found regardless of the size, configuration, internal structure, and chemical composition of the workpiece being inspected, as well as flaw orientation. Liquid penetrants can seep into (and be drawn into) various types of minute surface openings (as fine as  $0.1\text{ }\mu\text{m}$ , or  $4\text{ }\mu\text{in.}$ , in width) by capillary action. Therefore, the process is well suited to detect all types of surface cracks, laps, porosity, shrinkage areas, laminations, and similar discontinuities. It is used extensively to inspect ferrous and nonferrous metal wrought and cast products, powder metallurgy parts, ceramics, plastics, and glass objects.

The liquid-penetrant inspection method is relatively simple to perform, there are few limitations due to specimen material and geometry, and it is inexpensive. The equipment is very simple, and the inspection can be performed at many stages in the production of the part, as well as after the part is placed in service. Relatively little specialized training is required to perform the inspection. In some instances, liquid-penetrant sensitivity is greater for ferromagnetic steels than that of magnetic-particle inspection.

The major limitation of liquid-penetrant inspection is that it can detect only imperfections that are open to the surface; some other method must be used to detect subsurface defects and discontinuities. Another factor that can inhibit the effectiveness of liquid-penetrant inspection is the surface roughness of the object. Extremely rough and porous surfaces are likely to produce false indications.

Although the liquid-penetrant method often is used to inspect some types of powder metallurgy parts, the process generally is not well suited to inspect low-density powder metallurgy parts and other porous materials because the penetrant enters the pores and registers each pore as a defect.

## Physical Principles

Liquid-penetrant inspection depends mainly on the ability of liquid penetrant to effectively wet the surface of a solid workpiece or specimen; flow over the surface to form a continuous, reasonably uniform coating; and migrate into cavities that are open to the surface. The cavities of interest usually are very small, often invisible to the unaided eye. The ability of a given liquid to flow over a surface and enter surface cavities depends principally on:

- Cleanness of the surface
- Configuration of the cavity
- Size of the cavity
- Surface tension of the liquid
- Ability of the liquid to wet the surface

The cohesive forces between molecules of a liquid cause surface tension. An example of the influence of surface tension is the tendency of free liquid, such as a droplet of water, to contract into a sphere. In such a droplet, surface tension is counterbalanced by the internal hydrostatic pressure of the liquid. When the liquid comes into contact with a solid surface, the cohesive force responsible for surface tension competes with the adhesive force between the molecules of the liquid and the solid surface. These forces jointly determine the contact angle between the liquid and the surface. If the angle is less than  $90^\circ$ , the liquid has good wetting ability.

## Description of the Process

Regardless of the type of penetrant used and other variations in the basic process, liquid-penetrant inspection requires at least five essential steps:

**Surface Preparation.** All surfaces of a work-piece must be thoroughly cleaned and completely dried before inspection. Discontinuities exposed to the surface must be free from oil, water, and other contaminants for at least 25 mm (1 in.) beyond the area being inspected to increase the probability of detection.

**Penetrant Application.** Liquid penetrant is applied in a suitable manner to form a film of the penetrant over the surface for at least 13 mm ( $\frac{1}{2}$  in.) beyond the area being inspected. The penetrant is left on the surface for a sufficient time to allow penetration into flaws. Times are based on experience. Table 1 shows some typical times for different materials and defect types.

**Table 1 Typical penetration time for a dye penetrant**

Surface examination	Type of defect	Penetration time, min
<b>All</b>	Heat-treatment cracks	2
	Grinding	10
	Cracks	10
<b>Ceramics</b>	Cracks	2-5
	Porosity	2-5
<b>Aluminum welds</b>	Cracks and pores	10-20
<b>Steel welds</b>	Cracks and pores	10-20
<b>Forgings</b>	Cracks	20
	Laps	20
<b>Metal rollings</b>	Seams	10-20
<b>Die castings</b>	Surface porosity	3-10
	Cold shuts	10-20
<b>Metal-permanent mold casting</b>	Shrinkage porosity	3-10
<b>Carbide-tipped cutting tools</b>	Poor braze	2-10
<b>Cutting tools</b>	Cracks in steel	2-10
	Cracks in tip	2-10

**Removal of Excess Penetrant.** Uniform removal of excess penetrant is necessary for effective inspection, but overcleaning must be avoided. Penetrants can be washed off directly using water, treated first with an emulsifier and then rinsed with water, or removed using a solvent.

**Developer Application.** Developer can be applied by dusting (dry powdered) and immersion and spray (water developers) applications. Nonaqueous wet developers can only be applied by spraying. The developer should be allowed to dwell on the surface for a sufficient time (usually 10 min minimum) to permit it to draw penetrant out of any surface flaws to form visible indications of such flaws. Longer times could be necessary for tight cracks. The developer also provides a uniform background to assist visual inspection.

**Inspection.** After being sufficiently developed, the surface is visually examined for indications of penetrant bleedback from surface openings. This examination must be performed in a suitable inspection environment. Visible-penetrant inspection is performed in good white light. When fluorescent penetrant is used, inspection is performed in a suitably darkened area using black (ultraviolet) light, which causes the penetrant to emit visible light. The actions of penetrant and developer are shown in Fig. 1.

**Fig. 1** Actions of penetrant and developer. (a) Penetrant liquid is drawn into an open crack by capillary action. (b) Excess surface penetrant is removed by wiping with a cloth, washing directly with water, treating with an emulsifier and rinsing, or removing with a solvent. (c) Developer applied to the surface draws out penetrant liquid that seeps into the developer forming a visible indication of the surface crack. A colored dye or a fluorescence compound is usually added to the penetrant liquid. Depending on the amount of penetrant that seeps into the developer, the crack width can appear 100 times larger than its actual size.

## Penetrant Systems

Liquid penetrant inspection applications have been developed to handle the wide variations in three basic penetrant systems. They are broadly classified as (a) the water-washable system, (b) the postemulsifiable system, and (c) the solvent-removable system.

**The water-washable penetrant system** is designed so that the penetrant is directly washable from the surface of the workpiece using water. It can be used to process workpieces quickly and efficiently. However, it is important that washing is carefully controlled, because water-washable penetrants are susceptible to overwashing. The degree and speed of removal depend on processing conditions such as spray-nozzle characteristics, water pressure and temperature, duration of rinse cycle, surface condition of the workpiece, and inherent removal characteristics of the penetrant employed.

**The Postemulsifiable System.** High-sensitivity penetrants that are not water washable are used to ensure detection of minute discoveries in some materials. Because they are not water washable, the danger of washing the penetrant out of the flaws is reduced. These penetrants require an additional operation in the inspection process. An emulsifier must be applied after the application of penetrant and proper penetration (dwell) time. The emulsifier makes the penetrant soluble in water so the excess penetrant can be removed by water rinsing. Therefore, the emulsification time must be carefully controlled so the surface penetrant becomes water-soluble but penetrant in the flaws does not. Postemulsifiable penetrants include lipophilic (oil base) and hydrophilic (water base).

**The Solvent-Removable System.** Occasionally, it is necessary to inspect only a small area of a workpiece or to inspect a workpiece on site rather than at a regular inspection station. In such situations, solvent-removable penetrants are used. Normally, the same type of solvent is used both for precleaning and for removal of excess penetrant. This penetrant process is convenient and broadens the range of applications of penetrant inspection.

The solvent-removable penetrants have an oil base. Optimum solvent removal is accomplished by wiping off as much of the excess penetrant as possible with a paper towel or a lint-free cloth, then slightly dampening a clean cloth with solvent and wiping off the remaining penetrant. Final wiping with a dry paper towel or clean cloth is required.

The penetrant also can be removed by flooding the surface with solvent, in the same manner as for water-washable penetrants. The flooding technique is particularly useful for large workpieces, but it must be very carefully used to prevent removal of the penetrant from the flaws.

The solvent-removable system is used mainly in special applications; it is not practical for production applications because it is labor intensive.

## Liquid-Penetrant Materials

Two basic types of liquid penetrants are fluorescent and visible. Each type is available for any one of the three systems (water-washable, postemulsifiable, or solvent-removable).

Fluorescent-penetrant inspection uses penetrants that fluoresce brilliantly under ultraviolet light. The sensitivity of a fluorescent penetrant depends on its ability to form indications that appear as small sources of light in an otherwise dark area. Sensitivity levels of fluorescent penetrants are: ultralow (Level  $\frac{1}{2}$ ), low (Level 1), medium (Level 3), high (Level 4), and ultrahigh (Level 5).

Visible penetrant inspection uses a penetrant that is usually red in color and produces vivid red indications in contrast to the light background of the applied developer under visible light. The visible penetrant indications must be viewed under adequate white light. The sensitivity of visible penetrants is regarded as Level 1 and adequate for many applications.

Penetrant selection and use depend on the criticality of the inspection, the condition of the workpiece surface, the type of processing, and the desired sensitivity.

**Water-washable penetrants** are designed for the removal of excess surface penetrant by water rinsing directly after a suitable penetration (dwell) time. The emulsifier is incorporated into the water-washable penetrant. When this type of penetrant is used, it is extremely important that the removal of excess surface penetrant be properly controlled to prevent overwashing, which can cause the penetrant to be washed out of the flaws.

**Lipophilic and hydrophilic postemulsifiable penetrants** are insoluble in water, and, therefore, are not removable by water rinsing alone. They are designed to be selectively removed from the surface of the workpiece using a separate emulsifier. The emulsifier, properly applied and left for a suitable emulsification time, combines with the excess surface penetrant to form a water-washable surface mixture, which can be rinsed from the surface of the workpiece. The penetrant that remains within the flaw is not subject to overwashing if the emulsifier is confined to the surface and if the discontinuity is tight (no mechanical rinsing).

**Solvent-removable penetrants** are used primarily where portability is required and to inspect localized areas. To minimize the possibility of removing the penetrant from discontinuities, the use of excessive amounts of solvent must be avoided.

**Physical and Chemical Characteristics.** Both fluorescent and visible penetrants, whether water-washable, postemulsifiable, or solvent-removable, must have certain chemical and physical characteristics to perform their intended functions. Principal requirements of penetrants are:

- Chemical stability and uniform physical consistency
- A flash point not lower than 95 °C (200 °F); penetrants that have lower flash points constitute a potential fire hazard.

- A high degree of wettability
- Low viscosity to permit better coverage and minimum dragout
- Ability to penetrate discontinuities quickly and completely
- Sufficient brightness and permanence of color
- Chemical inertness with materials being inspected and with containers
- Low toxicity to protect personnel
- Slow drying characteristics
- Ease of removal
- Inoffensive odor
- Low cost
- Resistance to ultraviolet light and heat fade

## **Emulsifiers**

Emulsifiers are liquids used to render excess oily penetrant on the surface of a workpiece water washable. Emulsifiers are oil-base and water-base.

Oil-base emulsifiers function by diffusion. The emulsifier diffuses into the penetrant film and renders it spontaneously emulsifiable in water. The rate at which it diffuses into the penetrant establishes its emulsification time. Because the emulsifier is fast acting, the rinse operation should be done quickly to avoid over emulsification.

Water-base emulsifiers usually are supplied as liquid concentrates that are diluted in water to concentrations of 5 to 30% for dip-tank applications and of 0.05 to 5% for spray applications. Water-base emulsifiers function by displacing excess surface penetrant from the surface of the part by detergent action. The force of the water spray or air agitation of open dip tanks provides the scrubbing action while the detergent displaces the excess surface penetrant.

## **Solvent Cleaners**

Solvent cleaners differ from emulsifiers in that they remove excess surface penetrant through direct solvent action. The penetrant is dissolved by the solvent. Solvent cleaners are flammable and nonflammable. Flammable cleaners are free of halogens, but are potential fire hazards. Nonflammable cleaners usually contain halogenated solvents, which render them unsuitable for some applications--usually because of their high toxicity or because they have undesirable effects on some materials.

## **Developers**

Because the amount of penetrant that emerges from a small surface opening is minute, the visible evidence of its presence must be enhanced. Developers are used to spread the penetrant available at the defect, thus increasing the amount of light emitted, or the amount of contrast, that makes the defect visible to the unaided eye.

Developers must have the following properties/ characteristics for optimal performance.

- It must be adsorptive to maximize blotting.
- It must have fine grain size and a particle shape that will disperse and expose the penetrant at a flaw to produce strong and sharply defined indications of flaws.
- It must be capable of providing a contrast background for indications when color-contrast penetrants are used.
- It must be easy to apply.
- It must form a thin, uniform coating over a surface.
- It must be easily wetted by the penetrant at the flaw (the liquid must be allowed to spread over the particle surfaces).
- It must be nonfluorescent if used with fluorescent penetrants.
- It must be easy to remove after inspection.
- It must not contain ingredients harmful to parts being inspected or to equipment used in the inspection

operation.

- It must not contain ingredients harmful or toxic to the operator.

Four forms of developers commonly used are dry powder (Form A), water soluble (Form B), water suspendible (Form C), and nonaqueous solvent suspendible (Form D).

### ***Dry Developers***

Dry powder developers are widely used with fluorescent penetrants, but should not be used with visible-dye penetrants because they do not produce a satisfactory contrast coating on the surface of the workpiece. Ideally, dry powder developers should be light and fluffy to allow easy application and should cling to dry surfaces in a fine film. Powder adherence should not be excessive, because the amount of penetrant at fine flaws is insufficient to seep back into a thick coating.

For purposes of storage, handling, and application, powders should not be hygroscopic and should remain dry. Moisture impairs their ability to flow and dust easily, and they can agglomerate, pack, and lump up in containers and in developer chambers.

**Application and Removal.** Hand-processing equipment usually includes a developer station, which usually is an open tank for dry developers. Workpieces are dipped into the powder, or powder is picked up with a scoop or with the hands, and dropped onto the workpiece. Excess powder is removed by shaking and tapping the workpiece. Some powders are so light and fluffy that parts are dipped into them as easily as into a liquid.

Other effective methods of application are rubber spray bulbs and air-operated spray guns. An electrostatic-charged powder gun that can apply an extremely even and adherent coating of dry powder on metal parts also is used. For simple application--especially when only a portion of the surface of a large part is being inspected--a very soft bristle brush often is adequate.

Powder can dry the skin and irritate the lining of air passages. Operators should use rubber gloves and respirators. Modern equipment often includes an exhaust system on the developer spray booth or on the developer dust chamber, which prevents dust from escaping. Powder recovery filters often are included in such installations.

### ***Wet Developers***

Three types of wet developers are: suspensions of developer powder in water (the most widely used), aqueous solutions of suitable salts, and suspensions of powder in volatile solvents.

**Water-suspendible developers** can be used with both visible and fluorescent penetrants. With a fluorescent penetrant, the dried developer coating must not fluoresce or absorb or filter out black light used for inspection. Water-suspendible developers permit high-speed application of developer in mass inspection of small to medium-size workpieces using the fluorescent method. A basket of small, irregularly shaped workpieces that has gone through the steps of penetrant application, penetrant dwell, and washing can be coated with developer in one quick dip in a water suspension. This method not only is quick, but also, it provides thorough, complete coverage of all surfaces of the pieces being inspected. No dry-powder application method has all these advantages to the same degree.

Wet developer is applied just after excess penetrant is washed away and immediately before drying. After drying, surfaces are uniformly coated with a thin film of developer. Developing time is decreased because heat from the drier helps to bring penetrant back out of surface openings, and the developing action occurs immediately with the developer film already in place. Workpieces are ready for inspection in a shorter period of time, before excessive bleedout from large openings occurs, so better definition of flaw indications often is obtained.

Water-suspendible developers are supplied as a dry powder concentrate, which is then dispersed in water in recommended proportions, usually from 0.04 to 0.12 kg/L ( $\frac{1}{3}$  to 1 lb/gal). The amount of powder in suspension must be carefully maintained. Too much or too little developer on the surface of a workpiece can seriously affect sensitivity.

**Water-soluble developers** can be used for both fluorescent and visible postemulsifiable and solvent-removable penetrants. Water-soluble developers are not recommended for use with water-washable penetrants, because of the potential to wash the penetrant from within the flaw if the developer is not very carefully controlled. Water-soluble developers are supplied as a dry powder concentrate, which is then dispersed in water in recommended proportions, usually from 0.12 to 0.24 kg/L (1 to 2 lb/gal). Advantages of this form of developer are:

- The prepared bath is completely soluble and does not require any agitation
- The developer is applied prior to drying, thus decreasing the developing time
- The dried developer film on the workpiece is completely water soluble and is easily and completely removed following inspection by simple water rinsing

**Nonaqueous solvent-suspendible developers** are commonly used for both the fluorescent and the visible penetrant process. This form of developer produces a white coating on the surface of the part, which yields the maximum white color contrast with the red visible penetrant indication and extremely brilliant fluorescent indication.

Nonaqueous solvent-suspendible developers are supplied in the ready-to-use condition and contain particles of developer suspended in a mixture of volatile solvents. The solvents are carefully selected for their compatibility with the penetrants. Nonaqueous solvent-suspendible developers also contain surfactants in a dispersant that coat the particles and reduce their tendency to clump or agglomerate.

Nonaqueous solvent-suspendible developers are the most sensitive form of developer used with fluorescent penetrants because the solvent action contributes to the absorption and adsorption mechanisms. In many cases where tight, small flaws occur, dry powder, water-soluble, and water-suspendible developers do not contact the entrapped penetrant. This results in the failure of the developer to create the necessary capillary action and surface tension that serve to pull the penetrant from the flaw. The nonaqueous solvent-suspendible developer enters the flaw and dissolves into the penetrant. This action increases the volume and reduces the viscosity of the penetrant.

The manufacturer must carefully select and compound the solvent mixture. There are two types of solvent-based developers: nonflammable (chlorinated solvents) and flammable (nonchlorinated solvents). Both types are widely used. Selection is based on the nature of the application and the type of alloy being inspected.

Solvent developers are sometimes applied with a paintbrush, but this is likely to result in smeared indications; application by a pressure spray can is a preferred method.

### ***Selection of Developer***

Because developers play such an important role in penetrant inspection, it is very important to select the appropriate developer for a given job. For example, on very smooth or polished surfaces, dry powder does not adhere satisfactorily, and wet developers do a better job. Conversely, on very rough surfaces dry powder is far more effective.

Following are some general rules regarding developer selection:

- Use a wet developer instead of a dry developer on very smooth surfaces.
- Use a dry developer versus a wet developer on very rough surfaces.
- Wet developers are better suited for high-production inspection of small workpieces because of their greater ease and speed of application.
- Wet developers cannot be used reliably where sharp fillets unavoidably accumulate developer, which can mask flaw indications.
- Solvent developers are effective for revealing fine, deep cracks, but are not satisfactory for finding wide, shallow flaws.
- Cleaning and reinspecting a rough surface is difficult if a wet developer was used for a prior inspection.

The developer does not produce indications but simply absorbs the penetrant already present in or at the flaw and makes it more visible.

## Equipment Requirements

With the exception of a source of ultraviolet (black) light for use with fluorescent penetrants, there is no special equipment that is absolutely essential for liquid-penetrant inspection. Reasonably effective inspection can be performed with a minimum of simple and relatively crude equipment. However, this approach should be considered only when: (a) no more than a few workpieces are involved, (b) specific portions of very large workpieces are being inspected, (c) maximum sensitivity is not required, or (d) inspection must be performed in the field. Therefore, most liquid-penetrant inspection is done with equipment designed specifically for the purpose.

A variety of equipment is available. "Package units" that incorporate all the necessary stations and controls are widely used, especially where relatively small workpieces in a variety of sizes and shapes are being inspected. A typical package unit for inspection using a water-washable, fluorescent-penetrant system is shown in Fig. 2. This system is designed to process a steady flow of workpieces, which move through seven stations: application of penetrant, draining excess penetrant, water rinsing, inspection under ultraviolet light to check thoroughness of rinsing, drying, application of developer, and final ultraviolet-light inspection for flaws. The unit does not include stations for preliminary cleaning and postcleaning; these operations often are performed in another area. The equipment shown in Fig. 2 is available in a wide range of sizes and can be modified in many ways to fit specific needs. For example, if a postemulsifiable system is used, workpieces are coated with emulsifier after the penetrant has been allowed to drain and prior to rinsing.

**Fig. 2** Typical seven-station package equipment unit for inspecting workpieces using a water-washable, fluorescent-penetrant system

Workpiece sizes and shapes, and production quantities, are the major factors that influence the selection of equipment. An arrangement used in a foundry to process a variety of workpieces is shown in Fig. 3.

**Fig. 3** Equipment arrangement used in a foundry for liquid-penetrant inspection of a large variety of castings to rigid specifications. Castings are moved by crane and roller conveyor.

**Precleaning.** Regardless of the penetrant chosen, adequate precleaning of workpieces prior to penetrant inspection is absolutely necessary for accurate results. Inadequate removal of surface contamination can result in missed relevant indications because:

- The penetrant does not enter the flaw.
- The penetrant loses its ability to reveal the flaw because it reacts with a substance contained in the flaw.
- The surface immediately surrounding the flaw retains too much penetrant, which masks the true appearance of the flaw.

Also, nonrelevant (false) indications can be caused by residual materials holding penetrants.

Cleaning methods generally are classified as chemical, mechanical, solvent, and combinations of these.

Chemical cleaning methods include alkaline or acid cleaning, pickling or chemical etching, and molten salt bath cleaning.

Mechanical cleaning methods include tumbling, wet blasting, dry abrasive blasting, wire brushing, and high-pressure water or steam cleaning. Mechanical cleaning can mask flaws by smearing adjacent metal over them and by filling them with abrasive material.

Solvent cleaning methods include vapor degreasing, solvent spraying, solvent wiping, and ultrasonic immersion using solvents. Ultrasonic immersion is by far the most effective means of ensuring clean parts, but it can be a very expensive capital equipment investment.

Cleaning methods and their common uses are listed in Table 2. Major factors in the selection of a cleaning method is the type of contaminant to be removed, the type of alloy being cleaned, and knowing the chemical composition of the workpiece being cleaned. It is good practice to test the method on known flaws to ensure that it will not mask the flaws.

**Table 2 Applications of various methods of precleaning for liquid-penetrant inspection**

Method	Use
<b>Mechanical</b>	
<b>Abrasive tumbling</b>	Removing light scale, burrs, welding flux, braze stopoff, rust, casting mold, and core material; should not be used on soft metals such as aluminum, magnesium, and titanium
<b>Dry abrasive grit blasting</b>	Removing light and heavy scale, flux, stopoff, rust, casting mold and core material, sprayed coatings, and carbon deposits--in general, any friable deposit. Can be fixed or portable
<b>Wet abrasive grit blasting</b>	Same as dry except, where deposits are light, better surface and better control of dimensions are required
<b>Wire brushing</b>	Removing light deposits of scale, flux, and stopoff
<b>High-pressure water and steam</b>	Typically used with an alkaline cleaner or detergent; removing typical machine-shop soils such as cutting oils, polishing compounds, grease, chips, and deposits from electrical discharge machining; used when surface finish must be maintained; inexpensive
<b>Ultrasonic cleaning</b>	Typically used with detergent and water or with a solvent; removing adherent shop soil from large quantities of small parts
<b>Chemical</b>	
<b>Alkaline cleaning</b>	Removing braze stopoff, rust, scale, oils, greases, polishing material, and carbon deposits; typically used on large articles where hand methods are too labor intensive; also used on aluminum for gross metal removal
<b>Acid cleaning</b>	Strong solutions for removing heavy scale; solutions for light scale; weak (etching) solutions for removing lightly smeared metal
<b>Molten salt bath cleaning</b>	Conditioning and removing heavy scale
<b>Solvent</b>	
<b>Vapor degreasing</b>	Removing typical shop soil, oil, and grease; usually uses chlorinated solvents; not suitable for titanium
<b>Solvent wiping</b>	Same as for vapor degreasing except a hand operation; can use nonchlorinated solvents; used for localized low-volume cleaning

The surface finish of the workpiece must always be considered. When further processing is scheduled, such as machining or final polishing, or when a surface finish of 3.20  $\mu\text{m}$  (125  $\mu\text{in.}$ ) or coarser is allowed, an abrasive cleaning method is frequently a good choice. Generally, chemical cleaning methods have fewer degrading effects on surface finish than mechanical methods (unless the chemical used is strongly corrosive to the material being cleaned). Steam cleaning and solvent cleaning rarely have any effect on surface finish.

Choice of cleaning method can be dictated by Occupational Safety and Health Administration and Environmental Protection Agency health and safety regulations. Factors to consider include quantities of materials that will be used, toxicity, filtering, neutralization and disposal techniques, and worker safety.

**Penetrant Station.** The principal requirement of a penetrant station is to provide a means to coat workpieces with penetrant--the entire surface for small workpieces, or over small areas of large workpieces when only local inspection is required. The station also should provide a means to drain excess penetrant back into the penetrant reservoir, unless the expendable technique is being used. Draining racks usually serve the additional purpose of providing a storage place for parts during the time required for penetration (dwell time).

**Emulsifier Station.** Emulsifier liquid is contained in a tank large enough to permit immersion of the workpieces, either individually or in batches. Accessory equipment includes covers to reduce evaporation and drain valves for cleanout when the bath has to be renewed. Suitable drain racks are also a part of this station, to permit excess emulsifier to drain back into the tank.

Large workpieces must be coated with emulsifier as fast as possible. Multiple spraying or copious flowing of emulsifier from troughs or perforated pipes can be used on some types of automatic equipment. For local coating of large workpieces, spraying often is satisfactory, using the expendable technique described for application of penetrant.

**Rinse Station.** Water rinsing (washing) of small workpieces frequently is done by hand, either individually or in batches in wire baskets. The workpieces are held in the wash tank and cleaned with a hand-held spray using water at tap pressure and temperature (water temperature should not, however, be below 10 °C, or 50 °F).

**Drying Station.** The recirculating hot-air drier is one of the most important equipment components. The drier must be large enough to easily handle the type and number of workpieces being inspected. Heat input, air flow, rate of movement of workpieces through the drier, and temperature control are all factors that must be balanced. The drier may be of the

cabinet type illustrated in Fig. 2, or it can be designed so that the workpieces pass through on a conveyor (Fig. 3). If conveyor operation is used, the speed must be coordinated with the required drying cycle.

**Developer Station.** The type and location of developer station depend on whether dry or wet developer is used. For dry developer, the developer station is downstream from the drier, whereas for wet developer, it immediately precedes the drier, following the rinse station.

The dry-developer station usually consists of a simple bin containing the powder. Dried workpieces are dipped into the powder and the excess powder is shaken off. For larger workpieces that are difficult to immerse in the powder, a scoop can be used to throw powder over the surfaces, after which the excess is shaken off. The developer bin should be equipped with an easily removable cover to protect the developer from dust and dirt when not in use.

Dust-control systems are sometimes needed when dry developer is used (Fig. 4).

**Fig. 4** Dry-developer bin equipped with dust-control and reclaimer system

**The inspection station** essentially is a worktable on which workpieces can be handled under proper lighting. For fluorescent methods, the table usually is surrounded by a curtain or hood to exclude most of the white light from the area (see Fig. 2). For visible penetrants, a hood is not necessary.

Black (ultraviolet) lights can consist of batteries of 100 or 400 watt lamps for area lighting, or, in small stations, can be one or two 100 watt spot lamps mounted on brackets from which they can be lifted and moved about by hand. Because of the heat given off by black lights, good air circulation is essential in black-light booths.

For automatic inspection, workpieces are moved through booths equipped with split curtains, either by hand or by conveyor (see Fig. 3).

**Postcleaning Station.** Postinspection cleaning often is necessary to remove all traces of penetrant and developer. Drastic chemical or mechanical methods are seldom required for postcleaning. When justified by the volume of work, an emulsion cleaning line is effective and reasonable in cost. In special circumstances, ultrasonic cleaning may be the only satisfactory way of cleaning deep crevices or small holes. However, solvents or detergent-aided steam or water is almost always sufficient. The use of steam with detergent is probably the most effective of all methods.

## Selection of Penetrant System

Size, shape, and weight of workpieces, as well as number of similar workpieces to be inspected, can influence the selection of a penetrant system.

**Sensitivity and Cost.** The required level of sensitivity and cost usually are the most important factors in selecting a system. The methods capable of the greatest sensitivity are also the most costly. There are many inspection operations that require the ultimate in sensitivity, but there are also many where extreme sensitivity not only is not required, but also can produce misleading results.

On a practical basis, the three major penetrant systems are broken down into six systems or variations of systems. The six systems, in order of decreasing sensitivity and decreasing cost are:

1. Postemulsifiable fluorescent
2. Solvent-removable fluorescent
3. Water-washable fluorescent
4. Postemulsifiable visible
5. Solvent-removable visible
6. Water-washable visible

Table 3 compares the sensitivities and uses of the six systems.

Table 3 A comparison of penetrant systems

Water washable	Postemulsifiable	Solvent removable
Visible dye penetrants		
<b>Lowest in sensitivity</b>	Higher sensitivity than water washables	Where water rinse is not feasible, or desirable
<b>Suited for large surface areas</b>	Suited for large surface areas	For spot inspections
	Suited for large quantities of similar objects	Recommended for small areas and simple geometries
Fluorescent penetrants		
<b>Lowest in sensitivity of fluorescent penetrants</b>	Higher sensitivity than water washable fluorescent penetrants	Higher sensitivity than solvent-removable visible penetrant
<b>Suited for large surface areas</b>	Suited for large quantities of similar articles	Where water rinse is not feasible or desirable
<b>Suited for large quantities of similar objects</b>	Suited for wide, shallow discontinuities and tight cracks	For spot inspections
<b>Suited for deep, narrow discontinuities</b>	Contaminants must be removed prior to inspection	Recommended for small areas and simple geometries
<b>Recommended for rough surfaces (i.e., sand castings)</b>	Suited for stress, intergranular, and grinding cracks	

For environmental reasons, water washable penetrant systems are used even though the solvent system would be preferable.

Processing Cycles for Water-Washable Systems

After the workpieces have been precleaned, processing for penetrant inspection should begin immediately. A processing flow diagram for the water-washable system, from precleaning to postcleaning, is presented in Fig. 5. Time in each station, equipment used, and other factors can vary widely, depending on workpiece size and shape, production quantities of similar workpieces, and required sensitivity.

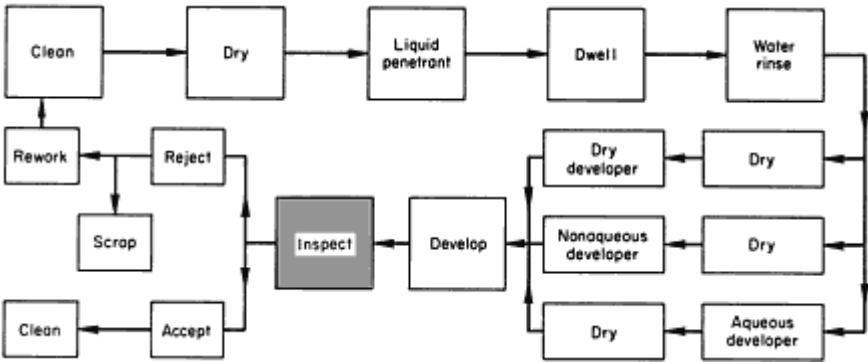

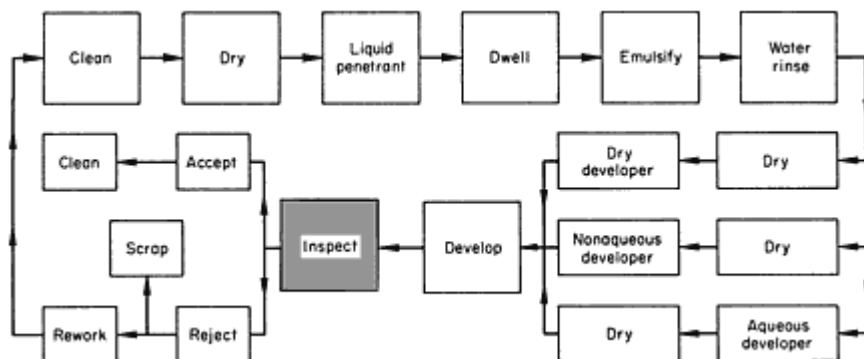

Fig. 5 Processing flow diagram for the water-washable, liquid-penetrant system

Processing Cycles for Postemulsifiable Systems

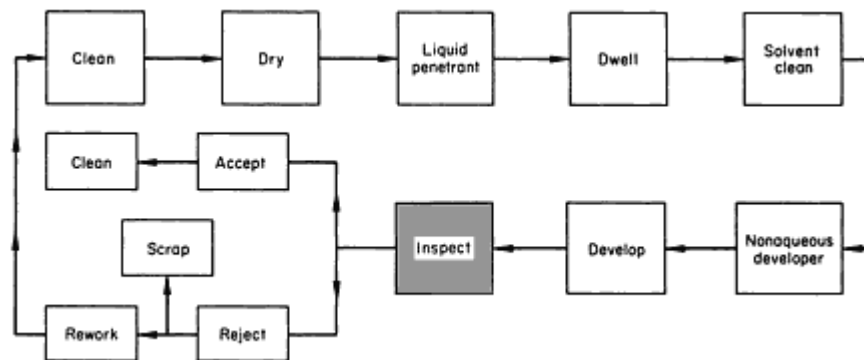

As indicated by the flow diagram in Fig. 6, the processing cycle for the postemulsifiable system is the same as for the water-washable system (see preceding description) except that the workpieces are dipped or otherwise treated with the emulsifier immediately following the dwell period that succeeds the penetrant treatment.

**Fig. 6** Processing flow diagram for the post-emulsifiable lipophilic (oil-base) liquid-penetrant system. For hydrophilic (water-base) systems, an extra prerinse step is required between the penetrant dwell and emulsifying steps.

## Processing Cycles for Solvent-Removable Systems

The basic sequence of operations for the solvent-removable, liquid-penetrant system is generally similar to that followed for the other systems. A typical sequence is shown by the flow diagram in Fig. 7. A notable difference is that with the solvent-removable system, excess penetrant very often is wiped from the workpiece.

**Fig. 7** Processing flow diagram for the solvent-removable, liquid-penetrant system

In practice, however, the techniques of the solvent-removable system are likely to be quite different from those of the other systems--largely because of differences in application. The solvent-removable system is very useful when inspection must be done in areas where it is not convenient to use water.

## Techniques Using Portable Equipment

Liquid-penetrant inspection is one inspection method where the testing materials can be brought to the work site when the workpiece cannot be brought to the inspection area. Portable penetrant inspection, by the solvent-removable system, is used extensively to inspect welded joints where only limited areas are being examined and where total immersion of the weldment would be impractical. In general, the methods and procedures used with portable equipment essentially are the same as those used with fixed, immersion-type inspection equipment.

**Portable kits** are available for both the fluorescent and the visible solvent-removable systems. The three components--cleaner, penetrant, and developer--are packaged both in bulk containers and in aerosol spray cans. The choice between spray and swabbing depends on the type and size of defect anticipated, the size of the area to be tested, and the degree of precleaning and postcleaning to be performed. Cleaning and penetrant removal is done using lint-free cloths and paper towels.

## Specifications and Standards

It has not been practical to establish any type of universal standardization due to the wide variety of components and assemblies subjected to penetrant inspection, the differences in the types of discontinuities common to them, and the differences in the degree of integrity required. Generally, quality standards for the types of discontinuities detected by penetrant inspection are established by one or more of the following methods:

- Adoption of standards that have been successfully used for similar workpieces
- Evaluation of the results of penetrant inspection by destructive examination
- Experimental and theoretical stress analysis

**Specifications.** A specification is a document that typically delineates design and performance requirements. A specification should include the methods of inspection and the requirements based on the inspection or test procedure. However, this is difficult with penetrant inspection; wording in quality specifications often is ambiguous and meaningless.

Specifications applicable to penetrant inspection generally are divided into two broad categories: those involving materials and equipment and those concerning methods and standards. There are several standards and specifications that are in common use; some are listed in Table 4.

**Table 4 Selected standards and specifications for liquid penetrant inspection**

Number	Title or explanation of standard or specification
ASTM standards	
<b>ASTM E 165</b>	Standard Practice for Liquid-Penetrant Inspection Method
<b>ASTM E 270</b>	Standard Definitions of Terms Relating to Liquid-Penetrant Inspection
<b>ASTM E 1208</b>	Standard Method for Fluorescent Liquid-Penetrant Examination Using the Lipophilic Post-Emulsification Process
<b>ASTM E 1209</b>	Standard Method for Fluorescent-Penetrant Examination Using the Water-Washable Process
<b>ASTM E 1210</b>	Standard Method for Fluorescent-Penetrant Examination Using the Hydrophilic Post-Emulsification Process
<b>ASTM E 1219</b>	Standard Method for Fluorescent-Penetrant Examination Using the Solvent-Removable Process
<b>ASTM E 1220</b>	Standard Method for Visible-Penetrant Examination Using the Solvent-Removable Process
<b>ASTM E 1135</b>	Standard Test Method for Comparing the Brightness of Fluorescent Penetrants
<b>ASTM D 2512</b>	Compatibility of Materials with Liquid Oxygen (Impact-Sensitivity Threshold Technique)
Test for AMS-SAE specifications	
<b>AMS 2647</b>	Fluorescent Penetrant Inspection--Aircraft and Engine Component Maintenance
ASME specifications	
<b>ASME-SEC V</b>	ASME Boiler and Pressure Vessel Code Section V, Article 6
U.S. military and government specifications	
<b>MIL-STD-6866</b>	Military Standard Inspection, Liquid Penetrant
<b>MIL-STD-410</b>	Nondestructive Testing Personnel Qualifications & Certifications
<b>MIL-I-25135</b>	Inspection Materials, Penetrant
<b>MIL-I-25105</b>	Inspection Unit, Fluorescent Penetrant, Type MA-2
<b>MIL-I-25106</b>	Inspection Unit, Fluorescent Penetrant, Type MA-3
<b>MIL-STD-271 (Ships)</b>	Nondestructive Testing Requirements for Metals

**Control Systems.** In conjunction with the specifications listed in Table 4, several methods and several types of standards are used to check the effectiveness of liquid penetrants. One of the oldest and most frequently used methods involves chromium-cracked panels, which are available in sets containing fine, medium, and coarse cracks. Many other types of inspection standards have been produced--often for specific indications needed for a unique application.

Acceptance and rejection standards for liquid penetrant inspection are usually established for each individual item or group of items by the designer. In most cases, acceptance and rejection standards are based on experience with similar items, the principal factor being the degree of integrity required.

# Magnetic-Particle Inspection

## Introduction

MAGNETIC-PARTICLE INSPECTION is used to locate surface and subsurface discontinuities in ferromagnetic materials. The method is based on the fact that when a material or part being tested is magnetized, discontinuities that lie in a direction generally transverse to the direction of the magnetic field cause a leakage field to form at and above the surface of the part. The presence of the leakage field, and, therefore, the presence of the discontinuity, is detected by the use of finely divided ferromagnetic particles applied over the surface. Some of the particles are gathered and held by the leakage field. The magnetically held particles form an outline of the discontinuity and generally indicate its location, size, shape, and extent. Magnetic particles are applied over a surface either as dry particles or as wet particles in a liquid carrier such as water and oil.

Nonferromagnetic materials cannot be inspected by this method. Such materials include aluminum alloys, magnesium alloys, copper and copper alloys, lead, titanium and titanium alloys, and austenitic stainless steels.

**Applications.** The principal industrial uses of magnetic-particle inspection are final inspection, receiving inspection, in-process inspection and quality control, maintenance and overhaul in the transportation industries, plant and machinery maintenance, and inspection of large components.

Although in-process, magnetic-particle inspection is used to detect discontinuities and imperfections in material and parts as early as possible in the sequence of operations, final inspection is required to ensure that rejectable discontinuities and imperfections detrimental to part use and function have not developed during processing.

**Advantages.** The magnetic-particle method is a sensitive means to locate small, shallow surface cracks in ferromagnetic materials. Cracks large enough to be seen by the naked eye can produce an indication, but very wide cracks will not produce a particle pattern if the surface opening is too wide for the particles to bridge.

Discontinuities that do not actually break through the surface also are indicated in many instances using magnetic particle inspection within certain limitations. Fine, sharp discontinuities close to the surface (a long stringer of nonmetallic inclusions, for example) can produce an indication. Indications of deeper discontinuities are less distinct.

**Limitations.** The operator must be aware of certain limitations of magnetic-particle inspection. For example, thin coatings of paint and nonmagnetic coverings, such as plating, adversely affect sensitivity. Other limitations include:

- Workpiece material must be ferromagnetic.
- The direction of the magnetic field must intercept the principal plane of the discontinuity at right angles for best results. This could require two or more sequential inspections with different magnetizations.
- Demagnetization following inspection often is necessary.
- Postcleaning to remove remnants of magnetic particles and carrying solutions on the surface could be required after testing and demagnetization.
- Inspection of very large parts could require very large current.
- Local heating and burning of finished parts and surfaces at the points of electrical contact is possible if not careful.
- Experience and skill in interpreting the significance of magnetic-particle indications is necessary.

## Description of Magnetic Fields

**Magnetized Ring.** When a magnetic material is placed across the poles of a horseshoe magnet having square ends (forming a closed or ring like assembly), the magnetic lines of force flow from the north pole through the magnetic material to the south pole (see Fig. 1a). (Magnetic lines of force flow preferentially through magnetic material rather than through nonmagnetic material or air.) The magnetic lines of force are enclosed within the ringlike assembly because no external poles exist, and iron filings or magnetic particles dusted over the assembly are not attracted to the magnet even though there are lines of magnetic force flowing through it.

**Fig. 1** (a) Horseshoe magnet with a bar of magnetic material across poles forms a closed, ringlike assembly, which will not attract magnetic particles. (b) Ringlike magnet assembly with an air gap, to which magnetic particles are attracted

If one end of the magnet is not square, leaving an air gap between the magnet end and the magnetic material, the poles still attract magnetic materials. Magnetic particles cling to the poles and bridge the gap between them, as shown in Fig. 1(b). A radial crack in a round magnetized piece creates north and south magnetic poles at the edges of the crack. Magnetic particles are attracted to the poles created by such a crack, forming an indication of the discontinuity.

The magnetic fields at cracks and other physical and magnetic discontinuities in the surface are called leakage fields. The strength of a leakage field determines the number of magnetic particles that will gather to form indications; strong indications are formed at strong fields, and vice versa. The density of the magnetic field determines its strength and is partly governed by the shape, size, and material of the part being inspected.

**Magnetized Bar.** A straight piece of magnetized material (bar magnet) has a pole at each end. Magnetic lines of force flow through the bar from the south pole to the north pole. Because the magnetic lines of force within the bar magnet run the length of the bar, it is said to be longitudinally magnetized or to contain a longitudinal field.

If a bar magnet is broken into two pieces, a leakage field with north and south poles is created between the pieces, as shown in Fig. 2(a). The field exists even if the fracture surfaces are brought together (see Fig. 2b). If the magnet is cracked but not broken completely into two pieces, a similar result occurs. A north and a south pole form at opposite edges of the crack, just as though the break were complete (see Fig. 2c). It is this field that attracts the iron particles that outline the crack. The strength of the poles is different from that of the completely broken pieces; it is a function of the crack depth and the width of the air gap at the surface.

**Fig. 2** Leakage fields between two pieces of a broken bar magnet (a) with magnet pieces apart, and (b) with magnet pieces together (simulating a flaw). (c) Leakage field at a crack in a bar magnet

**Circular Magnetization.** Electric current passing through any straight conductor such as a wire or bar creates a circular magnetic field around the conductor. The passage of current through a ferromagnetic conductor induces a magnetic field in both the conductor and surrounding space. A part magnetized in this manner is said to have a circular field or to be circularly magnetized, as shown in Fig. 3(a).

**Fig. 3** Magnetized bars showing directions of magnetic field: (a) Circular. (b) Longitudinal

**Longitudinal Magnetization.** Electric current also can be used to create a longitudinal magnetic field in magnetic materials. When current is passed through a coil of one or more turns, a magnetic field is established lengthwise, or longitudinally, within the coil, as shown in Fig. 3(b). The nature and direction of the field around the conductor that forms the turns of the coil produce longitudinal magnetization.

**Effect of Flux Direction.** To form an indication, the magnetic field must approach a discontinuity at a sufficiently large angle to cause the magnetic lines of force to leave the part and return after bridging the discontinuity. An intersection approaching  $90^\circ$  produces the best results. For this reason, discontinuity direction, size, and shape are important. The direction of the magnetic field, and the strength of the field in the area of the discontinuity also are important for optimum results.

Figure 4(a) illustrates a condition where the current is passed through the part, causing formation of a circular field around the part. Under normal circumstances, there would be no indication of the presence of a discontinuity such as one designated "A" in Fig. 4(a) because it is regular in shape and lies in a direction parallel to that of the magnetic field. A discontinuity having an irregular shape and predominantly parallel to the magnetic field, "B," has a good chance to form a weak indication. Where the predominant direction of the discontinuity is at a  $45^\circ$  angle to the magnetic field, such as "C," "D," and "E," the conditions are more favorable for detection regardless of the shape of the discontinuity. Discontinuities whose predominant directions, regardless of shape, are at a  $90^\circ$  angle to the magnetic field ("F," "G," and "H") produce the most pronounced indications.

**Fig. 4** Effect of direction of magnetic field or flux flow on detectability of discontinuities having various orientations. See text for discussion. (a) Circular magnetization. (b) Longitudinal magnetization

Figure 4(b) shows a bar that has been longitudinally magnetized. Discontinuities "L," "M," and "N," which are at about 45° to the magnetic field, would produce detectable indications, as they would in a circular field. Discontinuities "J" and "K" would display pronounced indications, but discontinuities "P," "Q," and "R" would probably not be detected.

**Magnetization Methods.** In magnetic-particle inspection, the magnetic particles can be applied to the part while the magnetizing current is flowing and after the current has ceased to flow, depending largely on the magnetization retention (residue magnetism) of the part. The former technique is known as the "continuous method"; the latter, as the "residual method."

If residual magnetism does not provide a leakage field strong enough to produce readable indications when magnetic particles are applied to the surface, the part must be continuously magnetized during application of particles. Consequently, the residual method can be used only on materials having sufficient retentivity; harder materials usually have higher retentivity. The continuous method is the only method used on low-carbon steels and iron having little or no retentivity.

## Magnetizing Current

Both direct and alternating currents are suitable to magnetize parts for magnetic-particle inspection. Magnetic-field strength, direction, and distribution are greatly affected by the current type used for magnetization.

The fields produced by direct and alternating current have different characteristics. The important difference in magnetic-particle inspection is that fields produced by direct current generally penetrate the cross section of the part, whereas fields produced by alternating current are confined to the metal at or near the surface of the part, which commonly is known as the skin effect. Therefore, alternating current should not be used to search for subsurface discontinuities.

**Direct Current.** The best source of direct current is rectified alternating current. Both single-phase and three-phase alternating current are furnished commercially. Rectifiers convert reversing alternating current to unidirectional current. Rectified three-phase alternating current is nearly equivalent to straight direct current for purposes of magnetic-particle inspection. The only difference between rectified three-phase alternating current and straight direct current is a slight ripple in the value of the rectified current, amounting to only about 5% of the maximum current value.

**Alternating current,** which must be single-phase when used directly to magnetize a part, is used directly from commercial power lines at a frequency of 50 or 60 Hz. When used for magnetizing, line voltage is stepped down by means of a transformer to the lower voltages required. Magnetizing currents of several thousand amperes often are used at the low voltages.

One problem in using alternating current is that residual magnetism in the part might be lower than that of the magnetism generated by the peak current of the alternating-current cycle. This is because the level of residual magnetism depends on where in the cycle the current is discontinued.

## Power Sources

**Portable equipment** is available in lightweight (16 to 41 kg, or 35 to 90 lb) power-source units that are easily transported to an inspection site. Generally, portable units are designed to use 115, 230 and 460 V alternating current, and supply 750 to 1500 A magnetizing-current outputs in half-wave or alternating current. Small, lightweight pulsed dc units that can produce up to 7000 A of magnetizing current also are available.

**Mobile Units** generally are mounted on wheels to facilitate transport to an inspection site. Mobile equipment usually supplies full-wave, half-wave, and alternating magnetizing-current outputs. Part inspection is accomplished by use of flexible cables, yokes, prod contacts, contact clamps, and coils. Instruments and controls are mounted on the front of the unit. Magnetizing current usually is controlled using a remote-control switch connected to the unit by an electrical cord. Quick-coupling connectors for connecting magnetizing cables are on the front of the unit.

Mobile equipment usually is powered by single-phase or three-phase, 60 Hz alternating current (230 and 460 V), and has an output range of 1500 to 10,000 A.

**Stationary equipment** is available in both general-purpose and special-purpose units. The general-purpose unit is primarily used in the wet method, and has a built-in tank containing a bath pump, which continuously agitates the bath and forces the fluid through hoses onto the part being inspected. Pneumatically operated contact heads, together with a rigid-type coil, provide capabilities for both circular and longitudinal magnetization. Self-contained ac and dc power supplies are available in amperage ratings from 1000 to 10,000 A.

Stationary power packs function as high-amperage, magnetizing-current sources used in conjunction with special fixtures, and with cable-wrap and clamp-and-contact techniques. Rated output varies from a customary 4000 to 6000 A to as high as 30,000 A. Higher-amperage units are used for over-all magnetization of large forgings and castings, which otherwise would require systematic prod inspection at much lower current levels. Some units feature three output circuits, which are systematically energized in rapid sequence, either electrically or mechanically, to effectively magnetize a part in several directions at virtually the same time. This allows exposure of discontinuities lying in any direction after only a single processing step.

Special-purpose stationary units are designed to handle and inspect large quantities of similar items. Generally, conveyors, automatic markers, and alarm systems are included in such units to expedite parts handling and disposition.

## Methods of Generating Magnetic Fields

A basic requirement of magnetic-particle inspection is to properly magnetize the part so leakage fields created by discontinuities attract magnetic particles. While permanent magnets can accomplish this to some degree, magnetization generally is produced using electromagnets and the magnetic field associated with the flow of electric current. Basically, magnetization is derived from the circular magnetic field generated when an electric current flows through a conductor. The direction of the field is dependent on the direction of current flow.

**Yokes.** Two basic types of yokes commonly used for magnetizing purposes are: permanent-magnets and electromagnetic yokes. Both are hand held, and, therefore, are mobile.

Electromagnetic yokes (see Fig. 5) consist of a coil wound around a U-shape core of soft iron. The legs of the yoke are either fixed or adjustable. Adjustable legs permit changing the contact spacing and the relative angle of contact to accommodate irregular-shape parts. Unlike a permanent-magnet yoke, an electromagnetic yoke can readily be switched on or off, a feature that makes it convenient to apply and remove the yoke from the test piece.

**Fig. 5** Electromagnetic yoke, showing position and magnetic field to detect discontinuities parallel to a weld bead. Discontinuities across a weld bead can be detected by placing the contact surfaces of the yoke next to and on either side of the bead (rotating yoke about 90° from position shown here).

Electromagnetic yoke design is based on the use of either direct or alternating current, or both. The flux density of the magnetic field produced by the direct-current type can be changed by varying the amount of current in the coil. The direct-current type of yoke has greater penetration, whereas the alternating-current type concentrates the magnetic field at the surface of the test piece, providing good sensitivity for revealing surface discontinuities over a relatively narrow area. Yokes using alternating current for magnetization have various applications, and can be used for demagnetization as well. Discontinuities generally need to be centrally located in the area between pole pieces and oriented perpendicular to an imaginary line connecting them (see Fig. 5) to be exposed.

In operation, the part completes the magnetic path for the flow of magnetic flux. The yoke is a source of magnetic flux, and the part becomes the preferential path completing the magnetic circuit between the poles. (In Fig. 5, only those portions of the flux lines near the poles are shown.)

**Coils.** Single-loop and multiple-loop coils (conductors) are used for longitudinal magnetization of components (see Fig. 3b and 4b). The field within the coil has a definite direction, corresponding to the direction of the lines of force running through it. The flux density passing through the interior of the coil is proportional to the product of the current,  $I$ , in amperes, and the number of turns in the coil,  $N$ . Thus, the magnetizing force of such a coil can be varied by varying either the current or the number of turns in the coil.

Coils for large parts can be made by winding several turns of a flexible cable around the part. Care must be taken to ensure that no indications are concealed beneath the cable.

Portable magnetizing coils are available that can be plugged into an electrical outlet. These coils can be used for in-place inspection of shaft-like parts in railroad shops, aircraft-maintenance shops, and shops for automobile, truck, and tractor repair. Transverse cracks in spindles and shafts are easily detected using such coils.

Most coils used for magnetizing are short, especially those wound on fixed frames. The relation of the length of the part being inspected to the width of the coil must be considered. For a simple part, the effective over-all distance that can be inspected is 150 to 225 mm (6 to 9 in.) on either side of the coil. Thus, a part 300 to 450 mm (12 to 18 in.) long can be inspected using a normal coil approximately 25 mm (1 in.) thick. In testing longer parts, either the part must be moved at regular intervals through the coil, or the coil must be moved along the part.

The ease with which a part can be longitudinally magnetized in a coil is significantly related to the length-to-diameter ( $L/D$ ) ratio of the part. This is due to the demagnetizing effect of the magnetic poles that are set up at the ends of the part. This demagnetizing effect is pronounced for  $L/D$  ratios of less than 10 to 1, and very significant for ratios of less than 3 to 1.

1. Where the  $L/D$  ratio is extremely unfavorable, pole pieces of similar cross-sectional area can be introduced to effectively increase the length of the part and consequently improve the  $L/D$  ratio.

**Central Conductors.** For many tubular and ring-shaped parts, it is advantageous to use a separate conductor to carry the magnetizing current, rather than the part itself. Such a conductor, commonly referred to as a central conductor, is threaded through the inside of the part (see Fig. 6) and is a convenient way to circularly magnetize a part without the need to make direct contact to the part itself. Central conductors are made of solid and tubular nonmagnetic and ferromagnetic materials that are good electrical conductors.

**Fig. 6** Use of central conductors for circular magnetization of (a) long hollow cylindrical parts and (b) short hollow cylindrical and ringlike parts to detect discontinuities on inner and outer surfaces

The basic rules regarding magnetic fields around a circular conductor carrying direct current are:

- The magnetic field outside a conductor of uniform cross section is uniform along the length of the conductor.
- The magnetic field is  $90^\circ$  to the path of the current through the conductor.
- The flux density outside the conductor varies inversely with the radial distance from the center of the conductor.

**Direct-Contact Method.** For small parts having no openings through the interior, circular magnetic fields are produced by direct contact to the part. Parts are clamped between contact heads (head shot), generally on a bench unit (see Fig. 7) that incorporates the source of current. A similar unit can be used to supply the magnetizing current to a central conductor (see Fig. 6).

**Fig. 7** Bench unit used to circularly magnetize workpieces clamped between contact heads (direct-contact, head-shot method). The coil on the unit can be used for longitudinal magnetization.

Contact heads must be constructed so the surfaces of the part are not damaged--either physically by pressure, or structurally by heat from arcing and from high resistance at the points of contact. Such heat can be especially damaging to hardened surfaces such as bearing races.

For complete inspection of a complex part, it could be necessary to attach clamps at several points on the part or to wrap cables around the part to get fields in the proper directions at all points on the surface. This often requires several magnetizations. The need for multiple magnetizations can be minimized by using the overall magnetization method, multidirectional magnetization, and induced-current magnetization.

**Prod Contacts.** Magnetization often is done using prod contacts to inspect large and massive parts too bulky to be put into a unit having clamping contact heads. The method passes current directly through the part or through a local portion of it (see Fig. 8). Such local contacts do not always produce true circular fields, but are very convenient and practical in many applications; prod contacts often are used in magnetic-particle inspection of large castings and weldments.

**Fig. 8** Single and double prod contacts. Discontinuities are detected by a magnetic field generated between the

prods.

Prod contacts have many advantages. Easy portability makes them convenient to use for field inspection of large tanks and welded structures. Sensitivity to defects lying wholly below the surface is greater with this method of magnetization than with any other, especially when half-wave current is used in conjunction with dry powder and the continuous method of magnetization.

The use of prod contacts has some limitations:

- Suitable magnetic fields exist only between and near the prod contact points. These points are seldom more than 300 mm (12 in.) apart, and usually much less. Therefore, it sometimes is necessary to relocate the prods so the entire surface of a part can be inspected.
- Interference of the external field that exists between the prods sometimes makes observation of pertinent indications difficult. The strength of the current that can be used is limited by this effect.
- Great care must be used to avoid burning the part under the contact points. Burning can be caused by dirty contacts, insufficient contact pressure, and excessive currents.

**Induced current** provides a convenient method to generate circumferential magnetizing current in ring-shaped parts without making electrical contact. This is accomplished by properly orienting the ring within a magnetizing coil such that it links or encloses lines of magnetic flux (flux linkage), as shown in Fig. 9(a). As the level of magnetic flux changes (increases or decreases), a current flows around the ring in a direction opposing the change in flux level. The magnitude of this current depends on the total flux linkages, rate of flux-linkage changes, and the electrical impedance associated with the current path within the ring. Increasing the flux linkages and the rate of change increases the magnitude of current induced in the ring. The circular field associated with this current takes the form of a toroidal magnetic field that encompasses all surface areas on the ring and that is conducive to revealing circumferential types of discontinuities. This is shown schematically in Fig. 9(b).

**Fig. 9** Induced-current method of magnetizing a ring-shape part. (a) Ring being magnetized by induced current. Current direction corresponds to decreasing magnetizing current. (b) Resulting induced current and toroidal magnetic field in a ring

The choice of magnetizing current for the induced-current method depends on magnetic properties of the part to be inspected. In instances where the residual method is applicable, such as for most bearing races and similar parts having high magnetic retentivity, direct current is used to magnetize. The rapid interruption of the current by quick-break circuitry results in a rapid collapse of the magnetic flux and the generation of a high-amperage, circumferentially directed single pulse of current in the part. Thus, the part is residually magnetized with a toroidal field, and subsequent application of magnetic particles produces indications of circumferentially oriented discontinuities.

A similar type of current of opposite polarity and lower amplitude is associated with the increasing flux due to the rapidly rising current, but in this case, only that current generated by the sudden breaking of the direct current serves a useful purpose.

Passing an alternating current through a conductor generates a fluctuating magnetic field as the level of magnetic flux rapidly changes from a maximum value in one direction to an equal value in the opposite direction. This is similar to the current that flows in a single-shortened-turn secondary of a transformer. The alternating induced current in conjunction with the continuous method renders the method applicable for processing magnetically soft, or less retentive, parts.

The induced-current method, in addition to eliminating the possibility of damaging the part, also is capable of magnetizing in one operation parts that otherwise would require more than one head shot. Two examples of this type of part are illustrated in Fig. 10 and 11. These parts cannot be completely processed by one head shot to reveal circumferential defects, because regions at the contact points are not properly magnetized. Therefore, a two-step inspection process is required for full coverage, with the part rotated approximately 90° prior to the second step. Conversely, the induced-current method provides full coverage in one processing step. The disk-shaped part shown in Fig. 11 presents an additional problem when the contact method is used to reveal circumferential defects in the vicinity of the rim. Even when a two-step process is used, as with the ring in Fig. 10, the primary current path through the part might not develop a circular field of sufficient magnitude in the rim area. The induced current can be selectively concentrated in the rim area by proper polepiece selection to provide full coverage (rim area) in a single processing step. The pole pieces depicted in Fig. 11(b) are hollow and cylindrical, with one on each side of the disk. The pole pieces direct the magnetic flux through the disk such that the rim is the only portion constituting a totally enclosing current path.

**Fig. 10** Current and magnetic-field distribution in a ring being magnetized with a head shot. Because regions at contact points are not magnetized, two operations are required for full coverage. With use of the induced-current method, parts of this shape can be completely magnetized in one operation.

**Fig. 11** Current paths in a rimmed disk-shape part magnetized by a head shot and by induced current. (a) Head-shot magnetization. (b) Induced-current magnetization

Pole pieces used in conjunction with this method are preferably constructed of laminated ferromagnetic material. This minimizes the flow of eddy currents within the pole pieces, which detract from the induced (eddy) current developed within the part being processed. Pole pieces also can be made of rods, wire-filled nonconductive tubes, and thick-wall pipe, saw cut to break up the eddy-current path.

## Magnetic Particles and Suspending Liquids

Magnetic particles are classified according to the vehicle by which they are carried to the part: by air (dry-particle method) and by a liquid (wet-particle method). Magnetic particles consist of fine iron; black, brown, and red iron oxide (magnetite  $\text{Fe}_3\text{O}_4$ ); brown iron oxide ( $\gamma\text{Fe}_2\text{O}_3$ ), ferrosin ferrites ( $\text{Ni}_x\text{Fe}_{2-x}\text{O}_4$ ), and some nickel alloys. Important particle characteristics include magnetic properties, size, shape, density, mobility, and degree of visibility and contrast.

**Magnetic Properties.** Particles used for magnetic-particle inspection should have high magnetic permeability so they can be readily magnetized by the low-level leakage fields that occur around discontinuities and can be drawn by these fields to discontinuities to form readable indications. (The fields at very fine discontinuities can be extremely weak.) Particles also should have low coercive force and low retentivity.

**Effect of Particle Size.** Large, heavy particles are not likely to be arrested and held by weak fields when moving over a part surface, but fine particles are held by very weak fields. However, extremely fine particles also can adhere to surface areas where there are no discontinuities (especially if the surface is rough) and form confusing backgrounds. Coarse, dry particles fall too fast and are likely to bounce off the part surface without being attracted by the weak leakage fields at imperfections. Finer particles can adhere to fingerprints, rough surfaces, and soiled or damp areas, thereby obscuring indications.

**Effect of Particle Shape.** Particle shape can be spherical, needlelike, and rodlike in form. Elongated needles tend to develop into little magnets with north-south poles, and, therefore, form into distinct, well-defined patterns, which provide a more clear indication of the presence of a weak magnetic field. However, there is an optimum elongation aspect ratio for particles. The ability of dry particles to flow freely and to form uniformly dispersed clouds of powder that will spread evenly over a surface is a necessary characteristic for rapid and effective dry-powder testing. The behavior of wet powder (suspensions) is less dependent on particle shape.

**Visibility and contrast** are enhanced by using particles with colors that make them easy to see against the color of the surface of the part being inspected. The natural color of the metallic powders used in the dry method is silver gray, but pigments are used to color them. The colors of particles for the wet method are limited to the black and red of the iron oxides commonly used as the base for wet particles.

For increased visibility, particles are coated with fluorescent pigment by the manufacturer. Inspection is conducted in total or partial darkness, using ultraviolet light to activate the fluorescent dyes. Inspected surfaces should be illuminated with a minimum of 1000  $\mu\text{W}/\text{cm}^2$  of black light, with a maximum of 2 ftc of general visible light at the inspection station. Fluorescent magnetic particles are available for use with both wet and dry methods. The fluorescent wet method is more common.

**Dry particles** are available in a variety of colors, some of them fluorescent. Color-contrast powders should be viewed in ordinary light of a minimum of 100 ftc at the inspection station. Dry particles are most sensitive for use on very rough surfaces and for detecting flaws beneath the surface. They are ordinarily used with portable equipment. Reclaiming and reusing dry particles is not recommended.

**Wet particles** are best suited for detection of fine discontinuities such as fatigue cracks. Wet particles commonly are used in stationary equipment where the bath can remain in use until contaminated or until the properties of the particles are exhausted. They also are used in field operations with portable equipment, but the bath should be agitated constantly.

**Oil Suspending Liquid.** The oil used as a suspending liquid for magnetic particles should be an odorless, well-refined light petroleum distillate of low viscosity and a high flash point. Oil viscosity should not exceed 0.03  $\text{cm}^2/\text{s}$  (3 cSt) when tested at 38 °C (100 °F), and must not exceed 0.05  $\text{cm}^2/\text{s}$  (5 cSt) when tested at the temperature prevailing at the point on the part being inspected. Above 0.05  $\text{cm}^2/\text{s}$ , the movement of magnetic particles in the bath is sufficiently retarded to have a definite effect in reducing buildup, and therefore visibility, of an indication of a small discontinuity. Parts should be precleaned to remove oil and grease because oil from the surface builds up in the bath and increases its viscosity.

**Water Suspending Liquid.** The use of water instead of oil for magnetic-particle, wet-method baths reduces costs and eliminates bath flammability. Water-suspendible particle concentrates include the necessary wetting agents, dispersing agents, rust inhibitors, and antifoam agents.

**Strength of the bath** is a major factor in determining the quality of the indications obtained. The proportion of magnetic particles in the bath must be maintained at a uniform level. The strength of indications varies with varying concentration, which could cause misinterpretation of indications. Fine indications can be missed entirely with a weak bath. High concentrations produce a confusing background and excessive adherence of particles at external poles, which interferes with distinct indications of extremely fine discontinuities.

The best method to ensure optimum bath concentration for any given combination of equipment, bath application, and type of part and discontinuities involved is to test the bath using parts with known discontinuities. Bath strength can be adjusted until satisfactory indications are obtained. This bath concentration can then be adopted as standard for similar conditions.

Bath concentration can be measured reasonably accurately using the settling test. In the test, 100 mL (0.03 gal) of well-agitated bath is placed in a pear-shape centrifuge tube. The volume of solid material that settles out after a predetermined interval (usually 30 min) is measured on the graduated cylindrical part of the tube. Dirt in the bath also will settle and usually shows as a separate layer on top of the oxide. The layer of dirt usually is easily distinguishable because it is different in color from the magnetic particles.

## Ultraviolet Light

A mercury-vapor lamp is a convenient source of ultraviolet light, emitting a light spectrum that has several intensity peaks within a wide band of wavelengths. When used for a specific purpose, emitted light is passed through a suitable filter so only a relatively narrow band of ultraviolet wavelengths is available. For example, a band in the long-wave ultraviolet spectrum is used for fluorescent liquid-penetrant or magnetic-particle inspection.

Fluorescence is the quality of an element or combination of elements to absorb the energy of light at one frequency and emit light of a different frequency. Fluorescent materials used in liquid-penetrant and magnetic-particle inspection are combinations of elements selected to absorb light in the peak energy band of the mercury-vapor lamp fitted with a Kopp glass filter. This peak occurs at about 365 nm (14.4  $\mu$ in.). The ability of fluorescent materials to emit light in the greenish-yellow wavelengths of the visible spectrum depends on the intensity of ultraviolet light at the workpiece surface.

## Detectable Discontinuities

The usefulness of magnetic-particle inspection in the search for discontinuities or imperfections depends on exactly what types of discontinuities the method is capable of finding. Of importance are the size, shape, orientation, and location of the discontinuity, with respect to its ability to produce leakage fields.

**Surface Discontinuities.** The largest and most important type of discontinuities consists of those that are exposed to the surface. Surface cracks or discontinuities are effectively located using magnetic particles. Surface cracks, such as those shown in Fig. 12, also are more detrimental to the service life of a component than are subsurface discontinuities, and, therefore, they are more frequently the object of inspection.

Fig. 12 Magnetic particle indications of cracks in a large cast splined coupling

Magnetic-particle inspection is capable of locating seams, laps, quenching and grinding cracks, and surface ruptures in castings, forgings, and weldments. The method also can detect surface fatigue cracks developed during service. Magnetizing and particle-application methods can be critical in certain instances, but in most applications the requirements are relatively easily met, because leakage fields usually are strong and highly localized.

To successfully detect a discontinuity, there must be a field of sufficient strength in a generally favorable direction to produce strong leakage fields. For maximum detectability, the field generated in the part should be at right angles to the length of a suspected discontinuity (see Fig. 4). This is especially true if the discontinuity is small and fine.

**Subsurface discontinuities** comprise those voids or nonmetallic inclusions that lie just beneath the surface. Nonmetallic inclusions are present in all steel products to some degree. They occur as scattered individual inclusions, or they may be aligned in long stringers. These discontinuities usually are very small and cannot be detected unless they lie very close to the surface because they produce highly localized but rather weak fields.

## Nonrelevant Indications

Nonrelevant indications are true patterns caused by leakage fields that do not result from the presence of flaws. The term "false indications" is sometimes used to describe this type of indication, because the indication falsely implies the presence of a flaw, even though the particle buildup actually results from a leakage field. There are several possible causes of nonrelevant indications, which require evaluation but should not be interpreted as flaws.

## Demagnetization after Inspection

All ferromagnetic materials retain a residual magnetic field to some degree after being magnetized. This field is negligible in magnetically soft metals, but in harder metals, it can be comparable to the intense fields associated with the special alloys used for permanent magnets.

It is not always necessary to demagnetize parts, but it is essential in many cases, even though it is costly and time consuming. The degree of difficulty in demagnetization depends on the type of metal. Metals having high coercive force are the most difficult to demagnetize. High retentivity is not necessarily related directly to high coercive force, so the strength of the retained magnetic field is not always an accurate indicator of the ease of demagnetizing.

There are several reasons to demagnetize a part after magnetic-particle inspection, or after any other magnetization. Demagnetize if:

- The part is used in an area where a residual magnetic field interferes with the operation of instruments sensitive to magnetic fields, or where it can affect the accuracy of instrumentation incorporated in an assembly that contains the magnetized part.
- Chips might adhere to the surface during subsequent machining and adversely affect surface finish, dimensions, and tool life.
- Chips might adhere to the surface during cleaning operations and interfere with subsequent operations such as painting and plating.
- Abrasive particles might be attracted to magnetized parts, such as bearing surfaces, bearing raceways, and gear teeth, resulting in abrasion and galling, and obstruction of oil holes and grooves.
- Strong residual magnetic fields can deflect the arc away from the point at which it should be applied during some arc-welding operations.
- A residual magnetic field in a part can interfere with remagnetization of the part at a field intensity too low to overcome the remanent field in the part.

Demagnetization might not be necessary if:

- Parts are made of magnetically soft steel having low retentivity; such parts usually will become demagnetized as soon as they are removed from the magnetizing source
- The parts are subsequently heated above their Curie point and consequently lose their magnetic

properties

- The magnetic field is such that it will not affect the function of the part in service
- The part is to be remagnetized for further magnetic-particle inspection or for some secondary operation in which a magnetic plate or chuck may be used to hold the part.

The last reasons for demagnetizing and not demagnetizing seem to be contradictory. The establishment of a longitudinal field after circular magnetization negates the circular field because two fields in different directions cannot exist in the same part at the same time. If the magnetizing force is not of sufficient strength to establish the longitudinal field it should be increased, or other steps taken to ensure that the longitudinal field actually has been established. The same is true in changing from longitudinal to circular magnetization. If the two fields (longitudinal and circular) are applied simultaneously, a field is established that is a vector combination of the two in both strength and direction. However, if the fields are impressed successively, the last field applied, if strong enough to establish itself in the part, destroys the remanent field from the previous magnetization.

# Magnetic Field Testing

## Introduction

MAGNETIC FIELD TESTING includes some widely used nondestructive evaluation methods to inspect magnetic materials for defects such as cracks, voids, and inclusions. Magnetic methods also are used to assess other material properties, such as grain size, texture, and hardness. Because of this diversion of applications, it is natural to divide the field of magnetic materials testing into two parts, one directed toward defect detection and characterization and the other aimed at material properties measurements.

All magnetic flaw-detection methods rely in some way on the detection and measurement of the magnetic flux leakage field near the surface of the material, which is caused by the presence of the flaw. Material properties characterization methods rely on bulk measurements of the hysteretic properties of material magnetization or of some related phenomenon, such as Barkhausen noise.

## Principles of Magnetic Leakage Field Testing

**Origin of Defect Leakage Fields.** Figure 1 illustrates the origin of the flaw leakage field. A uniformly magnetized rod, shown in Fig. 1(a), consists of a large number of elementary magnets aligned with the direction of magnetization. At the surfaces, magnetic poles are uncompensated and produce a magnetic field in the region surrounding the specimen; flux lines connect uncompensated elementary poles.

**Fig. 1** Origin of defect leakage fields. (a) Magnetic flux lines of a magnet without a defect. (b) Magnetic flux lines of a magnet with a surface defect

If a slot is cut in the rod, as illustrated in Fig. 1(b), the poles on the surface of the slot are now also uncompensated and produce a localized magnetic field near the slot. The additional magnetic field represented by the extra flux lines is the leakage field associated with the slot.

**Generation of a Magnetic Field.** In some ferromagnetic materials, the residual field (the field that remains after removal of an external magnetizing field) often is adequate for surface flaw detection. In practice, however, residual magnetization is rarely used because use of an applied magnetizing field ensures that the material is in the required magnetic state and because applied fields provide more flexibility. (It is possible to produce high or low flux density.)

Control of the strength and direction of the magnetization is useful to improve flaw detectability and to discriminate among different types of flaws. In general, the magnitude of the magnetization should be selected to maximize the flaw leakage field with respect to other field sources that might interfere with flaw detection; optimum magnetization usually is difficult to determine in advance of a test and is often approached by trial-and-error experimentation. The direction of the field should be perpendicular to the largest flaw dimension to maximize the effect of the flaw on the leakage field.

A magnetic field can be generated in a specimen either directly or indirectly. In direct magnetization, current is passed directly through the part. With the indirect approach, magnetization is induced by placing the part in a magnetic field that is generated by an adjacent current conductor or permanent magnet. Methods of magnetizing a part both directly and indirectly are illustrated schematically in Fig. 2.

**Fig. 2** Methods of magnetization. (a) Head-shot method. (b) Magnetization with prods. (c) Magnetization with a central conductor. (d) Longitudinal magnetization. (e) Yoke magnetization

The flaw leakage field can be detected using magnetic field sensors, such as the inductive coil and the Hall effect device.

The inductive coil sensor is based on Faraday's law of induction, which states that the voltage induced in the coil is proportional to the number of turns in the coil multiplied by the time rate of change of the flux threading the coil.

Detection of a magnetostatic field requires that the coil be in motion so that the flux through the coil changes with time. The principle is illustrated in Fig. 3, where the coil is oriented to sense the change in flux parallel to the surface of the specimen. Figure 4 shows the flux density typical of the leakage field from a slot and corresponding signal search as in Fig. 3.

Fig. 3 Flux leakage measurement using a search coil

Fig. 4 Leakage flux and search coil signal as a function of position

While an inductive coil measures flux gradient, a Hall effect sensor directly measures the component of the flux itself in the direction perpendicular to the sensitive area of the device. A Hall effect sensor can be scanned over the surface to be inspected at any rate because its response does not depend on probe motion. Hall effect sensors are more difficult to fabricate, are more fragile, and require more complex electronics than coil sensors.

Other magnetic field sensors include the flux gate magnetometer, magnetoresistive sensors, magnetic resonance sensors, and magneto-graphic sensors (in which the magnetic field at the surface of a part is registered on a magnetic tape pressed onto the surface).

**Analysis of Leakage Field Data.** Most leakage-field testing applications require flaw detection and an estimate of the severity.

Flaw characterization is based on the relation of leakage field signal amplitude to flaw size (and depth). Therefore, signal amplitude is a direct measure of flaw severity. This empirical method works well in situations where all flaws have approximately the same shape and where calibration shows that signal amplitude is proportional to the size parameter of concern. A more careful analysis of the relationship between signal and flaw characteristics is required in situations where flaw size varies (such as corrosion pits in steel tubing) and where different types of flaws (such as cracks and pits) are present in the same part to avoid serious errors.

## Principles of Magnetic Characterization of Materials

**Metallurgical and Magnetic Properties.** Metallurgical properties of ferromagnetic materials, such as crystallographic phase, chemical composition, and microstructure, affect their magnetic characteristics, which makes it possible to use magnetic measurements to monitor properties. Some parameters, such as grain size and orientation, dislocation density, and the existence of precipitates, are closely related to measurable characteristics of magnetic hysteresis; that is, to the behavior of the flux density,  $B$ , induced in a material as a function of the magnetic field strength,  $H$ .

Other magnetic properties, such as saturation magnetization, which is the maximum value  $B$  can achieve, and Curie temperature, at which there is a transition to a nonmagnetic state, are less dependent on microstructure, but are sensitive to such factors as crystal structure and chemical composition.

A Hall effect probe is used to measure magnetic field strength parallel to the surface of a part. A signal generator provides a low-frequency magnetizing field, typically of the order of a few Hertz, and the output of the flux measuring coil is integrated over time to give the flux density in the material.

Another magnetic testing method measures Barkhausen noise. As the magnetic field strength,  $H$ , is varied at a very slow rate, discontinuous jumps in the magnetization of the material occur during certain portions of the hysteresis cycle. The jumps are associated with the sudden growth of a series of magnetic domains that have been temporarily stopped from further growth by obstacles such as grain boundaries, precipitates, and dislocations. Therefore, Barkhausen noise is dependent on microstructure and can be used independently of hysteresis measurements, or in conjunction with such measurements, as another method of magnetic testing.

## Applications

**Flaw Detection.** Perhaps the most prevalent use of the flux leakage method is widely used to inspect ferromagnetic tubular products, such as gas pipelines, down hole casing, and a variety of other forms of steel piping. The technique is highly developed for use in petroleum-industry applications, such as inspection of large-diameter pipelines.

In most such tools, sensors are the inductive coil type, oriented to measure the axial component of the leakage field gradient. Data usually are recorded on magnetic tape as the system is propelled down a section of pipe. The recorded signals are compared with those from calibration standards to interpret flaw indications in terms of flaw type and size.

In addition to systems for inspecting rotationally symmetric cylindrical parts, flux leakage inspection is applied to irregular components, such as gear teeth and artillery projectiles.

The flux leakage method also is used to inspect ropes and cables made of strands of ferromagnetic material. One approach is to induce magnetization in the piece by means of an encircling coil energized by a direct current. With this method, the leakage field associated with broken strands is measured using a Hall effect probe or an auxiliary sensor coil.

Another area that uses the flux leakage method is inspection of rolling-element antifriction bearings. A schematic illustration of the method as applied to an inner bearing race is shown in Fig. 5. In this application, the part is magnetized by an electromagnet, as indicated in Fig. 5(a). The race is rotated by a spindle, and the surface is scanned using an induction coil sensor. The active portion of the raceway is inspected by incrementally indexing the sensor across the raceway. Magnetizing fields are applied in the radial and circumferential orientations. Radial field inspection works best for surface flaws, while circumferential field inspection shows greater sensitivity to subsurface flaws.

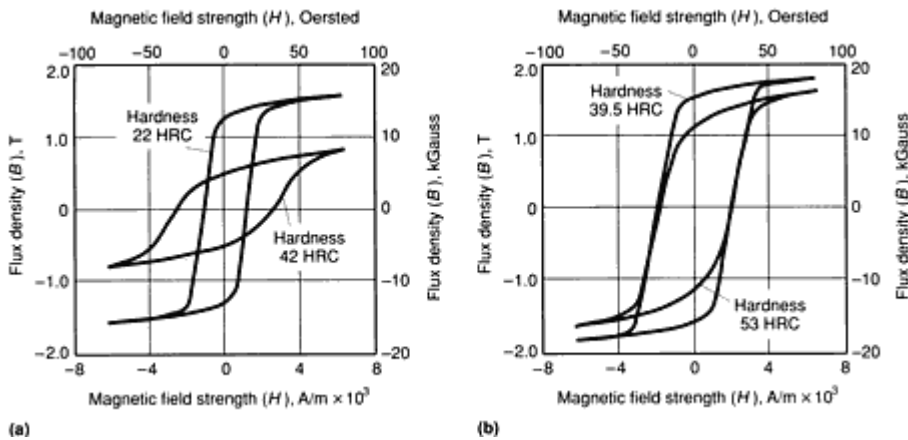

**Fig. 5** Flux leakage inspection of a bearing race. (a) Magnetization of inner race. (b) Perturbation in the magnetic flux at the surface of the inner race. (c) Probe scanning the surface

The flux leakage method also is used to inspect steel reinforcement in concrete beams. The basic function of the magnetic field disturbance (MFD) inspection equipment is to provide maps of the magnetic field across the bottom and sides of the beam. An electromagnet on an inspection cart, which is suspended on tracks below the beam, provides a magnetic field that induces magnetization in permeable structures in its vicinity, such as steel rebars, cables, and stirrups. An array of Hall effect sensors distributed across the bottom and sides of the beam measures the field produced by magnetized structures within the beam. If a flaw is present in one of these magnetized structures, it produces a disturbance of the normal magnetic field pattern associated with the unflawed beam.

A flaw, such as a broken wire in a cable or a fractured rebar, produces a distinctive magnetic field anomaly that depends on the size of the discontinuity and its distance from the sensor. Because the signal shape that results from such an anomaly is known, flaw detection is enhanced by searching magnetic field records for specific signal shapes; that is, those that are characteristic of discontinuities in magnetic materials. In the MFD system, this is accomplished by a computer program that compares signal shapes with typical flaw signal shapes.

**Nondestructive Characterization of Materials.** Two examples of magnetic methods for monitoring material properties illustrate the types of tests that can be used. Measurements of magnetic characteristics provide data that yield information on different material properties. For example, different features of magnetic hysteresis data can be interpreted in terms of heat treatment and microstructure, plastic deformation, residual stress, and mechanical hardness.

An example of the effects of mechanical hardness on hysteresis data is shown in Fig. 6. These data were obtained in the absence of applied tensile stress. Specimens of different hardness were prepared by tempering at different temperatures. The grain size (ASTM No. 7) was the same for all four specimens used in the tests. Other data show that grain size has little effect on hysteretic behavior for the classes of alloys studied.

**Fig. 6** Effect of mechanical hardness on hysteresis loop data. (a) AISI 410 stainless steel. (b) SAE 4340 steel

The main point illustrated in Fig. 6 is that the mechanically harder specimens of the same alloy are also harder to magnetize; that is, the flux density,  $B$ , obtained at a large value of  $H$  is smaller for mechanically harder specimens than for softer specimens. For one alloy, AISI 410 stainless steel, the hysteresis loop intersects the  $B = 0$  axis at larger values of  $H$  for the harder specimen than for the softer specimen; that is, the coercive force is greater for the harder material. However, for SAE 4340 steel, the coercive force does not change with hardness. This suggests that, for these two alloys, the saturation flux density provides a more reliable measure of hardness than the coercive force.

Certain features of both Barkhausen noise and incremental permeability data can be correlated with depth of decarburization. The Barkhausen noise method shows a somewhat stronger sensitivity to depth, but is useful over a smaller range of depths than the incremental permeability method. It can be concluded that both methods are useful. The optimum choice of methods depends on the accuracy required and the expected depth of decarburization.

# Eddy-Current Inspection

## Introduction

EDDY-CURRENT INSPECTION is based on the principles of electromagnetic induction and is used to identify or differentiate a wide variety of physical, structural, and metallurgical conditions in electrically conductive ferromagnetic and nonferromagnetic metals and metal parts. Eddy-current inspection is used:

- To measure and identify conditions and properties related to electrical conductivity, magnetic permeability, and physical dimensions (primary factors affecting eddy-current response)
- To detect seams, laps, cracks, voids, and inclusions
- To sort dissimilar metals and detect differences in their composition, microstructure, and other properties (such as grain size, heat treatment, and hardness)
- To measure the thickness of a nonconductive coating on a conductive metal, or the thickness of a nonmagnetic metal coating on a magnetic metal

Because eddy-current inspection is an electromagnetic-induction technique, it does not require direct electrical contact with the part being inspected. The eddy-current method is adaptable to high-speed inspection, and because it is nondestructive, it can be used to inspect an entire production output if desired. The method is based on indirect measurement, and the correlation between instrument readings and the structural characteristics and serviceability of parts being inspected must be carefully and repeatedly established.

Eddy-current inspection is extremely versatile, which is both an advantage and a disadvantage. The advantage is that the method can be applied to many inspection problems provided that the physical requirements of the material are compatible with the inspection method. However, in many applications, the sensitivity of the method to many inherent material properties and characteristics can be a disadvantage. Some variables in a material that are not important in terms of material or part serviceability can cause instrument signals that mask critical variables or are mistakenly interpreted to be caused by critical variables.

**Eddy-Current vs. Magnetic Inspection Methods.** In eddy-current inspection, eddy currents create their own electromagnetic field, which is sensed either through the effects of the field on the primary exciting coil or by means of an independent sensor. In nonferromagnetic materials, the secondary electromagnetic field is derived exclusively from eddy currents. However, with ferromagnetic materials, additional magnetic effects occur that usually are of sufficient magnitude to overshadow the basic eddy-current effects from electrical conductivity only. These magnetic effects result from the magnetic permeability of the material being inspected, and can be virtually eliminated by magnetizing the material to saturation in a static (direct-current) magnetic field. When the permeability effect is not eliminated, the inspection method is more correctly categorized as electromagnetic or magnetoinductive inspection.

## Principles of Operation

**Functions of a Basic System.** The part to be inspected is placed within or adjacent to an electrical coil in which an alternating current is flowing. As shown in Fig. 1, the alternating current, called the exciting current, causes eddy currents to flow in the part as a result of electromagnetic induction. These currents flow within closed loops in the part, and their magnitude and timing (or phase) depend on (a) the original or primary field established by the exciting currents, (b) the electrical properties of the part, and (c) the electromagnetic fields established by currents flowing within the part.

**Fig. 1** Two common types of inspection coils and the patterns of eddy-current flow generated by the exciting current in the coils. Solenoid-type coil is applied to cylindrical or tubular parts; pancake-type coil, to a flat surface. (a) Solenoid-type coil. (b) Pancake-type coil

The electromagnetic field in the region in the part and surrounding the part depends on both the exciting current from the coil and the eddy currents flowing in the part. The flow of eddy currents in the part depends on the electrical characteristics of the part, the presence or absence of flaws and other discontinuities in the part, and the total electromagnetic field within the part.

The change in flow of eddy currents caused by the presence of a crack in a pipe is shown in Fig. 2. The pipe travels along the length of the inspection coil, as shown. In section A-A in Fig. 2, no crack is present and the eddy-current flow is symmetrical. In section B-B, where a crack is present, the eddy-current flow is impeded and changed in direction, causing significant changes in the associated electromagnetic field. The condition of the part can be monitored by observing the effect of the resulting field on the electrical characteristics of the exciting coil, such as its electrical impedance, induced voltage, and induced currents. Alternatively, the effect of the electromagnetic field can be monitored by observing the induced voltage in one or more other coils placed within the field near the part being monitored.

**Fig. 2** Effect of a crack on the pattern of eddy-current flow in a pipe

Each and all of these changes can have an effect on the exciting coil and other coil or coils used to sense the electromagnetic field adjacent to a part. The effects most often used to monitor the condition of the part being inspected are the electrical impedance of the coil and the induced voltage of either the exciting coil or other adjacent coil or coils.

Eddy-current systems vary in complexity depending on individual inspection requirements. However, most systems must provide for the following functions:

- Excitation of the inspection coil with one or more frequencies
- Modulation of the inspection-coil output signal by the part being inspected
- Processing of the inspection-coil signal prior to amplification
- Amplification of the inspection-coil signals
- Detection or demodulation of the inspection-coil signal, usually accompanied by some analysis or discrimination of signals, which can be performed by a computer
- Display of signals on an instrument such as a meter, an oscilloscope, an oscillograph, and a strip-chart recorder; or recording of signals on paper punch tape and magnetic tape
- Handling of the part being inspected and support of inspection-coil assembly

**Elements of a typical inspection system** are shown schematically in Fig. 3. The particular elements in Fig. 3 are for a system developed to inspect bar or tubing. The generator supplies excitation current to the inspection coil and a synchronizing signal to the phase shifter, which provides switching signals for the detector. The loading of the inspection coil by the part being inspected modulates the electromagnetic field of the coil. This causes changes in the amplitude and phase of the inspection-coil voltage output.

**Fig. 3** Principal elements of a typical system for eddy current inspection of bar or tubing. See description in text.

The output of the inspection coil is fed to the amplifier and detected or demodulated by the detector. The demodulated output signal, after some further filtering and analyzing, is then displayed on an oscilloscope or a chart recorder. The displayed signals, having been detected or demodulated, vary at a much slower rate, depending on (a) the rate of changing the inspection probe from one part being inspected to another, (b) the speed at which the part is fed through an inspection coil, or (c) the speed with which the inspection coil is caused to scan past the part being inspected.

## Operating Variables

The principal operating variables encountered in eddy-current inspection include coil impedance, electrical conductivity, magnetic permeability, lift-off and fill factors, edge effect, and skin effect.

### Coil Impedance

When direct current flows in a coil, the magnetic field reaches a constant level and the electrical resistance of the wire is the only limitation to the flow of current. However, when alternating current flows in a coil, two limitations are imposed: the alternating-current resistance of the wire and a quantity known as inductive reactance ( $X_L$ ).

Impedance usually is plotted on an impedance-plane diagram. In such a diagram, resistance is plotted along one axis and inductive reactance (or inductance) along the other axis. Because each specific condition in the material being inspected can result in a specific coil impedance, each condition corresponds to a particular point on the impedance-plane diagram. For example, if a coil is placed sequentially on a series of thick pieces of metal, each having a different resistivity, each piece causes a different coil impedance and corresponds to a different point on a locus in the impedance plane. The curve generated might resemble that shown in Fig. 4, which is based on International Annealed Copper Standard (IACS) conductivity ratings. Other curves are generated for other material variables, such as section thickness and types of surface flaws.

**Fig. 4** Typical impedance-plane diagram derived by placing an inspection coil sequentially on a series of thick pieces of metal, each with a different International Annealed Copper Standard (IACS) electrical resistance or conductivity rating. The inspection frequency is 100 kHz.

By use of more than one test frequency, the impedance planes can be manipulated to accept a desirable variable (in flaws) and reduce the effects of undesirable variables--that is, lift-off and/or dimensional effects (see Fig. 3).

### Electrical Conductivity

All materials have a characteristic resistance to the flow of electricity. Those with the highest resistivity are classified as insulators; those having intermediate resistivity are classified as semiconductors; and those having low resistivity are

classified as conductors. Conductors, which include most metals, are of greatest interest in eddy-current inspection. The relative conductivities of common metals and alloys vary over a wide range.

Capacity to conduct current is measured in terms of either conductivity or resistivity. In eddy-current inspection, measurement often is based on IACS. In this system, the conductivity of annealed, unalloyed copper is arbitrarily rated at 100%, and the conductivities of other metals and alloys are expressed as percentages of this standard. Thus, the conductivity of unalloyed aluminum is rated 61% IACS, or 61% that of unalloyed copper. Table 1 gives the resistivities and IACS conductivity ratings of several common metals and alloys.

**Table 1 Electrical resistivity and conductivity of several common metals and alloys**

Metal or alloy	Resistivity $\mu\Omega \cdot \text{mm}$	Conductivity, %IACS
<b>Silver</b>	16.3	105
<b>Copper, annealed</b>	17.2	100
<b>Gold</b>	24.4	70
<b>Aluminum</b>	28.2	61
<b>Aluminum alloys</b>		
<b>6061-T6</b>	41	42
<b>7075-T6</b>	53	32
<b>2024-T4</b>	52	30
<b>Magnesium</b>	46	37
<b>70-30 brass</b>	62	28
<b>Phosphor bronzes</b>	160	11
<b>Monel</b>	482	3.6
<b>Zirconium</b>	500	3.4
<b>Zircaloy-2</b>	720	2.4
<b>Titanium</b>	548	3.1
<b>Ti-6Al-4V alloy</b>	1720	1.0
<b>Type 304 stainless steel</b>	700	2.5
<b>Inconel 600</b>	980	1.7
<b>Hastelloy X</b>	1150	1.5
<b>Waspaloy</b>	1230	1.4

### ***Magnetic Permeability***

Ferromagnetic metals and alloys, including iron, nickel, cobalt, and some of their alloys, concentrate the flux of a magnetic field. They are strongly attracted to a magnet and an electromagnet, have exceedingly high and variable susceptibilities, and have very high and variable permeabilities.

Magnetic permeability is not a constant for a given material, but depends on the strength of the magnetic field acting on it. For example, consider a sample of steel that has been completely demagnetized and then placed in a solenoid coil. As current in the coil is increased, the magnetic field associated with the current increases. However, the magnetic flux within the steel increases rapidly at first and then levels off so that an additionally large increase in the strength of the magnetic field results in only a small increase in flux within the steel. The steel sample achieves a condition known as magnetic saturation.

The curve showing the relation between magnetic-field intensity and the magnetic flux within the steel is known as a magnetization curve. Magnetization curves for annealed commercially pure iron and nickel are shown in Fig. 5. The magnetic permeability of a material is the ratio between the strength of the magnetic field and the amount of magnetic flux within the material. As shown in Fig. 5, at saturation (where there is no appreciable change in induced flux in the material for a change in field strength) the permeability is nearly constant for small changes in field strength.

**Fig. 5** Magnetization curves for annealed commercially pure iron and nickel

Magnetic permeability of the material being inspected strongly influences the eddy-current response. Consequently, the techniques and conditions used for inspecting magnetic materials differ from those used to inspect nonmagnetic materials.

### ***"Lift-Off" Factor***

When a probe inspection coil, attached to a suitable inspection instrument, is energized in air, it produces an indication even if there is no conductive material in the vicinity of the coil. The initial indication starts to change as the coil is moved closer to a conductor. Because the field of the coil is strongest close to the coil, the indicated change on the instrument continues to increase until the coil is directly on the conductor. These changes in indication with changes in spacing between the coil and the conductor, or part being inspected, are called "lift off." The lift-off effect is so pronounced that small variations in spacing can mask many indications resulting from the condition or conditions of primary interest. Consequently, it usually is necessary to maintain a constant relationship between the size and shape of the coil and the size and shape of the part being inspected.

The change of coil impedance with lift-off can be derived from the impedance-plane diagram shown in Fig. 6. When the coil is suspended in air away from the conductor, impedance is at a point at the upper end of the curve at far left in Fig. 6. As the coil approaches the conductor, the impedance moves in the direction indicated by the dashed lines until the coil is in contact with the conductor. When contact occurs, the impedance is at a point corresponding to the impedance of the part being inspected, which in this instance, represents its conductivity. The fact that the lift-off curves approach the conductivity curve at an angle can be used in some instruments to separate lift-off signals from those resulting from variations in conductivity or some other parameter of interest.

**Fig. 6** Impedance-plane diagram showing curves for electrical conductivity and lift off. Inspection frequency is 100 kHz.

Although lift off can be troublesome in many applications, it can be also be useful. For example, using the lift-off effect, eddy current instruments are excellent for measuring the thickness of nonconductive coatings, such as paint and anodized coatings, on metals.

### ***Fill Factor***

In an encircling coil, a condition comparable to lift-off is known as "fill factor." It is a measure of how well the part being inspected fills the coil. As with lift off, changes in fill factor resulting from factors such as variations in outside diameter must be controlled because small changes can produce large indications. The lift-off curves shown in Fig. 6 are very similar to those for changes in fill factor. For a given lift-off or fill factor, the conductivity curve shifts to a new position, as indicated in Fig. 6. Fill factor can sometimes be used as a rapid method to check variations in outside-diameter measurements in rods and bars.

## Edge Effect

When an inspection coil approaches the end or edge of a part being inspected, eddy currents are distorted because they are unable to flow beyond the edge of a part. The distortion of eddy currents results in an indication known as "edge effect." Because the magnitude of the effect is very large, it limits inspection near edges. Unlike lift-off, little can be done to eliminate edge effect. A reduction in coil size lowers the effect somewhat, but there are practical limits that dictate the sizes of coils for given applications. In general, it is not advisable to inspect any closer than 3.2 mm ( $\frac{1}{8}$  in.) from the edge of a part.

One alternative for inspection near an edge with minimal edge effect is to scan in a line parallel to the edge. Inspection can be carried out by maintaining a constant probe-to-edge relationship, but each new scan-line position requires adjustment of the instrument. Fixturing of the probe is recommended.

## Skin Effect

Eddy currents are not uniformly distributed throughout a part being inspected; rather, they are densest at the surface immediately beneath the coil and become progressively less dense with increasing distance below the surface. The concentration of eddy currents at the surface of a part is known as "skin effect." At some distance below the surface of a thick part, there essentially are no currents flowing. The depth of eddy-current penetration should be considered for thickness measurements and for detection of subsurface flaws.

Figure 7 shows how the eddy current varies as a function of depth below the surface. The depth at which the density of the eddy current is reduced to about 37% of the density at the surface is defined as the standard depth of penetration. This depth depends on the electrical conductivity and magnetic permeability of the material and on the frequency of the magnetizing current. Depth of penetration decreases with increases in conductivity, permeability, and inspection frequency. The standard depth of penetration can be calculated from the equation:

$$S = 1980 \sqrt{\rho / \mu f}$$

where  $S$  is standard depth of penetration, in inches;  $\rho$  is resistivity, in ohm-centimeters;  $\mu$  is magnetic permeability (1 for nonmagnetic materials); and  $f$  is inspection frequency, in hertz. Figure 8 shows the standard depth of penetration, as a function of inspection frequency, for several metals of various electrical conductivities.

Fig. 7 Variation in density of eddy current as a function of depth below the surface of a conductor, known as

## skin effect

**Fig. 8** Standard depths of penetration as a function of frequencies used in eddy-current inspection for several metals of various electrical conductivities

## Inspection Frequencies

The inspection frequencies used in eddy-current inspection range from about 60 Hz to 6 MHz. Most inspection of nonmagnetic materials is performed at a few kilohertz. In general, lower frequencies are used to inspect magnetic materials. However, the actual frequency used in any specific eddy-current inspection depends on the thickness of the material being inspected, the required depth of penetration, the degree of sensitivity or resolution required, and the purpose of the inspection.

Selection of inspection frequency normally is a compromise. For example, penetration should be sufficient to reach subsurface flaws that must be detected, and to determine material condition (such as case hardness). Although penetration is greater at lower frequencies, it does not follow that the lowest possible frequency should be used. Unfortunately, as the frequency is lowered, the sensitivity to flaws decreases somewhat and the speed of inspection could be reduced.

Typically, the highest possible inspection frequency that still is compatible with the penetration depth required is selected. The choice is relatively simple when only surface flaws must be detected, in which case frequencies up to several megahertz can be used. However, when flaws at some considerable depth below the surface must be detected, or when flaw depth and size must be determined, low frequencies must be used at the expense of sensitivity.

In inspection of ferromagnetic materials, relatively low frequencies typically are used because of the low penetration in these materials. Higher frequencies can be used when it is necessary to inspect for surface conditions only. However, even the higher frequencies used in these applications still are considerably lower than those used to inspect nonmagnetic materials for similar conditions.

## Inspection Coils

The inspection coil is an essential part of every eddy-current inspection system. The shape of the inspection coil depends to a considerable extent on the purpose of the inspection and on the shape of the part being inspected. In inspection for flaws, such as cracks and seams, it is essential that the flow of the eddy currents be as nearly perpendicular to the flaws as possible to obtain a maximum response from the flaws. If the eddy-current flow is parallel to flaws, there is little or no distortion of the currents, and, therefore, very little reaction on the inspection coil.

**Probe and Encircling Coils.** Of the almost infinite variety of coils used in eddy-current inspection, probe coils and encircling coils are the most common. A probe-type coil typically is used to inspect a flat surface for cracks at an angle to the surface because this type of coil induces currents that flow parallel to the surface, and therefore across a crack as shown in Fig. 9(a). Conversely, a probe-type coil is not suitable to detect a laminar type of flaw. For such a discontinuity, a U-shape, or horseshoe-shaped coil such as the coil shown in Fig. 9(b) is satisfactory.

**Fig. 9** Types and applications of coils used in eddy-current inspection. (a) Probe-type coil applied to a flat plate for crack detection. (b) Horseshoe-shape, or U-shape, coil applied to a flat plate for laminar-flaw detection. (c) Encircling coil applied to a tube. (d) Internal, or bobbin-type, coil applied to a tube

To inspect tubing and bar, an encircling coil (Fig. 9c) generally is used because of complementary configuration and because of the testing speeds that can be achieved. However, an encircling coil is sensitive only to discontinuities that are parallel to the axis of the tube and bar. The coil is satisfactory for this particular application because most discontinuities in tubing and bar are parallel to the major axis as a result of the manufacturing process. If it is necessary to locate discontinuities that are not parallel to the axis, a probe coil must be used, and either the coil or the part must be rotated during scanning. To detect discontinuities on the inside surface of a tube, an internal, or bobbin-type, coil (Fig. 9d) can be used. An alternative is to use an encircling coil with a depth of penetration sufficient to detect flaws on the inside surface. The bobbin-type coil, similar to the encircling coil, is sensitive to discontinuities that are parallel to the axis of the tube or bar.

**Multiple Coils.** In many eddy-current inspection setups, two coils are used. The two coils typically are connected in a series-opposing arrangement so there is no output from the pair when their impedances are the same. Pairs of coils can be used in either an absolute or a differential arrangement (see Fig. 10). In the absolute arrangement (Fig. 10a), a sample of acceptable material is placed in one coil, and the other coil is used for inspection. In this manner, the coils compare an unknown against a standard, the differences between the two (if any) are indicated by a suitable instrument. Arrangements of this type commonly are used in sort applications. Fixtures are used to maintain a constant geometrical relationship between coil and part.

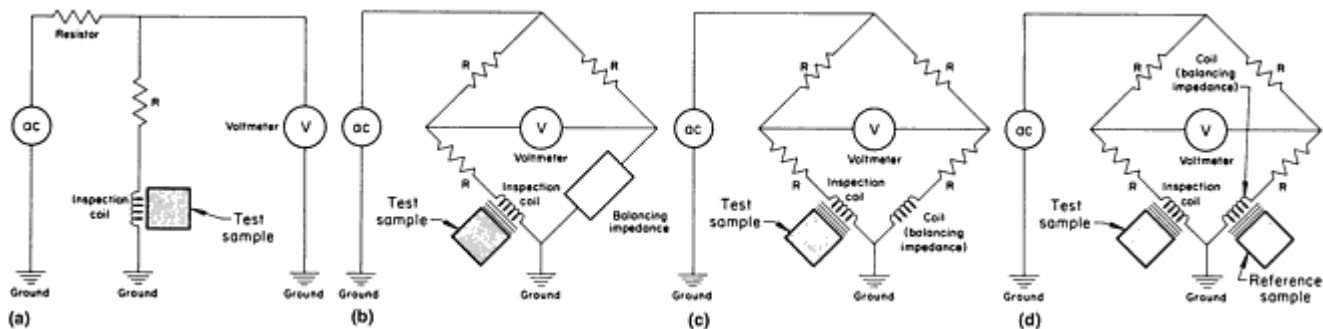

**Fig. 10 Absolute and differential arrangements of multiple coils used in eddy-current inspection. (a) Absolute coil arrangement. (b) Differential coil arrangement**

An absolute coil arrangement is not a good method in many applications. For example to inspect tubing, an absolute arrangement indicates dimensional variations in both outside diameter and wall thickness even though such variations can be well within allowable limits. To avoid this problem, a differential coil arrangement such as that shown in Fig. 10(b) can be used. Here, the two coils compare one section of the tube with an adjacent section. When the two sections are the same, there is no output from the pair of coils and no indication on the eddy-current instrument. Gradual dimensional variations within the tube or gross variations between individual tubes are not indicated, whereas discontinuities--which normally occur abruptly--are very apparent. In this way, it is possible to have an inspection system that is sensitive to flaws and relatively insensitive to changes that normally are not of interest.

**Sizes and Shapes.** Inspection coils are made in a variety of sizes and shapes. Selection of a coil for a particular application depends on the type of discontinuity. For example, when an encircling coil is used to inspect tubing and bar for short discontinuities, best resolution is obtained with a short coil. On the other hand, a short coil has the disadvantage of being sensitive to the position of the part in the coil. Longer coils are not as sensitive to position of the part, but are not as effective in detecting very small discontinuities. Small-diameter probe coils have greater resolution than larger ones but are more difficult to manipulate and are more sensitive to lift-off variations.

## Eddy-Current Instruments

A simple eddy-current instrument, in which the voltage across an inspection coil is monitored, is shown in Fig. 11(a). This circuit is adequate to measure large lift-off variations, if accuracy is not of great importance. A circuit designed for greater accuracy is shown in Fig. 11(b). This instrument consists of a signal source, an impedance bridge with dropping resistors, an inspection coil in one leg, and a balancing impedance in the other leg. The differences in voltage between the two legs of the bridge are measured by an alternating-current voltmeter. Alternatively, the balancing impedance in the leg opposite the inspection coil can be a coil identical to the inspection coil, as shown in Fig. 11(c), or it can have a reference sample in the coil, as shown in Fig. 11(d). In the latter, if all the other components in the bridge are identical, a signal occurs only when the inspection-coil impedance deviates from that of the reference sample.

**Fig. 11 Four types of eddy-current instruments. (a) A simple arrangement, in which voltage across the coil is monitored. (b) Typical impedance bridge. (c) Impedance bridge with dual coils. (d) Impedance bridge with dual coils and a reference sample in the second coil**

There are other methods to achieve bridge balance, such as varying the values of resistance of the resistor in the upper leg of the bridge and one in series with the balancing impedance. The most accurate bridges can measure absolute impedance to within 0.01%. However, in eddy-current inspection, it is not how an impedance bridge is balanced that is important, but rather how it is unbalanced by the effects of a flaw.

Another type of bridge system is an induction bridge, in which the power signal is transformer coupled into an inspection coil and a reference coil. In addition, the entire inductance-balance system is placed in the probe, as shown in Fig. 12. The probe consists of a large transmitter (or driver) coil and two small detector (or pickup) coils wound in opposite directions as mirror images of each other. An alternating current is supplied to the large transmitter coil to generate a magnetic field.

If the transmitter coil is not in the vicinity of a conductor, the two detector coils detect the same field, and the net signal is zero because they are wound in opposition to each other. However, if one end of the probe is placed near a metal surface, the field is different at the two ends of the probe, and a net voltage appears across the two coils. The resultant field is the sum of a transmitted signal, which is present all the time, and a reflected signal due to the presence of a conductor (the metal surface). This coil arrangement can be used both as a probe and as an encircling coil (see Fig. 12).

**Fig. 12** Induction-bridge probe in place at the surface of a workpiece. Schematic shows how power signal is transformer coupled from a transmitter coil into two detector coils--an inspection coil (at bottom) and a reference coil (at top).

**Readout Instrumentation.** An important part of an eddy-current inspection system is the instrument used for a readout. The readout device can be an integral part of the system, an interchangeable plug-in module, and a solitary unit connected by cable. The readout instrument should be of adequate speed, accuracy, and range to meet the inspection requirements of the system. Frequently, several readout devices are used in a single inspection system. A list of more common types of readout, in order of increasing cost and complexity, follows:

- Alarm lights alert the operator that a test-parameter limit has been exceeded.
- Sound alarms serve the same purpose as alarm lights but free the attention of the operator to allow manipulating the probe in manual scanning.
- Kick-out relays activate a mechanism that automatically rejects and marks a part when a test parameter is exceeded.
- Analog meters give a continuous reading over an extended range. They are fairly rapid (with a frequency of about 1 Hz), and the scales can be calibrated to read parameters directly. The accuracy of these devices is limited to about 1% of full scale. They can be used to set the limits on alarm lights, sound alarms, and kick-out relays.
- Digital meters are easier to read and can have greater ranges than analog meters. Numerical values are easily read without extrapolation, but fast trends of changing readings are more difficult to interpret. Although many digital meters have binary coded decimal (bcd) output, they are relatively slow.
- X-Y plotters can be used to display impedance-plane plots of the eddy-current response. They are very helpful in the design and set up of eddy-current, bridge-unbalance inspections and in discriminating against undesirable variables. They also are useful to sort out inspection results. They are fairly accurate and provide a permanent copy.
- X-Y storage oscilloscopes are very similar to X-Y plotters but can acquire signals at high speed. However, the signals have to be processed manually, and the screen can quickly become cluttered with signals. In some instruments, high-speed X-Y gates can be displayed and set on the screen.
- Strip-chart recorders furnish a fairly accurate (about 1% of full scale) recording at reasonably high

speed (about 200 Hz). However, once on the chart, the data must be read by an operator. Several channels can be recorded simultaneously, and the record is permanent.

- Magnetic-tape recorders are fairly accurate and capable of recording at very high speed (10 MHz). Moreover, the data can be processed by automated techniques.
- Computers. The data from several channels can be fed directly to a high-speed computer, either analog or digital, for on-line processing. The computer can separate parameters and calculate the variable of interest and significance, catalog the data, print summaries of the result, and store all data on tape for reference in future scans.

## Discontinuities Detectable by Eddy-Current Inspection

Basically, any discontinuity that appreciably alters the normal flow of eddy currents can be detected by eddy-current inspection. With encircling-coil inspection of either solid cylinders or tubes, surface discontinuities having a combination of predominantly longitudinal and radial dimensional components are readily detected. When discontinuities of the same size are located beneath the surface of the part being inspected at progressively greater depths, they become increasingly difficult to detect, and can be detected at depths greater than 13 mm ( $\frac{1}{2}$  in.) only with special equipment designed for this purpose.

Conversely, laminar discontinuities such as those in welded tubes might not alter the flow of the eddy currents enough to be detected unless the discontinuity breaks either the outside or inside surfaces, or unless it produces a discontinuity in the weld from upturned fibers caused by extrusion during welding. A similar difficulty could arise in trying to detect a thin planar discontinuity that is oriented substantially perpendicular to the axis of the cylinder.

Regardless of the limitations, a majority of objectionable discontinuities can be detected by eddy-current inspection at high speed and at low cost. Some of the discontinuities that are readily detected are seams, laps, cracks, slivers, scabs, pits, slugs, open welds, miswelds, misaligned welds, black and gray oxide weld penetrators, pinholes, hook cracks, and surface cracks.

**Reference Samples.** A basic requirement for eddy-current inspection is a reliable, consistent means to set tester sensitivity to the proper level each time it is used. A standard reference sample must be provided for this purpose. Without this capability, eddy-current inspection is of little value. In selecting a standard reference sample, the usual procedure is to select a sample of product that can be run through the inspection system without producing appreciable indications from the tester. Several samples might have to be run before a suitable one is found; the suitable one then has reference discontinuities fabricated into it.

The type of reference discontinuities that must be used for a particular application are specified (for example, by ASTM and API). In selecting reference discontinuities, some of the major considerations are: (a) they must meet the required specification, (b) they should be easy to fabricate, (c) they should be reproducible, (d) they should be producible in precisely graduated sizes, and (e) they should produce an indication on the eddy-current tester that closely resembles those produced by the natural discontinuities.

Figure 13 shows several discontinuities that have been used for reference standards, these include a filed transverse notch, milled or electrical discharge machined longitudinal and transverse notches, and drilled holes.

**Fig. 13** Several fabricated discontinuities used as reference standards in eddy-current inspection. ASTM standards for eddy-current testing include E 215 (aluminum alloy tube), E 376 (measurement of coating thickness), E 243 (copper and copper alloy tube), E 566 (ferrous metal sorting), E 571 (nickel and nickel alloy

tube), E 690 (nonmagnetic heat-exchanger tubes), E 426 (stainless steel tube), and E 309 (steel tube).

# Microwave Inspection

## Introduction

MICROWAVES (or radar waves) are a form of electromagnetic radiation with wavelengths between 1000 cm and 1 mm in free space. Because microwaves have wavelengths that are  $10^4$  to  $10^5$  times longer than those of light waves, microwaves penetrate deeply into materials, with the depth of penetration dependent on the conductivity, permittivity, and permeability of the materials. Microwaves are also reflected from any internal boundaries and interact with the molecules that constitute the material. For example, it was found that the best source for the thickness and voids in radomes was the microwaves generated within the radomes. Both continuous and pulsed incident waves were used in these tests, and either reflected or transmitted waves were measured.

One of the first important uses of microwaves in nondestructive evaluation (NDE) was for components such as waveguides, attenuators, cavities, antennas, and antenna covers (radomes). Subsequently, microwave inspection methods were developed for:

- Evaluation of moisture content in dielectric materials
- Thickness measurements of thin metallic coatings on dielectric substrates
- Detection of voids, delaminations, macroporosity, inclusions, and other flaws in plastic or ceramic materials.

## Advantages

In comparison with ultrasonic inspection and x-ray radiographic inspection, the advantages of inspection with microwaves are as follows:

- Broadband frequency response of the coupling antennas
- Efficient coupling through air from the antennas to the material
- No material contamination problem caused by the coupling
- Microwaves readily propagate through air, so successive reflections are not obscured by the first one.
- Information concerning the amplitude and phase of propagating microwaves is readily obtainable.
- No physical contact is required between the measuring device and the material being measured; therefore, the surface can be surveyed rapidly without contact.
- The surface can be scanned in strips merely by moving the surface or by scanning the surface with antennas.
- No changes are caused in the material; therefore, the measurement is nondestructive.
- The complete microwave system can be made from solid-state components so that it will be small, rugged, and reliable.
- Microwaves can be used for locating and sizing cracks in materials if the following considerations are followed. First, the skin depth at microwave frequencies is very small (a few micrometers), and the crack is detected most sensitively when the crack breaks through the surface. Second, when the crack is not through the surface, the position of the crack is indicated by a detection of the high stresses in the surface right about the subsurface crack. Finally, microwave crack detection is very sensitive to crack opening and to the frequency used. Higher frequencies are needed for the smaller cracks. If the frequency is increased sufficiently, the incident wave can propagate into the crack, and the response is then sensitive to crack depth.

## Limitations

The use of microwaves is in some cases limited by their inability to penetrate deeply into conductors or metals. This means that nonmetallic materials inside a metallic container cannot be easily inspected through the container. Another limitation of the lower-frequency microwaves is their comparatively low power for resolving localized flaws. If a receiving antenna of practical size is used, a flaw with effective dimension that is significantly smaller than the wavelength of the microwaves used cannot be completely resolved (that is, distinguished as a separate, distinct flaw). The shortest wavelengths for which practical present-day microwave apparatus exists are of the order of 1 mm (0.04 in.). However, the development of microwave sources with wavelengths of 0.1 mm (0.004 in.) are proceeding rapidly. Consequently, microwave inspection for the detection of very small flaws is not suited for applications in which flaws are equal to or smaller than 0.1 mm (0.004 in.). Subsurface cracks can be detected by measuring the surface stress, which should be much higher in the surface above the subsurface crack.

## Techniques of Microwave Inspection

The following general approaches have been used in the development of microwave nondestructive inspection:

- Fixed-frequency, continuous-wave transmission
- Swept-frequency, continuous-wave transmission
- Pulse-modulated transmission
- Fixed-frequency, continuous-wave reflection
- Swept-frequency, continuous-wave reflection
- Pulse-modulated reflection
- Fixed-frequency standing waves
- Fixed-frequency reflection scattering
- Microwave holography
- Microwave surface impedance
- Microwave detection of stress corrosion

Each of these techniques uses one or more of the several processes by which materials can interact with microwaves, namely, reflection, refraction, scattering, absorption, and dispersion. The basic components of the transmission technique are shown schematically in Fig. 1.

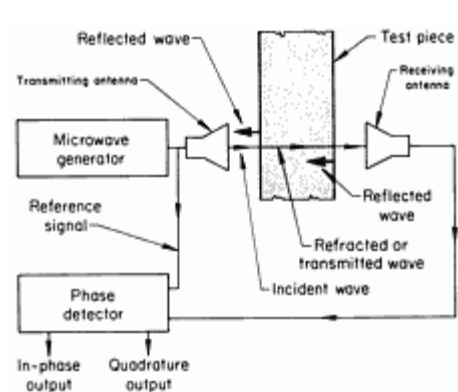

Fig. 1 Diagram of the basic components of the transmission technique used for microwave inspection

## Thickness measurements

Thickness measurements can be made with microwave techniques on both metallic and nonmetallic materials. For metals, two reflected waves are used from two waveguide arms that differ in length by an integral number of half-wavelengths for

detector output null. This measurement is made using the standing wave technique. When the wave is incident on a metal (electrically conductive), most of the wave is reflected; only a small amount is transmitted (refracted). The transmitted wave is highly attenuated in the metal within the first skin depth. For nonmetallic materials (electrically nonconductive), the reflected wave is much smaller than the incident wave, so that any standing wave that does develop does not have a large amplitude.

## **Detection of Discontinuities**

Discontinuities such as cracks, voids, delaminations, separations, and inclusions predominantly reflect or scatter electromagnetic waves. Wherever these types of flaws occur, there is a more or less sharp boundary between two materials having markedly different velocities for electromagnetic waves. At these boundaries, which are usually thin compared to the wavelength of electromagnetic radiation being used, the electromagnetic wave is reflected, refracted, or scattered. The reflected or scattered radiation has appreciable amplitude only if the minimum dimension of the discontinuity is larger than about one-half the wavelength of the incident radiation in the material being tested.

Porosity and regions of defective material such as departures from nominal composition do not produce strong reflection or scattering. They do influence the attenuation and the velocity of the electromagnetic wave. When there is absorption, the transmitted wave has an exponential decay with respect to the distance traveled.

## **Microwave Detection of Surface Cracks in Metals**

When an electromagnetic wave is incident on a metallic surface that has slits or cracks, the metallic surface reradiates (reflects) a signal because of induced current. Under the proper conditions, the reflected wave combines with the incident wave to produce a standing wave. The reflection from a surface without a crack is different from that surface with a crack and depends on the direction of the incident wave polarization relative to the crack. When the crack is long and narrow and the electric field is perpendicular to the length of the crack, the reflected wave (and therefore any standing wave) is affected by the presence of the crack. The amount of change is used to determine the size and depth of the crack.

# **Ultrasonic Inspection**

## **Introduction**

ULTRASONIC INSPECTION is a nondestructive method in which beams of high-frequency acoustic energy are introduced into a material to detect surface and subsurface flaws, to measure the thickness of the material, and to measure the distance to a flaw. An ultrasonic beam travels through a material until it strikes an interface or discontinuity such as a flaw. Interfaces and flaws interrupt the beam and reflect a portion of the incident acoustic energy. The amount of energy reflected is a function of (a) the nature and orientation of the interface or flaw and (b) the acoustic impedance of such a reflector. Energy reflected from various interfaces and flaws can be used to define the presence and locations of flaws, the thickness of the material, and the depth of a flaw beneath a surface.

Most ultrasonic inspections are performed using a frequency between 1 and 25 MHz. Short shock bursts of ultrasonic energy are aimed into the material from the ultrasonic search unit of the ultrasonic flaw-detector instrument. The electrical pulse from the flaw detector is converted into ultrasonic energy by a piezoelectric transducer element in the search unit. The beam pattern from the search unit is determined by the operating frequency and size of the transducer element. Ultrasonic energy travels through the material at a specific velocity that is dependent on the physical properties of the material and on the mode of propagation of the ultrasonic wave. The amount of energy reflected from or transmitted through an interface, other type of discontinuity, or reflector is dependent on the properties of the reflector. These phenomena provide the basis for establishing two of the most common measurement parameters used in ultrasonic inspection: the amplitude of the energy reflected from an interface or flaw and the time required (from pulse initiation) for the ultrasonic beam to reach the interface or flaw.

## **Ultrasonic Flaw Detectors**

Although the electronic equipment used for ultrasonic inspection can vary greatly in detail among equipment manufacturers, all general-purpose units consist of a power supply, a pulser circuit, a search unit, a receiver-amplifier

circuit, an oscilloscope, and an electronic clock. Many systems also include electronic equipment for signal conditioning, gating, automatic interpretation, and integration with a mechanical or electronic scanning system. Also, advances in microprocessor technology have extended the data acquisition and signal-processing capabilities of ultrasonic inspection systems. In most instances the entire electronic assembly, including the controls and display, is contained in a single instrument. A typical ultrasonic flaw detector is shown in Fig. 1. The major controls include:

- Frequency selector to select the operating or test frequency
- Pulse-tuning control to fine adjust the test frequency
- Pulse-repetition-rate control, which determines the number of times per second that an ultrasonic pulse is initiated from the transducer (typically 100 to 2000 pulses per second)
- Test-type or mode-selection switch to adjust instrument to pulse-echo or pitch-catch operation
- Sensitivity controls to adjust sensitivity or gain of the receiver-amplifier
- Sweep selector and delay to adjust time base and that portion of the inspection zone that is to be displayed
- Gate-position control to isolate the portion of the inspection zone that will be used for additional processing
- Oscilloscope, which provides the visual display of the time and amplitude parameters used to interpret the data from the ultrasonic inspection

Fig. 1 Typical pulse-echo instrument

## Ultrasonic Transducers and Search Units

Generation and detection of ultrasonic waves for inspection is accomplished by means of a transducer element. The transducer element is contained within a device most often referred to as a search unit (or sometimes as a probe). The active element in a search unit is a piezoelectric crystal. Piezoelectricity is pressure-induced electricity, a property characteristic of certain naturally occurring crystalline compounds and some man-made materials. An electrical charge is developed by the crystal when pressure is applied to it. Conversely, when an electrical field is applied, the crystal mechanically deforms (changes shape). Piezoelectric crystals have various deformation modes; thickness expansion is the principal mode used in transducers for ultrasonic inspection.

The most common types of piezoelectric materials used for ultrasonic search units are quartz; lithium sulfate; and polarized ceramics such as barium titanate, lead zirconate titanate, and lead metaniobate. Table 1 summarizes characteristics and applications of these materials.

**Table 1 Characteristics and applications of piezoelectric transducer elements**

Piezoelectric element	Characteristics of piezoelectric elements							Suitability of element in:		
	Efficiency				Tolerance to elevated temperature	Damping ability	Undesired modes (inherent noise)			Immersion inspection
	Transmit	Receive	Coupling							
			To water	To metal				Contact inspection	Angle-beam	
								Straight-beam		
Quartz	P	G	G	F	G	F	G	G	F	G
Lithium sulfate	F	E	E	P	P	E	E	P	F	E
Barium titanate	G	P	G	G	P	P	P	G	G	F
Lead zirconate titanate	E	F	F	E	E	F	P	E	E	F
Lead metaniobate	G	F	G	E	E	E	G	E	E	G

Search units come in a variety of types and shapes. Variations in search-unit construction include transducer-element material; transducer-element thickness, surface area, and shape; and type of backing material and degree of loading. Four basic types of search units are straight-beam contact, angle-beam contact, dual-element contact, and immersion, both flat and focused. Table 2 lists their primary areas of application. Sectional views of these search units, together with a special type (delay-tip, contact-type search unit), are shown in Fig. 2.

**Table 2 Primary applications of ultrasonic search units**

<b>Straight-beam, contact-type units</b>	
<ul style="list-style-type: none"> <li>Manufacturing-induced flaws: <ul style="list-style-type: none"> <li>Billets--inclusions, stringers, pipe</li> <li>Forgings--inclusions, cracks, segregations, seams, flakes, pipe</li> <li>Rolled products--laminations, inclusions, tears, seams, cracks</li> <li>Castings--slag, porosity, cold shuts, tears, shrinkage cracks, inclusions</li> </ul> </li> <li>Service-induced flaws: fatigue cracks, corrosion, erosion, stress-corrosion cracks</li> </ul>	
<b>Angle-beam, contact-type units</b>	
<ul style="list-style-type: none"> <li>Manufacturing-induced flaws: <ul style="list-style-type: none"> <li>Forgings--cracks, seams, laps</li> <li>Rolled products--tears, seams, cracks, cupping</li> <li>Welds--slag inclusions, porosity, incomplete fusion, incomplete penetration, droptrough, suckback, cracks in filler metal and base metal</li> <li>Tubing and pipe--circumferential and longitudinal cracks</li> </ul> </li> <li>Service-induced flaws: fatigue cracks, stress-corrosion cracks</li> </ul>	
<b>Dual-element, contact-type units</b>	

- Manufacturing-induced flaws:
  - Plate and sheet--thickness measurement, lamination detection
  - Tubing and pipe--measurement of wall thickness
- Service-induced flaws: wall thinning, corrosion, erosion, stress-corrosion cracks

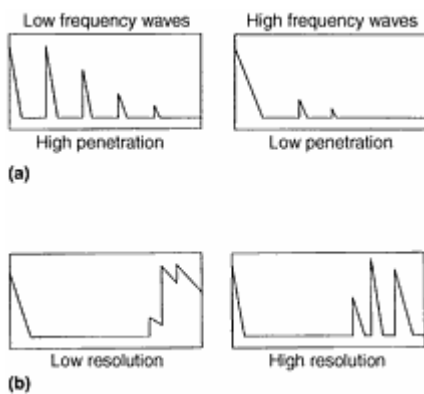

## Immersion-type units

- Manufacturing-induced flaws:
  - Billets--inclusions, stringers, pipe
  - Forgings--inclusions, cracks, segregations, seams, flakes, pipe
  - Rolled products--laminations, inclusions, tears, seams, cracks
  - Welds--inclusions, porosity, incomplete fusion, incomplete penetration, droptrough, cracks, base-metal laminations
  - Adhesive-bonded, soldered, or brazed products--lack of bond
  - Composites--voids, resin rich, resin poor, lack of filaments
  - Tubing and pipe--circumferential and longitudinal cracks
- Service-induced flaws: corrosion, fatigue cracks

**Fig. 2** Sectional views of five types of search units used in ultrasonic inspection. (a) Straight-beam (longitudinal-wave) contact. (b) Angle-beam (shear-wave) contact. (c) Dual-element contact. (d) Delay-tip (stand-off) contact. (e) Immersion

The selection of a transducer depends very much on the properties of the test specimen, particularly its sound attenuation. Ultrasonics of high frequency produce good resolution, which is the ability to separate echoes from closely spaced defects. Ultrasonics of low frequency penetrate deeper into materials because attenuation is generally lower. However, backscattering "noise" from grain boundaries is usually more important than attenuation, although the net result is the same because the signal-to-noise ratio also usually decreases with frequency. This is shown in Fig. 3. This means that the two requirements of high penetration and high resolution are mutually exclusive. For example, a specimen having high attenuation, such as steel, should be examined by a low frequency beam of about 0.5 MHz and a large transducer diameter about 50 mm (2 in.), which provides a high penetration, but a relatively low lateral resolution of about 6 mm ( $\frac{1}{4}$  in.). Improved resolution can be obtained by using shear waves, because these have shorter wavelengths than compression waves of the same frequency in the solid. (The velocity of a longitudinal wave in a solid is greater than that of the shear wave of the same frequency.) Large diameter transducers are chosen to produce a narrow focused beam, which enhances the lateral resolution.

**Fig. 3** Oscilloscope displays using ultrasonic transducers of (a) high and low penetration (ability to detect defects at distances within the solid), and (b) high and low resolution (ability to separate echoes from closely-spaced defects)

## Couplants

Air is a poor transmitter of sound waves at megahertz frequencies. Also, because the acoustic impedance mismatch between air and most solids is significant, even a very thin layer of air severely retards the transmission of sound waves from the transducer to the test piece. Therefore, it is necessary to use a couplant to eliminate air between the transducer and the test piece for satisfactory contact inspection.

Couplants normally used for contact inspection include water, oils, glycerin, petroleum greases, silicone grease, cellulose gum, and various commercial pastelike substances. Certain soft rubbers that transmit sound waves can be used where adequate coupling can be achieved by applying pressure to the search unit.

Factors that should be considered in selecting a couplant include:

- Surface finish of test piece
- Temperature of test surface
- Possibility of chemical reactions between test surface and couplant
- Cleaning requirements (some couplants are difficult to remove)

Water is a suitable couplant for use on a relatively smooth surface, but a wetting agent should be added. The addition of glycerin sometimes is necessary to increase viscosity.

Heavy oil or grease should be used on hot and vertical surfaces and on rough surfaces where irregularities need to be filled.

Cellulose gum is especially useful on rough surfaces when good coupling is needed to minimize background noise and yield an adequate signal-to-noise ratio.

## Basic Inspection Methods

Ultrasound can be used to measure material thickness by (a) determining resonant frequencies of a test piece and (b) measuring time required for an ultrasonic-wave packet (pulse) to traverse the test piece. The former uses reflected ultrasound to create standing waves in the test piece; the frequencies at which standing waves occur are used to compute thickness. In the latter method, the time it takes for a pulse of ultrasonic energy to be transmitted through the test piece is measured; this time period can be 100 nanoseconds or less. Thickness is calculated as the product of the measured time of flight and the known acoustic-wave velocity.

Ultrasound can be used to detect flaws by measuring (a) the amplitude of the acoustic pressure wave and time of flight of reflected acoustic waves and (b) the amplitude of the acoustic pressure wave of either transmitted or reflected acoustic waves. The pulse-echo technique is the most widely used ultrasonic technique. Flaws are detected and their sizes estimated by comparing the amplitude of a reflected echo from an interface (either within the test piece or at the back surface) with the amplitude of an echo reflected from a reference interface of known size or from the back surface of a test piece that has no flaws. The echo from the back surface (back reflection) serves as a reference point for time-of-flight measurements that enable measuring the depth of some internal flaws. It is necessary that an internal flaw reflect at least part of the sound energy onto the receiving transducer to measure depth. However, echoes from flaws are not essential to their detection. Just because the amplitude of an echo from back reflection of a test piece is lower than that of an echo from an identical flaw-free workpiece implies that the test piece contains one or more flaws. Detection of the presence of flaws by sound attenuation is used in both transmission and pulse-echo techniques. The inability to detect flaw depth is the main disadvantage of attenuation techniques.

## Pulse-Echo Method

In pulse-echo inspection, short bursts of ultrasonic energy (pulses, or wave packets) are introduced into a test piece at regular time intervals. If the pulses encounter a reflecting surface, some or all of the energy is reflected. The proportion of energy that is reflected is highly dependent on the size of the reflecting surface in relation to the size of the incident ultrasonic beam. The direction of the reflected beam (echo) depends on the orientation of the reflecting surface with respect to the incident beam. Reflected energy is monitored; both the amount of energy reflected in a specific direction and the time delay between transmission of the initial pulse and receipt of the echo are measured.

**Principles of Operation.** Most pulse-echo systems consist of (a) an electronic clock; (b) an electronic signal generator, or pulser; (c) a sending transducer; (d) a receiving transducer; (e) an echo-signal amplifier; and (f) a display device. In the most widely used version of pulse-echo systems, a single transducer acts alternatively as a sending and receiving transducer. The clock and signal generator usually are combined in a signal electronic unit. Frequently, circuits that amplify and demodulate echo signals from the transducer are housed in the same unit.

In a pulse-echo system with a single search unit, the electronic clock triggers the signal generator at regular intervals, which imposes a short burst of high-frequency alternating voltage on the transducer element. Simultaneously, the clock activates a time-measuring circuit connected to the display device. The operator preselects a constant interval between pulses by means of a "pulse-repetition-rate" control on the instrument; pulses usually are repeated 100 to 2000 times per second. The operator also can preselect the signal generator or pulser output frequency. For best results, frequency (and sometimes the pulse-repetition rate) should be tuned to achieve the maximum response of the transducer (resonance in the vibrating element) and maximum signal-to-noise ratio (lowest amount of electronic noise) in the electronic equipment. The transducer converts the pulse of alternating voltage into a pulse of mechanical vibration having essentially the same frequency as the imposed alternating voltage. The mechanical vibration (ultrasound) is introduced into a test piece through a couplant and travels by wave motion through the test piece at the speed of sound. When the pulse of ultrasound encounters a reflecting surface that is perpendicular to the direction of travel, ultrasonic energy is reflected and returns to the transducer. The returning pulse travels along the same path and at the same speed as the initial pulse, but in the opposite direction.

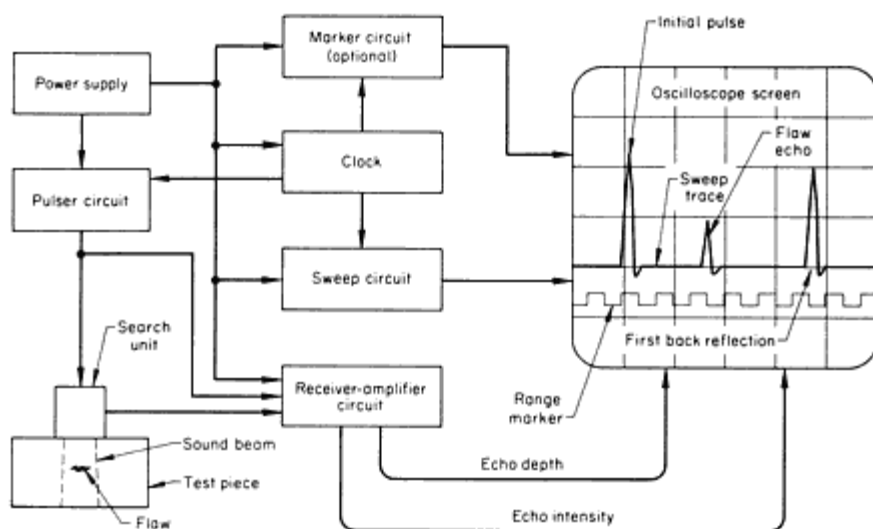

**Data Presentation.** Information from pulse-echo inspection can be displayed in one of three forms: (a) A-scan, which is a quantitative display of echo amplitude and time-of-flight data obtained at a single point on the surface of the test piece; (b) B-scan, which is a quantitative cross-sectional display of time-of-flight data obtained along a plane

perpendicular to the surface of the test piece; or (c) C-scan, which is a semiquantitative display of echo amplitude obtained over an area of the surface of the test piece. The A-scan display, which is the most widely used form, can be analyzed in terms of the type, size, and location (chiefly depth) of internal flaws.

**A-scan display** basically is a plot of amplitude versus time, in which a horizontal baseline on an oscilloscope screen indicates elapsed time and vertical deflections (called indications or signals) represent echos. A typical A-scan setup that illustrates the essential elements in a basic system for pulse-echo inspection is shown in Fig. 4. These elements include:

- Power supply, which can run on 110-volt alternating current or on batteries
- Electronic clock, or timing circuit, to trigger pulser and display circuits
- Pulser circuit, or rate generator, to control frequency, amplitude, and pulse-repetition rate of the voltage pulses that excite the search unit
- Receiver-amplifier circuit to convert output signals from the search unit into a form suitable for oscilloscope display
- Sweep circuit to control (a) time delay between search-unit excitation and start of oscilloscope trace and (b) rate at which oscilloscope trace travels horizontally across the screen
- Marker circuit (optional) to produce a secondary trace, on or below the main trace, usually in the form of a square wave, which is used for precise depth measurements
- Oscilloscope screen, including separate controls for trace brightness, trace focus, and illuminated measuring grid
- Flaw gate (not shown) to isolate the echo of interest for further processing

**Fig. 4** Typical A-scan setup, including video-mode display, for a basic pulse-echo, ultrasonic-inspection system

The search unit and the coaxial cable connecting the unit to the instrument, although not strictly part of the electronic circuitry, must be matched to the electronics.

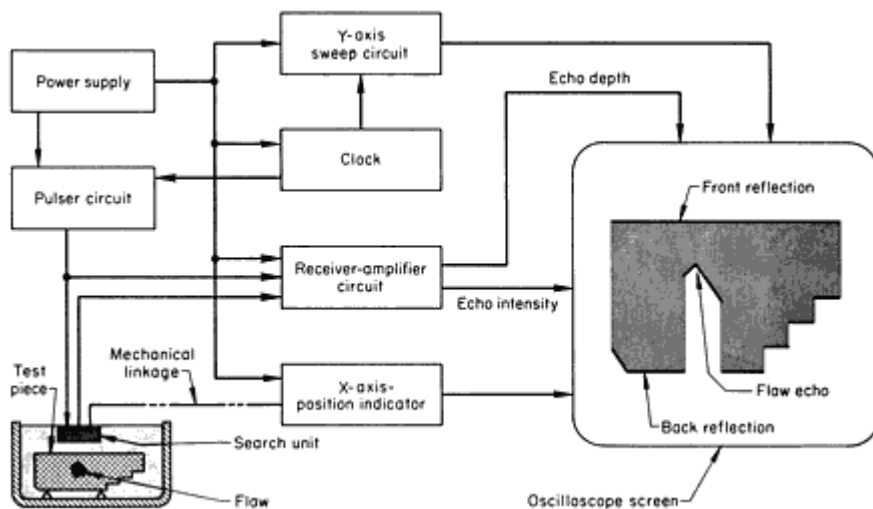

**B-scan display** is a plot of time versus distance, in which one orthogonal axis on the display corresponds to elapsed time, while the other axis represents the position of the search unit along a line on the surface of the test piece relative to the position of the search unit at the start of the inspection. Echo amplitude is not measured directly as in A-scan inspection, but often it is indicated semiquantitatively by the relative brightness of echo indications on an oscilloscope screen.

Figure 5 shows a typical B-scan system. System functions are identical to those of the A-scan system except for the following differences:

- The display is generated on an oscilloscope screen consisting of a long-persistence phosphor; that is, a

phosphor that continues to fluoresce long after the means of excitation ceases to fall on the fluorescing area of the screen. This allows the imaginary cross section to be viewed as a whole without having to resort to permanent imaging methods such as photographs. (Photographic equipment, facsimile recorders, or *x-y* plotters can be used to record B-scan data for later reference.)

- Oscilloscope input for one axis of the display is provided by an electromechanical device, which generates an electrical voltage proportional to the position of the search unit relative to a reference point on the surface of the test piece. Most B-scans are generated by scanning the search unit in a straight line across the surface of the test piece at a uniform rate. One axis of the display (usually the horizontal axis) represents the distance traveled along this line.
- Echoes are indicated by bright spots on the screen rather than by deflections of the time trace. The position of a bright spot along the axis orthogonal to the search-unit position axis (usually measured top to bottom on the screen) indicates the depth of the echo within the test piece.
- The echo-intensity signal from the receiver-amplifier is connected to the trace-brightness control on the oscilloscope to ensure that echoes are recorded as bright spots. In some systems, the brightnesses corresponding to different values of echo amplitude has sufficient contrast to permit semiquantitative appraisal of echo amplitude, which is related to flaw size and shape.

**Fig. 5** Typical B-scan setup, including video-mode display, for a basic pulse-echo, ultrasonic-inspection system

The oscilloscope screen in Fig. 5 illustrates the type of video-mode display that is generated by B-scan equipment. The internal flaw in the test piece shown at left in Fig. 5 is shown only as a profile view of its top reflecting surface. Portions of the test piece that are behind this large reflecting surface are in shadow.

**C-scan display** records echoes from internal portions of test pieces as a function of the position of each reflecting interface within an area. Flaws are shown on a readout, superimposed on a plan view of the test piece, and both flaw size (flaw area) and position within the plan view are recorded. Flaw depth typically is not recorded, although it can be measured semiquantitatively by restricting the range of depths within the test piece that is covered in a given scan.

In a basic C-scan system, shown schematically in Fig. 6, the search unit is moved over the surface of the test piece in a search pattern. The search pattern can take many forms, such as a series of closely spaced parallel lines, a fine zigzag pattern, and a spiral pattern (polar scan). Mechanical linkage connects the search unit to *x*-axis and *y*-axis position indicators, which in turn, feed position data to the *x-y* plotter or facsimile device. Echo-recording systems vary; some produce a shaded-line scan with echo amplitude recorded as a variation in line shading, while others indicate flaws by an absence of shading, so each flaw appears as a blank space on the display (see Fig. 6).

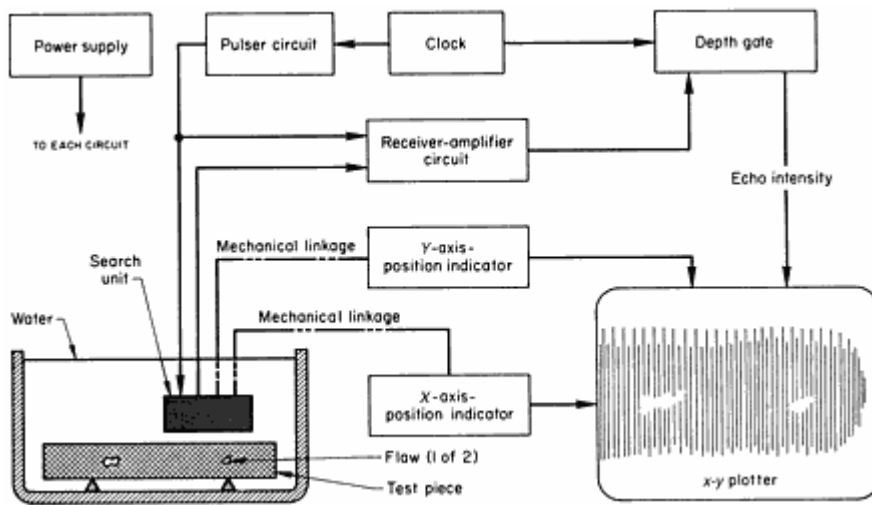

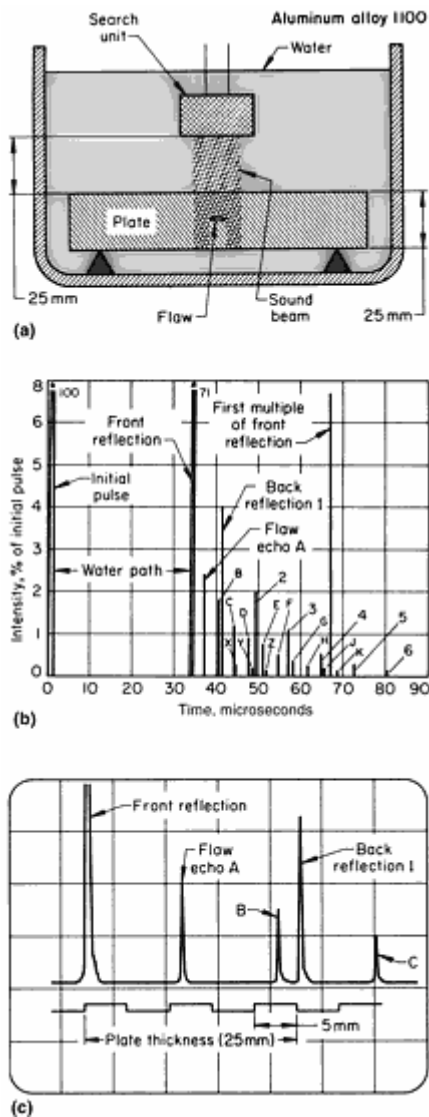

Fig. 6 Typical C-scan setup, including display, for a basic pulse-echo, ultrasonic-inspection system

## Interpretation of Pulse-Echo Data

Interpretation of pulse-echo data is relatively straightforward for B-scan and C-scan presentations. The B-scan always records the front reflection, while internal echoes and/or loss of back reflection are interpreted as flaw indications. Flaw depth is measured as the distance from the front reflection to a flaw echo, the latter representing the front surface of the flaw.

In contrast to normal B-scan and C-scan displays, A-scan displays can be complex. It is necessary to disregard electronic noise, spurious echoes, and extra echoes resulting from mode conversion of the initial pulse to focus attention on any flaw echoes that might be present.

**Basic A-scan displays** are of the type shown in Fig. 7 for immersion inspection of a plate containing a flaw. The test material is 25 mm (1 in.) thick aluminum alloy 1100 plate containing a purely reflecting planar flaw 11.25 mm (0.44 in.) deep. The flaw is 45% of plate thickness, exactly parallel to the plate surfaces, and has an area equal to one-third the cross section of the ultrasonic beam. Testing is by straight-beam immersion in a water-filled tank. There are no attenuation losses within the test plate, only transmission losses across front and back surfaces.

**Fig. 7** Schematic representation of straight-beam immersion inspection of a 25 mm thick aluminum alloy 1100 plate containing a planar discontinuity, showing (a) inspection setup, (b) complete video-mode A-scan display, and (c) normal oscilloscope display

The normal display (Fig. 7c) represents only a portion of the complete video-mode A-scan display (Fig. 7b). The normal display is obtained by adjusting horizontal-position and horizontal-sweep controls to display only the portion of the trace corresponding to the transit time (time of flight) required for a single pulse of ultrasound to traverse the test piece from front surface to back surface and return. Also, receiver-amplifier gain is adjusted until the height of the first back reflection equals some arbitrary distance on the screen, usually a convenient number of grid lines.

Most flaws are not exactly parallel to the surface of the testpiece, not truly planar (they have rough, curved interfaces), not ideal reflectors, and are of unknown size. These factors together with bulk material sound-attenuating characteristics affect echo signal size and shape.

**Angle-Beam Technique.** Most angle-beam testing is accomplished using shear waves, although refracted longitudinal waves and surface waves can be used in some applications. In contrast to straight-beam testing, only flaw indications appear on the display in an angle-beam test. Only rarely will a back surface be oriented properly to give a back-reflection indication. In most instances, ultrasonic beams are reflected from the back surface at an angle away from the search unit. The reflected pulses are capable of detecting discontinuities and are used extensively in angle-beam testing of welds, pipe and tubing, and sheet and plate.

The time base (horizontal sweep) on the oscilloscope must be carefully calibrated, because in angle-beam testing there is no back-reflection echo to provide a reference to estimate flaw depth. Usually, an extended time base is used so flaws are located with one or two skip distances from the search unit (see Fig. 8 for the definition of skip distance).

**Fig. 8** Angle-beam testing using a contact transducer on a (a) plate and (b) pipe

Figure 8(a) shows how a shear wave from an angle-beam transducer progresses through a flat testpiece--by reflecting from the surfaces at points called "nodes." The linear distance between two successive nodes on the same surface is called the "skip distance," and is important in defining the path over which the transducer should be moved for reliable and efficient scanning. The skip distance can easily be measured by using a separate receiving transducer to detect the nodes or by using an angle-beam test block, or it can be calculated. The region over which the transducer should be moved to scan the test piece can be determined once the skip distance is known.

Moving the search unit back and forth between one-half skip distance and one skip distance from an area of interest can be used not only to define the location, depth, and size of a flaw, but also to initially detect flaws. Figure 9 illustrates this back-and-forth movement as a way of scanning a weld for flaws.

**Fig. 9** Three positions of a contact type of transducer along the zigzag scanning path used during manual angle-beam ultrasonic inspection of welded joints. The movement of the sound beam path across the weld is

shown on a section taken along the centerline of the transducer as it is moved from the far left position in the (a) scanning path, (b) through an intermediate position, (c) to the far right position.

Sometimes, moving the search unit in an arc about the position of a suspected flaw or swiveling the search unit about a fixed position can be equally useful (Fig. 10a). As shown in Fig. 10(b), traversing the search unit in an arc about the location of a gas hole produces little or no change in the echo. The indication on the oscilloscope screen remains constant in both amplitude and position on the trace as the search unit is moved. Conversely, if the search unit was swiveled on the same spot, the indication would abruptly disappear after the search unit was swiveled only a few degrees.

**Fig. 10** Angle-beam inspection of a weldment, showing effect of search-unit movements on oscilloscope-screen display patterns from three different types of flaws in welds. (a) Positions of search units on the test piece. (b) Display pattern obtained from a gas hole as the result of traversing the search unit in an arc about the location of the flaw. (c) Display pattern obtained from a slag inclusion as the result of swiveling the search unit on a fixed point. (d) Display pattern obtained from a crack, using the same swiveling search-unit movement as in (c)

## Transmission Methods

Regardless of whether transmission ultrasonic testing is done using direct beams or reflected beams, flaws are detected by comparing the amount of ultrasound transmitted through the test piece with the amount transmitted through a reference standard made of the same material. Transmission testing requires two search units, one to transmit the ultrasonic waves and one to receive them.

The main application of transmission methods is the inspection of plate for cracks or laminations that have relatively large dimensions compared with the size of the search units. Immersion techniques and water-column (bubbler or squirter) techniques are most effective because they provide efficient and relatively uniform coupling between the search units and the test piece.

**Display** of transmission-test data can be oscilloscope traces, strip-chart recordings, and meter readings. Oscilloscopes are used to record data mainly when using pulsed sound beams; strip charts and meters are more appropriate for continuous beams. With all three types of display, alarms or automatic sorting devices can be used to give audible warning or to shunt defective workpieces out of the normal flow of production.

**Pitch-catch testing** can be done with either direct beams (through-transmission testing) or reflected beams. In both instances, pulses of ultrasonic energy pass through the material, and pulse intensities are measured at the point of emergence. An oscilloscope display is triggered simultaneously with the initial pulse, and the transmitted-pulse indication appears on the screen to the right of the initial-pulse indication in a manner similar to the back-reflection indication in pulse-echo testing. A major advantage of pitch-catch testing is that disturbances and spurious indications can be separated from the transmitted pulse by their corresponding transit times. Only the amplitude of the transmitted pulse is monitored; all other sound waves reaching the receiver are ignored. An electronic gate can be set to operate an alarm or a sorting device when the monitored amplitude of the ultrasonic wave drops below a preset value.

When reflected pulses are used, the technique is almost identical to the loss-of-back-reflection technique, which often is used in ordinary pulse-echo testing.

## General Characteristics of Ultrasonic Waves

In contrast to electromagnetic waves, such as light and x-rays, ultrasonic waves are mechanical waves consisting of oscillations, or vibrations, of the atomic or molecular particles of a substance about the equilibrium position of those particles. Ultrasonic waves can propagate in elastic media, which can be solid or liquid. Ultrasonic waves in the megahertz region are severely attenuated in air and cannot propagate in a vacuum. An ultrasonic beam is similar to a light beam. Both obey general wave equations and each travels at a characteristic velocity that depends on the properties of that medium. Ultrasonic beams, like light beams, are reflected from surfaces and are refracted when they cross boundaries between two media that have different acoustic velocities. Depending on the mode of particle motion, ultrasonic waves are classified as longitudinal waves, vertically and horizontally polarized shear and transverse waves, surface waves, Lamb waves, etc. Four wave modes are described in the following paragraphs.

**Longitudinal waves**, sometimes called compression waves, are most widely used in the inspection of metals. They travel through metal as a series of alternate compressions and rarefactions, in which the particles transmitting the wave vibrate back and forth in the direction of travel of the waves.

Longitudinal ultrasonic waves and the corresponding particle oscillation and resultant rarefaction and compression are represented schematically in Fig. 11(a). A plot of amplitude of particle displacement versus distance of wave travel, together with the resultant rarefaction trough and compression crest, is shown in Fig. 11(b). The distance from one crest to the next (which equals the distance for one complete cycle of rarefaction and compression) is the wavelength ( $\lambda$ ). The vertical axis in Fig. 11(b) could represent pressure instead of particle displacement. The horizontal axis could represent time instead of travel distance because the speed of sound is constant in a given material, and this relation is used in the measurements made in ultrasonic inspection.

**Fig. 11** Schematic representation of longitudinal ultrasonic waves. (a) Particle oscillation and resultant rarefaction and compression. (b) Amplitude of particle displacement versus distance of wave travel. The wavelength ( $\lambda$ ) is the distance corresponding to one complete cycle.

Longitudinal ultrasonic waves are readily propagated in liquids and elastic solids. The mean free paths of the molecules of liquids are so short that longitudinal waves can be propagated simply by the elastic collision of one molecule with the next. The velocity of longitudinal ultrasonic waves is about 6000 m/s (19,700 ft/s) in steel and about 1500 m/s (4900 ft/s) in water.

**Transverse waves (shear waves)** also are used extensively in ultrasonic inspection of metals. Transverse waves are visualized readily in terms of vibrations of a rope that is shaken rhythmically, in which each particle vibrates up and down in a plane perpendicular to the direction of propagation. A transverse wave is represented schematically in Fig. 12, which shows particle oscillation, wave front, direction of wave travel, and the wavelength ( $\lambda$ ) corresponding to one cycle.

**Fig. 12** Schematic representation of transverse (shear) waves. The wavelength ( $\lambda$ ) is the distance corresponding to one complete cycle.

Air and water do not support transverse waves. In gases, the forces of attraction between molecules are so small that shear waves cannot be transmitted. The same is true of a liquid, unless it is particularly viscous or is present as a very thin layer.

**Surface waves** (Rayleigh waves) are another type of ultrasonic waves used in the inspection of metals. These waves travel along the flat and curved surfaces of relatively thick solid parts. For propagation of waves of this type, the waves must be traveling along an interface bounded on one side by the strong elastic forces of a solid and on the other side by the practically negligible elastic forces between gas molecules. Surface waves, therefore, are essentially nonexistent in a solid immersed in a liquid, unless the liquid covers the solid surface only as a very thin film.

Surface waves are subject to less attenuation in a given material than are longitudinal and transverse waves. They have a velocity approximately 90% of the transverse-wave velocity in the same material. The region within which these waves propagate with effective energy is not much thicker than about one wavelength beneath the surface of the metal. At this depth, wave energy is about 4% of the wave energy at the surface, and the amplitude of oscillation decreases sharply to a negligible value at greater depths.

In Rayleigh waves, particle oscillation generally follows an elliptical orbit, as shown schematically in Fig. 13. The major axis of the ellipse is perpendicular to the surface along which the waves are traveling. The minor axis is parallel to the direction of propagation. Rayleigh waves can exist in complex forms, which are variations of the simplified wave form illustrated in Fig. 13.

**Fig. 13** Diagram of surface (Rayleigh) waves propagating at the surface of a metal along a metal-air interface. The wavelength ( $\lambda$ ) is the distance corresponding to one complete cycle.

**Lamb waves**, also known as plate waves, are propagated in a mode in which the ultrasonic beam is contained within two parallel boundary surfaces (such as a plate or the wall of a tube). A Lamb wave consists of a complex vibration that occurs throughout the thickness of the material. The propagation characteristics of Lamb waves depend on the density, elastic properties, and structure of the metal, and are influenced by material thickness.

Two basic forms of Lamb waves are (a) symmetrical, or dilatational and (b) asymmetrical, or bending. The form is determined by whether the particle motion is symmetrical or asymmetrical with respect to the neutral axis of the test piece. Each form is further subdivided into several modes having different velocities, which can be controlled by the angle at which the waves enter the test piece. Theoretically, there are an infinite number of specific velocities at which Lamb waves can travel in a given material. Within a given plate, the specific velocities of Lamb waves are complex functions of plate thickness and cyclic frequency.

In symmetrical Lamb waves, there is a compressional (longitudinal) particle displacement along the neutral axis of the plate and an elliptical particle displacement on each surface (see Fig. 14a). In asymmetrical Lamb waves, there is a shear (transverse) particle displacement along the neutral axis of the plate and an elliptical particle displacement on each surface (see Fig. 14b). The ratio of the major to minor axes of the ellipse is a function of the material in which the wave is being propagated.

**Fig. 14** Diagram of the basic patterns of (a) symmetrical (dilatational) and (b) asymmetrical (bending) Lamb waves. The wavelength ( $\lambda$ ) is the distance corresponding to one complete cycle.

## Factors Influencing Ultrasonic Inspection

Both the characteristics of ultrasonic waves used and the part being inspected must be considered in ultrasonic inspection. Equipment type and capability are influenced by these variables; often, different types of equipment must be selected to accomplish different inspection objectives.

Selection of inspection frequency is a compromise between the ability of the ultrasonic beam to penetrate the material and the time or depth resolution desired. A high frequency generally provides high resolution and high definition, while a lower frequency might be required to achieve the desired penetration.

Sensitivity, or the ability of an ultrasonic-inspection system to detect a very small discontinuity, generally is increased by using relatively high frequencies (short wavelengths). Frequency ranges commonly used in nondestructive testing (NDT) are listed in Table 3.

**Table 3** Common ultrasonic testing frequency ranges and applications

Frequency range	Applications
<b>200 kHz-1 MHz</b>	Coarse-grain castings: gray iron, nodular iron, copper, and stainless steels
<b>400 kHz-5 MHz</b>	Fine-grain castings: steel, aluminum, brass
<b>200 kHz-2.25 MHz</b>	Plastics and plastic like materials
<b>1-5 MHz</b>	Rolled products: metallic sheet, plate, bars, and billets
<b>2.25-10 MHz</b>	Drawn and extruded products: bars, tubes, and shapes
<b>1-10 MHz</b>	Forgings
<b>2.25-10 MHz</b>	Glass and ceramics
<b>1-2.25 MHz</b>	Welds
<b>1-10 MHz</b>	Fatigue cracks

**Acoustic Impedance.** When ultrasonic waves traveling through one medium impinge on the boundary of a second medium, a portion of the incident acoustic energy is reflected back from the boundary while the remaining energy is transmitted into the second medium. The characteristic that determines the amount of reflection is the acoustic impedance of the two materials on either side of the boundary. If the impedances of the two materials are equal, there is no reflection; if the impedances differ greatly (between a metal and air, for example), there is virtually complete reflection.

This characteristic is used in ultrasonic inspection of metals to calculate the amounts of energy reflected and transmitted at impedance discontinuities, and to aid in the selection of suitable materials for effective transfer of acoustic energy between components in ultrasonic-inspection systems.

The acoustic impedance for a longitudinal wave ( $Z_l$ ), in grams per square centimeter-second, is defined as the product of material density ( $\rho$ ), in grams per cubic centimeter, and longitudinal-wave velocity ( $V_l$ ), in centimeters per second:

$$Z_l = \rho V_l$$

Table 4 lists acoustic properties of several metals and nonmetals. The acoustic properties of metals and alloys are influenced by variations in structure and metallurgical condition. Therefore, for a given test piece, the properties may differ somewhat from the values shown in Table 4.

**Table 4 Acoustic properties of several metals and nonmetals**

**Angle of Incidence.** Only when an ultrasonic wave is incident at right angles on an interface between two materials (normal incidence, or angle of incidence = 0°) do transmission and reflection occur at the interface without any change in beam direction. At any other angle of incidence, the phenomena of mode conversion (a change in the nature of the wave motion) and refraction (a change in direction of wave propagation) must be considered. These phenomena can affect the entire beam or only a portion of the beam. The sum total of the changes that occur at the interface depends on the angle of incidence and the velocity of the ultrasonic waves leaving the point of impingement on the interface. All possible ultrasonic waves leaving this point are shown for an incident longitudinal ultrasonic wave in Fig. 15. Not all the waves shown in Fig. 15 will be produced in any specific instance of oblique impingement of an ultrasonic wave on an interface between two materials. The waves that propagate in a given instance depend on the angle of incidence of the initial beam, the velocities of the wave forms in both materials, and the ability of a wave form to exist in a given material.

**Fig. 15** Wave mode conversion at a boundary. There is an angle of incidence  $\alpha_1$  of the incoming longitudinal wave, such that the angle of the transmitted longitudinal wave  $\alpha_2$  becomes  $90^\circ$ . At angles of incidence greater than  $\alpha_1$ , the longitudinal wave of velocity does not penetrate into medium II, and only the shear wave is transmitted. This is used to separate longitudinal and shear waves to have only a single wave velocity traveling in medium II.

**Critical Angles.** If the angle of incidence ( $\alpha_1$  in Fig. 15) is small, sound waves propagating in a given medium undergo mode conversion at a boundary, resulting in simultaneous propagation of longitudinal and transverse (shear) waves in a second medium. If the angle is increased, the direction of the refracted longitudinal wave will approach the plane of the boundary ( $\alpha_2 \rightarrow 90^\circ$ ). At some specific value of  $\alpha_1$ ,  $\alpha_2$  will exactly equal  $90^\circ$ , and the refracted longitudinal wave will disappear, leaving only a refracted (mode-converted) shear wave to propagate in the second medium. This value of  $\alpha_1$  is known as the "first critical angle." If  $\alpha_1$  is increased beyond the first critical angle, the direction of the refracted shear wave will approach the plane of the boundary ( $\beta_2 \rightarrow 90^\circ$ ). At a second specific value of  $\alpha_1$ ,  $\beta_2$  will exactly equal  $90^\circ$  and the refracted transverse wave will disappear. This second value of  $\alpha_1$  is called the "second critical angle."

In ordinary angle-beam inspection, it usually is desirable to have only a shear wave propagating in the test material. Because longitudinal waves and shear waves propagate at different speeds, echo signals are received at different times, depending on which type of wave produces the echo. When both types are present in the test material, confusing echo patterns can be displayed on the readout device, which can lead to an erroneous interpretation. Frequently, it can be useful to produce shear waves in a material at an angle of  $45^\circ$  to the surface. In most materials, incident angles for mode conversion to a  $45^\circ$  shear wave lie between the first and second critical angles. Typical values of  $\alpha_1$  for all three of these (first critical angle, second critical angle, and incident angle for mode conversion to  $45^\circ$  shear waves) are listed in Table 5 for various metals.

**Table 5** Critical angles for immersion and contact testing, and incident angle for  $45^\circ$  shear-wave transmission, in various metals

Using angle block (wedge) made of acrylic plastic.

**Absorption** of ultrasonic energy occurs mainly by conversion of mechanical energy into heat. Elastic motion within a substance as a sound wave propagates through it alternately heats the substance during compression and cools it during rarefaction. Because heat flows so much more slowly than an ultrasonic wave, thermal losses are incurred, which progressively reduces energy in the propagating wave. A related thermal loss occurs in polycrystalline materials: a thermoelastic loss arises from heat flow away from grains that have received more compression or expansion in the course of wave motion than did adjacent grains. For most polycrystalline materials this effect is most pronounced at the low end of the ultrasonic-frequency spectrum.

**Scattering** of an ultrasonic wave occurs because most materials are not truly homogeneous. Crystal discontinuities such as grain boundaries, twin boundaries, and minute nonmetallic inclusions deflect small amounts of ultrasonic energy out of the main ultrasonic beam. Also, especially in mixed microstructures and anisotropic materials, mode conversion at crystallite boundaries occurs because of slight differences in acoustic velocity and acoustic impedance across the boundaries.

Scattering is highly dependent on the relation of crystallite size (mainly grain size) to ultrasonic wavelength. When grain size is less than 0.01 times the wavelength, scatter is negligible. Scattering effects vary approximately with the third power of grain size, and when the grain size is 0.1 times the wavelength or larger, excessive scattering may make it impossible to do valid ultrasonic inspections.

**Diffraction.** A sound beam propagating in a homogeneous medium is coherent; that is, all particles that lie along any given plane parallel to the wave front vibrate in identical patterns. When a wave front passes the edge of a reflecting surface, the front bends around the edge in a manner similar to that in which light bends around the edge of an opaque object. When the reflector is very small compared with the sound beam, as is usual for a pore or an inclusion, wave bending (forward scattering) around the edges of the reflector produces an interference pattern in a zone immediately behind the reflector because of phase differences among different portions of the forward-scattered beam. The interference pattern consists of alternate regions of maximum and minimum intensity that correspond to regions where interfering scattered waves are in phase and out of phase, respectively.

Diffraction phenomena must be taken into account during development of ultrasonic-inspection procedures.

**Near-Field and Far-Field Effects.** The face of the transducer element vibrates in a complex manner, which can most easily be described as a mosaic of tiny, individual crystals, each vibrating in the same direction but slightly out of phase with its neighbors. Each element in the mosaic functions as a point (Huygens) source, and radiates a spherical wave outward from the plane of the transducer face.

Along the central axis of the composite ultrasonic beam, the series of acoustic-pressure maximums and minimums become broader and more widely spaced as the distance from the transducer face,  $d$ , increases. Where  $d$  becomes equal to  $N$  (length of the near field), the acoustic pressure reaches a final maximum and decreases approximately exponentially with increasing distance, as shown in Fig. 16.

**Fig. 16** Variation of acoustic pressure with distance ratio for a circular search unit. Distance ratio is distance from crystal face,  $d$ , divided by length of near field,  $N$ .

**Beam Spreading.** In the far field of an ultrasonic beam, the wave front expands with increasing distance from a transducer. The angle of divergence from the central axis of the beam from a circular transducer is determined from ultrasonic wavelength and transducer size.

## **Advantages, Disadvantages, and Applications**

**Advantages.** The principal advantages of ultrasonic inspection compared with other methods of nondestructive inspection of metal parts are:

- Superior penetrating power, which permits detection of flaws deep in the part. Ultrasonic inspection is done routinely to depths of several feet in many types of parts and to depths of about 6 m (20 ft) in axial inspection of parts such as long steel shafts and rotor forgings.
- High sensitivity, permitting detection of extremely small flaws
- Greater accuracy than other nondestructive methods in determining the positions of internal flaws, estimating their sizes, and characterizing them in terms of nature, orientation, and shape
- Only one surface need be accessible.
- Operation is electronic, which provides almost instantaneous indications of flaws. This makes the method suitable for immediate interpretation, automation, rapid scanning, in-line production monitoring, and process control. With most systems, a permanent record of inspection results can be made.
- Volumetric scanning ability, permitting inspection of a volume of metal extending from the front surface to the back surface of a part
- Ultrasonic inspection presents no radiation hazard to operations or nearby personnel, and has no effect on equipment and materials in the vicinity
- Portability

**Disadvantages** of ultrasonic inspection include:

- Manual operation requires careful attention by experienced technicians.
- Technical knowledge is required to develop inspection procedures.
- Parts that are rough, irregular in shape, very small and thin, and not homogeneous are difficult to inspect.
- Discontinuities that are present in a shallow layer immediately beneath the surface might not be detectable.
- Couplants are needed to provide effective transfer of the ultrasonic beam between search units and parts being inspected.
- Reference standards are required, both to calibrate equipment and to characterize flaws.

**Applications.** Some of the major types of components that are ultrasonically inspected for the presence of flaws are:

- Mill components: rolls, shafts, drives, and press columns
- Power equipment: turbine forgings, generator rotors, pressure piping, weldments, pressure vessels, nuclear fuel elements, and other reactor components
- Jet-engine parts: turbine and compressor forgings, and gear blanks
- Aircraft components: forging stock, frame sections, and honeycomb sandwich assemblies
- Machinery materials: die blocks, tool steels, and drill pipe
- Railroad parts: axles, wheels, and bolted and welded rail
- Automotive parts: forgings, ductile castings, brazed and/or welded components

Ultrasonic inspection is an effective and inexpensive method for volumetric examination of structures and components of both regular and complex shapes.

# Acoustic Emission Inspection

## Introduction

ACOUSTIC EMISSION is defined as the high-frequency stress waves generated by the rapid release of strain energy that occurs within a material during crack growth, plastic deformation, phase transformation, etc. This energy may originate from stored elastic energy as in crack propagation, or from stored chemical-free energy as in phase transformation.

Sources of acoustic emission that generate stress waves in material include local dynamic movements such as the initiation and propagation of cracks, twinning, slip, sudden reorientation of grain boundaries, bubble formation during boiling, or martensitic phase transformations. The stresses in a metallic system may be well below the elastic design limits, and yet the region near a flaw or crack tip may undergo plastic deformation and fracture from locally high stresses, ultimately resulting in premature or catastrophic failure under service conditions.

Acoustic-emission inspection detects and analyzes minute acoustic-emission signals generated by discontinuities in materials under applied stress. Proper analysis of these signals can provide information concerning the location and structural significance of the detected discontinuities.

Another important feature of acoustic emission in general is its irreversibility. If a material is loaded to a given stress level and then unloaded, usually no emission will be observed upon immediate reloading until the previous load has been exceeded.

## Types of Acoustic Emissions

Basically, there are two types of acoustic emissions: continuous and burst. The wave form of continuous-type emissions is similar to Gaussian random noise, but the amplitude varies with acoustic-emission activity. In metals and alloys, this form of emission is thought to be associated with the dislocation movements in the grains. Burst-type emissions are of short-duration pulses (ten microseconds to a few milliseconds in length) and are associated with discrete releases of strain energy. Burst-type emissions are generated by twinning, microyielding, and the development of microcracks and macrocracks. Burst-type emissions have a greater amplitude than the continuous type.

## Relationship to Other Test Methods

Acoustic emission (AE) differs from most other nondestructive testing (NDT) methods in two key respects. First, the signal has its origin in the material itself, not in an external source. Second, acoustic emission detects movement, while most other methods detect existing geometrical discontinuities. Table 1 summarizes the consequences of these fundamental differences.

**Table 1 Characteristics of acoustic emission inspection compared with other inspection methods**

Acoustic emission	Other methods
<b>Detects movement of defects</b>	Detect geometric form of defects
<b>Requires stress</b>	Do not require stress
<b>Each loading is unique</b>	Inspection is directly repeatable
<b>More material sensitive</b>	Less material sensitive
<b>Less geometry sensitive</b>	More geometry sensitive
<b>Less intrusive on plant/process</b>	More intrusive on plant/process
<b>Requires access only at sensors</b>	Require access to whole area of inspection
<b>Tests whole structure at once</b>	Scan local regions in sequence
<b>Main problems: noise related</b>	Main problems: geometry related

A major benefit of AE inspection is that it allows the whole volume of the structure to be inspected nonintrusively in a single loading operation. It is not necessary to scan the structure looking for local defects; it is only necessary to connect a suitable number of fixed sensors, which are typically placed 1 to 6 m (4 to 20 ft) apart. This leads to major savings in

testing large structures, for which other methods require removal of insulation, decontamination for entry to vessel interiors, or scanning of very large areas.

Typically, the global AE inspection is used to identify areas with structural problems, and other NDT methods are then used to identify more precisely the nature of the emitting defects. Depending on the case, acceptance or rejection can be based on AE inspection alone, other methods alone, or both together.

## Range of Applicability

Acoustic emission is a natural phenomenon occurring in the widest range of materials, structures, and processes. The largest-scale acoustic emissions are seismic events, while the smallest-scale processes that have been observed with AE inspection are the movements of small numbers of dislocations in stressed metals. In between, there is a wide range of laboratory studies and industrial testing.

In the laboratory, AE inspection is a powerful aid to materials testing and the study of deformation and fracture. It gives an immediate indication of the response and behavior of a material under stress, intimately connected with strength, damage, and failure. Because the AE response of a material depends on its microstructure and deformation mode, materials differ widely in their AE response. Brittleness and heterogeneity are two major factors conducive to high emissivity. Ductile deformation mechanisms, such as microvoid coalescence in soft steels, are associated with low emissivity.

In production testing, AE inspection is used for checking and controlling welds, brazed joints, thermocompression bonding, and forming operations, such as shaft straightening and punch press operations. In general, AE inspection can be considered whenever the process stresses the material and produces permanent deformation.

In structural testing, AE inspection is used on pressure vessels, storage tanks, pipelines and piping, aircraft and space vehicles, electric utility plants, bridges, railroad tank cars, bucket trucks, and a range of other equipment items. Acoustic emission tests are performed on both new and in-service equipment. Typical uses include the detection of cracks, corrosion, weld defects, and material embrittlement.

Procedures for AE structural testing have been published by The American Society of Mechanical Engineers (ASME), the American Society for Testing and Materials (ASTM), and other organizations. Successful structural testing comes about when the capabilities and benefits of AE inspection are correctly identified in the context of overall inspection needs and when the correct techniques and instruments are used in developing and performing the test procedure.

Acoustic emission equipment is highly sensitive to any kind of movement in its operating frequency range (typically 20 to 1200 kHz). The equipment can detect not only crack growth and material deformation but also such processes as solidification, friction, impact, flow, and phase transformations. Therefore, AE techniques are also valuable for:

- In-process weld monitoring
- Detecting tool touch and tool wear during automatic machining
- Detecting wear and loss of lubrication in rotating equipment and tribological studies
- Detecting loose parts and loose particles
- Detecting and monitoring leaks, cavitation, and flow
- Monitoring chemical reactions, including corrosion processes, liquid-solid transformations, and phase transformations

When these same processes of impact, friction, flow, and so on, occur during a typical AE inspection for cracks or corrosion, they constitute a source of unwanted noise. Many techniques have been developed for eliminating or discriminating against these and other noise sources. Noise has always been a potential barrier to AE applicability.

## Instrumentation

The key element in an AE system is a piezoelectric crystal (transducer) that converts movement into an electrical voltage. The crystal is housed in a suitable enclosure with a wear plate and a connector, as shown in Fig. 1. The sensor is excited by the stress waves impinging on its face, and it delivers an electrical signal to a nearby preamplifier and then to the main

signal-processing equipment. The preamplifier can be miniaturized and housed inside the sensor enclosure, facilitating setup and reducing vulnerability to electromagnetic noise.

**Fig. 1** Typical construction of an acoustic-emission resonant sensor

During an AE test, the sensors on the testpiece produce any number of transient signals. A signal from a single, discrete deformation event is known as a burst-type signal. This type of signal has a fast rise time and a slower decay. Burst-type signals vary widely in shape, size, and rate of occurrence, depending on the structure and the test conditions. If there is a high rate of occurrence, the individual burst-type signals combine to form a continuous emission. In some cases, AE inspection relies on the detection of continuous emission as in the case of leak testing.

The instrumentation of an AE inspection provides the necessary detection of continuous emissions or detectable burst-type emissions. Typically, AE instrumentation must fulfill several other requirements:

- The instrumentation must provide some measure of the total quantity of detected emission for correlation with time and/or load and for assessment of the condition of the testpiece.
- The system usually needs to provide some statistical information on the detected AE signals for more detailed diagnosis of source mechanisms or for assessing the significance of the detected signals.
- Many systems can locate the source of detectable burst-type emissions by comparing the arrival times of the wave at different sensors. This is an important capability of great value in testing both large and small structures.
- The systems should provide a means for discriminating between signals of interest and noise signals from background noise sources such as friction, impact, and electromagnetic interference.

Instruments vary widely in form, function, and price. Some are designed to function automatically in automated production environments. Others are designed to perform comprehensive data acquisition and extensive analysis at the hands of skilled researchers. Still others are designed for use by technicians and NDT inspectors performing routine tests defined by ASME codes or ASTM standards.

# Radiography

## Introduction

RADIOGRAPHY is a nondestructive-inspection method that is based on differential absorption of penetrating radiation--either electromagnetic radiation of very short wavelength or particulate radiation--by the part or test piece (object) being inspected. Because of differences in density and variations in thickness of the part, or differences in absorption characteristics caused by variations in composition, different portions of a test piece absorb different amounts of penetrating radiation. Unabsorbed radiation passing through the part can be recorded on film or photosensitive paper, viewed on a fluorescent screen, or monitored by various types of radiation detectors. The term "radiography" usually

implies a radiographic process that produces a permanent image on film (conventional radiography) or paper (paper radiography or xeroradiography), although in a broad sense it refers to all forms of radiographic inspection. When inspection involves viewing of a real-time image on a fluorescent screen or image-intensifier, the radiographic process is termed "real-time inspection." When electronic, nonimaging instruments are used to measure the intensity of radiation, the process is termed "radiation gaging." Tomography, a radiation inspection method adapted from the medical computerized axial tomography CAT scanner, provides a cross-sectional view of an inspection object. All the previous terms are used mainly in connection with inspection that involves penetrating electromagnetic radiation in the form of x-rays or gamma rays. "Neutron radiography" refers to radiographic inspection using neutrons rather than electromagnetic radiation. This article discusses radiography methods using x-rays, gamma rays, and neutrons.

In conventional radiography, an object is placed in a beam of x-rays and the portion of the radiation that is not absorbed by the object impinges on a detector such as film. The unabsorbed radiation exposes the film emulsion, similar to the way that light exposes film in photography. Development of the film produces an image that is a two-dimensional "shadow picture" of the object. Variations in density, thickness, and composition of the object being inspected cause variations in the intensity of the unabsorbed radiation and appear as variations in photographic density (shades of gray) in the developed film. Evaluation of the radiograph is based on a comparison of the differences in photographic density with known characteristics of the object itself or with standards derived from radiographs of similar objects of acceptable quality.

## Uses of Radiography

Radiography is used to detect features of a component or assembly that exhibit differences in thickness or physical density compared with surrounding material. Large differences are more easily detected than small ones. In general, radiography can detect only those features that have a reasonable thickness or radiation path length in a direction parallel to the radiation beam. This means that the ability of the process to detect planar discontinuities such as cracks depends on proper orientation of the test piece during inspection. Discontinuities such as voids and inclusions, which have measurable thickness in all directions, can be detected as long as they are not too small in relation to section thickness. In general, features that exhibit differences in absorption of a few percent compared with the surrounding material can be detected.

**Applicability.** Radiographic inspection is used extensively on castings and weldments, particularly where there is a critical need to ensure freedom from internal flaws. For instance, radiography often is specified for inspection of thick-wall castings and weldments for steam-power equipment (boiler and turbine components and assemblies) and other high-pressure systems. Radiography also can be used on forgings and mechanical assemblies. When used with mechanical assemblies, radiography provides a unique NDT capability of inspecting for condition and proper placement of components. Certain special devices are more satisfactorily inspected by radiography than by other methods. For instance, radiography is well suited to the inspection of semiconductor devices for cracks, broken wires, unsoldered connections, foreign material, and misplaced components, whereas other methods are limited in ability to inspect semiconductor devices.

Sensitivity of x-ray radiography, real-time x-ray methods, and gamma-ray radiography to various types of flaws depends on many factors, including type of material, type of flaw, and product form. (Type of material in this context is usually expressed in terms of atomic number--for instance, metals having low atomic numbers are classified as light metals and those having high atomic numbers as heavy metals.) Table 1 indicates the general degrees of suitability of the three main radiographic methods for detection of discontinuities in various product forms and applications. In some instances, radiography cannot be used even though it appears suitable from Table 1, because the part is accessible from one side only. Both sides must be accessible for radiography.

**Table 1 Comparison of suitabilities of three radiographic methods for inspection of light and heavy metals**

- (a) G, good; F, fair; P, poor; U, unsatisfactory.
- (b) Real-time radiography offers the advantage that the part can be manipulated to present the best view--for example, align a crack. Also, when microfocus, magnification methods are used, real-time radiography presents excellent resolution and contrast.
- (c) Includes only visible cracks. Minute surface cracks normally are undetectable by radiographic inspection methods.
- (d) Radiation beam must be parallel to the cracks, laps, or flakes.
- (e) When calibrated using special thickness gages

Radiography can be used to inspect most types of solid material, with the possible exception of assemblies containing materials of very high or very low density. (Neutron radiography, however, often can be used in such instances, as discussed in the article "Thermal Inspection.") Both ferrous and nonferrous alloys can be radiographed, as can nonmetallic materials and composites.

**Limitations.** Compared with other nondestructive methods of inspection, radiography is expensive. Relatively large capital costs and space allocations are required for a radiographic laboratory or a real-time inspection station. Conversely, when portable x-ray or gamma-ray sources are used, capital costs can be relatively low. Operating costs can be high; large percentages of the total inspection time is spent in setting up for radiography. With real-time radiography, operating costs usually are much lower, because setup times are shorter and there are no extra costs for x-ray film and processing.

Field inspection of thick sections is a time-consuming process. Portable x-ray sources generally emit relatively low-energy radiation, up to approximately 400 keV, and also are limited as to the intensity of radiation output. These characteristics of portable sources combine to limit x-radiography in the field to sections having absorption equivalent to that of approximately 75 mm (3 in.) of steel. Radioactive sources also are limited in the thickness that can be inspected, primarily because high-activity sources require heavy shielding for protection of personnel. This limits field usage to sources of lower activity that can be transported in relatively lightweight containers. Because portable x-ray and gamma-ray sources are limited in effective radiation output, exposure times usually are long for thick sections. Recent developments, such as a portable linear accelerator, can speed up and increase the penetrating power of field radiographic methods.

Certain types of flaws are difficult to detect by radiography. Laminar defects such as cracks present problems unless they are essentially parallel to the radiation beam. Tight, meandering cracks in thick sections usually cannot be detected even when properly oriented. Minute discontinuities such as inclusions in wrought material, flakes, microporosity, and microfissures cannot be detected unless they are sufficiently segregated to yield a detectable gross effect. Laminations normally are not detectable by radiography because of their unfavorable orientation--usually parallel to the surface. Laminations seldom yield differences in absorption that enable laminated areas to be distinguished from lamination-free areas.

## Principles of Radiography

Three basic elements--a radiation source or probing medium, the test piece or object being evaluated, and a recording medium (usually film)--combine to produce a radiograph. These elements are shown schematically in Fig. 1. The test piece in Fig. 1 is a plate of uniform thickness containing an internal flaw that has absorption characteristics different from those of the surrounding material. Radiation from the source is absorbed by the test piece as the radiation passes through it; the flaw and surrounding material absorb different amounts of radiation. Thus, the amount of radiation that reaches the film in the area beneath the flaw is different from the amount that impinges on adjacent areas. This produces on the film a latent image of the flaw that, when the film is developed, can be seen as a "shadow" of different photographic density from that of the image of the surrounding material.

**Fig. 1** Diagram of the basic elements of a radiographic system, showing method of detecting and recording an internal flaw in a plate of uniform thickness

**Geometric Factors In Radiography.** Because a radiograph is a two-dimensional representation of a three-dimensional object, the radiographic images of most test pieces are somewhat distorted in size and shape.

In conventional radiography, the position of a flaw within the volume of a test piece cannot be determined exactly with a single radiograph; depth in the direction of the radiation beam cannot be determined exactly. Conclusions regarding depth sometimes can be drawn from the sharpness of the flaw image. Images of flaws close to the detector tend to appear sharper than images of flaws near the source side of the object. However, techniques such as stereoradiography, tomography, triangulation, or simply making two or more exposures (with the radiation beam being directed at the test piece from a different angle for each exposure) can be used to locate flaws more exactly within the test-piece volume.

## Sources of Radiation

Two types of electromagnetic radiation are used in radiographic inspection: x-rays and  $\gamma$ -rays. X-rays and  $\gamma$ -rays differ from other types of electromagnetic radiation (such as visible light, microwaves, and radio waves) only in their wavelengths, although there is not always a distinct transition from one type of electromagnetic radiation to another (Fig. 2). Only x-rays and  $\gamma$ -rays, because of their relatively short wavelengths (high energies), have the capability of penetrating opaque materials to reveal internal flaws.

**Fig. 2** Schematic representation of the portion of the electromagnetic spectrum that includes x-rays, gamma rays, ultraviolet and visible light, and infrared radiation, showing their relationship with wave length and photon energy

X-rays and  $\gamma$ -rays are physically indistinguishable; they differ only in the manner in which they are produced. X-rays result from the interaction between a rapidly moving stream of electrons and atoms in a solid target material, while  $\gamma$ -rays are emitted during the radioactive decay of unstable atomic nuclei.

The amount of exposure from x-rays or  $\gamma$ -rays is measured in roentgens (R), where 1 R is the amount of radiation exposure that produces one electrostatic unit ( $3.33564 \times 10^{-10}$  C) of charge from 1.293 mg ( $45.61 \times 10^{-6}$  oz) of air. The intensity of an x-ray or  $\gamma$ -ray radiation is measured in roentgens per unit time.

Although the intensity of x-ray or  $\gamma$ -ray radiation is measured in the same units, the strengths of x-ray and  $\gamma$ -ray sources are usually given in different units. The strength of an x-ray source is typically given in roentgens per minute at one meter (RMM) from the source or in some other suitable combination of time or distance units (such as roentgens per hour at one meter, or RHM). The strength of a  $\gamma$ -ray source is usually given in terms of the radioactive decay rate, which has the traditional unit of a Curie ( $1 \text{ Ci} = 37 \times 10^9$  disintegrations per second). The corresponding unit in the Système International d'Unités (SI) system is a gigabecquerel ( $1 \text{ GBq} = 1 \times 10^9$  disintegrations per second).

The spectrum of radiation is often expressed in terms of photon energy rather than as a wavelength. Photon energy is measured in electron volts, with 1 eV being the energy imparted to an electron by an accelerating potential of 1 V. Figure 2 shows the radiation spectrum in terms of both wavelength and photon energy.

**Production of X-Rays.** When x-rays are produced from the collision of fast-moving electrons with a target material, two types of x-rays are generated. The first type of x-ray is generated when the electrons are rapidly decelerated during collisions with atoms in the target material. These x-rays have a broad spectrum of many wavelengths (or energies) and are referred to as continuous x-rays or by the German word *bremsstrahlung*, which means braking radiation. The second

type of x-ray occurs when the collision of an electron with an atom of the target material causes a transition of an orbital electron in the atom, thus leaving the atom in an excited state. When the orbital electrons in the excited atom rearrange themselves, x-rays are emitted that have specific wavelengths (or energies) characteristic of the particular electron rearrangements taking place. These characteristic x-rays usually have much higher intensities than the background of bremsstrahlung having the same wavelengths.

**Production of  $\gamma$ -Rays.** Gamma rays are generated during the radioactive decay of both naturally occurring and artificially produced unstable isotopes. In all respects other than their origin,  $\gamma$ -rays and x-rays are identical. Unlike the broad-spectrum radiation produced by x-ray sources,  $\gamma$ -ray sources emit one or more discrete wavelengths of radiation, each having its own characteristic photon energy (or wavelength).

Many of the elements in the periodic table have either naturally occurring radioactive isotopes or isotopes that can be made radioactive by irradiation with a stream of neutrons in the core of the nuclear reactor. However, only certain isotopes are extensively used for radiography (Table 2).

**Table 2 Characteristics of  $\gamma$ -ray sources used in industrial radiography**

$\gamma$ -ray source	Half-life	Photon energy, MeV	Radiation output <sup>(a)</sup> , RHM/Ci	Penetrating power, mm (in.) of steel
<b>Thulium-170</b>	128 d	0.054 and 0.084 <sup>(b)</sup>	0.003	13 ( <sup>1</sup> / <sub>2</sub> )
<b>Iridium-192</b>	74 d	12 rays from 0.21-0.61	0.48	75 (3)
<b>Cesium-137</b>	33 yr	0.66	0.32	75 (3)
<b>Cobalt-60</b>	5.3 yr	1.17 and 1.33	1.3	230 (9)

- (a) Output for typical unshielded, encapsulated sources: RHM/Ci, roentgens per hour at 1 m per Curie.
- (b) Against strong background of higher MeV radiation.

## X-Ray Tubes

X-ray tubes are electronic devices that convert electrical energy into x-rays. Typically, an x-ray tube consists of a cathode structure containing a filament and an anode structure containing a target--all within an evacuated chamber or envelope (Fig. 3). A low-voltage power supply, usually controlled by a rheostat, generates the electric current that heats the filament to incandescence. This incandescence of the filament produces an electron cloud, which is directed to the anode by a focusing system and accelerated to the anode by the high voltage applied between the cathode and the anode. Depending on the size of the focal spot achieved, x-ray tubes are sometimes classified into three groups:

- Conventional x-ray tubes with focal-spot sizes between 2 by 2 mm (0.08 by 0.08 in.) and 5 by 5 mm (0.2 by 0.2 in.)
- Minifocus tubes with focal-spot sizes in the range of 0.2 mm (0.008 in.) and 0.8 mm (0.03 in.)
- Microfocus tubes with focal-spot sizes in the range of 0.005 mm (0.0002 in.) and 0.05 mm (0.002 in.)

**Fig. 3** Schematic diagram of the principal components of an x-ray unit

There are three important electrical characteristics of x-ray tubes:

- The filament current, which controls the filament temperature and in turn the quantity of electrons that are emitted
- The tube voltage, or anode-to-cathode potential, which controls the energy of impinging electrons and therefore the energy or penetrating power, of the x-ray beam
- The tube current, which is directly related to filament temperature and is usually referred to as the milliamperage of the tube

The strength, or radiation output, of the beam is approximately proportional to milliamperage, which is used as one of the variables in exposure calculations. This radiation output, or R output, is usually expressed in roentgens per minute (or hour) at 1 m.

When the accelerated electrons impinge on the target immediately beneath the focal spot, the electrons are slowed and absorbed, and both bremsstrahlung and characteristic x-rays are produced. Most of the energy in the impinging electron beam is transformed into heat, which must be dissipated. Severe restrictions are imposed on the design and selection of materials for the anode and target to ensure that structural damage from overheating does not prematurely destroy the target. Anode heating also limits the size of the focal spot. Because smaller focal spots produce sharper radiographic images, the design of the anode and target represents a compromise between maximum radiographic definition and maximum target life. In many x-ray tubes, a long, narrow, actual focal spot is projected as a roughly square effective focal spot by inclining the anode face at a small angle (usually about 20°) to the centerline of the x-ray beam, as shown in Fig. 4.

**Fig. 4** Schematic diagram of the actual and effective focal spots of an anode that is inclined at 20° to the centerline of the x-ray beam

**Tube Design and Materials.** The cathode structure in a conventional x-ray tube incorporates a filament and a focusing cup, which surrounds the filament. The focusing cup, usually made of pure iron or pure nickel, functions as an electrostatic lens whose purpose is to direct the electron beam toward the anode. The filament, usually a coil of tungsten wire, is heated to incandescence by an electric current produced by a relatively low voltage, similar to the operation of an ordinary incandescent light bulb. At incandescence, the filament emits electrons, which are accelerated across the evacuated space between the cathode and the anode. The driving force for acceleration is a high electrical potential (voltage) between anode and cathode, which is applied during exposure.

The anode usually consists of a button of the target material embedded in a mass of copper that absorbs much of the heat generated by electron collisions with the target. Tungsten is the preferred material for traditional x-ray tubes used in radiography because its high atomic number makes it an efficient emitter of x-rays and because its high melting point enables it to withstand the high temperatures of operation. Gold and platinum are also used in x-ray tubes for radiography, but targets made of these metals must be more effectively cooled than targets made of tungsten. Other materials are used, particularly at low energies, to take advantage of their characteristic radiation. Most high-intensity x-ray tubes have forced liquid cooling to dissipate the large amounts of anode heat generated during operation.

Tube envelopes are constructed of glass, ceramic materials or metals, or combinations of these materials. X-ray tubes are inserted into metallic housings that contain an insulating medium such as transformer oil or an insulating gas. The main purpose of the insulated housing is to provide protection from high-voltage electrical shock. Housings usually contain quick disconnects for electrical cables from the high-voltage power supply or transformer. On self-contained units, most of which are portable, both the x-ray tube and the high-voltage transformer are contained in a single housing, and no high-voltage cables are used.

**Microfocus X-Ray Tubes.** Developments in vacuum technology and manufacturing processes have led to the design and manufacture of microfocus x-ray systems. These systems are available with voltages varying from 10 to 360 kV at beam currents from 0.01 to 2 mA. To avoid excessive pitting of the target, the beam current is varied according to the desired focal-spot size and/or kilovolt level.

Microfocus x-ray systems having focal spots that approach a point source are useful in obtaining very high resolution images. A radiographic definition of 20 line pairs per millimeter (or a spatial resolution of 0.002 in.), using real-time radiography has been achieved with microfocus x-ray sources. This high degree of radiographic definition is accomplished by image enlargement, which allows the imaging of small details.

Microfocus x-ray systems have found considerable use in the inspection of integrated circuits and other miniature electronic components. Microfocus x-ray systems with specially designed anodes as small as 13 mm (0.5 in.) in diameter and several inches long also enable an x-ray source to be placed inside otherwise inaccessible areas, such as aircraft structures and piping. The imaging medium is placed on the exterior, and this allows for the single-wall inspection of

otherwise uninspectable critical components. Because of the small focal spot, the source can be close to the test area with minimal geometric unsharpness.

**X-Ray Spectrum.** The output of a radiographic x-ray tube is not a single-wavelength beam, but rather a spectrum of wavelengths somewhat analogous to white light. The lower limit of wavelengths,  $\lambda_{\min}$ , in nanometers, at which there is an abrupt ending of the spectrum, is inversely proportional to tube voltage,  $V$ . This corresponds to an upper limit on photon energy,  $E_{\max}$ , which is proportional to the tube voltage,  $V$ :

$$E_{\max} = aV$$

where  $a = 1 \text{ eV/volt}$ .

Figure 5 illustrates the effect of variations in tube voltage and tube current on photon energy and the intensity (number of photons). As shown in Fig. 5(a), increasing the tube voltage increases the intensity of radiation and adds higher-energy photons to the spectrum (crosshatched area, Fig. 5a). Conversely, as shown in Fig. 5(b), increasing the tube current increases the intensity of radiation but does not affect the energy distribution.

**Fig. 5** Effect of (a) tube voltage and (b) tube current on the variation of intensity with wavelength for the bremsstrahlung spectrum of an x-ray tube. See text for discussion.

The energy of x-rays determines the penetration capability. Table 3 gives penetrating capabilities of x-ray beams of various energy levels expressed as the range of steel thickness that can be satisfactorily inspected. The maximum values in this table represent thicknesses of steel that can be routinely inspected using exposures of several minutes' duration and with medium-speed film. Thicker sections can be inspected for each x-ray energy value by using faster films and long exposure times, but for routine work the use of higher-energy x-rays is more practical. Sections thinner than minimum thicknesses shown in Table 3 can easily be penetrated, but radiographic contrast may not be optimum.

**Table 3 Penetrating capabilities of conventional x-ray tubes and high-energy sources**

Maximum accelerating potential	Penetration range for steel	
	mm	in.
X-ray tubes		
150 kV	Up to 16	Up to $\frac{5}{8}$
250 kV	Up to 38	Up to $1\frac{1}{2}$
400 kV	Up to 64	Up to $2\frac{1}{2}$
1000 kV (1 MV)	6.4 to 89	$\frac{1}{4}$ to $3\frac{1}{2}$
High-energy sources		
2.0 MeV	6.4 to 250	$\frac{1}{4}$ to 10
4.5 MeV	25 to 305	1 to 12
7.5 MeV	57 to 460	$2\frac{1}{4}$ to 18
20.0 MeV	75 to 610	3 to 24

## Attenuation of Electromagnetic Radiation

X-rays and gamma rays interact with any substance, even gases such as air, as the rays pass through the substance. It is this interaction that enables parts to be inspected by differential attenuation of radiation, and that enables differences in the intensity of radiation to be detected and recorded. Both these effects are essential to the radiographic process. Attenuation characteristics of materials vary with type, intensity, and energy of the radiation, and with density and atomic structure of the material.

The attenuation of electromagnetic radiation is a complex process. The intensity of radiation varies exponentially with the thickness of homogeneous material through which it passes. This behavior is expressed as

$$I = I_0 \exp (-\mu t)$$

where  $I$  is the intensity of the emergent radiation,  $I_0$  is the initial intensity,  $t$  is the thickness of homogeneous material, and  $\mu$  is a characteristic of the material known as the linear-absorption coefficient. The coefficient  $\mu$  is constant for a given situation but varies with the material and with the photon energy of the radiation. The units of  $\mu$  are reciprocal length (for instance,  $\text{cm}^{-1}$ ). The absorption coefficient of a material is sometimes expressed as a mass-absorption coefficient ( $\mu/\rho$ ), where  $\rho$  is the density of the material.

There are three primary attenuation processes: photoelectric effect, Compton scattering, and pair production.

**Photoelectric effect** is an interaction with orbital electrons in which a photon of electromagnetic radiation is consumed in breaking the bond between an orbital electron and its atom. Energy in excess of the bond strength imparts kinetic energy to the electron.

The photoelectric effect generally decreases with increasing photon energy ( $E$ ) as  $E^{-3.5}$ . For elements of low atomic number, the photoelectric effect is negligible at photon energies exceeding about 100 keV. However, the photoelectric effect varies with the fourth to fifth power of atomic number; thus, for elements of high atomic number, the effect accounts for an appreciable portion of total absorption at photon energies up to about 2 MeV.

**Compton scattering** is a form of direct interaction between an incident photon and an orbital electron in which the electron is ejected from the atom and only a portion of the kinetic energy of the photon is consumed. The photon is scattered incoherently, emerging in a direction that is different from the direction of incident radiation and emerging with reduced energy. The relationship of the intensity of the scattered beam to the intensity of the incident beam, scattering angle, and photon energy in the incident beam is complex, yet is amenable to theoretical evaluation. Compton scattering varies directly with atomic number of the scattering element and approximately inversely with photon energy in the energy range that is of major interest.

**Pair production** is an absorption process that creates two 0.5 MeV photons of scattered radiation for each photon of high-energy incident radiation consumed; a small amount of scattered radiation of lower energy also accompanies pair production. Pair production is more important for heavier elements; the effect varies with atomic number,  $Z$ , approximately as  $Z(Z + 1)$ . The effect also varies approximately logarithmically with photon energy.

In pair production, a photon of incident electromagnetic radiation is consumed in creating an electron-positron pair that then is ejected from an atom. This effect is possible only at photon energies exceeding 1.02 MeV because, according to the theory of relativity, 0.51 MeV is consumed in the creation of the mass of each particle, electron, or positron. Any energy of the incident photon exceeding 1.02 MeV imparts kinetic energy to the pair of particles.

**Radiographic Equivalence.** The absorption of x-rays and gamma rays by various materials becomes less dependent on composition as radiation energy increases. For instance, at 150 kV, 25 mm (1 in.) of lead is equivalent to 350 mm (14 in.) of steel, but at 1000 kV, 25 mm of lead is equivalent to only 125 mm (5 in.) of steel. Approximate radiographic absorption equivalence factors for several metals are given in Table 4. When exposure charts are available only for certain common materials (such as steel or aluminum), exposure times for other materials can be estimated by determining the exposure time for an equal thickness of a common material from the chart, then multiplying by the radiographic equivalence factor.

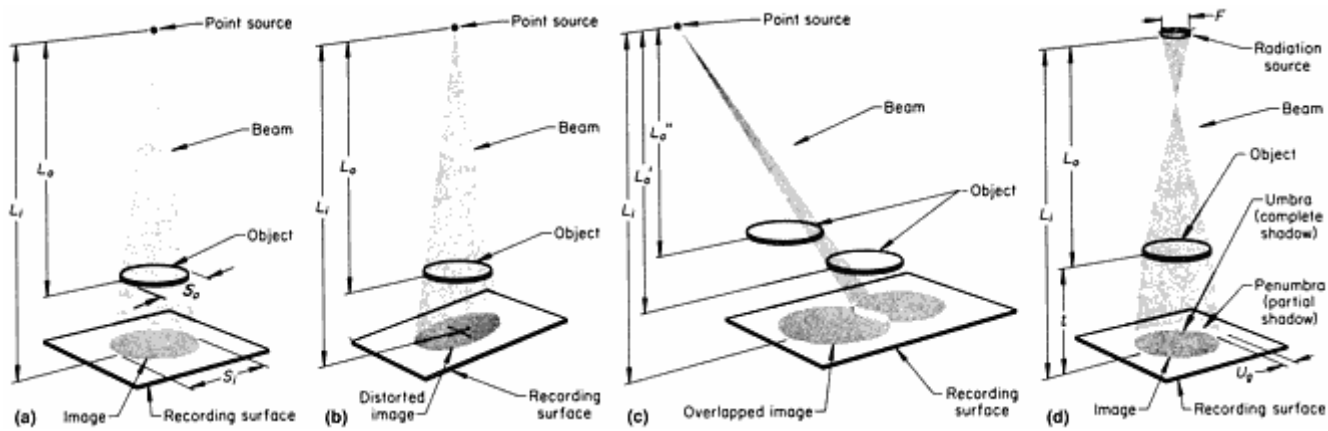

**Table 4 Approximate radiographic absorption equivalence for various metals**

Material	X-rays, kV					X-rays, MeV			Gamma rays			
	50	100	150	220	400	1	2	4-25	Ir-192	Cs-137	Co-60	Ra

(a)                                      Containing no tin or lead; absorption equivalence is greater than these values when either element is present.

## Principles of Shadow Formation

The image formed on a radiograph is similar to the shadow cast on a screen by an opaque object placed in a beam of light. Although radiation used in radiography penetrates an opaque object whereas light does not, the geometric laws of shadow formation are basically the same. X-rays, gamma rays, and light all travel in straight lines. Straight-line propagation is the chief characteristic of radiation that permits formation of a sharply discernible shadow. The geometric relationships of source, object, and screen to each other determine the three main characteristics of the shadow--the degrees of enlargement, distortion, and unsharpness (see Fig. 6).

**Fig. 6** Schematic representation of the effect of geometric relationships on radiographic image from point sources and actual radiation source. (a) Image size. (b) Image distortion. (c) Image overlap for point sources of radiation. (d) Degree of image unsharpness from an actual radiation source. See text for discussion.  $L_o$  = Source-to-object distance;  $L_i$  = source-to-image distance;  $S_o$  = size of object;  $S_i$  = size of image;  $U_g$  = geometric unsharpness;  $F$  = size of focal spot;  $t$  = object-to-image distance

**Enlargement.** The shadow of the object (test piece) is always farther from the source than the object itself. Thus, as illustrated for a point source in Fig. 6(a), dimensions of the shadow are always greater than corresponding dimensions of the object. Mathematically, the size of the image or degree of enlargement may be calculated from the relationship:

$$M = S_i/S_o = L_i/L_o$$

where  $M$  is the degree of enlargement (magnification),  $S_i$  is the size of the image,  $S_o$  is the size of the object,  $L_i$  is the source-to-image distance, and  $L_o$  is the source-to-object distance.

With very small focal spots, large values of geometric magnification can be used effectively. Values of 6 to 20 are common; magnification values as high as 100 can be used. Focal spots in microfocal x-ray equipment range from 5 to 20  $\mu\text{m}$  (0.0002 to 0.0008 in.). In addition to increased image size, magnification systems also offer improved contrast because radiation scattered in the object does not reach the detector.

**Distortion.** As long as the plane of a two-dimensional object and the plane of the recording surface are parallel to each other, the image of that object plane will be undistorted regardless of the angle at which the beam of radiation impinges on the object. Also, the degree of enlargement for different points in a given object plane is constant because the ratio  $L_i/L_o$  is invariant. However, as shown in Fig. 6(b), if the plane of the object and the plane of the recording surface are not parallel, the image will be distorted. For objects of appreciable thickness, the magnification for different object planes will vary because  $L_o$  varies.

**Geometric Unsharpness.** In reality, most radiation sources are too large to be approximated by a point. Most conventional x-ray tubes have focal spots several millimeters in size. Even high-energy sources have focal spots of appreciable size, although seldom exceeding 2 mm (0.08 in.) in diameter. Gamma-ray sources vary widely in size, depending on source strength and specific activity, but seldom are less than about 2.5 mm (0.1 in.) in diameter.

Geometric unsharpness is one of several unsharpness factors, and, at low and medium x-ray energies, is usually the largest contributor to maximum unsharpness. Neglecting the distance between the actual surface of the recording medium and the adjacent (facing) surface of the test piece, which usually is quite small in relation to test-piece thickness, the geometric unsharpness can be calculated for any source size, and can be expressed as a series of straight-line plots relating geometric unsharpness,  $U_g$ , to test-piece thickness,  $t$ , for various values of source-to-object distance,  $L_o$ . A typical series is shown in Fig. 7 for a 5 mm diam (0.2 in. diam) source. It is helpful to prepare graphs like the one in Fig. 7 for each source size used.

**Fig. 7** Relation of geometric unsharpness to test-piece thickness for various source-to-object distances when the source is 5 mm in diameter

## Image Conversion

The most important process in radiography is the conversion of radiation into a form suitable for observation or further signal processing. After penetrating the testpiece, the x-rays or  $\gamma$ -rays pass through a medium on the imaging surface. This medium may be a recording medium (such as film) or a medium that responds to the intensity of the radiation (such as fluorescent screen or a scintillation crystal in a discrete detector). These two types of media provide the images for subsequent observation.

Radiography can also utilize radiographic screens, which are pressed into intimate contact with the imaging medium. Radiographic screens include:

- Metallic screens placed over film, paper, or the screens used in real-time systems
- Fluorescent screens placed over film or photographic paper
- Fluorometallic screens placed over film

These screens are used to improve radiographic contrast by intensifying the conversion of radiation and by filtering the lower energy radiation produced by scattering.

Permanent images are recorded on x-ray film, radiographic paper, or electrostatically sensitive paper such as is used in the xeroradiographic process and are called radiographs. Real-time images, such as those presented on a fluorescent screen, image amplifier, or television monitor, differ in appearance from those on radiographs; records of these images may be made by photography or video recording. If the information is sensed or recorded using radiation-measuring instruments and does not appear as an image, the recording process is termed "radiation gaging." X-ray film is used more extensively than all other recording media combined.

**X-ray film** is constructed of a thin, transparent plastic support called a film base, which usually is coated on both sides (but occasionally on one side only) with an emulsion consisting mainly of grains of silver salts that are embedded in gelatin (see Fig. 8). These salts are very sensitive to electromagnetic radiation, especially x-rays, gamma rays, and visible light. The film base, usually tinted blue, is approximately 0.18 mm (0.007 in.) thick. An adhesive undercoat fastens the emulsion to the film base. A very thin but tough coating of gelatin called a protective overcoat covers the emulsion to protect it against minor abrasion. The total thickness of the x-ray film is approximately 0.23 mm (0.009 in.), including film base, two emulsions, two adhesive undercoats, and two protective overcoats.

**Fig. 8** Schematic cross section of a typical x-ray film

**Radiographic Paper.** Ordinary photographic paper can be used to record x-ray images, although its characteristics are not always satisfactory. Photographic paper has a low speed and the resulting image is low in contrast. However, photographic paper in various forms can be used effectively for some applications.

Radiographic paper can exhibit excellent sensitivity, which in many respects matches or exceeds that of fast direct-exposure x-ray films. Radiographic paper does not match the sensitivities of slow x-ray films, but because of their speed, convenience, and low cost, radiographic papers are being used both for radiography of materials that do not require critical examination and for "in-process" control.

**Xeroradiography** (dry radiography) is a form of imaging that uses electrostatic principles for formation of a radiographic image. In film radiography, a latent image is formed in the emulsion of a film; in xeroradiography, the latent image is formed on a plate coated with a photoconductive layer of selenium. Before use, the plate is given an even charge of static electricity over the entire surface. As soon as the plate is charged, it becomes sensitive to light as well as to x-radiation and must be protected from light by a rigid holder similar to a film cassette. In practice, the holder is used for radiography as though it contained film. X-radiation will differentially discharge the plate according to the amount of radiation received by different areas. This forms an electrostatic latent image of the test piece on the plate.

Development of the exposed plate is done by subjecting the plate, in the absence of light, to a cloud of fine powder charged opposite to the electrostatic charges remaining on the plate. The charged powder is attracted to the residual charges on the plate. The visible radiographic image can be made permanent by placing a piece of specially treated paper over the plate and transferring the powder to the paper, which then is heated to fix the powder in place.

Selenium-coated plates can be easily damaged by fingerprints, dirt, and abrasion. For this reason, automated equipment is used for charging and for development and image transfer to paper.

**Flourescent screens** consist of crystals that emit light in proportion to the intensity of the impinging radiation. The real-time image can then be viewed directly (with appropriate measures to protect the viewer from radiation) or can be monitored by low-level television camera tubes.

Direct viewing of flourescopic images is known as flouroscopy. This method is the predecessor of the modern methods of real-time radiography but fluoroscopy is now largely obsolete. The main problem with fluoroscopy is the low level of light output from the fluorescent screen. This requires the suppression of background light and about 30 min for the viewer's eyes to become acclimated. Moreover, radiation safety dictates viewing through leaded glass or indirectly by mirrors. Because of these limitations, image intensities have been developed to improve safety and to amplify the images from fluorescent screens.

The modern development of low-level television camera tubes and low-noise video circuitry also allows video monitoring of the dim images on fluorescent screens. The contrast sensitivity and the spatial resolution of fluorescent-screen systems are comparable to those of image intensifiers (discussed below), but the use of fluorescent screens is limited to lower radiation energies (below about 320 keV without intensifying screens and about 1 MeV with intensifying screens). Nevertheless, fluorescent screens can provide an unlimited field of view, while image intensifiers have a field of view

limited to approximately 300 mm (12 in.). The dynamic range of systems with fluorescent screens can vary from 20 to 1 for raw images to 1000 to 1 with digital processing and a large number of frames averaged.

**Image-intensifier tubes** are glass-enclosed vacuum devices that convert a low-intensity x-ray image or a low-brightness fluorescent-screen image into a high-brightness, visible-light image. Image intensification is achieved by a combination of electronic amplification and image minification. The image brightness at the output window of an image-intensifier tube is approximately  $0.3 \times 10^3 \text{ cd/m}^2$  ( $10^{-1}$  lambert) as compared to approximately  $0.3 \text{ cd/m}^2$  ( $10^{-4}$  lambert) for conventional fluoroscopic screen.

The early image intensifiers were originally developed for medical purposes and were limited to applications with low-energy radiation (because of low detection efficiencies at high energies). Consequently, industrial radiography with these devices was restricted to aluminum, plastics, or thin sections of steel. By the mid-1970s, other technological developments led to further improvements such as high-energy, x-ray sensitivity for image intensifiers, improved screen materials, digital video processing for image enhancement, and high-definition imaging with microfocus x-ray generators.

The early image intensifiers were only suitable for medical applications and the inspection of light materials and thin sections of steel. The image quality was not sufficient for general use in radiography, and, image intensifiers had to be redesigned for industrial material testing. The modern image intensifier for industrial application is a very practical imaging device for radiographic inspection with radiation energies up to 10 MeV. With the image intensifier, a 2% difference in absorption can be routinely achieved in production inspection applications. The typical dynamic range of an image intensifier before image processing is about 2000 to 1.

**Digital Radiography.** Another method of radiographic imaging involves the formation of an image by scanning a linear array of discrete detectors along the object being irradiated. This method directly digitizes the radiometric output of the detectors and generates images in near real time. Direct digitization (as opposed to digitizing the output of a TV camera or image intensifier) enhances the signal-to-noise ratio and can result in a dynamic range up to 100,000 to 1. The large dynamic range of digital radiography allows the inspection of parts having a wide range of thicknesses and densities. Discrete detector arrangements also allow the reduction of secondary radiation from scattering by using a fan-beam detector arrangement like that of computed tomography (CT) systems. In fact, industrial CT systems are used to obtain digital radiographs. The imaging performance with detector arrays is also comparable with that of computed tomography (Table 5).

**Table 5 Comparison of performance characteristics for film radiography, real-time radiography, and x-ray computed tomography**

Performance characteristic	Film radiography	Real-time radiography <sup>(a)</sup>	Computed or radiography <sup>(b)</sup> tomography digital
<b>Spatial resolution<sup>(c)</sup></b>	>5 line pairs/mm	~2.5 line pairs/mm	0.2-4.5 line pairs/mm
<b>Absorption efficiencies, %</b>			
Absorption efficiency (80 keV)	5	20	99
Absorption efficiency (420 keV)	2	8	95
Absorption efficiency (2 MeV)	0.5	2	80
<b>Sources of noise</b>	Scatter, poor photon statistics	Scatter, poor photon statistics	Minimal scatter
<b>Dynamic range</b>	200-1000	500-2000	Up to $1 \times 10^6$
<b>Digital image processing</b>	Poor, requires film scanner	Moderate to good; typically 8 bit data	Excellent; typically 16 bit data
<b>Dimensioning capability</b>	Moderate; affected by structure visibility and variable radiographic magnification	Moderate to poor; affected by structure visibility, resolution, variable radiographic magnification, and optical distortions	Excellent; affected by resolution, enhanced by low contrast detectability

- (a) General characteristics of real-time radiography with fluorescent screen-TV camera system or an image intensifier.
- (b) Digital radiographic imaging performance with discrete element detector arrays is comparable to computed tomography performance values.

(c) Can be improved with microfocus x-ray source and geometric magnification

The detectors used in digital radiography include scintillator photodetectors, phosphor photodetectors, photomultiplier tubes, and gas ionization detectors. Scintillator and phosphor photodetectors are compact and rugged, and they are used in flying-spot and fan-beam detector arrangements. Photomultiplier tubes are fragile and bulky, but do provide the capability of photon counting when signal levels are low. Gas ionization detectors have low detection efficiencies but better long-term stability than scintillator- and phosphor-photodetector arrays.

A typical phosphor-photodetector array for the radiographic inspection of welds consists of 1024 pixel elements with 25  $\mu\text{m}$  (1 mil) spacing, covering 25 mm (1 in.) in length perpendicular weld seam. The linear photodiode array is covered with a fiberoptic faceplate and can be cooled in order to reduce noise. For the conversion of the x-rays to visible light, fluorescent screens are coupled to the array by means of the fiber optics. A linear collimator parallel to the array is arranged in front of the screen. The resolution perpendicular to the array is defined by the width of this slit and the speed of the manipulator. A second, single-element detector is provided to detect instabilities of the x-ray beam. Using 100 kV radiation, a spatial resolution of 0.1 mm (0.004 in.) can be achieved with a scanning speed of 1 to 10 mm/s (0.04 to 0.4 in./s).

The data from the detector system are digitized and then stored in a fast dual-ported memory. This permits quasi-simultaneous access to the data during acquisition. Before the image is stored in the frame buffer and displayed on the monitor, simple preprocessing can be done, such as intensity correction of the x-ray tube by the data of the second detector and correction of the sensitivity for different array elements. If further image processing or automatic defect evaluation is required, the system can be equipped with fast image-processing hardware. All standard devices for digital storage can be utilized.

**Image Processing.** Because real-time systems generally do not provide the same level of image quality and contrast as radiographic film, image processing is often used to enhance the images from image intensifiers, fluorescent screens, and detector arrays. With image processing, the video images from real-time systems can compete with the image quality of film radiography. Moreover, image processing also increases the dynamic range of real-time systems beyond that of film (which typically has a dynamic range of about 1000 to 1).

Images can be processed in two ways: as an analog video signal and as a digitized signal. An example of analog processing is to shade the image after the signal leaves the camera. Shading compensates for irregularities in brightness across the video image due to thickness or density variations in the testpiece. This increases the dynamic range (or latitude) of the system, which allows the inspection of parts having larger variations in thickness and density.

After analog image processing, the images can be digitized for further image enhancement. This digitization of the signal may involve some detector requirements. In all real-time radiological applications, the images have to be obtained at low dose rates (around 20  $\mu\text{R/s}$ ). In digital x-ray imaging, however, the most often used dose is around 1 mR, in order to reduce the signal fluctuations that would result from a weak x-ray flux. This means that only a short exposure time (of the order of a few milliseconds) and a frequency of several images can be used if kinetic (motion) blurring is to be avoided. The resulting requirements for the x-ray detector are therefore:

- The capability of operating properly in a pulsed mode, which calls for a fast temporal response
- An excellent linearity, to allow the use of the simplest and most efficient form of signal processing
- A wide operating dynamic range in terms of dose output (around 2000 to 1)

Once the image from the video camera has been digitized in the image processor, a variety of processing techniques can be implemented. The image-processing techniques may range from the relatively simple operation of frame integration to more complex operations such as automatic defect evaluation.

**Radiation Gaging.** Radiation-measuring instruments do not produce images. The output from these instruments is a meter reading or a strip chart, which records the radiation transmitted through a test piece in terms of roentgens. Many of these instruments are routinely used to check areas surrounding a radiographic-inspection site for excessive radiation.

Radiation gaging can be applied to certain automated processes, such as thickness gaging of materials or determination of liquid levels in sealed containers. In these applications, it may not be necessary to actually measure the amount of

radiation passing through the material, but only to detect changes in the level of radiation--in other words, for a "go, no-go" type of inspection.

When a highly absorbing material such as thick lead or concrete must be inspected for voids and when usual radiographic techniques are impractical, radiation gaging can be used effectively. Voids can be located in these materials by noting increases in the readings of radiation-detecting instruments.

**Computed Tomography.** Cross-sectional images of an inspection object can be obtained by a series of radiation attenuation measurements all around the object. Typically, a fan beam of radiation about 1 or 2 mm in height is used along with a bank of detectors on the opposite side of the object. The attenuation data permit a computer reconstruction showing density differences in the cross section of the object (Fig. 9a).

**Fig. 9** Comparison of (a) computed tomography (CT) and (b) radiography. A high-quality digital radiograph (b) of a solid rocket motor igniter shows a serious flaw in a carefully oriented tangential shot. A CT image (a) at the height of the flaw shows the flaw in more detail and in a form an inexperienced viewer can readily recognize.

X-ray computed tomography has many of the same benefits and limitations as film and real-time radiography. The primary difference is the nature of the radiological image. Radiography (Fig. 9b) compresses the structural information from a three-dimensional volume into a two-dimensional image. This is useful in that it allows a relatively large volume to be interrogated and represented in a single image. This compression, however, limits the information and reduces the sensitivity to small variations. Radiographic images also can be difficult to interpret because of shadows from overlying and underlying structures superimposed on the features of interest. In contrast, the CT method provides sufficient information to localize a feature (Fig. 9a).

Some of the performance characteristics of radiography and computed tomography are compared in Table 5.

One of the limitations of CT inspection is that the CT image provides detailed information only over the limited volume of the cross-sectional slice. Full inspection of the entire volume of a component with computed tomography requires many slices, limiting the inspection throughput of the system. Therefore, CT equipment is often used in a digital

radiography (DR) mode during production operations, with the CT imaging mode used for specific critical areas or to obtain more detailed information on indications found in the DR image. Digital radiography capabilities and throughput can be significant operational considerations for the overall system usage. Computed tomography systems generally provide a DR imaging mode, producing a two-dimensional radiographic image of the overall testpiece.

### Characteristics of X-Ray Film

Three general characteristics of film--speed, gradient, and graininess--are primarily responsible for the performance of the film during exposure and processing and for the quality of the resulting image. Film speed, gradient, and graininess are interrelated; that is, the faster the film, the larger the graininess and the lower the gradient--and vice versa. Film speed and gradient are derived from the characteristic curve for a film emulsion, which is a plot of film density versus the exposure required for producing that density in the processed film. Graininess is an inherent property of the emulsion, but can be influenced somewhat by the conditions of exposure and development.

The selection of radiographic film for a particular application is generally a compromise between the desired quality of the radiograph and the cost of exposure time. This compromise occurs because slower films generally provide a higher film gradient and a lower level of graininess and fog.

**Film Types.** The classification of radiographic film is complicated, as evidenced by changes in ASTM standard practice E 94. The 1988 edition (and subsequent editions) of ASTM E 94 references an ASTM E 746, which describes a standard test method for determining the relative image-quality response of industrial radiographic film. Careful study of ASTM E 746 is required to arrive at a conclusive classification index suitable for the given radiographic film requirements of a facility.

Earlier editions (1984 and prior) of ASTM E 94 contained a table listing the characteristics of industrial films grouped into four types. Table 6 summarizes the general characteristics of these four types. This relatively simple classification method is referenced by many codes and specifications, which may state only that a type 1 or 2 film can be used for their specification requirements. However, because of this relatively arbitrary method of classification, many film manufacturers may be reluctant to assign type numbers to a given film. Moreover, the characteristics of radiographic films can vary within a type classification of Table 6 because of inherent variations among films produced by different manufacturers under different brand names and because of variations in film processing that affect both film speed and radiographic density. These variations make it essential that film processing be standardized and that characteristic curves for each brand of film be obtained from the film manufacturer for use in developing exposure charts.

**Table 6 General characteristics of the four types of radiographic film specified in the earlier (1984) edition of ASTM E 94**

Film type	Film characteristic		
	Speed	Gradient	Graininess
1	Low	Very high	Very fine
2	Medium	High	Fine
3	High	Medium	Coarse
4 <sup>(a)</sup>	Very high <sup>(b)</sup>	Very high <sup>(b)</sup>	<sup>(c)</sup>

- (a) Normally used with fluorescent screens.
- (b) When used with fluorescent screens.
- (c) Graininess is mainly a characteristic of the fluorescent screens.
- (d) When used for direct exposure or with lead screens. These groupings are given only for qualitative comparisons. For a more detailed discussion on film classification, see the section "Film Types" in this article.

Because the variables that govern the classification of film are no longer detailed in ASTM E 94, it is largely the responsibility of the film manufacturer to determine the particular type numbers associated with his brand names. Some manufacturers indicate the type number together with the brand name on the film package. If there is doubt regarding the type number of a given brand, it is advisable to consult the manufacturer. Most manufacturers offer a brand of film characterized as very low speed, ultrahigh gradient, and extremely fine grain.

**Film selection** for radiography is a compromise between the economics of exposure (film speed and latitude) and the quality desired in the radiograph. In general, fine-grain, high-gradient films produce the highest-quality radiographs. However, because of the low speed typically associated with these films, high-intensity radiation or long exposure times are needed. Other factors affecting radiographic quality and film selection are the type and thickness of the testpiece and the photon energy of the incident radiation.

Although the classification of film is more complex than the types given in Table 6, a general guide is that better radiographic quality will be promoted by the lowest type number in Table 6 that economic and technical considerations will allow. In this regard, Table 7 suggests a general comparison of film characteristics for achieving a reasonable level of radiographic quality for various metals and radiation-source energies. It should be noted, however, that the film types are only a qualitative ranking of the general film characteristics given in Table 6. Many radiographic films, particularly those designed for automatic processing, cannot be adequately classified according to the system in Table 6. This compounds the problem of selecting film for a particular application.

**Table 7 Guide to the selection of radiographic film for steel, aluminum, bronze, and magnesium in various thicknesses**

Thickness		Type of film <sup>(a)</sup> for use with these x-ray tube voltages, or radioactive isotopes:											
mm	in.	50-80 kV	80-120 kV	120-150 kV	150-250 kV	Ir-192	250-400 kV	1 MeV	Co-60	2 MeV	Ra	6-31 MeV	
Steel													
0-6	$\frac{1}{4}$	3	3	2	1	...	...	...	...	...	...	...	
6-13	$\frac{1}{4} - \frac{1}{2}$	4	3	2	2	...	1	...	...	...	...	...

25-50	1-2	2	1	1	1	1	...	...	...	...	...	...	
50-100	2-4	3	2	2	1	2	...	...	...	...	...	...	
100-200	4-8	...	3	2	2	3	...	...	...	...	...	...	
>200	>8	...	...	...	4	...	...	...	...	...	...	...	

- (a) These recommendations represent a usually acceptable level of radiographic quality and are based on the qualitative classification of films defined in Table 6. Optimum radiographic quality will be promoted by use of the lowest-number film type that economic and technical considerations will allow. The recommendations for type 4 film are based on the use of fluorescent screens.

## Exposure Factors

Exposure is the intensity of radiation multiplied by the time during which it acts; that is, the amount of energy that reaches a particular area of the film and that is responsible for producing a particular density on the developed film. Density is the quantitative measure of blackening of a photographic emulsion. Density, measured directly with an instrument called a densitometer, is the logarithm of the ratio of the light intensity incident on the film to that transmitted by the film. Therefore, a film with a density of 1.0 will transmit only 10% of the light, a film with a density of 2.0 will transmit only  $\frac{1}{100}$  of the light, and so on.

There are two kinds of density: (a) the density associated with transparent-base radiographic film, called transmission density, and (b) the density associated with opaque-base imaging material such as radiographic paper, called reflection density.

The exposure time in film radiography depends mainly on film speed, the intensity of radiation at the film surface, the characteristics of any screens used, and the desired level of photographic density. In practice, the energy of the radiation is first chosen to be sufficiently penetrating for the type of material and thickness to be inspected. The film type and the desired photographic density are then selected according requirements for contrast sensitivity (as discussed below). Once these factors are fixed, then the source strength, the source-to-film distance, and the characteristics of any screens used determine the exposure time.

With a given type of film and screen, the exposure time to produce the desired photographic density can be determined. Because intensity is inversely proportional to the square of distance from the source, the reciprocity law for equivalent exposures with an x-ray tube can be written as:

$$\frac{i_1 t_1}{L_1^2} = \frac{i_2 t_2}{L_2^2}$$

where  $i$  is the tube current,  $t$  is the exposure time,  $L$  is the source-to-film distance, and the subscripts refer to two different combinations that produce images with the desired photographic density. The parallel expression that applies to exposures made with a  $\gamma$ -ray source is:

$$\frac{a_1 t_1}{L_1^2} = \frac{a_2 t_2}{L_2^2}$$

where  $a$  is the source strength in gigabecquerel (Curies).

**Contrast sensitivity** refers to the ability of responding to and displaying small variations in subject contrast. Contrast sensitivity depends on the characteristics of the image detector and on the level of radiation being detected (or on the amount of exposure for films). The relationship between the contrast sensitivity and the level of radiation intensity (or film exposure) can be illustrated by considering two extremes. At low levels of radiation intensity, the contrast sensitivity of the detectors is reduced by a smaller signal-to-noise ratio, while at high levels, the detectors become saturated. Consequently, contrast sensitivity is a function of dynamic range (see below).

In film radiography, the contrast sensitivity is:

$$\text{Contrast sensitivity \%} = \frac{2.3\Delta D}{G_D} \times 100$$

where  $\Delta D$  is the smallest change in photographic density that can be observed when the film is placed on an illuminated screen. The factor  $G_D$  is called the film gradient or film contrast. The film gradient is the inherent ability of a film to record a difference in the intensity of the transmitted radiation as a difference in photographic density. It depends on film type, development procedure, and film density. For all practical purposes, it is independent of the quality and distribution of the transmitted radiation.

Contrast sensitivity in real-time systems is determined by the number of bits (if the image is digitized) and the signal-to-noise ratio (which is affected by the intensity of the radiation and the efficiency of the detector). The best contrast sensitivity of digitized images from fluorescent screens is about 8 bits (or 256 gray levels).

Another way of specifying the contrast sensitivity of fluorescent screens is with a gamma factor, which is defined by the fractional unit change in screen brightness,  $\Delta B/B$ , for a given fractional change in the radiation intensity,  $\Delta I/I$ . Most fluorescent screens have a gamma factor of about one, which is not a limiting factor. At low levels of intensity, however, the contrast is reduced because of quantum mottle (which is a form of screen unsharpness). Unsharpness may reduce the contrast depending on flaw size (Fig. 10).

**Fig. 10** Effect of geometric unsharpness on image contrast. (a) Flaw size,  $d$ , is larger than the unsharpness, then full contrast occurs. (b) Flaw size,  $d$ , is smaller than the unsharpness, then contrast is reduced.

**Dynamic range**, or latitude, describes the ability of the imaging system to produce a suitable signal over a range of radiation intensities. The dynamic range is given as the ratio of the largest signal that can be measured to the precision of the smallest signal that can be discriminated. A large dynamic range allows the system to maintain contrast sensitivity over a wide range of radiation intensities or testpiece thicknesses. Film radiography has a dynamic range of up to 1000 to 1, while digital radiography with discrete detectors can achieve 100,000 to 1.

The latitude, or dynamic range, of film techniques is the range of testpiece thickness that can be recorded with a single exposure. High-gradient films generally have narrow latitude, that is, only a narrow range of testpiece thickness can be imaged with optimum density for interpretation. If the testpiece is of nonuniform thickness, more than one exposure may have to be made (using different x-ray spectra or different exposure times) for complete inspection of the piece. The number of exposures, as well as the exposure times, can often be reduced by using a faster film of lower gradient but wider latitude, although there is usually an accompanying reduction in ability to image small flaws.

**Exposure Charts for X-Ray Radiography.** Equipment manufacturers usually publish exposure charts for each type of x-ray generator that they manufacture. These published charts, however, are only approximations; each particular unit and each installation is unique. Radiographic density is affected by such factors as radiation spectrum, film processing, setup technique, amount and type of filtration, screens, and scattered radiation.

Although published exposure charts are acceptable guides for equipment selection, more accurate charts that are prepared under normal operating conditions are recommended for each x-ray machine. A simple method for preparing accurate exposure charts is as follows:

1. Make a series of radiographs of a calibrated multiple-thickness step wedge, using several different values of exposure at each of several different tube voltage settings.
2. Process the exposed films together under conditions identical to those that will be used for routine application.
3. From the several densities corresponding to different thicknesses, determine which density (and thickness) corresponds exactly with the density desired for routine application. This step must be done with a densitometer because no other method is accurate. If the desired density does not appear on the radiograph, the thickness corresponding to the desired density can be found by interpolation.
4. Using the thickness determined in step 3 and the tube voltage (kilovoltage) and exposure (milliamp second or milliamp min) corresponding to that piece of film, plot the relation of thickness to exposure on semilogarithmic paper with exposure on the logarithmic scale.
5. Draw lines of constant tube voltage through the corresponding points on the graph.

**Spectral Sensitivity.** The shape of the characteristic curve of a given x-ray film is for all practical purposes unaffected by the wavelength distribution in the x-ray or gamma-ray beam used for the exposure. However, the sensitivity of the film in terms of roentgens required to produce a given density is strongly affected by radiation energy (beam spectrum of a given kilovoltage or given gamma-ray source).

Figure 11 shows the exposure required for producing a density of 1.0 on type 4 radiographic film developed in an x-ray developer (made from powder) for 5 min at 20 °C (68 °F). The exposures were made directly, without screens. The spectral-sensitivity curves for all x-ray films have approximately the same general features as the curves shown in Fig. 11.

**Fig. 11** Spectral-sensitivity curves for a type 4 radiographic film, showing exposure required to produce a density of 1.0

The classification of radiographic film is complicated; however, a relatively simple classification has been adopted by ASTM. According to the classification in ASTM E 94, radiographic films are grouped into four types. The general characteristics of these four types are summarized in Table 6. The relative image quality of x-ray film can also be determined in a quantitative manner using a multihole test piece as described in ASTM E 746.

Screens are often used with x-ray films during exposure. Metal screens, typically used at x-ray energies of over 150 kV, intensify the image by emission of photoelectrons and help reduce the effects of scatter by attenuating the lower-energy scattered radiation. Lead is typically used. Fluorescent screens are used in some situations to help reduce exposure times.

**Image Quality.** The quality level of an industrial radiograph is governed by the radiographic sensitivity exhibited on the radiograph itself. Radiographic sensitivity is determined through the use of penetrameters or image-quality indicators (IQI).

Penetrameters, or IQIs, are of known size and shape, and have the same attenuation characteristics as the material in the test piece. They are placed on the test piece or on a block of identical material during setup and are radiographed at the same time as the test piece. Penetrameters preferably are located in regions of maximum test-piece thickness and greatest test-piece-to-film distance, and near the outer edge of the central beam of radiation. The degree to which features of the penetrameter are visible in the developed image is a measure of the quality of that image. The image of the penetrameter that appears on the finished radiograph is evaluated during interpretation to ensure that the desired sensitivity, definition, and contrast have been achieved in the developed image.

Penetrameters of different designs have been developed by various standards-making organizations. Common types are plaques containing holes and a second type containing a series of wires. Plaque-type penetrameters consist of strips of material of uniform thickness with holes drilled through them specified by ASTM E 142. Wire-type penetrameters are widely used in Europe (see German standard DIN 54109). They are also used in the U.S. and are described in ASTM standard E 747. The sensitivity of a wire-type penetrameter is expressed in terms of wire diameter divided by object thickness.

## Neutron Radiography

Neutron radiography is a form of nondestructive inspection that uses a specific type of particulate radiation, called neutrons, to form a radiographic image of a test piece. The geometric principles of shadow formation, variation of attenuation with test-piece thickness, and many other factors that govern the exposure and processing of a neutron radiograph are similar to those for radiography using x-rays or gamma rays.

The section deals mainly with the characteristics that differentiate neutron radiography from x-ray or gamma-ray radiography. The application of neutron radiography is described, especially in terms of its advantages for improved contrast on low-atomic-number materials, discrimination between isotopes, or inspection of radioactive specimens.

Neutrons are subatomic particles that are characterized by relatively large mass and a neutral electric charge. The attenuation of neutrons differs from the attenuation of x-rays in that the processes of attenuation are nuclear rather than processes that depend on interaction with electron shells surrounding the nucleus.

Neutrons are produced by nuclear reactors, accelerators, or certain radioactive isotopes, all of which emit neutrons of relatively high energy (fast neutrons). Because most neutron radiography is performed with neutrons of lower energy (thermal neutrons), the sources are usually surrounded by a "moderator," which is a material that reduces the kinetic energy of the neutrons by scattering.

Neutron radiography differs from conventional radiography in that the attenuation of neutrons as they pass through the test piece is more related to the specific isotope present than to density or atomic number. X-rays are attenuated more by elements of high atomic number than by elements of low atomic number, and this effect varies relatively smoothly with atomic number. Also, x-rays are generally attenuated more by materials of high density than they are by materials of low density. For thermal neutrons, the attenuation tends to decrease with increasing atomic number, although the trend is by no means a smooth relationship. In addition to the high attenuation of several light elements (hydrogen, lithium, and boron), certain medium to heavy elements (especially cadmium, samarium, europium, gadolinium, and dysprosium) and certain specific isotopes have exceptionally high capabilities for absorbing thermal neutrons. This means that neutron radiography is capable of detecting these highly attenuating elements or isotopes when present in a structure of lower absorption capability.

Using neutrons, it is possible to radiographically detect certain isotopes--for instance, certain isotopes of hydrogen, cadmium, or uranium. Some neutron-image-detection methods are insensitive to gamma rays or x-rays and can be used to inspect radioactive materials such as reactor fuel elements. The high attenuation of hydrogen, in particular, opens many application possibilities, including inspection of assemblies for detection of adhesives, explosives, lubricants, water, hydrides, corrosion, plastic, or rubber.

## Neutron Sources

The excellent discrimination capabilities of neutrons generally refer to neutrons of low energy--that is, thermal neutrons. Characteristics of neutron radiography corresponding to various ranges of neutron energy are summarized in Table 8. Although any of these energy ranges can be used for radiography, this article emphasizes the thermal-neutron range, which is the most widely used for inspection.

**Table 8 Characteristics of neutron radiography at various neutron-energy ranges**

Type of neutrons	Energy range	Characteristics
<b>Cold</b>	Below 0.01 eV	High-absorption cross sections decrease transparency of most materials, but also increase efficiency of detection. An advantage is reduced scatter at energies below the Bragg cutoff, where neutrons can no longer undergo Bragg reflection.
<b>Thermal</b>	0.01 to 0.3 eV	Good discrimination between materials and ready availability of sources.
<b>Epithermal</b>	0.3 eV to 10 keV	Excellent discrimination for particular materials by working at energy of resonance. Greater transmission and less scatter in samples containing materials such as hydrogen and enriched reactor fuels.
<b>Fast</b>	10 keV to 20 MeV	Good point sources are available. At low-energy end of spectrum, fast-neutron radiography may be able to perform many inspections done with thermal neutrons, but with a panoramic technique. Good penetration capability because of low-absorption cross sections in all materials. Poor material discrimination

In thermal-neutron radiography, an object (test piece) is placed in a thermal-neutron beam in front of an image detector. The neutron beam may be obtained from a nuclear reactor, a radioactive source, or an accelerator. Several characteristics of these sources are summarized in Table 9. For thermal-neutron radiography, fast neutrons emitted by these sources must first be moderated and then collimated. The radiographic intensities listed in Table 9 typically do not exceed  $10^{-5}$  times the total fast-neutron yield of the source. Part of this loss is incurred in moderating the neutrons, and the remainder in bringing a collimated beam out of a large-volume moderator.

**Table 9 Several characteristics of thermal-neutron sources**

Type of source	Typical radiographic intensity <sup>(a)</sup>	Resolution	Exposure time	Characteristics
<b>Radioisotope</b>	$10^1$ - $10^4$	Poor to medium	Long	Stable operation, low to medium investment cost, possibly portable
<b>Accelerator</b>	$10^3$ - $10^6$	Medium	Average	On-off operation, medium cost, possibly transportable
<b>Subcritical assembly</b>	$10^4$ - $10^6$	Good	Average	Stable operation, medium to high investment cost, movement difficult
<b>Nuclear reactor</b>	$10^5$ - $10^8$	Excellent	Short	Medium to high investment cost, movement difficult

(a) Neutrons per cm<sup>2</sup> per second

Collimation is necessary for thermal-neutron radiography because there are no useful point sources of low-energy neutrons. Good collimation in thermal-neutron radiography is comparable to small focal-spot size in conventional radiography; the images of thick objects will be sharper with good collimation. Conversely, it should be noted that available neutron intensity decreases with increasing collimation.

## Neutron Detection Methods

Detection methods for neutron radiography generally make use of photographic or x-ray films. In the direct-exposure method, film is exposed directly to the neutron beam, with a conversion screen or intensifying screen providing secondary radiation that actually exposes the film. Alternatively, film can be used to record an autoradiographic image from a radioactive, image, carrying screen in a technique called the transfer method.

**Direct-Exposure Method.** Conversion screens of thin gadolinium foil or a scintillator have been most widely used in the direct-exposure method. When bombarded with a beam of neutrons, some of the gadolinium atoms absorb neutrons and promptly emit gamma rays and internal conversion electrons. Scintillators are fluorescent screens, often made of zinc sulfide crystals that also contain a specific isotope such as  $^6\text{Li}$  or  $^{10}\text{B}$ . Gadolinium oxysulfide, a scintillator originally developed for x-ray radiography, has been widely used for neutron radiography.

Scintillators provide useful images with total exposures as low as  $5 \times 10^5$  neutrons per  $\text{cm}^2$ . The high speed and favorable relative response make scintillators attractive for use with nonreactor neutron sources. Gadolinium screens provide greater uniformity and image sharpness (high-contrast resolution of  $10 \mu\text{m}$  has been reported), but an exposure about 30 or more times that of a scintillator is required, even with fast films.

**Transfer Method.** In the transfer method, a thin sheet of metal, typically of indium or dysprosium, is exposed to the neutron beam transmitted through the specimen. Neutron capture induces radioactivity--indium having a half-life of 54 min and dysprosium a half-life of 2.35 h. The "radiograph" to be interpreted is made by placing the radioactive transfer screen in contact with a sheet of film. Beta-particles and gamma-rays from the transfer screen expose the film.

The transfer method is especially valuable for inspection of a radioactive specimen. Although radiation emitted by the specimen (especially gamma rays) causes heavy film fogging during x-ray radiography or direct-exposure neutron radiography, the same radiation will not induce radioactivity in a transfer screen. Thus, a clear image of the specimen can be obtained even when there is a high level of background radiation.

In comparing the two primary detection methods, the direct-exposure method offers high speed, indefinite image-integration time and the best spatial resolution. The transfer method offers insensitivity to gamma rays emitted by the specimen and greater contrast because of lower amounts of scattered and secondary radiation.

**Real-time imaging**, in which light from a scintillator is observed by a television camera, also can be used for neutron radiography. Because of low brightness, most real-time neutron radiographic images are enhanced by an image-intensifier tube, which may be separate or integral with a television camera. This method can be used for applications such as the study of fluid flow in a closed system such as a heat pipe or engine or the study of metal flow in a mold during casting.

## ***Applications***

Various applications that are discussed in ASTM STP 586 emphasize the value of neutron radiography for inspection of ordnance, explosive, aerospace, and nuclear components. The presence, absence, or correct placement of explosives, adhesives, O-rings, plastic components, and similar materials can be verified. The presence of fluids or corrosion can be detected. Nuclear fuel and control materials can be inspected to determine distribution of isotopes and to detect foreign or imperfect material. Hydride deposition in metals and diffusion of boron in heat treated boron-fiber composites can be observed.

The characteristics of neutron radiography complement those of conventional x-radiography; one radiation provides a capability lacking or difficult for the other.

# **Thermal Inspection**

## **Introduction**

THERMAL INSPECTION comprises inspection by all methods in which heat-sensing devices or substances are used to detect irregular temperatures. Thermal inspection of workpieces can be used to detect flaws and to detect undesirable distribution of heat during service. There are several methods of thermal inspection and many types of temperature-measuring devices and substances. This article, however, is limited mainly to the discussion of:

- Thermography, which is the mapping of isotherms, or contours of equal temperature, over a test surface
- Thermometry, which is the measurement of temperature.

These techniques are separated into two categories: (a) direct contact, in which a thermally sensitive device or material is placed in physical and thermal contact with the test piece; and (b) noncontact techniques that depend on thermally generated electromagnetic energy radiated from the test piece.

## **Contact Thermographic Inspection**

Contact thermographic inspection consists of coating the surface of the test piece with a material that reacts to a change in temperature by changing color or other aspect of appearance. The reaction may be permanent or reversible. Many coatings having reversible reactions can be recovered for reuse.

The most commonly used materials for contact thermographic inspection can be classified as heat-sensitive paints, heat-sensitive papers, thermal phosphors, liquid crystals, and other temperature-sensitive coatings.

Material coatings are relatively low in cost and simple to apply, but they may have the disadvantage of providing qualitative temperature measurements (the exception is coatings with liquid crystals, which can be calibrated to show relatively small changes in temperature). Another disadvantage of coatings is that they may change the thermal characteristics of the surface.

**Cholesteric liquid crystals** are greaselike substances that can be blended to produce compounds having color transition ranges at temperatures from -20 to 250 °C (-5 to 480 °F). Liquid crystals can be selected to respond in a temperature range for a particular test and can have a color response for temperature differentials of 1 to 50 °C (2 to 90 °F). When illuminated with white light while in their color response range, liquid crystals will scatter the light into its component colors, producing an iridescent color that changes with the angle at which the crystals are viewed. Outside this color response range, liquid crystals are generally colorless. The response time for the color change varies from 30 to 100 ms. This is more than adequate to allow liquid crystals to show transient changes in temperature. The spatial resolution obtainable can be as small as 0.02 mm (0.0008 in.). In addition, because the color change is generally reversible, anomalies can be evaluated by repeating the test as many times as needed.

Techniques for applying liquid crystals are relatively straightforward once the proper blend of compounds is selected. Because liquid crystals function by reflecting light, they are more readily seen when used against a dark background. Therefore, if the specimen is not already dark, covering the surface with a removable, flat-black coating is strongly recommended before application. The crystals can then be applied by pouring, painting, spraying, or dipping. Care must be taken that the specimen or the coating is not attacked by the solvent base used with the liquid crystals. The applied film of liquid crystals must be of uniform thickness to prevent color irregularities caused by thickness differences rather than temperature differences. A good film thickness is about 0.02 mm (0.0008 in.). Successive layers used to build up the film thickness should not be allowed to dry between coats. A coating of proper thickness will have a uniform, low-gloss appearance when viewed with oblique illumination.

**Thermally quenched phosphors** are organic compounds that emit visible light when excited by ultraviolet light. The brightness of a phosphor is inversely proportional with temperature over a range from room temperature to about 400 °C (750 °F), as indicated in Fig. 1. Some phosphors exhibit a change in brightness of as much as 25%/°C (14%/°F). An individual phosphor should be selected to cover the temperature range used for a particular inspection. The coating is applied by painting a well-agitated mixture of the phosphor onto the surface to a thickness of about 0.12 mm (0.0047 in.).

**Fig. 1** Relative brightness of four thermally quenched phosphors (U.S. Radium Radelin phosphor numbers) as a function of temperature

**Heat-sensitive paints** that are effective from 40 to 1600 °C (about 100 to 2900 °F) are available. Some of these paints undergo several color transitions as their temperature is increased, and, under favorable conditions, an accuracy of  $\pm 5$  °C

( $\pm 9$  °F) is attainable with them. These paints have been used effectively for monitoring isotherms in heat-affected zones during welding, for monitoring preheating prior to welding, and for inspecting castings for porosity.

**Heat-Sensitive Papers.** Several types of heat-sensitive papers have been used in nondestructive inspection. They are applied by bonding directly to the surface of the test piece, or by means of a vacuum holddown arrangement.

One type consists of a porous paper coated with an organic compound. A finely divided white pigment is applied to a highly absorptive black paper in a binder soluble in a solvent that does not dissolve the pigment. When the melting temperature of the pigment is reached, the paper absorbs the coating and the initial white color is replaced by a black appearance. These papers are used to indicate when a specific temperature has been reached.

## Noncontact Thermographic Inspection

A large number of devices will respond to the radiant energy in the infrared bandwidth produced by an object at a temperature above absolute zero and convert it to a proportional electric signal that then may be displayed. Infrared imaging equipment is available with a wide range of capabilities. The simplest systems are responsive to the near-infrared portion of the optical spectrum. These include night-vision devices and vidicon systems with silicon or lead sulfide sensors. Silicon sensors provide sensitivity for temperatures above 425 °C (800 °F), while lead sulfide sensors respond to temperatures above 200 °C (400 °F).

There are two basic types of infrared detectors: photon-effect devices and thermal devices. The response of the photon-effect devices depends on the wavelength of the received radiation; therefore, the output signal depends on the wavelength of the infrared signal. Thermal detectors respond only to the heating caused by the incoming radiation, and the output signal is largely independent of the radiation wavelength. At certain wavelengths, the photon-effect devices will produce a much larger signal than thermal detectors.

**Hand-held infrared scanners** are portable imaging systems capable of responding in the far-infrared portion of the optical spectrum (wavelengths of 8 to 12  $\mu\text{m}$ ). This range is emitted by objects at or near room temperature. In general, hand-held scanners have poor imaging qualities and are not suitable for the accurate measurement of local temperature differences. However, they can be useful for detecting hot spots, such as over-heated components, thermal runaway in an electronic circuit, or unextinguished fires.

**High-resolution infrared imaging systems** are required for most part inspection applications. These systems use either pyroelectric vidicon cameras with image-processing circuitry or cryogenically cooled mechanical scanners to provide good-quality image resolution (150 pixels, or picture elements, per scan line) temperature sensitivity to 0.1 °C (0.2 °F). In addition to good image resolution and temperature sensitivity, response times of the order of 0.1 s or less facilitate the detection of transient temperature changes or differentials. These imaging systems will use either a gray scale or a color scale correlated to temperature ranges to depict the temperature distribution within the image.

**Thermal wave interferometer systems** combine modulated laser excitation with rapid phase and amplitude sensing that can be scanned across a surface to produce an image. One application for this type of system is the inspection of plasma-sprayed coatings. The system senses the interaction between the thermal waves of the laser and the thermal variations from coating defects and thickness variations.

## Contact Thermometric Inspection

There are several basic thermal detectors: bolometers, thermistors, thermocouples, and thermopiles. For the most part, they can be used either in direct contact with the test item or as radiation detectors (noncontact applications). These devices can detect infrared radiation of both short and long wavelengths, and very low-temperature or low-radiation levels without cryogenic cooling.

**Bolometers** are thermal detectors that are based on the principle that the resistance of a material changes as it is heated. The bolometer allows the radiation to impinge on a very fine wire or a thin metallic film, blackened to increase absorption. The change in resistance is then a direct function of the radiation absorbed. The temperature coefficient of a bolometer is from 0.3 to 0.5%/°C.

**Thermocouples.** A thermocouple consists of a junction of two dissimilar metals. As the junction temperature is raised, a thermoelectric electromotive force is produced. Thermocouples are always used in pairs in a bridge circuit so that the

measured temperature is a direct function of the electromotive force produced by the sensing thermocouple as subtracted from the electromotive force produced by a reference thermocouple held at a known temperature.

**Thermopiles.** A thermopile is merely a series of thermocouple junctions; it produces an increase in electromotive force as a direct function of the number of junctions.

**Melttable Substances.** Waxlike crayons that melt at temperatures in the range of 38 to 1760 °C (100 to 3200 °F) are commercially available. Such a crayon has a melting point within a nominal tolerance of  $\pm 1\%$  of its rated temperature value. These crayons are normally used by making a mark with one or more of them on a surface before it is heated.

## Noncontact Thermometric Inspection

The temperature-measuring devices used in noncontact thermometric inspection depend on response of a thermal detector to infrared radiation. They are particularly useful when it is necessary to monitor or measure surface temperatures remotely.

**Radiometers** are instruments used to measure incident radiation. They consist of some type of hollow cavity with an aperture in one end and a thermal detector mounted internally. The thermal detector is so located that the radiation is focused on it. Because thermal detectors have a uniform response without regard to infrared wavelength, a radiometer is often used to measure total radiation. If the radiometer has a lens system, it will be restricted to the infrared-transmission characteristics of the lenses.

**Pyrometers** (or infrared thermometers) are used in nondestructive testing in much the same way as are infrared scanning devices. These instruments have less accuracy than other scanning devices, but they are simpler, more rugged, more portable, and less expensive. A wide variety of this type of equipment is commercially available, with a corresponding variety of performance.

## Applicability

Thermal methods can be useful in the detection of subsurface flaws or voids, provided the depth of the flaw is not large compared to its diameter. Thermal inspection becomes less effective in the detection of subsurface flaws as the thickness of an object increases because the possible depth of the defects increases.

Thermal inspection is applicable to complex shapes or assemblies of similar or dissimilar materials and can be used in the one-sided inspection of objects. Moreover, because of the availability of infrared sensing systems, thermal inspection can also provide rapid, noncontact scanning of surfaces, components, or assemblies.

Thermal inspection does not include those methods that use thermal excitation of a test object and a nonthermal sensing device for inspection. For example, thermally induced strain in holography or the technique of thermal excitation with ultrasonic or acoustic methods does not constitute thermal inspection.

# Holography

## Introduction

HOLOGRAPHY is basically a two-step process for creating a whole image--that is, a three-dimensional image--of a diffusely reflecting object having some arbitrary shape. In the first step, both the amplitude and phase of any type of coherent wave motion emanating from the object are recorded by encoding this information in a suitable medium. This recording is called a hologram. At a later time, the wave motion is reconstructed from the hologram by a coherent beam in a process that results in the regeneration of an image having the true shape of the object. The utility of holography for nondestructive inspection of metal components and metal-containing structures lies in the fact that this regenerated image can then be used as a kind of three-dimensional template against which any deviations in the shape or dimensions of the object can be observed and measured.

In principle, holography can be performed with (a) any wave radiation encompassed in the entire electromagnetic spectrum, (b) any particulate radiation, such as neutrons and electrons, that possesses wave-equivalent properties; and (c) nonelectromagnetic wave radiation, such as sound waves. The two methods currently available for practical nondestructive inspection are optical holography, using visible light waves, and acoustical holography, using ultrasonic waves.

## Optical Holography

Optical holographic interferometry has been successfully used both in research and testing applications as a noncontacting tool for displacement, strain and vibration studies, depth-contour mappings, and transient/dynamic phenomena analyses. Specific applications of optical holography in nondestructive evaluation include:

- Detection of debonds within honeycomb-core sandwich structures
- Detection of unbonded regions within pneumatic tires and other laminates
- Detection of cracks in hydraulic fittings
- Qualitative evaluation of turbine blades

## Applicability

**The advantages** of using optical holographic interferometry for nondestructive inspection include the following:

- It can be applied to any type of solid material--ferromagnetic or nonferromagnetic; metallic, nonmetallic, or composite; electrically or thermally conductive or nonconductive; and optically transparent or opaque
- It can be applied to test objects of almost any size and shape, provided a suitable mechanism exists for stressing or otherwise exciting the object.
- Pulsed-laser techniques allow the inspection of test objects in unstable or hostile environments.
- It has an inherent sensitivity to the displacement or deformation of at least one-half an optical wavelength, or about 125 nm (1250 Å). This permits the use of low levels of stress during inspection. Further, special analysis techniques can provide improved sensitivity of almost 1000 fold.
- It does not rely on data acquisition by either point-by-point determinations or scanning processes; instead, three-dimensional images of interference fringe fields are obtained of the entire surface (front, back, and internal, if desired) or a large fraction thereof.
- It allows flexibility of readout. For example, in flaw detection applications, the images can be examined purely qualitatively for localized fringe anomalies within the overall fringe field. If, conversely, the application involves the strain analysis of an object subjected to a specific type of stress, the image can be analyzed to yield a highly quantitative point-by-point map of the resulting surface displacements.
- It permits comparison of the responses of an object to two different levels of stress or other excitation. The frame of reference for this differential measurement is usually, but not always, the unstressed or natural state of the test object. This differential type of measurement contrasts with absolute types, which are made without a frame of reference, and with comparative measurements, in which a similar but different object is used as a frame of reference.
- The interferograms can be reconstructed at any later time to produce three-dimensional replicas of the previously recorded test results.

**The disadvantages** of using optical holographic interferometry for nondestructive inspection include the following:

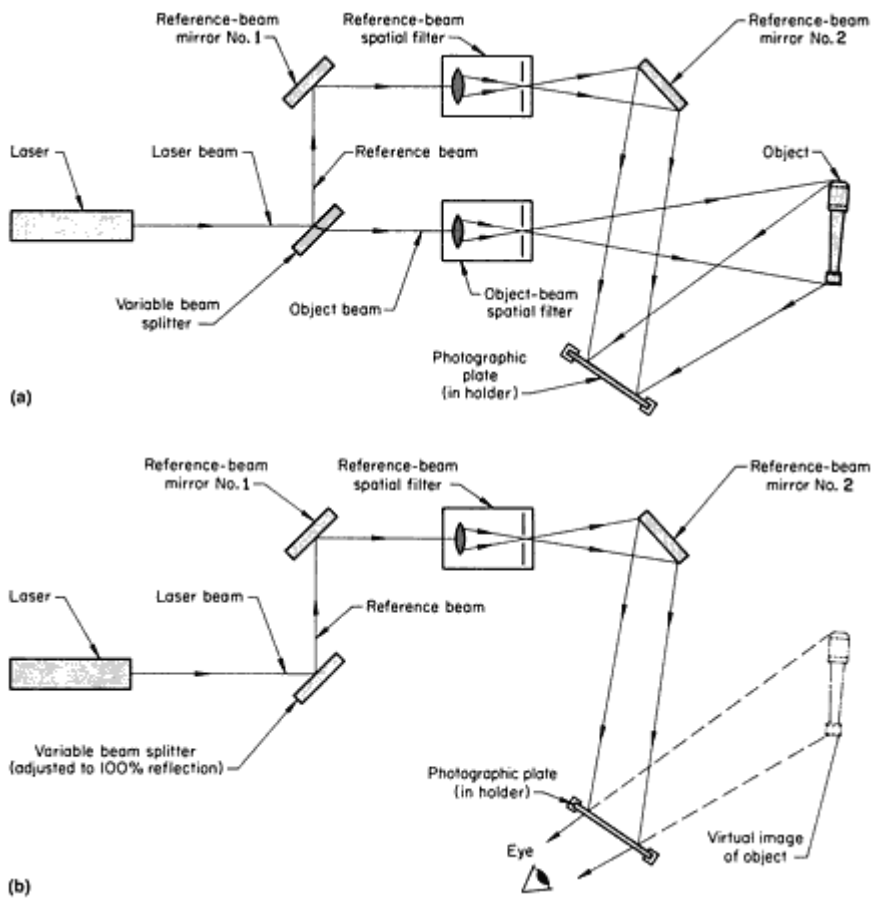

- Although no physical contact with the test object is required to effect the interaction of the coherent light with either the test object or the photographic plate, it is often necessary to provide fixturing not only for the test object but also for the stressing source. The success of a holographic inspection procedure depends largely on the adequacy of design and the practical performance of both the fixturing and the stress-imparting mechanisms.
- It is limited to test objects with wall or component thicknesses that will offer sufficiently large

displacements without requiring stressing forces that will cause rigid-body movement or damage to the object. For sandwich structures, the thickness of the skin is the limiting factor; the maximum skin thickness that can be tested is a function of the stressing method.

- Holographic methods are best suited to diffusely reflecting surfaces with high reflectivity. Removable coatings are often sprayed onto strongly absorbing materials and specularly reflecting surfaces
- Although holographic interferometry is capable of accurately locating a flaw within the surface area of the test object being inspected, the cross-sectional size of the flaw can often be only approximately determined, and information concerning the depth of the flaw, when obtainable at all, is qualitative in nature.
- Where visual interpretation of interferograms is to be performed, holographic interferometry may be limited in its dynamic range for some applications. However, electronic methods for fringe interpretation have been used to provide increased sensitivity and dynamic range.
- Test results sometimes cannot be analyzed because of the localization of the interference fringes in space rather than on the surface of the test object (in real-time holographic interferometry) or on the reconstructed image of the object (in double-exposure holographic interferometry).
- With the exception of holographic-contouring applications, holographic interferometry is currently limited to differential tests, in which the object is compared to itself after it has been subjected to changes in applied stress. Comparative tests, in which a given object can be compared to a standard object, are not feasible with holographic interferometry because of inherent random variations in test object surfaces.
- Personnel performing holographic inspection must be properly trained. The greater the sophistication of the equipment, the greater the required operating skill.

### ***Optical Holography Method***

**Holographic Recording.** When visible lightwaves are used, the hologram is recorded with an optical system called a holocamera (see Fig. 1a). A monochromatic laser beam of phase-coherent light is divided into two beams by a variable beam splitter. One beam, the object beam, is expanded by a spatial filter into a divergent beam directed to illuminate the object uniformly. A portion of the laser light reflected from the object is intercepted by a high-resolution photographic plate, as shown in Fig. 1(a). The second beam, the reference beam, originating from the beam splitter is directed by a mirror, diverges from a second spatial filter, and is directed onto the photographic plate by a second mirror. With either object beam or reference beam absent, a uniformly exposed photographic plate will result. However, with both coherent beams falling on the plate simultaneously, an interference pattern is generated as a result of the coherent interaction of the two beams, and this pattern is recorded by the photographic emulsion.

**Fig. 1** Schematic diagrams of the basic optical systems used in continuous-wave holography: (a) holocamera used to record hologram of an object on a photographic plate and (b) optical system for reconstructing a virtual image of the object from the hologram on the photographic plate

**Holographic Reconstruction.** In the reconstruction process, which is illustrated in Fig. 1(b), the hologram is used as a diffraction grating. When it is illuminated with the reference beam only, three beams emerge--a zero-order, or undeflected, beam and two first-order diffracted beams. The diffracted beams produce the real and virtual images of the object to complete the holographic process. The real image is pseudoscopic, or depth inverted, in appearance. Hence, the virtual image (also referred to as the true, primary, or nonpseudoscopic image) is the image that is of primary interest in practical applications of holography. In Fig. 1(b), only the first-order diffracted beam that yields the virtual image is shown, the other two beams having been omitted from the figure for the sake of clarity. If the original object is three-dimensional, the virtual image is a genuine three-dimensional replica of the object, possessing both parallax and depth of focus. However, if the configuration of the optical system or the wavelength of light used during reconstruction differs from that used during recording, distortion, aberration, and changes in magnification can occur. (The holographic recording and reconstruction systems can be designed to minimize these effects.)

**Interferometric Techniques of Inspection.** When optical holography is applied to inspection of parts, generation of a three-dimensional image of the object, per se, is of little value. Furthermore, for opaque materials, optical holography is strictly limited to surface observations. Hence, if optical holography is to be used for nondestructive inspection, supplementary means must be used to either stress or otherwise excite test objects to produce surface manifestations of the feature of interest. It is for measurement of such manifestations that the techniques of optical holography have been further developed to form the subfield of holography termed optical holographic interferometry.

As in conventional interferometry, holographic interferometric measurements can be made with great accuracy (to within a fraction of the wavelength of the light being used). Whereas conventional interferometry is usually restricted to the examination of objects having highly polished surfaces and simple shapes, holographic interferometry can be used to examine objects of arbitrary shape and surface condition. Because holographic interferometry produces a three-

dimensional fringe-field image, which can be examined from many different perspectives (limited only by the size of the hologram), a single holographic interferogram is equivalent to a series of conventional two-dimensional interferograms.

In contrast to conventional interferometry, which must be performed in real time, holographic interferometry can be performed either in real time or at two different times (time-lapse technique). In the time-lapse technique, advantage is taken of the fact that more than one hologram may be made on the same recording medium. Examples of this approach include the double-exposure, multiple-exposure, and continuous-exposure techniques.

## Acoustical Holography

Acoustical holography is the extension of holography into the ultrasonic domain. The principles of acoustical holography are the same as those of optical holography because the laws of interference and diffraction apply to all forms of radiation obeying the wave equation. Differences arise only because the methods for recording and reconstructing the hologram must accommodate the form of radiation used. This need to accommodate the form of radiation restricts the practical range of sound-wave frequency that can be used in acoustical holography.

At present, only two types of basic systems for acoustical holography are available--the liquid-surface type and the scanning type. These utilize two different detection methods, and these methods in turn dictate the application of the systems to nondestructive inspection. Neither of these two types of systems relies on the interferometric techniques of optical holographic inspection, where information on flaws at or near the surface of a test object is obtained from the pattern formed by interference between two nearly identical holographic images that are created while the object is differentially stressed. Instead, systems for acoustical holography obtain information on internal flaws directly from the image of the interior of the object.

**Liquid-Surface Acoustical Holography.** The basic system for liquid-surface acoustical holography is similar to the basic system for optical holography, except for the method of read out.

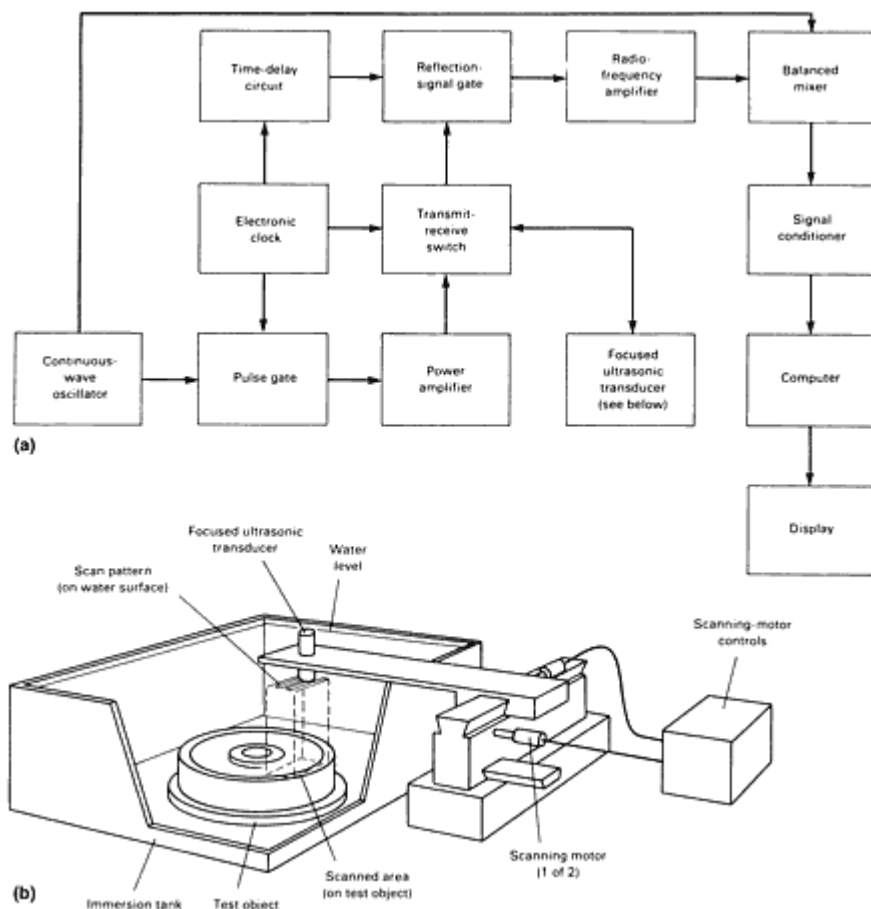

In liquid-surface systems, two separate ultrasonic transducers supply the object beam and reference beam, which are usually pulsed. The two transducers and the test object are immersed in a water-filled tank. The test object is positioned in the object plane of an acoustic (ultrasonic) lens, which also is immersed in the tank.

The practical limits for the object-beam transducer in a commercial system are a wave frequency of 1 to 10 MHz, a pulse length of 50 to 300 microseconds, and a pulse-repetition rate of 60 to 100 per second. This transducer is placed so that its beam passes through the test object. As the object beam passes through the test object, it is modified by the object. The modification is generally in both amplitude and phase. The object beam then passes through an acoustic lens, which focuses the image of the test object at the liquid surface. This image contains a wave front nearly identical to that emanating from the test object.

The reference-beam transducer is connected to the same oscillator as the object-beam transducer so that it emits a second wave front coherent with the wave front from the object-beam transducer. The reference-beam transducer is aimed at the same region of the liquid surface as the object beam, where the wave fronts interfere. The image is reconstructed from the hologram by reflecting a beam of coherent light from the ripple pattern in the isolation tank.

**Scanning Acoustical Holography.** The basic system for scanning acoustical holography is shown in Fig. 2. No reference-beam transducer is required in this system because electronic phase detection is used to produce the hologram: that is, the required interaction (mixing) between the piezoelectrically detected object-beam signal and the simulated reference-beam signal occurs in the electronic domain. A pulser circuit--consisting of a continuous-wave oscillator and a pulse gate that is triggered by an electronic clock--and a power amplifier feed a single focused ultrasonic transducer that is scanned over an area above the test object while alternately transmitting and receiving the ultrasonic signals. The transducer and the test object are immersed in a water-filled tank, as in Fig. 2(b), or they are coupled by a water column.

**Fig. 2** Diagrams of the basic system used in nondestructive inspection by scanning acoustical holography. See text for description. (a) Ultrasonic and light portions of systems. (b) Scanning and recording portions of system

The signal is pulsed so that time gating can be used to reject undesired surface echoes. The pulse length may be set to any desired value from a few periods of the wave frequency to an upper limit of 50% of the time between successive pulses. Long pulse lengths are used to examine regions lying deep within the metal, while short pulse lengths are required for the regions near the surface so that transmitted energy is not mixed with reflected energy. The practical limits of the transducer in a commercial system are a wave frequency of 1 to 10 MHz, a pulse length of 5 to 20 microseconds, and a pulse-repetition rate of 500 to 1000 per second. The frequency band of a given transducer is relatively narrow ( $\pm 5\%$  of the mean frequency).

The echo from the flaw is received by the transducer and processed by a time-interval counter or a pair of balanced mixers in quadrature. The resulting data are digitized and entered into the computer. As the transducer scans a rectangular area, a matrix of complex numbers accumulates in the computer. This matrix represents the phase and amplitude of the reflected wave taken on a set of sample points.

**Comparison of Liquid-Surface and Scanning Systems.** The outstanding feature of the liquid-surface system of acoustical holography is that it provides a real-time image, whereas the image provided by the scanning system requires reconstruction. The real-time feature makes the liquid-surface system suitable for rapid inspection of large amounts of material on a continuous basis. In contrast, inspection with the scanning system is relatively slow. Photographic or videotape records for later study may be made with either system.

The outstanding feature of the scanning system is its ability to determine accurately the position and dimensions of flaws lying deep in opaque test objects, especially when only one side of the object is accessible. (In contrast to the scanning system, the liquid-surface system is usually operated in the transmission mode, which requires access to both sides of the test object.) Although both systems offer about the same resolution, the sensitivity of the scanning system is greater by a factor of about  $10^6$ . The excellent flaw-measuring ability of the scanning system can be used to characterize accurately the flaws detected previously by faster inspection methods, such as scanning with a conventional ultrasonic search unit.

Another important feature of the scanning system is that the commercial equipment for this system is usually transportable, whereas liquid-surface equipment is usually stationary. In addition, scanning transducers can be coupled to very large test objects by water columns, whereas inspection by the liquid-surface system usually requires that the test objects be small enough to be placed in a water-filled tank and completely immersed.

A useful advantage of the scanning system is its capability of selectively producing either longitudinal or shear waves in the volume of metal under examination, by adjustment of the angle of incidence of the incoming ultrasonic beam.

# Mechanical Testing

## Hardness Testing

HARDNESS is a term that has different meanings to different people: it is resistance to penetration to a metallurgist, resistance to wear to a lubrication engineer, a measure of flow stress to a design engineer, resistance to scratching to a mineralogist, and resistance to cutting to a machinist. Although these various definitions of hardness appear to differ significantly in character, they are all related to the plastic flow stress of the material.

Table 1 lists the major types of hardness testers, which can be either portable instruments or laboratory devices. Only static indentation and rebound testing are discussed in this article. These two methods account for virtually all routine hardness testing in the metalworking industry. Static indentation hardness testing is the more widely used of the two methods, although rebound testing is extensively employed, particularly for hardness measurements on large workpieces or for applications in which visible or sharp impressions in the test surface cannot be tolerated.

**Table 1 Classification of hardness testers**

Method	Type
Indentation: standard operation	
<b>Vickers</b>	Macroindentation or microindentation
<b>Rockwell</b>	Macroindentation
<b>Brinell</b>	Macroindentation
Indentation: nonstandard operation	
<b>Rockwell</b>	Low-load
<b>Vickers</b>	Low-load
<b>Brinell</b>	Calibrated pin system (static or dynamic)
Indentation: equivalent hardness	
<b>Static</b>	"Press-and-read" type (mechanical or electronic)
	"Scissors" type
	Clamp type
<b>Dynamic</b>	Cylinder type
Other indentation methods	
<b>UCI method</b>	...
<b>Comparative hardness method</b>	Cylinder type
	Horizontal bar type
Dynamic	
<b>Reaction force</b>	Piezo-electric crystal principle
<b>Rebound</b>	Mechanical
	Electronic (EQUO) method

## Brinell Hardness Testing

The Brinell hardness test is basically simple, and it consists of applying a constant load, usually 500 to 3000 kg, on a hardened steel ball-type indenter, 10 mm in diameter, to the flat surface of a workpiece (Fig. 1). The 500 kg load is usually used for testing nonferrous metals, such as copper and aluminum alloys, whereas the 3000 kg load is most often used for testing harder metals, such as steels and cast irons. The load is held for a specified time (10 to 15 s for iron or steel and about 30 s for softer metals), after which the diameter of the recovered indentation is measured in millimeters. This time period is required to ensure that plastic flow of the work metal has stopped.

**Fig. 1** Sectional view of a Brinell indenter, showing the manner in which the application of force by the indenter causes the metal of the workpiece to flow

Hardness is evaluated by taking the mean diameter of the indentation (two readings at right angles to each other) and calculating the Brinell hardness number (HB) by dividing the applied load by the surface area of the indentation according to the following formula:

$$HB = L/(\pi D/2)[D - (D^2 - d^2)^{1/2}]$$

where  $L$  is the load, in kilograms;  $D$  is the diameter of the ball, in millimeters; and  $d$  is the diameter of the indentation, in millimeters.

It is not necessary, however, to make the calculation for each test. Such calculations are available in table form for all diameters of indentations in Section 1 of this Handbook.

Highly hardened steel (or other very hard metals) cannot be tested by a hardened steel ball by the Brinell method, because the ball will flatten during penetration and a permanent deformation will take place. This problem is recognized in specifications for the Brinell tests.

Tungsten carbide balls are recommended for Brinell testing materials of hardness from 444 HB up to about 627 HB (indentation of 2.45 mm in diameter). However, higher Brinell values will result when using carbide balls instead of steel balls because of the difference in elastic properties.

**Surface Preparation.** The degree of accuracy that can be attained by the Brinell hardness test can be greatly influenced by the surface smoothness of the workpiece being tested.

The surface of the workpiece on which the Brinell indentation is to be made must be filed, ground, machined, or polished with emery paper (3/0 emery paper is suitable) so that the indentation diameter is clearly enough defined to permit its measurement. There should be no interference from tool marks.

**Indentation Measurement.** The diameter of the indentation is measured by a microscope to the nearest 0.05 mm (0.002 in.). This microscope contains a scale, and usually a built-in light, to facilitate easy reading.

The indentations produced in Brinell hardness tests may exhibit different surface characteristics. These have been carefully studied and analyzed. In some instances there is a ridge around the indentation extending above the original surface of the workpiece. In other instances the edge of the indentation is below the original surface. Sometimes there is no difference at all. The first phenomenon is called a "ridging" type of indentation and the second a "sinking" type. Cold worked metals generally have the former type of indentation, and annealed metals the latter type.

**Brinell Hardness Testers.** Several types of testers that exert the prescribed force on the indenter are in general use. The two general types are hydraulic analog testers and newer digital hardness testers. Digital hardness testers have better resolution than analog testers. The resolution of digital testers reduces or eliminates the need for extrapolation, but they are not as durable as analog testers.

In statistical process control of Brinell testing, there is no adequate way to achieve high process capability indices ( $C_p$  and  $C_{pk}$  values) without making the investment in state of the art optics that utilize frame grabbers to read the impression. It is possible to take several impressions on pieces and take the average of these impressions to get a point in a subgroup, but this method requires larger sample sizes and inspection costs increase.

Many analog Brinell testers are typically manually operated hydraulic instruments like the one shown in Fig. 2. The workpiece is placed on the anvil and raised, by means of the elevating screw, to a position near the indenter. Fingertip rotation of the control knob allows a selected force (in kilograms), indicated on the gage, to be applied. This force is held for a pre-established length of time and then released. The specimen is removed and the indentation measured. The entire cycle, including indenting and measurement, requires approximately one minute.

**Fig. 2** Analog Brinell hardness tester

**Portable Brinell Hardness Testers.** Conventional Brinell hardness testers have limited use, for two reasons: (a) the workpieces to be tested must be brought to the testers, and (b) size and design of the workpieces must be such that they can be placed between the anvil and the indenter.

Some of the problems posed by these limitations can often be solved by use of a portable hardness tester. Hydraulic portable testers like the general design shown in Fig. 3 weigh no more than about 25 lb and can be easily transported to the workpieces. Smaller, digital testers are also available.

**Fig. 3** Hydraulic, manually operated portable Brinell hardness tester

**Spacing of Indentations.** To ensure accurate results, indentations should not be made too close to the edge of the workpiece being tested. Lack of sufficient supporting material on one side of the workpiece will cause the resulting indentation to be large and unsymmetrical. It is generally agreed that the error in a Brinell hardness number is negligible if the distance from the center of the indentation is not less than  $2\frac{1}{2}$  times (and preferably 3 times) the diameter of the indentation from any edge of the workpiece.

Similarly, indentations should not be made too close to one another. If indentations are too close together, the work metal may be cold worked by the first indentation, or there may not be sufficient supporting material for the second indentation. The latter condition would produce too large an indentation, whereas the former may produce too small an indentation. To prevent this, the distance between centers of adjacent indentations should be at least three times the diameter of the indentation.

**General Precautions.** To avoid misapplication of Brinell hardness testing, the fundamentals and limitations of the test procedure must be clearly understood. Further, to avoid inaccuracies, some general rules should be followed. Such rules include the following:

1. Indentations should not be made on a curved surface having a radius of less than 1 in.
2. Spacing of indentations should be correct, as outlined above under "Spacing of Indentations."
3. The load should be applied steadily to avoid overloading caused by inertia of the weights.
4. The load should be applied in such a way that the direction of loading and the test surface are perpendicular to each other within  $2^\circ$ .
5. The thickness of the workpiece being tested should be such that no bulge or mark showing the effect of the load appears on the side of the workpiece opposite the indentation. In any event, the thickness of the specimen shall be at least ten times the depth of indentation.
6. The surface finish of the workpiece being tested should be such that the indentation diameter is clearly outlined.

**Limitations.** The Brinell hardness test has three principal limitations:

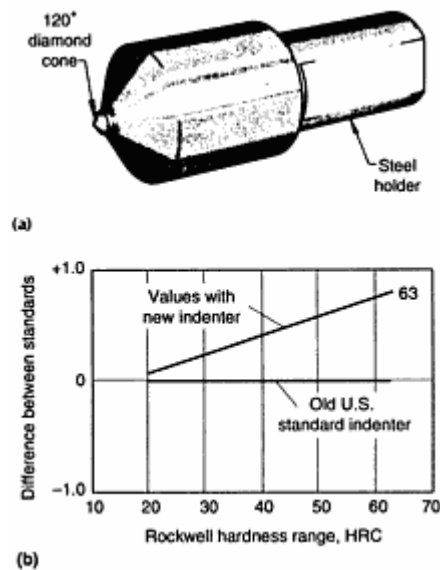

1. Size and shape of the workpiece must be capable of accommodating the relatively large indentations.
2. Because of the relatively large indentations, the workpiece may not be usable after testing.

3. The limit of hardness range--about 11 HB with the 500 kg load to 627 HB with the 3000 kg load--is generally considered the practical range.

## Rockwell Hardness Testing

Rockwell hardness testing is the most widely used method for determining hardness. There are several reasons for this distinction. The Rockwell test is simple to perform and does not require highly skilled operators. By use of different loads and indenters, Rockwell hardness testing can be used for determining hardness of most metals and alloys, ranging from the softest bearing materials to the hardest steels. A reading can be taken in a matter of seconds with conventional manual operation and in even less time with automated setups. No optical measurements are required (all readings are direct).

Rockwell hardness testing differs from Brinell hardness testing in that the hardness is determined by the depth of indentation made by a constant load impressed upon an indenter. Although a number of different indenters are used for Rockwell hardness testing, the most common type is a diamond ground to a  $120^\circ$  cone with a spherical apex having a 0.2 mm radius, which is known as a Brale indenter (Fig. 4a).

**Fig. 4** Rockwell indenter. (a) Diamond-cone Brale indenter (shown at about  $2\times$ ). (b) Comparison of old and new U.S. diamond indenters. The angle of the new indenter remains at  $120^\circ$  but has a larger radius closer to the average ASTM specified value of  $200\ \mu\text{m}$ ; the old indenter has a radius of  $192\ \mu\text{m}$ . The indenter with the larger radius has a greater resistance to penetration of the surface.

The shape of the Rockwell diamond indenter most widely used in the United States is different from indenters in the rest of the world. The ASTM specification calls for a diamond cone radius of  $200 \pm 10\ \mu\text{m}$  (0.0079 in.), but in practice, it is closer to  $192\ \mu\text{m}$  (0.0076 in.). While not out of tolerance, the old U.S. standard indenter is at the end of the specification. In the United States, the diamond was first set at  $192\ \mu\text{m}$  to match the nominal values of the hardness test blocks. However, the rest of the world has used a diamond size closer to  $200\ \mu\text{m}$  (0.0079 in.).

A comparison of the old ( $192\ \mu\text{m}$ ) U.S. standard diamond indenter and the current ( $200\ \mu\text{m}$  tip) U.S. indenter is shown in Fig. 4(b). The larger radius increases the indenter's resistance to penetration into the surface of the testpiece.

At higher HRC hardness, most of the indenter travel is along the radius; whereas at the lower hardnesses, more indenter travel is along the angle. This is why the hardness shift from old to new has been most significant in the HRC 63 range and not the HRC 25 range.

## Methods

As shown in Fig. 5, the Rockwell hardness test consists of measuring the additional depth to which an indenter is forced by a heavy (major) load (Fig. 5b) beyond the depth of a previously applied light (minor) load (Fig. 5a). Application of the minor load eliminates backlash in the load train and causes the indenter to break through slight surface roughness and to crush particles of foreign matter, thus contributing to much greater accuracy in the test. The basic principle involving minor and major loads illustrated in Fig. 5 applies to steel-ball indenters as well as to diamond indenters.

**Fig. 5** Indentation in a workpiece made by application of (a) the minor load, and (b) the major load, on a diamond Brale indenter in Rockwell hardness testing. The hardness value is based on the difference in depths of indentation produced by the minor and major loads.

The minor load is applied first, and a reference or "set" position is established on the measuring device of the Rockwell hardness tester. Then the major load is applied at a prescribed, controlled rate. Without moving the workpiece being tested, the major load is removed and the Rockwell hardness number is automatically indicated on the dial gage. The entire operation takes from 5 to 10 s.

Diamond indenters are used mainly for testing materials, such as hardened steels and cemented carbides. Steel-ball indenters available with diameters of  $\frac{1}{16}$ ,  $\frac{1}{8}$ ,  $\frac{1}{4}$ , and  $\frac{1}{2}$  in., are used for testing materials, such as soft steel, copper alloys, aluminum alloys, and bearing metals.

**Rockwell Testers.** There are two basic types of Rockwell hardness testers--regular and superficial. Both testers have similar basic mechanical principles and significant components.

Rockwell testers generally come with two different resolutions. The standard Rockwell analog tester (Fig. 6), which has been the industrial workhorse for years, has a resolution of 1.0 HRC. Many operators think they can improve resolution to 0.5 HRC or even 0.1 HRC by extrapolation, but this is not true. Extrapolation of readings only increases measurement error when several operators are checking parts.

**Fig. 6** Principal components of a regular (normal) Rockwell hardness tester. Superficial Rockwell testers are similarly constructed.

As with Brinell testing, better resolution can be achieved by investing in digital testing equipment. The newer digital Rockwell testers (Fig. 7) have a resolution of 0.1 HRC, and they eliminate the need for extrapolation (guessing). Similar resolution can be obtained on portable digital testers.

**Fig. 7** A digital Rockwell hardness tester

**Regular Rockwell Hardness Testing.** In regular Rockwell hardness testing, the minor load is always 10 kg. The major load, however, can be 60, 100, or 150 kg. No Rockwell hardness value is expressed by a number alone. A letter has been assigned to each combination of load and indenter, as shown in Table 2. Each number is suffixed by first the letter H (for hardness), then the letter R (for Rockwell), and finally the letter that indicates the scale used. For example, a value of 60 on the Rockwell C scale is expressed as 60 HRC, and so on. Regardless of the scale used, the "set" position is the same; however, when the diamond Brale indenter is used, the readings are taken from the black divisions on the dial gage. When testing with any of the ball indenters, the readings are taken from the red divisions.

**Table 2 Rockwell-hardness-scale designations for combinations of type of indenter and major load**

Scale designation	Indenter		Major load, kg	Dial figure
	Type	Diam, in.		
Regular Rockwell tester				
B	Ball	$\frac{1}{16}$	100	Red
C	Brale	...	150	Black
A	Brale	...	60	Black
D	Brale	...	100	Black
E	Ball	$\frac{1}{8}$	100	Red
F	Ball	$\frac{1}{16}$	60	Red
G	Ball	$\frac{1}{16}$	150	Red
H	Ball	$\frac{1}{8}$	60	Red
K	Ball	$\frac{1}{8}$	150	Red
L	Ball	$\frac{1}{4}$	60	Red
M	Ball	$\frac{1}{4}$	100	Red
P	Ball	$\frac{1}{4}$	150	Red
R	Ball	$\frac{1}{2}$	60	Red
S	Ball	$\frac{1}{2}$	100	Red
V	Ball	$\frac{1}{2}$	150	Red
Superficial Rockwell Tester				
15N	N Brale	...	15	...
30N	N Brale	...	30	...
45N	Brale	...	45	...
15T	Ball	$\frac{1}{16}$	15	...
30T	Ball	$\frac{1}{16}$	30	...
45T	Ball	$\frac{1}{16}$	45	...
15W	Ball	$\frac{1}{8}$	15	...
30W	Ball	$\frac{1}{8}$	30	...
45W	Ball	$\frac{1}{8}$	45	...
15X	Ball	$\frac{1}{4}$	15	...
30X	Ball	$\frac{1}{4}$	30	...
45X	Ball	$\frac{1}{4}$	45	...
15Y	Ball	$\frac{1}{2}$	15	...
30Y	Ball	$\frac{1}{2}$	30	...
45Y	Ball	$\frac{1}{2}$	45	...

One Rockwell number represents an indentation of 0.002 mm (0.00008 in.). Therefore, a reading of 60 HRC indicates indentation from minor to major load of  $(100 - 60) \times 0.002 \text{ mm} = 0.080 \text{ mm}$ , or 0.0032 in. A reading of 80 HRB indicates an indentation of  $(130 - 80) \times 0.002 \text{ mm} = 0.100 \text{ mm}$ , or 0.004 in.

**Superficial Rockwell hardness testing** employs a minor load of 3 kg, but the major load can be 15, 30, or 45 kg.

Just as in regular Rockwell testing, the indenter may be either a diamond or a steel ball, depending mainly on the nature of the metal being tested. Regardless of load, the letter N designates use of the superficial Brale, and the letters T, W, X, and Y designate use of steel-ball indenters. Scale and load combinations are presented in Table 2. Superficial Rockwell

hardness values are always expressed with the number suffixed by a number and a letter that show the load/indenter combination. For example, if a load of 30 kg is used with a diamond indenter and a reading of 80 is obtained, the result is reported as 80 HR30N (where H means hardness, R means Rockwell, 30 means a load of 30 kg, and N indicates use of a diamond indenter).

All tests are started from the "set" position. One Rockwell superficial hardness number represents an indentation of 0.001 mm or 0.00004 in. Therefore, a reading of 80 HR30N indicates indentation from minor to major load of  $(100 - 80) \times 0.001 \text{ mm} = 0.020 \text{ mm}$ , or 0.0008 in.

Dials on the superficial hardness testers contain only one set of divisions, which is used with all types of superficial indenters.

### Selection of Rockwell Scale

Where no specification exists or there is doubt about the suitability of a specified scale, an analysis should be made of those factors that influence the selection of the proper scale. These influencing factors are found in the following four broad categories:

- Type of work metal
- Thickness of work metal
- Width of area to be tested
- Scale limitation

**Influence of Type of Work Metal.** The types of work metal normally tested using the different regular Rockwell hardness scales are given in Table 3. This information also can be helpful when one of the superficial Rockwell scales may be required. For example, note that the C, A, and D scales--all with diamond indenters--are used on hard materials, such as steel and tungsten carbide. Any material in this hardness category would be tested with a diamond indenter. The choice to be made is whether the C, A, D, or the 45N, 30N, or 15N scale is applicable. Whatever the choice, the number of possible scales has been reduced to six. The next step is to find a scale, either regular or superficial, that will guarantee accuracy, sensitivity, and repeatability of testing.

Table 3 Typical applications of regular Rockwell hardness scales

Scale <sup>(a)</sup>	Typical applications
<b>B</b>	Copper alloys, soft steels, aluminum alloys, malleable iron
<b>C</b>	Steel, hard cast irons, pearlitic malleable iron, titanium, deep case-hardened steel, and other materials harder than 100 HRB
<b>A</b>	Cemented carbides, thin steel, and shallow case-hardened steel
<b>D</b>	Thin steel and medium case-hardened steel and pearlitic malleable iron
<b>E</b>	Cast iron, aluminum and magnesium alloys, bearing metals
<b>F</b>	Annealed copper alloys, thin soft sheet metals
<b>G</b>	Phosphor bronze, beryllium copper, malleable irons. Upper limit is 92 HRG to avoid flattening of ball.
<b>H</b>	Aluminum, zinc, lead
<b>K, L, M, P, R, S, V</b>	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not give anvil effect.

(a) The N scales of a superficial hardness tester are used for materials similar to those tested on the Rockwell C, A, and D scales but of thinner gage or case depth. The T scales are used for materials similar to those tested on the Rockwell B, F, and G scales but of thinner gage. When minute indentations are required, a superficial hardness tester should be used. The W, X, and Y scales are used for very soft materials

**Influence of Thickness of Work Metal.** The metal immediately surrounding the indentation in a Rockwell hardness test is cold worked, The depth of material affected during testing is on the order of ten times the depth of the indentation. Therefore, unless the thickness of the metal being tested is at least ten times the depth of the indentation, an accurate Rockwell hardness test cannot be expected.

The depth of indentation for any Rockwell hardness test can easily be computed; in practice, however, computation is not necessary, because tables of minimum thicknesses are available (for example, see Table 4). The values for minimum thickness do follow the 10-to-1 ratio in some ranges, but they are actually based on experimental data accumulated on various thicknesses of low-carbon steels and of steel strip that has been hardened and tempered.

**Table 4 Minimum work-metal hardness values for testing various thicknesses of metals with regular and superficial Rockwell hardness testers**

Metal thickness, in.	Minimum hardness for superficial hardness testing						Minimum hardness for regular hardness testing					
	Diamond Brale indenter			Ball indenter, $\frac{1}{16}$ in.			Diamond Brale indenter			Ball indenter, $\frac{1}{16}$ in.		
	15N (15 kg)	30N (30 kg)	45N (45 kg)	15T (15 kg)	30T (30 kg)	45T (45 kg)	A (60 kg)	D (100 kg)	C (150 kg)	F (60 kg)	B (100 kg)	G (150 kg)
0.005	...	...	...	93	...	...	...	...	...	...	...	...
0.006	92	...	...	...	...	...	...	...	...	...	...	...
0.008	90	...	...	...	...	...	...	...	...	...	...	...
0.010	88	...	...	90	87	...	...	...	...	...	...	...
0.012	83	82	77	...	...	...	...	...	...	...	...	...
0.014	76	80	74	...	...	...	...	...	...	...	...	...
0.015	...	...	...	78	77	77	...	...	...	...	...	...
0.016	68	74	72	...	...	...	86	...	...	...	...	...
0.018	(a)	66	68	...	...	...	84	...	...	...	...	...
0.020	(a)	57	63	(a)	58	62	82	77	...	100	...	...
0.022	(a)	47	58	...	...	...	78	75	69	...	...	...
0.024	(a)	(a)	51	...	...	...	76	72	67	...	...	...
0.025	...	...	...	(a)	(a)	26	...	...	...	92	92	90
0.026	(a)	(a)	37	...	...	...	71	68	65	...	...	...
0.028	(a)	(a)	20	...	...	...	67	63	62	...	...	...
0.030	(a)	(a)	(a)	(a)	(a)	(a)	60	58	57	67	68	69
0.032	(a)	(a)	(a)	...	...	...	(a)	51	52	...	...	...
0.034	(a)	(a)	(a)	...	...	...	(a)	43	45	...	...	...
0.035	...	...	...	(a)	(a)	(a)	...	...	...	(a)	44	46
0.036	(a)	(a)	(a)	...	...	...	(a)	(a)	37	...	...	...
0.038	(a)	(a)	(a)	...	...	...	(a)	(a)	28	...	...	...
0.040	(a)	(a)	(a)	(a)	(a)	(a)	(a)	(a)	20	(a)	20	22

These values are approximate only and are intended primarily as a guide: see test for example of use. Materials thinner than shown may be tested on a Tukon microhardness tester. The thickness of the workpiece should be at least  $1\frac{1}{2}$  times the diagonal of the indentation when using a Vickers indenter, and at least  $\frac{1}{2}$  times the long diagonal when using a Knoop indenter.

(a) No minimum hardness for metal of equal or greater thickness.

To use the values in Table 4, assume that it is necessary to check the hardness of a strip of steel 0.014 in. thick, of an approximate hardness of 63 HRC. According to Table 4, material having a hardness of 63 HRC must be approximately 0.028 in. thick for an accurate test using the C scale. Therefore, this steel strip should not be tested on the C scale. At this point, check the approximate converted hardness on the other Rockwell scales equivalent to 63 HRC. These values taken from a conversion table are 83 HRA, 70 HR45N, 80 HR30N, and 91 HR15N. Referring again to Table 4 for hardened 0.014 in. thick material, there are only three Rockwell scales to choose: 45N, 30N, and 15N. The 45N scale is not suitable because the material should be at least 74 HR45N. On the 30N scale, 0.014 in. thick material must be at least 80 HR30N, and the material at hand is 80 HR30N. On the 15N scale, the material must be at least 76 HR15N, and this material is 91.5 HR15N. Therefore, either the 30N or 15N scale may be used. After all limiting factors have been eliminated, and a choice exists between two or more scales, the scale applying the heavier load should be used. The heavier load will produce a larger indentation, covering a greater portion of the material, and a Rockwell hardness number more representative of the material as a whole will be obtained. In addition, the heavier the load, the greater the sensitivity of the scale. Checking any conversion table and comparing the 15N scale to the 30N scale will show that in the hard-steel range a difference in hardness of one point on the 30N scale represents a difference of only 0.5 point on the 15N scale. Therefore, smaller differences in hardness can be detected when using the 30N scale.

This approach would also apply in determining which scale should be used to measure the hardness of a case of known approximate depth and hardness.

**Influence of Test-Area Width.** In addition to the limitation of indentation depth for a workpiece of given thickness and hardness, there is a limiting factor on the minimum width of material. If the indentation is placed too close to the edge of a workpiece, the edge will deform outward and the Rockwell hardness number will be decreased accordingly.

Experience has shown that the distance from the center of the indentation to the edge of the workpiece must be at least  $2\frac{1}{2}$  times the diameter of the indentation to ensure an accurate test. Therefore, the width of a narrow test area must be at least five indentation diameters when the indentation is placed in the center.

**Limitations of Rockwell Scales.** The potential range of each Rockwell scale can be determined readily from the dial-gage divisions on the tester: the black scale (for diamond indenter) on all regular hardness-tester dial gages is numbered from 0 to 100, with 100 corresponding to the "set" position; the red scale (for ball indenters) is numbered from 0 to 130, with 130 being the "set" position. On the superficial hardness tester, the dial gage has only one set of divisions, numbered from 0 to 100.

Use of the diamond indenter when readings fall below 20 is not recommended, because there is loss of sensitivity when indenting this far down the conical section of the indenter. Brale indenters are not calibrated below values of 20; and if used on soft materials, there is no assurance that there will be the usual degree of agreement in results when replacing the indenters.

**Support for Workpiece.** A fundamental requirement of the Rockwell hardness test is that the surface of the workpiece being tested be approximately normal to the indenter and that the workpiece must not move or slip in the slightest degree as the major load is applied. The depth of indentation is measured by the movement of the plunger rod holding the indenter; therefore, any slipping or moving of the workpiece will be followed by the plunger rod and the motion transferred to the dial gage, causing an error to be introduced into the hardness test. As one point of hardness represents a depth of only 0.00008 in., a movement of only 0.001 in., could cause an error of over 10 Rockwell numbers. The support must be of sufficient rigidity to prevent its permanent deformation in use.

### ***Standardized Hardness Values***

In 1990, after several meetings between the American Society for Testing and Materials (ASTM) and standards groups from Europe and Asia, the U.S. government agreed to provide hardness standards for U.S. manufacturers. The reason for the change is that hardness, though based on traceable parameters, has had no absolute numbers. For example, the loads on a tester can be verified with a traceable load cell, but the hardness values themselves are empirical. The result is a value that is not directly traceable to any standard, national or otherwise. In the future, the values will be absolute, and will be traceable to a government standard.

The hardness program at the National Institute of Standards and Technology (NIST) involves traceable Standard Reference Materials (SRMs) blocks. The hardness standards are to be calibrated at NIST by means of a dead weight tester. Only two of these machines exist in the world. Other primary machines exist in other countries, but the only exact duplicate of the NIST machine is located at IMGC, which is the NIST equivalent in Italy.

The new NIST traceable blocks, at a nominal size of 60 mm (2.36 in.) diam and 15 mm (0.6 in.) thick, are larger than the typical Rockwell hardness test blocks. They are made of steel in the appropriate HRC range and have a polished mirror-like surface. Although most ASTM type HRC Rockwell test blocks are labeled  $\pm 0.5$  HRC on the high end (60 HRC range), the NIST blocks will have much tighter tolerances (down to 0.1). Test locations will be indicated on the block; associated hardness numbers and statistical information will be listed on the certificate, enabling the user to find more than the just arithmetic mean of the hardness.

The very first blocks for Rockwell tests will be Hardness Rockwell C (HRC). The blocks should appear for sale in the near future. However, it is possible that not all the Rockwell scales will be represented. Which scales are needed will be decided by the scientists at NIST.

### **Vickers Hardness Testing**

In 1925, Smith and Sandland of the United Kingdom developed a new indentation test for metals that were too hard to evaluate by the Brinell test, whose hardened steel ball was limited to steels with hardnesses below  $\sim 450$  HBS ( $\sim 48$  HRC). In designing the new indenter, they chose a square-based diamond pyramid (Fig. 8) geometry that would produce hardness numbers nearly identical to Brinell numbers within the range of both. This decision was very wise, as it made the Vickers test very easy to adopt.

**Fig. 8** Schematic representation of the square-base pyramidal diamond indenter used in a Vickers hardness tester and the resulting indentation in the workpiece

The ideal  $d/D$  ratio ( $d$  = impression diameter,  $D$  = ball diameter) for a spherical indenter is 0.375. If tangents are drawn to the ball at the impression edges for  $d/D = 0.375$ , they meet below the center of the impression at an angle of  $136^\circ$ , the angle chosen for the Vickers indenter.

The use of a diamond indenter allows the Vickers test to evaluate any material and, furthermore, has the very important advantage of placing the hardness of all materials on one continuous scale. The lack of a continuous scale is a major disadvantage of Rockwell type tests, for which 15 standard and 15 superficial scales were developed. Not one of these scales can cover the full hardness range. The HRA scale covers the broadest hardness range, but it is not commonly used.

In the Vickers test, the load is applied smoothly, without impact, and held in place for 10 or 15 s. The physical quality of the indenter and the accuracy of the applied load (defined in ASTM E 384) must be controlled to get the correct results. After the load is removed, the two impression diagonals are measured, usually with a filar micrometer, to the nearest  $0.1 \mu\text{m}$ , and then averaged. The Vickers hardness (HV) is calculated by:

$$\text{HV} = 1854.4L/d^2$$

where the load  $L$  is in grams-force, and the average diagonal  $d$  is in  $\mu\text{m}$  (although the hardness number units are expressed in units of  $\text{kgf}/\text{mm}^2$  rather than the equivalent  $\text{gf}/\mu\text{m}^2$ ).

The original Vickers testers were developed for test loads of 1 to 120 kgf, which produce rather large indents. Recognizing the need for lower test loads, the National Physical Laboratory (U.K.) experimented with lower test loads in 1932. The first low-load Vickers tester was described by Lips and Sack in 1936.

Because the shape of the Vickers indentation is geometrically similar at all test loads, the HV value is constant, within statistical precision, over a very wide test load range, as long as the test specimen is reasonably homogeneous. However, studies of microindentation hardness test results conducted over the, past several years on a wide range of loads have shown that results are not constant at very low loads. This problem, called the "indentation size effect" (ISE), has been attributed to fundamental characteristics of the material. In fact, the same effect is observed at the low-load test range of bulk Vickers testers.

**Procedure.** As noted, the Vickers hardness test follows the Brinell principle, in that an indenter of definite shape is pressed into the material to be tested, the load removed, and the diagonals of the resulting indentation measured. The indenter is made of diamond and is in the form of a square-base pyramid having an angle of  $136^\circ$  between faces (Fig. 8). This indenter has angle across corners, or so-called edge angle, of  $148^\circ 6' 42.5''$ . The facets are highly polished and free

from surface imperfections, and the point is sharp. The loads applied vary from 1 to 120 kg; the standard loads are 5, 10, 20, 30, 50, 100, and 120 kg. For most hardness testing, 50 kg is maximum.

With the Vickers indenter, the depth of indentation is about one-seventh of the diagonal length of the indentation. For certain types of investigation, there are advantages to such a shape. The Vickers hardness number (HV) is the ratio of the load applied to the indenter to the surface area of the indentation. By formula:

$$HV = 2P \sin(\theta/2)/d^2$$

where  $P$  is the applied load, in kilograms;  $d$  is the mean diagonal of the indentation, in millimeters; and  $\theta$  is the angle between opposite faces of the diamond indenter ( $136^\circ$ ).

**Equipment** for determining the Vickers hardness number should be designed to apply the load without impact, and friction should be reduced to a minimum. The actual load on the indenter should be correct to less than 1%, and the load should be applied slowly, because the Vickers is a static test. Some standards require that the full load be maintained for 10 to 15 s.

To obtain the greatest accuracy in hardness testing, the applied load should be as large as possible, consistent with the dimensions of the workpiece. Loads of more than 50 kg are likely to fracture the diamond, especially when used on hard materials.

The accuracy of the micrometer microscope should be checked against a stage micrometer, which consists of ruled lines, usually 0.1 mm apart, that have been checked against certified length standards. The average length of the two diagonals is used in determining the hardness value.

The corners of the indentation provide indicators of the length of the diagonals. The area must be calculated from the average of readings of both diagonals. The indentations are usually measured under vertical illumination with a magnification of about 125 diameters.

The included angle of the diamond indenter should be  $136^\circ$  with a tolerance of less than  $\pm 0.50^\circ$ , which is readily obtainable with modern diamond-grinding equipment. This would mean an error of less than 1% in the hardness number. The indenters must be carefully controlled during manufacture so that in use the indentations produced will be symmetrical. Tables are available for converting the values of the diagonals of indentation in millimeters to the Vickers hardness number.

**Vickers Hardness Testers.** Several types of Vickers hardness testers are available. The principal component of a basic Vickers tester is shown schematically in Fig. 9(a). A modern Vickers tester is shown in Fig. 9(b). Current equipment may include image analysis peripherals and other features for more automated handling and testing. Automation methods include motorized stage capabilities where long or repetitive hardness traverses are required. These can be programmed so that little operator involvement is required during the indentation mode. Digital display of the measured diagonals and automatic calculation of the hardness from the diagonals also simplify measurement but still require the operator to peer into the microscope portion of the tester. Some systems include a closed circuit television system to the tester so that the operator can look at the magnified image on the TV screen and measure the diagonals. This is easier on the operators, but resolution of the system may not be as high.

**Fig. 9** Vickers hardness testers. (a) Principal components of a mechanical type. (b) Modern Vickers tester with digital readout of diagonal measurements and hardness values

## Scleroscope Hardness Testing

The Scleroscope hardness test is essentially a dynamic indentation hardness test, wherein a diamond-tipped hammer is dropped from a fixed height onto the surface of the material being tested. The height of rebound of the hammer is a measure of the hardness of the metal. The Scleroscope scale consists of units that are determined by dividing the average rebound of the hammer from a quenched (to maximum hardness) and untempered water-hardening tool steel into 100 units. The scale is continued above 100 to permit testing of materials having hardnesses greater than that of fully hardened tool steel.

**Testers.** Two types of Scleroscope hardness testers are shown in Fig. 10. The Model C Scleroscope consists of a vertically disposed barrel containing a precision-bore glass tube. A base-mounted version of a Model C Scleroscope is shown in Fig. 10(a). The scale is graduated from 0 to 140. It is set behind and is visible through the glass tube. Hardness is read from the vertical scale, usually with the aid of the reading glass attached to the tester. A pneumatic actuating head, affixed to the top of the barrel, is manually operated by a rubber bulb and tube. The hammer drops and rebounds with the glass tube.

**Fig. 10** Principal components of two types of base-mounted Scleroscope hardness testers

The Model D Scleroscope hardness tester (Fig. 10b) is a dial-reading tester. The tester consists of a vertically disposed barrel that contains a clutch to arrest the hammer at maximum height of rebound, which is made possible because of the short rebound height. The hammer is longer and heavier than the hammer in the Model C Scleroscope and develops the same striking energy while dropping a shorter distance.

Both models of the Scleroscope hardness tester may be mounted on various types of bases. The C-frame base, which rests on three points and is for bench use in hardness testing small workpieces, has a capacity about 3 in. high by  $2\frac{1}{2}$  in. deep. A swing arm and post is also for bench use but has height and reach capacities of 9 and 14 in., respectively. Another type of base is used for mounting the Scleroscope hardness tester on rolls and other cylindrical objects having a minimum diameter of  $2\frac{1}{2}$  in., or on flat, horizontal surfaces having a minimum dimension of 3 by 5 in. The Model C Scleroscope hardness tester is commonly used unmounted. However, when the hardness tester is unmounted, the workpiece should have a minimum weight of 5 lb. The Model D Scleroscope hardness tester should not be used unmounted.

**Workpiece Surface-Finish Requirements.** As with other metallurgical hardness testers, certain surface-finish requirements on the workpiece must be met for Scleroscope hardness testing to make an accurate hardness determination.

An excessively coarse surface finish will yield erratic readings. Hence, when necessary, the surface of the workpiece should be filed, machined, ground, or polished to permit accurate, consistent readings to be obtained.

**Limitations on Workpiece and Case Thickness.** Case-hardened steels having cases as thin as 0.010 in. can be accurately hardness tested provided the core hardness is no less than 30 Scleroscope. Softer cores require a minimum case thickness of 0.015 in. for accurate results.

Thin strip or sheet may be tested, with some limitations, but only when the Scleroscope hardness tester is mounted in the clamping stand. Ideally, the sheet should be flat and without undulation. If the sheet material is bowed, the concave side should be placed up to preclude any possibility of erroneous readings due to spring effect. The minimum thicknesses of sheet in various categories (in inches) that may be hardness tested are as follows:

<b>Hardened steel</b>	<b>0.005</b>
<b>Cold finished steel strip</b>	0.010
<b>Annealed brass strip</b>	0.015
<b>Half-hard brass strip</b>	0.010

**Test Procedure.** To perform a hardness test with either the Model C or the Model D Scleroscope hardness tester, the tester should be held or set in a vertical position, with the bottom of the barrel in firm contact with the workpiece. The hammer is raised to the elevated position and then allowed to fall and strike the surface of the workpiece. The height of rebound is then measured, which indicates the hardness. When using the Model C Scleroscope hardness tester, the hammer is raised to the elevated position by squeezing the pneumatic bulb. The hammer is released by again squeezing the bulb. When using the Model D Scleroscope hardness tester, the hammer is raised to the elevated position by turning the knurled control knob clockwise until a definite stop is reached. The hammer is allowed to strike the workpiece by releasing the control knob. The reading is recorded on the dial

**Spacing of Indentations.** Indentations should be at least 0.50 mm (0.020 in.) apart and only one at the same spot. Flat workpieces with parallel surfaces may be hardness tested within  $\frac{1}{4}$  in. (6 mm) of the edge when properly clamped.

**Taking the Readings.** Experience is necessary to interpret the hardness readings accurately on a Model C Scleroscope hardness tester. Thin materials or those weighing less than 5 lb must be securely clamped to absorb the inertia of the hammer. The sound of the impact is an indication of the effectiveness of the clamping: a dull thud indicates that the workpiece has been clamped solid, whereas a hollow ringing sound indicates that the workpiece is not tightly clamped or is warped and not properly supported. Five hardness determinations should be made and their average taken as representative of the hardness of a particular workpiece.

**Advantages** of the Scleroscope hardness test are summarized as follows:

1. Tests can be made very rapidly. Over 1000 tests per hour are possible.
2. Operation is simple and does not require highly skilled technicians.
3. The Model C Scleroscope tester is portable and may be used unmounted for hardness testing workpieces of unlimited size: rolls, large dies, and machine-tool ways.
4. The Scleroscope hardness test is a nonmarring test; no crater is left, and only in the most unusual instances would the tiny hammer mark be objectionable on a finished workpiece.
5. A single scale accommodates the entire hardness range from the softest to the hardest metals.

**Limitations** of the Scleroscope hardness test are summarized as follows:

1. The hardness tester must be in a vertical position, or the free fall of the hammer will be impeded and result in erratic readings.
2. Scleroscope hardness tests are more sensitive to variations in surface conditions than some other hardness tests.

3. Because readings taken with the Model C Scleroscope hardness tester are those observed from the maximum rebound of the hammer on the first bounce, even the most experienced operators may disagree among themselves by one or two points in the reading.

## Microhardness Testing

The term "microhardness" usually refers to indentation hardness tests made with loads not exceeding 1 kg. Such hardness tests have been made with a load as light as 1 g, although the majority of microhardness tests are made with loads of 100 to 500 g. In general, the term is related to the size of the indentation rather than the load applied.

### *Fields of Application*

Microhardness testing is capable of providing information regarding the hardness characteristics of materials that cannot be obtained with hardness tests, such as the Brinell, Rockwell, or Scleroscope.

Because of the required degree of precision for both equipment and operation, microhardness testing is usually, although not necessarily, performed in a laboratory. Such a laboratory, however, is often a process-control laboratory and may be located close to production operations. Microhardness testing is recognized as a valuable method for controlling numerous production operations in addition to its use in research applications. Specific fields of application of microhardness testing include:

- Measuring hardness of precision workpieces that are too small to be measured by the more common hardness-testing methods
- Measuring hardness of product forms, such as foil or wire, that are too thin or too small in diameter to be measured by the more convenient methods
- Monitoring of carburizing or nitriding operations, which is usually accomplished by hardness surveys taken on cross sections of test pieces that accompanied the workpieces through production operations
- Measuring hardness of individual microconstituents
- Measuring hardness close to edges, thus detecting undesirable surface conditions, such as grinding bum and decarburization
- Measuring hardness of surface layers, such as plating or bonded layers

### *Indenter*

Microhardness testing is performed with either the Knoop or the Vickers indenter. The Knoop indenter is more widely used in the United States; the Vickers indenter is more widely used in Europe.

Knoop indentation testing is performed with a diamond ground to pyramidal form that produces a diamond-shape indentation having an approximate ratio between long and short diagonals of 7 to 1 (Fig. 11). The pyramidal shape employed has an included longitudinal angle of  $172^{\circ} 30'$  and an included transverse angle of  $130^{\circ}$ . The depth of indentation is about one thirtieth of its length. Because of the shape of the indenter, indentations of accurately measurable lengths are obtained with light loads.

**Fig. 11** Schematic representation of a pyramidal Knoop indenter and the resulting indentation in the workpiece

The Knoop hardness number (HK) is the ratio of the load applied to the indenter to the unrecovered projected area of indentation. By formula:

$$HK = P/A = P/CL^2$$

where  $P$  is the applied load, in kilograms;  $A$  is the unrecovered projected area of indentation, in square millimeters;  $L$  is the measured length of the long diagonal, in millimeters; and  $C$  is 0.07028, a constant of the indenter relating projected area of the indentation to the square of the length of the long diagonal.

Figure 12 presents a comparison of the indentations made by the Knoop and Vickers indenters. Each has some advantages over the other. For example, the Vickers indenter penetrates about twice as far into the workpiece as does the Knoop indenter, and the diagonal of the Vickers indentation is about one-third of the total length of the Knoop indentation. Therefore, the Vickers indenter is less sensitive to minute differences in surface conditions than is the Knoop indenter. However, the Vickers indentation, because of the shorter diagonal, is more sensitive to errors in measurement than is the Knoop indentation.

**Fig. 12** Comparison of indentations made by Knoop and Vickers indenters in the same work metal and at the same loads

The shortcoming of the Knoop indent is that the three-dimensional indent shape changes with test load and, consequently, HK varies with load. In fact, HK values may be reliably converted to other test scales only for HK values produced at the standard load, generally 500 gf, that was used to develop the correlations. However, at high loads the variation is not substantial. Note that all hardness scale conversions are based on empirical data; consequently, conversions are not precise but are estimates.

### ***Microhardness Testers***

Several types of microhardness testers are available. The most accurate operate through the direct application of load by dead weight or by weights and lever.

The Tukon tester is widely used for microhardness testing. Several different designs of this microhardness tester are available; they vary mainly in load range, but all can accommodate both Knoop and Vickers indenters.

The Tukon microhardness tester shown in Fig. 13 has a load range of 1 to 1000 g. Loads are applied by dead weight. The microscope is furnished with three objective lenses having magnifications of about 150, 300, and 600 diameters.

**Fig. 13** Principal components of a Tukon microhardness tester

Sources of tester error include inaccuracy in loading, vibration, rate of load application, duration of contact period, and impact. To limit the shock that can occur when the operator removes the load (this generally has an adverse effect on indentations made with loads below 500 g), an automatic test cycle is built into the Tukon microhardness tester. With this automatic test cycle, the load is applied at a constant rate, maintained in the work for 18 s, and smoothly removed. Thus, the operator does not need to touch the tester while the load is being applied and removed. The design of microhardness testers will vary from one type to another, but it is essential to remove the applied load without touching the tester if clear-cut indentations are to be obtained.

A movable stage to support the workpiece is an essential component of a microhardness tester. In many applications the indentation must be in a selected area, usually limited to a few thousandths of a square millimeter. In testing with the type of Tukon microhardness tester shown in Fig. 13, first the required area is located by looking through the microscope and moving the mechanical stage until the desired location is centered within the optical field of view. The stage is then indexed under the indenter, and the automatic indentation cycle is initiated by tripping the handle. After the cycle is completed, signaled by a telltale light, the stage is again indexed back under the objective for indentation measurement.

**Optical equipment** used in microhardness testers for measuring the indentation must focus on both ends of the indentation at the same time, as well as be rigid and free from vibration. Lighting is also important. Complete specifications of measurement, including the mode of illumination, are necessary in microhardness-testing techniques. Polarized light, for instance, results in larger measurements than does unpolarized light. Apparently, this is caused by the reversal of the diffraction pattern; that is, the indentation appears brighter than the background. When test data are recorded, it is recommended that both the magnification and the type of illumination used be reported.

In measuring the indentation, the proper illumination to obtain optimum resolution is essential, and the appropriate objective lens should be selected. In operation, the ends of the indentation diagonals should be brought into sharp focus. With the Knoop indenter, one leg of the long diagonal should not be more than 20% longer than the other. If this is not apparent or if the ends of the diagonal are not in focus, the surface of the workpiece should be checked to make sure it is normal to the axis of the indenter. With the Vickers indenter, both diagonals should be measured and the average used for calculating the Vickers hardness number (HV).

### ***Preparing and Holding the Specimen***

Regardless of whether the metal being tested for microhardness is an actual workpiece or a representative specimen, surface finish is of prime importance.

To permit accurate measurement of the length of the Knoop indentation or diagonals of the Vickers indentation, the indentation must be clearly defined. In general, as the test load decreases, the surface-finish requirements become more stringent. When the load is 100 g or less, a metallographic finish is recommended.

**Specific Applications of Microhardness Testing**

Microhardness testing is used extensively in research and for controlling the quality of manufactured products, as well as for solving shop problems.

**Testing of small workpieces** is an important use of microhardness testing. Many manufactured products, notably in the instrument and electronics industries, are too small to be tested for hardness by the more conventional methods. Many such workpieces can be tested without impairing their usefulness, generally by means of various types of holding and clamping fixtures.

Microhardness testing is also applied to product forms that cannot be tested by other means. Thin foils and small-diameter wires are typical examples.

**Monitoring of Surface-Hardening Operations.** Microhardness testing is the best method in present use for accurately determining case depth and certain case conditions of carburized or nitrided workpieces, using the hardness-survey procedure. In most instances this is accomplished by use of test coupons that have accompanied the actual workpiece through the heat treating operation. The coupons are then sectioned and usually mounted for testing. To ensure accurate readings close to the edge of the cross section, the 100 g is most often used, although a 500 g load is sometimes preferred. If the 100 g load is used, a metallographic finish is essential.

Readings are taken at pre-established intervals (commonly, 0.004 or 0.005 in.), usually beginning at least 0. 001 in. from the edge of the workpiece.

**Accuracy, Precision, and Bias.** Many factors (Table 5) can influence the quality of microindentation test results. In the early days of low-load (<100 gf) hardness testing, it was quickly recognized that improper specimen preparation can influence hardness test results. Most texts state that improper preparation yields higher test results because the surface contains excessive preparation-induced deformation. While this is certainly true, improper preparation may also create excessive heat, which reduces the hardness and strength of many metals and alloys. Either problem may be encountered due to faulty preparation.

**Table 5 Factors affecting precision and bias in microindentation hardness testing**

<b>Instrument factors</b> <ul style="list-style-type: none"><li>• Accuracy of the applied load</li><li>• Inertia effects, speed of loading</li><li>• Angle of indentation</li><li>• Lateral movement of the indenter or specimen</li><li>• Indentation time</li><li>• Indenter shape deviations</li><li>• Damage to the indenter</li><li>• Insufficient spacing between indents or from edges</li></ul>
<b>Measurement factors</b> <ul style="list-style-type: none"><li>• Calibration of the measurement system</li><li>• Resolving power of the objective</li><li>• Magnification</li><li>• Operator bias in sizing</li><li>• Inadequate image quality</li><li>• Nonuniform illumination</li></ul>
<b>Material factors</b>

- Heterogeneity in composition or microstructure
- Crystallographic texture
- Quality of the specimen preparation
- Low reflectivity or transparency

For many years, it was considered necessary to electrolytically polish specimens so that the preparation-induced damage could be removed, thus permitting bias-free low-load testing. However, the science behind mechanical specimen preparation, chiefly due to the work of L. Samuels, has led to development of excellent mechanical specimen preparation procedures, and electropolishing is no longer required.

In addition, several operational factors must be controlled for optimum test results. First, it is good practice to inspect the indenter periodically for damage, for example, cracking or chipping of the diamond. If you have metrology equipment, you can measure the face angles and the sharpness of the tip. Specifications for Vickers and Knoop indenter geometries are given in ASTM E 384.

A prime source of error is the alignment of the specimen surface relative to the indenter. The indenter itself must be properly aligned perpendicular ( $\pm 1^\circ$ ) to the stage plate. Next, the specimen surface must be perpendicular to the indenter. Most testers provide holders that align the polished face perpendicular to the indenter (parallel to the stage). If a specimen is simply placed on the stage surface, its back surface must be parallel to its polished surface. Tilting the surface more than one degree from perpendicular results in nonsymmetrical impressions and can produce lateral movement between specimen and indenter. However, in most cases, intending procedures are not the major source of error.

It is important to regularly check the performance of the tester with a certified test block. The safest choice is a test block manufactured for microindentation testing and certified for the test (Vickers or Knoop) as well as the specified load. Strictly speaking, a block certified for Vickers testing at 300 or 500 gf (commonly chosen loads) should yield essentially the same hardness with loads from about 50 to 1000 gf. That is, if you take the average of about five indents and compare the average at test load to the average at the calibrated load (knowing the standard deviation of the test results), statistical tests can tell (at any desired confidence level) if the difference between the mean values of the tests at the two loads is statistically significant or not.

When considering a new tester, it is prudent to perform a series of indents (five is adequate) at each test load ( $L$ ) available. Then, plot the mean and 95% confidence limits of each test as a function of load. Because of the method of defining HV and HK, which involves dividing by  $d^2$ , measurement errors become more critical as  $d$  gets smaller; that is, as  $L$  decreases and the material's hardness increases. Therefore, departure from a constant hardness for the Vickers or Knoop tests as a function of load becomes a greater problem as the hardness increases. For the Knoop test, HK increases as  $L$  decreases because the indent geometry changes with indent depth and width. But the change in HK varies with the test load. At a higher test load the change is greater as  $L$  decreases.

The greatest source of error is measuring the indent. The indent should be placed in the center of the measuring field, because lens image quality is best in the center. The light source should provide adequate, even illumination to provide maximum contrast and resolution. The accuracy of the filar micrometer or other measuring device should be verified by a stage micrometer.

Specimen preparation quality becomes more important as the load decreases, and it must be at an acceptable level. Specimen thickness must be at least 2.5 times the Vickers diagonal length. Because the Knoop indent is shallower than the Vickers at the same load, somewhat thinner specimens can be tested. Spacing of indents is important because indenting produces plastic deformation and a strain field around the indent. If the spacing is too small, the new indent will be affected by the strain field around the last indent. ASTM recommends a minimum spacing (center to edge of adjacent indent) of 2.5 times the Vickers diagonal. For the Knoop test, in which the long diagonals are parallel, the spacing is 2.5 times the short diagonal. The minimum recommended spacing between the edge of the specimen and the center of the indent should be 2.5 times. Again, Knoop indents can be placed closer to the surface than Vickers indents.

## Tension Testing

---

THE TENSION TEST is the test most commonly used to evaluate the mechanical properties of materials. Its chief use is the determination of properties related to the elastic design of machines and structures. In addition, the tension test gives information on a material's plasticity and fracture. The chief advantages of the tension test are the stress state is well established, the test has been carefully standardized, and the test is relatively easy and inexpensive to carry out. This article does not detail this test technique, because it is well covered by standard methods, such as ASTM specification E 8; instead, the interpretation and limitations of the test results are discussed.

## Engineering Stress-Strain Curve

In the conventional engineering tension test, stress is defined by the applied load divided by the original cross-sectional area of the specimen. Engineering strain,  $e$ , is the change in length divided by the initial length:

$$e = \frac{L - L_0}{L_0} = \frac{\Delta L}{L_0} \quad (\text{Eq 1})$$

In the elastic region of the stress-strain curve (Fig. 14), stress is linearly related to strain,  $\sigma = E \cdot e$ , where  $E$  is the elastic modulus. As long as the specimen is loaded within the elastic region, the strain is totally recoverable and the specimen will return to its original length when the load is relaxed to zero. However, when the load exceeds a value corresponding to the yield stress, the specimen undergoes gross plastic deformation and is permanently deformed when the load returns to zero. The stress to produce continued plastic deformation increases with increasing strain--the metal strain hardens. To a good engineering approximation, the volume remains constant during plastic deformation,  $AL = A_0L_0$ , and, as the specimen elongates, it decreases uniformly in cross-sectional area along its gage length. Initially, the strain hardening more than compensates for this decrease in area, and the engineering stress continues to rise with increasing strain. Eventually a point is reached where the decrease in area is greater than the increase in deformation load arising from strain hardening. This condition will be reached first at some point in the specimen that is slightly weaker than the rest. All further plastic deformation is concentrated in this region, and the specimen begins to neck or thin down locally. Because the cross-sectional area is now decreasing far more rapidly than the deformation load is being increased by strain hardening, the engineering stress continues to decrease until fracture occurs.

Fig. 14 Engineering stress-strain curve

The maximum in the engineering stress-strain curve corresponds to the ultimate tensile strength,  $\sigma_u$ . The strain at maximum load, up to which point the cross-sectional area decreases uniformly along the gage length as the specimen elongates, is the uniform elongation,  $e_u$ . For stretching-type forming operations, such as stretch forming of aircraft components or forming of automobile fenders, local necking determines the formability limit, and in such applications uniform elongation can be an important measure of ductility. In many metals, the engineering stress-strain curve is relatively flat in the vicinity of necking, and it may not be possible to establish the maximum load without ambiguity.

## Ductility

The conventional measures of ductility that are obtained from the tension test are the engineering strain at fracture,  $e_f$  (usually expressed as a percentage elongation), and the reduction of area at fracture,  $RA$  (also usually expressed as a percentage):

$$e_f = \frac{L_f - L_0}{L_0} \quad (\text{Eq 2})$$

$$RA = \frac{A_0 - A_f}{A_0} \quad (\text{Eq 3})$$

Because an appreciable fraction of the deformation will be concentrated in the necked region of the specimen, the value of  $e_f$  will depend on the gage length  $L_0$  over which the measurement was taken. The smaller the gage length, the greater the contribution from the neck, and the higher the value of  $e_f$ .

To eliminate this difficulty and to provide a measure of ductility that correlates with forming operations in which the gage length is very short, it is possible to determine the zero-gage-length elongation,  $e_0$ . From the constancy-of-volume relationship for plastic deformation,  $AL = A_0L_0$ :

$$\begin{aligned} \frac{L}{L_0} &= \frac{A_0}{A} = \frac{1}{1 - RA} \\ e_0 &= \frac{L - L_0}{L_0} = \frac{A_0}{A} - 1 \\ &= \frac{1}{1 - RA} - 1 = \frac{RA}{1 - RA} \end{aligned} \quad (\text{Eq 4})$$

Thus, the zero-gage-length elongation may be determined directly from the reduction of area at fracture or from the change in length of grid marks near the actual fracture.

## True-Stress/True-Strain Curve

The necking phenomenon that occurs in the tension test clouds the usefulness of the engineering stress-strain curve beyond the maximum load. The falloff in stress that occurs beyond  $P_{\max}$  is artificial and occurs only because the stress continues to be calculated on the basis of the original cross-sectional area,  $A_0$ , when in fact the area at the necked region is now much smaller than  $A_0$ . If the true stress, based on the actual cross-sectional area of the specimen, is used, the stress-strain curve increases continuously up to fracture. Then, if strain is expressed as true strain, we have a plot called the true-stress/true-strain curve (Fig. 15).

**Fig. 15 True-stress/true-strain curve (flow curve)**

Note that this curve continues to rise beyond necking all the way to fracture. However, once necking occurs, the constraints produced by the nonforming region outside the neck produce a state of triaxial stress in the neck. Thus, the average stress required to cause flow from maximum load to fracture is higher than would be required if only a uniaxial stress were present. Mathematical analysis of the stresses in the neck that permits correction of the true-stress/true-strain curve for the existence of triaxial stresses.

The region from yielding to necking is one of uniform plastic deformation in which the specimen gage length increases and the diameter decreases uniformly along the gage length. In this region the true-stress/true-strain curves for many ductile metals can be expressed by a power-law relation:

$$\sigma = K \epsilon^n \quad (\text{Eq 5})$$

where  $K$  is the strength coefficient, defined by the value of true stress at  $\epsilon = 1.0$ , and  $n$  is the strain-hardening exponent. Equation 5 is valid if a plot of  $\sigma$  versus  $\epsilon$  is a straight line on log-log coordinates. The strain-hardening exponent is the slope of this line. Thus:

$$n = \frac{d(\log \sigma)}{d(\log \epsilon)} = \frac{d(\ln \sigma)}{d(\ln \epsilon)} = \frac{\epsilon}{\sigma} \frac{d\sigma}{d\epsilon} \quad (\text{Eq 6})$$

The strain-hardening exponent may have values from  $n = 0$  (a perfectly plastic solid) to  $n = 1$  (an elastic solid). Values of  $n$  for most metals are between 0.05 and 0.50.

An increase in strain rate increases the stress to produce plastic deformation (the flow stress). The effect is modest for cold working but is quite significant for hot working. The dependence of flow stress on strain rate, at constant strain and temperature, is given by:

$$\sigma = C(\dot{\epsilon})^m |_{\epsilon, T} \quad (\text{Eq 7})$$

where  $m$  is the strain-rate sensitivity. The exponent  $m$  can be evaluated from the slope of a plot of  $\log \sigma$  versus  $\log \dot{\epsilon}$ , or it can be obtained from rate-change tests in which the change in flow stress caused by a step change in  $\dot{\epsilon}$  is measured:

$$\begin{aligned} m &= \left( \frac{d \log \sigma}{d \log \dot{\epsilon}} \right) \approx \left( \frac{\Delta \log \sigma}{\Delta \log \dot{\epsilon}} \right)_{\epsilon, T} \\ &= \frac{\log \sigma_2 - \log \sigma_1}{\log \dot{\epsilon}_2 - \log \dot{\epsilon}_1} = \frac{\log (\sigma_2/\sigma_1)}{\log (\dot{\epsilon}_2/\dot{\epsilon}_1)} \end{aligned} \quad (\text{Eq 8})$$

## Analysis of Tensile Instability

The development of a necked region in a specimen loaded in uniaxial tension represents a plastic instability. Because this disturbs the simple analysis of the tension test and limits the engineering usefulness of the test, it has become the subject of considerable study. A practical application of the ideas presented is given in the work of Ghosh (*Met. Trans.*, Vol 8A, 1977, p 1221), who developed a numerical analysis for predicting the shape of the engineering strain-stress curve beyond maximum load as a function of strain hardening, strain-rate hardening, and plastic anisotropy properties of the metal.

Consider a tensile specimen loaded to a value  $P$ . At any point a distance  $L$  along the specimen, the cross-sectional area is  $A$  and  $P = \sigma A$ . Since  $P$  does not vary along the length of the specimen, and  $\sigma = f(\epsilon, \dot{\epsilon})$ :

$$\frac{dP}{dL} = 0 = A \left\{ \left( \frac{d\sigma}{d\epsilon} \right)_{\epsilon} \frac{d\epsilon}{dL} + \left( \frac{d\sigma}{d\dot{\epsilon}} \right)_{\epsilon} \frac{d\dot{\epsilon}}{dL} \right\} + \sigma \frac{dA}{dL} \quad (\text{Eq 9})$$

Because the volume of the specimen remains constant, the true strain can be written:

$$d\epsilon = \frac{dL}{L} = -\frac{dA}{A} \quad (\text{Eq 10})$$

and

$$\frac{d\epsilon}{dL} = -\frac{1}{A} \frac{dA}{dL} \quad (\text{Eq 11})$$

Also, from Eq 10, the strain-rate  $\dot{\epsilon}$  can be expressed:

$$d\dot{\epsilon} = \frac{d\epsilon}{dt} = -\frac{1}{A} \frac{dA}{dt} = -\frac{\dot{A}}{A} \quad (\text{Eq 12})$$

so that

$$\frac{d\dot{\epsilon}}{dL} = -\frac{1}{A} \frac{d\dot{A}}{dL} + \frac{\dot{A}}{A^2} \frac{dA}{dL} \quad (\text{Eq 13})$$

The material parameters important to the necking process are the dimensionless work-hardening coefficient:

$$\gamma = \frac{1}{\sigma} \frac{d\sigma}{d\epsilon} \quad (\text{Eq 14})$$

and the strain-rate sensitivity:

$$m = \left( \frac{d \ln \sigma}{d \ln \dot{\epsilon}} \right)_{\epsilon} = \frac{\dot{\epsilon}}{\sigma} \left( \frac{d\sigma}{d\dot{\epsilon}} \right)_{\epsilon} \quad (\text{Eq 15})$$

When Eq 12 and 13 are substituted into Eq 9, and the definitions for  $\gamma$  and  $m$  are added through Eq 14 and 15, the result is:

$$\frac{dA}{dL} (\sigma - m\sigma - \gamma\sigma) = \frac{d\dot{A}}{dL} \frac{m\sigma A}{\dot{A}} \quad (\text{Eq 16})$$

A final rearrangement gives

$$\frac{(1/\dot{A}) (d\dot{A}/dL)}{(1/A) (dA/dL)} = \frac{(d/dL) (\ln \dot{A})}{(d/dL) (\ln A)} = \frac{m + \gamma - 1}{m} \quad (\text{Eq 17})$$

This equation describes the rate of change of area with length, and gives the criterion for the onset of necking.

Any real tension specimen will have variations in cross-sectional area along its length. These can arise from an intentional taper, from machining errors, or from heterogeneities of structure that lead to weaker cross sections. Deformation becomes unstable when the smallest cross section of the specimen shrinks faster than the rest. This occurs when  $d\dot{A}/dA > 0$ . Deformation will be uniform and stable when  $d\dot{A}/dA < 0$ . Because  $\dot{A}/A$  is negative in tension, stable deformation in tension occurs when  $d\dot{A}/dA \geq 0$ . Therefore, from Eq 17, the condition for stable, uniform tensile deformation is:

$$\gamma + m \geq 1 \quad (\text{Eq 18})$$

Necking is involved with the interplay between the applied stress and the flow resistance of the material. As the specimen elongates under a given load the area decreases and the stress increases. If necking is not to occur, the material's strength must increase through strain hardening ( $\gamma$ ) and strain-rate hardening ( $m$ ).

For room-temperature deformation,  $m \rightarrow 0$  and the instability criterion reduces to  $\gamma \geq 1$ . Thus, stable tensile deformation occurs for

$$d\sigma/d\varepsilon \geq \sigma \quad (\text{Eq 19})$$

If the true-stress/true-strain curve is given by  $\sigma = K\varepsilon^a$ , then

$$d\sigma/d\varepsilon = nK\varepsilon^{n-1} = \sigma = K\varepsilon^n$$

and necking occurs when

$$\varepsilon = n \quad (\text{Eq 20})$$

Because  $n$  in tension rarely exceeds 0.5, the available uniform strain in the tension test is limited.

## Elongation Measurements in Tension Testing

The measured elongation depends on the gage length or the dimensions of the cross section of the specimen. This is because the total extension consists of two components, the uniform extension up to the point of necking and the localized extension after necking (Fig. 16). The extent of uniform extension will depend on the metallurgical condition of the material (through  $n$ ) and the effect of specimen size and shape on the development of a neck.

**Fig. 16** Local elongation measured at positions away from fracture in tension specimens for two aluminum alloys

However,

$$L_f - L_0 = a + e_u L_0 \quad (\text{Eq 21})$$

where  $a$  is the local necking extension and  $e_u L_0$  is the uniform extension. We then have

$$e_f = \frac{L_f - L_0}{L_0} = \frac{a}{L_0} + e_u \quad (\text{Eq 22})$$

which clearly indicates that the total elongation is a function of the gage length. Numerous attempts to rationalize the strain distribution in the tension test have been made, dating back to 1850. Following Barba's law, which states that geometrically similar specimens develop geometrically similar necks, it is usually assumed that the local extension at the neck is proportional to the linear dimension of the cross-sectional area,  $a = \beta \sqrt{A_0}$ , so that the elongation equation becomes:

$$e_f = \frac{\beta \sqrt{A_0}}{L_0} + e_u \quad (\text{Eq 23})$$

This equation for elongation clearly shows the rationale for the use of fixed ratios of gage length to diameter or gage length to square root of cross-sectional area in specifying tensile-specimen dimensions. It also reinforces the importance of stating the gage length over which the measurement was made when reporting elongation values. In the United States, the standard tensile specimen is 0.505 in. (12.83 mm) in diameter and 2 in. (50.8 mm) in gage length, so  $1/D \approx 4$ . However, the testing standards in other countries specify different gage lengths for the measurement of elongation (Table 6).

**Table 6 Dimensional relationships for specimens used in different countries for measurement of elongation**

Type of specimen	Dimensional relationship	United Kingdom		United States (ASTM)	Germany
		Before 1962	Current		
Sheet	$L_0/\sqrt{A_0}$	4.0	5.65	4.5	11.3
Round bar	$L_0/D_0$	3.54	5.0	4.0	10.0

To compare the ductilities of different metals by elongation measurements, the gage length should be adjusted as a function of the cross-sectional area of the test specimen. However, when flat specimens are cut from sheet or plate primarily to determine whether quality of individual lots meets specifications, it is usual to use fixed gage lengths, because of the lower cost of preparing and testing a large number of such specimens.

The effect of specimen geometry on total elongation is of particular concern in testing of sheet-metal specimens. Although the Unwin equation (Eq 23) may be obeyed (within considerable scatter), a simpler equation due to Templin is possibly in better agreement with the results:

$$e_f = C(A)^b \quad (\text{Eq 24})$$

Analysis of the results showed that the exponent  $b$  in Templin's equation depends on both uniform strain and localized fracture strain. Thus it will vary with processing and heat-to-heat differences in the metal, and it cannot be considered to be a real constant of the metal. A general trend was shown to exist between the exponent  $b$  in Templin's equation and the logarithm of the ratio of the zero-gage-length (fracture-strain) elongations to the infinite-gage-length (uniform-strain) elongations.

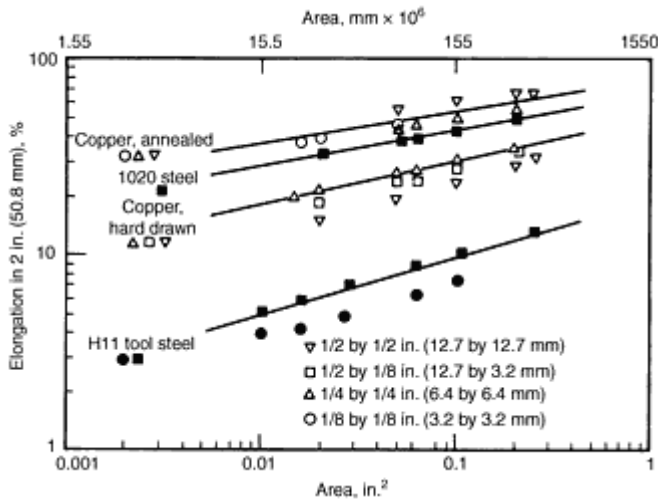

Although (even after 100 years of study) opinions differ in detail concerning the effect of specimen geometry on elongation, there is general agreement concerning the validity and importance of one factor--the ratio  $\sqrt{A/L}$ . Even here it appears to be better validated for round bars than for rectangular specimens. However, if sufficient data on the influence of specimen size on elongation are not available, the elongation of a specimen of arbitrary size can be estimated

by using the concept that a constant elongation is obtained if  $\sqrt{A/L}$  is maintained constant, as suggested by Eq 23.

Then, at a constant value of elongation,  $\sqrt{A_1/L_1} = \sqrt{A_2/L_2}$ , where  $A$  and  $L$  are the areas and gage lengths of two different specimens, 1 and 2, of the same metal. To predict the elongation in length  $L_2$  on a specimen with area  $A_2$  from measurements on a specimen with area  $A_1$ , it is only necessary to adjust the gage length of specimen 1 to conform to  $L_1 =$

$L_2 \sqrt{A_1/L_1}$ . As an example, suppose that sheet  $\frac{1}{8}$  in. (3.2 mm) thick is available, and it is desired to predict the elongation in 2 in. (50.8 mm) in identical material 0.080 in. (2.03 mm) thick. Using sheet specimens  $\frac{1}{2}$  in. (12.7 mm)

wide, it is predictable that a test specimen with  $L = 2 \sqrt{0.125/0.080} = 2.5$  in. (63.5 mm) from the  $\frac{1}{8}$  in. (3.2 mm) sheet would give the same elongation as a 2 in. (50.8 mm) gage length in sheet 0.080 in. (2.0 mm) thick. The usefulness of this procedure is shown in Fig. 17, where solid lines are experimental and points indicate predicted elongations for specimens of different areas.

**Fig. 17** Calculated variation of elongation in 2 in. (50.8 mm) with specimen cross-sectional area. Source: E.G. Kula and N.N. Fahey, *Mat. Res. Std.*, Vol 1, 1961, p 631

This discussion indicates that the measures of ductility available with the tension test leave a great deal to be desired in providing quantitative values. The main difficulty arises from the necking of the specimen. The occurrence of uniform and localized deformation makes the percentage elongation at fracture of little value as a quantitative measure of ductility, although it is usually required in metallurgical specifications. Reduction of area is a better measure of ductility, but its quantitative use is made difficult by the poorly defined triaxial stress state introduced by the formation of a neck.

## Plane-Strain Tension Test

A special type of tension-test specimen has been designed to give maximum plastic constraint so as to emphasize the differences in fracture behavior of nominally ductile materials (Fig. 18). The deep grooves in the specimen restrict the deformation to the grooved region. The ratio  $B/L$  is large enough so that approximately plane-strain conditions are achieved in the test section. Thus, strain occurs in the thickness and length directions but not in the width direction. The true strain is given:

$$\epsilon = \ln h_0/h \quad (\text{Eq 25})$$

where  $h_0$  is the initial thickness of the reduced section and  $h$  is the thickness at any time after deformation has begun. However, the ratio  $L/h$  is large enough so that there is no notch effect, and thus a specimen designed to the specification in Fig. 18 is an unnotched plane-strain specimen. Thus, the true stress can be determined from the load divided by the area ( $h \times B$ ).

Fig. 18 Plane-strain tension specimen where  $B = 1$  in.;  $L = \frac{1}{4}$  in.;  $h = 0.080$  in.;  $r = \frac{1}{16}$  in.

The plane-strain tension specimen described in Fig. 18 has the disadvantage that it may not be practical to machine such a specimen in a thin sheet. Also, because deformation is confined to the notch region, it may be difficult to make axial-strain measurements in those limited confines. A special clip-on fixture allows a regular sheet specimen to be converted to a plane-strain specimen.

This plane-strain tension specimen is 38 mm wide and 200 mm long. The specimen contains two circular edge notches with a 19 mm radius. A special fixture containing four knife edges is clamped to the surface of the specimen. The knife edges run parallel to the tensile axis of the specimen and fall just inside the reduced cross section. These knife edges prevent any deformation in the width direction. As a result, necking and failure occur perpendicular to the tensile axis.

## Summary

The tension test is a "benchmark test" or "reference test" that provides much basic information about the mechanical state of a material. This test provides information on the flow of a material and its ductility.

The flow resistance is evaluated on the basis of yield stress. The yield stress is variously determined by the first deviation from linear elastic behavior, or more precisely by the stress corresponding to the intersection with the stress-strain curve at an offset strain of 0.002 (the 0.2% offset yield strength). If the stress-strain curve can be expressed by Eq 5, then the yield stress corresponding to a particular cold reduction, expressed as reduction of area, RA, is given by the following equation:

$$\sigma_y = K \ln \left( \frac{1}{1 - RA} \right)^n \quad (\text{Eq 26})$$

This shows that a high strain-hardening exponent  $n$  leads to higher flow stress. In addition, with high  $n$  values, the deformation is spread out and local points of weakness, which can lead to thinning or fracture, are minimized. At elevated temperatures, strain-rate sensitivity becomes important, and strain hardening becomes less important.

Elongation and reduction of area in the tension test cannot be calculated from each other because the occurrence of necking prevents the constant-volume relationship ( $A_0 L_0 = A_1 L_1$ ) from being invoked over a distance containing the necked region. While elongation and reduction of area usually vary in the same way--for example, as a function of test temperature or alloy content--this is not always the case. Generally speaking, elongation and reduction of area measure different types of material behavior. Elongation measurements in the tension test are chiefly influenced by uniform

elongation (except when the gage length is very short) and thus depend on the strain-hardening capacity of the material. Reduction of area is more a measure of the deformation required to produce fracture. It is the most structure-sensitive ductility parameter.

## Compression Testing

---

THE CONCEPTS of uniaxial tensile and compressive loading are quite similar. In both cases, a strain is produced parallel to the applied load that has the same sign as the applied load, and two-transverse strains are produced that are opposite in sign to the applied load. Below the proportional limit, the strain in the load direction, in both cases, can be calculated using a single value of Young's modulus. Similarly, the transverse strain can be calculated using a second material constant, Poisson's ratio ( $\nu$ ):

$$\epsilon_{\text{transverse}} = \nu \epsilon_{\text{axial}}$$

Compression testing is an extremely valuable testing procedure, which is often overlooked because it is not properly understood. One of the main advantages of the compression test is that tests can be performed with a minimum of material, and thus mechanical properties can be obtained from specimens that are too small for tension testing. Compression tests are also very helpful for predicting the bulk formability of materials (behavior in forging, extrusion, rolling, etc.).

In compression testing, the material does not neck as in tension, but undergoes barreling; failure occurs by different mechanisms and therefore there is no ultimate tensile strength (UTS). In general, ductile materials do not fail in compression but tend to flow in response to the imposed loads. Brittle cylindrical specimens loaded in compression fail in shear on a plane inclined to the load, and therefore actually break into two or more pieces. In this case, an ultimate (compressive) stress can be defined.

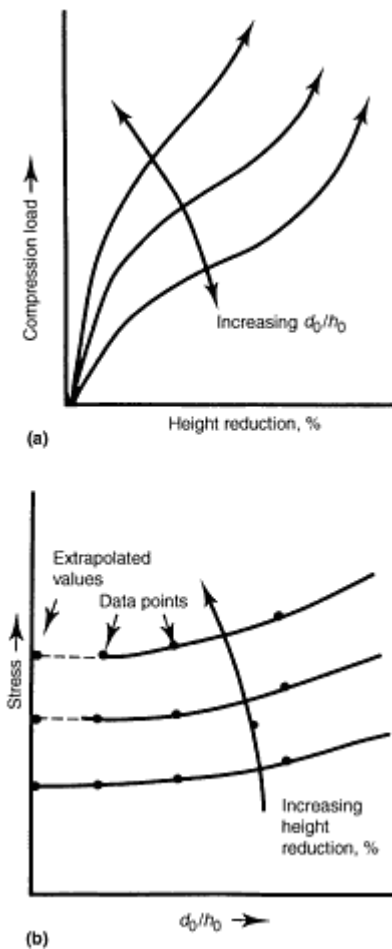

In comparison with tension testing, several difficulties are encountered in conducting compression tests and interpretation of the experimental data. For example, maintaining complete axiality of the applied load is important. In tension testing, self-aligning grips make this relatively simple to accomplish. In compression testing, if the specimen is tall in relation to its diameter, this can present a major difficulty. Nonaxiality of the load induces a bending load in the specimen, in addition to the axial load, that potentially will cause buckling. Alignment of the loading platens to impose strict uniaxial loading is easier if the specimen contact area is large, but this in turn introduces other difficulties.

Frictional forces exist at the specimen/platen interface that tend to restrict the increase in diameter of the specimen as it decreases in height. These forces are directly related to the coefficient of friction,  $\mu$ , and thus care must be given to minimizing  $\mu$ .  $P$  is the compressive load. Due to these frictional forces, loading on the specimen is not uniaxial. The effect of these frictional forces is two fold; an analysis indicates that the magnitude of the applied stress is increased over what it would be if the specimen were loaded uniaxially (i.e., the situation if  $\mu$  equals 0), and diametral expansion is hindered near the platens, but not in material well removed from the platen, so that the specimen becomes barrel shaped (Fig. 19). Because of the increased magnitude of the applied stress, deformation at midheight is plastic, whereas it is still elastic near the specimen/platen interface. The ratio of the elastically strained material to the plastically strained material increases as the specimen height decreases, so that barreling increases during the course of a test. The unfortunate consequence of barreling is that specimens selected for easy axial alignment are the same specimens that show extensive barreling and for which the internal stresses in the material have a large biaxial component. Therefore, some compromise must be made in selecting specimen dimensions. A height-to-diameter ratio of about 3 to 1 often is selected to minimize buckling that occurs due to bending loads generated by nonaxial alignment of the load.

**Fig. 19** Elastically loaded region and barreling in a compression specimen for two different height-to-width ratios

Because of the increasing contact area and the elastically strained material near the platen, the load-deflection curve bends upward as the specimen decreases in height (Fig. 20). A dramatic increase in load occurs if the elastically strained regions of Fig. 19 overlap.

**Fig. 20** Load-deflection curves. (a) Curves illustrating the relationship of compression load to height reduction for various  $d_0/h_0$  ratios. (b) Replot of curves for extrapolation to  $d_0/h_0=0$ .  $d_0$  is initial diameter;  $h_0$  is initial height.

Due to the presence of frictional forces, the pressure distribution across the specimen is not uniform, as shown in Fig. 21. The pressure distribution is given:

$$p = \sigma_0 \exp[(2\mu/h)(r-x)]$$

where  $p$  is pressure,  $\sigma_0$  is yield stress,  $\mu$  is coefficient of friction,  $r$  is cylinder radius,  $x$  is distance from center of cylinder to data point on  $x$ -axis, and  $h$  is cylinder height.

**Fig. 21 Line-loaded compression disk**

Figure 20 also shows how the pressure distribution changes as the height decreases and as the coefficient of friction changes. The load needed to deform the cylinder can be estimated by multiplying the average pressure on the specimen by the contact area. Figure 20 indicates that the load required to deform materials increases dramatically as the diameter-to-height ratio becomes greater and also increases with rise in the coefficient of friction. Without overload protection on the load cell, precautions must be taken so that the large loads required to cause plastic flow do not damage the load cell by exceeding its capacity, especially at the large plastic strains characteristics of forming processes.

Coefficients of friction are kept as low as possible to minimize barreling and the development of large loads by providing lubrication at the platen/specimen interface. Two possibilities are the use of lubricating oil and oil grooves in the specimen or platen, or thin Teflon (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) sheet between the platen and the specimen.

An alternative procedure to minimize friction effects and the attendant barreling phenomenon is the sequential loading of the specimen; that is, to load until plastic deformation just starts, unload, determine the change in dimensions and relubricate, then reload again until plastic flow initiates. This locus of points is then connected to provide a constructed stress-strain curve (Fig. 20).

A tedious but accurate way to determine a true uniaxial compression stress-strain curve is to use a series of specimens having varying  $l/D$  ratios. The stress at a given height reduction is then determined for each  $l/D$  ratio, plotted as a function of  $l/D$  ratio, and extrapolated to an  $l/D$  ratio of 0. This might be done at only one value of offset (i.e., corresponding to 0.2% strain) to provide a true flow stress, or a complete curve could be constructed.

## Line-Loaded Compression Testing

For the line-loaded test, a flat disk is loaded (Fig. 21). If the disk is of brittle material so that fracture occurs before plastic flow initiates, the thickness of the disk does not affect the calculated stress to cause fracture. The tensile stress at fracture for this case is calculated:

$$s = 2P/\pi Dt$$

where  $s$  is maximum tensile stress,  $P$  is applied load,  $D$  is specimen diameter, and  $t$  is specimen thickness. This test is known as the "Brazilian test" and is routinely applied to determine the tensile strength of rocks.

## Plain-Strain Compression Testing

The common forming operations--rolling, swaging, and forging--are forming operations in which there is little or no change in dimension in one direction. For example, in rolling, a decrease in thickness is converted into an increase in length with little increase in width. Such a state of strain is then two dimensional; it is planar strain. Plane-strain deformation is referred to when the development of a local neck is discussed; and in that case, the plane-strain deformation occurred due to an internal state of strain in the body. Two loading situations that develop plane-strain deformation are illustrated here; one in which the plane-strain deformation is developed due to external constraint on the flowing material, and a second, in which the constraint is developed internally in the material.

In Fig. 22(a), metal can flow in the  $x$  and  $z$  directions due to the applied stress in the  $z$  direction, but cannot flow in the  $y$  direction because of the die wall. In Fig. 22(b), the load  $P$  causes flow in the  $z$  and  $y$  directions, but flow occurs in the  $x$  direction if the  $x$  dimension or the width-to-thickness ratio of the sheet is large. This is because the material not under the die has no load imposed on it and, therefore, has no tendency to spread in either the  $x$  or  $y$  direction. Therefore, this unloaded material restrains flow of the material in the  $x$  direction (but not the  $y$  direction) under the die. There is net flow, in the  $y$  direction, because the unloaded material is simply pushed out by the expanding material under the die. Plane-strain conditions are realized when the width-to-thickness ratio is about 10 to 1. Because of frictional forces under the die, the  $b/t$  ratio should be held to between 2 to 1 and 4 to 1. If large decreases in thickness are obtained in the test, sequential loading with a change in die dimension is necessary to maintain this ratio. In any event, it is again possible to construct a stress-strain curve.

**Fig. 22** Plane-strain compression. (a) Plane-strain compression of a block in a die. (b) Indenting dies for plane-strain compression testing. Source: R.N. Parkins, *Mechanical Treatment of Metals*, Elsevier, 1968, p 22

Because the strains are large, true stresses and strains frequently are calculated rather than the nominal stresses and strains. The stress and strain developed in the plane-strain compression test are then given:

$$\sigma_T = \frac{\text{load}}{\text{area}} = \frac{P}{(w)(b)}$$

and

$$\epsilon T = \ln(t/t_0)$$

Although not derived here, the mean stresses and the strain in the load direction in plane-strain deformation are related to the stress and strain developed in a uniaxial compression test of a cylinder:

$$\sigma_{\text{plane strain}} = 1.15 \sigma_{\text{uniaxial compression}}$$

and

$$\epsilon_{\text{plane strain}} = 1.15 \epsilon_{\text{uniaxial compression}}$$

Therefore, stresses and strains measured in the plane-strain compression test must be divided by the factor 1.15 if an equivalent curve for uniaxially loaded material is to be constructed or if the data are to be compared with data obtained in a uniaxial test.

## Upset Testing

Bulk forming processes, such as forging, extrusion, and rolling, are also evaluated for formability by upset testing. In the simplest form of this test, a short cylinder is flattened (upset) into a pancake shape. The bulging at the edges produces tensile stresses that cause fractures. Workability is evaluated by determining the largest deformation that can be achieved without producing edge cracking. More typical, however, is use of the hot upset test over a range of temperatures to establish the working temperature that minimizes fracture.

A precision upset test has been developed to determine the three-dimensional analog of the forming-limit diagram. If grid lines are electroetched on the surfaces of small cylinders, then the compressive axial strain ( $\epsilon_z$ ) and the tensile hoop strain ( $\epsilon_\theta$ ) at which fracture occurs can be determined. By varying the length-to-diameter ratios ( $l/D$ ) of the cylinders and the lubrication at the cylinder ends, a wide range of stress states can be developed. By observing the strain in the upset cylinder at which surface fracture just occurs for each of the stress states, a fracture-locus line can be established (Fig. 23). For any combination of strains below the fracture-locus line, fracture has not yet occurred and the condition is safe. When the strain path crosses the fracture line, surface fracture has occurred. This procedure is helpful in predicting the bulk formability of metals.

Fig. 23 Fracture-locus lines

## Dynamic Fracture Testing

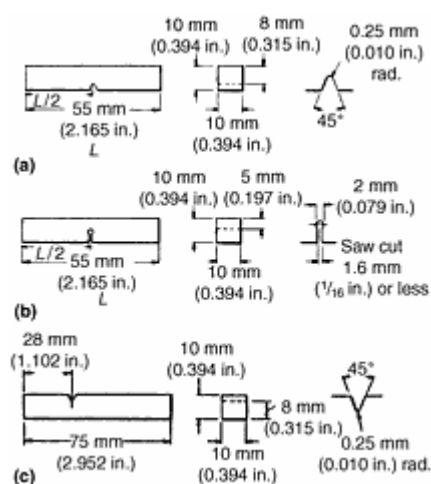

THE MOST IMPORTANT fracture tests can be grouped into two categories: impact (dynamic-fracture) tests and fracture-toughness tests. However, the variety of service circumstances--different types of materials, differing crack morphologies, differing environments and loading rates, effects of size--have spawned a large number of fracture tests, some highly specialized.

The most common impact tests are the Charpy test and the Izod test. Both are used primarily for low- and medium-strength materials (typically steels). These materials may break at stresses either above or below yield, depending on the circumstances (temperature, size of crack, etc.). Fracture-toughness tests are intended primarily for medium- and high-strength materials that may break at below-yield stresses, if a crack or other sharp flaw--often quite small--is present. Fracture-toughness tests are based on the theoretical developments of fracture mechanics and give results that can be directly used in calculations relating the size of cracks to applied loads and stresses. In fracture-toughness tests, unlike in impact tests, loads are normally applied relatively slowly--at about the same rate as in an ordinary tension test--and temperature need not be of concern. Although fracture-toughness tests can be conducted in a tension-test machine, the specimen looks quite different. Generally, it is a plate containing a crack grown from a machined notch, rather than the smooth round bar used in tension testing.

Impact tests feature a high but generally indeterminate rate of loading, typically generated by a swinging pendulum or falling weight. The results are not directly related to the stresses and deformations normally calculated during the course of engineering analysis and design, although the results may relate to the temperatures experienced in service. In general, impact-test results have significance based on empirical correlations with service experience, or as a means of comparing materials. The Charpy test is most commonly used to evaluate the effects of metallurgical processes on dynamic mechanical properties. Another test, the Izod impact test, employs a cantilevered specimen hit by a swinging pendulum.

### Charpy Tests

Specimens used for Charpy tests come in several different configurations. Two examples are the V-notch test specimen, containing a shallow 45° machined notch as a stress concentrator, and the Charpy keyhole specimen, with a stress raiser that looks something like a keyhole (Fig. 24a and b). The V-notch test is the more common of the two tests.

**Fig. 24** Notched-bar impact-test specimens. (a) Simple beam V-notch Charpy specimen. (b) Simple beam keyhole-notch Charpy specimen. (c) Cantilever beam notched Izod specimen. Source: Notched Bar Impact Testing of Metallic Materials, E 23-81, ASTM, 1981

Charpy tests have the virtue of being simple and inexpensive. Furthermore, the specimen is small--also one of the limitations of the test--and Charpy testing machines are widely available. The principal application is for delineating the transition-temperature region in low- and medium-strength steels; in the common test sequence, a series of nominally

identical specimens is broken at different temperatures. (Occasionally this test is used for materials other than low- and medium-strength steel.) Material specifications often include required levels of Charpy test performance, but the results of the test have limited fundamental significance. Results only have meaning in terms of correlations with ductile or brittle behavior under service conditions based on actual experience. However, because Charpy tests have been employed for so many years, a good deal of this experience is available in the form of general rules that can be exploited by designers.

Figure 25 illustrates the Charpy bar supported at its ends and struck on the surface opposite the notch so that the loading is three-point bending. The source of the blow is a heavy, swinging pendulum with a range of 35 to 325 J (25 to 240 ft · lb) of energy at impact. The weight and height of the pendulum striking head may be modified to produce various joules (foot-pounds) of energy. Testing-machine and specimen details for Charpy tests, together with test procedures, are standardized, as described in ASTM E 23.

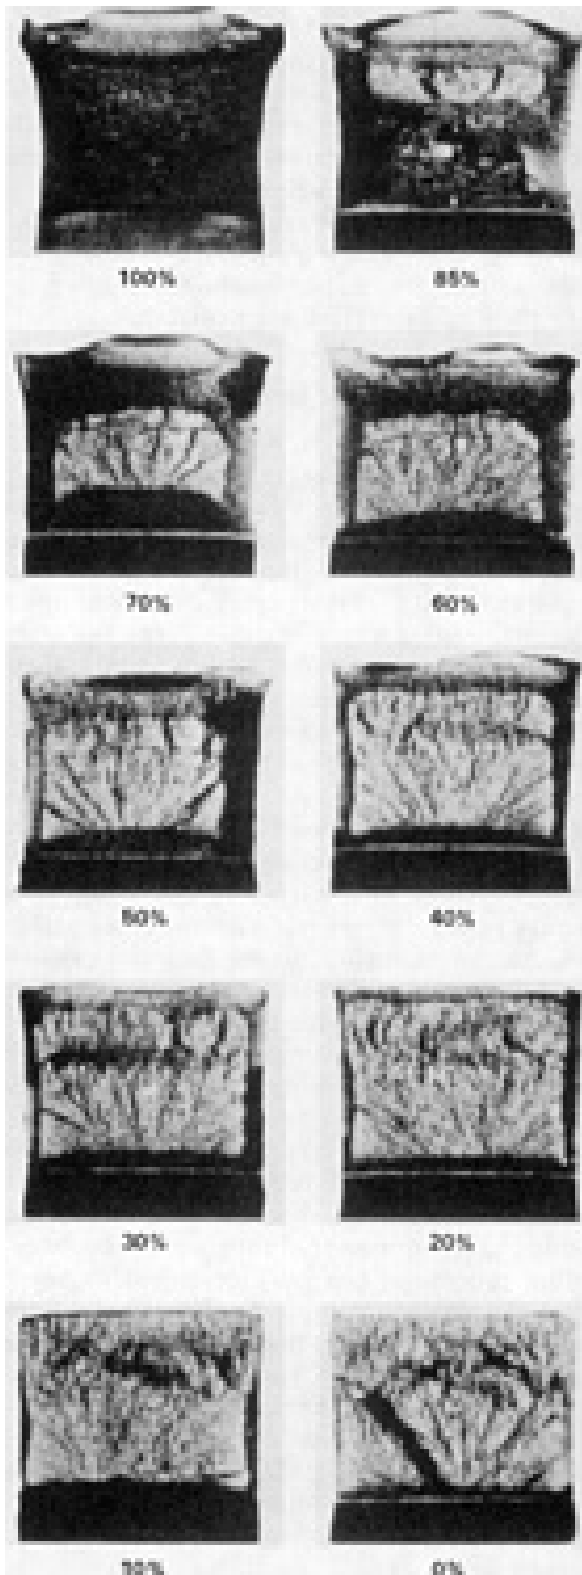

**Fig. 25 Setup and specimen for Charpy impact testing**

Machining of specimens should be controlled to provide specimen uniformity. The orientation of the bars, with respect to the rolling direction, often has considerable effect on impact behavior.

In its simplest form, a Charpy test is conducted by inserting a specimen into the machine, cocking the pendulum, and releasing it to fracture the test bar. Typically, a series of tests is performed at different temperatures. Charpy machines should be periodically checked against standardized specimens to determine their accuracy.

In addition to data on energy absorbed, two other quantities are commonly determined for each impact-test specimen. First, the percentage of fibrous fracture area visible on the cross section of the broken specimen is compared with the percentage of cleavage area. Second, the lateral contraction of the broken bar at the root of the notch is measured.

Figure 26 shows a series of fracture surfaces from Charpy V-notch tests at different temperatures. The fracture surface is entirely fibrous in appearance above the transition-temperature region, indicating ductile behavior; it is entirely cleavage below. In the transition region, small decreases in temperature increase the percentage of cleavage fracture. As Fig. 26 shows, the texture difference between fibrous and cleavage regions makes identification straightforward for specimens (such as annealed low-carbon steel), which fail by cleavage at low temperatures. The percentages can be estimated visually or, if more precision is needed, the fracture surfaces can be photographed and further analyzed. Note that in the transition region, cleavage takes place in the center of the specimen, with fibrous fracture near the outer surfaces of the bar. This is a result of the differing states of stress in the interior and near the surface. The inner material is constrained against plastic deformation and more likely to fracture by cleavage.

**Fig. 26** Series of fractographs of Charpy V-notch specimens of 4340 steel tested at different temperatures, showing the change in appearance and estimated percentages of fibrous fracture. Source: Army Materials and Mechanics Research Center, Watertown Arsenal

Notch-root contraction is also a direct indication of fracture behavior--in this case, of the amount of plastic deformation accompanying the fracture. The contraction is usually easiest to measure with a micrometer caliper. The thickness of the unbroken specimen at the notch root should be measured before the test.

The energy absorbed and the fracture-surface appearance are the most commonly specified results of the Charpy test. For example, steels for certain applications may be required to have a certain minimum level of energy absorption--15 or 20 J (10 or 15 ft · lb) are common values--at the lowest expected service temperature. Alternately, some minimum percentage of fibrous fracture (e.g., 50%) may be required. Again, note that such requirements have no intrinsic significance and can only be defined based on correlations with service experience.

The energy absorbed in impact, percentage of fibrous fracture, and notch-root contraction can be plotted against temperature to determine the ductile-to-brittle transition temperature. However, the particular definition of the ductile-to-brittle transition temperature must be clearly specified in the data report.

The standard Charpy impact test yields direct readings only of the energy absorbed. "Instrumented" tests make use of testing machines with auxiliary sensors to acquire other data, typically load data. A specially made striking tup instrumented with strain gages can give a load-time history that allows initiation of the crack from the machined notch to be distinguished from propagation of that crack through the specimen. This is a relatively specialized test utilized for specific limited applications. The advantages of the basic Charpy test, small specimen size, and low cost, are retained, while allowing fracture-mechanics parameters, such as toughness, to be estimated under specific circumstances.

## The Izod Test

The Izod test is a cantilever-beam test as compared to the simple-beam Charpy test. As shown in Fig. 27, the Izod specimen is held in a fixture with the V-notch facing the striking anvil of the pendulum. The center of the V-notch is in the same plane as, and parallel to, the supporting fixture. The actual fracture test is performed in the same manner as the Charpy test, and data on energy consumed are reported in joules (foot-pounds). The Izod test does not lend itself to variable-temperature testing because of the appreciable time required to place and clamp the specimen, which results in rapid temperature change due to specimen and fixture contact. Izod tests are generally specified for materials tested at room temperature and where the engineering part is designed to operate under cantilever loading.

Fig. 27 Setup and specimen for Izod impact testing

## Dynamic Tear Tests

Dynamic tear tests and drop-weight tear tests come in several varieties, two of which have been standardized by ASTM. All are similar to the Charpy test in the use of the kinetic energy of a swinging pendulum (or occasionally a falling weight) to break an artificially notched test specimen. In essence, they are larger versions of the Charpy test, with test specimens that are both thicker and wider to represent the fracture behavior of thick-section structural materials. While the Charpy test is used almost exclusively to investigate the transition-temperature behavior of low- and medium-strength steels, dynamic tear (DT) tests can be used as well for high-strength steels and for aluminum and titanium alloys. When such materials are broken in a Charpy machine, the energy absorbed is typically so low, compared to the testing machine's capacity, that little meaningful information can be obtained. The larger DT specimen allows different alloys and heat treatments to be more reliably compared.

Typical DT specimens are shown in Fig. 28. The larger specimen is used only where full-thickness tests representative of actual structures must be undertaken.

**Fig. 28** Two sizes of the standard specimen for the Naval Research Laboratory standardized dynamic tear test. In the specimens, a crack with a sharp tip is produced by making a brittle electron beam weld or by pressing with a knife edge. With either method of providing the crack tip, and with either size of specimen, maximum-constant conditions are attained. Dimensions are in inches.

As in a Charpy test, the basic information obtained from a DT test is the energy absorbed in breaking the specimen, although fracture-surface appearance and the extent of plastic deformation near the fracture can also be useful.

The two varieties of ASTM standard dynamic tear or drop-weight tests have the designations E 436 ("Drop-Weight Tear Tests for Ferritic Steels") and E 604 ("Dynamic Tear Testing of Metallic Materials"). As the names imply, the purposes are quite different, even though the general features are similar.

The E 436 drop-weight tear test uses a specimen, normally of the actual thickness of the steel plate being investigated, with an easily produced, pressed notch (see ASTM E 436 for details). The test is used only for steel and indicates the transition temperature between ductile and brittle behavior. To this end, specimens are tested at increasing (or decreasing) temperatures until the crack propagates as a fully developed fibrous fracture away from the notch (it makes no difference if the crack initiates by a cleavage mechanism). This is determined by visual examination of the fractured specimen; no quantitative data need be gathered. Thus, the test is simple and inexpensive. It is used primarily for quality control purposes on structural steels, notably for pipeline applications.

The ASTM E 604 test differs in two fundamental ways: the energy absorbed in fracturing the specimen is measured, and the test can be used on materials other than steels.

The standard dimensions of the specimen are less than for either of the specimens shown in Fig. 28; the notch is machined, and the specimen is always 15.9 mm ( $\frac{5}{8}$  in.) thick. Tests can be conducted at a fixed temperature to compare several materials; or over a range of temperatures to investigate transition-temperature effects. Considerable effort has gone into correlating DT test results with plane-strain fracture-toughness values, because the more sophisticated testing procedures required for the latter are more costly and time consuming. In some cases, the DT test can be used to estimate plane-strain toughness.

## Drop Weight Test

As the name implies, in a drop weight test (DWT) the specimen is broken by a falling weight rather than by a pendulum. However, the essential difference between this test and those described earlier is that it provides the operational definition of an important parameter termed the nil-ductility temperature (NDT). The NDT is the highest temperature at which a particular steel is likely to fracture in brittle fashion by cleavage. Above this temperature, the fracture will be accompanied by some macroscopic plastic flow associated with fibrous fracture and a microvoid-coalescence process on the microscale. The DWT procedure does not, however, require interpretation of the fracture appearance, nor must any

quantitative data be gathered beyond the temperature of the specimen. As the definition of the term NDT implies, the test is used only for low- and medium-strength steels that show a cleavage-fibrous transition as the temperature is increased.

The DWT also has been standardized by ASTM (E 208). The specimen is a flat plate with a hard-surfacing weld bead deposited on one side, as shown in Fig. 29. The brittle weld is notched to act as a crack starter. The fixture for DWT tests holds the specimen with the notched weld facing downward so that the falling weight will load the specimen in bending. The weld is thus on the tensile surface, and the specimen is backed up so that it can bend only a limited amount (approximately 5°). Well below the NDT, a DWT will produce complete fracture (Fig. 29). Well above the NDT, the specimen will bend elastically and plastically but will not break. The NDT, as defined by this test, is the temperature at which a crack starting at the notched hard-surfacing weld propagates to one or both edges of the tensile surface of the specimen. To conduct a DWT series, specimens are tested over a range of temperatures; the operationally defined NDT is the highest of these temperatures at which the specimen "breaks," according to this definition. The NDT is a widely applied parameter for structural steels and is referenced, for example, in the ASME Boiler and Pressure Vessel Code.

## Fracture Toughness Testing

FRACTURE TOUGHNESS is defined as a "generic term for measures of resistance to extension of a crack" (ASTM E 616). The term fracture toughness is usually associated with the fracture mechanics methods that deal with the effect of defects on the load-bearing capacity of structural components. Fracture toughness is an empirical material property that is determined by one or more of a number of standard fracture toughness test methods. In the United States, the standard test methods for fracture toughness testing are developed by the American Society for Testing and Materials (ASTM). These standards are developed by volunteer committees and are subjected to consensus balloting. This means that all objecting points of view to any part of the standard must be addressed. Other industrial countries have equivalent standards writing organizations that develop fracture toughness test standards. In addition, international bodies, such as the International Organization for Standardization (ISO), develop fracture toughness test standards that have an influence on products intended for the international market. In this review of fracture toughness testing, the ASTM approach will be emphasized to give the article a consistent point of view.

The standard fracture toughness test methods have been written mostly with metals in mind. Toughness testing of nonmetals is also an important consideration. For many nonmetals, the equivalent standard for metals is adapted with some possible modification. Fracture toughness test methods that are written specifically for a particular nonmetal are mostly in preparation. Therefore, this review emphasizes those standards written for metals without intending to make them apply exclusively to metals.

## Fracture Toughness Behavior

Fracture toughness is the resistance to the propagation of a crack. This propagation is often thought to be unstable, resulting in a complete separation of the component into two or more pieces. Actually, the fracture event can be stable or unstable. With unstable crack extension, often associated with a brittle fracture event, the fracture occurs at a well defined point and the fracture characterization can be given by a single value of the fracture parameter. With stable fracture, often associated with a ductile fracture process, the fracture is an ongoing process that cannot be readily described by a point. This fracture process is characterized by a crack growth resistance curve or *R*-curve. This is a plot of a fracture parameter

versus the ductile crack extension,  $\Delta a$ . An example  $K$ -based  $R$ -curve is shown in Fig. 30(a). Sometimes a single point is chosen on the  $R$ -curve to describe the entire process; this is mostly done for convenience and does not give a complete quantitative description of the fracture process.

**Fig. 30** Plane-strain fracture toughness ( $K_{Ic}$ ) test. (a) Schematic of  $K$ -based crack resistance ( $R$ ) curve with definition of  $K_{Ic}$ . (b) Specimens used in the  $K_{Ic}$  test as defined in ASTM E 399

Whether the fracture is ductile or brittle does not directly influence the deformation process that a component or specimen might undergo during the measurement of toughness. The deformation process is generally described as being linear-elastic or nonlinear. This determines which parameter is used in the fracture toughness test characterization. All loading begins as linear-elastic. For this, the primary fracture parameter is the well known crack tip density factor,  $K$ , originally defined by Irwin. If the toughness is relatively high, the loading may progress from linear-elastic to nonlinear during the toughness measurement, and a nonlinear parameter is needed. The nonlinear parameters that are most often used in toughness testing are the  $J$ -integral, labeled  $J$ , and the crack tip opening displacement (CTOD), labeled  $\delta$ . Because all loading starts as linear-elastic, the nonlinear parameters are all written as a sum of a linear component incorporating  $K$  and a nonlinear component.

## Test Methods

Fracture toughness test methods include linear-elastic and nonlinear loading, slow and rapid loading, crack initiation, and crack arrest. The development of the test methods follows a chronological pattern; that is, a standard was written for a particular technology soon after that technology was developed. Standards written in this matter tend to become exclusive to a particular procedure or parameter. Because most fracture toughness tests use the same specimens and procedures, this

exclusive nature of each new standard did not allow much flexibility in the determination of a toughness value. The newer approach is to write standards to encompass all parameters and measures of toughness into a single test procedure. This approach is labeled the common method approach and is being developed by ASTM as well as standards organizations in other countries. The standards for fracture toughness testing are periodically revised, and several new ones are often in development. Volume 3.01 of the *Annual Book of ASTM Standards* should be consulted for the current tests or new test standards.

The fracture toughness test is generally conducted on a test specimen containing a preexisting defect; usually the defect is a sharp crack introduced by fatigue loading and called the precrack. The test is conducted on a machine that loads the specimen at a prescribed rate. Measurements of load and a displacement value are taken during the test. The data resulting from this are subjected to an analysis procedure to evaluate the desired toughness parameters. These toughness results are then subjected to qualification procedures (or validity criteria) to see if they meet the conditions for which the toughness parameters are accepted. Values meeting these qualification conditions are labeled as acceptable standard measures of fracture toughness. The standard fracture toughness test then has these ingredients: test specimens, types, and preparation; loading and instrumentation requirements taken; data analysis; and qualification of results.

### ***Linear-Elastic Fracture Toughness Testing***

Fracture mechanics and fracture toughness testing began with a strictly linear-elastic methodology using the crack-tip stress-intensity factor,  $K$ . Later, nonlinear parameters were developed. However, the first test methods developed used the linear-elastic parameters and were based on  $K$ . These methods are described first in this article.

### ***Plane-Strain Fracture Toughness ( $K_{Ic}$ ) Test***

The first fracture toughness test that was written as a standard was the  $K_{Ic}$  test method, ASTM E 399. This test measures fracture toughness that develops under predominantly linear-elastic loading with the crack-tip region subjected to near-plane-strain constraint conditions through the thickness. The test was developed for essentially ductile fracture conditions, but can also be used for brittle fracture. As a ductile fracture test, a single point to define the fracture toughness is desired. To accomplish this, a point where the ductile crack extension equals 2% of the original crack length is identified. This criterion is illustrated schematically with a  $K$ - $R$  curve in Fig. 30(a). This criterion gives a somewhat size-dependent measurement, and so validity criteria are chosen to minimize the size effects as well as restrict the loading to essentially linear-elastic regime. The details of this test can be found in ASTM E 399.

**Test Specimen Selection.** The first element of the test is the selection of a test specimen. Five different specimen geometries are allowed (Fig. 30b). These are the single edge-notched bend specimen, SE(B); compact specimen, C(T); arc-shape tension specimen, A(T); disk-shape compact specimen, DC(T); and the arc-shape bend specimen, A(B). Many of these specimen geometries are used in the other standards besides ASTM E 399.

The bend and compact specimens are traditional fracture toughness specimens used in nearly every fracture toughness test method. The other three are special geometries that represent special component structural forms. Therefore, most fracture toughness tests are conducted with either the edge-notched bend or compact specimens. The choice between the bend and compact specimen is based on the following:

- The amount of material available (the bend takes more)
- Machining capabilities (the compact has more detail and costs more to machine)
- The loading equipment available for testing

All of the specimens for the  $K_{Ic}$  test must be precracked in fatigue before testing.

The choice of the specimen also requires a choice of the size. Because the validity criteria depend on the size of the specimen, it is important to select a sufficient specimen size before conducting the test. However, the validity criteria cannot be evaluated until the test is completed; therefore, choosing the correct size is a guess that may turn out to be wrong. There are guidelines in ASTM E 399 for choosing a correct size, but no guarantee that the chosen size will pass the validity requirement. The test specimen must also be chosen so that the proper material is sampled. This means that the location in the material source and the orientation of the sample must be correct and accounted for. As the specimens

are prepared, requirements for tolerances on such things as locations of surfaces, size and location of the notch and pin holes, and surface finishes must be followed.

**Loading Machines and Instrumentation.** Most tests are conducted on either closed-loop servo-hydraulic machines or a constant-rate crosshead drive machine. The first machine allows load, displacement, or other transducer control, but it is more expensive. It is preferred for precracking, which is usually done at a constant load range so load control is desired. The second type of loading machine is less expensive and may give more stability, but it allows only crosshead control. Because this is required in most of the fracture toughness tests, this type of machine is quite satisfactory for the actual fracture toughness testing but is not so good for precracking.

Loading fixtures must be designed for the test. Two types can be used, choice of loading fixture depends on the test specimen chosen. The bend specimens SE(B) and A(B) use a bend fixture. The tension specimens C(T), DC(T), and A(T) require a pin-and-clevis loading.

For the  $K_{Ic}$  test, a continuous measurement of load and displacement is required during the test. The load is measured by a load cell, which should be on all loading machines. The measurement of displacement is usually done with a strain-gaged clip gage that is positioned over the mouth of the crack in the specimen. The ASTM E 399 standard gives guidelines for the working requirements of the load and displacement gages used in the tests.

The loading of the specimen is done at a prescribed rate. It must be done fast enough so that any environmental or temperature interactions are not a problem. On the other hand, it must be done slowly enough so that it is not considered a dynamically loaded test. For the  $K_{Ic}$  test, the load must be applied at a rate so that the increase in  $K$  is given by the range  $0.55$  to  $2.75 \text{ MPa}\sqrt{\text{m}}/\text{s}$ . The loading is done in displacement control, which usually means test machine crosshead control. During the loading, the load and displacement are measured continuously either autographically or digitally.

**Test Data and Analysis.** The load-and-displacement record provides the basic data of the test. The data are then analyzed to determine a provisional  $K_{Ic}$  value labeled  $K_Q$ . This provisional value is determined from a provisional load,  $P_Q$ , and the crack length. The  $P_Q$  value is determined with a secant slope on the load-and-displacement record (Fig. 31). The  $P_Q$  value determined by drawing the original loading slope of the load-versus-displacement record. A slope of 5% less than the original slope is then drawn from the origin. For a monotonically increasing load, the  $P_Q$  is taken where the 5% secant intersects the load-versus-displacement curve, this is shown as type I in Fig. 31. For other records in which an instability or other maximum load is reached before the 5% secant, the maximum load reached up to and including the possible intersection of the 5% secant is the  $P_Q$ . Type II shown in Fig. 31 is an example of one of the other types of load-versus-displacement records. The 5% secant corresponds to about 2% ductile crack extension; this may be physical crack extension or effective crack extension related to plastic zone development. Unstable failure before reaching the 5% offset also marks a measurement point for  $P_Q$  at the maximum load reached at the point of instability.

**Fig. 31** Typical load-versus-displacement record for the  $K_{Ic}$  test, two types

The  $P_Q$  value is used to determine the corresponding  $K_Q$  value, which is calculated:

$$K = P f(a/W) / B \sqrt{W}$$

where  $P$  is load,  $B$  and  $W$  are specimen thickness and width, and  $f(a/W)$  is a calibration function that depends on the ratio of crack length to specimen width,  $a/W$ , and is given in the standard. For the calculation of  $K$ , a crack length value,  $a$ , is required. This comes from a physical measurement on the fracture surface of a broken specimen half. The specimen must be fractured into halves if it is not already that way from the test. The crack length is measured to the tip of the precrack using an averaging formula in the test standard. This value of crack length normalized with width,  $W$ , is used in the calibration function  $f(a/W)$  to determine the  $K_Q$  value.

The  $K_Q$  is provisional  $K$  value that may be the  $K_{Ic}$  if it passes the validity requirements. The two major validity requirements are to ensure that crack resistance does not increase significantly with crack growth and that linear-elastic loading and plane-strain thickness are achieved. The first of these two requirements is quantified:

$$\frac{P_{\max}}{P_Q} \leq 1.10$$

which limits the  $R$ -curve behavior to an essentially flat trend and ensures that some physical crack extension. The second requirement is:

$$a, B \geq 2.5 \left( \frac{K_Q}{\sigma_{ys}} \right)$$

which guarantees linear-elastic loading and plane-strain thickness,  $P_{\max}$  is the maximum value of load reached during the test. An example of  $P_{\max}$  is shown in Fig. 31;  $\sigma_{ys}$  is the 0.2% offset yield strength. Values of  $K_Q$  that pass these validity requirements are labeled as valid  $K_{Ic}$  and are reported as such in a standard prescribed reporting of test results.

**Fatigue precracking** should be done in accordance with ASTM E 399. The  $K$  level used for precracking each specimen should not exceed about two-thirds of the intended starting  $K$ -value for a given environmental exposure. This prevents fatigue damage, or residual compressive stress at the crack tip, which may alter the fracture toughness behavior, particularly when testing at a  $K$ -level near the  $K_Q$  value for the specimen.

Chevron notches are sometimes used to facilitate starting such mechanical precracks. These modifications also may be necessary to control fatigue precracking of some materials.

### **Rapid-Load $K_{Ic}(t)$**

A value of fracture toughness labeled  $K_{Ic}(t)$  can be determined for a rapid-load test. Details of this method are given in a special annex to the method E 399. For the static loading rate  $K_{Ic}$  value, the maximum loading rate is defined as  $2.75 \text{ MPa}\sqrt{\text{m}}/\text{s}$ . Anything faster than that is labeled as a rapid-load fracture toughness. The specimen apparatus and procedure are much the same as for the regular  $K_{Ic}$  test. Special instructions are given to ensure that the instrumentation can handle the rapidly changing signals. The interpretation of results must be based on a dynamic value of the yield stress,  $\sigma_{YD}$ . An equation for  $\sigma_{YD}$  is given in the Annex to E 399. Results are reported  $K_{Ic}(t)$ , where the loading time of the test is written in parentheses after the measured toughness value.

### ***K-R Curve (ASTM E 561)***

Ductile fracture toughness behavior is measured by a crack growth resistance curve or " $R$ -curve," which is defined as "a plot of crack-extension resistance as a function of slow-stable crack extension." Although many ductile fracture processes can be measured as a single point, such as with  $K_{Ic}$ , the  $R$ -curve is a more complete description of the fracture toughness. When the  $R$ -curve increases significantly, a single-point measurement is even less descriptive of the actual fracture toughness. Steeply rising  $R$ -curves occur in many metallic materials but especially in thin plate or sheet materials. The

steeply rising  $R$ -curve makes the single-point definition more size- and geometry-dependent and does not lend to structural evaluation.

The  $K$ - $R$  curve is a good method for fracture toughness characterization in cases where the  $R$ -curve is steeply rising but the fracture behavior occurs under predominantly linear-elastic loading conditions. The  $K$ - $R$  curve procedure is given by ASTM E 561. The objective of the method is to develop a plot  $K$ , the resistance parameter, versus effective crack extension,  $\Delta a_e$ .

The method allows three different test specimens: the compact, C(T); the center-cracked tension panel, M(T); and the crack-line-wedge-loaded specimen, C(W). The compact specimen is the same as the compact type in ASTM E 399 for  $K_{Ic}$  tests (Fig. 30b). The center-cracked tension panel and the crack-line-wedge-loaded specimens are shown in Fig. 32(a) and 32(b), respectively. The first two specimens use a conventional loading machine with fixtures that are specified in the test method. The C(W) specimen is wedge loaded to provide a stiff, displacement-controlled loading system (Fig. 32b). The can prevent rapid, unstable failure of the specimen under conditions where the  $R$ -curve toughness is so low that the  $R$ -curve can be measured to larger values of  $\Delta a_e$ . All specimens must be precracked in fatigue.

**Fig. 32** Specimens for crack growth resistance testing. (a) Center-cracked tension specimen, M(T). (b) Crack-line-wedge-loaded compact specimen, C(W), in loading fixture

The instrumentation required on the specimens is similar to that for the  $K_{Ic}$  test, except for the case of the C(W) specimen. The basic test result is a plot of load versus displacement measured across the specimen mouth. From this, an effective crack length is determined from secant offset slopes to the load-versus-displacement record (Fig. 33). An effective crack extension is the difference between the original and effective crack lengths. Effective crack length is determined from the slope of the secant offset using the appropriate compliance function, which relates this slope to crack length. The  $K$  is determined as a function of the load and corresponding effective crack length:

$$K = Pf(a_e/W)/B\sqrt{W}$$

The resulting plot of  $K$  versus effective crack length is the desired  $K$ - $R$  curve fracture toughness. The result is subjected to a validity requirement that limits the amount of plasticity. For the C(T) and C(W) specimens:

$$b = (W - a) \geq (4/\pi)(K_{\max}/\sigma_{ys})^2$$

where  $b$  is the uncracked ligament length,  $\sigma_{ys}$  is the 0.2% offset yield strength, and  $K_{\max}$  is the maximum level of  $K$  reached in the test. For the M(T) specimen, the net section stress based on the physical crack size must be less than the yield strength.

**Fig. 33** Secant offset measurement of effective crack length

For the C(W) specimen, a load is not measured. The data collected are a series of displacement values taken at two different points along the crack line, one near the crack mouth and one nearer the crack tip. From the two different displacement values, an effective crack length can be determined from the ratio of the two displacement values and from calibration values given in a table in E 561. From the crack length and displacement, a  $K$ -value can be determined and the  $K$ - $R$  curve constructed. The toughness result is then a curve of  $K$  versus  $\Delta a_e$ , somewhat similar to the one in Fig. 30.

### **Crack Arrest, $K_{Ia}$ (ASTM E 1221)**

This procedure allows a toughness value to be determined based on the arrest of a rapidly growing crack, which may be lower than the initiation value. The specimen and procedure are somewhat different from the previously discussed toughness test methods that determine initiation toughness values only. The specimen for crack arrest testing is called the compact-crack-arrest compact specimen (Fig. 34). It is similar to the crack-line-wedge-loaded specimen, C(W), of the  $K$ - $R$  curve method and requires wedge loading in order to provide a very stiff loading system to arrest the crack. The notch preparation is different from the other standards in that the specimen has a notch with no precrack. Generally, a brittle weld bead is placed at the notch tip to start the running crack, although other methods are allowed. The running crack advances rapidly into the test material and must be arrested by the test material to produce a  $K_{Ia}$  result. The only instrumentation on the specimen is a displacement gage. A load cell is placed on the loading wedge, but it does measure the load on the specimen. The displacements at the beginning of the unstable crack extension and at the crack arrest position are measured and converted to  $K$  values. To eliminate effects of non-linear deformation, which cannot be directly measured with only a displacement gage, a series of loads and unloads are conducted on the specimen until the unstable cracking occurs. When the specimen is unloaded, the crack tip can be marked by a procedure called "heat tinting." Heat tinting consists of marking the physical crack extension by heating the specimen until oxidation occurs on the crack. The specimen is then broken open, and the crack extension measured on the fracture surface.

**Fig. 34** Crack-line-wedge-loaded compact-crack-arrest specimen

The value of  $K_{Ia}$  is determined from a displacement value and the crack length at the arrest point. Validity is determined from the size criterion:

$$W - a \geq 1.25(K/\sigma_{YD})^2$$

where  $\sigma_{YD}$  is a dynamic yield strength. To complete a successful  $K_{Ia}$  test, careful attention must be paid to the instructions in E 1221.

### ***Nonlinear Fracture Toughness Testing***

Linear-elastic parameters are used to measure fracture toughness for relatively low toughness materials that fracture under or near the linear loading portion of the test. For many materials used in structures, it is desirable to have high toughness, a value at least high enough so that the structure would not reach fracture toughness before significant yielding occurs. For these materials, it is necessary to use the nonlinear fracture parameters to measure fracture toughness properties. The two leading nonlinear fracture parameters are  $J$  and  $\delta$ . For high toughness materials, fracture is often by a ductile mechanism, but this is not necessarily the case for all materials.

**$J_{Ic}$  Testing (ASTM E 813).** One of the first tests developed using the  $J$  parameter is the  $J_{Ic}$  test per ASTM E 813. In this test, an  $R$ -curve is developed using  $J$  versus  $\Delta a$  pairs and a point near the beginning of the  $R$  curve is defined as  $J_{Ic}$  "a value of  $J$  near the onset of stable crack extension" (ASTM E 813). The specimens for the  $J_{Ic}$  test are the bend SE(B) and compact C(T). These specimens are similar to the ones used for  $K_{Ic}$  testing; however, the compact specimen for  $J$  testing has a cutout on the front face so that a displacement gage can be mounted directly on the load line; that is, in the line of the applied loads. The loading fixtures required are the bend fixture for the bend and the pin-and-clevis for the compact. Again, a clevis with a loading flat at the bottom of the pin hole in the clevis is essential to get free rotation of the specimen. The instrumentation required is the load cell and a displacement measuring clip gage. If the electrical potential system is used additional instrumentation is required. The clip gage for the  $J_{Ic}$  test requires more resolution than that for the  $K_{Ic}$  test if a single specimen test method is used. For the bend specimen, a loadline clip gage is needed to measure  $J$ . Additionally, a second clip gage can be used over the crack mouth if a single specimen method is used.

The basic output of the test is a plot of  $J$  versus physical crack extension ( $\Delta a$ ). (Unlike the  $K$ - $R$  curve method, which uses effective crack extension, the  $J_{Ic}$  test uses physical crack extension.) To obtain the required  $J$  versus  $\Delta a$  data measurements of load, displacement and physical crack length are required during the test. There are two techniques used to develop these data. The first is the multiple-specimen test method, in which each specimen develops a single value of  $J$  and  $\Delta a$  but no special crack monitoring equipment is needed during the test. Crack extension is measured on the fracture surface at the conclusion of the test. However, for this technique a number of specimens are required to develop the plot of  $J$  versus  $\Delta a$  values needed for the result. The other method is the single specimen test from which all the  $J$  versus  $\Delta a$

values are developed from one test. To accomplish this, a method of crack length monitoring is needed during the test. The primary method for crack length monitoring during the test is called the elastic unloading compliance method, in which crack length is measured from an elastic slope. The measurement of the elastic slope requires only a clip gage that measures displacement. The compact specimen uses the gage mounted on the load line. The bend specimen could use two gages: one on the loadline to measure  $J$  and one over the crack mouth to measure slope. The second single-specimen method is the electrical potential crack monitoring system, in which the electrical resistivity of the specimen is measured and correlated with crack length during the test. This is a secondary method to measure crack length and is not described in detail in the E 813. It requires some additional expertise on the part of the tester to use.

The test procedure depends on the method of crack length monitoring. For the multiple-specimen test, five or more specimens are loaded to prescribed displacement values that are thought to give some physical crack extension but not complete separation of the specimen. This results in a number of individual load-versus-displacement records, as shown in Fig. 35. When the prescribed displacement is reached, the specimen is unloaded and the crack tip is marked by heat tinting.

**Fig. 35** Load versus displacement for multiple-specimen tests

The single-specimen method using elastic compliance is initially loaded in the same way; however, during the test partial unloadings are taken to develop elastic slopes from which crack length can be evaluated using compliance relationships (Fig. 36). The compliance relationships are given in E 813. For the electrical potential method, the load, displacement, and potential change are measured simultaneously. Potential changes are related to crack length through either an analytical or empirical correlation.

**Fig. 36** Load versus displacement with unloading slopes

From these test results,  $J$  is evaluated from the load-versus-loadline displacement record. The  $J$  is calculated from a linear combination of an elastic term and a plastic term:

$$J = J_{el} + J_{pl} = \frac{K^2(1 - \nu^2)}{E} + \frac{\eta_{pl}}{Bb} \int_0^{v_{pl}} P dv_{pl}$$

where  $K$  is the stress-intensity factor,  $E$  is elastic modulus,  $\nu$  is Poisson's ratio,  $P$  is load,  $\nu_{pl}$  is plastic displacement,  $B$  is specimen thickness,  $b$  is specimen uncracked ligament ( $W - a$ , where  $W$  is specimen width), and  $\eta_{pl} = 2 + 0.522b/W$  for the compact specimen. This equation is the basic  $J$  formula for the case of a nongrowing crack. It is based on a  $K$  equivalence for the elastic component of  $J$  and an area term for the plastic component of  $J$ . Alternate  $J$  formulas are given in E 813 for the growing crack. The crack length is used to determine  $\Delta a = a - a_0$ , where  $a_0$  is the original crack length at the beginning of the test.

The  $J$  versus  $\Delta a$  results form a part of the  $J$ - $R$  curve and are the basic data of the  $J_{Ic}$  method. The objective is to get  $J$  versus  $\Delta a$  values in a certain restricted range. These data are then subjected to a prescribed evaluation scheme to choose a point on the  $J$ - $R$  curve that is near the initiation of stable cracking. The method for developing the  $J_{Ic}$  is somewhat complicated, and the details are given in E 813. Basically, the  $J$  versus  $\Delta a$  pairs are evaluated to see which fall in a prescribed range. The pairs falling in the correct range are fitted with a power-law equation:

$$J = C_1(\Delta a)^{C_2}$$

where  $C_1$  and  $C_2$  are constants. A construction line is drawn, and the intersection of this with the fitted line is the evaluation point for a candidate  $J_{Ic}$  value. This candidate value is labeled  $J_Q$ .

The candidate  $J_Q$  value is subjected to qualification criteria to see if it comprises an acceptable value. The basic one is to guarantee a sufficient specimen size:

$$b, B \geq 25(J_Q/\sigma_Y)$$

where  $\sigma_Y$  is an effective yield strength and

$$\sigma_Y = (\sigma_{ys} + \sigma_{uts})/2$$

where  $\sigma_{ys}$  and  $\sigma_{uts}$  are the yield strength and ultimate tensile strength, respectively. If the qualification requirements are met, the  $J_Q$  is  $J_{Ic}$ , and the results are reported following the prescribed format in E 813. A more complete evaluation of fracture toughness for ductile fracture based on  $J$  is the  $J$ - $R$  curve procedure in ASTM E 1152. This standard uses the same specimens, instrumentation, and test procedures as the  $J_{Ic}$  test. The  $J_{Ic}$  and  $J$ - $R$  curve methods are very similar, hence a combined  $J$  standard is being prepared.

**Crack Tip Opening Displacement (CTOD) (ASTM E 1290).** The crack tip opening displacement method of fracture toughness measurement was the first one that used a nonlinear fracture parameter to evaluate toughness. The first CTOD standard was written by the British Standards Institution (BS 5762, 1979). Subsequently, ASTM E 1290 was written as the U.S. version of this test method. The basic idea of the test method is to evaluate a fracture toughness point for brittle fracture or to evaluate a safe point for the case of ductile fracture. The primary measurements of toughness are at unstable fracture before significant ductile crack extension, labeled  $\delta_c$ ; unstable fracture after significant crack extension,  $\delta_u$ ; or the point of maximum load in the test,  $\delta_m$ . The method originally had a point near the beginning of stable crack extension,  $\delta_i$ , that was measured as a point on an  $R$ -curve in a similar manner to  $J_{Ic}$ . This point was subsequently removed from the test method.

The CTOD standard uses the same bend and compact specimens that are used in the  $J_{Ic}$  test; thus, the same loading fixtures are used. The method requires measurement of load and displacement during the test. The formulas for  $\delta$  calculation use a combination of an elastic and a plastic component for  $\delta$ :

$$\delta = K^2(1 - \nu^2)/2 \sigma_{ys}E + r_p(W - a_0)\nu_p/[r_p(W - a) + a_0 + z]$$

In this equation, the elastic component of  $\delta$  is based on an equivalent  $K$  and the plastic component is based on a rigid plastic rotation of the specimen about a neutral stress point at  $r_p(W - a_0)$  from the crack tip. In the equation,  $\nu$  is Poisson's ratio,  $\sigma_{ys}$  is the yield strength,  $r_p$  is a rotation factor,  $\nu_p$  is a plastic component of displacement,  $W - a_0$  is the uncracked ligament length, and  $z$  is the position of the clip gage from the crack measurement position.

For many years, the CTOD test was the only one that measured toughness for a brittle, unstable fracture event using a nonlinear fracture parameter. In addition, the method allows the measurement of toughness after a "popin," which is described as a discontinuity in the load-versus-displacement record usually caused by a sudden, unstable advance of the crack that is subsequently arrested.

### ***New Test Methods***

The development of standard fracture toughness test methods is an ongoing process. Some new test methods for fracture toughness testing include:

- The combined  $J$  standard (ASTM E 1737-96)
- The common test method (ASTM E 1820-96)
- The transition fracture toughness standard
- The standard for testing of weldments

The latter two methods will likely become test standards in the near future.

### **Fatigue Life Testing**

FATIGUE TESTS can be classified as crack initiation or crack propagation tests. In crack initiation testing, specimens or parts are subjected to the number of stress (or strain-controlled) cycles required for a fatigue crack to initiate and to subsequently grow large enough to produce failure. In crack propagation testing, fracture mechanics methods are used to determine the crack growth rates of pre-existing cracks under cyclic loading. Both methods can be used in a benign environment, or by the combined effects of cyclic stresses and an aggressive environment (corrosion fatigue).

This section focuses on fatigue life test methods and general fatigue life data. In general, fatigue life (crack initiation) testing is stress controlled (SN) or strain controlled ( $\epsilon$ -N). The test specimens (Fig. 37) are described primarily by the mode of loading, such as direct (axial) stress, plane bending, rotating beam, alternating torsion, and combined stress.

**Fig. 37** Typical fatigue life test specimens. (a) Torsional specimen. (b) Rotating cantilever beam specimen. (c) Rotating beam specimen. (d) Plate specimen for cantilever reverse bending. (e) Axial loading specimen. The design and type of specimen used depend on the fatigue testing machine used and the objective of the fatigue study. The test section in the specimen is reduced in cross section to prevent failure in the grip ends and should be proportioned to use the upper ranges of the load capacity of the fatigue machine (i.e., avoiding very low load amplitudes where sensitivity and response of the system are decreased).

## Test Methods

Testing machines are defined by several classifications: the controlled test parameter (load, deflection, strain, twist, torque, etc.); the design characteristics of the machine (direct stress, plane bending, rotating beam, etc.) used to conduct the specimen test; or the operating characteristics of the machine (electromechanical, servohydraulic, electromagnetic, etc.). Machines range from simple devices that consist of a cam run against a plane cantilever beam specimen in constant-deflection bending to complex servohydraulic machines that conduct computer-controlled spectrum load tests.

Axial and rotating-bending machines are most commonly used for fatigue tests. Surface preparation of specimens is critical in all fatigue life tests.

**Axial Fatigue Life Tests.** ASTM E 466 specifies specimens to be used in axial fatigue tests. The specific dimensions of specimens depend on the objective of the experimental program, machine to be used, and available material. ASTM does not specify dimensions but details preparation techniques and reporting techniques. In reporting, a sketch of the

specimen, with dimensions, should be given. The surface-roughness and out-of-flatness dimensions should be included. Specimens should not be subjected to any surface treatment.

For axial loading, ASTM E 466 states that regardless of the machining, grinding, or polishing method used, the final metal removal should be in a direction approximately parallel to the longitudinal axis of the specimen. Improper preparation methods can greatly bias the results. Hence, preparation techniques should be carefully developed; if a change in the preparation technique is made, it has to be demonstrated that it does not introduce any bias in the results.

**Rotating-bending fatigue tests** of the simple beam type are performed in testing machines such as that shown in Fig. 38, sometimes called the R.R. Moore testing machine. In operation, an electric motor rotates a cylindrical specimen, usually at 1800 rpm or higher, while a simple mechanical counter records the number of cycles. Loads are applied to the center of the specimen by a system of bearings and dead weights. A limit switch stops the test when the specimen breaks and the weights descend.

Fig. 38 Loading arrangement for a rotating-beam fatigue-testing machine. *S*, specimen; *P*, load

The weights produce a moment that causes the specimen to bend. A strain gage placed on the specimen shows compressive stresses on the top and tensile stresses when the gage is rotated to the bottom. Stresses range from maximum tension to maximum compression during each revolution of the testing machine.

Bending moments can be converted to stress by assuming that they are elastic and by employing the flexure formula:

$$\sigma = MC/I$$

For circular specimens,  $I = \pi C^4/4$ , where  $C$  is the specimen radius. The maximum stress at the outer fiber,  $\sigma$ , is proportional to the bending moment,  $M$ . This moment is the product of the moment arm and the force.

The specimen is machined from the material to be tested and is fastened into the bearing housing with special cap screws. The effective dead weight of the R.R. Moore machine and weighing apparatus is 4.54 kg (10 lb), which is deducted from the total weight required and added to the weight pan (Fig. 38) to provide the desired stress:

$$\begin{aligned} 18.22 \text{ kg} - 4.54 \text{ kg} &= 13.68 \text{ kg} \\ (40.13 \text{ lb} - 10 \text{ lb}) &= 30.13 \text{ lb} \end{aligned}$$

When the drive motor is actuated, a counter records the number of revolutions. If the specimen breaks, the bearing housing descends and actuates a switch that shuts off the drive motor. If the specimen does not break (carbon and low-alloy steels may achieve a million or more cycles), the stress is at or below the endurance limit. Next, the machine is shut off and another specimen is run at a higher stress level. A series of tests is performed to provide sufficient data at varying stress levels.

For cantilever-beam rotating-bending machines of the White-Souther type (Fig. 39), a different bending moment is used in stress calculation. A weight,  $P$ , is supported by fixture to a ball-bearing housing at the free end of the specimen. This produces a bending moment,  $M$ , that equals  $P \times L$ , which is the distance of the specimen from the center of the applied load, 75 mm (3 in.). The stress in the outer fiber is

$$S = \frac{PL}{lc}$$

The weight added to the weight pan is the calculated weight minus the weight of the weighing apparatus.

**Fig. 39** Loading arrangement for a cantilever-beam fatigue machine for rotating-bending testing. *S*, specimen; *P*, load

**Plate-Bending Machines.** In rotating-bending tests, the mean or average stress is always zero. The effect of mean stress, which is very important in fatigue, is evaluated by cantilever bending machines that are used to test plate materials. In these machines, sometimes called Kraus plate-bending machines, specimens are loaded with constant deflection by means of an eccentric crank (Fig. 40). Stresses can be calculated by assuming that they are elastic. In many cases this is not a good assumption, because, when tested, some soft materials may involve small amounts of plastic stress.

**Fig. 40** Reciprocating-bending fatigue-testing machine, and typical specimen (at lower left) for testing of sheet

Specimens are usually tapered to provide a constant-stress test area. The approximate stress, *S*, is given by:

$$S = \frac{yIE}{l^2}$$

where *y* is the specimen deflection, *t* is the thickness of the specimen, *E* is the elastic modulus, and *l* is the distance from load application to the back of the specimen. Constant-deflection beam-type machines are used to test both strip and plate. A typical specimen is shown at lower left in Fig. 40.

**Resonant-Testing Machines.** Machines for resonant testing are basically spring-mass, vibrating systems. The frame design is based on a resonant, spring-mass system that consists of two masses linked by the specimen and grip string and that oscillates as a dipole. The system is excited by an electromagnet housed in the machine base. The masses and load

string are positioned in the vertical frame, which is suspended and guided on leaf springs. The eight springs are arranged in a special configuration to make a unique and compact design without the need for a heavy seismic block.

Mean load is applied by a motor located in the base of the system. The motor drives the four corner gearboxes through two shafts and applies mean loads in both tension and compression. The mean-load force is carried by the box-type structure of springs, and the level either is adjusted by a hand-held controller or is maintained at a level preset by the controller. The magnet air gap is maintained automatically by the action of the gap servomotor driving a wedge beneath the electromagnet. A linear variable displacement transformer (LVDT) constantly monitors the air gap, and control is maintained even when the mean load is changed while the machine is running. A manually operated drive located in the upper mass permits major adjustment of specimen spacing.

The electromagnet excites the dual-mass system at its natural frequency by means of pulse excitation. This feature enables a simple switch to replace the conventional power amplifier, thus providing high reliability at low cost and, in addition, eliminating the need to tune an oscillator to the natural frequency of the system. Closed-loop amplitude control is achieved by controlling the pulse power to the magnet from the error between the actual and demanded load amplitudes, thereby providing fast response to changing load demands. A strain-gaged load cell provides accurate load monitoring and digital indication of peak dynamic load, mean load, and frequency.

**Ultrasonic fatigue testing** involves cyclic stressing of material at frequencies typically in the range of 15 to 25 kHz. The major advantage of using ultrasonic fatigue is its ability to provide near-threshold data within a reasonable length of time. High-frequency testing also provides rapid evaluation of the high-cycle fatigue limit of engineering materials as described in the article "Ultrasonic Fatigue Testing" in *Mechanical Testing*, Volume 8, *Metals Handbook*, 9th edition.

**Corrosion Fatigue Life Testing.** High-cycle corrosion fatigue tests (performed in the range of  $10^5$  to  $10^9$  cycles to failure) are typically done at a relatively high frequency of 25 to 100 Hz to conserve time. Multiple, inexpensive rotating-bend machines are often dedicated to these experiments. Low-cycle corrosion fatigue tests (in the regime where plastic strain,  $\epsilon_p$ , dominates) follow from the ASTM standard for low-cycle fatigue testing in air (ASTM E 606).

For aqueous media, the typical cell for corrosion fatigue life testing includes an environmental chamber of glass or plastic that contains the electrolyte. The specimen is gripped outside of the test solution to preclude galvanic effects. The chamber is sealed to the specimen, and solution can be circulated through the environmental cell. The setup should include reference electrodes and counter electrodes to enable specimen (working electrode) polarization with standard potentiostatic procedures. Care should be taken to uniformly polarize the specimen, to account for voltage drop effects, and to isolate counter electrode reaction products. If potential is controlled, control of the oxygen content of the solution may not be necessary, although highly deaerated solutions are considered prudent.

Environmental containment for high-cycle and low-cycle corrosion fatigue life testing is similar, but the overall setup for low-cycle (strain-controlled) testing is more complicated because gage displacement must be measured. For strain-controlled fatigue life, testing in simple aqueous environments, diametral or axial displacement is measured by a contacting but galvanically insulated extensometer, perhaps employing pointed glass or ceramic arms extending from an extensometer body located outside of the solution. Hermetically sealed extensometers or linear-variable-differential transducers can be submerged in many electrolytes over a range of temperatures and pressures. Alternately, the specimen can be gripped in a horizontally mounted test machine and be half submerged in the electrolyte with the extensometer contacting the dry side of the gage. For simple and aggressive environments, grip displacement can be measured external to the cell-contained solution, such as for high-temperature water in a pressurized autoclave. It is necessary to conduct low-cycle fatigue tests in air (at temperature), with an extensometer mounted directly on the specimen gauge, to relate grip displacement and specimen strain.

## Fatigue Life Data

It has long been recognized that fatigue data, when resolved into elastic and plastic terms, can be represented as linear functions of life on a logarithmic scale. Figure 41 schematically shows this representation of elastic and plastic components, which together define the total fatigue life curve of a material. The general fatigue-life relation, expressed in terms of the strain range ( $\Delta\epsilon$ , where  $\Delta\epsilon$  is the strain change from cyclic loading), is as follows:

$$\Delta\epsilon = \Delta\epsilon_e + \Delta\epsilon_p \quad (\text{Eq 27})$$

where  $\Delta\epsilon_e$  is the elastic strain range,  $\Delta\epsilon_p$  is the plastic strain range, and where:

$$\frac{\Delta\epsilon_e}{2} = \frac{\sigma'_f}{E} (2N_f)^b \quad (\text{Eq 28})$$

$$\frac{\Delta\epsilon_p}{2} = \epsilon'_f (2N_f)^c \quad (\text{Eq 29})$$

Therefore, the total strain amplitude (or half the total strain range,  $\Delta\epsilon/2$ ) can be expressed as the sum of Eq 28 and 29:

$$\frac{\Delta\epsilon}{2} = \epsilon'_f (2N_f)^c + \frac{\sigma'_f}{E} (2N_f)^b \quad (\text{Eq 30})$$

where  $\epsilon'_f$  is the fatigue ductility coefficient,  $\sigma'_f$  is the fatigue strength coefficient,  $b$  is the fatigue strength exponent,  $c$  is the fatigue ductility exponent, and  $N_f$  is the number of cycles to failure.

**Fig. 41** Schematic of fatigue life curve with the Manson four-point criteria for the elastic and plastic strain lines.  $D$  is the tensile ductility,  $\sigma_f$  is the fracture stress (load at fracture divided by cross-sectional area after fracture), and UTS is conventional ultimate tensile strength.

These four empirical constants ( $b$ ,  $c$ ,  $\sigma'_f$ ,  $\epsilon'_f$ ) form the basis of modeling strain-life behavior for many alloys, although it must be noted that some materials (such as some high-strength aluminum alloys and titanium alloys) cannot be represented by Eq 30.

For many steels and other structural alloys, substantial data have been collected for the four parameters in Eq 30. In many cases, the four fatigue constants have been defined by curve fitting of existing fatigue life data. A collection of this data is tabulated in *Fatigue and Fracture*, Volume 19, *ASM Handbook*.

The four fatigue constants can also be estimated from monotonic tensile properties. With the availability of extensive data, however, these techniques are not widely used. Nonetheless, the "four-point method" is a method to estimate fatigue life behavior from tensile properties. This method can be used to compare fatigue and tensile properties.

In addition, it should also be mentioned that the four fatigue constants are also related to the following parameters:

$$K' = \frac{\sigma'_f}{(\epsilon'_f)^{n'}} \quad (\text{Eq 31})$$

$$n' = b/c \quad (\text{Eq 32})$$

where  $K'$  is the cyclic strength coefficient and  $n'$  is the cyclic strain hardening exponent in the power-law relation for a log-log plot of the completely reversed stabilized cyclic true stress ( $\sigma$ ) versus true plastic strain ( $\epsilon_p$ ), such that  $\sigma = K'(\epsilon_p)^{n'}$ . The use of power-law relationship is not based on physical principles, although the relationships in Eq 31 and 32 may be convenient for mathematical purposes. The parameters  $K'$  and  $n'$  are usually obtained from a curve fit of cyclic stress-strain data.

### Four-Point Method

Numerous studies have been devoted to the development of techniques for estimating strain-controlled fatigue characteristics (per Eq 30). For the most part, these studies dealt with data generated under completely reversed strain cycling (i.e.,  $R = -1$ , or  $A = \infty$ ) and usually attempted to relate fatigue properties with tensile properties. Extensions of these studies have carried the estimating procedures a step further, addressing the correlation of fatigue data obtained at various strain ratios ( $R$ ).

Two common methods for approximating the shape of a fatigue curve are the "method of universal slopes" and the "four-point correlation" method. These two methods have been known for many years. The method of universal slopes, first proposed by Manson, is based on the relation:

$$\Delta\epsilon = 3.5 \frac{\text{UTS}}{E} (N_f)^{-0.12} + \epsilon_f^{0.6} (N_f)^{-0.6} \quad (\text{Eq 33})$$

where UTS is ultimate strength,  $E$  is modulus of elasticity, and  $\epsilon_f$  is true fracture ductility, or  $\ln [1/(1 - RA)]$ .

This approximation thus requires only tensile strength, modulus, and reduction in area (RA). However, note that it is based on strain range ( $\Delta\epsilon$ ) rather than strain amplitude ( $\Delta\epsilon/2$ ).

The four-point method also allows construction of fatigue life curves from more readily available handbook data (i.e., monotonic tensile data). This method can be compared with the traditional strain-based approach (Fig. 41) or a stress-based approach. In both cases, the four-point method is based on the premise that total fatigue life per Eq 30 can be estimated as the sum of elastic strain (Eq 28) and plastic strain (Eq 29) components. The step-by-step process for locating points on the plastic- and elastic-strain-life lines is described below for both strain-based and stress-based data.

**Strain-Based Four-Point Method.** The four-point method initially was developed in terms of strain range by Manson (Fig. 41). The four points in Fig. 41 are determined as follows:

- *Point  $P_1$  on the elastic strain line* is positioned at  $N_f = 0.25$  cycles (where a monotonic test is  $\frac{1}{4}$  of one fatigue cycle) and at an elastic strain range of  $2.5 \sigma_f / E$  (where  $\sigma_f$  is the fracture stress in a tensile test and  $E$  is the elastic modulus).
- *Point  $P_2$  on the elastic strain line* is positioned at  $N_f = 10$  cycles and at an elastic strain range of  $0.9 \text{ UTS} / E$ , where UTS is the conventional ultimate tensile strength.
- *Point  $P_3$  on the plastic strain line* is positioned at  $N_f = 10$  cycles, where the plastic strain range is  $0.25D^{3/4}$  and  $D$  is the conventional logarithmic ductility (also known as  $\epsilon_f$ ).
- *Point  $P_4$  on the plastic strain line* is positioned at  $N_f = 10^4$  cycles, where the plastic strain range is given by  $\Delta\epsilon_p$  (at  $10^4$  cycles) =  $0.0069 - 0.525 \Delta\epsilon_e$  (at  $10^4$  cycles), where the elastic strain-range line at  $N_f = 10^4$  cycles; ( $\Delta\epsilon_e$  at  $10^4$ ) is shown as  $\Delta\epsilon^*_e$  in Fig. 41.

Point  $P_1$  depends on fracture stress, which is not readily available in literature. However, fracture stress (which is the load at fracture divided by the area as measured after fracture) can be estimated by means of the following approximate relationship among fracture stress, ultimate tensile stress, and fracture ductility, thus,

$$\sigma_f = \text{UTS}(1 + D) \quad (\text{Eq 34})$$

This relation follows from Fig. 42, where each point is fixed by the data for one material.

**Fig. 42** Fracture stress versus tensile ductility

On the basis of the approximate equality in Eq 34, Manson noted that when  $E$  is known, only two tensile properties--ultimate tensile strength (UTS) and the reduction in area (to give  $D$ )--are needed to position the lines in Fig. 41 and thus obtain a prediction of fatigue behavior. Figure 43 shows a convenient graphical solution by Manson for locating the four points. For example, if  $\text{UTS}/E$  is 0.01 and the reduction in area is 50% ( $D = 0.694$ ), the value of  $P_2$  from the right-hand scale is 0.009 and that of  $P_3$  from the top scale is 0.18. Locating the point with the coordinates  $\text{UTS}/E = 0.01$  and reduction in area equal to 50% gives values for  $P_1$  and  $P_4$  of 0.042 and 0.0009, respectively. These points will locate the two strain-range lines, and the total strain-range curve can then be positioned to relate  $\Delta\epsilon$  and  $N_f$  for the material in question.

**Fig. 43** Graphical solution to obtain the four points ( $P_1$ ,  $P_2$ ,  $P_3$ , and  $P_4$ , in Fig. 41) to position the elastic and plastic strain-range lines.

**Stress-Based Four-Point Method.** The four-point also applies to the construction of a stress-based  $S-N$  fatigue curve, as shown in Fig. 44. The four points A, B, C, and D in Fig. 44 can be defined in terms of either stress or strain. In terms of strain, the points are identical to points  $P_1$ ,  $P_2$ ,  $P_3$ , and  $P_4$  in Fig. 41. For construction of an  $S-N$  fatigue curve, the points are determined as described below.

**Fig. 44** Schematic summary of four-point method for estimating fatigue strength or strain life

**Point A** (in terms of stress) is simply the ultimate tensile strength of the metal, plotted on the vertical axis of the graph at  $N = \frac{1}{4}$ . As in the strain-based approach, this assumes that the simple tensile test represents one-fourth of a single, completely reversed fatigue cycle--the peak positive value of the applied stress.

**Point B**, the right-hand locator of the elastic curve, is defined as the fatigue-endurance limit, if the metal has one; otherwise, point B is the endurance strength. Some ferrous alloys have an endurance limit, that is, a stress level below which fatigue failure will never occur, regardless of number of cycles. This is generally around  $10^7$  or  $10^6$  cycles, at which point the fatigue curve approaches zero-slope, or a horizontal line.

Many metals, particularly those that do not work harden, have no detectable endurance limit. Their long-life fatigue curves never become truly horizontal. For these metals, a pseudo-endurance limit, called endurance strength, is reported. Usually, this value is defined as the failure stress at some large number of cycles, for example,  $10^7$  to  $10^{10}$ .

Point B can also be obtained from tensile-test data--a virtue of this technique, as handbook values for fatigue-endurance strengths or limits are often not available. Figure 45 is used to find the fatigue-endurance value from yield strength and true ultimate tensile strength for the material. The "ductility parameter" is simply calculated from handbook tensile data using the equation on the horizontal axis of the graph. Then find the "endurance-to-yield" strength ratio for the appropriate material. Multiply this ratio by "yield strength" to find the endurance value, which is point B.

**Fig. 45** Plot for estimating fatigue-endurance limits (point B in Fig. 44) for common structural alloy groups

Beyond point B, the ratio of ultimate tensile strength to yield strength can be used to approximate the slopes of the long-life portion of the fatigue curve. According to many researchers, a ratio greater than 1.2 suggests that the material strain hardens sufficiently to produce a pronounced endurance limit value, and the curve assumes a zero slope. For ratios less than 1.2, however, the curve will continue to drop beyond point B. The lower the ratio below 1.2, the further the fatigue curve deviates from a horizontal, zero-slope line beyond point B.

Because both endurance strength and endurance limit are reported in terms of stress, this value must be divided by Young's modulus for the metal if the fatigue curve is being constructed in terms of strain.

**Point C** is a value known as "fracture ductility." If natural, or true, strain at fracture for a simple tension test is known (which would be the distance between gage points at fracture divided by initial gage length), fracture ductility is the natural log of this value.

In most cases, however, reduction of area for a simple tensile test is given in handbooks. As before in the discussion on the universal slopes method, fracture ductility,  $\epsilon_f$ , is estimated.

$$\epsilon_f = \ln \frac{100}{100 - RA} \quad (\text{Eq 35})$$

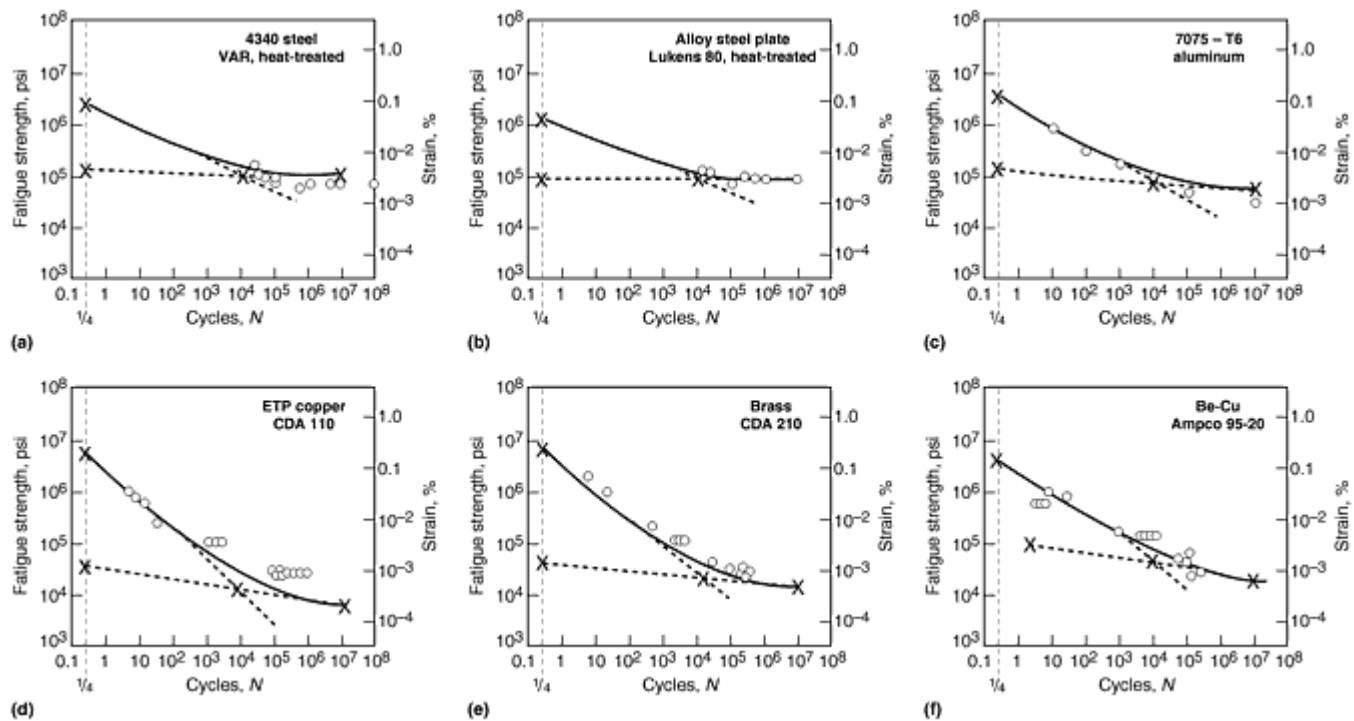

where RA is percentage reduction of area.

Because fracture ductility is in units of strain, this value must be multiplied by Young's modulus to obtain point C in terms of stress. In all cases, point C is also plotted at  $N = \frac{1}{4}$ .

**Point D** is defined as the intersection of the plastic and elastic curves at  $10^4$  cycles. (According to the theory of "universal slopes," elastic and plastic strain curves intersect at  $N = 10^4$ ). Thus, locate point D on the elastic curve and draw the plastic curve between points C and D. Now the fatigue curve can be drawn as the arithmetic summation of the elastic and plastic lines.

**Comparison with Data for Steel, Aluminum, and Copper Alloys.** To demonstrate the validity of the method described here, actual fatigue test results for various steel, aluminum, and copper alloys were compared with curves approximated from handbook data (P. Weihsmann, *Mater. Eng.*, March 1980, p 53). In addition, a more recent analysis by J.H. Ong (*Int. J. Fatigue*, Vol 15, 1993, p 13-19) on 49 steels demonstrates that the predicted values by the four-point correlation method and the universal slopes method give satisfactory agreement with experimental data. The analysis by Ong shows that the four-point method gives the best estimates for predicting fatigue properties from uniaxial tension tests.

Of the six comparisons shown (Fig. 46), fatigue data for steels and aluminum were taken from published sources. The measurements for copper fatigue are original, taken from tests on simulated squirrel-cage rotor, bar-to-end ring joints for induction motors.

**Fig. 46** Comparison of actual fatigue test results (open circles) with fatigue curves constructed by the four-point method from tensile data. Total fatigue life is a solid line and elastic and plastic components are dashed lines constructed from tensile data point (shown by Xs). (a) 4340 steel. (b) Alloy steel plate (Lukens 80). (c) 7075-T6 aluminum. (d) Electrolytic-tough-pitch (ETP) copper. (e) Brass. (f) Beryllium-copper alloy

Because these parts had been brazed prior to testing, the copper fatigue test data were assumed to represent essentially annealed material. Traceability of the data is not "ideal" in these cases, as handbook tensile data for the approximated curves were selected for truly annealed materials. Nevertheless, correlation between fatigue test data and the curves drawn from annealed tensile data is quite good, indicating that this technique appears to be perfectly acceptable for copper alloys as well.

Figures 46(a) to (f) were prepared from actual fatigue-test data (open circles) and from handbook tensile data (Xs). Fatigue curves constructed according to the techniques outlined in this article are shown in solid curves. Elastic and

plastic strain curves used in the construction of the fatigue curves are dashed. While this is no substitute for thorough, conventional fatigue testing, reasonable correlation between the actual fatigue data and the simulated curves indicates that this technique can be a quick shortcut for approximating fatigue-life information.

## Fatigue Crack Growth Testing

TESTING OF SMOOTH OR NOTCHED SPECIMENS generally characterizes the overall fatigue life of a specimen material. This type of testing, however, does not distinguish between fatigue crack initiation life and fatigue crack propagation life. With this approach, pre-existing flaws or crack-like defects, which would reduce or eliminate the crack initiation portion of the fatigue life, cannot be adequately addressed. Therefore, testing and characterization of fatigue crack growth is used extensively to predict the rate at which subcritical cracks grow due to fatigue loading. For components that are subjected to cyclic loading, this capability is essential for life prediction, for recommending a definite accept/reject criterion during nondestructive inspection, and for calculating in-service inspection intervals for continued safe operation.

## Fracture Mechanics in Fatigue

Linear elastic fracture mechanics is an analytical procedure that relates the magnitude and distribution of stress in the vicinity of a crack tip to the nominal stress applied to the structure; to the size, shape, and orientation of the crack or cracklike imperfection; and to the crack growth and fracture resistance of the material. The procedure is based on the analysis of stress-field equations, which show that the elastic stress field in the region of a crack tip can be described by a single parameter,  $K$ , called the stress-intensity factor. This same procedure is also used to characterize fatigue crack growth rates ( $da/dN$ ) in terms of the cyclic stress-intensity range parameter ( $\Delta K$ ).

When a component or a specimen containing a crack is subjected to cyclic loading, the crack length ( $a$ ) increases with the number of fatigue cycles,  $N$ , if the load amplitude ( $\Delta P$ ), load ratio ( $R$ ), and cyclic frequency ( $\nu$ ) are held constant. The crack growth rate,  $da/dN$ , increases as the crack length increases during a given test. The  $da/dN$  is also higher at any given crack length for tests conducted at higher load amplitudes. Thus, the following functional relationship can be derived from these observations:

$$\left( \frac{da}{dN} \right)_{R\nu} = f(\Delta P, a)$$

where the function  $f$  is dependent on the geometry of the specimen, the crack length, the loading configuration, and the cyclic load range.

The general nature of fatigue-crack growth and its description using fracture mechanics can be briefly summarized by the example data shown in Fig. 47. This figure shows a logarithmic plot of the crack growth per cycle,  $da/dN$ , versus the stress-intensity-factor range,  $\Delta K$ , corresponding to the load cycle applied to a specimen. The  $da/dN$ -versus- $\Delta K$  plot shown is from five specimens of ASTM A 533 B1 steel tested at 24 °C (75 °F). A plot of similar shape is expected with most structural alloys; the absolute values of  $da/dN$  and  $\Delta K$  are dependent on the material. Results of fatigue-crack-growth-rate tests for nearly all metallic structural materials have shown that the  $da/dN$ -versus- $\Delta K$  curves have the following characteristics: a region at low values of  $da/dN$  and  $\Delta K$  in which fatigue cracks grow extremely slowly or not at all below a lower limit of  $\Delta K$  called the threshold of  $\Delta K$ ,  $\Delta K_{th}$ ; an intermediate region of power-law behavior described by the Paris equation:

$$\frac{da}{dN} = C(\Delta K)^n$$

where  $C$  and  $n$  are material constants; and an upper region of rapid, unstable crack growth with an upper limit of  $\Delta K$  that corresponds either to  $K_{Ic}$  or to gross plastic deformation of the specimen.

**Fig. 47** Fatigue-crack-growth behavior of ASTM A 533 B1 steel with a yield strength of 470 MPa (70 ksi). Test conditions:  $R = 0.10$ ; ambient room air; 24 °C (75 °F)

## Test Methods

Testing procedures for measuring fatigue-crack-growth rates are described in ASTM method E 647. This method applies to medium-to-high crack-growth rates—that is, above  $10^{-8}$  m/cycle ( $3.9 \times 10^{-7}$  in./cycle). For applications involving fatigue lives of up to about  $10^8$  load cycles, the procedures of E 647 can be used. Fatigue lives greater than about  $10^6$  cycles correspond to growth rates below  $10^{-8}$  m/cycle, and these require special testing procedures, which are related to the threshold of fatigue-crack growth shown in Fig. 47.

ASTM method E 647 describes the use of center-cracked specimens and compact specimens. The specimen thickness-to-width ratio,  $B/W$ , is smaller than the 0.5 value for  $K_{Ic}$  tests; the maximum  $B/W$  values for center-cracked and compact specimens are 0.125 and 0.25, respectively. With the thinner specimens, it is feasible to use crack-length measurements on the sides of the specimens as representations of through-thickness crack-growth behavior. The specimens are loaded in the same general manner as for  $K_{Ic}$  testing. For tension-tension fatigue loading, the  $K_{Ic}$  loading fixtures often can be used. For this type of loading, both the maximum and minimum loads are tensile, and the load ratio,  $R = P_{min}/P_{max}$ , is in the range  $0 < R < 1$ . A ratio of  $R = 0.1$  is commonly used. Tension-compression loading can be performed with the compact specimen, but it is a more complex type of loading and requires more care.

Testing normally is performed in laboratory air at room temperature; however, any gaseous or liquid environment and temperature of interest may be used in order to determine the effect of corrosion or other chemical reaction on cyclic loading. Cyclic loading may involve various wave forms for constant-amplitude loading, spectrum loading, or random loading.

For constant-amplitude loading, a set of crack-length-versus-elapsed-cycle data ( $a$  versus  $N$ ) is collected, with the specimen loading,  $P_{max}$  and  $P_{min}$ , generally held constant. The minimum crack length increment  $\Delta a$ , between data points is required by ASTM E 647 to be larger than a certain measurement of erroneous growth rates from a group of data points

that are too closely spaced relative to the precision of data measurement and relative to the scatter of the data. The growth rates may be calculated by either of two methods. The secant method is simply the slope of the straight line connecting two adjacent data points. This method, although simpler, results in more scatter in measured crack-growth rate. The polynomial method fits a second-order polynomial expression (parabola) to typically 5 to 7 adjacent points, and the slope of this expression is the growth rate. The polynomial method, particularly when used with a large number of adjacent points, eliminates some of the scatter in growth rate, which is inherent in fatigue testing. The measured values of growth rate typically are plotted as in Fig. 47, where  $\Delta K$  is calculated from  $\Delta P = P_{\max} - P_{\min}$  (for tension-tension loading) using a  $K$  expression.

The measured growth-rate data are represented by an equation of the form of the Paris equation:

$$\frac{da}{dN} = C(\Delta K)^n$$

where the material constants  $C$  and  $n$  apply only within a certain range of  $da/dN$  and  $\Delta K$  values. Other relationships based on the Paris equation, such as the commonly used Forman equation, are used to represent the variation of  $da/dN$  with other key variables, including load ratio,  $R$ , and the critical  $K$  value,  $K_c$ , at which fast fracture of the specimen occurs. The Forman equation is:

$$\frac{da}{dN} = \frac{C (\Delta K)^n}{(1 - R) K_c - \Delta K}$$

where  $C$  and  $n$  are material constants of the same types as those in the Paris equation, but of different values. An advantage of the Forman equation is that it describes the type of accelerate  $da/dN$  behavior that is often observed at high values of  $\Delta K$  and is not described by the Paris equation. For example, for zero-to-tension loading (in which  $R = P_{\min}/P_{\max} = 0$ ), as  $\Delta K$  approaches  $K_c$  in the Forman equation,  $da/dN$  increases rapidly, and this is often observed in tests. In addition, the Forman equation describes the often-observed decrease in  $da/dN$  associated with an increase in  $R$  from zero toward one. So when it is necessary to describe the effect of  $\Delta K$  approaching  $K_c$ , or the effect of  $R$  on  $da/dN$ , the Forman equation can be used to represent the  $da/dN$  behavior. When only  $\Delta K$ , the primary variable affecting  $da/dN$ , is involved, the less complex Paris equation may be used.

**Cyclic crack growth rate testing in the low-growth regime** (region 1 in Fig. 47) complicates acquisition of valid and consistent data, because the crack growth behavior becomes more sensitive to the material, environment, and testing procedures in this regime. Within this regime, the fatigue mechanisms of the material that slow the crack growth rates are more significant (see the article "Fatigue Crack Threshold Behavior and Analysis" in *Fatigue and Fracture*, Volume 19, *ASM Handbook*).

It is extremely expensive to obtain a true definition of  $\Delta K_{th}$ , and in some materials a true threshold may be nonexistent. Generally, designers are more interested in the fatigue crack growth rates in the near-threshold regime, such as the  $\Delta K$  that corresponds to a fatigue crack growth rate of  $10^{-8}$  to  $10^{-10}$  m/cycle ( $3.9 \times 10^{-7}$  to  $10^{-9}$  in./cycle). Because the duration of the tests increases greatly for each additional decade of near-threshold data ( $10^{-8}$  to  $10^{-9}$  to  $10^{-10}$ , etc., m/cycle), the precise design requirements should be determined in advance of the test. Although the methods of conducting fatigue crack threshold testing may differ, ASTM E 647 addresses these requirements.

In all areas of crack growth rate testing, the resolution capability of the crack measuring technique should be known; however, this becomes considerably more important in the threshold regime. The smallest amount of crack length resolution as possible is desired, because the rate of decreasing applied loads (load shedding) is dependent on how easily the crack length can be measured. The minimum amount of change in crack growth that is measured should be ten times the crack length measurement precision. It is also recommended that for noncontinuous load shedding testing, where  $(P_{\max 1} - P_{\max 2})/P_{\max 1} > 0.02$ , the reduction in the maximum load should not exceed 10% of the previous maximum load, and the minimum crack extension between load sheds should be at least 0.50 mm (0.02 in.).

In selecting a specimen, the resolution capability of the crack measuring device and the  $K$ -gradient (the rate at which  $K$  is increased or decreased) in the specimen should be known to ensure that the test can be conducted appropriately. If the measuring device is not sufficient, the threshold crack growth rate may not be achieved before the specimen is separated

in two. To avoid such problems, a plot of the control of the stress intensity ( $K$  versus  $a$ ) should be generated before selection of the specimen.

When a new crack-length measuring device is introduced, a new type of material is used, or any other factor is different from that used in previous testing, the  $K$ -decreasing portion of the test should be followed with a constant load amplitude ( $K$ -increasing) to provide a comparison between the two methods. Once a consistency is demonstrated, constant-load amplitude testing in the low crack growth rate regime is not necessary under similar conditions.

## Creep, Stress-Rupture, and Stress-Relaxation Testing

THE FLOW or plastic deformation of a metal held for long periods of time at stresses below the normal short-time yield strength is known as creep. Although we normally think of creep as occurring only at elevated temperatures, room temperature can be high enough for creep to occur in some metals. In lead, for example, creep at room temperature is common. In many cases, lead pipes must be supported to prevent sagging under their own weight.

The development of steam turbines and jet engines has greatly increased interest in creep because, in these, the metal parts must withstand high loads at high temperatures for long times. The high centrifugal loads tend to cause certain parts to elongate or distort. Tolerances must be kept close to be efficient; yet if the metal parts deform too much, this spacing will be eliminated and failure will occur. In most cases, the parts cannot be made sufficiently heavy to prevent all creep because the weight penalty would reduce efficiency too much. Many such parts are therefore designed for a certain expected life span. For this, accurate data are needed to determine how much the metal part can be expected to deform under the conditions of stress and temperature to be encountered in service. Tests that measure the deformation of a metal as a function of time at constant load and temperature are known as creep tests.

## Creep Phenomena

A typical creep curve is shown in Fig. 48. The vertical ( $y$ ) axis is creep strain and the horizontal ( $x$ ) axis is time plotted on logarithmic coordinate. The curve consists of three parts: primary, secondary, and tertiary creep, or first-, second-, and third-stage creep. The strain shown is plastic or permanent strain. When a creep specimen is loaded, there will be some elastic extension of the specimen, but this is not shown in this curve. In the primary stage, the initial creep rate shows a continuous decrease with time. In second-stage creep, the creep rate is considered essentially constant. In the third stage, the strain rate increases rapidly to fracture. This increase in the third stage is due, in part, to the reduction in cross-sectional area and thus the increasing true stress. Measurements made of specimen cross section during third-stage creep indicate that the increase in strain rate is not due only to necking or reduction in cross-sectional area, however.

**Fig. 48** Idealized creep curve

Although, in the idealized creep curve shown in Fig. 48, the creep rate is shown as constant in the second stage, this does not occur in practice. If the test is long enough to show all stages of creep, the curve will show a continually diminishing

rate of creep to a point where the curve inverts and the creep rate starts to increase again (Fig. 49). The change in rate may be very slight over time; in some cases, the curve may approach a straight line.

**Fig. 49** Creep curve with minimum creep rate and point of inversion

## Rupture Tests

The rupture test is valuable in determining tendencies of materials that may have to break under an overload. It finds much use in selection of materials for applications where dimensioned tolerances are not critical but rupture could not be tolerated. The rupture test is similar to a creep test except that no strain measurements are made during the test. The specimen is stressed under a constant load at constant temperature as in the creep test, and the time for fracture to occur is measured. Measurements are also made of the elongation and reduction in area of the broken specimen. Stresses are higher than those used for creep tests. An example of a typical application of the rupture test would be for testing boiler pipes. This test is also called the stress-rupture test, or time-to-rupture test.

## Relaxation Tests

The relaxation test is somewhat similar to the creep test, but the load continually decreases instead of remaining constant. This test is primarily of value in evaluating bolt materials. When a bolt is drawn up tight, a tensile load is present in the bolt and the bolt is elongated slightly. This causes a clamping load on whatever the bolt is mounted on. If the bolt creeps (extends or relaxes), this clamping load will be reduced. If the bolt elongates sufficiently to remove all tension, it no longer fulfills its function. In a relaxation test, the load is reduced at intervals in order to maintain a constant elongation (strain). A relaxation curve thus takes the general shape shown in Fig. 50. Note that the y-axis in this curve is stress or load rather than strain (elongation) as in the creep curve.

**Fig. 50** Relaxation curve

## Typical Procedure for Making a Creep Test

**Selection and Preparation of Specimen.** The same precautions used in selecting and preparing a specimen for a short-time tension test apply to specimens for creep testing. The specimen should be selected to be truly representative of that which it is supposed to represent. Machining and grinding should follow procedures to produce a surface as nearly stress-free as possible. There should be no undercutting at the fillets, and the gage length should be uniform in cross section or very slightly smaller at the center of the gage length.

The specimen is carefully identified in as much detail as is appropriate--type of metal, heat number, vendor, etc.--and this information is recorded with the specimen's measurements. Sometimes gage marks, for measuring total extension, are made on the specimen. Such marks or scribe lines must be used with care, because the depressions or scribe lines can cause premature failure on some materials. Any operation, such as stamping the ends of the specimen, must be used with care to avoid any damage to the specimen.

**Loading.** In mounting the specimen in the adapters and load train, care is needed to avoid straining of the specimen in handling. Strain can occur when threading the specimen into the adapters and when handling the load train with the specimen in place, especially if the specimen is very small or brittle. The load train (specimen adapters or grips, pull rods, etc.) with the specimen in place should be carefully examined for any misalignment that will cause bending of the specimen under load. The upper load train should be suspended from the lever arm and the compensating weight adjusted so that the lever arm balances. The strain-measuring clamps and extensometer or the platinum strips are attached to the specimen, and the load train is inserted into the furnace with the specimen centered. The specimen must be stabilized at temperature before being loaded. Also, the extensometer should be adjusted and zeroed.

Loading of the weight pan should be done smoothly and without excessive shock. If the specimen is to be step loaded, the weight is placed on the weight pan in measured increments and the strain corresponding to each step of loading is recorded. The loading curve thus obtained is used in determining the elastic modulus. If step loading is not used, a method of applying the load smoothly must be used. Smooth application can be done by having a support such as a scissors jack under the load pan during loading. When all weights are in place, the supporting jack is smoothly lowered from under the weight pan.

**Data Collection.** Reading of strain should be made frequently enough to define the curve well. This diligence will necessitate much more frequent readings during the early part of the test than later. The elastic portion of the stress-strain curve can be obtained by measurement of the instantaneous contraction when the load is removed at the end of the test if the specimen has not broken.

**Temperature Control.** In bringing the specimen to temperature, it is important that the specimen not be overtemperated. A common practice is to bring the specimen up to about 30 °C (50 °F) below the desired temperature in about 1 to 4 h, and then take considerably longer in bringing the specimen to the desired temperature and adjusting for good stabilization. It should be understood that a period of time above the desired temperature is not cancelled in effect by an equal period at a temperature the same amount below the desired temperature. Any rise in temperature above the desired temperature of more than a small amount (such as defined by ASTM Recommended Practice for Conducting Creep and Time for Rupture Tension Tests of Materials) should be rejected. The limits specified in this recommendation are  $\pm 1.7$  °C ( $\pm 3$  °F) up to 980 °C (1800 °F) and  $\pm 2.8$  °C ( $\pm 5$  °F) above 980 °C (1800 °F). At temperatures very much above 1095 °C (2000 °F), the limits are broadened somewhat. Variation of temperature along the specimen from the nominal test temperature should vary no more than these limits at these temperatures. These limits refer to indicated variations in temperature according to the temperature recorder.

Every effort should be made to ensure that the indicated temperature is as close to true temperature as possible. There is the possibility of both thermocouple error and instrument error. Thermocouples, especially base-metal thermocouples, drift in calibration with use or because of contamination. Other possible errors can result from incorrect lead wires or incorrect connection of lead wires, direct radiation on the thermocouple bead, or other causes. Representative thermocouples should be calibrated from each lot of wires used for base-metal thermocouples, and, except at low temperatures, base-metal thermocouples should not be re-used without slipping back to remove the wire exposed to high temperatures and rewelding. Noble-metal couples are generally more stable. However, they are also subject to error due to contamination and need to be annealed periodically. Annealing can be done by connecting a variable transformer to the two wires and sending enough current through the wire to make it incandescent.

When the thermocouple is attached to the specimen, the junction must be kept in intimate contact with the specimen. The bead at the junction should be as small as possible, and there must be no twisting of the thermocouple elsewhere that could cause shorting. Any other metal contact across the two wires will cause shorting and erroneous readings. Many authorities recommend shielding the thermocouple junction from radiant heating.

Temperature-measuring, controlling, and recording instruments must be calibrated periodically against some standard. The calibration is usually done by connecting a precision potentiometer to the thermocouple terminals on the instrument and feeding in millivoltages corresponding to the output of the thermocouple at each of several temperatures. Tables of millivolt output for various types of thermocouples are readily available from manufacturers of precision potentiometers. Most creep and rupture machines are equipped with a switch that automatically shuts off the timer when the specimen breaks. In creep tests, the load is usually selected low enough so that rupture does not occur. The microswitch that shuts off the timer also shuts off or lowers the temperature of the furnace on many other creep-rupture units. In some furnaces, the life of the heating element is severely reduced if the furnace is shut off after each test; so for some furnaces the temperature is lowered to some lower control temperature, such as 540 or 650 °C (1000 or 1200 °F).

**Interrupted Tests.** Sometimes, because of a power failure or other problem, it becomes necessary to interrupt a test, for instance, the specimen is cooled, then reheated. For many materials, this change appears to have little effect on either creep properties or time to rupture if the times of cooling and heating are not very great. It cannot be stated, however, that such treatment will not affect any materials. Any interruption of a test should be reported.

## Presentation of Data

**Creep.** The usual method for presenting creep data is in the form of a curve showing percent creep strain as the vertical axis and time as the horizontal axis. Time is usually plotted on a log scale to show the early part of the curve in good detail and yet prevent the curve from being excessively long. Sometimes a whole family of curves is plotted on the same coordinates to show the effect of different temperatures or different stresses on one material.

Other methods for plotting data include time to reach a given percent of creep versus load at a constant temperature or time to reach a given percent of creep versus temperature at constant load.

The loading curve, showing the strain versus load as the specimen is loaded, is plotted separately and is used in computing the elastic modulus of the material at temperature.

**Rupture.** Rupture data are presented in several types of graphs. One type has stress as the vertical axis versus log of time-to-rupture (at constant temperature) on the horizontal axis. Usually, stress-rupture data are presented by means of a parameter plot. Stress is plotted against a parameter value that relates to both time and temperature. Several different parameters have been used. A widely used one, the Larson-Miller parameter, follows the formula  $P = (T + 460)(\log t + c)$ . This means that the parameter value  $P$  equals the Rankine temperature (460 + the temperature,  $T$ , in degrees Fahrenheit) times the log (base 10) of the time,  $t$ , in hours plus a constant  $c$ . The constant ( $c$ ) has various values depending on the material but usually runs from about 17 to 23 for most materials tested. The value of  $c$  is determined by plotting log of time versus  $1/[T(^{\circ}\text{F}) + 460]$  using rupture data from several tests at constant stress but different temperatures on the same material. This produces a series of straight lines converging as on a single point. At this point  $\log t = c$ , and this constant is theoretically the best constant to use for the data involved.

## Shear Testing

---

IN GENERAL, the amount of existing shear-strength data is seriously less than the published data available for other mechanical properties. Stores of data that deal with mechanical properties, such as tensile and yield strength, hardness, and ductility for virtually all metals and metal alloys, and in a wide variety of conditions, are readily obtainable.

At least two reasons can be identified to explain the scarcity of shear-strength data. First, the demand is low, because the number of components that are loaded in shear under service conditions is far less than that of components loaded in tension, compression, bending, or torsion. Probably the primary reason for the lack of published data on shear strength is the difficulty in obtaining accurate test data. Shear testing inherently involves a number of variables; thus, the tests are less reproducible than testing for properties, such as tensile or yield strength. Therefore, most shear testing has been

performed by means of nonstandard equipment and procedures operating on arbitrary bases, thus producing results that are empirical.

The greatest needs for shear-test data are in the designing of structures that are riveted, pinned, or bolted together and where service stresses are actually in shear. Notable examples of such structures are found in the aerospace industry. The required standardization is given by ASTM B 565.

## Single- and Double-Shear Testing

In the many tests that have been devised for evaluating shear strength, both single- and double-shear testing have been used. The double-shear technique is far more accurate, however, making those results more reproducible than results for the single-shear technique.

Compression-type loading for a shear fixture is shown in Fig. 51, with a specimen being tested in double shear. This type of fixture may also be used for single-shear tests.

**Fig. 51** Shear test fixture of the compression loading type used for single or double shear test. Courtesy Tinius Olsen Testing Machine Company

**Procedure.** The test specimen is assembled in the fixtures, per ASTM B 565, and loaded in tension until complete failure occurs. Crosshead speed during the test should not exceed 19.1 mm/min (0.750 in./min), and loading rate should not exceed 690 MPa/min (100 ksi/min). The maximum load in double shear is determined by the direct reading on the testing machine.

## Calculation of Shear Stress

The calculation of stress in double shear is a simple matter of dividing the machine load by the area of the cross section ( $\pi D^2/4$ ). It follows, then, that single-shear stress is one-half of this value, or:

$$\text{Single-shear stress} = \frac{P/2}{\pi D^2/4}$$

where  $P$  is load in kilograms (pounds), and  $D$  is diameter in millimeters (inches).

As previously stated, shear testing is more vulnerable to the effects of variables than certain other mechanical tests, such as tests for tensile or yield strength. Even when the fixtures and test specimens meet specified tolerances, some variations are bound to exist in the test-jig assembly that will be reflected as variables in the results.

The presence or absence of lubricant on the surfaces of the specimens and test fixtures can be responsible for substantial variations in the results. For example, a lubricated specimen may cause a reduction in shear strength of as much as 3%.

To minimize this variable, it is recommended that the test fixtures and specimens be carefully cleaned prior to testing, preferably by means of ultrasonic cleaning in a suitable solvent.

## Torsion Testing

IN THE TORSION TEST, a specimen is subjected to twisting or torsional loads to simulate service stresses for such parts as axles, crankshafts, twist drills, and spring wire. The test has not been standardized and is rarely specified. However, the torsion test provides information such as modulus of elasticity in shear (sometimes called modulus of rigidity), the shearing yield strength, and the modulus of rupture (apparent ultimate shear strength). The torsion test may also be performed as a high-temperature twist test on materials such as tool steels to determine forgeability. The test does not provide meaningful results for very brittle materials such as cast irons, because these materials would fail in diagonal tension before the shear-strength limit was reached.

## General Procedure

In torsion testing, the specimen is clamped in clamping heads so that the specimen remains as straight as possible during testing. The test specimen is then twisted at a slow, uniform rate until it breaks, or until a specified number of turns is obtained. The number of turns is recorded. If the number of turns falls within an acceptable range, the test specimen is considered to have passed the test. Results of the torsion test are largely comparative and have no standardized values.

Torsion testing is frequently employed to assess the quality of brazed joints for sheet-metal products. A T-joint of sufficient length is brazed and then subjected to two full turns in torsion. Visual examination is made to determine if failure has occurred in the brazed joint.

One of the only standardized applications of the torsion test applies to torsion testing of wire (ASTM E 558).

An example of a torsion-testing machine is presented in Fig. 52.

**Fig. 52** Close-up of a 10,000 in. · lb (1100 N · m) torsion-testing machine with special tooling for Phillips screwdriver bits. Courtesy of Tinius Olsen Testing Machine Company

## Data

Torsion data are usually presented as torque-twist curves, in which the applied torque is plotted against the angle of twist. Torsion produces a state of stress known as pure shear, and the shear stress at yielding can be calculated from the torque at yielding and the specimen dimensions. The maximum stress for a cylindrical specimen (at the surface) can be calculated from the following relation:

$$S = \frac{16T}{\pi d^3}$$

where  $S$  is maximum shear stress in MPa (ksi),  $T$  is torque in N · m (lb · in.), and  $d$  is specimen diameter in cm (in.). This formula holds only when the strain is proportional to stress, but it is commonly used for computing higher stresses and for determining modulus of rupture (apparent ultimate shear strength).

The total torsional deformation is measured as angular twist of one end of the gage length in relation to the other. In order to obtain the angular twist per inch of gage length, the total angular twist is divided by the gage length. The angular twist per inch of gage length can then be converted into shear strain, in inches per inch, by multiplying by half the diameter of the specimen.

$E_s$ , the modulus of elasticity in shear (sometimes called the modulus of rigidity), can be calculated from the following formula:

$$E_s = \frac{SL}{r\theta}$$

where  $S$  is maximum shear stress, in MPa (ksi);  $L$  is the gage length of the specimen, in cm (in.);  $r$  is the distance from the axis of the specimen to the outermost fiber (half the diameter), in cm (in.); and  $\theta$  is the angle of twist, expressed in radians, in length  $L$ .

The yield strength is generally defined as the maximum stress developed by a torque producing an offset of 0.2% from the original modulus line, analogous to the method used for determining tensile yield strength.

## Comparison of Torsional and Tension Data

From the torque-twist diagram it is simple to obtain a shear stress-shear strain diagram. The great advantage of the torsion test over the tension test is that large values of strain can be obtained without complications such as necking. One problem of torsional tests is that the stress is not constant throughout the cross section. This problem can be circumvented by using tubular specimens. If the results of a tension test and a torsion test are plotted for the same low-carbon steel, the two curves will be markedly different. However, if the two curves are normalized by converting the normal stress and longitudinal strain in the uniaxial test and the shear stress and strain in the torsion test into effective stress and strain, the two curves come into close correspondence. The effective stresses and strains are determined by well-known equations (for instance, Eq. 1.67 and 1.81 in *Mechanical Metallurgy: Principles and Applications*, by M.A. Meyers and K.K. Chawla, Prentice-Hall, 1984). These results show that the work hardening of the material is a function of the amount of plastic strain and does not depend on the state of stress. Such is not the case for all materials, however. Differences in texture due to different constraints can be responsible for substantial differences in the effective stress-strain curve.

## Formability Testing

FORMABILITY is the technical term used to describe the ease with which a metal can be shaped through plastic deformation. Usually, it is synonymous with the term "workability." The evaluation of the formability of a metal involves both measurement of resistance to deformation (strength) and determination of the extent of plastic deformation that is possible before fracture (ductility). The emphasis in most formability tests, however, is on the amount of deformation required to cause fracture.

Because of the diverse geometries of the tools and workpieces and the various ways that forces of deformation are applied, different metalworking processes produce varying stress states. These can be divided into two broad categories: bulk-deformation processes, such as forging, extrusion, and rolling, where the stress state is three-dimensional, and sheet-forming processes, such as deep drawing and stretch forming, where the stress state is two-dimensional and lies in the plane of the sheet. The tests that simulate bulk-formability testing are given in the section "Compression Testing" in this article.

## Bend Tests

Bend tests are among the most frequently used tests for evaluating the ductility of a metal or welded joint by measuring its ability to resist cracking during bending. Bending is the process by which a straight length is transformed into a curved length. The fibers of the metal on the outer (convex) surface of the bend are stretched, thus inducing tensile stresses. Simultaneously, the fibers on the inner (concave) surface of the bend are placed in compression. ASTM methods E 190, E 290, and E 855 provide descriptions of the various procedures.

## General Methods

**Bend Radius.** For a given bending operation, the bend radius,  $R$ , cannot be made smaller than a certain value, or the metal cracks on the outer (tensile) surface. Usually, this minimum bend radius ( $R_{\min}$ ) is expressed in terms of multiples of the specimen thickness,  $t$ . Thus, a material with a  $3t$  minimum bend radius can be bent without cracking through a radius equal to three times the specimen thickness. It follows, then, that a material with a minimum bend radius of  $1t$  has greater formability; whereas a minimum bend radius of  $5t$  indicates a less formable material.

**Test Specimens.** Bend-test specimens are usually in the form of a rectangular beam. Wherever possible, as with a plate or a sheet, the full thickness of the material should be used. Generally, the specimen thickness should not exceed 40 mm ( $1\frac{1}{2}$  in.). When using a machined specimen of reduced thickness, the as-fabricated surface should be retained as a surface of the bend specimen. This surface should be oriented in the bend fixture as the tensile surface. For specimens cut from plate material, the width should be twice the thickness, but no less than 20 mm ( $\frac{3}{4}$  in.). For thin specimens cut from sheet, the width should exceed eight times the thickness. The ratio of width to thickness affects the stress state produced in bending and, therefore, the ductility measured in the test. For this reason, bend-test results made on thin sheet should not be compared with those obtained with thicker plate to avoid erroneous conclusions about the formability of the materials.

The length of a bend-test specimen must be of some minimum that varies with thickness. Length, however, is not critical if the specimen is long enough to accomplish the bending operation. The edges of the specimen may be rounded to a radius not to exceed 1.6 mm ( $\frac{1}{16}$  in.) to minimize edge cracking. Flame-cut surfaces should be machined to remove heat-affected metal. Sheared edges should be machined or smoothed on an abrasive belt to remove the sheared edge. Although bend testing usually is performed with specimens of rectangular cross section, round specimens may also be used.

Bend specimens may be cut from sheet or plate to evaluate the basic formability of the material or test the formability of an as-fabricated surface. Because most fabricated products have mechanical properties that are directional (anisotropic), directionality is an important consideration in making the test. Figure 53 shows the orientation of the bend-test specimen with the rolling direction for a longitudinal orientation and a transverse orientation. The transverse orientation generally shows lower ductility, because the tensile bending stresses are oriented perpendicular to the fiber structure developed by the rolling deformation.

**Fig. 53** Relative orientations of specimens for longitudinal and transverse bend tests. Arrows indicate direction of rolling. Source: Semi-Guided Bend Test for Ductility of Metallic Materials, ASTM E 290-80

The quality of welds often is evaluated by bend testing (ASTM E 190). A specimen is cut from the welded assembly with the weld in the center of the specimen. The weld may be either transverse or parallel to the length of the specimen.

## Free Bend Tests

A free bend test is one in which the curvature of the bend is left "free" to take its natural shape. As shown in Fig. 54, the specimen is given a preliminary bend in a bending fixture (Fig. 54a) and then is transferred to a free bend fixture (Fig. 54b) where the bend is completed.

**Fig. 54** Free bend tests. (a) A partial bend is made with the specimen in a horizontal position. (b) The specimen is positioned vertically, and the two knurled jaws are forced together until the specimen fractures or makes a 180° U-bend.

For moderately ductile materials, the formability is evaluated by the bend angle ( $\alpha$ ) that can be achieved before cracking occurs on the tensile face (outside surface) of the bend. For a highly ductile material that can be bent flat on itself ( $\alpha = 80^\circ$ ), the ductility is evaluated on the thickest specimen for which this can be done without cracking.

### ***Restricted (Controlled) Bend Tests***

A restricted bend test is one in which the test specimen is made to bend closely around a predetermined radius,  $R$ . Various examples of this test are shown in Fig. 55. The test shown in Fig. 55(a) usually is called a guided-bend test. The need for a test fixture sometimes may be eliminated by using a soft metal support to accommodate the punch, as in Fig. 55(b). For thin sheet metal, the bending force may be applied by a hand-operated lever, or alternatively, the sheet may be hammered over the bending die with a plastic or rawhide mallet (Fig. 55c). ASTM E 290 describes this test in detail.

**Fig. 55** Restricted bend tests. (a) Guided bend test wherein the test material is forced through a fixture of predetermined radius. (b) Modification of guided bend test using soft metal for the fixture. (c) Method of clamping the specimen while bending it over a predetermined radius

Ordinarily, a grid pattern is lightly scribed on the tensile surface of the bend specimen before the restricted bend test. This surface is observed during the test, either with a mirror or by bending in small increments, to determine when the cracks first appear. At this point, the angle of bend is recorded, or the elongation of the tensile surface is determined from the

grid network. Alternatively, the minimum bend radius that will permit bending through a fixed bend angle is determined as the measure of formability.

### ***Bend Tests on Very Ductile Materials***

Bend tests on very ductile materials are less controlled than those discussed earlier, but they are more severe tests. For a sheet, the basic test is to determine whether the sheet can be bent flat on itself through  $180^\circ$  without cracking. A further test of ductility is to cross fold the sheet once again across the first fold (Fig. 56a). Bend tests are made on tubes by first flattening the tube, as shown in Fig. 56(b). This applies two separate transverse bends of nearly  $180^\circ$ . Subsequently, the flattened tube can be folded along its longitudinal axis (Fig. 56c).

**Fig. 56** Fold tests on ductile sheet or tube (see text)

### **Sheet-Formability Tests**

Several tests have been developed to evaluate the formability of sheet metal. Most complex sheet-forming operations can be resolved into a combination of bending plus stretching and drawing. In a pure stretch-forming operation, the edges of the blank strip are clamped, and the shape is produced by multidirectional stretching over the contours of the deforming tool or punch. Sheet-metal drawing, usually called deep drawing, utilizes the radial drawing of the sheet-metal blank into the die under the action of the punch. In deep drawing, the outer portion of the blank shrinks in diameter under circumferential compression. To prevent the blank from buckling, the blankholder must exert sufficient pressure to prevent wrinkling but not enough pressure to restrict the sheet from drawing into the die. Thus, in deep drawing, no deformation occurs in the central region of the punch directly under the punch; whereas in stretch forming, the maximum deformation occurs in this region. Figure 57 shows the essential differences between stretching and drawing.

**Fig. 57** Two operations that simulate stamping: (a) deep drawing and (b) stretching

The ability of the metal to undergo stretching is enhanced by a high value of strain hardening. Thus, a high value of strain-hardening exponent minimize failure in stretch forming. The ability to withstand deformation in deep drawing, without failure, derives from the crystallographic texture of the metal sheet produced during rolling. The desired texture is such that the slip systems are aligned to give higher strength in the thickness of the sheet than in the plane of the sheet. As the plastic-strain ratio,  $r$ , becomes greater, the limiting draw ratio, LDR, becomes larger. The plastic-strain ratio is obtained by taking a tensile specimen and straining it to the point of necking. The longitudinal, thickness, and lateral (with-direction) strains are determined and are, respectively,  $\epsilon_l$ ,  $\epsilon_t$ , and  $\epsilon_w$ . The plastic-strain ratio is defined as:

$$r = \frac{\epsilon_w}{\epsilon_l}$$

ASTM E 517 describes the test used to determine  $r$ . The limiting draw ratio (LDR) is the largest ratio of blank diameter to punch diameter for which the blank can be drawn into a cup of diameter  $D_p$  without tearing.

Many laboratory tests have been developed to measure and control the formability characteristics of sheet metals. Some, such as the hydraulic bulge test, are fundamental tests, while others attempt to simulate actual sheet-forming operations. Finally, the forming of actual parts on which a grid of circles has been imprinted in combination with the forming-limit curves (or Keeler-Goodwin curves) can be used to measure the formability of a given sheet metal.

In the hydraulic bulge test, metal is tested under uniaxial tension in the tension test and under local compression in the hardness test. In a typical press-forming operation, the metal is deformed under biaxial tension or biaxial tension-compression, in which the metal is strained simultaneously in two directions in the plane of the sheet. The hydraulic bulge test can be used to measure the properties of sheet metal when strained under biaxial conditions.

In the bulge test, a circular sheet is clamped at the edge and deformed by hydraulic pressure into a dome. For an isotropic sheet, essentially uniform biaxial stress and strain exist over an appreciable region at the center of the diaphragm. Failure eventually occurs in this central region.

Another sheet-formability test is the stretch bend test, which measures the ability of a sheet metal to be bent around a sharp radius under tension. It is a more severe test than the simple bend test and, in addition, can be used to measure the sensitivity of a metal to tearing from a stretched cut edge (a major problem in components with hole or stretch flanges).

In the stretch bend test, a sheared strip specimen of the material to be tested is clamped firmly between jaws and bent under tension, burr side outward, over a radiused punch. Normally, an autographic record of punch load and punch travel is obtained during the test. The punch travel--either at maximum load when cracks start to run into the material from the sheared edges, or at failure--is taken as the measure of specimen formability.

## **Ball Punch Deformation Test (Olsen and Erichsen Tests)**

The Olsen test simulates sheet-metal performance under stretching conditions. It is a simple test in which the sheet metal is clamped rigidly in a blankholder, then stretched over a small hemispherical punch 22.2 mm ( $\frac{7}{8}$  in.) in diameter. The stretchability of the sheet is then assessed by measuring the height to which the sheet can be stretched before fracture occurs. In a typical Olsen tester, both the punch travel and punch load are recorded, and the fracture point is established by noting the point at which the load suddenly decreases. Figure 58 shows sheet specimens that were subjected to four different formability tests.

**Fig. 58** Results typical of ductility tests on sheet-metal blanks. (a) Olsen and Erichsen tests. (b) Deep draw cup test. (c) Fukui test. (d) Hole-expansion test. Courtesy of Tinius Olsen Testing Machine Co.

The Olsen test has been replaced by the "ball punch deformation test" standardized by ASTM (ANSI/ASTM E 543). In this test, many of the test parameters that previously were left to the discretion of the individual performing the test are normalized. The standardized test applies to specimens with thicknesses between 0.2 and 2.0 mm. The machine to which the tooling is attached should have the capability of holding down the specimen (pressure between the top and bottom die) with a force of at least 10,000 N (2200 lbf).

Because the punch surface and the sheet-metal surface are in contact during this test, the friction between the two surfaces has a large effect on the test conditions. To maintain standard friction conditions from one test to the next, the lubricant is standardized. Commercial available petroleum jelly is applied to the punch only. ASTM E 643 also states that other lubrication systems (e.g., polyethylene sheet plus oil) may be used as agreed between supplier and user.

The speed of the penetrator shall be between 0.08 and 0.4 mm/s (0.2 and 1 in./min). The end of the test corresponds to the drop-in load, which is caused by necking of the sheet. If the machine is not equipped with a load indicator, the end point will be either visible necking or fracture of the test specimen in the dome. The cup height is measured at this point and is the penetrator (punch) displacement.

The Erichsen test, which is common in Europe where it was standardized, is similar to the Olsen test in principle--that is, the test simulates sheet-metal performance under stretching conditions. The punch diameter for the Erichsen test is slightly smaller than the punch used for the Olsen test (20 mm, or 0.79 in.).

The Erichsen test may be performed with or without lubrication, but the use of lubrication introduces a new variable, as described in the above discussion of the Olsen test. A portable instrument for performing the Erichsen test is available and has been widely used for control of formability or drawability in sheet-metal working, especially for quality control of incoming material.

## **Limiting Dome Height Test**

In the Erichsen, Olsen, and bulge tests, fracture occurs at conditions that are close to equibiaxial strain (when the strain is the same in the two perpendicular directions). In the uniaxial tension test, fracture occurs at a combination of tensile strain plus a small amount of contraction strain in the width direction. In practical press-forming operations, most fractures occur at close to plane-strain conditions, such as a tensile strain in one direction with zero strain in the other direction--which is somewhere between the conditions in the Olsen, Erichsen, and bulge tests on the one hand and conditions in the tension test on the other.

The limiting dome height test has been developed to simulate more effectively the fracture conditions found in most parts. In this test, a large-diameter hemispherical punch, usually 100 mm (4 in.) in diameter, is used, and strips of sheet steel of

varying widths are clamped and then stretched over the punch. The strips are marked with a grid of small circles, 2.5 mm (0.1 in.) in diameter, and the width strain at fracture is measured from the circle closest to the fracture. The width strain increases as the width of the sheet becomes greater.

The advantage of the limiting dome height test is that it more closely simulates the fracture conditions in a practical press-forming operation. It is a complex and time-consuming test, however, and the results are critically dependent on sheet thickness. In this test, lubrication is not critical; the standard practice is to perform the test dry (without lubricant).

### ***Swift Cup Test***

This test simulates the drawing operation and involves drawing of a small flat- or hemispherical-bottom, parallel-side cup. The sheet is held under a blankholder, as shown in Fig. 59, but is well lubricated with polyethylene and oil to ensure that the blank can be drawn in under the blankholder. Typical Swift cup test forming tools are available in 19, 32, and 50 mm diameters for use with specimens ranging in thickness from 0.3 to 1.24, 0.32 to 1.30, and 0.45 to 1.86 mm, respectively. For drawing 40 mm square cups from 80 mm diam round specimens from 0.2 to 2 mm thick, a 40 mm square forming tool is recommended.

**Fig. 59** Swift cut test. Punch diameter is 50 or 32 mm (2 or 1.3 in.).

The drawability of the metal is estimated by drawing a series of blanks of increasing diameter. The maximum blank size that can be drawn without fracture occurring over the punch nose is used to calculate the limiting draw ratio. For example, forming a 66 mm diam disk using a 33 mm forming tool provides an LDR of 2.0. Because the condition of the edge of each blank can have an important effect on the test result, the blank edges usually are turned in a lathe to ensure strain-free, burr-free edges.

The results of this test correlate well with the performance of sheet metal in deep-drawn components, but, because of shape and alignment, reproducibility between laboratories is not good. The main problem with this test, however, is that it is time consuming, and a large number of blanks of different sizes must be tested to obtain a reliable result.

Apart from measuring drawability, this test also can be used as a quality control check to measure the tendency toward earing of the sheet metal. In this case, a blank of fixed diameter is drawn, and the height between the peaks and troughs in the cup wall are measured.

The Englehardt or draw fracture test is a variation of the Swift cup test for measuring drawability that overcomes the problems of complexity and time involved in that test. The draw fracture test involves drawing of a cup to the point of maximum drawing load, then clamping the flange and continuing the punch travel to fracture. A load-penetration curve similar to that in Fig. 60 is obtained and the Englehardt value,  $T$ , is calculated from the maximum draw and fracture loads,  $P_d$  and  $P_f$ :

$$T = \frac{P_f - P_d}{P_f}$$

This result depends on strip thickness and usually is corrected, using an empirical relationship, to a nominal thickness. Because of its simplicity of operation and reproducibility, the draw fracture test is the most suitable for testing of drawability on a routine basis.

Fig. 60 Draw fracture test. A and B: drawing. C and D: clamping and fracture

### ***Fukui Conical Cup Test***

The Fukui conical cup drawing test (Fig. 61) was developed to assess the performance of a material during forming operations involving both drawing and stretching. The advantage of this test is that no holddown is necessary if the correct relationship between sheet thickness and blank diameter is maintained.

Fig. 61 Fukui conical cup test

A blank of the appropriate size is laid over a 30° conical entry die and forced into the cavity by a flat-bottom or hemispherical punch. The height of the cup at failure is used as a measure of formability. The test requires various tooling for different sheet thicknesses, and the result is thickness dependent. It has been demonstrated that the Fukui cup depth is influenced mainly by stretchability, but with some dependence on drawability. Thus, this test does not correlate as highly with uniform elongation and  $r$ -values as do other tests that are predominately stretch or draw, which may explain why the conical cup test has not been as widely accepted as other simulative tests.

Typical tooling commercially available for the Fukui test includes a cutting ring, cutting ram, and ball indenter available for specimen thicknesses from 0.5 to 1.6 mm.

### **Forming-Limit Curves**

The poor correlation often found between results of the common "cupping" test and actual metal performance led investigators to look at some more fundamental parameters. Localized necking requires a critical combination of major and minor strains (along two perpendicular directions in the sheet plane). This concept led to the development of diagrams known as the Keeler-Goodwin or forming-limit curves. The forming-limit curve (FLC) is an important addition to formability testing techniques.

Each type of steel, aluminum, brass, or other sheet metal can be deformed only to a certain level before local thinning (necking) and fracture occur. This level depends principally on the combination of strains imposed, that is, the ratio of major and minor strains. The lowest level occurs at or near plane strain, that is, when the minor strain is zero.

This information was first represented graphically as the forming limit diagram, which is a graph of the major strain at the onset of necking for all values of the minor strain that can be realized. Figure 62 shows a typical forming limit diagram for steel. The diagram is used in combination with strain measurements, usually obtained from circle grids, to determine how close to failure (necking) a forming operation is or whether a particular failure is due to inferior work material or to a poor die condition.

Fig. 62 Typical forming limit diagram for steel

For most low-carbon steels, the forming limit diagram has the same shape as the one shown in Fig. 62, but the vertical position of the curve depends on the sheet thickness and the  $n$  value. The intercept of the curve with the vertical axis, which represents plane strain and is also the minimum point on the curve, has a value equal to  $n$  in the (extrapolated) zero thickness limit. The intercept increases linearly with thickness to a thickness of about 3 mm (0.12 in.).

The rate of increase is proportional to the  $n$  value up to  $n = 0.2$ , as shown in Fig. 63. Beyond these limits, further increases in thickness and  $n$  value have little effect on the position of the curve. The level of the forming limits also increases with the  $m$  value.

Fig. 63 Effect of thickness and  $n$  value on the plane-strain intercept of a forming limit diagram

The shape of the FLC for aluminum alloys, brass, and other materials differs from that in Fig. 62 and varies from alloy to alloy within a system. The position of the curve also varies and rises with an increase in the thickness,  $n$  value, or  $m$  value, but at rates that are generally not the same as those for low-carbon steel.

The forming limit diagram is also dependent on the strain path. The standard FLC is based on an approximately uniform strain path. Diagrams generated by uniaxial straining followed by biaxial straining, or the reverse, differ considerably from the standard diagram. Therefore, the effect of the strain path must be taken into account when using the diagram to analyze a forming problem.

These FLCs provide helpful guidelines for press-shop formability. Coupled with circle-grid analysis, they can serve as a guide in modifying the shapes of stampings. Circle-grid analysis consists of photoprinting a circle pattern on a blank and stamping it, thereby determining the major and minor strains in its critical areas. This is then compared with the FLC to verify the available safety margin. The strain pattern can be monitored with changes in lubrication, hold-down pressure, and size and shape of drawbeads and the blank; this can lead to changes in experimental procedure. Circle-grid analysis also serves, in conjunction with the FLC, to indicate whether a certain alloy might be replaced by another one, possibly cheaper or lighter. During production, the use of occasional circle-grid stampings provides valuable help with respect to wear, faulty lubrication, and changes in hold-down pressure.

## **Wear Testing**

Peter J. Blau, Metals and Ceramics Division, Oak Ridge National Laboratory

## **Introduction**

WEAR is mechanically-induced surface damage that results in the progressive removal of material. Because different types of wear occur in machinery, many different types of wear tests have been developed to evaluate its effects on materials and surface treatments. Consequently, the selection of the right type of wear test for each investigation is important in order to achieve useful and meaningful engineering data. More than one type of wear can attack the same part, such as sliding wear and impact wear in printing presses, or erosive wear and abrasive wear on extrusion machine screws for plastics. Sometimes wear can operate in the presence of corrosive or chemically-active environments, and synergistic chemo-mechanical effects are possible. Selection of appropriate wear test methods begins with an assessment of the type of wear involved in each problem area. Having a structure to classify wear types can make this process easier, and one such structure is provided in this article.

Wear testing is performed for one or more of the following reasons: to screen materials, surface treatments, or lubricants for a certain application; to help develop new, wear-resistant materials, surface treatments, or lubricants; to establish the relationship between the manufacturing, processing, or finishing methods applied to a certain machine part and its wear performance; or to better understand and model the fundamental nature of a certain type of wear. Surprising to some, the wear resistance of a given material is not a basic material property, like elastic modulus or yield strength. Rather, a material's wear behavior depends on the conditions of its use. Therefore, the first step in wear testing is to recognize how the results of the work will be used. Only then can the appropriate test method(s), testing parameters, and a useful format for reporting the results be selected. While this strategy may seem straightforward, its implementation in practice is not necessarily so.

A test intended to mimic the environment seen by a particular machine component is called a tribosimulation. The initial challenge in designing a tribosimulation is identifying the major wear-causing factors and finding a test that will produce the same type of wear response from test coupons as for operating parts. Conducting a tribosystem analysis involves gathering as much data as possible from the field, consulting the component designers, if possible, and attempting to define the relevant contact conditions (mechanical, thermal, and chemical) accurately.

Deciding which test to use and then selecting the proper variables and controls for that test often involves an iterative process of testing, analyzing the results, examining the worn surfaces, and possibly adjusting the testing parameters to better establish the usefulness and repeatability of the results. Because the subject of wear testing encompasses a wide variety of machine designs and testing strategies, this article focuses principally on the basic principles of wear test selection and use. The selected references listed in the bibliography provide additional detailed information, particularly when there is a need to screen materials for specific, wear-critical applications.

German standard DIN 50-322 elucidates a convenient method for grouping types of wear tests. The six levels of wear testing are as follow: (1) field testing (e.g., a truck for hauling rock), (2) full-scale machine test stand trials (e.g., the truck carrying a known load running on a wheel dynamometer stand), (3) machine subassembly test stand trials (e.g., the transmission of the truck on a dynamometer), (4) sub-scale tests (e.g., a small version of the transmission on a dynamometer), (5) component tests (e.g., a gear-testing machine), and (6) simple specimen tests (e.g., a simple curved specimen sliding on another curved specimen). Most laboratory wear tests, including a number of ASTM standard wear test methods, fall into categories (5) or (6). These bench-type tests are the focus of this article.

## Wear Mechanisms

Before describing specific types of tests, it will be helpful to identify the major forms of wear. Different classification schemes for wear have been developed, because those developing wear classification schemes have come from different backgrounds and experiences with wear. No one scheme is universally accepted, but most of them have reasonably similar features. Figure 1 shows an approach to wear classification; here, wear is classified by the type of relative motion. Note that galling, scratching, scoring, and damage from the impact of a foreign body are not strictly forms of wear because material is not necessarily removed (it may instead be displaced to one side), and even if some material is removed, the process is not repetitive and progressive. Rather, these latter phenomena are referred to as "surface damage."

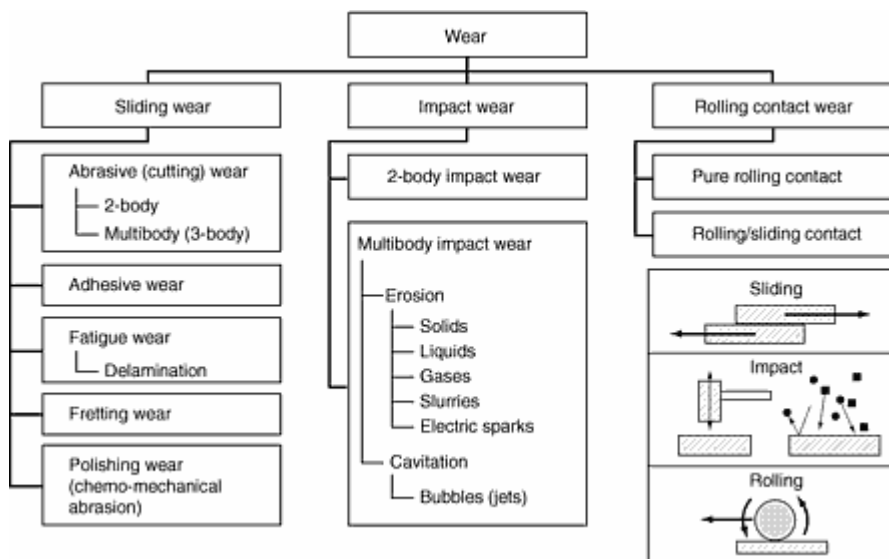

Fig. 1 Major categories of wear

## Forms of Wear

The three categories of contact depicted in Fig. 1 are tangential motion (sliding), impact, and rolling. There are a number of subcategories. Formal definitions for the important types of wear, such as those shown in Fig. 1, have been compiled from a variety of sources in the Glossary of *Friction, Lubrication, and Wear Technology*, Volume 18, *ASM Handbook*. The Glossary also contains reviews of each major form of wear and detailed discussions of both wear mechanisms and wear control. An abbreviated summary of the characteristics of the wear types shown in Fig. 1 follows.

**Sliding wear** is the consequence of relative tangential motion between solid surfaces being pressed together. If one of the surfaces is much harder and contains sharp points that plow or cut through the other surface, possibly producing thin chips, then two-body abrasive wear is said to occur. An example of this is sandpaper abrading wood. In contrast, three-body abrasive wear is produced by foreign particles trapped between relatively-moving solid surfaces. An example of this is the accelerated wear of a bushing by hard particles (grit) that have somehow found their way into the lubricant. It is possible that what starts out as a sliding wear situation can become a three-body abrasive wear situation after a period of time due to the generation and abrasive action of work hardened wear debris particles.

Adhesive wear is a somewhat archaic term, based on a proposed mechanism for the severe wear of metals, in which material from one surface is observed to adhere to the other at high spots (asperities) that are subsequently sheared off. While factors other than adhesion may be involved, it is so historically ingrained in the tribology literature that it will be

used here for convenience to describe sliding wear other than the other than abrasive, fretting, fatigue, and polishing wear. Repeated stressing of a surface by sliding contact can cause cracks to nucleate and grow, producing the flake-like delaminations and pitting that are associated with fatigue wear. Fretting wear is a special case of reversed oscillating sliding wear in which the relative displacements between bodies are quite small ( $<50$  to  $150\ \mu\text{m}$ ), and the wear debris exhibits a characteristic powdery appearance. Likewise, polishing wear is a special case of three-body abrasive wear that can involve chemical as well as mechanical aspects of fine-scale material removal.

**In impact wear**, there is a repetitive impulse component normal to the wearing surface. One example of two-body impact wear is a mechanical printing plate repeatedly striking the paper. Thus, impact wear generally produces surface fatigue. Impact wear may also occur in combination with sliding wear, as in the case of a type face striking the surface of a moving printer ribbon or when the tip of a jet engine turbine blade impacts and rubs on its surrounding shroud.

Multibody impact wear can be further broken down into erosive wear and cavitation wear (or cavitation erosion). Erosive wear involves the cumulative effects of many particles striking a surface. These particles can be solids, liquid droplets (e.g., rain), collapsing bubbles, or solid-liquid mixtures called slurries. Electric sparks can also cause erosion, as in the opening and closing of electrical contacts carrying high currents. Cavitation or cavitation-erosion is caused by the collapse of tiny bubbles against a solid surface submerged in a liquid. This situation occurs in pumps and high-pressure piping. The noise of cavitation is a concern to those who build automotive fluid pumps and the propellers of "quiet" submarines.

**Rolling Contact Wear.** The rolling of one body over another, as in a rolling element bearing, can result in repeated stressing of the subsurface material, the nucleation of microcracks, and the eventual production of pits and spalls. Analysis of bearings and gears indicates that some degree of slip occurs in many rolling contact situations, such as in the cam and roller assembly in an automobile valve train and in the engagement of gear teeth. Thus, it is common to observe sliding wear features (e.g., scuffed or polished-looking areas) on components that are ordinarily considered to be in "rolling contact." The degree to which sliding governs the total wear of components must be ascertained in individual cases, but there are wear tests that have been developed specifically to permit the proportion of rolling to sliding contact (slide/roll ratio or percent slip) to be adjusted.

## ***Causes of Wear***

Wear is one of the ways in which the surface of a solid body can dissipate energy that is being externally supplied to it. Figure 2 schematically shows how the mechanical energy into a surface can be partitioned. In sliding contact, the product of the kinetic friction force,  $F$ , and relative velocity,  $v$ , equates to work into the surface per unit time (e.g.,  $\text{N} \cdot \text{m/s}$  or  $\text{lbf} \cdot \text{ft/min}$ ). The kinetic friction force is, by definition, the product of the kinetic friction coefficient ( $\mu_k$ ) and the normal force,  $P$ . Therefore, most models for frictional heating include  $F \cdot v$  or  $\mu_k \cdot F \cdot v$ ; however, not all of the frictional energy turns into heat. It is the part that goes into forming new surfaces and deforming and fracturing the surface material that is addressed here. Energy can also be supplied, for example, from the impact of small particles (erosive wear) or larger bodies repetitively impacting the surface (impact wear).

**Fig. 2 Distribution of energy from surface contact**

The shaded bar in the Fig. 2 represents the partition of the available energy. In all likelihood, most of the energy is converted into heat, but the relative proportion going into the other categories is a function of the specific tribosystem configuration and the materials involved. Therefore, even if two different pairs of materials exhibit the same friction coefficient, their relative wear rates could be much different, because the available frictional energy is not being partitioned in the same way in both couples. A good wear-resistant material should dissipate heat well, but not use the energy input to create new surfaces (i.e., minimize the energy going into fracture, plastic deformation, or micro chip cutting).

## Measuring Wear and Reporting Wear Test Results

The units selected for measuring and reporting wear and wear rates will depend on the type of wear being measured, the total mass or volume of wear typically generated from the given type of test, and the geometry and size of the test specimens. In tribosimulation work, there is an additional consideration of providing a measure of wear that best corresponds to the manner in which wear is determined on the parts being simulated. Often, however, the wear volume or wear mass loss is not well quantified in the field. Instead, wear out is based on visual inspection or on some other adverse characteristic of the machine behavior, like wear particles in the lubricant, higher vibration levels, or fluid leakage. Thus, it is not always possible to directly relate numerical wear data obtained in laboratory studies to component behavior. Alternative criteria for wear acceptability include the appearance (roughness) of the contact surface and the ranking of reference ("benchmark") materials in the laboratory in the same order as they rank in field trials.

Wear rates are combinations of units that can express either a normalized or relative figure of merit. The general form of a wear rate is a fraction in which the numerator corresponds to the mass, length, or volumetric quantity of wear, and the denominator represents one or more normalization parameters, or alternatively, the wear quantity for a reference material tested under the same conditions. An example of the former is a wear factor for sliding wear: volume of material lost per unit of applied normal force per unit of distance slid,  $\text{mm}^3/\text{N} \cdot \text{m}$ . An example of the latter is mass loss of the material of interest per unit sliding distance divided by mass loss of a reference material per unit sliding distance. In particle impingement erosion testing, the wear rate is often expressed as mass of material lost per unit mass of particles impacting the surface (g/g). In that case, the quantity first appears to be dimensionless (g/g), yet it is not so, because grams of specimen material are not the same as grams of erodant material.

Implicit in the use of wear rates is the assumption that those wear rates are linear with respect to the quantities in the denominator, notably sliding distance or time of contact. In fact, several types of wear, like sliding wear and solid particle erosive wear, do not experience linear wear rates throughout their histories. For example, running in (wear in) can occur in newly replaced bearings. The initial wear rate in that case is many times higher than the steady-state wear rate. In

consideration of such effects, it is sometimes useful to subject the test specimens to a standard running-in or conditioning period and then make the first wear measurement, continuing the experiment for another time period to make a second measurement. This practice will help establish the steady-state wear rate of the material system and will not be affected so greatly by running-in phenomena. In other cases, it is important to know the total amount of wear of the material, including the pre-steady-state wear. Testing results should indicate whether the total wear or the steady-state post-running-in wear was used in computing the wear rates.

Table 1 lists common units for reporting the quantities and rates of various wear types. Common techniques used to measure wear include measuring the length or thickness change of the test specimen, profiling surfaces to determine the wear depth or cross-sectional area worn away, using a precision balance to measure mass loss, measuring the relative displacement of specimens on the testing machine (in situ ) with a mounted sensor of some type, and making measurements of wear scar dimensions with microscopy. Other, less common methods include making replicas of surfaces before and after testing, placing hardness impressions in surfaces, and measuring the change in their sizes after wear. Lubricant filtration or ferrography (see the article "Lubricant Analysis" in *Friction, Lubrication, and Wear Technology*, Volume 18, *ASM Handbook*) is also a method to measure wear, as is surface layer activation by radionuclides.

**Table 1 Common units for reporting wear and wear rates**

Wear category	Subcategory	Wear quantities	Wear rate quantities
<b>Sliding</b>	Abrasive, two-body	$M, V, D$	$M \cdot P^{-1} \cdot X^{-1}, V \cdot t^{-1}, M \cdot t^{-1}, M \cdot M_{\text{ref}}^{-1}, V \cdot V_{\text{ref}}^{-1}$
	Abrasive, three-body	$M, V, D$	$M \cdot t^{-1}, D \cdot t^{-1}, M \cdot M_{\text{ref}}^{-1}, V \cdot V_{\text{ref}}^{-1}$
	Sliding, uni-directional	$M, V, D$	$M \cdot P^{-1} \cdot X^{-1}, V \cdot t^{-1}, M \cdot t^{-1}, V \cdot X^{-1}, M \cdot X^{-1}, M \cdot M_{\text{ref}}^{-1}, V \cdot V_{\text{ref}}^{-1}$
	Sliding, reciprocating	$M, V, D$	$M \cdot P^{-1} \cdot X^{-1}, M \cdot P^{-1} \cdot N^{-1}, V \cdot t^{-1}, M \cdot t^{-1}$
	Fretting	$V, SR$	...
	Polishing wear	$M, V, D, SR$	$M \cdot t^{-1}, D \cdot t^{-1}$
<b>Impact</b>	Two-body	$M, V, D, SR$	$V \cdot t^{-1}, M \cdot t^{-1}, V \cdot N^{-1}, M \cdot N^{-1},$
	Erosion, solid particle	$M, V, D, SR$	$M \cdot M_p^{-1}$ , various quantities based on erosion-time curves (see ASTM test method G 32 for description)
	Cavitation	$M$	$M \cdot t^{-1}$
<b>Rolling</b>	Rolling contact fatigue	$T_{\text{ind}}, N_f$	$L_{10}$
	Rolling with slip	$t_{\text{ind}}, N_f$	...

$D$  = length or dimensional change,  $L_{10}$  = rating life in millions of revolutions or hours at a given operating speed and load that 90% of a given lot of bearings will survive,  $M$  = mass loss of the specimen,  $M_p$  = mass of impinging particles,  $M_{\text{ref}}$  = mass loss of a specified reference material under the same conditions,  $N$  = number of cycles or number of impacts,  $N_f$  = number of cycles to failure indication,  $P$  = normal force (load),  $SR$  = surface roughness,  $t$  = time of exposure to wearing conditions,  $t_{\text{ind}}$  = time to indication of problem (for example, noise or vibration level),  $V$  = volume of material lost,  $V_{\text{ref}}$  = volume of material lost by a reference material tested under the same conditions,  $X$  = total length of contact (sliding distance)

Each measure of wear has limitations in both its precision and accuracy. Table 2 shows the results of an experiment in which sliding wear of a specimen was measured by three independent methods. Tests involved sliding polished aluminum bronze blocks against a rotating bearing steel ring in argon gas. Wear was assessed by weight change, the depth of the wear scar (using a mechanical stylus), and optical microscope measurement of the width of the wear scar. Four replicate block specimens were tested, each sliding on a new ring. On closer examination of the measurement methods, a number of assumptions and potential sources of error are found. In using weight measurement, it is assumed that the specimens were completely cleaned of wear debris deposits before weighing and that the correct figure for the density of the bronze test specimen has been chosen. The following possibilities are also ignored: some of the steel wear particles adhesively transfer to the bronze specimen adding to its weight, there is some adsorption of ambient species onto the specimen surfaces, and oxides form as a result of the wear exposure. In using depth data, it is assumed that there are no adherent deposits of debris on the bottom of the wear scar. In using a microscope to measure wear scar dimensions, a judgment must be made as to where to place the cursor across the edges of the scar, which may in reality be irregular. Furthermore, it is assumed in calculating volume from scar width that the scar has a cylindrical shape. Had wear been measured by a

displacement sensor, it would be important not to introduce significant error by allowing trapped deposits of wear particles in the interface to force surfaces apart. On the scale of micrometers or milligrams of total wear loss, such considerations can lead to significant errors in wear volume measurement. Considerations like this are particularly important in measuring the wear of thin coatings where the amount of material lost during the test is quite small.

**Table 2 Comparison of three different methods for measuring the wear of block-on-ring specimens**

Method	1	2	3	4	Average, mm <sup>3</sup>
<b>Mass loss, g</b>	0.162	0.173	0.212	0.185	0.183
<b>Wear width, mm</b>	0.283	0.264	0.349	0.268	0.291
<b>Scar depth, <math>\mu\text{m}</math></b>	0.245	0.275	0.256	0.228	0.251

The original raw data in these units were converted to volume in order to compare the four methods. Weight loss was divided by density of the bronze specimen to obtain volume. Scar depth was converted to cross-sectional area, assuming a contact curvature equal to the ring specimen radius, and multiplied by scar length to obtain volume. Scar width was converted to the cross-sectional area of a cylindrical segment and multiplied by scar length to obtain volume. Source: P.J. Blau, Needs and Challenges in the Precision Measurement of Wear, *J. Test. Eval.*, Vol 25 (No. 2), 1997

Each type of wear test method lends itself to certain techniques of wear measurement. Provided that systematic errors can be eliminated, the importance of conducting multiple tests to improve confidence in the results becomes obvious. It should also be noted that even if the accuracy of wear testing methods and metrology can be refined to a high degree, the ultimate limiting factor is the variability of the material behavior itself. In summary, the sources of variations in wear data can be related to the testing machine characteristics, the method of wear measurement, intrinsic material variations, and sometimes the operator's judgment in making measurements.

## Tribosystem Analysis and Test Method Selection

In order to screen materials or lubricants for a certain application, a tribosystem analysis of the component of interest should be conducted. The following should be considered:

- The nature of relative motion (unidirectional, reciprocating, combined motions, etc.)
- The contact loads and/or contact pressures
- The speed of relative motion and its level of constancy
- The contact geometry of the wearing surfaces
- The temperature and chemical environment of the contact zone
- Whether third-bodies play a part, and if they do, their characteristics
- The method of surface preparation and cleaning
- The duration of exposure to wearing conditions
- Other requirements, such as cosmetic considerations, corrosion resistance, and fatigue strength
- The most important form(s) of wear and characteristic surface features that are present

In non-component-specific cases, such as the development of a new wear-resistant material, surface treatment, or lubricant that might have a variety of potential applications, it makes sense to conduct more than one type of wear test. A suite of tests will help to define the conditions for which a particular material is best suited. Conducting several types of wear tests on the material will also suggest a range of applications that might be promoted and reveal other situations that are less promising. The same set of materials can rank in opposite order when exposed to different types of wear.

## Test Methods

**Standardized Wear Testing Methods.** The use of standard testing methods will not meet everyone's needs for wear data; however, if a tribosystem analysis suggests that an existing standard test method will be appropriate, the following advantages will ensue:

- Any new test results will be comparable with historical data obtained under the same conditions.
- Standards, such as ASTM standard test methods, involve a rigorous certification and validation process that identifies the important test variables and environmental factors that must be controlled to assure repeatability.
- Standards documentation provides excellent guidelines for assessing the significance of wear test results and indicates the potential sources of variability.
- Standard test methods could be used for routine quality control testing.

Organizations such as ASTM, the International Organization for Standardization (ISO), and the Society of Automotive Engineers (SAE) have standardized some kinds of wear tests. Most ASTM wear test methods were developed by committees D-2 on Lubricants and G-2 on Wear and Erosion. Unfortunately, standard test methods do not exist for all of the forms of wear shown in Fig. 1. Some of the existing standards are designed for specific applications while others are more generic and involve simple geometries.

A list of ASTM wear test methods, organized by type of wear and surface damage, is given in Table 3. These standards were developed by more than one autonomous standards-writing subcommittee within the society and vary in the means specified for preparing test specimens, precleaning them, measuring wear, and reporting the data. Thus, even wear standards are not standardized in that sense. This should not be surprising in light of the many forms of wear and the many types of materials that are used in wear applications. If a suitable standard test method cannot be found in the literature, an organization may decide to develop its own internal wear-testing standards best suited to its purposes.

**Table 3 ASTM wear test methods grouped by wear type**

Form of wear	Designation	Title	Means of wear measurement
<b>Abrasive wear, 2-body</b>	G 56	Test Method for Abrasiveness of Ink-Impregnated Fabric Printer Ribbon	Surface profiling or other method
	G 132	Test Method for Pin Abrasion Testing	Mass loss
	G 119	Guide for Determining Synergism between Wear and Corrosion	Mass loss and corrosion-related measurements
<b>Abrasive wear, 3-body</b>	G 65	Test Method for Measuring Abrasion Using the Dry Sand/Rubber Wheel Apparatus	Mass loss
	G 81	Practice for Jaw Crusher Gouging Abrasion Test	Mass loss ratio
	G 105	Test Method for Conducting Wet Sand/Rubber Wheel Abrasion Tests	Mass loss, normalized by wheel dimensions
<b>Erosive wear, cavitating fluid</b>	G 32	Test Method for Cavitation Erosion Using Vibratory Apparatus	Mass loss
<b>Erosive wear, liquid droplets</b>	G 73	Practice for Liquid Impingement Erosion Testing	Mass loss
<b>Erosive wear, slurry</b>	G 75	Test Method for Determination of Slurry Abrasivity (Miller Number) and Slurry Abrasion Resistance Response of Materials (SAR Number)	Mass loss
<b>Erosive wear, solid particles</b>	G 76	Test Method for Conducting Erosion Tests by Solid Particle Impingement Using Gas Jets	Mass loss
<b>Fretting wear</b>	D 4170	Test Method for Fretting Wear Protection of Lubricating Greases	Mass loss ratio
<b>Sliding wear</b>	D 2266	Test Method for Wear Preventative Characteristics of Lubricating Grease (Four-Ball Method)	Wear scar diameter
	D 2670	Test Method for Measuring Wear Properties of Fluid Lubricants (Falex Pin and Vee Block Method)	"Teeth wear"--apparatus-specific measurement of wear
	D 2882	Test Method for Indicating Wear Characteristics of Petroleum and Non-Petroleum Hydraulic Fluids in a Constant Volume Vane Pump	Mass loss
	D 2981	Test Method for Wear Life of Solid Lubricants in Oscillating Motion	Number of revolutions to failure, as indicated by friction
	D 3702	Test Method for Wear Rate of Materials in Self-Lubricated Rubbing Contact Using a Thrust Washer Testing Machine	Thickness change
	D 3704	Test Method for Wear Preventative Properties of Lubricating Greases Using the (Falex) Block on Ring Test Machine in Oscillating Motion	Wear scar width

	D 4172	Test Method for Wear Preventative Characteristics of Lubricating Fluid (Four-Ball Method)	Wear scar diameter
	D 5001	Test Method for Measurement of Lubricity of Aviation Turbine Fuels by the Ball-on-Cylinder Lubricity Evaluator (BOCLE)	Wear scar diameter
	G 77	Test Method for Ranking Resistance of Materials to Sliding Wear Using Block on Ring Wear Test	Wear scar width
	G 99	Test Method for Wear Testing with a Pin-on-Disk Apparatus	Ball: wear scar diameter, disk: profile
	G 119	Guide for Determining Synergism between Wear and Corrosion	Mass loss and corrosion-related measurements
	G 133	Test Method for Linearly Reciprocating Ball-on-Flat Sliding Wear	Ball: wear scar diameter, flat: profile
	G 137	Test Method for Ranking Resistance of Plastic Materials to Sliding Wear Using a Block-on-Ring Configuration	Mass loss
<b>Surface damage, galling</b>	G 98	Test Method for Galling Resistance of Materials	Visual inspection, critical load for galling
<b>Surface damage, scoring</b>	D 2782	Test Method for Extreme-Pressure Properties of Lubricating Fluids	"OK" value of maximum mass (weight) for load just below critical scoring condition

**Variables to be Controlled in Wear Testing.** Each wear mode is influenced by a different set of physical variables. Therefore, it is important to recognize what factors must be controlled, or at least monitored, in the design of wear testing procedures. As noted before, valuable guidance can be found in the literature and in standards documents. Table 4 lists the major experimental variables that are controlled in conducting wear tests of various types. Environmental and other factors, which should be considered in interpreting the results of the wear tests, are also listed. Sometimes these secondary factors must be controlled in order to simulate a given application, but usually it is sufficient just to measure and document them as an aid to interpreting the data.

**Table 4 Parameters that are commonly controlled and reported when conducting wear tests of various types**

Category	Subcategory	Typical variables	Supplementary characterizations or variables <sup>(a)</sup>
<b>Sliding</b>	Abrasive wear, 2-body	Load (contact pressure), abrasive type, binder type, backing body, whether repeated contact or sliding against fresh abrasive lubricant or coolant, surface speed, temperature, duration of contact	Method of surface preparation, material characterization
	Abrasive wear, 3-body	Load (contact pressure), abrasive type, concentration, hardness of counterbody <sup>(b)</sup> , coolant or lubricant, whether repeated contact or continual motion against fresh abrasive surface, surface speed, temperature, duration of contact	Method of surface preparation, material characterization
	"Adhesive"	Load (contact pressure or stress), relative velocity, contact geometry, type of motion (unidirectional or oscillating), duration, sliding distance, or time of sliding, temperature	Method of surface preparation, cleaning, surface finish of bodies, type of material/lubricant, method of supplying the lubricant, relative humidity
	Fretting wear	Load (contact stress), contact geometry, amplitude of oscillation, frequency of oscillation, number of cycles or time, choice of lubricant	Surface finish, relative humidity, debris characteristics
	Polishing wear	Size of polishing medium, concentration of medium, liquid used for suspension, normal pressure, type of motion bodies (platen and specimen), time of exposure, temperature, substrate (pad type)	Particle composition and geometric description, method of medium introduction, initial surface finish of specimen
<b>Impact</b>	2-body	Force of impact, speed of impact, geometry of contact, angle of impact, repetition rate, duration/number of impacts, temperature	Material characterization, environment and relative humidity, surface finish of bodies
	Impingement, liquid and solid	Average impact velocity, particle stream shape (by nozzle design), impingement angle of the stream to the surface, duration of exposure, temperature of the specimen and/or jet	Particle velocity or flux distribution, density of particles, particle shape description, particle size distribution, particle composition
	Cavitation erosion	Test geometry, frequency of moving body oscillation, temperature of the fluid, fluid type, duration of exposure	Material characterization
<b>Rolling</b>	Rolling contact	Load (elastic contact stress), rpm of roller(s), test duration,	Lubricant/material characterization, surface

	fatigue	temperature	finish of rollers
	Rolling with slip	Load (elastic contact stress), rpm of roller(s), % slip, test duration, temperature	Lubricant/material type, surface finish of rollers

- (a) These quantities are often used to characterize the testing conditions or materials even though they may not be directly controlled in an experiment. In certain cases, they could be treated as variables themselves.
- (b) In certain types of 3-body abrasive wear tests, notably the dry sand-rubber wheel test, the hardness of the material that is pressing the loose abrasive particles against the test specimen can have a significant effect on the results.

One way to depict the influence of more than one variable at a time on a particular type of wear is through the construction of what are called "wear maps." Wear maps are graphical representations in which two or more independent variables are plotted against a third dependent variable, such as the wear rate or the dominant type of dominant wear mechanism. Wear rates or boundaries between dominating wear mechanisms are represented as families of curves or boundaries on the "map." Examples of the variables used in wear maps for sliding wear are load (or normal force or contact pressure) and velocity and for fretting wear, slip amplitude, and oscillating frequency. Many other combinations are possible, but it should be remembered that some of the variables are not completely independent of the others. For example, sliding velocity influences the temperature, and normal load can influence the sliding surface roughness. Figure 2 shows that the product of the load and velocity affects the energy to produce wear. The limit of usefulness for some bearing materials, notably polymers, are expressed in terms of a  $P \cdot V$  (contact pressure times velocity) limit. When using or generating wear maps, the conditions used to obtain the data should be carefully considered so that unwarranted extrapolations of the data are avoided.

**Specimen Surface Preparation and Cleaning.** Test specimen surfaces should be prepared in such as way as to eliminate the possible effects of machining, grinding, and finishing processes. However, if the specimen is intended to screen a material for a certain application, then the surface finishing should be chosen to mimic that application. An additional consideration for tribosimulations is to make certain that testing is done in the proper orientation with respect to the grinding direction (lay). The relative sliding direction can affect the running-in process as well as the regime of lubrication, if one is running lubricated tests. Also, the methods of surface preparation and cleaning should be reported along with the other testing results.

The method of cleaning should not alter the chemistry of the test surface or cause it to be significantly abraded. Surface cleaning is particularly important in sliding wear tests in which friction will also be measured. The lower the contact force and the less abrasive the testing conditions, the more important is the cleaning procedure for obtaining reproducible friction and wear data. When running lubricated tests, soap and solvent residues could conceivably interfere with the action of lubricant additives and thus affect test results as well.

For cleaning metal and ceramic specimens, the following techniques have been used successfully. Rub lightly with a cotton swab saturated with acetone, then ultrasonically clean in methanol for 60 s, and dry with a hot air blower. Use a good grade of nonspotting laboratory glass cleaner, rinse in hot water, and hot air dry. Because oxidation, tarnishing, and/or recontamination of freshly cleaned specimen surfaces can occur under normal ambient exposure of most metals and ceramics, cleaning should be conducted immediately before testing or else the time between cleaning and testing should be controlled. In some cases, specimen surfaces can be rewiped with methanol after mounting them in the testing machine to ensure that handling smudges are removed. Store specimens to protect test surfaces.

Because polymeric materials can react with some solvents, some plastics are tested "as-received." In this case, it is doubly important to avoid touching the contact surfaces with the fingers during specimen preparation and mounting. In addition, thin films and surfaces covered with soft deposits should also be handled carefully to avoid disturbing the morphology and structure. Further guidance for specimen preparation and cleaning is provided in ASTM standard wear-testing methods.

Not only the specimens, but the test fixtures themselves should be kept clean and free of oil and grit. This detail is particularly important when conducting unlubricated tests but also applies to other situations. There are enough variables in wear testing without introducing additional problems from using oily or dirty testing machines.

**Location of the Testing Machine.** One factor that has been shown to cause problems in the repeatability and reproducibility of wear data is proximity of the wear testing machine to other machinery. For example, it is not advisable to locate a tester intended for dry sliding experiments right next to a lubricant testing machine because cross-contamination is possible. The same is true for locating wear testing machines in dirty areas of the plant when grit could

become a problem. Vibrations have also been shown to affect friction and wear results. In summary, wear testing equipment should be treated much the same way in which quality control and precision metrology instruments are treated. Keep them clean, isolate them from vibrations, and avoid extremes of temperature and humidity. This extra care will accrue benefits in both the quality and repeatability of test results.

**Proper documentation** of wear testing procedures is important. Complete documentation is most helpful when comparing results to other tests or when trying to analyze the possible causes for differences in wear behavior among different materials. The widespread availability of computer spreadsheets and database programs linked directly to data acquisition systems makes test documentation easy after the initial set up. For example, Fig. 3 lists the type of information that might be incorporated into a computer data file for block-on-ring wear testing results. All ASTM standard wear test methods (Table 3) include a reporting section in which the important variables are delineated. In addition ASTM G 118 lists variables that may be reported. One advantage in using standard test methods is that once the method is specified, the applied testing parameters, such as normal force and length of test, are already implied and need not be redocumented.

Data sheet  
for constant load and speed block-on-ring tests

Test number		Date	
Operator		Machine used	
Block specimen description			
Block cleaning method			
Ring specimen description			
Ring cleaning method			
Lubricant description, temp (°C)			

Testing parameters

Normal force (N)		Ring, rpm	
Test length (rev)		Ambient temp. (°C)	
Environment (%RH)		Run-in procedure, if used	

Results

Block wear measurement method		Block wear amount	
Ring wear measurement method		Ring wear amount	
Steady-state friction coefficient ( $\mu$ )		Stability of friction coefficient ( $\pm\mu$ )	

Other observations of wear and friction behavior  
(add additional sheets or photographic documentation)

**Wear Testing Devices: Commercially Manufactured and Custom Made.** As stated earlier, the diverse nature of wear has led to the design of many types of wear testing machines. Table 5 exemplifies the types of simple testing geometries common to evaluating the various forms of wear. While simple geometries, such as those in Table 5, represent one approach to testing, some of wear machines are either one-of-a-kind or highly specialized for simulating a particular application. Commercially manufactured sliding and rolling contact wear testing machines are available in a number of contact geometries (Fig. 4). Abrasion and erosion testing machines are also commercially available. Some testers, called "universal" or "multimode" testers, are configured to permit the user to change the contact geometry from, for example, block-on-ring to pin-on-disk, using accessory fixtures and drive mechanisms. Several manufacturers or retail sellers of wear testing machines advertise on the Internet and can be found through key-word searches.

**Table 5 Typical testing geometries for wear tests of various types**

Category	Subcategory	Testing geometry
<b>Sliding</b>	Abrasive wear, 2-body	Flat pin-on-rotating abrasive drum (spiral path), reciprocating pin-on-abrasive flat, flat pin-on-moving abrasive belt, traversing pin-on-abrasive disk (spiral path), twin rotating abrasive wheels
	Abrasive wear, 3-body	Dry sand fed between a rotating rubber wheel and a flat coupon, reciprocating flat pin-on-a plate in a slurry bath, block-on-rotating ring in a slurry bath, ball mill, or tumbling wear test
	"Adhesive"	Block-on-ring (flat or conformal face), pin-on-disk, double rub-shoe on rotating disk, reciprocating pin-on-flat, flat-on-flat (thrust washer), pin clamped between V-blocks, ball spinning on three flats (120° apart)
	Fretting wear	Oscillating pin-on-flat, pivoting ball-in-socket, clamped specimen on the sides of a tensile coupon
	Polishing wear	Flat specimen-on-vibrating lap, flat specimens in an orbital polishing or lapping machine
<b>Impact</b>	2-body	Repetitive "hammer"-on-flat
	Impingement, liquid and solid	Liquid jet aimed at the specimen, gas jet with entrained particles, spinning specimens through a gravity-fed stream of particles, centrifugal particle "slinger" apparatus
	Cavitation erosion	Oscillatory "horn" suspended above the specimen in a fluid, flowing fluid through a submerged nozzle aimed at the specimen
<b>Rolling</b>	Rolling contact fatigue	Disk-on-disk rolling contact (equal circumferential speed), rod spinning between three captive balls
	Rolling with slip	Disk-on-disk rolling contact (unequal circumferential speed)

**Fig. 4 Typical configurations of commercially manufactured wear testing machines**

As indicated earlier, wear and chemical attack can have synergistic effects. Special procedures have been developed to study these phenomena (ASTM G 119). Specialized commercial testing machines have also been developed to study such effects, like machines that simulate the movements of surgical knee and hip replacement components in bodylike fluids.

As with mechanical testing in general, commercial wear testing machines are being computer automated. While automation has definite advantages, it also drives up the price of these machines. Testers with infrequent wear problems, or who do not want to make a significant capital investment in wear testing, may be faced with the decision as to whether to construct their own machine, purchase a commercial machine, have a custom machine built, or obtain the services of a fee-testing laboratory.

Published surveys, conducted years ago by organizations such as the American Society of Lubrication Engineers (now called the Society of Tribologists and Lubrication Engineers) and the European Space Agency, have revealed the existence of hundreds of different wear testing devices. Some of these devices have similar geometries and operational features; however, even relatively similar-looking machines can produce different wear results due to subtle differences in construction features (fixture stiffness, method of specimen mounting, mechanical damping capacity, natural frequencies,

heat flow, etc.). The number of custom-designed wear testing devices probably exceeds the number of commercially produced machines. Unfortunately, people who decide to build their own wear testing machines may not be aware of certain subtleties in wear tester design and, thus, may ultimately generate questionable results or results that cannot be reproduced elsewhere. There is still a great deal of applied research needed to better understand differences in wear results arising from different machine designs and measurement techniques.

## Summary

Select a wear testing method that meets the purposes for which the data are needed, and take steps to understand the characteristics and repeatability of results from the testing machine. The units used to report wear vary with type of wear and with the purpose for which the data are to be used. Screening materials for general wear-resistance or preparing a tribosimulation for a particular component involves careful study of the application and an analysis of the type of wear damage that occurs in service. Standards can provide both testing set-up information and the means to produce repeatable results. Documentation is also critical to allow the effective interpretation of the wear data. Whether to use commercially-available wear testing machines, contract wear testing, or develop customized testing equipment must be determined on a case-by-case basis from an examination of both economic and technical issues.

# Corrosion Testing

## Tests for Stress-Corrosion Cracking

STRESS-CORROSION CRACKING (SCC) is a cracking phenomenon that occurs in susceptible alloys and is caused by the conjoint action of a tensile stress and the presence of a specific corrosive environment. For SCC to occur on an engineering structure, three conditions must be met simultaneously, namely, a specific crack-promoting environment must be present, the metallurgy of the material must be susceptible to SCC, and the tensile stresses must be above some threshold value. The tensile stress may be residual stress resulting from heat treatment or fabrication of the metal, may be developed by external loading, or may be a combination of these conditions.

Stress-corrosion cracking occurs under service conditions, which can result, often without any prior warning, in catastrophic failure. Many different mechanisms for SCC have been proposed, but in general, these mechanisms can be divided into two general groups, anodic dissolution mechanisms and cathodic mechanisms. The parameters that control SCC can be divided into materials, environmental, and mechanical parameters.

Stress-corrosion cracking failures resemble brittle fracture; typically there is little, if any, indication of metal ductility at the origin of fracture. The cracking actually is a form of subcritical flaw growth, either intergranular or transgranular, depending on the particular combination of microstructure, environment, and strain rate. However, it is more difficult to design against environmentally assisted cracking than against fracture. Reasons for this difficulty include the compositional, mechanical, and metallurgical synergism and the consequent need to consider a range of environmental variables, as well as their variations with time and their interactions with loading and metallurgical variables.

## SCC Evaluation

In order to determine the susceptibility of alloys to SCC, several types of testing are available. If the objective of testing is to predict the service behavior or to screen alloys for service in a specific environment, it is often necessary to obtain SCC information in a relatively short period of time, which requires acceleration of testing by increasing the severity of the environment or the critical test parameters. The former can be accomplished by increasing the test temperature or the concentration of corrosive species in the test solution and by electrochemical stimulation. Test parameters that can be changed to reduce the testing time include the application of higher stresses, continuous straining, and precracking, which allows bypassing of the crack nucleation phase of the SCC process.

Stress-corrosion specimens can be divided into two categories: smooth specimens and precracked or notched specimens. Further distinction can be made in the loading mode, such as constant deflection, constant load, and constant extension or strain rate. These different loading modes will be discussed in more detail in the following sections.

During alloy processing operations used in the production of wrought alloys, the metal is forced in a predomination direction, so that the grains are elongated in the direction of flow. Because it is important to relate the application of stress and the grain flow direction, two conventions are used to relate the two parameters. In one system, which is primarily used for smooth specimens, the three stressing directions are designated by indicating the direction of the stress, namely longitudinal (L), long-transverse (LT), transverse (T), and short transverse (ST) (Fig. 1).

**Fig. 1** Grain orientations in standard wrought forms of alloys

A second system, which is particularly useful for precracked specimens, indicates both the cracking plane and the direction of crack propagation. The system used three letters (L, T, and W) to indicate three perpendicular directions: L for the longitudinal direction, T for the thickness direction, and W for the width direction. The crack plane is indicated by the direction normal to the crack, and the crack propagation is indicated by one of the directions L, T, or W. Figure 2 demonstrates the various orientations for a double-cantilever-beam (DCB) specimen.

**Fig. 2** Fracture plane identification. L, direction of grain flow; T, transverse grain direction; S, short transverse grain direction; C, chord of cylindrical cross section; R, radius of cylindrical cross section; first letter, normal to the fracture plane; second letter, direction of crack propagation in fracture plane

Other parameters that play an important role in SCC testing are surface condition and residual stress. The nucleation of stress-corrosion cracks strongly depends on initial surface reactions, and thus the surface condition of the test specimens, particularly smooth specimens, has a significant effect on the test results. Smooth test specimens are often tested with a mechanically (machined or abraded) or (electro)chemically treated surface. It is very important to avoid or to remove machining marks or scratches perpendicular to the loading direction.

## Smooth Specimen Testing

Smooth SCC specimens allow for the evaluation of the total SCC life, which includes crack nucleation and propagation. Testing can be conducted under constant extension or strain, constant load, and constant extension or strain rate. The

selection of a specific test method for SCC strongly depends on the particular service application and the time allowed for testing.

### Constant Extension Testing

Constant extension or constant strain tests on smooth specimens are widely used and do not require elaborate testing fixtures. Depending on the specific configuration of the test articles, different types of constant extension tests are being used. The most common types are bent-beam, U-bend, C-ring, and tensile type specimens.

**Bent-Beam Specimens.** The different types of bent-beam specimens are illustrated in Fig. 3. These specimens may be used to test sheet plate and flat extruded material, or wires and extrusions with a circular cross section. Figure 3 shows that the bending can be accomplished in several ways depending on the dimension of the specimen. Stressing of the specimen is accomplished by bending the specimen in a stressing device while restraining the ends. During stress-corrosion testing both specimen and stressing devices are exposed to the test environment. The most simple loading arrangement is the two-point loaded bent-beam, which can only be used on relatively thin sheet or wire material. The elastic stress at the midpoint of the specimen can be estimated:

$$L = (ktE/\sigma)\sin^{-1} (H/ktE)$$

where  $L$  is the specimen length,  $\sigma$  is the maximum stress,  $E$  is the elastic modulus,  $H$  is the length of holder,  $t$  is the specimen thickness, and  $k$  is the empirical constant (1.280).

**Fig. 3** Schematic specimen and holder configurations for bent-beam specimens. (a) Two-point loaded specimen. (b) Three-point loaded specimen. (c) Four-point loaded specimen. (d) Welded double-beam specimen

**Three-point bend specimen** tests are commonly used because of the ease of load application and the ability to use the same loading rigs for different stresses. The load is applied by turning a bolt in the rig, deflecting the specimen. The elastic stress at the midpoint of the specimen is calculated:

$$\sigma = 6Ety/H^2$$

where  $\sigma$  is the maximum tensile stress,  $E$  is the elastic modulus,  $t$  is the specimen thickness,  $y$  is the maximum deflection, and  $H$  is the length of holder.

This test has a number of disadvantages. First, dissimilar metal corrosion and/or crevice corrosion can occur under the bolt. Secondly, once the crack has formed, the stress condition changes such that the outer layer of the specimen is not subject to a tensile stress only but to a complex combination at tensile and bending stresses. The propagating crack will then deviate from the centerline. Thus, the three-point bend test can only be used as a qualitative test to assess the susceptibility to stress-corrosion cracking. With the four-point bend test, tensile stresses can be maintained during the growth of the crack.

**Four-point bend specimen** testing provides a uniform tensile stress over a relatively large area of the specimen. The elastic stress in the outer layer of the specimen between the two inner supports can be calculated:

$$\sigma = 12Ety/(3H^2 - 4A^2)$$

where  $\sigma$  is the maximum tensile stress,  $E$  is the elastic modulus,  $t$  is the specimen thickness,  $y$  is the maximum deflection,  $H$  is the distance between outer supports, and  $A$  is the distance between outer and inner supports.

**U-bend specimens** are prepared by bending a strip 180° around a mandrel with a predetermined radius (Fig. 4). The figure shows that bends less than 108° are also used. Standardized test methods are described in ASTM G 30. Because of the ease of fabrication, a large amount of specimens can be fabricated, and this test is therefore widely used to qualitatively evaluate the susceptibility of alloy and heat treatment to stress-corrosion cracking.

**Fig. 4 Schematic two-stage stressing of a U-bend specimen**

A good approximation of the strain at the apex of the U-bend is:

$$\epsilon = t/2R, \text{ when } t < R$$

where  $t$  is the specimen thickness and  $R$  is the radius of the bend.

Then, an appropriate value for the maximum stress can be obtained from the stress-strain curve of the test material.

**C-ring specimens** are commonly used to determine the susceptibility to stress-corrosion cracking of alloys in different product forms. This test is particularly useful for testing tubing, rod, and bar in the short-transverse direction, as illustrated in Fig. 5. The specimens are typically bolt loaded to a constant strain or constant load per ASTM G 338. If the stresses in the outer layers of the apex of the C-rings are in the elastic region, the stresses can be accurately calculated:

$$D_f = D - \Delta$$

$$\Delta = \sigma d^2 / 4EtZ$$

where  $D$  is the outer diameter of the C-ring before stressing,  $D_f$  is the outer diameter of the stressed C-ring,  $\sigma$  is the elastic stress,  $\Delta$  is the change of  $D$  at the desired stress,  $d$  is the mean diameter ( $D - t$ ),  $t$  is the wall thickness,  $E$  is the elastic modulus, and  $Z$  is the correction factor for curved beam.

**Fig. 5 Sampling procedure for testing various products with C-rings. (a) Tube. (b) Rod and bar. (c) Plate**

The stress on C-ring specimens can be more accurately determined by attaching circumference and transverse strain gages to the stressed surface. The circumferential ( $\sigma_C$ ), and transverse ( $\sigma_T$ ) elastic stresses can be calculated:

$$\sigma_C = E(1 - \mu^2) \times (\epsilon_C + \mu\epsilon_T)$$

$$\sigma_T = E(1 - \mu^2) \times (\epsilon_T + \mu\epsilon_C)$$

where  $E$  is the elastic modulus,  $\mu$  is the Poisson's ratio,  $\epsilon_C$  is the circumferential strain, and  $\epsilon_T$  is the transverse strain.

**Tensile Specimens.** For specific purposes, such as alloy development, a large number of stress-corrosion specimens need to be evaluated. Tensile specimens have been used for this purpose where specimens used to determine tensile properties in air are adapted to SCC, as discussed in ASTM G 49. When uniaxially loaded in tension, the stress pattern is simple and uniform, and the magnitude of the applied stress can be accurately determined. Specimens can be quantitatively stressed by using equipment for application of either a constant load, a constant strain, or an increasing load or strain.

This type of test is one of the most versatile methods of SCC testing because of the flexibility permitted in the type and size of the test specimen, stressing procedures, and the range of stress level. It allows the simultaneous exposure of unstressed specimen (no applied load) with stressed specimens and subsequent tension testing to distinguish between the effects of true SCC and mechanical overload.

A wide range of test specimen sizes can be used, depending primarily on the dimensions of the product to be tested. Stress-corrosion test results can be significantly influenced by the cross section of the test specimen. Although large specimens may be more representative of most structures, they often cannot be prepared from the available product forms being evaluated. They also present more difficulties in stressing and handling in laboratory testing.

Smaller cross-sectional specimens are widely used. They have a greater sensitivity to SCC initiation, usually yield test results rapidly, and permit greater convenience in testing. However, the smaller specimens are more difficult to machine, and test results are more likely to be influenced by extraneous stress concentrations resulting from nonaxial loading, corrosion pits, and so on. Therefore, use of specimens less than about 10 mm (0.4 in.) in gage length and 3 mm (0.12 in.) in diameter is not recommended, except when testing wire specimens.

Tension specimens containing machined notches can be used to study SCC and hydrogen embrittlement. The presence of a notch induces a triaxial stress state at the root of the notch, in which the actual stress will be greater by a concentration factor that is dependent on the notch geometry. The advantages of such specimens include the localization of cracking to

the notch region and acceleration of failure. However, unless directly related to practical service conditions, the results may not be relevant.

Tension specimens can be subjected to a wide range of stress levels associated with either elastic or plastic strain. Because the stress system is intended to be essentially uniaxial (except in the case of notched specimens), great care must be exercised in the construction of stressing frames to prevent or minimize bending or torsional stresses.

The simplest method of providing a constant load consists of a dead weight hung on one end of the specimen. This method is particularly useful for wire specimens. For specimens of larger cross section, however, lever systems such as those used in creep-testing machines are more practical. The primary advantage of any dead-weight loading device is the constancy of the applied load.

Constant-strain SCC tests are performed in low-compliance tension-testing machines. The specimen is loaded to the required stress level, and the moving beam is then locked in position. Other laboratory stressing frames have been used, generally for testing specimens of smaller cross section.

### ***Constant Load Testing***

Although the constant extension tests are widely used for evaluating the susceptibility of alloys to SCC because of the ease of specimen preparation and the ability to test a large number of specimens at one time, there is one major drawback. Once stress-corrosion cracks have formed, the gross cross-sectional stress decreases, which will eventually cause the crack to stop. Application of a constant or a static load provides an alternative test method that represents some actual field conditions that can provide threshold values. It should be cautioned, however, that such threshold values are strongly dependent on the method of loading (i.e., dead weight or spring) and the specimen size and cannot be considered a materials property. Moreover, Fig. 6 shows that as a crack develops, the stress at the crack tip increases, possibly decreasing the time to failure.

(a)

(b)

**Fig. 6** Schematic comparison of determination of threshold stress integrity factor ( $K_{ISCC}$  or  $K_{th}$ ). (a) Constant-load ( $K$ -increasing) test. (b) Constant crack opening displacement ( $K$ -decreasing) test

### Constant Strain-Rate Testing

Constant or slow strain-rate testing is a very useful technique to evaluate the susceptibility of materials to SCC in a relatively short period of time. Typical strain rates range between  $10^{-5}/s$  and  $10^{-7}/s$ , but for most materials the typical strain rate is at  $10^{-6}/s$ . The strain sensitivity to SCC can change for different alloys, even of the same metal. Figure 7 shows that for the 2000-series aluminum alloys, the critical strain rate for the highest susceptibility to cracking is  $10^{-6}/s$ , whereas no such critical strain rate exists for the 7000-series aluminum alloys. This difference in slow strain-rate behavior of the two alloys may indicate different mechanisms for SCC. The slow strain-rate behavior indicates that the principal mechanism for cracking of the 2000-series alloys is film rupture (anodic dissolution model), while the predominant mechanism for cracking of the 7000-series alloys is hydrogen embrittlement.

**Fig. 7** Strain rate regimes for SCC of 2000, 5000, and 7000 series aluminum alloys in a 3% aqueous NaCl solution plus 0.3% H<sub>2</sub>O<sub>2</sub>

The parameters that are typically measured in slow strain-rate testing to determine the susceptibility to SCC are:

- Time to failure
- Percent elongation
- Percent reduction in cross-sectional area at the fracture surface
- Reduction in ultimate (UTS) and yield (YTS) tensile stress
- Presence of secondary cracking on the specimen gage section
- Appearance of the fracture surface

In order to assess the susceptibility of a material to SCC, the results of the slow strain-rate test in a particular environment must be compared with those in an inert environment, such as dry nitrogen gas.

## Precracked Specimen Testing

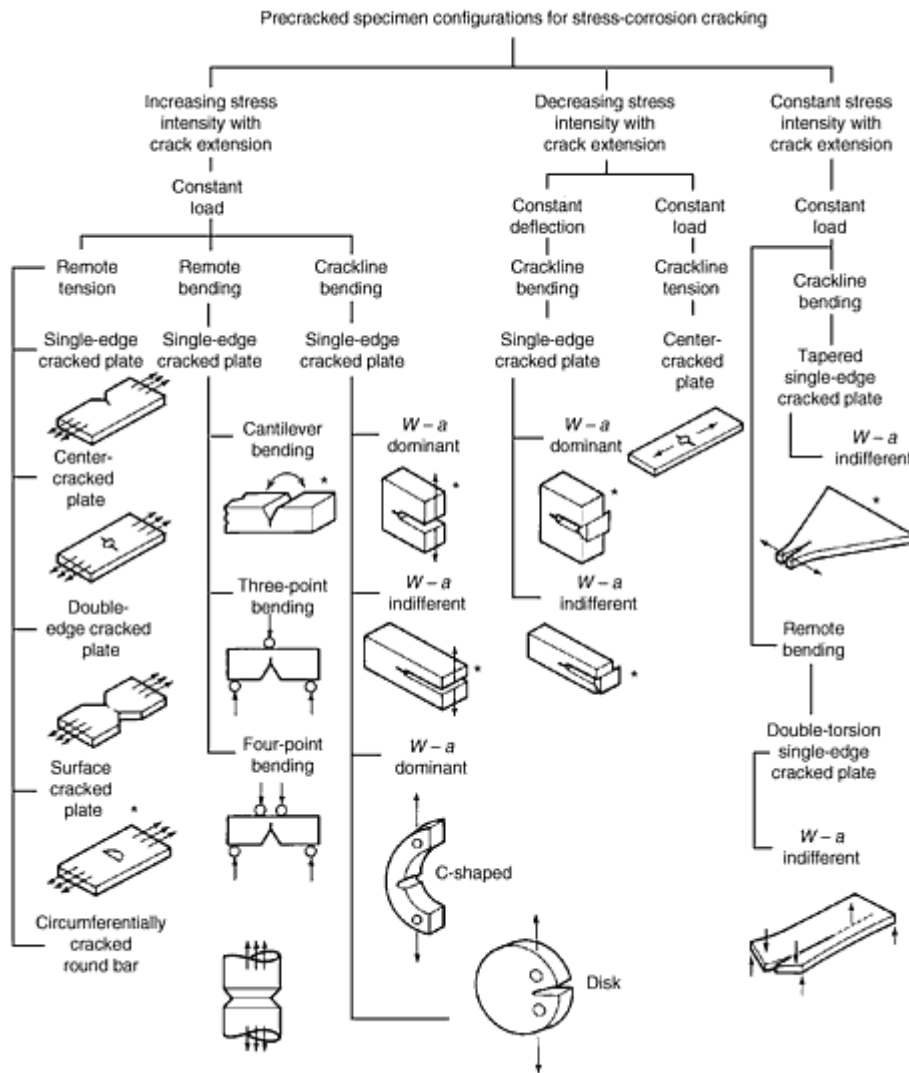

The use of precracked specimens in the evaluation of SCC is based on the engineering concept that all structures contain cracklike flaws. Moreover, precracking can contribute to the susceptibility to SCC of alloys, such as titanium alloys, and this susceptibility may not always be evident from smooth specimens.

Precracking eliminates the uncertainties that are associated with crack nucleation and can provide a flaw geometry for which a stress analysis is available through fracture mechanics. Expressing stress-corrosion characteristics in terms of fracture mechanics provides a relationship between applied stress, crack length, and crack growth in a corrosive environment. When the plasticity can be ignored, or in other words, when the plastic zone ahead of the propagating crack is below a certain value and a triaxial or plane strain stress state exists at the crack tip, linear elastic fracture mechanics (LEFM) can be applied to describe the relationship between crack length ( $a$ ) and the applied stress ( $\sigma$ ) by stress intensity factor  $K$ :

$$K = \sigma \sqrt{a} \cdot F$$

where  $F$  is a polynomial factor that accounts for the specimen geometry. Linear elastic fracture mechanics, and thus  $K$ -factor, cannot be used to describe the relationship between applied stress and the crack length when there is significant plasticity or when the stress state at the crack tip is biaxial or plane stress. Then, a more fundamental parameter, the  $J$ -integral, is used.

Almost all standard plane-strain fracture mechanics test specimens can be adapted to SCC testing. Several examples are shown schematically in Fig. 8. ASTM Standard E 399 describes the allowable specimen dimensions and test procedures for precracked specimens.

**Fig. 8** Classification of precracked specimens for SCC testing

**Specimen Preparation.** When using precracked fracture mechanics specimens, specific dimensional requirements need to be considered, as well as crack configuration and orientation. The basic dimensional requirement for application of LEFM is that dimensions are such that plane-strain condition can be maintained. In general, for a valid  $K$  measurement, neither that crack length nor the specimen thickness should be less than  $2.5 (K_{IC}/\sigma_Y)^2$ .

Several designs of initial crack configuration are available. ASTM E 399 recommends that the notch root radius is not greater than 0.127 mm (0.005 in.) unless a chevron notch is used, in which case it may be 0.25 mm (0.01 in.). In order to start out with a crack as sharp as possible, ASTM E 399 describes procedures for precracking. The  $K$ -level used for precracking should not exceed about two-thirds of the intended initial  $K$ -value. This procedure prevents the forming of compressive stresses at the crack tip, which may alter the SCC behavior of the alloys.

Aluminum alloys can also be precracked by the pop-in method, where the wedge-opening method is used to the point of tensile overload. This method cannot be used for steels and titanium alloys, because of their strength.

**Loading Procedures.** Stress-corrosion crack growth in precracked specimens can be studied in  $K$ -increasing and  $K$ -decreasing tests. In constant load or  $K$ -increasing test, crack growth results in increased crack opening, which keeps the environment at the crack tip and corrosion products from interfering with crack growth. One of the problems with this mode of loading is that with increasing  $K$ , the plastic zone ahead of the crack tip may increase and at some point interfere with crack propagation. Moreover, for this type of testing, bulky and relatively expensive equipment is required.

Constant displacement ( $K$ -decreasing) tests do not have the problems of the  $K$ -increasing tests. The plastic zone ahead of the crack tip does not increase with increasing crack size, so that the stress condition always remains in the plane-strain mode. Also, the constant displacement tests can be self-loaded, and thus external testing equipment is not needed. Because in these tests the stress-intensity factor,  $K_{ISCC}$ , can be easily determined by exposing a number of specimens loaded to different initial  $K_I$  values. This can even be accomplished by crack arrest in one specimen.

A major problem with this test method occurs when corrosion products form in the crack, blocking the crack mouth and interfering with the environment at this crack tip. Moreover, the oxide can wedge open the crack and change the originally applied displacement and load.

**Measurement of Crack Growth.** In order to quantify the crack growth behavior in precracked stress-corrosion specimens, the crack length needs to be monitored, so that the crack velocity ( $da/dt$ ) can be calculated, and the relationship between the increasing  $K$  and the crack velocity can be determined. There are basically three methods to monitor the growth of stress-corrosion cracks: visual/optical measurements, measurement of the crack-opening displacement using clip gages, and the potential drop measurement, which monitors the increase in resistance across two on either side of the propagating crack.

## Tests for Hydrogen Embrittlement

HYDROGEN EMBRITTLEMENT is a time-dependent fracture process caused by the absorption and diffusion of atomic hydrogen into a metal, which results in a loss in ductility and tensile strength. Hydrogen embrittlement is distinguished from stress-corrosion cracking generally by the interactions of the specimens with applied currents. Cases where the applied current makes the specimen more anodic and accelerates cracking are considered to be stress-corrosion cracking, with the anodic-dissolution process contributing to the progress of cracking. On the other hand, cases where cracking is accentuated by current in the opposite direction, which accelerates the hydrogen-evolution reaction, are considered to be hydrogen embrittlement.

Tests for hydrogen embrittlement are performed to determine the effect of hydrogen damage in combination with residual or applied stresses. In the past decade, conventional testing methods have been modified to incorporate fracture mechanics, and the various types of hydrogen damage have been classified further in terms of crack nucleation, crack growth rates, and threshold stress-intensity measurements.

## Testing Methods

As described in the section "Tests for Stress-Corrosion Cracking" in this article, the cantilever beam test and the wedge-opening load test result in a parameter called  $K_{ISCC}$ , which is the threshold stress intensity for SCC. Many different designations, such as  $K_{th}$ ,  $K_{IHE}$ , and  $K_{SH}$ , denote this parameter for steels that undergo a similar phenomenon in which the mechanism is internal hydrogen embrittlement.

The threshold stress intensity for hydrogen stress cracking is designated by  $K_{IHE}$ , and  $K_{ISCC}$  is used for SCC. The mechanisms are different in that SCC occurs under anodic polarization conditions, whereas hydrogen embrittlement and hydrogen stress cracking occur under cathodic polarization conditions, which normally are generated to protect steels from corrosion. Such is the case when a sacrificial anode is galvanically coupled to the steel hull of a ship to prevent the hull from corroding. In such a couple, the steel is the cathode and hydrogen is produced at the cathode in an electrochemical reaction. This results in a steel structure, apparently free of corrosion (with a clean, metallic luster), that fails by intergranular cracking due to internal diffusion of hydrogen generated at the surface. This type of hydrogen embrittlement is found in types 410 and 17-4PH stainless steel and AISI type 4340 steel.

**The cantilever beam test** is a constant-load test in which a V-notched specimen is inserted along a portion of the beam and enclosed by an environmental chamber (Fig. 9). A crack at the root of the V-notch is initiated and extended by fatigue before testing. Notch-root thickness is prescribed by ASTM, although the requirement often is excessive for high-toughness steels. The specimen is subjected to a constant load over a preset time period. As the crack grows, the stress intensity increases. Time to time failure is plotted versus applied stress intensity. The lower limit of the resultant curve is a threshold for hydrogen embrittlement (Fig. 10).

Fig. 9 Fatigue-cracked cantilever beam test specimen and fixtures

Fig. 10 Procedure to obtain  $K_{IHE}$  with precracked cantilever beam test specimen

The  $K_{IHE}$  results of a cantilever beam test depend on how much time elapses before the test is terminated. Recommended testing periods to establish the true stress-intensity threshold vary, ranging from 200 h, which is typical for hydrogen embrittlement testing, to as long as 5000 h. Another limitation of this testing method is that it can be expensive in terms of materials and machining. As many as 12 specimens, placed under different loads in separate test machines, are needed per test to obtain valid  $K_{IHE}$  values.

**The wedge-opening load test** applies a constant wedge or crack opening displacement; as the crack extends, stress intensity decreases until crack arrest occurs (Fig. 11). The initial load is assumed to be slightly above  $K_{IHE}$ . The specimen is maintained under these conditions for about 5000 h to establish the threshold. The crack grows to a point after which further growth is not measured ( $K_{IHE}$ ). However, it is difficult to determine precisely when the "no growth" criterion is met. Crack tip opening displacement should also be monitored. Corrosion reactions accompanied by expansion in volume may occur at the crack tip. This changes the opening displacement and increases the load, thus altering desired testing conditions.

Fig. 11 Schematic showing basic principle of modified wedge-opening load test specimen

As subcritical crack extension occurs, stress intensity increases in the cantilever beam test and decreases in the wedge-opening load test (Fig. 12). Generally, the threshold stress intensity measured with the wedge-opening load test is lower than with the cantilever beam test. The advantage of the wedge-opening load test is that only a single specimen is required to measure  $K_{IHE}$ .

Fig. 12 Influence of time, crack extension, and load on stress-intensity behavior of modified wedge-opening load, cantilever beam, and contoured double-cantilever beam test specimens

**The contoured double-cantilever beam test** is used to measure crack growth rate at a constant stress-intensity factor. This test simplifies the calculation of stress intensity by using a contoured specimen so that stress intensity is proportional to the applied load and is independent of the crack length. Under a constant load, stress intensity also remains constant with crack extension. For the test geometry shown in Fig. 13, the stress-intensity factor equals 20 times the load ( $K = 20P$ ).

Fig. 13 Dimensions and configuration for double-cantilever beam test specimen. Specimen contoured to  $3a^2/h^3 + 1/h = C$ , where  $C$  is a constant. All values given in inches (1.0 in. = 25.4 mm).

Data on hydrogen embrittlement can be obtained with subthickness specimens, even in excess of the ASTM requirement of  $K_{\max}^2 < 0.4 B/(YS)^2$  (where  $B$  is thickness and  $YS$  is yield strength of the specimen), by using side grooves, which provide additional constraint on the material being tested. Side grooves enable the maintenance of a plane-strain condition in a thin specimen by enhancing stress triaxiality. This method has been used extensively to study the effect of heat treatment (hardness) and environment on hydrogen stress cracking of AISI type 4340 steels (Fig. 14).

Fig. 14 Hydrogen embrittlement crack growth rate as a function of applied stress intensity for two different hardnesses and environments for an AISI 4340 steel contoured double-cantilever beam test specimen

The contoured double-cantilever beam test has also been used to study the stress-history effect that produces an incubation time before hydrogen stress cracking. Figure 15 shows that incubation time is dependent on the type of steel. A decrease in the stress-intensity factor from 44 to 22  $\text{MPa}\sqrt{\text{m}}$  (40 to 20  $\text{ksi}\sqrt{\text{in.}}$ ) may change the incubation time from less than 1 h for AISI type 4340 steel to about 1 year for type D-6AC steel.

Fig. 15 Incubation time prior to hydrogen stress cracking for AISI type 4340 and type D-6AC steel contoured double-cantilever beam test specimens as a function of decrease in stress intensity

**Three-Point and Four-Point Bend Tests.** The contoured double-cantilever beam test uses a constant load to maintain a constant stress-intensity factor with crack extension. The same effect can be produced by using a three- or four-point bend test under displacement control. These tests use heavily side-grooved Charpy V-notch specimens (Fig. 16). Because crack opening displacement is constant as the crack extends, the load decreases, so that there is a slight initial increase in stress intensity to a maximum value that drops slightly as the ratio of crack depth to specimen width exceeds 0.5. Typically, stress intensity is constant, within a small range. Figure 17 compares the change in stress-intensity factor with crack extension as a function of load control to that of displacement control for a three-point bend specimen.

Fig. 16 Standard side-grooved Charpy V-notch test specimen used for three- and four-point bend tests

Fig. 17 Use of three-point bend displacement control as constant- $K$  specimen

The **rising step-load test** provides a stress intensity that is different at each load but remains constant with crack extension as each load level is sustained. Crack initiation is signaled by a drop in load (Fig. 18). The rising step-load test was developed as an accelerated low-cost test to measure resistance of steels (particularly weldments) to hydrogen embrittlement. The threshold obtained by this method will be somewhat high, as test duration at each load is short.

Fig. 18 Typical load-time record for four-point rising step-load test

To index susceptibility to hydrogen-assisted cracking, the test should last no longer than 24 h, and the hydrogen source should reflect the most aggressive environment. In one experiment, a 3.5% sodium chloride solution was selected to simulate seawater, and a cathodic potential of -1.2 V (saturated calomel electrode) was used to generate hydrogen to reproduce the extreme conditions of sacrificial anodic protection generally found on a ship hull.

A Charpy specimen was chosen, because such specimens are small and easy to machine and handle. In this test, however, the specimen was modified. Instead of using a fatigue precrack, the notch-root radius was machined to less than  $7.6 \mu\text{m}$  (3 mil). This was done to lower the cost and give less ambiguous environmental conditions at the crack tip. Also, hydrogen cracks nucleate below the surface.

The specimen was deeply side grooved, a common practice used in hydrogen stress cracking tests to prevent the crack from branching. Side grooves are also used in crack opening displacement or  $J$ -integral testing to cause load-displacement curves to increase monotonically to fracture by inducing a highly triaxial stress field at the crack tip. Because a Charpy specimen is small, deep side grooves produce a triaxial stress field at the notch to promote hydrogen stress cracking. The extent of the side grooving is such that the remaining ligament is only 40% of the original thickness. The modified Charpy specimen dimensions are shown in Fig. 16.

The specimen was loaded by means of beams and an instrumented bolt (Fig. 19). Four-point bending under constant displacement control and stress intensity produced crack growth. Once cracking initiated at the notch ( $a/W = 0.2$ , where  $a$  is crack length and  $W$  is width of the specimen), arrest did not occur until the crack was nearly through the specimen. The load was increased manually at 1 h intervals. An environmental chamber encompassed the specimen and included a potentiostat to produce hydrogen while under stress.

Fig. 19 Loading frame used for rising step-load test

The rising step-load test was used to evaluate high-strength HY ship steels and weldments in an environment simulating seawater under conditions of cathodic protection commonly used to protect ship hulls. Samples from the heat-affected zone and other locations in the weld metal were tested. Interlayer gas tungsten arc heating was evaluated as a means of providing a refined, homogeneous, tempered microstructure with improved resistance to hydrogen stress cracking. As a baseline, comparison was made between HY-130 and HY-180 steels.

Figure 20 plots rising step-load test results for HY-130 and HY-180 base metals, in addition to combinations of modified HY steel compositions and programmed-cooling-rate thermal cycles for the base metal and weld wire. The vertical axis is a plot of a parameter derived from the specimen strength ratio in ASTM E 399, "Test Method for Plane-Strain Fracture Toughness of Metallic Materials"--i.e.,  $6 P_{\max}/B(W - a)^2 YS$ , where  $P_{\max}$  is the maximum load that the specimen is able to sustain,  $B$  is the specimen thickness,  $W$  is the specimen width,  $a$  is the crack length, and  $YS$  is the yield strength in tension. For the data shown in Fig. 13,  $P_{\max}$  was replaced by the crack initiation load. The horizontal axis is a ratio of  $K_{IHE}/YS$ , measured in a separate test program with cantilever beam and wedge-opening load specimens.

Fig. 20 Analytical correlation of strength ratio with threshold stress-intensity data

The resistance to hydrogen embrittlement of the two base metals and six locations in HY-130 weldments was ranked using this testing method. Test results showed that HY-180 is more susceptible to hydrogen stress cracking than HY-130 and that the resistance to hydrogen embrittlement of specimens taken from the heat-affected zone and fusion line is consistently higher than that of weld-metal specimens. The resistance of the weld metal is affected by the grain structure; interlayer gas tungsten arc reheating homogenized the weld structure, but did not temper the weld metal. Specimens from the gas tungsten arc reheated weldment consistently exhibited higher hardness and lower resistance to hydrogen embrittlement than similar specimens from the standard HY-130 weld metal.

**The disk-pressure testing method** measures susceptibility to hydrogen embrittlement of metallic materials under a high-pressure gaseous environment. The test is used for the selection and quality control of materials, protective coatings, surface finishes, and other processing variables.

A thin disk of the metallic materials to be tested is placed as a membrane in a test cell and subjected to helium pressure until the bursts. Because helium is inert, the fracture is caused by mechanical overload; no secondary physical or chemical action is involved. An identical disk is placed in the same test cell and subjected to hydrogen pressure until it bursts. Metallic materials that are susceptible to environmental hydrogen embrittlement fracture under a pressure lower than the helium-burst pressure; materials that are not susceptible fracture under the same pressure for both hydrogen and helium. The ratio ( $SH_2$ ) between the helium-burst pressure ( $P_{He}$ ) and the hydrogen-burst pressure ( $P_{H_2}$ ) indicates the susceptibility of the material to environmental hydrogen embrittlement:

$$S_{H_2} = \frac{P_{He}}{P_{H_2}}$$

If  $SH_2$  is equal to or less than 1, the material is not susceptible to environmental hydrogen embrittlement. When  $SH_2$  is greater than 2, the material is considered to be highly susceptible. At values between 1 and 2, the material is moderately susceptible, with failure expected after long exposure to hydrogen; therefore, the material must be protected against exposure.

**Slow strain-rate tensile test** can be used to evaluate many product forms, including plate, rod, wire, sheet, and tubing, as well as welded parts. Smooth, notched, or precracked specimens can be used. The principal advantage of this standardized test is that the susceptibility to hydrogen stress cracking for a particular metal-environment combination can be assessed rapidly.

A variety of specimen shapes and sizes can be used; the most common is a smooth bar tensile coupon, as described in ASTM E 8, "Methods of Tension Testing of Metallic Materials." The specimen is exposed to the environment and is stressed under displacement control. For stainless steel in chloride solution, the strain rate is  $10^{-6}$ s. One or more of the following parameters are applied to the tensile test at the same initial strain rate; time-to-failure; ductility, as assessed by reduction in area or elongation to fracture, for example; maximum load achieved; and area bounded by a nominal stress-elongation curve or a true stress-true strain curve.

**Potentiostatic Slow Strain-rate Tensile Testing.** The use of dissociated water under potentiostatic conditions that produce hydrogen on the surface of the tensile test specimen while under slow strain-rate displacement control has been studied. Results suggest that hydrogen is the most significant parameter in stress cracking under conditions of hydrogen sulfide stress-corrosion cracking found in oil fields.

# Metallographic Practices Generally Applicable to All Metals

Edited by George F. Vander Voort, Buehler Ltd.

## Metallographic Methods

THE METHODS AND EQUIPMENT described in this article cover the preparation of specimens for examination by light optical microscopy (LOM), scanning electron microscopy (SEM), electron microprobe analysis (EMPA) for microindentation hardness testing, and for quantification of microstructural parameters, either manually or by the use of image analyzers.

In this article, it is assumed that the specimen or specimens being prepared are representative of the material to be examined. Random sampling, as advocated by statisticians, can rarely be performed by metallographers. Instead, systematically chosen test locations are employed based on convenience in sampling. In failure studies, specimens are usually removed to study the origin of the failure, to examine highly stressed areas, and to examine secondary cracks.

All sectioning processes produce damage; some methods (such as flame cutting) produce extreme amounts of damage. Traditional laboratory sectioning procedures using abrasive cut-off saws introduce minor damage that varies with the material being cut and its thermal and mechanical history. This damage must be removed if the true structure is to be examined. However, because abrasive grinding and polishing steps also produce damage, where the depth of damage decreases with decreasing abrasive size, the preparation sequence must be carefully planned and performed. Otherwise, preparation-induced artifacts will be interpreted as structural elements. A properly prepared specimen has the following characteristics:

- Deformation induced by sectioning, grinding, and polishing is removed or shallow enough to be removed by the etchant.
- Coarse grinding scratches are removed; fine polishing scratches are tolerated in routine metallographic studies.
- Pullout, pitting, cracking of hard particles, and smear are avoided.
- Relief (i.e., excessive surface height variations between structural features of different hardness) is minimized.
- The surface is flat particularly at edges (if they are to be examined) and at coated surfaces to permit examination at high magnifications.
- Specimens are cleaned adequately between preparation steps, after preparation, and after etching.

Preparation of metallographic specimens generally requires five major operations: sectioning, mounting (optional), grinding, polishing, and etching (optional).

## Sectioning

Many metallographic studies require more than one specimen. For example, a study of deformation in wrought metals usually requires two sections--one perpendicular and the other parallel to the direction of deformation. A failed part may best be studied by selecting a specimen that intersects the origin of the failure, if the origin can be identified. Depending on the type of failure, it may be necessary to take several specimens from the area of failure and from adjacent areas.

**Sampling.** Bulk samples for sectioning may be removed from larger pieces or parts using methods such as core drilling, band or hack sawing, flame cutting, etc. However, when these techniques are used, precautions must be taken to avoid alteration of the microstructure in the area of interest. Laboratory abrasive-wheel cutting is recommended to establish the

desired plan of polish. In the case of relatively brittle materials, sectioning may be accomplished by fracturing the specimen at the desired location.

**Abrasive-Wheel Cutting.** By far, the most widely used sectioning devices in metallographic laboratories are abrasive cut-off machines (Fig. 1). All abrasive-wheel sectioning should be done wet. An ample flow of water, with a water-soluble oil additive for corrosion protection, should be directed into the cut. Wet cutting will produce a smooth surface finish and, most importantly, will guard against excessive surface damage caused by overheating. Abrasive wheels should be selected according to the recommendations of the manufacturer. Specimens must be fixtured securely during cutting, and cutting pressure should be applied carefully to prevent wheel breakage.

**Fig. 1** A tabletop automated abrasive cutoff saw

## Mounting of Specimens

The primary purpose of mounting metallographic specimens is for convenience in handling specimens of difficult shapes or sizes during the subsequent steps of metallographic preparation and examination. A secondary purpose is to protect and preserve extreme edges or surface defects during metallographic preparation. The method of mounting should in no way be injurious to the microstructure of the specimen. Mechanical deformation and heat are the most likely sources of injurious effects.

**Clamp Mounting.** Clamps have been used for mounting metallographic cross sections in the form of thin sheets. Several specimens can be clamped conveniently in sandwich form. This method is quick and convenient for mounting sheet type specimens; and when done properly, edge retention is excellent. There is no problem with seepage of fluids from crevices between specimens. The outer clamp edges must be beveled to minimize damage to polishing cloths. If clamps are improperly used so that gaps exist between specimens, fluids and abrasives can become entrapped and will seep out obscuring edges. The problems can be minimized by proper tightening of clamps, by use of plastic spacers between specimens, or by coating specimen surfaces with epoxy before tightening.

**Compression Mounting.** The most common mounting method uses pressure and heat to encapsulate the specimen with a thermosetting or thermoplastic mounting material. Common thermosetting resins include phenolic, such as Bakelite (Union Carbide Corp., Danbury, CT) and diallyl phthalate, while methyl methacrylate is the most common thermoplastic mounting resin. Both thermosetting and thermoplastic materials require heat and pressure during the molding cycle; but after curing, mounts made of thermoplastic resins must be cooled to ambient under pressure, while mounts made of thermosetting materials may be ejected from the mold at the maximum molding temperature. However, cooling thermosetting resins under pressure to at least 55 °C (130 °F) before ejection will reduce shrinkage gap formation. A thermosetting resin mount should never be water cooled after hot ejection from the molding temperature. Thermosetting epoxy resins provide the best edge retention of these resins and are less affected by hot etchants than phenolic resins. Mounting presses vary from simple laboratory jacks with a heater and mold assembly to full automated devices (Fig. 2).

**Fig. 2** Mounting presses vary from a simple laboratory manual device (a) to a fully automated press (b)

**Cold mounting** materials require neither pressure nor external heat and are recommended for mounting specimens that are sensitive to heat and/or pressure. Acrylic resins are the most widely used castable resin due to their low cost and fast curing time; however, shrinkage is somewhat of a problem. Epoxy resins, although more expensive than acrylics, are commonly used because epoxy will physically adhere to specimens and can be drawn into cracks and pores, particularly if a vacuum impregnation chamber is employed. Hence, epoxies are very suitable for mounting fragile or friable specimens and corroded or oxidized specimens. Dyes or fluorescent agents are added to some epoxies for the study of porous specimens, such as thermal spray coated specimens. Most epoxies are cured at room temperature, and curing times can be as long as 6 to 12 h. Some epoxies can be cured at slightly elevated temperatures in less time. Hard filler particles have been added to epoxy mounts for edge retention, but this addition is really not a satisfactory solution.

**Taper sectioning** (mounting) generally is regarded as a special mounting technique; it enables the metallographer to examine in greater detail the immediate subsurface structure or surface topography of a specimen. Microhardness determinations and thickness measurements of thin surface coatings or diffusion zones may be performed on taper-sectioned specimens. Taper sectioning (Fig. 3) is accomplished by establishing a plane of polish at a small angle to the surface of the specimen.

**Fig. 3** Schematic of taper sectioning (mounting), as applied to a coated specimen. Taper magnification equals the cosecant of taper angle,  $\alpha$ .

**Edge preservation** is a long-standing metallographic problem and many "tricks" have been promoted (most pertaining to mounting, but some to grinding and polishing). These methods include the use of backup material in the mount, the application of coatings to the surfaces before mounting, and the addition of a filler material to the mount. Plating of a

compatible metal on the surface to be protected (electroless nickel has been widely used) is generally considered to be the most effective procedure.

However, introduction of new technology has greatly reduced edge preservation problems. First, use of mounting presses, which cool the specimen to near ambient temperature under pressure, produces much tighter mounts. Gaps that form between specimen and resin are a major contributor to edge rounding. Second, use of semi-automatic and automatic grinding/polishing equipment, rather than manual (hand) preparation, increases surface flatness and edge retention. Third, the use of harder, woven or nonwoven, napless surfaces for polishing with diamond abrasives, rather than softer cloths, such as canvas, billiard, and felt, maintains flatness. Final polishing using low-nap cloths for short times introduces very little rounding compared to use of higher nap, softer cloths.

## Grinding

Grinding should commence with the finest grit size that will establish an initially flat surface and remove the effects of sectioning within a few minutes. An abrasive grit size of 180 or 240 grit is coarse enough to use on specimen surfaces sectioned by an abrasive cut-off wheel. Hack-sawed, band-sawed, or other rough surfaces usually require abrasive grit sizes from 120 to 180 grit. The abrasive used for each succeeding grinding operation should be one or two grit sizes smaller than that used in the preceding operation. A satisfactory fine grinding sequence might involve grit sizes of 240, 320, 400, and 600 grit. This sequence is known as the "traditional" approach.

As in abrasive-wheel sectioning, all grinding should be done wet provided that water has no adverse effects on any constituents of the microstructure. Wet grinding minimizes loading of the abrasive with metal removed from the specimen being prepared and minimizes specimen heating.

Each grinding step, while producing damage itself, must remove the damage from the previous step. The depth of damage decreases with the abrasive size but so does the metal removal rate. For a given abrasive size, the depth of damage introduced is greater for soft materials than for hard materials.

Besides SiC paper, a number of other options are available to circumvent their use. One option, used chiefly with semi-automatic and automatic systems, is to grind a number of specimens placed in a holder simultaneously using a conventional grinding stone generally made of coarse grit alumina. This step, often called "planar grinding," has the second goal of making all of the specimen surfaces coplanar. This process requires a special-purpose machine because the stone must rotate at a high speed,  $\geq 1500$  rpm, to cut effectively. The stone must be dressed regularly with a diamond tool to maintain flatness.

Other materials have also been used both for the planar grinding stage or, afterwards, to replace SiC paper. For very hard materials such as ceramics and sintered carbides, two or more metal-bonded or resin-bonded diamond disks with grit sizes from about 70 to 9  $\mu\text{m}$  can be used. An alternate type of disk has diamond particles suspended in a resin applied in small blobs, or spots, to a disk surface. These disks are available with diamond sizes from 120 to 6  $\mu\text{m}$ . Another type of disk available in several diamond sizes uses diamond attached to the edges of a perforated, screen-like metal disk. Another approach uses a stainless steel woven mesh "cloth" on a platen charged with coarse diamond, usually in slurry form, for planar grinding. Once planar surfaces have been obtained, there are several single-step procedures available for avoiding the finer SiC papers. These processes include the use of platens, woven polyester thick cloths, or rigid grinding disks. With each of these, a coarse diamond size, most commonly 9  $\mu\text{m}$ , is used.

**Grinding Media.** The grinding abrasives commonly used in the preparation of metallographic specimens are silicon carbide (SiC), aluminum oxide ( $\text{Al}_2\text{O}_3$ ), emery ( $\text{Al}_2\text{O}_3\text{-Fe}_3\text{O}_4$ ), composite ceramics, and diamond. All except diamond are generally bonded to paper or cloth-backing materials of various weights in the form of sheets, disks, and belts of various sizes. Limited use is made of grinding wheels consisting of abrasives embedded in a bonding material. The abrasives may be used also in powder form by charging the grinding surfaces with loose abrasive particles or with abrasive in a premixed slurry or suspension.

**Grinding Equipment.** Although it is rarely used in industry, students still use stationary grinding paper that is supplied in strips or rolls (Fig. 4). The specimen is slid against the paper from top to bottom. Grinding in one direction is usually safer than grinding in both directions. While this can be done dry for certain delicate materials, water is usually added to keep the specimen surface cool and to carry the swarf away.

**Fig. 4** A simple stationary grinding apparatus

Belt grinders (Fig. 5) are usually present in most laboratories. They are mainly used to remove burrs from sectioning, to round edges that need not be preserved for examination, to flatten cut surfaces to be macroetched, or to remove sectioning damage. Generally only very coarse abrasive papers grits from 60 to 240 grits are used. Most grinding work is done on rotating wheels; that is, a motor-driven platen upon which the SiC paper is attached (Fig. 6).

**Fig. 5** Single and dual belt grinders for rough grinding

**Fig. 6** Laboratory flush mounted semi-automatic grinder/polisher system

**Lapping** is an abrasive technique in which the abrasive particles roll freely on the surface of a carrier disk. During the lapping process, the disk is charged with small amounts of a hard abrasive, such as diamond or silicon carbide. Lapping produces a flatter specimen surface than grinding, but it does not remove metal as in grinding. Consequently, lapping is not commonly employed in metallography. Some platens, referred to as laps, are charged with diamond slurries. Initially, the diamond particles roll over the lap surface (just as with other grinding surfaces), but they soon become embedded and cut the surface, producing chips.

## Polishing

Polishing is the final step in producing a deformation-free surface that is flat, scratch-free, and mirror-like in appearance. Such a surface is necessary for subsequent metallographic interpretation, both qualitative and quantitative. The polishing technique used should not introduce extraneous structures, such as disturbed metal, pitting, dragging out of inclusion, "comet tailing," and staining. Polishing usually is conducted in several stages. Rough polishing generally is traditionally done with 6 or 3  $\mu\text{m}$  diamond abrasive charged onto napless or low-nap cloths. Hard materials, such as through-hardened steels, ceramics, and cemented carbides, may require an additional polishing step. For such materials, initial rough polishing may be followed by polishing with 1  $\mu\text{m}$  diamond on a napless, low-nap, or medium-nap cloth. A compatible lubricant should be used sparingly to prevent overheating or deformation of the surface. Intermediate polishing should be performed thoroughly so that final polishing may be of minimal duration. Manual, or "hand," polishing is usually conducted using a rotating "wheel" (Fig. 7).

Fig. 7 Manual "hand" polishing setup

### ***Mechanical Polishing***

The term *mechanical polishing* is frequently used to describe the various polishing procedures involving the use of fine abrasives on cloth. The cloth may be attached to a rotating wheel or a vibrating bowl (Fig. 8). The specimens are held by hand, held mechanically, or merely confined within the polishing area.

Fig. 8 Vibratory polishing unit

**Hand Polishing.** Aside from the use of improved polishing cloths and abrasives, hand-polishing techniques still follow the basic practice established many years ago:

- *Specimen Movement.* The specimen is held with one or both hands, depending on the operator's preference, and is rotated in a direction counter to the rotation of the polishing wheel. In addition, the specimen is continuously moved back and forth between the center and the edge of the wheel, thereby ensuring even distribution of the abrasive and uniform wear of the polishing cloth. Some metallographers use a small wrist rotation while moving the specimen from the center to the edge of one side of the wheel. The main reason for rotating the specimen is to prevent formation of "comet tails." This polishing artifact (Fig. 9) is a result of directional polishing of materials containing inclusions, fine precipitates, voids, or other similar features.
- *Polishing Pressure.* The correct amount of applied pressure must be determined by experience. In general, firm hand pressure is applied to the specimen in the initial movement.

- *Washing and Drying.* The specimen is washed and swabbed in warm running water, rinsed with ethanol, and dried in a stream of warm air. Scrubbing with cotton soaked with an aqueous soap solution followed by rinsing with water is also commonly employed. Alcohol usually can be used for washing when the abrasive carrier is not soluble in water or if the specimen cannot tolerate water.
- *Cleanness.* The precautions for cleanness, as previously mentioned, must be strictly observed.

**Fig. 9** "Comet tails" due to directional polishing and pull out of hard particles. 200×

For routine metallographic work, a fine diamond abrasive (1  $\mu\text{m}$ ) may be used as the last step. Traditionally, aqueous fine alumina slurries have been used for final polishing with medium-nap cloths. Alpha alumina (0.3  $\mu\text{m}$ ) and gamma alumina (0.05  $\mu\text{m}$ ) slurries (or suspensions) are popular for final polishing, either in sequence or singularly. Colloidal silica (basic pH about 9.5) and acidic alumina suspensions are newer final polishing abrasives being used for difficult to prepare materials. Vibratory polishers (Fig. 8) are often used for final polishing, particularly with more difficult to prepare materials, for image analysis studies, or for publication-quality work.

**Automatic Polishing.** Mechanical polishing can be automated to a high degree using a wide variety of devices ranging from relatively simple systems to rather sophisticated minicomputer- or microprocessor-controlled devices (Fig. 10). Units also vary in capacity from a single specimen (Fig. 11) to a half dozen or more at a time (Fig. 12). Most units can be used for all grinding and polishing steps. These devices enable the operator to prepare a large number of specimens per day, often with a higher degree of quality than that of hand polishing and at reduced consumable costs. Automatic polishing devices also are desirable for preparing radioactive specimens by remote control or for using corrosive-attack polishing procedures safely without hand contact.

**Fig. 10** A fully automatic polishing system

**Fig. 11** An automatic single-specimen grinder/polisher

**Fig. 12** A semi-automatic grinder/polisher

**Polishing Cloths.** The requirements of a good polishing cloth include the ability to hold an abrasive, long life, absence of any foreign material that may cause scratches, and absence of any processing chemical (such as dye or sizing) that may react with the specimen. More than a hundred cloths of different fabrics (woven or nonwoven) with a wide variety of naps (or napless) are available for metallographic polishing. Napless or low-nap cloths are recommended for rough polishing using diamond abrasive compounds. Low-, medium-, and occasionally high-nap cloths are used for final polishing, but this step should be as brief as possible to minimize relief.

**Polishing Abrasives.** Polishing usually involves the use of one or more of the following abrasives: diamond, aluminum oxide ( $\text{Al}_2\text{O}_3$ ), magnesium oxide ( $\text{MgO}$ ), and/or silicon dioxide ( $\text{SiO}_2$ ). For certain materials, cerium oxide, chromium oxide, or iron oxide may be used. With the exception of diamond, these abrasives normally are used in a distilled-water suspension. If the metal to be polished is not compatible with water, other suspensions, such as ethylene glycol, alcohol, kerosene, or glycerol, may be required. The diamond abrasive should be extended only with the carrier recommended by the manufacturer.

### ***Electrolytic Polishing***

Even with the most careful mechanical polishing, some disturbed metal, however small the amount, will remain after preparation of a metallographic specimen. This remainder is no problem if the specimen is to be etched for structural investigation, because etching is usually sufficient to remove the slight layer of disturbed metal. If the specimen is to be examined in the as-polished condition using polarized light or if no surface disturbance can be tolerated, either electrolytic polishing (also called "electropolishing") or chemical polishing is preferred. Alternatively, vibratory polishing

with (basic) colloidal silica, acidic alumina suspensions, or attack polishing agents added to these abrasives (or to  $\alpha$ - or  $\gamma$ -alumina suspensions) will remove minor amounts of residual damage providing good polarized light response. A simple laboratory setup (Fig. 13) is sufficient for most electropolishing requirements, and the more sophisticated commercial units (Fig. 14) are all based on the same principle. Direct current from an external source is applied to the electrolytic cell under specific conditions, and anodic dissolution produces leveling and brightening of the specimen surface.

Fig. 13 Simple laboratory system for electropolishing and electroetching

Fig. 14 A commercially available electrolytic polishing and etching system

Not all materials respond equally well to electrolytic polishing. Wrought solid solution-type alloys, such as aluminum, nickel, nickel-iron, and titanium alloys, are particularly good candidates for electrolytic polishing. Electropolishing is usually reserved for single-phase alloys, because second phases and inclusions may be preferentially attacked during polishing.

### ***Chemical Polishing***

Chemical polishing involves simple immersion of a metal specimen into a suitable solution to obtain a metallographic polish. The results of chemical polishing are similar to those of electropolishing. They vary from an etched specimen surface that has been macrosmoothed but not brightened to a bright dipped surface that has been brightened but not macrosmoothed.

### **Etching**

Metallographic etching encompasses all processes used to reveal particular structural characteristics of a metal that are not evident in the as-polished condition. Examination of a properly polished specimen before etching may reveal

structural aspects, such as porosity, cracks, and nonmetallic inclusions. In certain nonferrous alloys, grain size can be revealed adequately in the as-polished condition using polarized light.

**Electrolytic Etching.** The procedure for electrolytic etching is basically the same as for electropolishing, except that voltage and current densities are considerably lower. The specimen is connected to be the anode, and some relatively insoluble but conductive material, such as stainless steel, graphite, or platinum, is used for the cathode. Direct-current electrolysis is used for most electrolytic etching, and for small specimens (13 by 13 mm, or  $\frac{1}{2}$  by  $\frac{1}{2}$  in., surface to be etched), one or two standard  $1\frac{1}{2}$  V flashlight batteries provide an adequate power source. A setup like the one shown in Fig. 13 is usually all that is required.

**Etching for Macrostructure.** Macroscopic examination differs from microscopic examination in that it employs very low magnifications (up to approximately 50 $\times$ ) and is used for the investigation of defects and structure of a large area as opposed to a microscopic portion of that area. This technique is used to reveal solidification structure, flow lines, segregation, and structural changes due to welding, general distribution of sulfide inclusions, porosity, ingot defects, and fabricating defects. It is important that the investigator be aware that macroetching can exaggerate the size of inhomogeneities or defects that could lead to misinterpretation of the actual condition of the material.

**Etching for Microstructure.** In this article, microscopic examination is limited to a maximum magnification of 2500 $\times$ --the approximate useful limit of light microscopy. Microscopic examination of a properly prepared specimen will clearly reveal structural characteristics, such as grain size, segregation, and the shape, size, and distribution of the phases and inclusions, that are present. The microstructure revealed also indicates prior mechanical and thermal treatment that the metal has received.

Etching is done by immersion or by swabbing (or electrolytically) with a suitable chemical solution that basically produces selective corrosion. Swabbing is preferred for those metals and alloys that form a tenacious oxide surface layer with atmospheric exposure, such as stainless steels, aluminum, nickel, niobium, and titanium and their alloys. It is best to use surgical grade cotton that will not scratch the polished surface. Etch time varies with etch strength and can only be determined by experience. In general, for high magnification examination, the etch should be shallower, while for low magnification examination a deeper etch yields better image contrast. Some etchants produce selective results in that only one phase will be attacked or colored. A vast number of etchants have been developed; the more commonly used etchants will be listed in this article (see also ASTM E 407).

## Macroscopic Examination

There are aspects of structure, termed macrostructure, which can be observed with the unaided eye. Macrostructural examination is often a prelude to microstructural examination but also includes routine quality tests for material acceptance. These tests may also be useful for failure studies and research programs. The most common macrostructural tests include macroetching, sulfur printing, lead exudation, and fracture tests.

**Macroetching** is used to detect variations in soundness, chemistry, hardness, or strain. A disk is cut from the part, smooth ground, and subjected to etching with an appropriate solution. In a wrought product, a disk cut perpendicular to the deformation axis (i.e., transverse) is most commonly chosen as it reveals conditions that vary around the product. Less commonly, a section along the centerline parallel to the deformation axis will be chosen to better reveal segregation, which usually elongates with deformation and is more readily detected in this way. A finely polished surface is not required. On the other hand, a saw-cut surface, due to its roughness, will permit observation of only the coarsest features. A smoothly ground surface is best. For small products, a mounted and polished metallographic section will reveal most macrostructural features when standard microstructural etching solutions are used.

Macroetchants tend to be rather strong in concentration compared to microetchants, so that contrast is adequate for visual examination. Generally, the depth of etch attack of a macroetchant is substantially greater than for microetchants. Macroetchants may be used at room temperature or at temperatures up to about 80 °C (180 °F) depending upon the purpose of the study and the nature of the material. As an example, to study the macrostructure of weldments in ferrous alloys, macroetching with an aqueous 10% nitric acid solution at room temperature for 30 to 60 s is preferred. However, to evaluate the macrostructural soundness of a steel billet, hot acid etching with an aqueous 50% HCl solution at 70 to 80 °C (160 to 180 °F) for 15 to 30 min is preferred. Macroetching solutions for many metals can be found in ASTM E 340 and in other standard compilations.

Evaluation of the macrostructure of steel forgings, billets, bars, and continuously cast products is defined in various standards, such as ASTM E 381, MIL-STD-430A, ASTM A 561, and ASTM A 604. Features are classified based on their location (center, random, or subsurface) and nature (bursts, inclusions, flake, pipe ring patterns, freckles, white spots, cracks, etc.). Macroetching can also be applied to cast metals to reveal the grain structure, dendrites, blowholes, pin holes, sand holes, shrinkage cavities, etc. In forged components, particularly closed die forgings, the flow pattern is often evaluated by macroetching a disk cut across the component and etching to reveal the flow lines. Welding processes are often evaluated by macroetching sections taken through test welds. In failure analysis, macroetching often detects unusual or unexpected features that contribute to or cause failures.

## Contact Print Methods

Although a number of special contact print methods have been developed, the most commonly employed is the sulfur print, used to reveal the distribution of sulfur in a steel product. A smoothly ground disk, carefully cleaned, is covered by a sheet of photographic paper that has been soaked for 1 to 5 min in an aqueous 2% sulfuric acid solution (1 to 5% solutions can be used). The excess solution is allowed to drip off the paper. Then, the emulsion side of the paper is placed against the ground surface of the steel specimen and left in contact for 2 to 10 min, depending on the sulfur content of the steel. The lower the sulfur content, the longer the time of contact. Any bubbles under the paper must be moved to the edge using a roller, squeegee, or sponge being careful not to move the paper. The print is then peeled off carefully, washed in running water, fixed, washed, and dried. Details of the sulfur print method are given in ASTM E 1180.

The distribution of sulfur is shown by the presence of darkly colored areas of silver sulfide on the print. The print is a mirror image of the sulfur distribution. Voids, holes, or cracks may be represented by dark spots or lines due to hydrogen sulfide gas becoming trapped in these openings under the paper. Other printing methods have been developed, but their use is infrequent.

## Microscopic Examination

Metallurgical microscopes differ from biological microscopes primarily in the manner by which the specimen is illuminated. Unlike biological microscopes, metallurgical microscopes must use reflected light. Figure 15 is a simplified ray diagram of a metallurgical microscope, while Fig. 16 shows a typical inverted metallurgical microscope ("metallograph"). The prepared specimen is placed on the stage with the surface perpendicular to the optical axis of the microscope and is illuminated through the objective lens by light from the source. The light is focused by the condenser lens into a beam that is made approximately parallel to the optical axis of the microscope by the half-silvered mirror. The light is then reflected from the surface of the specimen through the objective, the half-silvered mirror, and the eyepiece to the observer's eye.

Fig. 15 Image formation in a metallurgical microscope employing brightfield illumination

**Fig. 16** Example of an inverted metallurgical reflecting microscope for photomicroscopy (referred to as a metallograph). Courtesy of C. Brandmaier, Nikon Inc.

## ***Light Sources***

The amount of light lost during passage from the source through a reflecting type of microscope is appreciable because of the intricate path the light follows. For this reason, it is generally preferable that the intensity of the source be high, especially for photomicroscopy. Several light sources are used, including tungsten-filament lamps, tungsten-halogen lamps, quartz-halogen lamps, and xenon arc bulbs.

**Tungsten-filament** lamps generally operate at low voltage and high current. They are widely used for visual examination because of their low cost and ease of operation.

**Tungsten-halogen** lamps are the most popular light source today due to their high light intensity. They produce good color micrographs when tungsten-corrected films are employed.

**Xenon arc** lamps produce extremely high intensity, and their uniform spectra and daylight color temperature makes them suitable for color photomicrography. The first xenon lamps produced ozone, but modern units have overcome this problem. Light output is constant and can only be reduced using neutral density filters.

## ***Microscopic Techniques***

Most microscopic studies of metals are made using brightfield illumination. In addition to this type of illumination, several special techniques (oblique illumination, darkfield illumination, opaque-stop microscopy, phase-contrast microscopy, and polarized-light microscopy) have particular applications for metallographic studies.

**Köhler Illumination.** Most microscopes using reflected or transmitted light use Köhler illumination, because it provides the most intense, even illumination possible with standard light sources. The reflected light microscope has two adjustable diaphragms, the aperture diaphragm and the field diaphragm, located between the lamp housing and the objective. Both diaphragms are adjusted to improve illumination and the image. To obtain Köhler illumination, the image of the field diaphragm must be brought into focus on the specimen plane. This situation normally occurs automatically when the microstructural image is brought into focus. The filament image must also be focused on the aperture diaphragm plane. This focus produces uniform illumination of the specimen imaged at the intermediate image plane and magnified by the eyepiece.

**In brightfield illumination,** the surface of the specimen is normal to the optical axis of the microscope, and white light is used. Figure 15 shows the ray diagram for this type of illumination in a standard type of bench microscope. Light that passes through the objective and strikes a region of the specimen surface perpendicular to the beam will be reflected back up the objective through the eyepieces to the eyes, where it will appear to be bright or white. Light that strikes grain boundaries, phase boundaries, and other features not perpendicular to the optical axis will be scattered at an angle and will not be collected by the objective. These regions will appear to be dark or black in the image. Brightfield is the most common mode of illumination used by metallographers.

**Oblique illumination** reveals the surface relief of a metallographic specimen. This process involves offsetting the condenser lens system or, as is more usually done, moving the condenser aperture to a position slightly off the optical axis. Although it should be possible to continually increase the contrast achieved by oblique illumination by moving the condenser farther and farther from the light axis, the numerical aperture of a lens is reduced when this happens because only a portion of the lens is used. For this reason, there is a practical limit to the amount of contrast that can be achieved.

Illumination also becomes uneven as the degree of obliqueness increases. Because differential interference contrast systems have been available, oblique illumination is rarely offered as an option on new microscopes.

**Darkfield illumination** (also known as dark ground illumination) often is used to distinguish features not in the plane of the polished-and-etched surface of a metallographic specimen. This type of illumination gives contrast completely reversed from that obtained with brightfield illumination: the features that are light in brightfield will be dark in darkfield, and those that are dark in brightfield will be light in darkfield. This highlighting of angled surfaces (namely, those of pits, crack, or etched grain boundaries) allows more positive identification of their nature than can be derived from a black image under brightfield illumination. Due to the high image contrast obtained and the brightness associated with features at an angle to the optical axis, it is often possible to see details not observed with brightfield illumination.

**Polarized-Light Microscopy.** is particularly useful in metallography, because many metals and metallic and nonmetallic phases are optically anisotropic. Polarized light is obtained by placing a polarizer in front of the condenser lens of the microscope and placing an analyzer before the eyepiece (Fig. 17). The polarizer produces plane-polarized light that strikes the surface and is reflected through the analyzer to the eyepieces. If an anisotropic metal is examined with the analyzer set  $90^\circ$  to the polarizer, the grain structure will be visible. However, viewing of an isotropic metal (cubic metals) under such conditions will produce a dark, extinguished condition. Polarized light is particularly useful in metallography for revealing grain structure and twinning in anisotropic metals and alloys and for identifying anisotropic phases and inclusions.

**Fig. 17** Basic components of a polarizing light microscope

**Differential Interference Contrast Microscopy.** When crossed polarized light is used along with a double quartz prism (Wollaston prism) placed between the objective and the vertical illuminator, two light beams are produced that exhibit coherent interference in the image plane. This occurrence leads to two slightly displaced (laterally) images differing in phase ( $\lambda/2$ ) that produces height contrast. The image produced reveals topographic detail somewhat similar to that produced by oblique illumination but without the loss of resolution. Images can be viewed with natural colors similar to those observed in brightfield, or artificial coloring can be introduced by adding a sensitive tint plate.

**High-Temperature Microscopy.** Several microscopes have been developed with devices that allow simultaneous heating and examination of specimens. These have permitted direct examination of thermal effects in metals, such as grain growth, precipitation reactions, phase changes, sintering, diffusion, and certain types of surface reactions. For some limited studies of this type, it is possible simply to surround the specimen with a small furnace and microscopically examine a polished surface. An alternative means of heating the specimen is by electrical resistance. Unfortunately, these simple methods have very limited usefulness because most metals and alloys oxidize at elevated temperatures, and oxidation must be avoided if unobstructed observations are to be made.

Heating in a vacuum presents a problem in that certain phases exposed on the surface of the specimen can evaporate and then condense on the viewing window thereby hindering observation. This situation can be partly overcome by using a

double viewing window with the window nearer the specimen being removable and the remaining window being used for photography. Evaporation usually can be eliminated by operating in an inert-gas atmosphere; however, to prevent surface oxidation or contamination, the inert gas generally must be of very high purity.

A serious problem in high-temperature microscopy is potential damage to the microscope parts, particularly the objective lens, by the high temperatures. This danger is partly corrected by water cooling the parts of the hot stage near the objective; however, high magnifications are still not possible because the short working distances of most objectives do not permit examination through the viewing windows. To overcome this, long-working-distance objectives have been used. The most widely used type employs a reflecting concave mirror in conjunction with a standard objective.

**Low-Temperature Microscopy.** Certain reactions that occur in metals at low temperatures can be observed by microscopy. Stages have been constructed for this purpose; most are either adaptations of high-temperature stages or similar to them. Generally a refrigerant, such as liquid nitrogen, cools the stage that holds the specimen. A thermocouple on the specimen measures the temperature controlled by the supply of refrigerant. Low-temperature microscopy has found only limited use in metallography.

**Straining Stages.** Several other devices can be fitted to the stages of microscopes so that a specimen can be viewed while experiments are being performed on it. Stages constructed so as to allow straining of a specimen while it is being viewed have been particularly useful for studies of deformation, twinning, slip, and strain-induced transformations. Because of the development of scanning electron microscopes (SEM), these types of experiments are more commonly performed within the SEM.

**Interferometry** is the most sensitive and accurate optical method of measuring the microtopography of surfaces. Two interference methods are in common use in metallography: the two-beam and the multiple-beam methods.

Figure 18 shows the principles of the two-beam method. In a two-beam interferometer, monochromatic light from the source is split into two beams. One beam travels through the microscope objective to the specimen and then is reflected back through the objective and into the eyepiece. The other beam passes through an identically matched objective onto an optically flat reference plate and then back through the same objective and is directed by the beam splitter to the eyepiece. The two beams meet in the eyepiece and either reinforce each other (where the optical-path difference between them is equal to, or a multiple of, half the wavelength of the monochromatic light) or interfere with each other (where the optical-path difference does not satisfy the above conditions). From this reinforcement or interference, contour lines are formed with each line connecting points of the same level. The difference in height between fringes is one-half the wavelength of the light. Thallium light, which has a wavelength of 540 nm, is commonly used. It is usually possible to measure to an accuracy of one-tenth of a displacement, which means that differences in height of about 27 nm can be measured.

**Fig. 18** Principle of two-beam interferometry

Figure 19 shows the principles of multiple-beam interferometry. Instead of creating interference between two light beams, the multiple-beam method produces interference among many beams. An optically flat reference plate that is partly transmitting and partly reflecting to light is placed onto the surface of the specimen. The plate and the specimen are positioned slightly out of parallel but usually by not more than one or two wavelengths. Several objectives with reference plates built into them are commercially available for use on standard metallurgical microscopes. Monochromatic light is directed perpendicular to the specimen surface through the objective. Some of this light is reflected from the surface of

the reference plate and into the eyepiece of the microscope, whereas most of the light passes through the plate and onto the specimen. A series of reflections occurs between the reference plate and the specimen, such that with each reflection some of the light passes through the reference plate and into the eyepiece of the microscope. This light either reinforces or interferes with the light reflected from the surface of the plate, and contour lines result. If the components are correctly positioned, the multiple-beam method can produce such fine fringes that displacements as small as 1/100 of the fringe displacement can be measured, thereby allowing measurements of differences in level as small as about 3 nm.

**Fig. 19** Principle of multiple-beam interferometry

## Macrophotography

Metallographers frequently need to take low magnification photographs of components, etch disks, fractures, and so forth, using either black and white or color film. A wide variety of approaches are possible. If the pictures are made on site, for example at an accident investigation, ordinary 35 mm medium-format or large-format cameras may be used, aided by various light sources, if needed. A macrotype lens for close-up work is very useful.

In the laboratory, it is helpful to use a camera stand, such as the Kaiser stand (Fig. 20). Generally, the most critical aspect of this work is adjustment of the lighting so that it is uniform, the desired details are visible, and undesirable shadows are minimized. A light box is a useful aid for such work.

**Fig. 20** Versatile camera stand for macrophotography

Many stereoscopic microscopes can be equipped with a camera for taking pictures at magnifications under 50×. Some microscopes have a trinocular head where the camera is inserted into the third port (the other two are for the eyepieces).

In all work, it is important to use a light meter to gauge the proper exposure. This precaution greatly reduces film waste and improves results. Generally, depth of field is an important criterion in macrophotography, because many objects to be photographed are not flat. Basically, depth of field improves as the  $f$ -number of the lens is increased and is reduced as the magnification increases. The focal length of the lens has a minor influence on the depth of field. However, as long focal length lenses produce a greater working distance between subject and lens, they are preferred. The depth of detail (the ability to separate detail throughout the depth of focus), is usually optimal between about  $f/10$  and  $f/16$ , although this range varies with magnification.

A wide range of films can be used as well as electronic media. Historically, wet-processed films have yielded the finest results, and that is still true today. If enlargements are required, particularly for sizes greater than 8 by 11 in. (21.5 by 28 cm), a medium-format film or a large-format film is better. Generally, panchromatic films are best for black-and-white work. For color work, the film type must be compatible with the color temperature of the lighting. Digital cameras are becoming popular, and rather high pixel densities are available at a reasonable price. Alternatively, a charge-coupled device (CCD) camera can be mounted on a macro lens to provide images to a capture system. Digital formats are very convenient especially for annotation of images and ease of image storage, but very high quality printers, approaching the resolution of photographs, are still rather expensive.

## Microphotography

All metallographs come equipped with one or more camera ports, as well as provisions for attaching CCD cameras (or other types, although the CCD is by far the most common type used). While biologists frequently use 35 mm cameras to record microstructures, they are less popular with metallographers. A small percentage of metallographers still prefer to use wet processed sheet film, usually 4 by 5 in. (10 by 12.5 cm) size. Orthochromatic film is no longer available in this size, and panchromatic films must be employed. These are less convenient to use because loading, unloading, and developing must be done in total darkness. Otherwise, results are the same. Contact printing is most commonly performed.

The majority of metallographers switched to instant films (Polaroid), which were introduced in the 1960s. At that time, few (if any) metallographs had exposure meters, and wastage was significant because instant films have no latitude (exposures must be exactly controlled to get good images, unlike wet processed films). Instant films are convenient because dark room work is avoided. However, except for the P/N type, there is no negative so extra prints cannot be made in the same way as by traditional photography. Instead, multiple photographs must be made anticipating future needs.

Electronic photography is becoming very popular and will eventually become the dominant mode as it features all the convenience of instant photography with none of the disadvantages. The biggest problem now is the cost of a high quality, high resolution printer, but that should become less of a problem in the future.

## Principles of Technique Selection in Mechanical Polishing

---

THREE DISTINCT OPERATIONS are involved in determining the microstructure of metals with the use of a light optical microscope: preparation of a section surface; development of the structure on that surface, usually by chemical etching; and microscopic examination. The effectiveness of the examination is dependent upon these prior steps. Improper specimen preparation will impair examination and may result in artifact structures being confused as true structure. Etching must also be performed properly, although poor etch results are usually obvious and can be easily corrected. Selection of the best etchant for a given specimen is more difficult, generally requiring trial and error based on past experience.

The primary objective of a preparation procedure must be to produce a surface that fully represents the microstructure as it existed in the metal before sectioning. All structural features characteristic of the metal must be detectable, and false structures must not be introduced. This requirement is more demanding than the mere production of what appears to be a highly polished surface.

The main purpose of this section is to illustrate how objective experiments and comparisons can be used to develop preparation procedures that not only give better results but also are simpler and less laborious to use. The emphasis is on principles that can be used as guides in the development of practical preparation procedures, rather than on the details of those procedures.

## Abrasion Damage and Abrasion Artifacts

Figure 21(a) shows the general pattern of a surface layer that has been plastically deformed for abraded cartridge brass (Cu-30%Zn), an alloy in which the effects of prior plastic deformation, generally from sectioning or grinding, can readily be revealed by a range of etchants. This micrograph highlights several characteristic features. The shallow, dark-etching, unresolved band contouring the surface scratches is known as the outer fragmented layer; it is a layer in which the strains have been very large. Beneath this layer extends a layer in which the strains have been comparatively modest, and in which the strains tend to concentrate in rays extending beneath individual surface scratches. The bands of etch markings, known to develop at the sites of slip bands, show the strains as well as the more diffuse rays, known to indicate the presence of kink bands. These effects extend to many times the depth of the surface scratches.

**Fig. 21** Annealed cartridge brass (Cu-30%Zn). (a) Taper section (horizontal magnification, 600 $\times$ ; vertical magnification, 4920 $\times$ ) of surface damage from abrasion with 220-grit silicon carbide paper. (b) Micrograph taken after abrasion on 220-grit silicon carbide paper and then polished until about 5  $\mu\text{m}$  of metal was removed. The banded markings are abrasion artifacts (false structures). (c) Micrograph showing the true microstructure taken after abrasion on 220-grit silicon carbide paper and then polished until about 15  $\mu\text{m}$  of metal was removed. All three specimens were etched in an aqueous ferric chloride solution.

Figures 21(b) and 21(c) show the importance of the surface damage shown in Fig. 21(a). A specimen of annealed cartridge brass was abraded on 220-grit silicon carbide paper and then polished to remove a surface layer about 5  $\mu\text{m}$  (200  $\mu\text{in.}$ ) thick. All traces of the abrasion scratches were removed; and, ostensibly, a satisfactory surface was produced, but the bands of deformation etch markings (Fig. 21b) appeared when the surface was etched. When layers of greater thickness were removed during polishing, these bands gradually reduced in number and intensity, and eventually were eliminated, as shown in Fig. 21(c), which shows the true structure.

The deep abrasion-damage effects discussed thus far cause difficulties in only a limited range of alloys, but effects due to an outer fragmented layer are likely to be found in all metals. Certain distinctive artifacts caused by disturbance in the outer fragmented layer are observed in pearlitic steels. Taper sections of abraded surfaces of these steels have shown that the cementite plates of pearlite may simply be bent adjacent to some scratches and may be completely fragmented adjacent to others.

Austenitic steels generally are quite susceptible to abrasion artifacts, and the common etchants reveal effects due to prior deformation with considerable sensitivity. The structure of a typical abrasion-damaged layer is comparable to that for brass. A shallow, unresolved layer contours the surface scratches, and deep rays of deformation etch markings extend beneath the surface scratches. Bands of these deformation etch markings may appear in a final-polished surface as abrasion artifacts. Good abrasion practice and efficient polishing processes are required for removal of the abrasion artifacts in acceptable polishing time.

**Embedding of Abrasives.** The points of the contacting abrasive particles of an abrasive paper fracture readily during abrasion, and these fragments may become embedded in the surface of a very soft metal, such as lead (Fig. 22) or annealed high-purity aluminum. Embedded particles are difficult to discern in the surface by light microscopy, but a surface with a high concentration of embedded abrasive characteristically has a rough, torn appearance.

**Fig. 22** Embedding of SiC (arrows) abrasive in a nearly pure lead specimen (prepared up to 1  $\mu\text{m}$  diamond finish). 200 $\times$

## Preparation Damage

The mechanical preparation procedures commonly used in metallographic practice remove metal by mechanical cutting processes analogous to those occurring during abrasion. Grinding and polishing always produce a series of scratch grooves on the surface of the specimen; these scratches may be difficult to detect by light microscopy, particularly with bright-field illumination. Moreover, a plastically deformed, damaged layer is also introduced; the layer produced by mechanical polishing is much shallower than that produced by grinding, but its structure is similar. A layer analogous to the outer fragmented layer in ground surfaces can be recognized contouring the surface scratches, and there are occasional rays of deformed metal extending to greater depths, many times the depth of the polishing scratches. The presence of this damaged layer has important practical consequences--it affects the response of the surface to etching.

Even on well-prepared surfaces, a very fine layer of damaged material will remain that can be removed by mechanical-chemical polishing ("attack" polishing). In mechanical-chemical polishing, a small amount of dilute etchant is used together with the abrasive suspension. The etchant attacks the surface chemically while the abrasive removes the product of this chemical attack.

An excessive amount of the chemical component in a mechanical-chemical process may cause detrimental effects, such as severe etch pitting. Proper balance between the mechanical and chemical components can preserve most of the benefits provided by mechanical polishing and yet produce a damage-free surface--a most desirable combination in a final-polishing stage.

An alternative to attack polishing is provided by modern non-neutral polishing suspensions, for example, colloidal silica with a pH of 9.5 to 10 and acidic alumina suspensions with a pH of 2.5 to 3. A dilute etchant can also be added to these abrasive suspensions to further enhance metal removal. These suspensions are particularly effective when used with a vibratory polisher.

**Enlargement of Polishing Scratches by Etching.** It is a frequent annoyance in metallographic practice to find that a surface, which appeared to be free of scratches when examined as-polished with brightfield illumination, turns out to be severely scratched after etching. The scratches were actually there all the time, but they were too fine to be detected when the specimen was in the unetched condition; they were enlarged, or shown in greater contrast, by etching.

In some cases, the etchant is revealing the damage present beneath scratches removed during preparation. Scratches are attacked preferentially during etching because of the disturbed metal, or damaged layer, associated with them. Severity of attack varies directly with the ability of the etchant to reveal deformation. Color "tint" etchants are perhaps the most sensitive etchants to preparation-induced damage not fully removed during preparation. The appearance of scratches also depends on the etching time. A certain minimum etching time is necessary to develop the scratches fully; thereafter, the scratches recede with increasing etching time, because etching progressively removes the damaged layer. It may be difficult to distinguish scratches enlarged by the final polishing stages from scratch traces introduced during the previous polishing stage. The problem can be resolved by making the earlier set of scratches unidirectional and parallel to a known direction in the specimen surface. The scratch traces can then be recognized. This technique only works with manual preparation because automatic devices produce randomly oriented scratch patterns.

**Flatness.** Quality in polishing practice means a surface that is adequately free from confusing polishing scratches and sufficiently flat for all constituents and local regions to be examined properly. Different types of flatness problems are encountered in metallography. Nonflat situations may arise in a variety of ways, but they are generally associated with microstructures that exhibit local hardness variations or at free surfaces. Height differences can be markedly influenced by the preparation practice. This condition is usually called "relief." For example, hard particles (oxides, carbides, nitrides, or intermetallics) in a softer matrix stand above ("proud") the matrix in positive relief, while soft particles (sulfide inclusions, soft metal insoluble phases, graphite, etc.) in a harder matrix lie below the matrix in negative relief. Negative relief is common at surfaces, such as exterior specimen surfaces, but also at interior surfaces, such as cracks or pores. Even if there is no hardness difference at these edges, they can easily become "rounded" (negative relief) due to a lack of support during preparation.

These conditions can be controlled to a large extent by the preparation procedure used. Flatness is improved if napless, or very low-nap, surfaces are employed, particularly in the polishing stage. Figure 23(a) shows the structure of a braze between Monel and type 304 stainless steel prepared using a procedure to minimize relief, while Fig. 23(b) shows the same specimen using a procedure that will create height differences where there are hardness differences.

**Fig. 23** Example of control of relief (a) and creation of excessive relief (b) in a braze between 304 stainless steel and Monel. Glyceregia etch, 200×

**Retention of Graphite in Gray Iron.** Graphite in cast iron can be damaged severely during the abrasion stage of preparation; however, it is possible by suitable choice of abrasion process to obtain a reasonably true representation of the structure. There remains the problem of retaining the graphite during polishing. The solution to the problem depends heavily on the length of the nap of the polishing cloth.

Graphite flakes in a gray iron invariably look much larger when long-nap cloths (Fig. 24a) are used for polishing. This apparent enlargement is caused by erosion, which occurs at the interface between graphite and matrix, producing an enlarged cavity from which the flake itself eventually is removed. With a cloth of reasonably short nap, many of the flakes are well retained, although some may appear to be slightly enlarged. Examination of sections of such a surface indicates that flakes aligned perpendicular to the surface are well sectioned but that slight erosion occurs around flakes that happen to be acutely aligned to the section surface. Correct representation of the graphite flakes is obtained after polishing with a napless cloth (Fig. 24b). Only a limited number of abrasives, notably diamond abrasives, produce

satisfactory results on napless cloths. The use of napless cloths for all of the polishing steps yields the best retention of graphite.

**Fig. 24** Retention of graphite in cast iron. (a) Coarse graphite flakes in a gray iron specimen that was polished with a long-nap cloth. Note enlarged cavities where the graphite phase has been torn out. (b) Well-preserved graphite flakes in a gray iron specimen that was polished with a napless cloth. Both specimens not polished, not etched, and shown at 100 $\times$

**Removal of Scratches.** Only rarely is it required that final-polished surfaces be completely free of scratches, particularly in production work. A more reasonable and practical requirement is that no coarse scratches should be detectable under the particular conditions of examination. Attainment of this objective will depend on the specimen material (more difficult with soft materials), the etching conditions (more difficult with etchants that are sensitive to deformed structures), and the optical conditions (more difficult with optical conditions that are sensitive to surface irregularities, such as darkfield and polarized light). A metallographer should have available a variety of final-polishing processes capable of producing increasingly higher qualities of finish from which to select the most suitable for a particular need.

**Vibratory polishing** methods are attractive for final polishing because they operate automatically. An advantage of vibratory polishing is that it can be adapted to chemical-mechanical polishing. The important variables in vibratory polishing are the abrasive, the nature of the liquid in which the abrasive is suspended, and the load applied to the specimen.

Not all polishing cloths can be used on a vibratory polisher. Low- to medium-napped cloths are generally used. Colloidal silica works very well on a vibratory polisher, partly because it stays in solution, being a colloid and partly because of its basic pH, around 9.5 to 10, which adds a chemical action to mechanical polishing.

**Electrochemical Differences.** A further example of chemical effects arising during mechanical polishing is found in specimens containing constituents that differ considerably in their electrochemical characteristics. In galvanized steels, marked electrochemical effects arise between the zinc of the coating and the steel base metal. Severe etching of the coating occurs when the specimen is polished with an aqueous suspension or cleaned with water. This effect can be eliminated by using a suspending liquid that has a pH very close to 7.0, thus suppressing electrochemical effects. This pH can be achieved with the use of a standard buffer solution. Others prefer to avoid the use of water in at least the final preparation step.

**Edge Retention.** With few exceptions, the abrasion rates of the plastics in which metallographic specimens are mounted are much greater than those of metals. The plastic abrades to a lower level than the metal, and rounding of the

specimen edge occurs to adjust for differences in level. The degree of edge rounding may be increased or decreased during polishing; long-nap polishing cloths increase edge rounding.

However, the abrasion rates of different types of plastics differ significantly, and edge retention can be improved by choosing a mounting plastic that has an abrasion rate matching as closely as possible that of the specimen. For example, improved edge retention is obtained with the change from a phenolic to a thermosetting epoxy. Metals that have very low abrasion rates, such as chromium and tungsten, show poorer edge retention than steels. Metals that have higher abrasion rates, such as copper and aluminum, show good edge retention even when mounted in phenolic plastics.

Attempts have been made to reduce the difference in abrasion rate between the specimen and mount to improve edge retention. Mounting specimens using a press that cools the specimen back to near room temperature under pressure virtually eliminates the shrinkage gaps between specimen and mount, which has produced a vast improvement in edge retention.

**Layers and Coatings.** Determination of the structure of a surface, coating, or a layer of oxide (scale) on a specimen is sometimes the principal reason for metallographic examination. A specimen with such layers presents a problem in edge retention. An oxide layer is usually friable, and thus susceptible to chipping and cracking during preparation. In these cases, impregnation with epoxy resin is recommended. Because the detection of porosity or cracking in the layer is an important feature of the examination, it is essential to avoid the development of preparation artifacts that might be mistaken for such features. The development of such artifacts during abrasion is possible, because grinding with standard abrasive papers may result in extensive chipping of the oxide layer. Polishing with diamond abrasives on a hard napless cloth ensures that a high degree of surface flatness will be maintained and that no polishing damage will be introduced.

## Electrolytic Polishing

ELECTROLYTIC POLISHING, also called electropolishing, is useful with stainless steels, copper alloys, aluminum alloys, magnesium, zirconium, and other metals that are difficult to polish by conventional mechanical methods. The electrolytic technique can completely remove all traces of worked metal remaining from the cutting, grinding, and mechanical polishing operations used in preparing specimens. When electropolishing is used in metallography, it is usually preceded by at least preliminary mechanical polishing and is often followed by etching.

## Mechanism

Although the mechanism of electropolishing is not understood in all its aspects, the process is generally considered to include both a leveling (or smoothing) action and a brightening action. According to a theory developed by P.A. Jacquet in 1936, smoothing is accomplished by preferential solution of the "hills" or ridges on a rough surface, such as those that result from grinding. When a rough surface is made the anode of a suitable electrolytic cell, a viscous liquid layer immediately adjacent to this surface is produced by the reaction between metal and electrolyte. This layer of solution, known as the polishing film, has a greater electrical resistance than the remainder of the solution and controls the smoothing action. The brightening action is related to the elimination of irregularities as small as about  $0.01\ \mu\text{m}$  and to the suppression of etching on the metal surface. This behavior is generally attributed to the formation of a thin, partly passivating film directly on the surface of the metal and following its contours.

**Current-Voltage Relations.** In electropolishing, current-voltage relationships vary in different electrolytes and for different metals. Figure 25 shows the simple relation wherein polishing occurs over an extensive continuous range of currents and voltages. At low voltages, a film forms on the surface and little or no current passes; thus, etching occurs but not polishing. At higher voltages, polishing occurs. The perchloric acid electrolytes used for aluminum conform to this relation.

**Fig. 25** Schematic relationship between current density and the single electrode potential for electrolytes having polishing action over a wide range of voltages and currents

A more complex relation, frequently encountered, is shown by the curve in Fig. 26. This curve depicts cell voltage as a function of anode current density for electropolishing of copper in an aqueous solution of orthophosphoric acid using a potentiometric circuit. Five distinct regions can be distinguished on the cell voltage-current density curve. In the region A-B, current density increases with the potential, some metal dissolves, and the surface has a dull etched appearance. The region B-C reflects an unstable condition, while region C-D indicates a stable plateau at which the polishing film, previously formed, reaches a point of equilibrium and polishing occurs; during the latter stage, current density remains constant. Optimum polishing conditions occur along C-D near D. In the region D-E, gas bubbles evolve slowly, breaking the polishing film and causing severe pitting. Polishing with rapid evolution of gas is represented by the region E-F.

**Fig. 26** Cell voltage as a function of anode current density for electropolishing of copper in orthophosphoric acid (900 g/L of water) using a potentiometric circuit

Electrolytes of the sulfuric-phosphoric acid and chromic-acetic acid types used for stainless steels also typify the complex, multistage relationship shown in Fig. 26. In establishing voltage-current relationships like those in Fig. 25 and 26, electrolysis must be allowed to proceed under fixed conditions until enough metal has dissolved to produce a steady state condition at the anode.

## Apparatus and Procedure

The electrical equipment used for electropolishing can vary from the simplest arrangement of dry cells to elaborate arrays of rectifiers and electronic control devices. Various types of apparatus are available commercially. The choice of equipment depends on the number and type of specimens to be treated and the versatility and control desired.

**Current Source.** Direct current is usually employed. The current source may consist of a battery, a direct-current generator, or a rectifier. In general, a battery supply is used for low voltages only, because a bank of batteries would be needed to produce higher voltages. These three types of current source deliver a constant supply of direct current.

**Electrical Circuits.** Two typical circuits, one for low and one for high current densities, are shown in Fig. 27. For solutions in which a small drop in potential occurs across the cell, a potentiometric circuit, for low current densities, is

more suitable (Fig. 27a). Conversely, when the drop in potential across the cell is high, a series circuit, for high current densities, should be used (Fig. 27b). Provision must be made for controlling both voltage and current.

Fig. 27 Two electrical circuits and equipment arrangements for electropolishing metallographic specimens

Alternating current is used for electropolishing and electroetching the metals of the platinum group (platinum, iridium, palladium, rhodium, osmium, and ruthenium), using a series circuit and schematic arrangement as shown in Fig. 27(b) with an alternating current source.

**The electrolytic cell** is simply a container for the electrolyte, in which are suspended the cathode and the anode. The cell is usually made of glass, but it may be polyethylene or polypropylene for solutions containing fluoride ions. Sometimes a stainless steel cell is used, which may serve also as the cathode. Frequently, the cell is surrounded by water or an ice bath or is cooled in some other manner.

The specimen to be polished (anode) should be arranged for quick removal from the electrolyte. The electrical connection to the specimen should be simple and easily broken so that the specimen can be rinsed immediately after polishing. The cathode should be made of a metal that is inert in the electrolyte being used; stainless steel is satisfactory for most applications.

For many applications, stirring, pumping, or air agitation of the electrolyte is necessary. During electropolishing under steady-state conditions, the anodic reaction products accumulate on the surface of the polished metal. Often, natural diffusion and convection processes cannot remove these products from the anode surface into the bulk of the electrolyte rapidly enough, and excessive accumulation of reaction products interferes with the electropolishing process. The use of agitation usually requires an increase in the current density in order to maintain a sufficiently thick polishing film.

**Arrangement of Anode and Cathode.** Two ways to position the specimen (anode) and the cathode are shown in Fig. 27. In each arrangement, only the portion of the specimen to be polished is exposed to the electrolyte. In Fig. 27(a), the surface to be polished is horizontal and facing upward, toward the cathode. This arrangement helps to maintain a stable layer near the surface being polished, and is ordinarily used when polishing occurs under a viscous layer. In Fig.

27(b), the surface to be polished is vertical and facing toward the cathode. This arrangement is sometimes used when polishing occurs with gas evolution, because it allows easy escape of the gas bubbles.

## Mounting of Specimens

Only the portion of the specimen to be polished should be in contact with the electrolyte. Small specimens may be mounted by conventional molded-plastic-mounting procedures, for ease in handling for mechanical preparation and subsequent electropolishing. Electrical contact can be made through a small hole drilled through the back of the mount into the metal specimen, or by the use of an indirect connection (Fig. 28).

**Fig. 28** Example of a method for creating electrical conductivity of a small specimen in a polymeric mount

When specimens are mounted in plastic, the possibility of violent reaction between the plastic and some electrolytes must be considered. For example, phenol-formaldehyde mounting materials, acrylic-resin mounting materials, and cellulose-base insulating lacquers and materials should not be used in solutions containing perchloric acid, because of the danger of explosion. Polyethylene, polystyrene, epoxy resins, and polyvinyl chloride can be used as mounting materials in perchloric acid solutions without danger.

Mounting of specimens in dissimilar metals is undesirable, because the metal in contact with the electrolyte is likely to interfere with polishing and also because fusible mounting alloys containing bismuth may be dangerously reactive in certain electrolytes that contain oxidizing agents. Bismuth-containing alloys may form explosive compounds in perchloric acid solutions.

In preparing an unmounted specimen for electropolishing, a suitable chemically inert, electrically insulating coating can be applied to all surfaces of the specimen (and specimen holder) except the surface to be polished. Plastic electrician's tape is also an effective stop off, being impervious to most electrolytes and readily removable from the specimen after electropolishing.

## Development of Procedures for Electropolishing

Metallographers may be asked to electropolish a metal or alloy that has not previously been encountered. In developing a suitable procedure, the problem should be viewed in comparison with known procedures and with information gained through previous experience.

**Effect of Alloy Type.** It is generally helpful to compare the position of the major component of the alloy with elements of the same general group in the periodic table, and to study the phase diagram, if available, to predict the number of phases and their characteristics. Single-phase alloys are generally easiest to electropolish, whereas multiphase alloys are likely to be difficult or impossible to electropolish. Even minor alloying additions to a metal may profoundly affect the response of the metal to polishing in a given electrolyte.

**General Principles.** The possibility of polishing a metal and the conditions for polishing a metal in a given electrolyte can sometimes be ascertained by plotting current density versus electrode potential. The curve in Fig. 25 is typical of those electrolytes that polish over a very wide range or that will not polish at all. The curve in Fig. 26 is characteristic of those electrolytes that form an ionic film; polishing will occur between points C and D on this curve; polishing is usually best near point D.

After the polishing range is determined, the other constants, such as preparation, agitation, and time, can be determined experimentally. The amount of preparation required depends on the nature of the specimen and on the results desired.

**Specimen preparation** can be accomplished in many cases by grinding through a series of graded abrasives up to a 600 grit SiC paper finish. In other cases it is necessary or desirable to prepolish the specimen with 6  $\mu\text{m}$  diamond before starting to electropolish. For some metals, it is best to completely polish the specimen mechanically and then use a brief electropolish stage to remove any remaining preparation-induced damage.

The surface to be polished should be clean to allow uniform attack by the electrolyte. To avoid contamination with oil from fingers, the specimen should be handled with forceps or tongs after final preparation for electropolishing.

## Advantages and Disadvantages of Electropolishing

When properly applied, electropolishing can be a useful tool for the metallographer. The principal advantages of electropolishing include:

- For some metals, electropolishing can produce a high-quality surface finish that is equivalent to the best that can be obtained by mechanical methods.
- Once a procedure has been established, good results can be obtained with less operator skill than that required for mechanical polishing.
- There can be a marked saving of time if many specimens of the same material are to be polished sequentially.
- Electropolishing is especially suited for the softer metals, which may be difficult to polish by mechanical methods.
- No scratches are produced in electrolytic polishing. The absence of scratches is a definite advantage in viewing high-quality electropolished surfaces of optically-active materials with polarized light.
- Artifacts resulting from mechanical deformation--such as disturbed metal or mechanical twins, which are produced on the surface even by careful grinding and mechanical polishing--do not occur in electropolishing.
- Surfaces resulting from electropolishing are completely unworked by the polishing procedure. This feature is important in low-load hardness testing or x-ray studies.
- With some electrolytes, etching can be accomplished by simply reducing the voltage to approximately one-tenth the potential required for polishing, then continuing electrolysis for a few seconds.
- Electropolishing is frequently useful in electron metallography (where high resolution is often important) because it can produce thin undistorted metal surfaces.

Metallographic preparation by electropolishing is subject to several limitations; these should be recognized to prevent misapplication of the method and disappointment in the results. The principal disadvantages include:

- The chemicals and combinations of chemicals used in electropolishing are poisonous; many are highly flammable or potentially explosive. Only well-trained personnel thoroughly familiar with chemical laboratory procedures should be permitted to handle or mix the chemicals or to operate the polishing baths.
- The conditions and electrolytes required to obtain a satisfactorily polished surface differ for different alloys; hence, considerable time may be required to develop a procedure for a new alloy, if it can be developed at all. This limitation does not apply if appropriate procedures exist.
- In multiphase alloys, the rates of polishing of different phases often are not the same. Polishing results depend heavily on whether the second or third phases are strongly cathodic or anodic with respect to the matrix. The matrix is dissolved preferentially if the other phases are relatively cathodic, thus causing the latter to stand in relief. Preferential attack may also occur at the interface between two phases. These effects are most pronounced when phases other than the matrix are virtually unattacked by the polishing bath. The effects are reversed when the matrix phase is relatively cathodic.
- A large number of electrolytes may be needed to polish the variety of metals encountered by a given

laboratory.

- Plastic or metal mounting materials may react with the electrolyte.
- Electropolished surfaces are not flat but exhibit an undulating surface, and in some cases may not be suited for examination at all magnifications. Under some conditions, furrowing and pitting may be produced.
- Edge attack effects limit applications involving small specimens, surface phenomena, coatings, interfaces, and cracks.
- Attack around nonmetallic particles and adjacent metal, voids, and various inhomogeneities may not be the same as that of the matrix, thus exaggerating the size of the voids and inclusions.
- Electropolished surfaces of certain materials may be passive and difficult to etch.

## Electrolytes

Formulations of electrolytes, sorted into eight groups, may be found in *Metallography, Structures, and Phase Diagrams*, Volume 8, *Metals Handbook*, 8th ed., p 30-31; *Metallography and Microstructures*, Volume 9, *ASM Handbook*, p 52-53; and ASTM E 1558. Other compilations of electrolyte compositions may be found in *Metallography: Principles and Practice*, by G.F. Vander Voort, McGraw-Hill, 1984. Preferred (or sometimes required) characteristics of an electrolyte are:

- It should be somewhat viscous.
- It must be a good solvent for the anode metal (the specimen) during electrolysis conditions.
- It should preferably not attack the anode metal when no current is flowing.
- It should contain one or more ions of large radii, such as  $(\text{PO}_4)^{-3}$ ,  $(\text{ClO}_4)^{-1}$ , or  $(\text{SO}_4)^{-2}$ , and sometimes large organic molecules.
- It should be simple to mix, stable, and safe to handle (many effective electrolytes are deficient in these respects).
- It should function effectively at room temperature and not be sensitive to temperature changes.

## Procedures and Precautions for Preparation and Handling of Etchants

IN THIS SECTION, the term *etchant* is used in its broadest sense, to include reagents used in metallographic work for microetching, macroetching, electropolishing, chemical polishing, and similar operations.

The formulations of etchants given elsewhere in this Volume are adequate for the majority of applications, but they may occasionally require modification. Adjustments in etchant composition (as well as in etching time and technique), based on the experience and skill of the metallographer, and magnification to be used, may be needed in order to obtain satisfactory results.

## Expression of Composition

Etchants are generally either aqueous or alcoholic solutions containing one or more active chemicals (acids, bases, or salts). Liquids other than water or alcohol are used as solvents in some formulations. Compositions of most etchants described in this section are expressed in terms of the amounts of the substances to be used in preparing small quantities of these reagents. For etchants that are solutions of solid substances in liquids, the amounts of the solid substances are usually expressed in grams (g), and the amounts of liquids (or the total volumes of solution) are expressed in milliliters (mL). The liquids may be individual commercially available substances, or they may be stock solutions containing two or more substances. Compositions of some etchants that are prepared by mixing together two or more liquids are given in parts by volume or percentage by volume. Compositions of some etchants consisting of solutions of solid substances in liquids are described in terms of percentage by weight.

In long-established (although nonstandard) usage in metallography, such terms as 1%, 2%, and 4% have been used to describe the approximate strength of an etchant, such as picral, and are understood to mean 1, 2, and 4 g, respectively, of picric acid per 100 mL of alcohol.

## Purity of Chemicals

In the preparation of solutions for microetching and electropolishing, recommended practice is to use chemicals meeting the requirements of NF (National Formulary), USP (U.S. Pharmacopoeia), laboratory or purified grades, or grades of still higher purity (reagent, ACS, or certified grades). The commercial or technical grades of certain special-purpose industrial chemicals (such as  $\text{CrO}_3$  and synthetic methanol) are extremely pure and are equivalent to reagent, ACS, or certified grades for use in microetching and electropolishing. Where water is specified, distilled water is preferred because of wide variations in the purity of tap water. For macroetching, technical grades of chemicals are satisfactory, unless specifications indicate otherwise, and potable tap water of good quality is generally acceptable.

## Identification of Chemicals

The practices generally followed in the technical literature on metallography are used to identify the chemicals utilized in the preparation of etchants.

**Aqueous Acids.** In identification of aqueous acids, the name or formula alone, sometimes followed by "conc" or "concentrated," refers to the common commercially available concentrated laboratory grade (Table 1). Where more than one concentration is commonly available, the percentage by weight of the active constituent is shown after the name or formula.

**Table 1 Characteristics of aqueous liquid chemicals used in many metallographic etchants**

Except for sulfuric acid, all data apply to both laboratory and technical or commercial grades of chemicals.

Name	Active constituent	Nominal composition <sup>(a)</sup> , wt%	Specific gravity	Degrees Baumé <sup>(b)</sup>
Aqueous acids				
<b>Acetic acid, glacial</b>	$\text{HC}_2\text{H}_3\text{O}_2$	99.5	1.05	7.0
<b>Fluoboric acid</b>	$\text{HBF}_4$	48	1.32	35
<b>Hydrochloric acid<sup>(c)</sup></b>	$\text{HCl}$	37	1.18	22
<b>Hydrofluoric acid</b>	$\text{HF}$	48	1.15	19
<b>Lactic acid</b>	$\text{HC}_3\text{H}_5\text{O}_3$	85	1.20	24
<b>Nitric acid</b>	$\text{HNO}_3$	70	1.42	43
<b>Perchloric acid</b>	$\text{HClO}_4$	70	1.67	58
		60	1.53	50
<b>Phosphoric acid (ortho)</b>	$\text{H}_3\text{PO}_4$	85	1.70	60
<b>Sulfuric acid</b>	$\text{H}_2\text{SO}_4$	96 <sup>(d)</sup>	1.84 <sup>(e)</sup>	66 <sup>(e)</sup>
Miscellaneous aqueous chemicals				
<b>Ammonium hydroxide</b>	$\text{NH}_4\text{OH}$	28 <sup>(f)</sup>	0.90	26
<b>Hydrogen peroxide</b>	$\text{H}_2\text{O}_2$	3 <sup>(g)</sup>	1.01	1.4
		30 <sup>(h)</sup>	1.11	15

- (a) Nominal percentage of the active constituent: remainder is water. Reagents made by different manufacturers may differ slightly in nominal concentration and allowable range of concentration.
- (b) Specific gravity as indicated on the Baumé scale: sometimes used for technical grades and in laboratory measurements.
- (c) Technical grade is also called muriatic acid.
- (d) Laboratory grade. Technical grade has concentration of 93%.
- (e) Specific gravity and degrees Baumé are nearly constant for 93 to 100% sulfuric acid.
- (f) Percent  $\text{NH}_3$ .
- (g) Sometimes called "10 volume."
- (h) Sometimes called "100 volume."
- (i) Sometimes called "170 volume."

Where an acid is designated as "tech," the technical grade that has the same concentration as the common laboratory grade is meant. The concentration of technical grades is sometimes expressed by suppliers in terms of specific gravity or degrees Baumé (°Bé), as shown in Table 1. Most technical-grade chemicals are available in several different concentrations.

**Miscellaneous Aqueous Chemicals.** A variety of aqueous chemicals, such as ammonium hydroxide and hydrogen peroxide (Table 1), which are used in various etchants, are identified similarly to aqueous acids. Concentration must always be specified for hydrogen peroxide, which is available in several widely differing concentrations.

**Alcohols.** The alcohols most frequently used in etchants are methanol and ethanol (Table 2). It is important to use alcohol that has the desired water content (anhydrous or 95% alcohol, whichever is specified) in etchants that contain only a small percentage of water.

**Table 2 Characteristics of pure methanol and ethanol**

Name	Active constituent	Nominal composition <sup>(a)</sup> , vol%
<b>Methanol (methyl alcohol)</b>	CH <sub>3</sub> OH	99.5 <sup>(b)</sup>
<b>Methanol (methyl alcohol), 95%</b>	CH <sub>3</sub> OH	95 <sup>(c)</sup>
<b>Ethanol (ethyl alcohol), anhydrous</b>	C <sub>2</sub> H <sub>5</sub> OH	99.5 <sup>(d)(e)</sup>
<b>Ethanol (ethyl alcohol), 95%</b>	C <sub>2</sub> H <sub>5</sub> OH	95 <sup>(e)</sup>

- (a) Nominal percentage of the active constituent: remainder is water unless otherwise specified.
- (b) Synthetic methanol: the commercial grade is of high purity and is satisfactory for use in all ordinary metallographic etchants where methanol is specified (wood alcohol has not been manufactured commercially in the United States since 1969). Methanol is available only as an anhydrous (also called absolute) grade containing less than 0.1 or 0.2% water as packaged, and usually not more than about 0.5% water at time of use, depending on storage and handling.
- (c) Where methanol, 95%, is called for, the ordinary anhydrous grade must be diluted by the user with 5% water by volume.
- (d) The anhydrous (also called absolute) grade of ethanol is ordinarily used only where no significant amount of water can be tolerated. It contains less than 0.1 or 0.2% water as packaged, and usually not more than about 0.5% water at time of use, depending on storage and handling.
- (e) Available only with special government permit

Practice with regard to the substitution of methanol for ethanol, or vice versa, and with regard to the use of some grades of denatured ethanol in etchants, varies greatly among metallographic laboratories. In most alcoholic etchants, ethanol can be substituted for methanol. This substitution is desirable, because methanol is a cumulative poison, while ethanol is not. Safety considerations may rule out alcohol substitutions in accepted formulations for electropolishing without a thorough chemical study. Also, ethanol should not be substituted for methanol in nital containing more than 3% by volume of concentrated nitric acid. In addition, it should not be substituted in other methanol-based etchants that contain strong oxidants and only a small percentage of water (if they are being stored in tightly stoppered bottles) due to possible pressure buildup and explosion. Mix these ingredients fresh and do not store them. *Never* store mixtures based on higher-order alcohols.

In a wide variety of applications for which the etchant is specified to contain ethanol (excluding electropolishing electrolytes), a number of laboratories have found it convenient and satisfactory to substitute for pure "anhydrous" or "absolute" (99.5%) ethanol and for pure 95% ethanol (Table 2), either a proprietary solvent or denatured "reagent" alcohol having a suitable water content (as shown in the lower part of Table 3), which are available without permit from suppliers of laboratory chemicals. These grades have been formulated in accordance with U.S. government regulations to be suitable for general laboratory purposes and have been denatured with small percentages of volatile solvents; they may be substituted for pure ethanol having the same water content, except where pure ethanol is required for some special reason.

**Table 3 Nominal compositions of various grades of denatured alcohol (ethanol) used in some metallographic etchants**

See text for discussion of suitability of the various grades for use in etchants.

Component	Parts by volume in specially denatured alcohol <sup>(a)</sup>					
	Formula SD-1 <sup>(b)</sup>		Formula SD-3A		Formula SD-30	
	Anhydrous	95% <sup>(c)</sup>	Anhydrous	95% <sup>(c)</sup>	Anhydrous	95% <sup>(c)</sup>
Ethanol, anhydrous	100	95	100	95	100	95
Water	...	5	...	5	...	5
Methanol	4	4	5	5	10	10
Methyl isobutyl ketone	1	1	...	...	...	...

Component	Parts by volume in proprietary solvent <sup>(d)</sup>		Parts by volume in "reagent" alcohol <sup>(d)</sup>	
	Anhydrous	95% <sup>(c)</sup>	Anhydrous	95% <sup>(c)</sup>
SD-1 anhydrous <sup>(b)</sup>	100	...	...	...
SD-1, 95% <sup>(b)(c)</sup>	...	100	...	...
SD-3A, anhydrous	...	...	95	...
SD-3A, 95% <sup>(c)</sup>	...	...	...	95
Methyl isobutyl ketone	1	1	...	...
Hydrocarbon solvent or gasoline	1	1	...	...
Ethyl acetate	1	1	...	...

- (a) Specially denatured alcohol is available only with special government permit.
- (b) The formula shown here has replaced the old SD-1 formula in which wood alcohol was specified: wood alcohol has not been manufactured commercially in the United States since 1969.
- (c) The designation of type of denatured alcohol as "95%" means that the denatured product contains 5 parts of water for every 95 parts of anhydrous (absolute) ethanol, plus denaturants as specified.
- (d) Available without government permit from suppliers of laboratory chemicals, for scientific and general laboratory purposes.

The specially denatured (SD) alcohols described in Table 3 are generally suitable for use in etchants. However, SD alcohol is obtainable only with special government permits and usually can be purchased only in larger quantities than the proprietary solvent and "reagent" alcohol in Table 3, and only from major suppliers of solvents.

**Water of Hydration.** With some exceptions, it has been common practice since the earliest days of metallography to identify solid salts and acids used in etchants only by names and abbreviated formulas, without showing the presence or absence of water of hydration. Historically, in developing and preparing etchants, the most stable hydrate (which was the common commercial form) was ordinarily used, except for salts that do not form hydrates. Current practice varies from laboratory to laboratory.

Using the specified amount of either the anhydrous or a hydrated form of a solid salt or acid in preparing an etchant will in most cases produce essentially the same etching behavior. Any difference in results will usually be small in comparison with the effects of normal differences in technique and other variables in specimen preparation. Exceptions are the preparation of etchants that must be anhydrous or must contain only a small and fairly critical percentage of water for proper etching activity; for such etchants, the need to use specific anhydrous or hydrated forms of each component should be clearly stated.

Some salts (such as ferric nitrate) do not exist in an anhydrous form. Conversely, some nominally water-free compounds contain a substantial percentage of water. One of these is picric acid, for which the 10 to 15% water content found in laboratory grades is necessary for satisfactory performance of etchants based on it (Table 4). Always keep picric acid moist to eliminate the possibility of explosion.

**Table 4 Descriptions of miscellaneous chemicals used in metallographic etchants**

aluminum chloride, anhydrous. <b>Solid</b> ; $\text{AlCl}_3$ ; reacts violently with water, evolving HCl gas; use of hydrated form, $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$ , is <b>preferred</b> .
ammonium molybdate. <b>Crystals</b> ; also called ammonium paramolybdate or heptamolybdate; $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$ ; can be used <b>interchangeably with molybdic acid, 85%</b> .
benzalkonium chloride. <b>Crystals</b> ; essentially alkyldimethyl-benzyl-ammonium chloride. May not be readily available in this form; <b>see zephiran chloride</b> .
1-butanol. <b>See n-butyl alcohol</b> .
2-butoxyethanol. <b>See butyl cellosolve</b> .
n-butyl alcohol. <b>Liquid</b> ; normal butyl alcohol; also called butyl alcohol and 1-butanol.
butyl carbitol. <b>Liquid</b> ; diethylene glycol monobutyl ether.
butyl cellosolve. <b>Liquid</b> ; ethylene glycol monobutyl ether; also called 2-butoxyethanol.
carbitol. <b>Liquid</b> ; diethylene glycol monoethyl ether.
cellosolve. <b>Liquid</b> ; ethylene glycol monoethyl ether.
chromic acid. <b>Dark-red crystals or flakes</b> ; $\text{CrO}_3$ ; also called chromic anhydride, chromic acid anhydride, and chromium trioxide. ( <b>See chromic oxide, <math>\text{Cr}_2\text{O}_3</math></b> .)
chromic anhydride. <b>See chromic acid</b> .
chromic oxide. <b>Fine green powder</b> ; $\text{Cr}_2\text{O}_3$ ; a polishing abrasive. Do not confuse with <i>chromic acid</i> ( $\text{CrO}_3$ ), which is a strong acid and a component of many etchants.
cupric ammonium chloride. <b>Crystals</b> ; a double salt, $\text{CuCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot 2\text{H}_2\text{O}$ . If not available, substitute 0.6 g $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ plus 0.4 g $\text{NH}_4\text{Cl}$ for each gram of the double salt.
diethylene glycol. <b>Syrupy liquid</b> ; also called 2,2'-oxydiethanol and dihydroxydiethyl ether; $(\text{HOCH}_2\text{CH}_2)_2\text{O}$ . More viscous than <b>ethylene glycol</b> ; otherwise similar in behavior.
diethylene glycol monobutyl ether. <b>See butyl carbitol</b> .
diethylene glycol monoethyl ether. <b>See carbitol</b> .
diethyl ether. <b>See ether</b> .
ether. <b>Liquid</b> ; also called ethyl ether and diethyl ether; very low flash point, highly explosive; boiling point is 34.4 °C (94 °F).
ethylene glycol. <b>Syrupy liquid</b> ; also called 1,2-ethanediol and dihydroxyethane; $(\text{CH}_2)_2(\text{OH})_2$ . Less viscous than diethylene glycol; otherwise similar in behavior.
ethylene glycol monobutyl ether. <b>Liquid</b> ; also called 2-butoxyethanol or butyl cellosolve.
ethylene glycol monoethyl ether. <b>See cellosolve</b> .
ethyl ether. <b>See ether</b> .
ferric nitrate. <b>Crystals</b> ; $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ . There is no anhydrous form of this salt.
fluoboric acid, 48%. <b>Liquid</b> ; $\text{HBF}_4$ ; if not readily available in small quantities, substitute 10.3 mL HF (48%) plus 4.4 g $\text{H}_3\text{BO}_3$ for each 10 mL of 48% fluoboric acid specified.
glycerol. <b>Syrupy liquid</b> ; also called glycerin or glycerine; $\text{C}_3\text{H}_5(\text{OH})_3$ ; contains up to 5% (by weight) water.
molybdic acid, 85%. <b>Crystals or powder</b> containing the equivalent of 85% $\text{MoO}_3$ . This misnamed chemical consists mostly of ammonium molybdate (or paramolybdate), which is $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$ . The two chemicals can be used interchangeably. <b>See ammonium molybdate</b> .
muriatic acid. <b>Liquid</b> ; technical grade HCl (see Table 1).
picric acid. <b>Crystals</b> ; 2,4,6-trinitrophenol; crystals of laboratory chemical contain 10 to 15% water; explosive; its crystalline <b>metallic salts are even more explosive</b> . Do not use grades that do not have the 10 to 15% water content.
pyrophosphoric acid. <b>Crystals or viscous liquid</b> ; $\text{H}_4\text{P}_2\text{O}_7$ , anhydrous; hydrolyzes to phosphoric acid ( $\text{H}_3\text{PO}_4$ ) slowly in cold water and <b>rapidly in hot water</b> .
zephiran chloride. <b>Aqueous solution</b> ; a proprietary material produced in grades containing about 12% and 17% (by weight) benzalkonium chloride (alkyldimethyl-benzyl-ammonium chloride) as the active constituent, plus some ammonium acetate; also called sephiran chloride. Available from pharmacies or pharmaceutical distributors. <b>See benzalkonium chloride</b> .

**Miscellaneous Chemicals.** Correct identification may present problems because of similarity in names of different chemicals or because of misleading or nonstandard nomenclature and trade names (Table 4). Also included are certain chemicals for which some aspects of composition or behavior are important.

## Metallographic Practices Generally Applicable to All Metals

## Safety Precautions

All chemicals are potentially dangerous and persons formulating and using etchants should be thoroughly familiar with the chemicals involved, and with the proper procedures for handling and mixing them. The discussion that follows indicates many of the potential hazards that attend the use of chemicals and describes precautions and safe practice for averting these hazards.

**Ventilation.** All mixing, handling, and use of etchants should be done in a well-ventilated area, preferably within an exhaust hood, to prevent exposure to, or inhalation of, toxic and corrosive fumes. Use of an exhaust hood is mandatory whenever large quantities of chemicals are handled or large areas of metal are etched (as in macroetching), and when carrying out lengthy electropolishing operations or electropolishing large areas. Special hoods are available for work with perchloric acid.

**Protection of Personnel.** When chemicals and etchants are being poured, mixed, or handled, and when etchants are being used, suitable protective equipment and clothing (glasses, face shield, gloves, apron, and other items, as appropriate) should always be worn, to prevent contact of chemicals with the eyes, skin, or clothing.

If chemicals contact the skin, they should be washed off promptly with water and soap. Medical attention should be obtained as soon as possible for chemical burns, especially if there are cuts or abrasions in the skin. If chemicals contact the eyes, the eyes should be flushed at once with large quantities of water, and medical attention should be obtained without delay. A face-and-eye fountain should be available for use wherever chemicals or etchants are stored or handled. Wherever quantities large enough to be hazardous are stored or handled, a safety shower is needed also. This washing equipment should be readily available and should be tested at scheduled intervals to ensure dependable performance in an emergency.

Hydrofluoric and fluosilicic acids can cause painful and serious ulcers on contacting the skin, unless washed off immediately. Also especially harmful to the skin are concentrated  $\text{HNO}_3$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{CrO}_3$ ,  $\text{H}_2\text{O}_2$  (30 or 50%),  $\text{NaOH}$ ,  $\text{KOH}$ ,  $\text{Br}_2$ , and anhydrous  $\text{AlCl}_3$ . Inhalation of vapors or mist from these chemicals or etchants containing them can also cause irritation or serious damage to the respiratory system.

**Container Material and Design.** In preparing, storing, and handling etchants, use containers and equipment made of materials suitable for the chemicals used. Glass is resistant to nearly all chemicals. Polyethylene, polypropylene, and similarly inert plastics are resistant to hydrofluoric, fluosilicic, and fluoboric acids, unlike glass, as well as to solutions containing salts of these acids. These inert plastics are also recommended for prolonged storage of strongly alkaline solutions and strong solutions of phosphoric acid, both of which attack glass (especially, ordinary grades of glass).

Certain mixtures of chemicals can generate gaseous reaction products over a period of time or if inadvertently exposed to heat, and can build up dangerous pressures if stored in tightly sealed containers. The use of vented or pressure-relief types of stoppers instead of tightly sealed screw caps or conventional stoppers on bottles of etchants that are prepared in quantity and stored is a worthwhile safety precaution.

**Heat Evolution in Preparing Etchants.** Exercise caution and follow accepted laboratory procedures when mixing chemicals. In general, heat is evolved, sometimes in large amounts, when strong acids (particularly  $\text{H}_2\text{SO}_4$ ), alkalis ( $\text{NaOH}$  and  $\text{KOH}$ ), anhydrous  $\text{AlCl}_3$ , or their concentrated solutions are added to water, alcohols, or solutions of other chemicals, and when combining acidic with alkaline substances or solutions.

The acid, alkali, or anhydrous  $\text{AlCl}_3$  should be introduced slowly to the water, alcohol, or solution, while stirring continuously to avoid local overheating. Incomplete mixing can permit layering, with danger of a delayed violent reaction. Special attention and special cooling procedures may be needed when large quantities of etchants are prepared and large areas of metal are etched, as in some macroetching, and when high currents are used in electropolishing.

**Mixing of Oxidizing Agents with Reducing Agents.** Exercise special care in mixing oxidizing agents ( $\text{HNO}_3$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{HClO}_4$ ,  $\text{CrO}_3$ , salts of these acids, persulfates,  $\text{Br}_2$ , and  $\text{H}_2\text{O}_2$ ) with reducing agents (alcohols and other organic solvents, acetic acid, acetic anhydride, and most organic compounds); failure to follow accepted safe procedures can result in violent or explosive reactions. Acetic anhydride cannot be used safely in electropolishing solutions except in limited ranges of composition and water content, and its use is not recommended.

**Care with Cyanides.** The use of etchants that contain cyanides presents special toxicity hazards, because poisoning can result from inhaling hard-to-detect small amounts of  $\text{HCN}$  gas evolved from acidic solutions, from ingesting small amounts of cyanides, and from absorbing cyanides through the skin or exposed body tissues. Careful handling and the use of an effective exhaust hood are especially important. Used cyanide-containing solutions should be made slightly alkaline with ammonia and poured into a chemically resistant waste-disposal drain, and the drain flushed thoroughly with a copious amount of water.

**Disposal of Etchants.** Spent etchant solutions should be discarded individually promptly after use. They should be poured slowly into a chemically resistant waste-disposal drain in an exhaust hood, while at the same time running a substantial flow of tap water down the drain, after which the drain should be flushed thoroughly with a copious amount of water. Strongly acidic, strongly alkaline, corrosive, or toxic solutions should be handled with extra care when being disposed, because of the hazards described in the section "Protection of Personnel."

Special attention should be given to the safe discarding of used solutions that contain substantial amounts of volatile solvents, so as to avoid the creation of toxicity, fire, or explosion hazards from vapors of the solvents. Procedures for safe disposal of etchants may be controlled by local regulations that may vary substantially by location.

# Metallographic Technique for Ferrous Metals

Edited by George F. Vander Voort, Buehler Ltd.

## Technique for Carbon and Alloy Steels

THE PREPARATION OF SPECIMENS of carbon and alloy steels can require special consideration, and these special procedures are discussed in this article. However, procedures described in the section "Metallographic Methods" in the article "Metallographic Practices Generally Applicable to All Metals" regarding sectioning and polishing of specimens are, for the most part, applicable to carbon and alloy steels.

### Sectioning

Proper sectioning of the surface to be examined is a very important step in preparing steel specimens, because in this step, the metallurgical structure of the specimen can easily be altered. Care in sectioning is necessary for all steels, but it is especially necessary for fully hardened (untempered) steels. Precautions against overheating and excessive mechanical deformation of the steel during sectioning are mandatory.

The first step in preventing damage to the metallurgical structure is to minimize the amount of sectioning that is done. Regardless of whether the test pieces are separate pieces or are coupons attached to forgings or castings, they should be designed, whenever possible, to require a minimum amount of sectioning.

Abrasive-wheel cutting is the preferred method for sectioning of specimens. It is the required method for sectioning hardened steels, and it is a convenient method for sectioning all steels. Abrasive-wheel sectioning produces less damage to the structure and yields a smoother surface than band sawing or power hack sawing (techniques generally limited to steels below 35 HRC). When the specimen must be removed from a large mass of material, sectioning by sawing (provided that the steel is not too hard for sawing) usually precedes cutting with an abrasive wheel.

Rubber-bonded aluminum oxide wheels 52.5 mm (0.10 in.) thick are recommended. To minimize damage to the specimen, select a grade of cutoff wheel designed for the hardness of the steel being cut. For cutting hardened steels, a relatively softly bonded wheel is preferred.

Heating can be minimized by directing an ample flow of water containing a water-soluble oil over the surface being cut. The water-soluble oil helps protect the saw from corrosion and should always be used.

**Separate Test Pieces.** Because a major use of metallography is process control (for example, control of heat treating processes), separate test pieces are commonly used. They must have the same composition and thermal history as the steel for which the tests are run. A single test piece often suffices as a tensile-test bar and as a metallographic specimen. The size and design of the test piece depend largely on which tests are planned. When the test piece is to be used only for metallography, it is usually designed so that it can be cut into two or more small specimens.

Figure 1 shows two types of test pieces used for monitoring of heat treating processes. The solid, button-type test piece (Fig. 1a) is easy to prepare and is usually adequate. The washer-type test piece (Fig. 1b) has two advantages over the solid, button type. First, the washer-type piece can be more easily hung or otherwise secured in various locations of a heat treating furnace. Second, when it is sectioned, inside edges, which are less susceptible to edge rounding during grinding and polishing, are available for examination. To produce metallographic specimens, the test pieces are cut slightly off center so that a full half is available, and further specimen cutting proceeds (Fig. 2). Better edge retention is obtained if a compression mounting compound is used followed by a contemporary preparation practice.

**Fig. 1** Two types of test pieces used for metallographic monitoring of heat treatment processes. Dimensions are in inches.

**Fig. 2** Method of (a) cutting a test specimen from a test button and (b) mounting the test specimen to retain flatness for metallographic examination. Dimensions are in inches.

## Mounting

A thermosetting phenolic resin is commonly used for mounting steel specimens. Phenolics are inexpensive and offer the advantages of quick mounting and reasonable hardness; the latter helps maintain flatness of the specimen during grinding and polishing. A disadvantage of phenolics is their thermosetting curing temperature (135 to 150 °C, or 275 to 300 °F); some steel specimens must not be heated in this range because it will affect their microstructure. Temperature control of

the process is essential when specimens are mounted in phenolic, and some steels (for example, untempered tool steels) cannot be mounted in phenolic. Another disadvantage is that fragile specimens may be damaged by the pressure required during preparation of the mount. Phenolic, by itself, may not provide adequate support for edge retention. Phenolics give adequate edge protection when cured in a press that maintains the mount under pressure during cooling back to ambient temperatures and when automatic preparation devices are used. Under other conditions, edge rounding may occur in varying degrees.

Powdered epoxy is an improved thermosetting mounting product. The required time, temperature, and pressure of mounting are similar to those for phenolics, but they produce a superior mount with better edge retention. Phenolics are badly degraded by hot etchants, while thermosetting epoxy holds up well.

Plastics that cure at room temperature, such as acrylics, polyesters, and epoxy resins, are preferred by some metallographers. Because use of these mounting materials involves casting, many molds can be poured at one time. Room-temperature curing plastics usually require several hours (or overnight) to set; however, some formulations, set in 1 to 2 h, depending on the amount of hardener used. Such mounts are usually fairly soft and thus require the same special techniques for edge retention as those used for thermoplastic materials. Care must be taken in mounting large specimens with castable epoxy. In some cases, high temperatures can be generated, resulting in cracking of the mount. Acrylics provide the shortest curing times, generally less than 10 min but do not provide good edge retention. They are less expensive than epoxies.

**Mounting Techniques.** The specific technique used for mounting carbon and alloy steel specimens depends on the magnification to be used, requirements for edge preservation, and mounting material. When examination will be made at no more than 100 $\times$ , edges are of no particular interest, the maximum temperature incurred in mounting is not a problem, no special measures are necessary, and all mounting materials discussed are satisfactory. In contrast, when a magnification of more than 100 $\times$  will be used and when edge preservation is of prime concern (especially when one of the softer mounting materials must be used), the mounting procedure must be carefully planned and special techniques may be required.

Plating the test piece with nickel is common practice. The nickel plate protects and preserves the edges during final cutting and helps maintain flatness during grinding and polishing. Electroless nickel plating solutions are commonly used. A plating thickness of about 5 to 10  $\mu\text{m}$  (0.0002 to 0.0004 in.) is usually sufficient. It is best to hot compression mount electroless nickel-plated specimens using a press that cools the specimen to ambient temperature under pressure as hot ejection and rapid cooling often causes the plating to separate from the specimen, which greatly lessens its ability to protect the edge.

Another common practice, but less effective in obtaining and maintaining maximum flatness, is shown in Fig. 2. In this practice, a test button, such as that shown in Fig. 1, is sectioned by first cutting slightly off center and then cutting off a 19 by 6.4 mm ( $\frac{3}{4}$  by  $\frac{1}{4}$  in.) specimen, as shown at the right in Fig. 2(a). The specimen is mounted in phenolic ready for grinding and polishing (Fig. 2b). The mount features the use of hard metal pieces surrounding the specimen (Fig. 2b). Often, these are small hardened steel balls, but chilled iron shot costs less and is equally satisfactory for most purposes. Alumina pellets have also been used, but these greatly reduce the grinding and polishing rates. Another alternative is to surround the specimen with a pipe section. For the specimen shown in Fig. 2, the inside diameter of the pipe section would have to be about 22 mm ( $\frac{7}{8}$  in.). These techniques are less effective than plating, and there is no guarantee that they will improve edge retention as much as needed.

## Grinding and Polishing

**Mechanical Grinding.** In the traditional approach, steel specimens are ground using a series of progressively finer abrasive papers, for example, 120, 240, 320, 400, and 600 grit SiC using water as a coolant. Stationary or rotating (300 rpm) wheels are used. Grinding times are 60 to 120 s with the direction of grinding changed after each paper. SiC paper has a short life and is not reusable. Coarse, waterproof aluminum oxide paper is now available for rough (planar) grinding, and its life is substantially greater than that of standard SiC paper.

**Mechanical Polishing.** In the traditional method, polishing is broken into two steps, rough and fine with one or two different abrasive sizes being used in each stage. For rough polishing, a napless cloth impregnated with diamond paste is preferred. Nylon, silk, thin cotton, canvas, and cotton drill cloth are traditionally used. Polishing with 6  $\mu\text{m}$  diamond

paste usually is sufficient, but some metallographers prefer to polish with 9  $\mu\text{m}$  followed by 3  $\mu\text{m}$  paste or to use 6 and 1  $\mu\text{m}$  or 3 and 1  $\mu\text{m}$  diamond.

Powdered alpha alumina ( $\text{Al}_2\text{O}_3$ ) in the same range of sizes as diamond can be substituted for diamond paste, but diamond is a much more efficient abrasive. Rough polishing is most often done on a cloth-covered disk rotating at 150 rpm. The specimen is held by hand and moved in the direction opposite to the direction of wheel rotation. Alternatively, automatic devices can be used for grinding and polishing. Fine polishing is traditionally done on a napped cloth with a slurry of gamma alumina and water. Almost any soft cloth can be used, but the most satisfactory is one with synthetic fibers on a cotton backing. Alumina in a 0.05  $\mu\text{m}$  size is used most often, although some metallographers prefer to fine polish in two steps--first with 0.3  $\mu\text{m}$  and then with 0.05  $\mu\text{m}$  alumina. Wheel speed and specimen rotation for fine polishing are the same as for rough polishing. Time required for rough and fine polishing varies with hardness and size of the specimen, but the average time is 60 to 120 s per step, using the technique previously described.

**Contemporary Procedures.** The increased use of automated polishing devices has fostered the adoption of more efficient, improved preparation procedures designed to reveal the true structure ("specimen integrity" concept). If an automated system is used with a specimen holder that accommodates a number of specimens (which varies with size and format, i.e., 8 or 12 in. wheel size), mounted or unmounted, and if the pressure is applied centrally, then the first step of grinding must remove the damage introduced by sectioning and make all of the specimens coplanar. This step is often called "planar grinding." If the force is applied to each specimen individually (most practical with mounted specimens), then the first step of grinding is used to remove sectioning damage as the specimens are not rigidly constrained in the holder. The application of force to each individual specimen seats each specimen independently of the others. In grinding or polishing, the head can rotate in either the same direction as the platen (complementary) or in the opposite direction to the platen (contra). Contra rotation is more aggressive than complementary, and thus produces a higher removal rate, but this does not always produce better results. Complementary rotation is safer to use. For final polishing, contra rotation is helpful in that the polishing slurry is not swept off the surface as readily as with complementary rotation.

Numerous surfaces can be used for the rough grinding or planar grinding step depending upon the equipment available and the nature of the work. For planar grinding, a high speed grinder using a coarse grit aluminum oxide stone commonly has been used. This setup produces fast, efficient removal of sectioning damage. However, it requires purchase of an expensive single-purpose machine. Grinding stones are expensive; their surface must be trued with a diamond tool before each use, and the stone creates a significant depth of damage.

If the specimen has been cut using the proper abrasive wheel, then the depth of damage and the roughness of the cut are substantially less than from band sawing or power hack sawing. In such a case, a relatively fine abrasive can be employed to remove the sectioning damage. Going to a stone is a step back to a much coarser grit than needed. Wafering blades or thin abrasive cutoff wheels produce even less damage than a standard abrasive wheel. If the grinding/polishing machine has individual force ability, then the starting grinding surface can be equivalent to 240 or 320 grit SiC paper.

Obviously, ordinary SiC abrasive (waterproof) paper can be used for the first grinding step. Waterproof aluminum oxide abrasive papers are also highly effective. Other surfaces are also possible, such as lapping platens, rigid grinding disks, and metal-bonded or resin-bonded diamond disks, depending upon the material being prepared. These procedures yield extremely good surface flatness.

Modern preparation practices are designed to yield acceptable surfaces (for the application) with a minimum number of steps. For carbon and alloy steels, and for most other steels, four or five step practices are possible. After the initial grinding step, several options are possible involving platens, rigid grinding disks, or napless, heavy polyester cloths. The latter is the most universal in application and the best choice for low to medium hardness carbon and alloy steels. Rigid grinding disks may be ineffective at removing deformation from ferrite. In general, the heavy napless woven polyester cloths are used with 15 or 9  $\mu\text{m}$  diamond slurries (either polycrystalline or monocrystalline synthetic diamond) as these are easiest to add while the machine is running. Coarse polishing times of about 5 min are common.

In the next step, a hard, synthetic chemotextile cloth is generally used with a 3  $\mu\text{m}$  diamond slurry for 3 to 5 min. This is followed by a 1  $\mu\text{m}$  diamond slurry on a hard, napless cloth (acetate is often used) for 2 to 3 min. This step is often optional; some prefer to skip this step and go to final polishing with alumina or colloidal silica. At this point, the amount of residual damage in the specimen is very low. The inclusions are fully retained, and the edge is flat and can be examined with ease at 500 $\times$  or above. Etching may bring out a few minor scratches that are well within the level that can be tolerated in production metallography.

If publication-quality micrographs are needed, an extra step can be added to completely eliminate any remaining deformation or scratches. Vibratory polishing using colloidal silica, acidic alumina suspensions, or with neutral alumina suspensions produces the highest quality results. However, these abrasives can be used nearly as effectively on a rotating wheel covered by a suitable cloth. If edge preservation is required, a short nap cloth, such as those recommended for use with colloidal silica, should be used. If edge preservation is not critical, then a somewhat softer, medium-nap cloth, such as the popular synthetic suede cloths can be used.

**Electrolytic polishing** has limited application to carbon and alloy steels because it removes inclusions, severely rounds edges, and results in preferential attack in multiphase systems. Electropolishing has the advantage of speed: a high-quality polish that will reveal ferritic grain size can be obtained in about 2 min. In most instances, it is not necessary to mount the specimen for electrolytic polishing, although a conductive mount can be used.

## Etching

Compositions of etchants used for microscopic examination of carbon and alloy steels are given in Table 1. Table 1 also lists the major characteristics of microstructures that each etchant reveals. Nital is by far the most widely used etchant for carbon and alloy steels.

**Table 1 Etchants for microscopic examination of carbon and alloy steels**

No.	Etchant	Purpose, or characteristic revealed
1	Nital: 1 to 5 mL HNO <sub>3</sub> in 99 to 95 mL ethanol (95%) or methanol (95%)	Develops ferrite grain boundaries in low-carbon steels; produces contrast between pearlite and a cementite or ferrite network; develops ferrite boundaries in structures consisting of martensite and ferrite; etches chromium-bearing low-alloy steels resistant to action of picral. Preferred for martensitic structures.
2	Picral: 4 g picric acid in 100 mL ethanol (95%) or methanol (95%)	Reveals maximum detail in pearlite, spheroidized carbide structures, and bainite; reveals undissolved carbide particles in martensite; differentiates ferrite, martensite, and massive carbide by coloration; differentiates bainite and fine pearlite; reveals carbide particles in grain boundaries of low-carbon steel. Addition of about 0.5 to 1 mL zephiran chloride wetting agent increases speed of attack.
3	Vilella's reagent: 5 mL HCl, 1 g picric acid, 100 mL ethanol (95%) or methanol (95%)	For contrast etching <sup>(a)</sup> ; may reveal prior austenite grains in tempered martensite and in austempered steels; reveals pearlite colonies.
4	1 to 1.5 mL HCl (conc), 2 to 4 g picric acid, 100 mL ethanol (95%)	Reveals pearlite colonies <sup>(b)</sup> .
5	30 g K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> in 225 mL hot distilled water; and 30 mL acetic acid (glacial)	Reveals lead inclusions, causing them to appear yellow or gold when specimen is examined under polarized light <sup>(c)</sup>
6	16 g CrO <sub>3</sub> in 145 mL distilled water; add 80 g NaOH <sup>(d)</sup>	Reveals intergranular oxidation due to overheating prior to hot working <sup>(e)</sup>
7	10 g potassium metabisulfite, 100 mL water	For resolution of hardened structures. Should be preceded by an etch in nital or picral.
8	Howarth's reagent: 10 mL H <sub>2</sub> SO <sub>4</sub> , 10 mL HNO <sub>3</sub> , 80 mL water	For detection of overheating and burning, and for examination of steel forgings.
9	8 g sodium metabisulfite in 100 mL water	Produces good contrast in as-quenched martensitic structures
10	1 g KCN in 100 mL water, mixed with 0.25 g diphenylthiocarbazone in 10 mL chloroform	Reveals lead inclusions by coloring them red; coloration is most visible when specimens are viewed under polarized light.
11	Saturated aqueous picric acid plus 1 g/100 mL sodium tridecylbenzene sulfonate	Most successful etch for revealing prior austenite grain boundaries in medium- or high-carbon martensitic steels. Steels should be untempered, or tempered below 540 °C (1000 °F). Immerse or swab for up to 20 min.
12	2 g picric acid, 25g sodium hydroxide, 100 mL water	Alkaline sodium picrate. Use boiling for 30 s or more to darken cementite. Solution will attack mounts made from Bakelite.
13	50 mL cold saturated aqueous sodium thiosulfate, 1 g potassium metabisulfite	Klemm's tint etch; colors ferrite. Immerse for 40 to 100 s until surface is colored. A light pre-etch with nital or picral improves sharpness.

- (a) Specimen should be tempered for 20 to 30 min at 315 °C (600 °F).
- (b) Immerse specimen for 5 to 10 s in solution at room temperature.
- (c) Etch for 10 to 20 s in solution at room temperature, rinse in hot water and dry.

- (d) Sodium hydroxide (NaOH) must be added slowly, with constant stirring.
- (e) Immerse specimen in boiling solution for 10 to 30 min, rinse in hot water, dry in air blast.

**Nital versus Picral.** Although nital and picral are so similar in etching action that they are often regarded as being interchangeable, they differ in several important respects. For some structures, there may be little difference in etching action between nital and picral; for others, the difference is significant.

In general, picral is preferred when ferrite-carbide aggregates are to be examined. Nital, which is sensitive to crystal orientation, is preferred for revealing ferrite grain boundaries and for the study of martensitic structures. Picral does not reveal ferrite grain boundaries unless the specimen is overetched.

**Special-Purpose Etchants.** Addition of hydrochloric acid to picral (Vilella's reagent in Table 1) brings about radical changes in etching behavior. For medium-carbon alloy steels quenched and tempered between 315 and 480 °C (600 and 900 °F), Vilella's reagent may occasionally reveal the prior-austenite grain structure by producing grain contrast. The color differences between grains in a specimen result from deeper attack of some grains than of others (contrast etching). In general, large austenite grains are more sharply and clearly resolved than small ones.

The most successful etchant for revealing prior-austenite grain boundaries is saturated aqueous picric acid plus about 1 g/100 mL of a wetting agent (sodium tridecylbenzene sulfonate is the most popular wetting agent). This procedure works best on medium-carbon, high-carbon, and alloy steels in the as-quenched or tempered (up to about 540 °C, or 1000 °F) condition. The steel must contain  $\geq 0.005\%$  P for this etchant to work. Etching may be done by immersion or swabbing for times up to about 20 min. Light repolishing to remove some of the structure etching helps to bring out the grain-boundary attack.

An etchant consisting of 8 g of sodium metabisulfite in 100 mL of water develops good contrast in as-quenched martensitic structures. Several other special-purpose etchants are listed in Table 1.

## Macroetching of Carbon and Alloy Steels

Macroetching of carbon and alloy steels is an inspection procedure for revealing certain aspects of the quality and structure of a steel by subjecting it to the corrosive action of an etchant and examining it visually or at low magnification. Macroetching is widely used for inspection of bars, billets, forgings, castings, and other steel products. Specimens usually are selected to represent a given batch or lot of metal and are tested by etching in acid until the structural characteristics or conditions are revealed. ASTM E 381 describes the macroetch test procedure.

### *Equipment of Macroetching*

The principal equipment for macroetching comprises a container for the etchant, provision for heating the etchant (if necessary), a ventilating system to contain and carry away corrosive fumes, and some means for washing and drying the specimen.

### *Etchants*

Table 2 lists the etchants that are most commonly used for macroetching of carbon and alloy steels. A 50% solution composed of hydrochloric acid and water (etchant 1 in Table 2) is the most widely used macroetchant and is capable of revealing a number of characteristics in carbon and alloy steels (last column in Table 2). ASTM E 340 lists many macroetchants for steels as well as other metals.

**Table 2 Etchants and recommendations for macroetching of carbon and alloy steels**

Etchant No.	Composition (parts listed are by volume) <sup>(a)</sup>	Etching time <sup>(b)</sup>	Surface required <sup>(c)</sup>	Purpose, or characteristic revealed
Etchants for use 71 to 82 °C (160 to 180 °F) <sup>(b)</sup>				
1	1 part HCl, 1 part water	15 to 60 min	A or B	Segregation, porosity, hardness penetration, cracks, inclusions, dendrites, flow lines, soft spots, structure, weld examination
2	50 parts HCl, 7 parts H <sub>2</sub> SO <sub>4</sub> , 18 parts water	30 to 60 min	A	Same as for etchant 1
3	38 parts HCl, 12 parts H <sub>2</sub> SO <sub>4</sub> , 50 parts water	30 to 60 min	A or B	Same as for etchant 1
Etchants for use at room temperature				
4	2 to 25% HNO <sub>3</sub> in water or ethanol	1 to 30 min	B or C	Carburization and decarburization, hardness penetration, cracks, segregation, weld examination
5	2.5 g CuCl <sub>2</sub> ·2H <sub>2</sub> O, 20 g MgCl <sub>2</sub> ·6H <sub>2</sub> O, 10 mL HCl, 500 mL ethanol	Until coppery sheen appears	B or C	Phosphorus-rich areas, banding
6	50 g (NH <sub>4</sub> ) <sub>2</sub> S <sub>2</sub> O <sub>8</sub> , 500 mL water	Swab until desired etch is obtained	C	Grain size, weld examination
7	40 g FeCl <sub>3</sub> , 3 g CuCl <sub>2</sub> , 40 mL HCl, 500 mL water	15 to 30 s	B or C	Dendritic structure of cast steel. (Precede use of this etchant with etch in 10% nital for 10 to 20 s.)
8	30 g FeCl <sub>3</sub> , 1 g CuCl <sub>2</sub> , 0.5 g SnCl <sub>2</sub> , 50 mL HCl, 500 mL ethanol, 500 mL water	30 s to 2 min	C	Dendritic structure of cast steel. (Overetching deposits excessive copper, which may obscure details of structure.)
9	4 g picric acid in 100 mL methanol	3 to 5 h	C	Carbon segregation

(a) All acids listed are of concentrated strength; commercial grades ordinarily can be used instead of laboratory or reagent grades. Water or alcohol should never be poured into an acid; rather, the acid should always be poured and gradually stirred into the other liquid.

(b) See text for discussion of variations in time and temperature.

(c) A, saw-cut or machined surface; B, average ground surface; C, polished surface.

### Etching Procedure

The usual procedure in macroetching is to put the prepared specimen directly into the etching solution, with the surface to be examined either face up or vertical to permit the gas generated to escape freely. Nonuniform etching will result if specimens are overlapped or are stacked too close together. When heated etchants are used, have the etching solution at the pre-established temperature before the specimens are immersed.

**Temperature of Etchant.** For the etchants in Table 2 used above room temperature, an etching temperature of 71 to 82 °C (160 to 180 °F) is recommended. At temperatures on the lower side of this range, the etching reaction is sufficiently vigorous to provide effective etching, and yet evaporation of the solution is not excessive. However, in production-control etching, temperatures on the higher side of the range are preferred, because they decrease the time of etching.

**Time of etching** depends on the type of steel, surface condition, and physical condition of the specimen. For best reproducibility of results with a large number of specimens, the time should be measured and should not vary from batch to batch. If the etching time is too short, all of the desired information may not be revealed.

**Specimen Preservation.** After a specimen has been properly etched, it should be removed from the etchant, rinsed thoroughly under running water, scrubbed with a stiff fiber brush to remove the deposit of "smut" from the surface, rinsed again, and dried by a warm-air blast or by blotting with paper or cloth towels. A cold-water rinse is used. Immersion in the etchant for a few minutes after scrubbing results in better definition, especially of flow lines.

As a temporary means of avoiding rust, the etched specimen may be rinsed in water, dipped in a dilute alkaline solution (e.g., aqueous ammonium hydroxide) to neutralize the remaining traces of acid, and washed in hot water. The residual acid can also be neutralized by dipping the specimen in a dilute solution of potassium carbonate or sodium carbonate; in addition to neutralizing the acid, these solutions also leave a film that prevents rust after drying.

### Technique for Low-Carbon Steel Sheet

Complete examination of a specimen of low-carbon steel sheet requires at least three specimens: a longitudinal cross section, which runs parallel to the rolling direction; a transverse cross section, which runs perpendicular to the rolling direction, and a surface specimen taken parallel to the rolling plane and viewed perpendicular to the rolling direction.

## ***Mounting***

Mounting techniques for steel sheet specimens are basically the same as those described in the section "Metallographic Methods" in the article "Metallographic Practices Generally Applicable to All Metals." a thermosetting mounting material, such as a phenolic, is commonly used, although compression-mounting epoxy mounts provide much better edge retention. A mounting press that cools the specimen back to ambient under pressure enhances edge retention with any mounting material. When the microstructure is likely to be affected by the curing temperature of a phenolic (150 °C, or 300 °F), or when steel sheet specimens are so thin that they may be crushed or distorted by the mounting pressure, cold mounting or mechanical mounting may be used.

Clamp mounting is quite successful for holding steel sheet specimens during preparation. Sometimes this technique is used where no mounting press is available, but more often it is used where many specimens are being prepared or where speed of preparation is important. In clamp mounting, several specimens can be clamped in sandwich form between two plates (Fig. 3). Bleeding problems are eliminated if the clamp is tightened very securely. Some users insert thin spacers, generally plastic, between the specimens before tightening. Edge retention with clamps is excellent.

**Fig. 3** Typical arrangement for clamp mounting of longitudinally or transversely oriented sheet steel sections

## **Technique for Coated Steel Sheet**

Most techniques for preparing metallographic specimens of coated steel sheet are the same as those used for preparing specimens of uncoated steel sheet, with minor variations and precautions.

### ***Galvanized Steel Sheet***

Care in cutting galvanized steel sheet is necessary in order to avoid delamination of cut edges at the interface of the zinc coating and the steel backing. Cutting should be done with an abrasive wheel, rather than by shearing.

### ***Aluminum-Coated Steel Sheet***

Preparation of hot-dip aluminum-coated steel for metallographic study is similar to preparation of galvanized steel; both types of coating are quite soft. Staining is not a problem with aluminum-coated steel sheet, so water can be used as a suspending fluid and lubricant.

### ***Stainless-Clad and Chromized Steel Sheet***

Stainless-clad and chromized steel sheets, although manufactured by different processes, consist of a relatively soft low-carbon steel core sandwiched between stainless steel or chromium-rich surface layers. The surface layers are harder than the low-carbon steel base metal.

### ***Porcelain Enameled Steel Sheet***

Because of the brittleness of porcelain enamel coatings, cutting a specimen from porcelain enameled steel sheet requires the use of procedures that will minimize or prevent chipping of the friable coating. A thin alumina cutoff wheel or a diamond blade on a precision saw may be used. When the cutoff wheel is used, the cut should be made about 3 mm ( $\frac{1}{8}$  in.) away from the area to be examined. The specimen is then mounted and ground back about 3 mm to remove areas damaged in cutting. Use of a precision diamond saw permits cutting directly adjacent to the area to be examined.

**Mounting specimens** of porcelain enameled steel sheet may present a problem, because they cannot be bent into "L" or "Z" shapes without damaging the coating. There are, however, several other techniques that may be used. Clamp mounting is applicable to porcelain enameled specimens and preferred in some laboratories. Another method for mounting several specimens simultaneously is to clip them together or to glue them together with an epoxy resin. The specimens may be interleaved with strips of plastic or soft metal, such as copper or lead. Either the clipping or the gluing technique will provide a section thickness sufficient to be self supporting when placed upright in a mold. Alternatively, plastic chips can be used to hold the specimen perpendicular. Castable resins, chiefly epoxy, are preferred for mounting.

## **Technique for Steel Plate, Tube, and Pipe**

Steel tube and pipe do not present any special problems in specimen extraction; steel plate does. Because plate may be quite thick, it often is necessary to examine specimens from three or more locations in order to observe true conditions. Extraction of specimens from a thick plate is likely to require a considerable amount of cutting. Various machining methods, including sawing and hollow boring, are used to obtain the initial test pieces. During machining, care must be taken to prevent the specimen from becoming overheated, which might change the structure of the steel.

## **Examination of Welded Joints**

Steel sheet, strip, plate, tube, and pipe are often welded; therefore, techniques for metallographic examination of welded joints are needed. Welds are usually examined at a low magnification so that a large area can be viewed. Specimens from weldments are sectioned, mounted, ground, and polished in the same manner as other metallographic specimens. Whenever possible, the specimen should contain the weld nugget, heat-affected zone, and a portion of the adjacent base metal.

## **Technique for Carbon and Alloy Steels of Medium Carbon Content**

This group of steels is comprised of wrought steels that have carbon contents ranging from about 0.25 to 0.50%, and, for the alloy grades, total alloy contents up to about 7% (but mostly less than 3%). The methods of preparing metallographic specimens discussed in this article and in the article "Metallographic Practices Generally Applicable to All Metals" are generally applicable to carbon and alloy steels of medium carbon content. Many large forgings, because they are too costly to destroy or too difficult to section, are designed with an allowance of metal on the end from which test coupons can be taken, usually by sawing or hollow boring. Small forgings (up to about 5 lb) may be sectioned instead of being designed with test coupons. Test coupons are cut into specimens, usually by sawing or abrasive-wheel cutting. Often, specially designed test specimens are used.

## **Technique for Carbon and Alloy Steels of High Carbon Content**

Heat treated, high-carbon steels are more sensitive to damage by abrasive cutting than low-carbon steels. A hardened high-carbon steel specimen should not be heated to more than 150 °C (300 °F) during cutting, and sometimes (for example, when the steel is to be examined in the as-quenched condition) the specimen should not be heated to more than about 66 °C (150 °F). Excessive heat will temper the martensite and change its appearance, and it could result in misinterpretation of the structure of the steel.

Abrasive cutting must always be done using a coolant (water containing a soluble oil) and a softly bonded wheel to prevent burning. Etching of the cut specimen in nital will reveal this condition and indicate the corrective measures that must be taken to bring out the original structure of the specimen, such as removal of more stock from the surface to be examined. Avoiding burning during cutting is a far better practice than trying to grind away burning damage.

## **Technique for Case Hardening Steels**

NITRIDED STEELS require special preparation. Techniques described in the first part of this section are oriented primarily toward preparation of specimens from carburized and carbonitrided steels, although they are also applicable to preparation of specimens from cyanided steels.

## Carburized Steel and Carbonitrided Steel

Most steels used for carburizing and carbonitriding have an initial carbon content ranging from 0.10 to 0.30%, and they may or may not contain one or more alloying elements. Sometimes, to satisfy special requirements, medium-carbon steels are carburized.

Because the carbon content of carburized steel may range from that of the uncarburized core (0.10 to 0.30% C) to as much as 1.20% C in the case, specimens are difficult to extract and prepare. Even for a steel that has been carburized but not hardened, the hardness varies considerably from surface to center of a cross section. When the carburized steel has been hardened, the hardness difference between the core and the outermost portion of the case may exceed 40 points on the HRC scale.

**Sectioning.** Separate small test pieces designed to minimize the amount of sectioning required are often used. If the production parts are very small, one or more of them are sectioned for metallographic study. When the specimen must be removed from a large mass of material, the same meticulous care must be used.

**Mounting techniques** and precautions used for specimens of high-carbon steels are applicable to specimens of carburized steel. Overheating of specimens must be avoided to prevent changes in structure. The use of cold mounting and wet grinding is required for examination for retained austenite.

Preservation of the edges of carburized cases is of the utmost importance. Edge preservation is easier when the surface hardness is high. A mounting press that cools the specimen to near room temperature under pressure virtually eliminates shrinkage gaps that lead to edge rounding. Harder epoxy compression mounting compounds further aid edge preservation. Automatic polishing devices and use of napless and low-nap cloths are important. Nickel plating provides the best possible edge protection but by itself may not be adequate.

**Grinding and polishing** techniques are the same as those described for specimens of other steels. Automated polishing devices are advisable when the hardness varies widely within a specimen providing even pressure and uniform removal. It is highly desirable to minimize polishing time. Because of the wide differences in hardness within a single specimen, some constituents may polish in relief, and flatness of the specimen may be destroyed. Frequently, specimens that have been over polished must be completely reworked to regain flatness. Use of low-nap polishing cloths will reduce this problem.

**Etching.** Nital is a general-purpose etchant for routine metallographic study. It is well suited for revealing case depth, retained austenite, carbide networks, and surface decarburization. Nital is preferred for examining the hardened surface region. Picral will reveal nonmartensitic phases very clearly but not martensitic regions (unless they are highly tempered). Picral is preferred for examining the transition region and the unhardened core region.

## Nitrided Steels

Preparation of nitrided steel specimens to reveal the true microstructure requires more exacting techniques than are normally required. The extreme hardness differential between the case and the core (case hardness  $\geq 900$  HK) causes problems. Also, the nitride concentration at the surface (white layer), which often is the primary subject of metallographic examination, may be entirely destroyed by ordinary preparation techniques. This layer is extremely thin.

**Test Pieces.** The principal use of metallography for nitrided steels is quality control of production nitriding. Often, the workpieces being nitrided are too valuable to permit destructive testing, and so separate test pieces are prepared of the same steel with the same preliminary heat treatment as the workpieces.

Test pieces must be made with great care. In one recommended practice, bars of the same steel of convenient length and 41 mm ( $1\frac{5}{8}$  in.) in diameter are quenched and tempered, unless they are already in the heat treated condition. They are then turned and ground to a diameter of 38 mm ( $1\frac{1}{2}$  in) so as to remove any decarburization or carburization that may have occurred in the preliminary heat treatment. The ground surface should be no rougher than 0.13  $\mu\text{m}$  (5  $\mu\text{in.}$ ). Next,

the turned and ground bars are cut into slices about 6 mm ( $\frac{1}{4}$  in.) thick. This step can be done with a lathe; an abrasive cutoff machine can be used if coolant is supplied copiously to prevent burning. A hole can be drilled in the completed test piece, permitting it to be hung in the furnace to prevent its being lost during nitriding.

**Plating of nitrided test pieces** prior to sectioning is the best practice for protection of the edges and preservation of the white layer. Plating must be done without blasting or severe etching. Nickel plating has proved best. The thickness of the deposit is not critical; 0.05 mm (0.002 in.) is sufficient. Chromium plating is unsatisfactory, because the plate does not adhere well to nitrided surfaces without an unacceptable amount of surface preparation. Copper, zinc, and cadmium plates are too soft.

**Mounting of Specimens.** Compression mounting epoxy is preferred for mounting specimens of nitrided steel. The mounting temperature does not affect nitriding steels. Placing chilled iron shot or hardened steel balls around the specimen can be used for preserving flatness of the specimen during manual grinding and polishing. These are unnecessary when automated preparation devices are used.

**Grinding and polishing** nitrided steel specimens is the same as grinding and polishing of other steel specimens. Napless and low-nap cloths are recommended for edge retention.

**Etching.** Common practice is to etch the polished specimen, immediately repolish very lightly (just enough to remove evidence of etching), and then etch again. Some metallographers continue this procedure for two or more cycles to ensure that all disturbed metal is removed and that the true structure is revealed. These practices are not needed if proper care is taken during grinding and polishing.

For routine examination, nitrided steel specimens are most often etched in nital--2% nital for microscopic examination and up to 5% nital for case-depth measurements at low magnification. Nital reveals the white layer, the depth of case, and the structure of nitrided alloy steels, such as AMS 6470, 4140, and H13.

## Technique for Steel Castings

CARBON AND ALLOY STEEL CASTING specimens are prepared by the same techniques as those used for preparing specimens of wrought carbon and alloy steels of the same composition.

## Extraction of Specimens

In a single steel casting, section thickness can vary from a fraction of an inch to many inches. These differences in section thickness will result in different cooling rates, and thus in different microstructures, within the casting. This difference is true both for as-cast and for heat treated castings. Therefore, for complete examination of a casting, several specimens may have to be extracted.

Steel castings, both as-cast and heat treated, are usually soft enough to permit sawing or hollow boring for initial extraction of test pieces, after which the oversize pieces are reduced to specimen size by abrasive-wheel cutting. If the casting is hard, abrasive-wheel cutting is used for all operations. Precautions must be taken to avoid overheating during cutting.

## Mounting

Phenolic resins are often used for mounting specimens. The microstructures of most steel castings are not affected by the high thermosetting temperature of phenolics.

## Grinding and Polishing

Preparation of cast steels is the same as for wrought steels except that the casting may contain porosity or microshrinkage cavities. If these holes are not filled by epoxy (or wax), bleeding problems will occur. It may be necessary to vacuum impregnate partially prepared specimens with epoxy to fill the voids on the specimen surface. Grinding and polishing media, etchant solutions, and water will enter these openings and must be removed, or they may impair examination--

especially when an inverted microscope is used. Ultrasonic cleaning followed by careful drying (a heat lamp or an oven may help) may suffice if the holes are not filled.

## Etching

Nital is the etchant most often used for specimens from steel castings. As usual, it is preferred for martensitic structures. Nital is easier to remove from pores and cavities than picral. Picral sometimes is used for etching specimens from steel castings, especially those from castings with carbon contents of more than 0.30%. Carbide structures are resolved better with picral than with nital.

## Technique for Cast Irons

THE PRESENCE OF GRAPHITE in gray, malleable, and ductile cast irons makes preparation of these metals more difficult than steels. The soft and friable nature of the graphite phase, in combination with the relatively hard matrix, presents difficulties during preparation not normally experienced with other ferrous metals. Techniques that will promote a scratch-free and distortion-free surface for the matrix may not retain the graphite so that it can be observed after preparation. Similarly, techniques for polishing soft and friable phases, such as graphite, do not easily lend themselves to successful preparation of the harder matrix. The peculiar friability of graphite in cast iron results in the phase being torn out wholly, or in part, leaving cavities that are either opened up or burnished over, depending on the preparation procedure adopted. As a result, the shape and size of the graphite may not be truly represented, and an accurate assessment of the microstructure cannot be made. To obtain a scratch-free and distortion-free matrix containing well-preserved and polished graphite, special preparation procedures specific to cast irons containing graphite have to be adopted. The preparation of white cast iron specimens does not have the limitations imposed by the presence of graphite and conventional techniques are used.

## Sectioning

Specimens can be obtained from iron castings using conventional cutting techniques, such as mechanical hacksawing or abrasive wheel sectioning. Sawing produces a rough-cut face and deforms the base metal to a much greater extent than does abrasive cutting. When specimens are obtained by sawing, a lubricant should be used, and grinding must commence with coarser-grit SiC papers than would be needed if the specimens were obtained by abrasive cutting. In cutting of hard materials, such as white irons, it is necessary to use a cutoff machine employing thin, softly bonded aluminum oxide wheels, and overheating must be avoided. Cutting with copious water flow is recommended to minimize heat effects. Abrasive cutting is preferred to bandsawing as damage to the surface is much less and the surface is smoother. This facilitates subsequent grinding.

## Mounting

Specimens that are difficult to handle should be mounted using the hot compression mounting technique. In many laboratories, it may be convenient to mount all specimens, and mounting is often essential if polishing is to be done on automatic equipment. A suitable thermosetting phenolic plastic should be used as the mounting medium. It should provide sufficient adhesion and edge support to the specimen and minimize the rounding of edges that results in loss of sharpness during examination when a modern mounting press is used (specimen cooled to near room temperature under pressure). Castable resins may be used, particularly when edge retention is unimportant.

## Grinding

After mounting, the specimen is abraded (ground) to a condition suitable for polishing. The traditional approach utilizes a series of 120, 240, 320, 400, and 600 grit waterproof silicon carbide abrasive papers. Water is used as the lubricant and to remove abrasion debris from the paper. Many metallographers use a second 600-grit grinding operation without water (i.e., dry) to maximize graphite retention.

If grinding is performed manually on rotating wheels, the specimen is held against the paper, being careful not to rock the specimen. It is moved from edge to center as the wheel rotates (generally at 150 to 300 rpm). After grinding with each

paper, the specimen is reoriented 45 to 90° from the prior direction and ground with the next paper. When automatic devices are used, a multidirectional scratch pattern is produced, and thus specimen reorientation is not required. Automatic devices provide best flatness and graphite retention.

Abrasion on the final paper is an important stage in the preparation procedure, because it is here that the graphite phase may be damaged. For most gray irons containing fine graphite structures, white irons, and alloy irons, careful abrasion on 600 grit paper is normally sufficient before polishing. A generally recommended 600 grit grinding procedure is first stage with water lubrication and the second stage dry.

In the article "Metallographic Practices Generally Applicable to All Metals," Fig. 24(a) shows a coarse-flake gray iron that has been abraded on a poor-quality abrasive paper. The graphite flakes have been torn out and the cavities enlarged. This effect can also be due to other factors, such as grinding with worn or loaded papers, or grinding in the same direction with each paper grade. Figure 24(b), which is essentially the same field as Fig. 24(a), shows the specimen after it has undergone correct abrasion. The graphite flakes are well preserved, and the matrix is uniformly scratched. In this article, Fig. 4 and 5 show (at high magnification) a single graphite nodule in a ductile cast iron in the incorrectly and correctly abraded states.

**Fig. 4** Nonretained graphite nodule in a ductile iron specimen after incorrect abrasion. The graphite phase has been torn away. Not polished, not etched. 800×

**Fig. 5** Same specimen as in Fig. 4 but after correct abrasion, which yields a fully retained nodule. Note that the graphite spherulite has been well preserved. As polished, not etched. 800×

## Polishing

For cast iron, polishing with diamond abrasives has been found to be most satisfactory. Polishing in two stages is recommended. Coarse polishing frequently is performed with 6  $\mu\text{m}$  diamond, and fine polishing with 1  $\mu\text{m}$  diamond. In some instances, finer diamond pastes can be employed. The paste is supplied in syringe applicators from which it is squeezed in the form of a thin ribbon. The action of diamond-impregnated carrier pastes produces rapid polishing with minimum deformation. Diamond slurries are also utilized.

Polishing is an important phase of the preparation sequence, because properly ground specimens can be damaged by poor polishing technique. Use of inadequate lubricant, a worn cloth, an inadequately charged cloth, or excessive pressure or wheel speed can degrade graphite retention, enlarge the apparent size of the graphite, produce scratched surfaces, and

reduce interface sharpness. For gray irons, in order to polish the graphite and remove distorted and smeared metal, alternate polishing and etching is sometimes practiced.

The type of polishing cloth used with the diamond abrasive has a significant effect on retention of graphite. Polishing cloths with a high nap or pile are extremely effective in removing scratches from previous operations, but they have an adverse effect on retention of graphite. Napless or short-pile cloths are more suitable for retaining graphite but suffer from the limitation that they are less efficient in removing abrasion scratches. With two-stage polishing, a napless cloth is used for the rough polishing stage, while a low-nap or napless cloth is used for the final diamond polishing stage.

After polishing, the specimen surface is cleaned by swabbing with a soapy water solution followed by rinsing with alcohol from a squeeze-type wash bottle. If cavities are present, ultrasonic cleaning may be needed. The specimen is dried by flooding it with high-purity alcohol and then holding it under the hot air blast from a specimen dryer.

## Etching

If an assessment of graphite shape, size, and distribution is required, this is best done when the specimen is in the as-polished (not etched) condition. Examination for porosity or the presence of nonmetallic inclusions is also more easily achieved when the specimen is polished but not etched. However, observation of other important structural details can be made only after the specimen has been suitably etched. This step is normally done by holding the specimen with a pair of tongs and immersing it, with intermittent agitation, in the desired reagent for a suitable period of time.

The production and interpretation of correctly etched cast iron structures is often dependent on practice and experience, because consideration usually has to be given to both the characteristics of the reagents used and the nature of the investigation. Table 3 gives some of the more common etching reagents employed for cast iron, together with techniques for use and their principal applications. Most cast irons can be satisfactorily etched with either 4% picral or 2% nital.

**Table 3 Etchants for microscopic examination of cast irons**

Etchant	Composition	Etching technique	Applications
<b>Picral</b>	4% picric acid, 96% ethanol	Dip etch for 2-10 s	General-purpose etching of all pearlitic gray, malleable, and ductile cast irons. Best etchant for pearlite. Etches some austenitic cast irons, Ni-hard, and acicular irons.
<b>Nital, 5%</b>	5% nitric acid, 95% ethanol	(1) Dip etch for 2-10 s (2) Electrolytic etch <sup>(a)</sup>	(1) General-purpose etching of all ferritic gray, malleable, and ductile cast irons. Etches grain boundaries. Etches some austenitic irons and containing martensite. (2) High-chromium irons
<b>Nital, 2%</b>	2% nitric acid, 98% ethanol	Dip etch for 2-10 s	Observation of ferritic grain boundaries at high magnification
<b>Ferric chloride</b>	10 g ferric chloride, 100 mL water	Dip etch for 3-20 s	Austenitic cast irons
<b>Mixed acid in glycerol</b>	10 mL HNO <sub>3</sub> , 20 mL HF, 40 mL glycerol	Dip etch for 10-40 s	High-silicon irons (14 to 16% Si)
<b>Vilella's reagent</b>	1 vol HNO <sub>3</sub> , 2 vol HCl, 3 vol glycerol	Dip etch for up to 20 s	High-chromium irons
<b>Potassium ferricyanide</b>	10% alkaline aqueous solution of potassium ferricyanide	Dip etch for 5-30 s, in etchant at 50 °C (122 °F)	High-chromium irons
<b>Murakami's reagent</b>	10 g KOH, 10 g K <sub>3</sub> Fe(CN) <sub>6</sub>	(1) Dip etch for 2-3 min (2) Dip etch for 10-30 s	(1) 30% chromium irons. (2) High-phosphorus irons, to distinguish between iron phosphide and iron carbide
<b>Alkaline sodium picrate</b>	2 g picric acid, 25 g NaOH, 100 mL water; warm to dissolve	(1) Dip etch for 10 s to 2 min at boiling point (2) Electrolytic etch <sup>(b)</sup>	(1) Blackens cementite. (2) Blackens cementite

(a) Specimen is anode; platinum cathode. Current density, 0.13 to 0.31 A/cm<sup>2</sup> (0.5 to 2.0 A/in.<sup>2</sup>) for up to 2 min.

(b) Specimen is anode; stainless steel cathode. Current density, 0.13 to 0.31 A/cm<sup>2</sup> (0.5 to 2.0 A/in.<sup>2</sup>) for up to 2 min in cold solution.

Picral is the best general-purpose etchant for all predominantly pearlitic gray, malleable, and ductile cast irons. It gives a clean, uniform etch to both coarse and fine pearlitic structures. Pearlite should be etched until it is medium-to-light brown in color, so that graphite present in the structure can be clearly seen. Picral does not damage graphite but gives an added sharpness to the outline of the flakes or nodules.

## Macroexamination

Macroetching of cast iron is used to reveal such features as chill formation and segregation. Table 4 gives the more commonly used macroetchants for cast iron. Usually, picral, nital, and ammonium persulfate are the most suitable reagents because they do not cause extensive staining. The specimens should be immersed in the solution and swabbed with cotton. After removal from the etchant, they are flooded with water, rinsed with alcohol, and dried with hot air.

**Table 4 Etchants for macroscopic examination of cast irons**

Etchant	Composition	Etching technique	Application
<b>Stead's reagent</b>	10 g cupric chloride, 40 g magnesium chloride, 20 mL hydrochloric acid, 1000 mL ethanol <sup>(a)</sup>	Immersion for up to 3 h	Used to reveal the eutectic cell number in gray cast irons
<b>Rapid cell-etching reagent</b>	10 g cupric chloride, 50 mL water, 100 mL hydrochloric acid	Dip etch for about 60 s	As above, but results are less distinct
<b>Ammonium persulfate</b>	10 g ammonium persulfate, 100 mL water, few drops H <sub>2</sub> SO <sub>4</sub> (conc) <sup>(b)</sup>	Immersion and swabbing	Reveals carbide and phosphide distribution
<b>Nital</b>	5 or 10% nitric acid, 95 or 90% ethanol	Dip etch for up to 3 min	Used to reveal macrostructure in white irons
<b>4% picral</b>	4% picral acid, 96% ethanol	Dip etch for up to 3 min	Used to reveal macrostructure in white irons

- (a) Dissolve cupric chloride in a minimum quantity of hot water (10-15 mL); add magnesium chloride and dissolve; add ethanol, then hydrochloric acid.
- (b) Add H<sub>2</sub>SO<sub>4</sub> just before use.

Eutectic cells in gray irons are generally revealed by etching with Stead's reagent. The reagent selectively darkens low-phosphorus regions in the iron, leaving high-phosphorus regions (normally segregated at cell boundaries) unattacked and light. The specimens can be etched by immersion in a stock solution for periods up to 3 h. The time of immersion is found by trial, but, in general, irons containing coarse cell structures take longer than irons containing fine cell structures.

## Technique for Tool Materials

METALLOGRAPHIC TECHNIQUES for tool steels, cast cobalt alloy tool materials, cemented carbides, and ceramic tool materials are described in this section because of the similar nature of their use and metallographic procedures, despite the fact that only tool steels are iron-base materials.

## Tool Steels

The procedures used for specimen preparation and macroscopic and microscopic examination of tool steels are essentially the same as those used for carbon and alloy steels.

**Macroetching.** A solution containing one part hydrochloric acid and one part water at 71 to 82 °C (160 to 180 °F) is the etchant most often used for revealing segregation, porosity, cracks, inclusions, and flow lines. This etchant also can be used for revealing hardness penetration and soft spots. A solution of nitric acid (2 to 10% in water or ethanol) is often favored for showing the depth of the hardened zone, carburized case depth, or decarburized depth; it is used to a lesser extent for revealing defects.

**Preparation of Specimens for Microscopy.** The test piece is obtained from the larger mass by breaking, hacksawing, or abrasive cutoff. Hacksawing is limited to annealed specimens. Use of abrasive cutoff wheels for sectioning tool steels requires extreme care to prevent overheating. In sectioning of pieces that have been hardened but not tempered, it is inadvisable to permit them to exceed a temperature of about 66 °C (150 °F). Steels that contain large

amounts of massive carbide particles, such as D2 and T15, are very difficult to cut, even when in the annealed condition, and require ultimate care when abrasive cutoff is used. A soft grade of cutoff wheel, a copious supply of coolant, and slow cutting speed are mandatory. The cut surface must always be inspected for evidence of burning.

Mounting techniques are the same for tool steels as for other steels. Phenolics or epoxies are most often used as the mounting materials. Phenolics are a satisfactory material except for mounting hardened but untempered specimens, which should not be subjected to the required thermosetting temperatures. A castable mounting compound (e.g., an epoxy) that hardens at room temperature, or at no more than about 66 °C (150 °F), is preferred for most hardened but untempered tool steels.

Grinding and polishing techniques are basically the same for tool steel specimens as for specimens of carbon and alloy steels. It is important to keep polishing times as short as possible, especially for steels such as D2 and T15. Excessive polishing produces a relief effect due to the carbide particles and may pull out or drag inclusions. Use of napless or low-nap cloths help reduce relief problems.

**Microetching with Nital.** For routine metallographic examination, tool steel specimens are most often etched in 2 to 5% nital (2 to 5 mL of nitric acid added to ethanol or methanol to make 100 mL of etchant). Nital is a general-purpose etchant and can be used on all tool steels in nearly all conditions: annealed, quenched, and quenched-and-tempered. Nital, however, is relatively poor for spheroidize-annealed tool steels. Picral, perhaps aided by a small addition of HCl (0.5 to 4%), is far better for revealing the spheroidized carbides. Vilella's reagent is also widely used to study tool steel structures.

Because of the many variables affecting etching time, it is impractical to prescribe specific etching times. Common practice is to immerse the specimen in the etchant with the polished side up, agitate it gently, and observe it carefully. The surface of the specimen first changes from a polished appearance to light brown. If etching proceeds too far, the specimen turns dark gray. Overetching causes a loss of detail in the matrix and shows the carbides heavily in relief. Overetching may result in removal of the carbide particles. Alternate etching and microscopic observation may be required to obtain the ideal etch for the magnification to be used. Etching of quenched but untempered highly alloyed tool steels for grain-size observation may require up to 4 or 5 min in 2% nital.

**Microetching with picral,** a 4% solution of picric acid in ethanol, is applicable for most grades of tool steel, particularly in the annealed condition. Various carbide structures are shown better if the specimen is etched with picral rather than with nital. Techniques for etching with picral are essentially the same as those for etching with nital. Picral is not as effective as nital for the study of martensitic structures. The addition of HCl or the use of Vilella's reagent overcomes this problem.

**Special-purpose etchants** are occasionally used for etching of tool steels. They are used for greater distinction of specific microconstituents (Table 5), particularly carbides.

**Table 5 Special-purpose etchants for tool steels**

Feature	Etchant	Comments
<b>Cementite</b>	2 g picric acid, 25 g NaOH, 100 mL water	Immerse in boiling solution or use electrolytically (6V dc, 20 °C, 30-120 s). Will not darken cementite if it contains substantial Cr.
<b>M<sub>6</sub>C, Mo<sub>2</sub>C</b>	4 g KMnO <sub>4</sub> , 4 g NaOH, 100 mL water	Use by immersion.
<b>MC, M<sub>7</sub>C<sub>3</sub></b>	1 g CrO <sub>3</sub> , 100 mL water	Electrolytic at 2-3 V dc, 30 s

## Cast Cobalt Alloy Tool Materials

The cast cobalt alloy tool materials are a unique family of proprietary alloys that are hard in the as-cast condition and are used without further heat treatment. Most of them contain 38 to 50% Co, 25 to 32% Cr, 4 to 25% W, and 1 to 4% C. Some of these alloys contain up to 4% V, and others have up to about 5.5% Nb and 3.5% Fe.

**Microstructure.** The most noticeable constituent is large carbides that appear in elongated or acicular form and have been identified as chromium carbide, Cr<sub>7</sub>C<sub>3</sub>, in which some of the chromium may be replaced by cobalt or tungsten. M<sub>6</sub>C

and  $M_{23}C_6$  carbides have been identified in some alloys. The matrix usually consists of various binary and ternary eutectics containing all constituents of the alloy.

**Specimen Preparation.** Sectioning is done using abrasive cutoff wheels. The greatest care must be used to prevent damage from overheating. Use a very softly bonded wheel with copious water cooling. If phenolics are used as the mounting material, the heat involved in curing is not sufficient to alter the structure of the alloys. Grinding and polishing are done by the same procedures as those used for grinding and polishing carbon steels, alloy steels, and tool steels.

**Etching** procedures and etchants for cast cobalt alloy tool materials differ among various laboratories. The two procedures that follow are commonly used.

The first commonly used procedure begins by activating the surface of the polished specimen with a short (about 2 s) electrolytic etch in 2% chromic acid, then immersing the specimen for 10 s in an alkaline permanganate solution. The alkaline permanganate solution is prepared immediately before use by mixing equal parts of a saturated solution of potassium permanganate and an 8% solution of sodium hydroxide. It should be discarded immediately after use. After etching, wash the specimen in running water and then in ethanol or methanol, and dry it in an air blast. The etched specimen must not be rubbed.

The other method starts by etching the specimen for about a minute (the exact time is determined by trial and error) in a solution of six parts of concentrated hydrochloric acid and one part of 30% hydrogen peroxide. Etching must be done under a hood.

## Cemented Carbides

Both low and high magnifications are used for examining microstructures of cemented carbides.

**Examination at Low Magnifications.** Macroscopic examination of cemented carbides is usually practiced with a low-power microscope at 20 or 30 diameters for detecting pits, pressing flaws, contamination, segregation, free carbon, and carbon deficiency (eta phase). Free carbon is characterized on an as-sintered surface or a fracture surface by clustered dark spots. Often, a specimen with excessive free carbon has an as-sintered surface that feels slippery to the touch. Carbon deficiency is manifested by the appearance of shiny stringers, dots, and clusters that turn dark when etched with Murakami's reagent. Because defects, such as pits and pressing flaws, lower the strength of the material, fracture will initiate in them and propagate through them. For this reason, they are easy to identify on a fracture surface.

**Preparation of Specimens for Microscopy.** The specimen is extracted from a larger mass by breaking or by abrasive-wheel cutting. Cutting with a precision diamond saw is widely practiced because it produces little damage and yields a surface requiring a minimum of grinding. Diamond is the most effective abrasive for sectioning these very hard materials. Because cemented carbides are difficult to polish (due to the structure and hardness), it is recommended that the size of the specimen be kept as small as possible. Specimens having a face area no larger than  $160 \text{ mm}^2$  ( $\frac{1}{4} \text{ in.}^2$ ) are preferred.

The mounting materials and techniques that are applicable to steels are applicable also to cemented carbides. All compression mounting compounds may be used.

Because cemented carbides are very hard, hand grinding and polishing is quite tedious, and use of automatic devices is recommended. If the specimen has been cut with a precision diamond saw, a high-quality surface is obtained that requires a minimum of grinding. SiC papers are rather inefficient for grinding cemented carbide specimens. Metal- or resin-bonded diamond disks are preferred. These disks are available with a wide range of nominal diamond sizes, depending upon the type and source, but generally are in the range of 165 to  $15 \mu\text{m}$  (may be available with coarser or finer diamond sizes). If the surface to be polished has been sectioned by fracturing, the coarsest diamond size should be used first. If the surface was cut with a precision diamond saw, grinding can commence with the  $30 \mu\text{m}$  diamond disk. Grinding is done with relatively high pressure, copious water cooling, and a speed of 100 to 300 rpm.

Polishing generally is conducted in several stages using diamond paste on napless or low-nap cloths. Nylon is frequently used. Diamond charging is heavier than for polishing of steels. The cloth should be moistened with extender lubricant and not be permitted to dry out. Polishing with 6 and  $1 \mu\text{m}$  diamond paste is recommended. Again, the pressure is somewhat higher than that used for steels, and automatic devices are definitely preferred. For most work, final polishing with  $1 \mu\text{m}$

diamond is adequate. A short 30 s final hand polish with colloidal silica may be desirable for best results. This step is performed using a short- or medium-nap synthetic cloth attached to a glass plate (i.e., stationary) using a figure-eight motion. This step will reveal the interfaces between the cobalt binder and the carbides with a minimum of relief. Alternatively, a vibratory polisher may be used.

**Etching.** The most commonly used etchant for cemented carbides is aqueous alkaline potassium ferricyanide, known as Murakami's reagent (10 g potassium ferricyanide, 10 g potassium hydroxide, or 7 g sodium hydroxide), and 100 mL water. A short etch (2 to 10 s) colors only eta phase. Longer etching times attack the eta phase but reveal the phase boundaries. Etching is performed at room temperature.

To preferentially darken the cobalt binder phase, etch for 1 to 5 min at room temperature in hydrochloric acid saturated with ferric chloride (Chaporova's reagent). The cobalt binder phase also may be revealed preferentially by heat tinting the polished specimen (unmounted) at 315 °C (600 °F) for 5 min in a laboratory furnace. This practice colors the cobalt rust brown. Higher temperatures will color the carbide grains. Considerable use has also been made of the Pepperhoff vacuum-deposition interference-film technique (Ref 1).

**Apparent porosity** is a "catch-all" term that refers to all microstructural features observed at a magnification of 200 diameters on properly prepared, unetched surfaces of cemented carbides. The apparent porosity rating is made by comparing the observed field with a porosity chart, such as that provided by ASTM B 276. Free carbon can be confirmed as C-type apparent porosity at 200 diameters. Segregation and contamination can be observed also.

**Microstructure.** Examination of the microconstituents of cemented carbides is best done at magnifications of 1000 to 1500 diameters after etching by immersion in Murakami's reagent at room temperature. Tungsten carbide is revealed as gray angular crystals; cobalt, unattacked by the etch, appears as a white or light-cream matrix. If tantalum carbide, titanium carbide, or solid-solution phases are present, they will appear brownish or gold in color, and will stand above the polished surface when etched. The different phases are distinguished by slight differences in color.

Because each producer manufactures cemented carbide materials for performance under given conditions according to its own specifications as to microstructure, considerable differences will be observed in the microstructures of materials from different producers. Thus, the value of a microscopic examination, beyond evaluation of apparent porosity and examination for extraneous phases, will depend on the correlation developed between a specific microstructure and performance.

To estimate the grain size of cemented carbide materials, the microstructure is compared with a set of standard charts or micrographs. A visual comparison procedure for evaluating the apparent grain size of cemented tungsten carbide materials is described in ASTM B 390. Alternatively, the size of the WC grains can be measured manually or by image analysis.

## Ceramic Tool Materials

The steps used in preparing and polishing specimens from ceramic (oxide-base) tool materials for microscopic examination are essentially the same as those for preparing specimens from cemented carbides. Because of the absence of a ductile matrix phase in most ceramic tool materials, extreme care is required during polishing to prevent pullout of hard, brittle particles. Specimens to be etched are not mounted in plastic, because of the high temperatures that may be required for etching.

The polished, unetched specimen is viewed at magnifications of 100 to 1000 diameters to determine porosity, flaws, and segregation. Because complete freedom from pullouts may be difficult to attain, density measurements are used as the primary means of determining porosity, with microscopic examination employed for confirmation.

If etching is desired, the polished, unmounted specimen is immersed in 85%  $\text{H}_3\text{PO}_4$  at 180 to 250 °C (360 to 480 °F) for 8 to 10 min. The etchant preferentially attacks second phases and grain boundaries, and this must be taken into account in an interpretation of the etched microstructure.

## Technique for Ferrous Powder Metallurgy Alloys

POWDER METALLURGY PARTS may not be compacted to full density, with the result that there are invariably some pores, the number and size of which will vary with density. The major difference between parts made from metal powders and those made from wrought metal is in the amount of porosity (voids). The presence of pores is likely to cause difficulty in the preparation of metallographic specimens. First, there is the possibility that grinding debris, abrasive or particles of other metals will become embedded in the pores during cutting, grinding, and polishing. Also, moisture may become entrapped in the pores and may bleed out during etching, resulting in staining. Another possibility is the entrapment of etchant, which may bleed out and stain the surface.

## Specimen Selection and Sectioning

Selection of representative specimens of powder metallurgy alloys requires careful consideration, primarily because porosity is seldom uniform. Density (and therefore porosity) may vary from surface to center of a relatively thick part, thus necessitating examination of the entire cross section. Also, when a powder metallurgy part is subjected to a furnace atmosphere, as in sintering or heat treatment, microstructural characteristics may be different within a given cross section.

## Washing

Following sectioning, specimens should be washed to remove foreign material that may have infiltrated the pores. Two devices used for removing contaminants from pores are an extractor-condenser and an ultrasonic cleaner.

**Extractor-Condenser.** The use of an extractor-condenser is the more efficient and the less expensive of the two methods of washing. The extractor-condenser consists of a flask, a siphon cup, and a condensing-coil unit that fits on the top of the flask (Fig. 6). A solvent, such as acetone, is placed in the flask, and the specimens to be washed are placed in the siphon cup. A cold-water line is connected to the condensing coil. The flask is heated to the boiling temperature of the solvent. The solvent evaporates and, when the vapor comes in contact with the cold condensing coil, it condenses and drips into the siphon cup. When the siphon cup becomes filled to a predetermined level, it empties, returning the solvent to the flask. Recycling allows a continuous flow of clear solvent over the specimen.

Fig. 6 Extractor-condenser used to wash P/M specimens to remove contaminants from pores

**Ultrasonic Cleaning.** The ultrasonic cleaner used for washing powder metallurgy specimens consists of a power supply and a small tank, which holds a solvent bath. Numerous solvents may be used, for example, a warm aqueous solution containing a detergent, alcohol, or acetone. The specimens must be fully dried after cleaning, which may require baking in an oven at 50 to 65 °C (120 to 150 °F).

## Impregnation

After the specimen has been washed, some means of preventing abrasives, water, and etchant from entering the pores should be provided. For specimens that are to be ground and polished without mounting or that are to be mounted using heat and pressure (as required for a phenolic), wax impregnation is recommended. Specimens are impregnated by soaking them in a molten synthetic wax at 175 °C (350 °F) for 2 to 4 h. After cooling and removal of the surface wax, the specimens are ready for mounting or for grinding and polishing without mounting.

Vacuum impregnation using a very low viscosity epoxy is also commonly performed. Impregnation is done after grinding. When the epoxy is dry, the surface is lightly reground with the finest grit used before polishing. Figure 7 shows views of a commercially available system for vacuum impregnating specimens in epoxy.

**Fig. 7** Vacuum impregnation equipment. (a) Complete system. (b) A view of the inside of the chamber prior to use

These practices will fill only those pores connected to the surface. After grinding and polishing, new pores may be opened at the surface that were not previously filled because they were not connected to the surface. A second wax treatment or epoxy infiltration step may be needed before the final preparation step.

## Mounting and Grinding

Mounting of specimens is always preferable, and it is required for very small specimens and for edge preservation. The materials and techniques used for mounting powder metallurgy specimens are similar to those for mounting specimens of other metals.

**Grinding.** Procedures for grinding powder metallurgy specimens are generally the same as for specimens of other metals.

**Polishing.** Rough polishing is best accomplished on a napless cloth, such as nylon, charged with abrasive, usually diamond, with sizes from 9 to 3  $\mu\text{m}$ . Automated polishing devices are helpful when preparing porous metals. Excessive relief introduced during polishing will enlarge the porosity and give a false impression of its size and amount. Fine polishing of powder metallurgy alloys is generally the same as for other metals employing fine diamond (e.g., 1  $\mu\text{m}$ ) or alumina (0.3 and/or 0.05  $\mu\text{m}$ ). Colloidal silica and acidic alumina solutions are also popular for final polishing, particularly with a vibratory polisher.

**Etching.** Ferrous powder metallurgy alloys are almost always etched by immersion in 2% nital, although picral is sometimes used and is preferred by some metallographers for revealing certain structures. Staining problems usually are easier to control after etching with nital than with picral.

## Technique for Wrought Stainless Steels

WROUGHT STAINLESS STEELS are complex alloys containing a minimum of 11% Cr plus other elements to produce ferritic, martensitic, austenitic, duplex, or precipitation-hardenable grades. Procedures used to prepare wrought stainless steels for macroscopic and microscopic examination are similar to those used for carbon and alloy steels and for tool steels. However, certain types require careful attention to prevent artifacts. Because the austenitic grades work-harden readily, cutting and grinding must be carefully executed to minimize deformation. The high-hardness martensitic grades that contain substantial undissolved chromium carbide are difficult to polish while fully retaining the carbides. The most difficult of such grades to prepare is AISI 440C, particularly in the annealed or annealed-and-quenched conditions. For the most part, preparation of stainless steels is reasonably simple if the basic rules for metallographic preparation are followed. However, unlike carbon, alloy, and tool steels, etching techniques are more difficult due to the high corrosion resistance of stainless steels and the various second phases that may be encountered.

### Macroexamination

The procedures used to select and prepare stainless steel disks for macroetching are identical to those used for carbon, alloy, and tool steels. Because these grades are more difficult to etch, however, all surfaces to be etched must be smooth ground or polished. Saw-cut surfaces will yield little useful information if they are macroetched.

Macroetchants for stainless steels are listed in Table 6. Heated macroetchants are used with stainless steels in the same manner as carbon, alloy, or tool steels. Etchant compositions are often more complex and more aggressive. In the study of weld macrostructures, it is quite common to polish the section and use one of the general-purpose microetchants.

**Table 6 Macroetchants for wrought stainless steels**

Etchant	Comments
<b>1</b> 50 mL HCl, 10 g CuSO <sub>4</sub> (copper sulfate), 50 mL H <sub>2</sub> O <sup>(a)</sup>	Marble's reagent. General-purpose macrotech; can be heated
<b>2</b> 50 mL HCl, 50 mL H <sub>2</sub> O, 20 mL 30% H <sub>2</sub> O <sub>2</sub>	Mix HCl and H <sub>2</sub> O, heat to 70-75 °C (160-170 °F). Immerse specimen and add H <sub>2</sub> O <sub>2</sub> in steps when foaming stops; do not mix
<b>3</b> (a) 15 g (NH <sub>4</sub> ) <sub>2</sub> S <sub>2</sub> O <sub>8</sub> (ammonium persulfate) and 75 mL H <sub>2</sub> O (b) 250 g FeCl <sub>3</sub> and 100 mL H <sub>2</sub> O (c) 30 mL HNO <sub>3</sub>	Lepito's No. 1 etch. Combine (a) and (b), then add (c); immerse specimen at room temperature; use fresh
<b>4</b> 1 part HCl and 1 part H <sub>2</sub> O	Standard hot-etch. Use at 70-80 °C (160-180 °F), 15-45 min; desmut by dipping in warm 20% aqueous HNO <sub>3</sub> solution to produce a bright surface
<b>5</b> 10-40 mL HNO <sub>3</sub> , 3-10 mL 48% HF, 25-50 mL H <sub>2</sub> O	Use at 70-80 °C (160-180 °F); immerse until the desired degree of contrast is obtained
<b>6</b> 50 mL HCl and 25 mL saturated CuSO <sub>4</sub> in H <sub>2</sub> O	Use at 75 °C (170 °F); immerse until the desired degree of contrast is obtained

(a)

When water is specified, use distilled water.

### Microexamination

**Sectioning and mounting techniques** for stainless steels are identical to those for carbon, alloy, or tool steels.

**Grinding** is performed using 120, 240, 320, 400, then 600 grit water-cooled SiC papers. Care must be taken, particularly when grinding austenitic grades, to remove the cold work from cutting and from each grinding step. In general, speeds of approximately 300 rpm and moderate, firm pressure are used. Grinding times are 1 to 2 min per step. If grinding is carried out by hand, the specimen should be rotated 45 to 90° between each step. Automatic grinding devices produce omnidirectional grinding patterns.

**Polishing.** After grinding, specimens are usually rough polished using 6 or 3  $\mu$ m diamond as a paste, spray, or slurry on napless, low-nap, or medium-nap cloths. Edge flatness and inclusion retention are usually improved by using napless cloths, although scratch removal may not be as complete as with medium-nap cloths. A lubricant extender compatible

with the diamond abrasive should be used to moisten the cloth and reduce drag. A wheel speed of approximately 150 rpm is usually adequate. Pressure should be moderate and firm; specimen rocking should be avoided if polishing is carried out by hand.

To produce high-quality, scratch-free surfaces suitable for photomicroscopy, specimens should be final polished using one or more fine abrasives. The most commonly used final abrasives are 0.3  $\mu\text{m}$   $\alpha$ -alumina ( $\text{Al}_2\text{O}_3$ ) or 0.05  $\mu\text{m}$   $\gamma$ - $\text{Al}_2\text{O}_3$ . Medium-nap cloths are usually used. Polishing with these abrasives, mixed as a water slurry, is performed in the same manner as diamond polishing. Specimens should be carefully cleaned between each rough and final polishing step to avoid contamination at the next step. Colloidal silica is a highly suitable final abrasive for stainless steels.

Stainless steels, particularly the austenitic grades, are often polished electrolytically. In most cases, electropolishing is performed after grinding to a 600 grit SiC finish. Table 7 lists recommended procedures. Electropolishing usually produces high-quality, deformation-free surfaces; however, inclusion attack is encountered, and second phases may be attacked preferentially.

**Table 7 Electropolishing procedures for wrought stainless steels**

Electrolyte composition	Comments
<b>1</b> 50 mL $\text{HClO}_4$ (per chloric acid), 750 mL ethanol, 140 mL $\text{H}_2\text{O}$ <sup>(a)</sup>	Add $\text{HClO}_4$ last, with care. Use at 8-20 V dc, 0.3-1.3 $\text{A}/\text{cm}^2$ (1.9-8.4 $\text{A}/\text{in.}^2$ ), 20 °C (70 °F), 20-60 s. Rinse immediately after polishing
<b>2</b> 78 mL $\text{HClO}_4$ , 90 mL $\text{H}_2\text{O}$ , 730 mL ethanol, 100 mL butyl cellulosolve	Add $\text{HClO}_4$ last, with care. Use at 0.5-1.5 $\text{A}/\text{cm}^2$ (3.2-9.7 $\text{A}/\text{in.}^2$ ), 20 °C (70 °F) max
<b>3</b> 62 mL $\text{HClO}_4$ , 700 mL ethanol, 100 mL butyl cellulosolve, 137 mL $\text{H}_2\text{O}$	Add $\text{HClO}_4$ last, with care. Use at 1.2 $\text{A}/\text{cm}^2$ (7.7 $\text{A}/\text{in.}^2$ ), 20 °C (70 °F), 20-25 s
<b>4</b> 25 g $\text{CrO}_3$ , 133 mL acetic acid, 7 mL $\text{H}_2\text{O}$	Use 20 V dc, 0.09-0.22 $\text{A}/\text{cm}^2$ (0.58-1.4 $\text{A}/\text{in.}^2$ ), 17-19 °C (63-66 °F), 6 min. Dissolve $\text{CrO}_3$ in solution heated to 60-70 °C (140-160 °F)
<b>5</b> 37 mL $\text{H}_3\text{PO}_4$ , 56 mL glycerol, 7 mL $\text{H}_2\text{O}$	Use at 0.78 $\text{A}/\text{cm}^2$ (5.0 $\text{A}/\text{in.}^2$ ), 100-120 °C (212-250 °F), 5-10 min
<b>6</b> 6 mL $\text{HClO}_4$ and 94 mL ethanol	Use at 35-40 V dc, 24 °C (75 °F), 15-60 s

(a) When water is specified, use distilled water.

**Etching.** For inclusion examination, etching is not required, although it is necessary for examining the microstructure. Although the stainless steels are reasonably easy to polish, etching is generally a more difficult step. The corrosion resistance of stainless steels and the potential microstructural complexity of these alloys makes selection of the best etchant a more difficult problem than for carbon and alloy steels.

Stainless steel etchant ingredients are dissolved in water, methanol or ethanol, glycerol, or a mixture of these solvents. Reagents with alcohol or glycerol as the solvent provide better wetting of the surface than water-based reagents and generally provide more uniform etching. Because alcohol reduces dissociation, alcohol-base reagents can be made more concentrated without becoming too powerful for controlled etching. Stainless steel surfaces passivate; therefore, reducing conditions are preferred to oxidizing conditions that promote passivity. Consequently, stainless steel etchants often contain hydrochloric ( $\text{HCl}$ ), sulfuric ( $\text{H}_2\text{SO}_4$ ), or hydrofluoric ( $\text{HF}$ ) acid, although nitric acid ( $\text{HNO}_3$ ) may be used alone or mixed with  $\text{HCl}$  to produce aqua regia or a modified aqua regia. Swabbing, instead of immersion, may be desired to obtain more uniform etch results. Electrolytic etching is also very popular because it produces uniform etching, is easier to control, and gives reproducible results. Table 8 lists numerous etchants used for microexamination of stainless steels.

**Table 8 Microetchants for wrought stainless steel**

Etchant	Comments
<b>1</b> 1 g picric acid, 5 mL $\text{HCl}$ , 100 mL ethanol	Vielella's reagent. Use at room temperature to 1 min. Outlines second-phase particles (carbides, $\sigma$ phase, $\delta$ -ferrite), etches martensite
<b>2</b> 1.5 g $\text{CuCl}_2$ (cupric chloride), 33 mL $\text{HCl}$ , 33 mL $\text{H}_2\text{O}$ <sup>(a)</sup>	Kalling's No. 1 reagent for martensitic stainless steels. Use at room temperature. Martensite dark, ferrite colored, austenite not attacked
<b>3</b> 5 g $\text{CuCl}_2$ , 100 mL $\text{HCl}$ , 100 mL ethanol	Kalling's No. 2 reagent. Use at room temperature. Ferrite attacked rapidly, austenite slightly attacked, carbides not attacked
<b>4</b> 5 g $\text{CuCl}_2$ , 40 mL $\text{HCl}$ , 30 mL $\text{H}_2\text{O}$ , 25 mL ethanol	Fry's reagent. For martensitic and precipitation-hardenable grades. Use at room temperature.
<b>5</b> 4 g $\text{CuSO}_4$ , 20 mL $\text{HCl}$ , 20 mL	Marble's reagent. Used primarily with austenitic grades. Use at room temperature to 10 s. Attacks

H <sub>2</sub> O	$\sigma$ phase
<b>6</b> 3 parts glycerol, 2-5 parts HCl, 1 part HNO <sub>3</sub>	Glyceregia. Popular etch for all stainless grades. Higher HCl content reduces pitting tendency. Use fresh, never stored. Discard when reagent is orange colored. Use with care under a hood. Add HNO <sub>3</sub> last. Immerse or swab few seconds to a minute. Attacks $\sigma$ phase, outlines carbides. Substitution of water for glycerol increases attack rate.
<b>7</b> 45 mL HCl, 15 mL HNO <sub>3</sub> , 20 mL methanol	Methanolic aqua regia. Used with austenitic grades to reveal grain structure, outline ferrite and $\sigma$ phase
<b>8</b> 15 mL HCl, 5 mL HNO <sub>3</sub> , 100 mL H <sub>2</sub> O	Dilute aqua regia for austenitic grades. Uniform etching of austenite, outlines carbides, $\sigma$ phase, and ferrite (sometimes attacked)
<b>9</b> 4 g KMnO <sub>4</sub> (potassium permanganate), 4 g NaOH, 100 mL H <sub>2</sub> O	Groesbeck's reagent. Use at 60-90 °C (140-195 °F) to 10 min. Colors carbides dark, $\sigma$ phase gray, ferrite and austenitic not affected
<b>10</b> 30 g KMnO <sub>4</sub> , 30 g NaOH, 100 mL H <sub>2</sub> O	Modified Groesbeck's reagent. Use at 90-100 °C (195-212 °F) for 20 s to 10 min to color ferrite dark in duplex alloys. Austenite not affected
<b>11</b> 10 g K <sub>3</sub> Fe(CN) <sub>6</sub> , 10 g KOH or 7 g NaOH, 100 mL H <sub>2</sub> O	Murakami's reagent. Use at room temperature to 60 s to reveal carbides; $\sigma$ phase faintly revealed by etching to 3 min. Use at 80 °C (176 °F) to boiling to 60 min to darken carbides. Sigma may be colored blue, ferrite yellow to yellow-brown, austenite not attacked. Use under a hood.
<b>12</b> 30 g KOH, 30 g K <sub>3</sub> Fe(CN) <sub>6</sub> , 100 mL H <sub>2</sub> O	Modified Murakami's reagent. Use at 95 °C (203 °F) for 5 s. Colors $\sigma$ phase reddish brown, ferrite dark gray, austenite unattacked, carbide black. Use under a hood.
<b>13</b> 10 g oxalic acid and 100 mL H <sub>2</sub> O	Popular electrolytic etch, 6 V dc, 25 mm spacing. 15-30 s reveals carbides; grain boundaries revealed after 45-60 s; $\sigma$ phase outlined after 6 s. Lower voltages (1-3 V dc) can be used. Dissolves carbides. Sigma strongly attacked, austenite moderately attacked, ferrite not attacked
<b>14</b> 10 g NaCN (sodium cyanide) and 100 mL H <sub>2</sub> O	Electrolytic etch at 6 V dc, 25 mm spacing, 5 min, platinum cathode. Sigma darkened, carbides light, ferrite outlined, austenite not attacked. Good for revealing carbides. Use with care under a hood.
<b>15</b> 10 mL HCl and 90 mL methanol	Electrolytic etch at 1.5 V dc, 20 °C (70 °F) to attack $\sigma$ phase. Use at 6 V dc for 3-5 s to reveal structure.
<b>16</b> 60 mL HNO <sub>3</sub> and 40 mL H <sub>2</sub> O	Electrolytic etch to reveal austenite grain boundaries (but not twins) in austenitic grades. With stainless steel cathode, use at 1.1 V dc, 0.075-0.14 A/cm <sup>2</sup> (0.48-0.90 A/in. <sup>2</sup> ), 120 s. With platinum cathode, use at 0.4 V dc, 0.055-0.066 A/cm <sup>2</sup> (0.35-0.43 A/in. <sup>2</sup> ), 45 s. Will reveal prior-austenite grain boundaries in solution-treated (but not aged) martensitic precipitation-hardenable alloys
<b>17</b> 50 g NaOH and 100 mL H <sub>2</sub> O	Electrolytic etch at 2-6 V dc, 5-10 s to reveal $\sigma$ phase in austenitic grades.
<b>18</b> 56 g KOH and 100 mL H <sub>2</sub> O	Electrolytic etch at 1.5-3 V dc for 3 s to reveal $\sigma$ phase (red-brown) and ferrite (bluish). Chi colored same as sigma
<b>19</b> 20 g NaOH and 100 mL H <sub>2</sub> O	Electrolytic each at 20 V dc, for 5-20 s to outline and color $\delta$ -ferrite tan.
<b>20</b> NH <sub>4</sub> OH (conc)	Electrolytic etch at 1.5-6 V dc for 10-60 s. Very selective. At 1.5 V, carbide completely etched in 40 s; sigma unaffected after 180 s. At 6 V, $\sigma$ phase etched after 40 s
<b>21</b> 10 g (NH <sub>4</sub> ) <sub>2</sub> S <sub>2</sub> O <sub>8</sub> and 100 mL H <sub>2</sub> O	Use at 6 V for 10 s to color carbide dark brown
<b>22</b> 200 mL HCl and 1000 mL H <sub>2</sub> O	Beraha's tint etch for austenitic, duplex, and precipitation-hardenable grades. Add 0.5-1.0 g K <sub>2</sub> S <sub>2</sub> O <sub>5</sub> per 100 mL of solution (if etching is too rapid, use a 10% aqueous HCl solution). Immerse at room temperature (never swab) for 30-120 s until surface is reddish. Austenitic colored, carbides not colored. Longer immersion colors ferrite lightly. If coloration is inadequate, add 24 g NH <sub>4</sub> F·HF (ammonium bifluoride) to stock reagent at left.
<b>23</b> 20 g picric acid and 100 mL HCl	Etch by immersion. Develops grain boundaries in austenite and $\delta$ -ferrite in duplex alloys
<b>24</b> Saturated aqueous Ba(OH) <sub>2</sub> (barium hydroxide)	Attacks carbides well before $\sigma$ phase in austenitic grades when used at 1.5 V dc, but attacks both equally when used at 3-6 V dc. Has been used to differentiate $\chi$ phase and Laves phase (use at 4.3 V dc, platinum cathode, 20 s). Chi is stained mottled-purple, Laves is not colored, ferrite is stained tan
<b>25</b> 50 mL each H <sub>2</sub> O, ethanol, methanol, and HCl; plus 1 g CuCl <sub>2</sub> , 3.5 g FeCl <sub>3</sub> , 2.5 mL HNO <sub>3</sub>	Ralph's reagent. Use by swabbing. Can be stored. General purpose etch for most stainless steels. Does not attack sulfides in free-machining grades

(a)

When water is specified, use distilled water.

## Technique for Stainless Steel Casting Alloys

STAINLESS STEEL CASTING ALLOYS referred to in this section are widely used to resist corrosion by aqueous solutions at or near room temperature and by hot gases and high-boiling-point liquids at temperatures up to 650 °C (1200 °F). All these alloys, which are identified in the United States by ACI designations, contain more than 11% Cr and up to 30% Ni.

**Microstructures** of stainless steel casting alloys generally are similar to those of their wrought counterparts, except that the segregation inherent in the casting process is not altered. Hence, the microstructures usually are coarser and more diverse, and porosity or shrinkage cavities may be observed.

**Grinding and Polishing.** The techniques and equipment used for mounting, grinding, and polishing specimens of stainless steel casting alloys for metallographic examination are essentially the same as those used for wrought stainless steels. Coarse and fine grinding, by the traditional method, require the successive use of increasingly finer abrasive papers. Coarse grinding is generally done on SiC papers with grit sizes of 80, 100, or 120 grit (depending upon the roughness and depth of damage of the cut surface), and it is followed by fine grinding on papers with grit sizes of 240, 320, 400, and 600 grit. Coarse grinding can be avoided if the surface being prepared is properly sectioned using an abrasive cutoff wheel. Rough polishing entails the successive use of rotating disks covered with napless cloth impregnated with diamond abrasive with particle sizes of 9, 6, 3, and 1  $\mu\text{m}$  (two of these steps are sufficient). Rotating wheels covered with medium-nap cloths and slurries of alumina of 0.3 and 0.05  $\mu\text{m}$  particle size are used for fine polishing. Alternatively, colloidal silica or acidic alumina may be used as the final abrasive.

Cast stainless steel specimens may also be prepared using the contemporary preparation procedure described previously. This type of practice is more efficient, and, when napless and low-nap cloths are used, surfaces are produced that accurately reflect the amount of porosity and reveal the structure with proper relief control.

**Etching.** Among the etchants used to delineate the microstructure of stainless steel casting alloys are those for which compositions are given in the upper part of Table 9. As shown in the lower part of Table 9, the alloys are etched to reveal general microstructure or to emphasize a microconstituent of major interest, such as ferrite or carbide. The presence of ferrite in the CF-type alloys is of practical significance, because small amounts of ferrite improve resistance to hot cracking.

**Table 9 Compositions and applications of etchants for stainless steel casting alloys**

Etchant No. and name	Composition
<b>1</b> Oxalic acid (electrolytic, 6 V)	10 g oxalic acid, 100 mL water
<b>2</b> Vilella's reagent	5 mL HCl, 1 g picric acid, 100 mL ethanol (95%) or methanol (95%)
<b>3</b> Kalling's reagent number 2	100 mL HCl, 5 g $\text{CuCl}_2$ , 100 mL ethanol (95%)
<b>4</b> Murakami's reagent (unheated)	1 to 4 g $\text{K}_3\text{Fe}(\text{CN})_6$ , 10 g KOH (or 7 g NaOH), 100 mL water
<b>5</b> Murakami's reagent (boiling)	Same composition as etchant 4, above, but heated to boiling temperature for use
<b>6</b> Chromic acid (electrolytic, 6V)	10 g $\text{CrO}_3$ , 100 mL water
<b>7</b> 10N potassium hydroxide (electrolytic, 6 V)	560 g KOH diluted with distilled water to a volume of 1000 mL
<b>8</b> HCl, $\text{HNO}_3$ , acetic acid	15 mL HCl, 10 mL $\text{HNO}_3$ , 10 mL acetic acid
<b>9</b> Acid ferric chloride	Saturated solution of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ in HCl (conc); add few drops $\text{HNO}_3$
<b>10</b> Glycergia	10 mL $\text{HNO}_3$ , 20 to 50 mL HCl, 30 mL glycerol
<b>11</b> Sodium cyanide (electrolytic, 6 V) (use with extreme care)	10 g NaCN, 90 mL water

Alloy	Normal heat treatment	Etchants for revealing:

## Technique for Fe-Cr-Ni Heat-Resistant Casting Alloys

THE ALLOYS DISCUSSED in this section are iron-base and nickel-base heat-resistant casting alloys containing enough chromium to confer oxidation resistance.

**Microstructures.** Alloy HA and sometimes, depending on specific composition, alloy HB are hardened by the transformation of austenite during quenching. Thus, austenite transformation products, such as bainite and martensite, may appear in their microstructures. Also, depending on specific composition, the HB and HC alloys may have a matrix of ferrite or austenite, or a mixture of ferrite and austenite; the austenite may be unstable and transform, at least partly, on cooling to room temperature.

Except for the nickel-free alloy HA and low-nickel alloys HB and HC, the matrix of the alloys in the series is austenite. Other microconstituents usually observed are ferrite, several types of chromium carbide, sigma phase, inclusions, and oxides. The HD and HE alloys are intended to be partly ferritic; the presence of ferrite results in lower creep resistance and higher ductility at temperatures of 870 to 1150 °C (1600 to 2100 °F) than for the wholly austenitic alloys. Alloys HD and HE are also more susceptible to the development of the undesirable sigma phase if exposed to temperatures in the range of 650 to 870 °C (1200 to 1600 °F). The HF, HH, HI, HK, and HL alloys are borderline; they can be partly ferritic and partly austenitic or wholly austenitic, depending on composition. As usually supplied, the HI and HK alloys seldom show ferrite. The HN, HP, HT, HU, HW, and HX alloys are wholly austenitic; neither ferrite nor sigma phase is likely to be present.

**Mounting, Grinding, and Polishing.** The techniques and equipment used for mounting, grinding, and polishing specimens of Fe-Cr-Ni heat-resistant casting alloys for metallographic examination are essentially the same as those used for wrought and cast stainless steels.

**Etching.** The etchants used for the Fe-Cr-Ni alloys are given in Table 10. They fall into three categories: delineating etchants (usually acid), which provide contrast and reveal general structure; staining or film-forming etchants (alkaline); and solutions for electrolytic etching.

**Table 10 Etchants for microscopic examination of Fe-Cr-Ni heat-resistant casting alloys**

Common name	Composition	Remarks on use
Etchants for delineating general structure		
<b>Aqua regia</b>	20 mL HNO <sub>3</sub> , 60 mL HCl	Immerse specimen
<b>Glyceregia</b>	10 mL HNO <sub>3</sub> , 20-50 mL HCl, 30 mL glycerol	Immerse specimen; use a hood.
<b>Hydrochloric acid (50%)</b>	50 mL HCl, 50 mL water	Outlines ferrite; immerse specimen
<b>Marble's reagent</b>	10 g CuSO <sub>4</sub> , 50 mL HCl, 50 mL water	Immerse specimen
<b>Vilella's reagent</b>	1 g picric acid, 5 mL HCl, 100 mL ethanol	Immerse specimen
Etchants for staining or film-forming		
<b>Alkaline hydrogen peroxide</b>	25 mL NH <sub>4</sub> OH, 50 mL H <sub>2</sub> O <sub>2</sub> (3%), 25 mL water	Ordinarily used after a delineating etchant; immerse specimen
<b>Alkaline potassium ferricyanide</b>	10 g K <sub>3</sub> Fe(CN) <sub>6</sub> , 10 g NaOH, 100 mL water	Same as above
<b>Alkaline potassium permanganate</b>	4 g NaOH, 10 g KMnO <sub>4</sub> , 85 mL water	Same as above
<b>Alkaline sodium picrate</b>	2 g picric acid, 25 g NaOH, 100 mL water	Same as above
<b>Emmanuel's reagent</b>	30 g K <sub>3</sub> Fe(CN) <sub>6</sub> , 30 g KOH, 60 mL water	Attacks sigma phase with little or no effect on carbide particles; immerse specimen
<b>Murakami's reagent</b>	10 g K <sub>3</sub> Fe(CN) <sub>6</sub> , 10 g KOH, 100 mL water	Stains carbide particles without staining sigma phase <sup>(a)</sup> ; immerse specimen
Solutions for electrolytic etching		
<b>Ammonium hydroxide</b>	Concentrated NH <sub>4</sub> OH	Final electrolytic etch after etching in Vilella's reagent and in 10N KOH (electrolytic)
<b>Cadmium acetate</b>	10 g cadmium acetate, 100 mL water	Attacks (Cr,Fe) <sub>23</sub> C <sub>6</sub> carbide particles
<b>Chromic acid</b>	2-10 g Cr <sub>2</sub> O <sub>3</sub> , 100 mL water	Outlines carbide particles; extracts sigma phase
<b>Lead acetate (2N)</b>	38 g Pb(C <sub>2</sub> H <sub>3</sub> O <sub>2</sub> ) <sub>2</sub> ·3H <sub>2</sub> O, distilled water to make 100 mL	Stains austenite, then sigma phase, then carbide particles; 1.5 V for 30 s
<b>Oxalic acid</b>	10 g oxalic acid, 100 mL water	Outlines carbide and sigma; 6 V, 1 to 5 s
<b>Potassium hydroxide (1N)</b>	5.6 g KOH, 100 mL water	Blackens sigma phase without outlining other phases; 1.5 V for 1 s
<b>Potassium hydroxide (10N)</b>	56 g KOH, 100 mL water	Intermediate etch between Vilella's and ammonium hydroxide (electrolytic)
<b>Sodium cyanide</b>	10 g NaCN, 100 mL water	Used after glyceregia; outlines carbide particles, stains sigma phase; use at 0.15 A/cm <sup>2</sup> (1 A/in. <sup>2</sup> ) for 1 to 5 s, under hood with extreme care

(a) Sometimes sigma phase is stained. Behavior must be established on a given composition.

**Delineating Etchants.** Glyceregia is the most widely used delineating etchant. Marble's reagent, "waterless" Kalling's reagent, and aqua regia (several modifications) are sometimes used but to a far lesser extent than glyceregia.

**Staining etchants** form films of reaction products on the surface of the specimen. The films exhibit color, the hue of which depends on the film thickness, which is controlled by etching time, temperature, and the etchant used. These etchants grow the films on certain second-phase constituents or on the matrix (film thickness may be a function of grain orientation, residual deformation, or composition/hardness differences). The etchants are generally aqueous solutions of potassium or sodium hydroxide with an oxidizing agent added. Picrates, potassium permanganate, hydrogen peroxide, and ferricyanides are used as oxidizing agents.

Murakami's reagent, which contains potassium hydroxide with potassium ferricyanide as the oxidizing agent, is a versatile staining etchant. By staining in different tints, it permits differentiation of several types of carbide and sigma phase. Murakami's reagent is used cold, warm, or boiling to obtain a variety of effects, but it must be used with discrimination. Because the response of the reagent indicates sensitivity to the composition of the phase being stained, a given constituent does not respond identically when it appears in alloys of different composition.

**Electrolytic etching**, when properly controlled, has the advantages of precision and reproducibility. Normally, the specimen to be etched is made the anode; the cathode usually is stainless steel, nickel, graphite, or platinum. The current

can be supplied by one or more dry-cell batteries or a rectified power supply. Current density ranges from less than 0.15 to more than 2.0 A/cm<sup>2</sup> (less than 1 to more than 13 A/in.<sup>2</sup>). Unmounted specimens are held with stainless steel tongs. If the specimen is mounted in a nonconducting material, the electrical connection can be conveniently made by means of a brass machine screw that contacts the underside of the specimen through a tapped hole. Or, the polished surface can be touched by a probe connected to the positive terminal.

# Typical Microstructures of Iron-Base Alloys

Edited by George F. Vander Voort, Buehler Ltd.

## Introduction

COMMONLY OBSERVED MICROSTRUCTURES in iron-base alloys (carbon and alloy steels, cast irons, tool steels, and stainless steels) occur as a result of variations in chemical analysis and processing. Comprehensive coverage of the microstructures of ferrous alloys is presented in *Metallography and Microstructures*, Vol 9, *ASM Handbook*.

A wide range of constituents (a phase or combination of two phases, in a specific configuration) are encountered in iron-base alloys. Single-phase constituents in iron-base alloys include austenite, ferrite, delta ferrite, cementite, various alloy carbides, graphite, martensite, and a variety of intermetallic phases, nitrides, and nonmetallic inclusions. Two-phase constituents include tempered martensite, pearlite, and bainite. Nonmetallic inclusions that consist of two or more phases can be present in steels. The nomenclature used to describe the constituents observed in steels has evolved over many years (see, for example, N.F. Kennon, Nomenclature in the Metallography of Steel, *J. Aust. Inst. Met.*, Vol 18 (No. 2), June 1973, p 57-73). The literature documents several names for the same constituent, which can lead to some confusion.

If only matrix phases are considered (i.e., if very small amounts of carbides, inclusions, or nitrides are ignored), the only single-phase ferrous metals or alloys are those consisting solely of ferrite, austenite, or martensite. Because as-quenched martensite is rather brittle, tempering is almost always performed before commercial utilization.

## Common Constituents in Ferrous Alloys

**Ferrite.** Fully ferritic steels are only obtained when the carbon content is quite low. Examples include electrolytic iron, certain sheet steels, Fe-Si electrical alloys, and ferritic stainless steel. The most obvious microstructural features in such metals are the ferrite grain boundaries (Fig. 1). Ferrite is a very soft, low-strength phase. If the ferrite grain size is quite fine, good ductility and formability are obtained. Ferritic stainless steels, due to their alloy content, are not nearly as ductile as ferritic sheet steel. Because ferrite has a body centered cubic (bcc) crystal structure, ferritic metals and alloys exhibit a transition from ductile to brittle behavior as the temperature decreases or as the strain rate increases.

**Fig. 1** Ferrite grains and grain boundaries in a low-carbon ferritic sheet steel etched with 2% nital. 100×

**Austenite.** Obtainment of fully austenitic steels requires careful balancing of chemical composition. In other words, rather large amounts of the austenite-stabilizing elements (carbon, nitrogen, nickel, and manganese) must be present compared with those elements that stabilize ferrite. Examples of fully austenitic ferrous alloys are austenitic stainless steels and austenitic manganese steel. Again, the most visible microstructural features of these single-phase alloys are the austenite grain boundaries. However, unlike ferritic structures, these alloys will also contain annealing twin boundaries in the wrought, solution-annealed condition (Fig. 2). Austenite is also a rather soft, low-strength phase; however, cold working produces substantial strengthening and, if extensive, may produce strain-induced martensite in some alloys. Due to their face centered cubic (fcc) crystal structures, austenitic alloys remain ductile irrespective of temperature or strain rate unless detrimental phase changes occur.

**Fig. 2** Examples of fully austenitic iron-base alloys in the solution-annealed condition. (a) AISI type 316 stainless steel. Etched with HCl/HNO<sub>3</sub>/H<sub>2</sub>O (equal parts). 100×. (b) Hadfield's manganese steel. Etched with 2% nital (3 s) and 20% Na<sub>2</sub>S<sub>2</sub>O<sub>5</sub> (20 s). 100×. (c) Fe-48%Ni alloy (annealed in H<sub>2</sub>). Etched with FeCl<sub>3</sub>/HCl/H<sub>2</sub>. 1×

**Cementite**, or iron carbide, contains 6.67% C (by weight), corresponding to the formula Fe<sub>3</sub>C. In carbon and alloy steels, some of the carbide-forming elements (e.g., manganese and chromium) will replace some of the iron in cementite. Hence, the formula for cementite is often referred to as M<sub>3</sub>C, where M stands for the carbide-forming elements present. Pure Fe<sub>3</sub>C is quite hard (about 800 HV) and brittle. Substitution of other elements (e.g., chromium) for some of the iron in cementite will increase the hardness appreciably. Because of the brittleness of cementite, only limited amounts are present in steels. No alloy consisting solely of cementite is produced commercially. The highest cementite contents are observed in white cast irons (Fig. 3), which are used in applications where high wear resistance is desired, and the brittle nature of such alloys is not a problem.

**Fig. 3** Massive cementite (white) in a white cast iron specimen with a pearlitic (dark) matrix. Etched with 4% picral. 500×

Addition of carbide forming elements will result in formation of alloy carbides of various compositions depending upon the amount of the element added. These alloy carbides are generally harder than cementite. Elements that promote formation of alloy carbides include Cr, Mo, V, W, Ti, and Nb.

**Graphite** is a very soft, brittle phase produced in certain steels and cast irons by adjustment of chemical composition. Because cementite is not a true equilibrium phase under conditions of long-time elevated-temperature exposure, the cementite in certain carbon and alloy steels will decompose. Several tool steels are deliberately designed to produce a small amount of graphite in the structure to enhance machinability (Fig. 4). The graphite in cast irons is produced in a variety of forms, such as flake, compacted, and spheroidal. Gray cast iron containing flake graphite is quite brittle; however, if the graphite is spheroidal, as in ductile iron, good ductility is achieved. Figure 5 illustrates flake and spheroidal graphite shapes. As with cementite, graphite is only present as a minor phase, even in cast irons.

**Fig. 4** Graphite in a spheroidize-annealed AISI type O6 graphitic tool steel specimen (transverse plane). The irregular black particles are graphite. The matrix is ferrite containing spheroidized cementite. Etched with 4% picral. 500×

**Fig. 5** Examples of two extremes in graphite shapes in cast irons. (Left) Flake graphite in gray iron. 100 $\times$ . (Right) Spheroidal graphite in ductile iron (viewed in polarized light). 500 $\times$

**Martensite** is not an equilibrium phase in steels. Formation of martensite is dependent upon chemical composition and cooling rate from the high-temperature austenite region. Unlike other austenite transformation products, martensite forms instantaneously once the specimen is cooled below a specific temperature, known as the martensite start ( $M_s$ ) temperature, which is a function of the carbon and alloy content of the parent austenite phase. The transformation is completed when the specimen reaches a lower temperature, the martensite finish temperature ( $M_f$ ). The hardness of martensite is governed primarily by carbon content but is also influenced slightly by alloy content. The ability to form martensite in a steel as a function of section size and quench rate depends on the hardenability of the steel. Hardenability is increased by increasing carbon and alloy contents and by enlargement of grain size. Coarsening of grain size to improve hardenability is rarely done with wrought steels because most mechanical properties are impaired.

The nature of martensite is influenced markedly by carbon content. Basically, two types of martensite can be formed in steels. At low carbon contents, lath martensite is formed. The laths are present in a packet arrangement where the individual laths within the packet have essentially the same orientation. At high carbon contents, plate martensite is formed. The plates form as individual lenticular crystals in a wide range of sizes. Many terms have been used to denote these two types of martensite, but lath and plate are the preferred terms. At intermediate carbon contents, mixtures of lath and plate martensite are obtained. Figure 6 illustrates the appearance of lath and plate martensite; the shape of the latter is best observed when only a small amount of martensite has been formed and when the grain size is coarse.

**Fig. 6** Examples of lath and plate martensite. Both heat treated at higher-than-normal temperature to reveal the martensite more clearly. Both etched with 2% nital. (Left) Lath martensite in low-carbon alloy steel. 500 $\times$ . (Right) Plate martensite (retained austenite matrix) in an Fe-1.4%C alloy. 200 $\times$

Because of the important influence of grain size on the properties of martensitic steels, much effort has been expended on refining the grain size of such steels. However, unlike ferritic and austenitic alloys, the critical grain size for martensitic steels is that of the parent austenite phase (i.e., the prior-austenite grain size). Delineation of the prior-austenite grain boundaries in martensitic steels by use of selective etchants is difficult but can often be achieved (Fig. 7). In general, the low-carbon martensitic steels are much more difficult to etch in this manner than medium- and high-carbon steels. In the case of lath martensite, the packet size has also been found to be an important microstructural measurement that correlates with toughness.

**Fig. 7** Prior-austenite grain boundaries revealed by etching a heat treated medium-carbon alloy steel. Etched with saturated aqueous picric acid plus a wetting agent. 100×

As the carbon content of martensite increases, its hardness and strength increase; however, it also becomes more brittle. Martensite has a body centered tetragonal (bct) structure. The degree of tetragonality increases with carbon content. Tempering decreases the strength of martensite and increases its toughness. However, tempering of alloy steels within certain temperature ranges can reduce toughness due to embrittlement problems (temper martensite embrittlement or temper embrittlement). However, the tempering process, along with composition selections, can permit achievement of a very wide range of useful strengths and toughness, a factor that makes tempered martensite the most commercially important constituent in steels.

Tempering is a complex process from a microstructural viewpoint. In commercial practice, tempering is conducted at temperatures from about 125 °C (255 °F) to values slightly below the lower critical temperature, depending on the alloy in question and the intended application. Tempering of carbon steels is simpler than tempering of alloy steels. In the case of carbon steels, four stages have been identified.

The first stage covers the range up to about 250 °C (480 °F), where the tetragonality of the bct lattice is lost and a transition carbide,  $\text{Fe}_{2.4}\text{C}$ , precipitates. This carbide is extremely small and cannot be resolved by light microscopy. In the second stage, generally in the range of about 200 to 300 °C (390 to 570 °F), retained austenite (when present) decomposes. In order for retained austenite to be resolvable by light microscopy, it must be present in amounts of at least 10 to 20%--a condition obtainable only in high-carbon steels. The third stage occurs in the range of about 200 to 350 °C (390 to 660 °F) and is characterized by formation of cementite. The fourth stage occurs between about 300 °C (570 °F) and the lower critical temperature and concerns the growth of cementite to sizes visible in a light microscope and production of equiaxed ferrite grains by recrystallization. Figure 8 shows these changes for a low-carbon alloy steel, and Fig. 9 shows a high-carbon alloy steel. Neither of these grades contains enough strong carbide formers to produce more complex alloy carbides. When substantial quantities of elements, such as chromium, molybdenum, vanadium, and tungsten are present, alloy carbides are formed in the region of about 500 to 600 °C (930 to 1110 °F) along with a modest increase in hardness, termed "secondary hardening."

**Fig. 8** Light microscopy and transmission electron microscopy (thin foil) views of AISI 8620 alloy steel after tempering at various temperatures. All specimens were water quenched from 900 °C (1650 °F) prior to tempering. Light microscopy: 2% nital, 500×; TEM: 25,000×

**Fig. 9** Light microscopy and transmission electron microscopy (thin foil) views of AISI 5160 alloy steel after tempering at various temperatures. All specimens were oil quenched from 803 °C (1525 °F) prior to tempering. Light microscopy: 2% nital, 500×; TEM: 25,000×

**Pearlite** is a mixture of ferrite and cementite where the two phases are formed from austenite in an alternating lamellar pattern. Formation of pearlite requires relatively slow cooling from the austenite region. Pearlite forms at temperatures close to the lower critical temperature of the steel in question and may be formed either isothermally or by continuous cooling. As the hardenability of the steel decreases, the cooling rate can be increased without forming other constituents.

As the isothermal reaction temperature decreases or the cooling rate increases, the interlamellar spacing decreases. The strength and toughness of pearlitic steels are increased as the interlamellar spacing decreases.

For rather slow cooling rates, the relative amounts of ferrite and pearlite in carbon steels can be estimated using the iron-carbon equilibrium diagram. Knowledge that the maximum solubility of carbon in ferrite is nearly zero and a fully pearlitic microstructure is obtained when a steel containing about 0.8% C is slowly cooled from the austenite region can be used to estimate the volume fractions of ferrite and pearlite.

Figure 10 demonstrates the influence of carbon content on the amounts of ferrite and pearlite in iron-carbon alloys containing 0.2, 0.4, 0.6, 0.8, and 1.0% C. The amount of pearlite in the Fe-0.2%C alloy is simply  $0.2/0.8$  or 25%, and the remainder of the structure (75%) is ferrite. In like manner, the amount of pearlite in the 0.4% C alloy is 50%, and the amount in the 0.6% C alloy is 75%.

**Fig. 10** Examples of pearlite formation in slowly cooled iron-carbon alloys as a function of carbon content. Etched with 4% picral. 500×

In these alloys, the ferrite forms prior to the eutectoid reaction (which produces the pearlite) and is termed "proeutectoid ferrite." Below about 0.4% C, the proeutectoid ferrite forms as equiaxed patches and is the continuous phase. Above about 0.4% C, the proeutectoid ferrite generally exists as isolated, equiaxed patches or as a grain-boundary layer.

Carbon steels are referred to as hypoeutectoid, eutectoid, or hypereutectoid when carbon contents are below 0.8%, about 0.8% or above 0.8%, respectively. In the case of hypereutectoid steels, such as the Fe-1%C alloy (Fig. 10), excess cementite above the amount required to form pearlite will precipitate in the austenite grain boundaries prior to the eutectoid reaction. This excess cementite is referred to as "proeutectoid cementite." A grain-boundary cementite network renders such steels quite brittle.

The strength and hardness of ferrite-pearlite steels increase with increasing pearlite content and are further increased by reductions in the interlamellar spacing. Pure ferrite (no carbon) has a hardness of about 70 HV, whereas very fine pearlite in a eutectoid carbon steel has a hardness of nearly 400 HV. Fine pearlite is the most desirable structure for wire drawing, where extremely high strengths can be obtained. Figure 11 shows the microstructures of cold drawn low-carbon and high-carbon wire (longitudinal views).

**Fig. 11** Examples of cold worked carbon steel microstructures (longitudinal planes; etched with 2% nital). (a) AISI 1008, 500 $\times$ . (b) AISI 1020, 1000 $\times$ . (c) AISI 1080, 500 $\times$

Carbon steels are widely utilized in the hot-rolled condition. The austenite grain size of the steel as it enters the final rolling pass establishes the relative sizes of the ferrite and pearlite produced during subsequent air cooling. On the other hand, the cooling rate influences the fineness of the pearlite, the morphology of the proeutectoid ferrite, and the amounts of the various constituents. Figure 12 shows the influence of austenite grain size on the sizes, shapes, and amounts of ferrite and pearlite, where an AISI 1040 carbon steel has been air cooled from 900, 980, and 1095  $^{\circ}\text{C}$  (1650, 1800, and 2000  $^{\circ}\text{F}$ ).

**Fig. 12** The influence of austenitizing temperature on the amount, size, and fineness of the transformation products, ferrite and pearlite, of normalized AISI 1040 carbon steel. (Left) Austenitized at 900  $^{\circ}\text{C}$  (1650  $^{\circ}\text{F}$ ), air cooled. (Center) Austenitized at 980  $^{\circ}\text{C}$  (1800  $^{\circ}\text{F}$ ), air cooled. (Right) Austenitized at 1095  $^{\circ}\text{C}$  (2000  $^{\circ}\text{F}$ ), air

cooled. All etched with 4% picral. 200×

To obtain maximum ductility and formability, carbon steels may be subjected to a special annealing treatment that spheroidizes the cementite. This treatment is commonly used on tool steels to improve their machinability. To best observe the spheroids of cementite, specimens of steels so treated should be etched with 4% picral, which reveals the ferrite/carbide interfaces but not the ferrite grain boundaries. Figure 13 illustrates this problem of structure visibility using a spheroidized low-carbon steel. Etching with 2% nital obscures the spheroidized cementite. As the carbon content increases, the volume fraction of cementite increases. Figure 14 shows the microstructure of spheroidized AISI W2 (1.1% C) tool steel.

**Fig. 13** Influence of etchant upon the ability to observe spheroidized cementite in AISI 1008 sheet steel. (Left) Etched with 4% picral. (Right) Etched with 2% nital. 500×

**Fig. 14** Spheroidized cementite in AISI W2 carbon-vanadium (1.10% C) tool steel. Etched with 4% picral.

1000×

**Bainite**, an austenite transformation product, is a lathlike aggregate of ferrite and cementite that forms under conditions intermediate to those that result in formation of pearlite and martensite. Bainite is commonly classified as either upper bainite or lower bainite. Upper bainite forms either isothermally or during continuous cooling at temperatures just below those that produce pearlite. Lower bainite forms at still lower temperatures, down to the  $M_s$  temperature, or slightly below in certain cases.

Formation of upper bainite (Fig. 15) begins by growth of long ferrite laths that are devoid of carbon. Because the carbon content of the ferrite laths is very low, the austenite at the lath boundaries is enriched in carbon. The shape of the cementite formed at the lath boundaries varies with carbon content. In low-carbon steels, the cementite will precipitate as discontinuous stringers and isolated particles, whereas at higher carbon contents the stringers are more continuous. In some instances, carbide is not precipitated but is retained as austenite or transforms to plate martensite.

**Fig. 15** Upper bainite formed isothermally at 480 °C (900 °F) in AISI 4142 alloy steel. (Left) 845 °C; 480 °C for 30 s; water quenched. (Right) 845 °C; 480 °C for 2 h; water quenched. Both etched with 4% picral. 1000×

Lower bainite (Fig. 16) has a more acicular appearance compared with that of upper bainite. The ferrite plates are broader than those in upper bainite and are more similar in appearance to plate martensite. As with upper bainite, the appearance of lower bainite varies with carbon content. Lower bainite is characterized by formation of rodlike cementite or  $Fe_{2.4}C$  (depending on the transformation temperature or steel composition) within the ferrite plates.

**Fig. 16** Lower bainite formed isothermally at 370 °C (700 °F) in AISI 4142 alloy steel. (Left) 845 °C; 370 °C for 60 s; water quenched. (Right) 845 °C; 370 °C for 30 min; water quenched. Both etched with 4% picral. 1000×

**Nonmetallic inclusions** in steel are either indigenous or exogenous in origin. Indigenous inclusions form as a natural result of the decrease in solubility of oxygen or sulfur that occurs as the metal freezes. Exogenous inclusions are

introduced from external sources (e.g., slag or refractories) that enter the steel and become trapped during solidification. In most instances, these included phases are undesirable.

There are, however, two basic types of ferrous alloys that are deliberately made with additions of either exogenous or indigenous inclusions. Wrought iron (Fig. 17) is made by mixing together slag and relatively pure iron. In the hot worked condition, the slag becomes elongated, thus promoting considerable anisotropy. The toughness of wrought iron is very good if the crack is perpendicular to the fiber axis but very poor if it is parallel to the fiber axis. Free-machining steels are a classic example of the deliberate addition of indigenous inclusions, most commonly manganese sulfide, to enhance machinability. Figure 18 illustrates the appearance of MnS in a free-machining steel. Some free-machining steels are also given deliberate additions of either lead or bismuth. Both of these elements are virtually insoluble in solid steel and exist as small elemental globules often associated with the sulfides.

**Fig. 17** Microstructure of wrought iron (longitudinal plane). Etched with 2% nital. 50×

**Fig. 18** Manganese sulfide inclusions in wrought AISI 1214 free-machining carbon steel (longitudinal plane). 200×

Manganese sulfides precipitate in different forms depending primarily on the oxygen content of the steel. Very high oxygen contents (low carbon contents, no strong deoxidizers) promote formation of large, globular, isolated manganese sulfides referred to as type I sulfides. Type I sulfides generally are desirable in free-machining steels. Lower oxygen contents and moderate deoxidation, particularly by small amounts of aluminum, promote precipitation of sulfides in a fanlike or chainlike pattern at the grain boundaries; these sulfides are referred to as type II sulfides. Type II sulfides are most detrimental to toughness and ductility. Very low oxygen contents and strong deoxidation by aluminum promote formation of small, angular, dispersed sulfides, referred to as type III sulfides. These are less harmful to properties than are type II sulfides. Figure 19 illustrates these three classic sulfide forms, which are most easily observed in the as-cast

condition. Other more complex types of sulfides can be produced due to the addition of other elements that influence sulfide composition and the precipitation reaction (e.g., calcium and rare earth elements).

**Fig. 19** Examples of the three most common forms of manganese sulfides viewed in the as-cast condition. (Left) Type I; 250 $\times$ . (Center) Type II; 250 $\times$ . (Right) Type III; 1600 $\times$

## Examples of Complex Mixtures of Constituents

The micrographs previously presented show many of the more common complex mixtures of microstructures in ferrous alloys. There are a few others, however, that deserve mention. Figure 20, for example, shows the microstructure of a dual-phase sheet steel that was austenitized in the two-phase region and then slowly cooled. The white matrix phase is ferrite, the small outlined white particles are retained austenite, and the small dark patches are auto-tempered martensite (and a minor amount of retained austenite). A large nitride particle is also shown at the bottom of the field.

**Fig. 20** Microstructure of heat treated dual-phase low-carbon sheet steel. Etched with 20%  $\text{Na}_2\text{S}_2\text{O}_5$  in  $\text{H}_2\text{O}$ . 1000 $\times$

The higher alloy, high-carbon tool steels contain undissolved alloy carbides in a matrix of tempered martensite after commercial heat treatment. When properly heat treated, many of these alloys also contain small amounts of retained austenite, although such amounts are usually too low to be resolved by light microscopy, unless an excessively high austenitizing temperature was used by error. Figure 21 shows two such alloys: AISI D2 and M2 tool steels. Both were austenitized at the recommended temperatures and then tempered. The white outlined particles are the alloy carbides, also called primary carbides, and the matrix is tempered martensite plus a small amount of retained austenite not visible by light microscopy. Because these specimens were tempered at relatively low temperatures, the prior-austenite grain boundaries are visible after etching.

**Fig. 21** Microstructure of two common high-carbon, high-alloy tool steels in the heat treated condition. (Top) AISI D2 tool steel. Etched with 4% picral plus HCl. (Bottom) AISI M2 tool steel. Etched with 10% nital. 1000×

Stainless steels can also exhibit a wide range of complex structures that can be even more complex after long-time, high-temperature exposure (Fig. 22). AISI type 440C martensitic stainless steel contains undissolved alloy carbides in a high-carbon martensitic matrix (some retained austenite is also present but cannot be resolved by light microscopy). The AISI type 304 austenitic weld metal contains delta ferrite, which prevents hot cracking. The 17-4 PH (precipitation-hardening) stainless steel contains delta ferrite stringers in a low-carbon martensitic matrix. The duplex stainless steel (as cast and annealed) contains austenite in a ferritic matrix.

**Fig. 22** Examples of two-phase stainless steels with various microstructural combinations. (a) AISI 440C, annealed. Structure: ferrite and carbides. Vilella's reagent; 500 $\times$ . (b) 17-4 PH, solution annealed and aged. Structure: martensite and delta ferrite (white). Fry's reagent; 500 $\times$ . (c) Austenitic AISI 304, welded. Structure: delta ferrite and austenite (dark). Heat tinted; 500 $\times$ . (d) Duplex alloy, as cast and annealed. Structure: austenite and ferrite (dark). Tint etched; 200 $\times$

Various surface treatments can also be applied to ferrous alloys to produce considerable microstructural complexity at the treated surface. These processes can simply involve the application of sufficient heat to austenitize and subsequently harden the surface, as in flame hardening or induction hardening. Hardened surface layers may also be formed when low-hardenability carbon tool steels are water or brine quenched. The net result of these treatments is a martensitic surface layer and an unhardened core with a transition layer between them. The transition-layer microstructure may be more complex for flame- or induction-hardened specimens than for quenched carbon tool steels.

Other processes are also utilized that change the composition of the surface layer so as to develop unique combinations of properties, such as a strong and highly wear-resistant surface on a more-ductile, lower-strength core. The most common treatments used to produce these effects are carburizing, nitriding, and carbonitriding. These practices are usually applied to low- or medium-carbon steels. Figure 23 shows the carburized surface of a low-carbon steel. At the extreme surface, the carbon content is above the eutectoid carbon content and a grain-boundary cementite layer is observed. Beneath this zone, the structure is fully pearlitic. At still greater depths, the amount of pearlite decreases until the matrix is reached. This specimen was cooled slowly after carburizing. Before such a steel would be placed in service, it would be heat treated to form martensite in the carburized case.

**Fig. 23** Microstructures at the surface and core of carburized AISI 1020 carbon steel slowly cooled from the carburizing temperature. 2% nital; 200×

Nitriding is commonly performed on medium-carbon alloy steels that have been austenitized, quenched, and tempered between about 540 and 620 °C (1000 and 1150 °F). Nitriding is generally performed at temperatures slightly below this range for rather long times compared with those used for carburizing. Diffusion of nitrogen into the surface layer produces iron nitrides, which promote high surface hardness and beneficial residual compressive stresses. Figure 24 shows a nitrided specimen of AISI type 4150 steel on which a rather thick surface layer of undesirable, brittle iron nitride has formed.

**Fig. 24** Microstructure at the surface of a heavily nitrided AISI 4150 alloy steel that was heat treated prior to nitriding. Note the heavy iron nitride "white" layer and grain-boundary penetration at the surface. 4% picral, 200×

Decarburization due to improper control of the furnace atmosphere also produces a variation in surface microstructure. Figure 25(a) shows a partially decarburized surface layer on hot-rolled AISI type 9260 mod spring steel. The white layer at the surface is nickel plating (applied for edge protection). The gray layer beneath the nickel plating is scale. The decarburized surface contains a range of ferrite and pearlite, and the matrix is nearly all pearlite. The other two micrographs in Fig. 25 show decarburization on hardened AISI 5160H and 5160 mod spring steels. The view at the center shows a very minor loss of carbon on a bar whose surface was turned prior to heat treatment. No free ferrite is present. The structure at the surface is a mixture of bainite and martensite. Figure 25(c) shows a thick layer of free ferrite (total loss of carbon) with a columnar grain structure after heat treatment. Note the narrow zone beneath the free ferrite, where the structure changes gradually to all martensite.

**Fig. 25** Examples of different degrees of decarburization in spring steels. (a) Partial decarburization of as-rolled AISI 9260 mod spring steel that was nickel plated edge protection. (b) Partial decarburization of hardened AISI 5160H spring steel whose surface was turned prior to hardening (no protective atmosphere). (c) Complete decarburization of hardened AISI 5160 mod spring steel that was given no surface preparation prior to hardening (no protective atmosphere). All specimens etched with 2% nital. 200×

The examples in this article represent many of the microstructures commonly encountered in ferrous alloys. The natures of the structures present depend on the composition of the alloy and the manner of processing. To reveal these constituents clearly, the specimens must be properly prepared and etched with the reagent most appropriate for the constituents present.

# Metallographic Technique for Nonferrous Metals and Special-Purpose Alloys

Edited by George F. Vander Voort, Buehler Ltd.

## Technique for Aluminum Alloys

ALUMINUM ALLOYS encompass a wide range of chemical composition and, as a result, a fair range of hardness; consequently, there is considerable variation in the techniques required for metallographic preparation and examination. The softer alloys generally are more difficult to prepare by mechanical polishing, because deformation caused by cutting and grinding extends to a greater depth. Embedding of abrasive particles in the metal during polishing is more likely, and relief between the matrix and second-phase particles, which are much harder than the matrix, will develop more readily during polishing.

## Metallography on the Macroscopic Scale

The same principles of preparation for macroscopic examination apply to aluminum alloys as to metals in general.

**Chemical Preparation.** Removal of cutting oils and other greasy contaminants from aluminum surfaces before etching is a wise precaution but not always necessary. The caustic etch (etchant 1 in Table 1) is, in itself, an excellent degreaser. The acidic etchants are more likely than the caustic etch to act in an uneven manner if the surface is not precleaned. Table 1 lists a selection of etchants and etching methods that will accomplish all necessary tasks of preparing specimens for macroexamination. Table 2 indicates the etchants in Table 1 that are most applicable to various classes of alloys. If Table 1 presents a choice between caustic and mixed-acid etching, the selection should be based on the primary purpose of the examination.

**Table 1 Etchants for use in macroscopic examination of aluminum alloys**

See Table 2 for applicability to specific alloys.

Etchant	Composition (parts are by volume)	Procedure for use
<b>1 Caustic etch</b>	10 g NaOH to each 90 mL water	Immerse specimens 5 to 15 min in solution heated to 60 to 70 °C (140 to 160 °F) <sup>(a)</sup> , rinse in water, dip in 50% HNO <sub>3</sub> solution to desmut, rinse in water, dry.
<b>2 Tuckers's reagent</b>	45 parts HCl (conc), 15 parts HNO <sub>3</sub> (conc), 15 parts HF (48%), 25 parts water	Mix fresh before using. Immerse or swab specimen for 10 to 15 s, rinse in warm water, dry, and examine for desired effect. Repeat as much as necessary until desired effect is obtained.
<b>3</b>	1 part HF (48%), 9 parts water	Requires fairly smooth surface. Immerse until desired effect is obtained, hot-water rinse, dry.
<b>4 Poulton's reagent</b>	12 parts HCl (conc), 6 parts HNO <sub>3</sub> (conc), 1 part HF (48%), 1 part water	May be premixed and stored for long periods <sup>(b)</sup> . Etch by brief immersion or by swabbing. Rinse in cool water, and do not allow either the etchant or the specimen to heat up during etching.
<b>5</b>	50 parts HCl (conc), 15 parts HNO <sub>3</sub> (conc), 3 parts HF (48%), 5 parts FeCl <sub>3</sub> solution (conc)	Mix fresh before use. Cool solution to 10 to 15 °C (50 to 60 °F) with jacket of cold water. Immerse a few seconds, rinse in cold water; repeat until desired effect is obtained.

(a) This etchant may be used without being heated, but the etching action will be slower.

(b) Solution should be stored in a vented container, preferably under a fume hood, to prevent buildup of gas pressure. The container should be made of polyethylene or be lined with wax.

**Table 2 Applicability of etchants in Table 1 to macroexamination of aluminum alloys**

Alloy	Etchant
<b>High-purity aluminum</b>	4 or 5
<b>Commercial-purity aluminum: 1xxx series</b>	4, 2, or 1
<b>All high-copper alloys: 2xxx series and casting alloys</b>	1
<b>Al-Mn alloys: 3xxx series</b>	4, 2, or 1
<b>Al-Si alloys: 4xxx series and casting alloys<sup>(a)</sup></b>	4, 2, or 3
<b>Al-Mg alloys: 5xxx series and casting alloys</b>	4, 2, or 1
<b>Al-Mg-Si alloys: 6xxx series and casting alloys</b>	4, 2, or 1
<b>Al-Cu-Mg-Zn alloys: 7xxx series and casting alloys</b>	1

(a) Also, welds and brazed joints made with the use of these alloys as filler metals

## Metallurgy on the Microscopic Scale

The determination of the best procedure for microscopic examination is governed by the same considerations as in macroscopic examination, but the area that can conveniently be examined is usually more limited.

**Mounting** in a plastic medium to form a cylindrical piece is the generally accepted procedure, unless the specimen is of such dimensions that it can easily be hand held for subsequent grinding and polishing. In general, details given in the general section on mounting apply here as well. Special problems relating to choice of mounting method or material may have many causes:

- The inclusion of alloys of greatly dissimilar hardness in the same mount
- The need for preservation of flatness to the very edge
- The need to mount thin sheet specimens that must be polished in a plane perpendicular to the rolled surface
- The need for connecting electrical leads to one or more specimens for subsequent electropolishing or electrolytic etching

**Grinding and Rough Polishing.** Because aluminum and its alloys are relatively soft compared with many other metals, most abrasives are satisfactory for grinding, although SiC papers are most commonly used. In the traditional approach, grinding progresses through the standard sequence of grit sizes (i.e., 120, 240, 320, 400, and 600 grit). For control of relief, it is possible to use grinding paper with still finer grits. Rough polishing follows, using a napless or low-nap cloth for relief control or a medium-nap cloth if relief is not a problem. The most commonly used abrasive for rough polishing is 6  $\mu\text{m}$  diamond.

**Final Polishing.** Historically, the most commonly used final-polishing medium for aluminum alloys has been a pure grade of magnesium oxide powder, used on a medium-nap or short-nap cloth of uniform texture. The abrasive is rendered pastelike by applying about a teaspoonful near the center of the cloth and moistening it with distilled or deionized water, working it to a proper consistency with the finger. A low wheel speed, 50 to 80 rpm, is required for final polishing. High hand pressure and frequent rotation of the specimen are used for the first few minutes, and only enough water is added to avoid dryness and pulling of the specimen by the cloth. Gradually, pressure is relaxed and more water is added to wash away excess abrasive. Toward the end of the polish, copious quantities of water can be used to remove all abrasive, and the polishing cloth, in effect, serves to wipe the specimen clean. Residual abrasive may be removed by lightly applying a clean, wet cotton swab.

In recent years, high quality MgO has been difficult to obtain, and MgO always presents problems in its use. Basic colloidal silica polishing suspensions have been found to be highly effective for final polishing of aluminum and its alloys and have largely replaced use of magnesia abrasives.

**Etching for Microscopic Examination.** Microscopic examination of the polished specimen before etching is always advisable, because etching can obscure as well as reveal important details, such as incipient melting, fine cracks, and nonmetallic inclusions. Table 3 gives a selection of etchants that encompass all ordinary purposes of microscopic examination of commercial aluminum alloys. Table 4 describes these purposes and suggests etchants that are most likely to be successful on various classes of alloys. Often, it may be possible to apply a second etch directly over the first,

without repolishing, as dictated by experience. A general rule of thumb is that the etchants that reveal grain structure are the most aggressive and should be applied last.

**Table 3 Etchants for use in microscopic examination of aluminum alloys**

See Table 4 for applicability to specific alloys

Etchant	Composition	Procedure for use
<b>1 Hydrofluoric acid etch</b>	1 mL HF (48%), 200 mL water	Swab for 15 s, or immerse for 30 to 45 s
<b>2</b>	1 g NaOH, 100 mL water	Swab for 5 to 10 s
<b>3A Keller's reagent</b>	2 mL HF (48%), 3 mL HCl (conc), 5 mL HNO <sub>3</sub> (conc), 190 mL water	Immerse for 8 to 15 s, wash in stream of warm water, blow dry. Do not remove etching products from surface
<b>3B Dilute Keller's reagent</b>	20 mL etchant 3A, 80 mL water	Mix fresh before using. Immerse specimen for 5 to 10 s
<b>4 Modified Keller's reagent</b>	2 mL HF (48%), 3 mL HCl (conc), 20 mL HNO <sub>3</sub> (conc), 175 mL water	Immerse for 10 to 60 s, wash in stream of warm water, blow dry. Do not remove etching products from surface.
<b>5 Barker's reagent</b>	4 to 5 mL HBF <sub>4</sub> (48%), 200 mL water	Electrolytic: use Al, Pb, or stainless steel for cathode; specimen is anode. Anodize 40 to 80 s at about 0.2 A/cm <sup>2</sup> (about 20 V dc). Check results on microscope with crossed polarizers.
<b>6</b>	25 mL HNO <sub>3</sub> (conc), 75 mL water	Immerse at 70 °C (160 °F) for 45 to 60 s
<b>7</b>	20 mL H <sub>2</sub> SO <sub>4</sub> (conc), 80 mL water	Immerse at 70 °C (160 °F) for 30 s; rinse in cold water.
<b>8</b>	10 mL H <sub>3</sub> PO <sub>4</sub> (85%), 90 mL water	Immerse at 50 °C (120 °F) 1 min, or 3 to 5 min (see Table 4)
<b>9</b>	5 mL HF (48%), 10 mL H <sub>2</sub> SO <sub>4</sub> , 85 mL water	Immerse for 30 s
<b>10</b>	4 g KMnO <sub>4</sub> , 2 g Na <sub>2</sub> CO <sub>3</sub> , 94 mL water, few drops wetting agent	Specimen surface must be well polished, and be precleaned in 20% H <sub>3</sub> PO <sub>4</sub> at 95 °C (205 °F) for uniform wettability. After precleaning, rinse in cold water and immediately immerse in etchant for 30 s.
<b>11</b>	2 g NaOH, 5 g NaF, 93 mL water	Immerse for 2 to 3 min.
<b>12</b>	50 mL Poulton's reagent (etchant 4 in Table 1), 25 mL HNO <sub>3</sub> (conc), 40 mL of solution of 3 g chromic acid per 10 mL of water	Put a few drops on as-rolled or as-extruded surface for 1 to 4 min, rinse, and swab to desmut. Examine on microscope with crossed polarizers to show grains. Repeat etching, if necessary. For some 5xxx alloys, increase amount of HNO <sub>3</sub> in solution to 50 mL
<b>13</b>	8 mL HNO <sub>3</sub> (conc), 2 mL HCl (conc), 45 mL water, 45 mL methanol	Immerse for 10 s
<b>14</b>	5 mL acetic acid (glacial), 1 mL HNO <sub>3</sub> (conc), 94 mL water	Immerse for 20 to 30 min.

**Table 4 Applicability of etchants in Table 3 to microscopic examination of aluminum alloys**

Alloy	Etchant	Evidence revealed
Examination for grain size and shape		
<b>1xxx, 3xxx, 5xxx, 6xxx series; most casting alloys</b>	5 or 12	Grain contrast when using crossed polarizers, with or without sensitive tint
<b>2xxx, 7xxx series; Al-Cu or Al-Zn casting alloys</b>	3A or 11	Grain contrast or grain-boundary lines
<b>5xxx series alloys with more than 3% Mg</b>	8 (3-5 min)	Precipitation in grain boundaries
Examination for cold working		
<b>1xxx, 3xxx, 5xxx, 6xxx series alloys</b>	5 or 12	Deformation bands or markings that cause streaked effect when using crossed polarizers
<b>2xxx, 7xxx series alloys</b>	3A or 11	Deformation bands or markings that accompany relatively great amounts of cold working
<b>5xxx series alloys with more than 3% Mg</b>	8 (3-5 min)	Precipitation in bands of slip
Examination for incomplete recrystallization		
<b>1xxx, 3xxx, 5xxx, 6xxx series alloys</b>	5 or 12	Even-toned, well-outlined grains that are recrystallized, otherwise streaked, or banded
<b>2xxx series alloys, hot worked and heat treated</b>	3A or 11	Unrecrystallized grains made up of multiple, very fine subgrains
<b>6xxx series alloys, hot worked and heat treated</b>	9	Unrecrystallized grains made up of multiple, very fine subgrains
<b>7xxx series alloys, hot worked and heat treated</b>	8 (3-5 min) or 14	Unrecrystallized grains made up of multiple, very fine subgrains

Examination for preferred orientation		
<b>1xxx, 3xxx, 5xxx, 6xxx series alloys</b>	5 or 12	Predominance of certain gray tones when crossed polarizers are used, lack of randomness
<b>2xxx series alloys in T4 temper</b>	3A or 11	Lack of randomness in grain contrast
Examination for overheating (partial melting)		
<b>2xxx series alloys</b>	8 (1 min)	Rosettes and grain-boundary eutectic
<b>6xxx series alloys</b>	2	Grain-boundary eutectic formations
<b>7xxx alloys</b>	3B	Rosettes and grain-boundary eutectic formations
Examination for general constituent size and distribution		
<b>All wrought alloys and casting alloys</b>	1, 8 (1 min) or any etchant that does not pit solid-solution matrix	Coarse insoluble particles and fine precipitate particles. Longer etching time exaggerates size of fine particles.
Examination for distinction between solution heat treated (T4) and artificially aged (T6) tempers		
<b>2xxx series alloys</b>	3A or 11	Loss of grain contrast, general darkening, in T6 compared with T4
<b>6061</b>	9	Clear outlining of grain boundaries in T6; faint outlining in T4
<b>7075, recrystallized</b>	4	More grain contrast, sharper grain-boundary outlining, in T4
Examination for over-aging or poor quenching of solution heat treated alloy		
<b>2017 and 2024, in T4 temper</b>	6	Faint dark precipitate at grain boundaries
Examination for cladding thickness		
<b>Alclad 2014, 2024, 7075</b>	3A or 11	Boundary between high grain contrast or outlining of alloy core and lighter-etching cladding
<b>Brazing sheet</b>	1 (swab) or 13	Boundary of high-silicon cladding alloy
<b>Other clad alloys</b>	1 (immerse), 2, 3A, 5, or 11	Any differences in structure that demarcate one layer from another
Examination for solid-solution coring or segregation, and diffusion effects		
<b>3xxx, 5xxx series; Al-Mg casting alloys</b>	10	Interference colors due to differences in thickness of tarnish films laid down on the surface
<b>2xxx series alloys and others with more than 1% Cu</b>	3A or 11	Brownish-colored films due to redeposition of copper

## Technique for Copper and Copper Alloys

PREPARATION OF SPECIMENS of wrought and cast copper and copper alloys for macroexamination and microexamination is subject to the same general rules and recommendations as those that apply to preparation of specimens of other metals.

## Technique for Macroexamination

Specimens for macroscopic examination are extracted from larger masses using common cutting techniques.

**Surface preparation** for macroetching usually can be obtained in two machining operations. In the first operation, a heavy cut is taken to remove the metal that was cold worked during sectioning; in the second operation, a light cut is taken using a V-shaped tool, or the specimen is ground to remove the remaining effects of cold work.

**Etching.** Deep etching removes the effects of cold work but produces a rough surface, and so it is common practice to deep etch the machined or rough-ground surface, regrind it lightly, and then give it a light etch. Selection of an etchant for a macrospecimen depends mainly on the alloy to be etched and the features to be examined. Frequently, the capabilities of two or more etchants overlap (or are the same), so that selection of a specific etchant is arbitrary. Table 5 gives compositions of the more commonly used macroetchants, along with etching procedures, purposes of the etchants or characteristics revealed, and alloys for which they are ordinarily used.

**Table 5 Etchants for macroscopic examination of coppers and copper alloys**

Procedure for use: immerse at room temperature, rinse in warm water, dry

Composition of etchant	Copper or copper alloy	Purpose, or characteristic revealed
<b>50 mL HNO<sub>3</sub>, 0.5 g AgNO<sub>3</sub>, 50 mL water</b>	All coppers and copper alloys	Produces a brilliant, deep etch
<b>10 mL HNO<sub>3</sub>, 90 mL water</b>	Coppers and all brasses	Grains; cracks and other defects
<b>50 mL HNO<sub>3</sub>, 50 mL water<sup>(a)</sup></b>	Coppers, all brasses, aluminum bronze <sup>(b)</sup>	Same as above; reveals grain contrast
<b>30 mL HCl, 10 mL FeCl<sub>3</sub>, 120 mL water or methanol</b>	Coppers and all brasses	Same as etchant above <sup>(c)</sup>
<b>20 mL acetic acid, 10 mL 5% CrO<sub>3</sub>, 5 mL 10% FeCl<sub>3</sub>, 100 mL water<sup>(d)</sup></b>	All brasses	Produces a brilliant, deep etch
<b>2 g K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>, 4 mL saturated solution of NaCl, 8 mL H<sub>2</sub>SO<sub>4</sub>, 100 mL water<sup>(e)</sup></b>	Coppers, high-Cu alloys, phosphor bronze	Grain boundaries, oxide inclusions
<b>40 g CrO<sub>3</sub>, 7.5 g NH<sub>4</sub>Cl, 50 mL HNO<sub>3</sub>, 8 mL H<sub>2</sub>SO<sub>4</sub>, 100 mL water</b>	Silicon brass, silicon bronze	General macrostructure

- (a) Solution should be agitated during etching, to prevent pitting of some alloys.
- (b) Aluminum bronzes may form smut, which can be removed by brief immersion in concentration HNO<sub>3</sub>.
- (c) Excellent for grain contrast.
- (d) Amount of water can be varied as desired.
- (e) Immerse specimen for 15 to 30 min, then swab with fresh solution.

## Technique for Microexamination

Specimens of copper and copper alloys for microscopic examination are extracted from larger masses by sawing, shearing, filing, hollow boring, or abrasive-wheel cutting.

**Mounting.** In general, the practice used for mounting copper and copper alloy specimens is the same as for mounting specimens of other metals.

**Grinding.** Wet grinding is preferred for all coppers and copper alloys. In the traditional approach, the practice is first to rough grind the specimen surface so as to remove metal that has been cold worked, then finish grind to obtain a suitable surface. Finish grinding is done on flat wheels using silicon carbide papers of progressively finer grit sizes, usually 240, 320, 400, and 600 mesh.

**Rough Polishing.** Most copper and copper alloys are relatively soft and thus require a polishing medium that provides maximum cutting action with minimum rubbing. Rough polishing should be done on diamond-impregnated nylon cloth. Duck, canvas, wool broadcloth, and cotton (listed in order of decreasing preference) are also used for polishing.

Although diamond paste is more expensive than other coarse abrasives, it is preferred by metallographers because it provides faster and more effective polishing. Diamond paste of 3 to 9  $\mu\text{m}$  size is the preferred abrasive for rough polishing on any of the cloths mentioned above. A wheel speed of about 150 to 300 rpm is generally recommended.

**Finish Polishing.** Generally, napped cloths are preferred for finish polishing. Abrasive is usually 0.3  $\mu\text{m}$  alpha alumina or 0.05  $\mu\text{m}$  gamma alumina; both abrasives are used with water as a vehicle. Other abrasives that have proved satisfactory for finish polishing are magnesium oxide in distilled water and colloidal silica. A wheel speed of 150 to 300 rpm is recommended.

There are numerous opinions on how the specimen should be rotated during polishing. In hand polishing, the specimen generally is rotated in a direction opposite the wheel rotation while moving from edge to center. After polishing, the specimen is rinsed in water and dried with warm air. Automatic polishing (usually vibratory) has proved highly successful for polishing copper and its alloys. In automatic polishing, human variables are greatly minimized. Attack polishing (combined polishing and etching) with 1% ferric nitrate or with ammonium hydroxide-ammonium persulfate (Table 6) can be more safely done with automatic equipment than by hand.

**Table 6 Etchants and procedures for microetching of coppers and copper alloys**

Etchant composition <sup>(a)</sup>	Procedure	Copper or copper alloy
<b>20 mL NH<sub>4</sub>OH, 0 to 20 mL water, 8 to 20 mL H<sub>2</sub>O<sub>2</sub> (3%)</b>	Immersion or swabbing for 1 min. (H <sub>2</sub> O <sub>2</sub> content varies with copper content of alloy to be etched; use fresh H <sub>2</sub> O <sub>2</sub> for best results.) <sup>(b)</sup>	Coppers and copper alloys. Film on etched aluminum bronze can be removed with weak Grard's solution.
<b>1g Fe(NO<sub>3</sub>)<sub>3</sub> 100 mL water</b>	Add dropwise to the cloth during polishing with an abrasive, such as alumina.	Attack polishing of coppers and copper alloys
<b>25 mL NH<sub>4</sub>OH, 25 mL water, 50 mL (NH<sub>4</sub>)<sub>2</sub>S<sub>2</sub>O<sub>8</sub> (2.5%)</b>	Add dropwise to the cloth during polishing with an abrasive, such as alumina.	Attack polishing of coppers and some copper alloys
<b>2 g K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>, 8 mL H<sub>2</sub>SO<sub>4</sub>, 4 mL NaCl (saturated solution), 100 mL water</b>	Immersion. (NaCl replaceable by 1 drop HCl per 25 mL solution; add just before using.) Follow with FeCl <sub>3</sub> or other contrast etch.	Coppers; copper alloys of beryllium, manganese, and silicon; nickel silver; bronzes; chromium copper
<b>CrO<sub>3</sub> (saturated aqueous solution)</b>	Immersion or swabbing	Coppers, brasses, bronzes, nickel silver
<b>50 mL CrO<sub>3</sub> (10 to 15%), 1 to 2 drops HCl</b>	Immersion (add HCl at time of use)	Same as above. Color by electrolytic etching or with FeCl <sub>3</sub> etchants.
<b>10 g (NH<sub>4</sub>)<sub>2</sub>S<sub>2</sub>O<sub>8</sub>, 90 mL water</b>	Immersion (use either cold or boiling)	Coppers, brasses, bronzes, nickel silver, aluminum bronze
<b>10% aqueous solution of copper ammonium chloride plus ammonium hydroxide to neutrality or alkalinity</b>	Immersion. Wash specimen thoroughly.	Coppers, brasses, nickel silver; darkening large areas of beta in alpha-beta brass
<b>FeCl<sub>3</sub>, g      HCl, mL      Water, mL</b>	Immersion or swabbing. Etch lightly or by successive light etches to required results	Coppers, brasses, bronzes, aluminum bronze; darkens beta in brass: gives contrast following dichromate and other etches
<b>5                      50                      100</b>		
<b>20                      5                      100<sup>(c)</sup></b>		
<b>25                      25                      100</b>		
<b>1                      20                      100</b>		
<b>8                      25                      100</b>		
<b>5                      10                      100<sup>(d)</sup></b>		
<b>5 g FeCl<sub>3</sub>, 100 mL ethanol, 5 to 30 mL HCl</b>	Immersion or swabbing for 1 s to several minutes.	Coppers and copper alloys
<b>Nitric acid (various concentrations)</b>	Immersion or swabbing. AgNO <sub>3</sub> (0.15 to 0.3%) added to 1:1 solution gives a brilliant, deep etch.	Coppers and copper alloys
<b>Ammonium hydroxide (dilute solutions)</b>	Add dropwise to the cloth during polishing with an abrasive	Attack polishing of brasses and bronzes
<b>50 mL HNO<sub>3</sub>, 20 g CrO<sub>3</sub>, 30 mL water</b>	Immersion	Aluminum bronze, free-cutting brass. Film from polishing can be removed with 10% HF.
<b>5 mL HNO<sub>3</sub>, 20 g CrO<sub>3</sub>, 75 mL water</b>	Immersion	Same as above
<b>50 mL cold saturated solution of sodium thiosulfate, 1 g potassium metabisulfite</b>	Lightly pre-etch specimen with 10% aqueous ammonium persulfate. Immerse in solution until surface is colored. Gently agitate.	Tint etch for many copper and copper alloys. Produces brilliant colors. Colors beta more rapidly than alpha. Can be stored and used over.
<b>5 g ferric nitrate, 25 mL HCl, 70 mL water</b>	Immersion solution for 10 to 30 s	Excellent general-purpose etchant for coppers and copper alloys. Good grain-boundary etchant.
<b>3 g ammonium persulfate, 1 mL ammonium hydroxide, 100 mL water</b>	Swab for 5 to 20 s	Excellent etchant for coppers and copper alloys, particularly beryllium copper. Reveals grain boundaries in solution-annealed specimens.

(a) The use of concentrated etchants is intended unless otherwise specified.

(b) May be alternated with FeCl<sub>3</sub>.

(c) Grard's No. 1 etchant. Plus 1 g CrO<sub>2</sub>.

(d) Grard's No. 2 etchant. Plus 1 g CuCl<sub>2</sub> and 0.05 g SnCl<sub>2</sub>.

**Chemical Etching.** Table 6 lists chemical etchants that are used for microetching copper and copper alloys, and it includes etching procedures and the alloys to which each etchant is commonly applied. The solution listed first in Table 6

is by far the most widely used etchant. It is probably the best for routine work and is applicable to many copper and copper alloys.

## Technique for Lead and Lead Alloys

PREPARATION OF LEAD AND LEAD ALLOY SPECIMENS for metallographic examination presents problems that are not common to preparation of most other metals, because lead and lead alloys are so soft that they deform even under low pressure. Consequently, considerable surface flow or distortion can occur and abrasives can become embedded during grinding and polishing and, if not removed, can obscure the true structure of the specimen being examined. In the traditional method, preparation entails grinding with 400 grit SiC abrasive, rough polishing with 9  $\mu\text{m}$  diamond paste on a napless cloth and 0.3  $\mu\text{m}$   $\text{Al}_2\text{O}_3$  slurry on a medium-nap cloth, and final polishing with colloidal silica on a medium-nap cloth using light pressure until the surface is bright and scratch-free. In addition, because of the low melting points of lead and lead alloys, deformation of the specimen in metallographic preparation can be sufficient to cause heating and recrystallization. Therefore, in preparation of lead and lead alloy specimens, it is mandatory to employ a technique that will result in minimum surface distortion and heating. Use of a cold mounting procedure will enable the metallographer to avoid microstructural and crystallographic changes.

## Etching

Table 7 gives compositions of the etchants most often used for macroetching and microetching of lead and lead alloy specimens. Etching procedures and specific uses for the various etchants are also included in Table 7. All but two of these etchants are used by immersing or swabbing the specimen; only etchants 9 and 10 are used electrolytically.

**Table 7 Recommended etchants and procedures for macroscopic and microscopic examination of lead and lead alloys**

Etchant No.	Composition (parts are by volume)	Procedure	Use
<b>1</b>	1 part acetic acid (glacial) 1 part nitric acid (conc) 4 parts glycerol	Use freshly prepared solution at 80 °C (175 °F); discard after use. For macroetching: etch several minutes, rinse in water. For microetching: etch several seconds. For best results, alternate etching with polishing.	Macroetching of lead; development of microstructures and grain boundaries in lead, and in lead-calcium, lead-antimony, and lead-tin (low-Sn) alloys
<b>2</b>	100 parts acetic acid (glacial) 10 parts hydrogen peroxide (30%)	Etch for 10-30 min, depending on the depth of the disturbed layer. Dry and clean with concentrated nitric acid if required.	Microetching of lead-antimony alloys containing up to 2% antimony
<b>3</b>	3 parts acetic acid (glacial) 1 part hydrogen peroxide (30%)	Etch by immersing specimen in solution for 6-15 s. Dry with alcohol.	Microetching of lead, lead-calcium alloys, and lead-antimony alloys containing more than 2% antimony. Also removes disturbed metal.
<b>4</b>	Solution A: 15 g ammonium molybdate 100 mL distilled water Solution B: 6 parts nitric acid (conc) 4 parts distilled water	Mix equal quantities of solutions A and B. Etch by alternately swabbing specimen and washing in running water.	Macroetching of lead. A very rapid etchant; well suited for removing thick layers of disturbed metal from specimens.
<b>5</b>	3 parts acetic acid (glacial) 4 parts nitric acid (conc) 16 parts distilled water	Use freshly prepared solution at 40 to 42 °C (104 to 108 °F). Immerse specimen for 4-30 min until disturbed layer is removed. Clean with cotton in running water.	Microetching of unalloyed lead, and lead-tin alloys containing up to 3% tin
<b>6</b>	2 parts acetic acid	Etch for 2-10 s by swabbing. Rinse specimen in	Macroetching of unalloyed lead, and of lead-

	(glacial) 2 parts nitric acid (conc) 2 parts hydrogen peroxide (30%) 5 parts distilled water	running water and dry with alcohol.	bismuth, lead-tellurium, and lead-nickel alloys
7	1 part nitric acid (conc) 1 part distilled water	Etch for 5-10 min by immersion. If thick layer of disturbed metal is to be removed, solution can be heated to boiling. Rinse in running water, rinse in alcohol, and dry.	Developing macrostructure of welds and laminations in lead products.
8	Solution A: 10% aqueous solution of ammonium persulfate Solution B: 30% aqueous solution of tartaric acid	Mix 5 mL of solution A with 2 mL of solution B. Swab specimen for 5-10 s. Rinse in running water.	Microetching to distinguish cuboidal SbSn phase from Sb-rich phases in Pb-Sb-Sn alloys, such as bearing alloys or type metals. Solution A blackens SbSn phase; solution B etches Sb-rich phases.
9	6 parts perchloric acid (70%) 4 parts water	Immerse specimen (cathode) in electrolyte; anode is platinum spiral. Etch 45-90 s at 6 V, 4 A, from a rectifier.	Electrolytic etching of lead-antimony alloys containing more than 2% antimony
10	1 part hydrochloric acid (conc) 9 parts water	Same as for etchant 9	Same as for etchant 9
11	10 g ammonium molybdate 10 g citric acid 100 mL water	Etch for 15-30 s by immersion, rinse in warm water and alcohol and blow dry.	Delicate etch for lead and lead alloys. Ideal for revealing phases for high-magnification examination, microstructures, and grain boundaries in lead and in lead-calcium, lead-antimony, and lead-tin (low-Sn) alloys

Primarily because lead and lead alloys smear so easily, etch-polishing alternated with examination under the microscope was traditionally recommended. Sometimes, several cycles of polishing, etching, and examination were considered necessary; thus, a great deal of skill and patience was required. In addition to smearing, lead-antimony alloys are susceptible to tarnishing (or blackening) during etching. One or two light turns on the final polishing wheel, followed by immersion of the specimen in water, rinsing in ethanol or methanol, and drying in warm air, is often sufficient to remove this tarnish and reveal the true structure. Another technique involves use of a camel hair brush and liquid hand soap to remove the black etching product, followed by rinsing in a strong stream of running water and drying with alcohol and a warm air blast. Discoloration resulting from overetching or oxidation, or both, can sometimes be removed by lightly swabbing the specimen with EDTA (a solution of ethylenediamine tetraacetic acid disodium salt). Final vibratory polishing with colloidal silica eliminates most of these problems and a sensitive etch, such as number 11 from Table 7, can be used without need of multiple etch-polish cycles.

Lead and lead alloys begin to oxidize immediately after metallographic preparation and should be examined as soon as possible. Although EDTA sometimes removes the discoloration resulting from oxidation, the best solution is thorough drying of the specimen after etching. EDTA will not solve the problem of overetching.

## Technique for Magnesium Alloys

SPECIMENS OF MAGNESIUM ALLOYS for metallographic examination should be chosen with care so as to be representative. For example, both longitudinal and transverse specimens of sheet should be examined, edge and center sections of large ingots should be considered, and the mouth of a casting crack should be studied as the point of origin of the crack.

## Specimen Preparation

Specimens are removed from the metal mass by band sawing, hacksawing or abrasive cutting. Care should be exercised to prevent cold working of the metal, because cold working can alter the microstructure and complicate interpretation of constituents.

Specimens that have been severely cold worked by rough sawing, squeezing in a vise, or heavy stamping are likely to be mechanically twinned close to the worked surface. The cold worked surface can be removed by extending the time of each grinding and polishing operation up to twice the time required for removing scratches from the preceding stage. Removal of metal to a depth of approximately 1 mm (0.040 in.) during preparation of the specimen is recommended. The safest procedure is to minimize deformation in sectioning so that twinning is avoided or at least minimized.

**Grinding.** Wet grinding can be done on abrasive belts, rotating disks, or on abrasive papers by hand.

**Mechanical polishing** is traditionally done in two stages: rough and finish. Rough polishing removes the major part of the disturbed metal remaining after the final grinding step. Finish polishing removes the superficial scratches that remain after rough polishing.

Wheels used for both polishing stages are covered with medium-nap cloths. A suspension of 600 grit aluminum oxide powder in distilled water (35 g of aluminum oxide per 500 mL of water) is used on the wheel for rough polishing; for best results, the cloth is maintained just moist enough to prevent seizure of the specimen. The specimen is rotated counter to wheel direction. Polishing time should be twice as long as is needed to remove the scratches from the final grinding operation. A moderate amount of pressure should be used to minimize relief polishing caused by the difference in rate of stock removal between the harder and softer microconstituents.

For finish polishing, a suspension of alpha alumina in distilled water (10 g of alumina per 500 mL of water) is used on the wheel. Sometimes, to facilitate polishing, 15 mL of filtered or other soft soap is added to the abrasive solution.

**Macroetching.** The macroetchant most often used for showing discontinuities in castings and flow lines in forgings is an aqueous solution containing 5 to 20% acetic acid. The etchant is swabbed on the prepared surface for 10 s to 3 min and then washed away in running water. To show the grain structure of impact extruded or forged parts that have a homogeneous recrystallized structure and a minimum of alloy gradients, and for castings, one of the acetic-picral etchants listed in Table 8 as etchants 6, 7, or 8 should be used. The part is immersed in the etchant for 10 s to 1 min, transferred to a pan of ethanol to rinse the etched surface uniformly, rinsed in flowing ethanol, and then dried in a blast of air.

**Table 8 Selected etchants for macroscopic and microscopic examination of magnesium alloys**

Etchant No.	Composition	Etching procedure	Characteristics and use
<b>1</b>	<i>Nital</i> : 1 to 5 mL HNO <sub>3</sub> (conc), 100 mL ethanol (95%) or methanol (95%)	Swab or immerse specimen for a few seconds to 1 min. Wash in water then alcohol and dry.	Shows general structure.
<b>2</b>	<i>Glycol</i> : 1 mL HNO <sub>3</sub> (conc), 24 mL water, 75 mL ethylene glycol	Immerse specimen face up and swab with cotton for 3-5 s for as-cast or aged metal, and up to 1 min for heat treated metal. Wash in water, then alcohol and dry.	Shows general structure. Reveals constituents in Mg-rare earth and Mg-Th alloys.
<b>3</b>	<i>Acetic glycol</i> : 20 mL acetic acid, 1 mL HNO <sub>3</sub> (conc), 60 mL ethylene glycol, 20 mL water	Immerse specimen face up with gentle agitation for 1-3 s for as-cast or aged metal, and for 10 s for heat treated metal. Wash in water, then alcohol and dry.	Shows general structure and grain boundaries in heat treated castings. Shows grain boundaries in Mg-rare earth and Mg-Th alloys.
<b>4</b>	10 mL HF (48%), 90 mL water	Immerse specimen face up for 1-2 s. Wash in water, then alcohol and dry.	Darkens Mg <sub>17</sub> Al <sub>12</sub> phase and leaves Mg <sub>32</sub> (Al,Zn) <sub>49</sub> phase unetched and white.
<b>5</b>	<i>Phospho-picral</i> : 0.7 mL H <sub>3</sub> PO <sub>4</sub> , 4 to 6 g picric acid, 100 mL ethanol (95%)	Immerse specimen face up for about 10-20 s, or until polished surface is darkened. Wash in alcohol and dry.	For estimating the amount of massive phase. Stains matrix and leaves phase white. Staining improves as magnesium-ion content increases with use.
<b>6</b>	<i>Acetic-picral</i> : 5 mL acetic acid, 6 g picric acid, 10 mL water, 100 mL ethanol (95%)	Immerse specimen face up with gentle agitation until face turns brown. Wash in a stream of alcohol and dry with a blast of air.	A universal etchant. Defines grain boundaries in most alloys and tempers by etch rate and color of stain. Reveals cold work and twinning readily.
<b>7</b>	<i>Acetic-picral</i> : 20 mL acetic acid, 3 g picric acid, 20 mL water, 50 mL ethanol (95%)	Same as for etchant 6, above, but etch for at least 15 s to develop a heavy film.	Orientation of crackled film is parallel to trace of basal plane. Film crackles in high-alloy areas. Distinguishes between fusion voids surrounded by normal level of alloy and microshrinkage with low alloy content.
<b>8</b>	<i>Acetic-picral</i> : 10 mL acetic	Same as for etchant 6, above	Reveals grain boundaries more readily than etchant 6,

	acid, 4.2 g picric acid, 10 mL water, 70 mL ethanol (95%)		above, especially in dilute alloys.
<b>9</b>	0.6 g picric acid, 10 mL ethanol (95%), 90 mL water	Immerse specimen face up for 15-30 s. Wash in alcohol and dry.	Use after HF etchant to darken matrix to give better contrast between matrix and white ternary phase.
<b>10</b>	2 mL HF (48%), 2 mL HNO <sub>3</sub> (conc), 96 mL water	Immerse specimen face up with gentle agitation. Do not swab.	Grain structure and coring in Mg-Zn-Zr alloys.

## Microexamination

The etchants used and etching times depend on the physical condition and temper of the specimen. Time may vary from 5 to 10 s for a specimen of an alloy in the as-cast or aged condition to 30 s for one in the solution heat treated condition. Etchants used for specimens of magnesium alloys are listed in Table 8, along with their compositions, etching procedures, characteristics, and uses. For sand, permanent mold, and die cast alloys in the as-cast condition and for virtually all of the alloys in the aged condition, the glycol etchant is used; it is especially good for the magnesium-rare earth alloys and magnesium-thorium alloys. Acetic-picral etchants are used to selectively stain the grains, especially for viewing with sensitive-tint or polarized light.

## Technique for Nickel and Nickel Alloys

PREPARATION OF METALLOGRAPHIC SPECIMENS is divided into two classes of nickel alloys: alloys containing 96% or more nickel (Nickel 200, Nickel 270, and Duranickel 301) and nickel-copper alloys (Monel 400, Monel R-405, and Monel K-500). Techniques for nickel-base magnetic alloys and wrought heat-resisting alloys are discussed elsewhere in this article.

The procedures and materials used in sectioning, mounting, grinding, and polishing of specimens are essentially the same for all of the nickel alloys. In preparing specimens for metallographic examination, it is important to prevent cold working of the surface.

## Preparation for Macroscopic Examination

The preparation steps and macroetching procedures for these alloys are essentially the same as for steels. Resolution of detail is improved as the quality of the ground surface increases. Macroetching of nickel alloys is performed by immersion or swabbing using a cold solution of nitric acid and acetic acid (equal parts by volume) for times less than about 30 s. For nickel-copper alloys, fresh concentrated nitric acid is preferred. Times up to 5 min may be needed. Stale nitric acid may produce staining. Shorter times are recommended to observe sulfur embrittlement in Monel welds whereas longer times reveal macrostructural features.

## Preparation for Microscopic Examination

Sectioning, mounting, grinding, and polishing steps for nickel and nickel-copper alloys are quite similar to those for austenitic stainless steels. The chief danger is introduction of cold work to the structure. As with austenitic stainless steels, removal of fine scratches requires careful final polishing.

SiC papers are recommended for grinding, in the traditional manner, using the sequence 120, 240, 320, 400, and 600 grit with water cooling. Rough polishing with 6  $\mu$ m diamond paste on a low- or medium-nap cloth followed by 1  $\mu$ m diamond on the same type of cloth will produce excellent results. Final polishing with a 0.05  $\mu$ m alumina slurry or colloidal silica on a medium-nap cloth produces excellent results. Vibratory polishing with either of these abrasives may be required to obtain optimum results.

An alternative procedure is to electropolish specimens after mechanical polishing to remove fine scratches and deformation. Recommended electrolytes and current densities for electropolishing these alloys are given in Table 9. A platinum cathode should be used, and the electrolyte should be water cooled and continuously stirred.

**Table 9 Electrolytes and current densities for electropolishing of nickel and nickel-copper alloys**

Composition of electrolyte	Applicable alloys	Current density	
		A/cm <sup>2</sup>	A/in. <sup>2</sup>
<b>37 mL H<sub>3</sub>PO<sub>4</sub> (conc), 56 mL glycerol, 7 mL water</b>	Nickel 200	1.4-1.6	9-10
	Nickel 270	1.6-1.9	10-12
	Duranickel 301	1.2-1.6	8-10
	Monel 400	0.9-1.1	6-7
<b>33 mL HNO<sub>3</sub> (conc), 66 mL methanol</b>	Monel 400, R-405, K-500	1.6-2.3	10-15

**Etching.** The solutions and conditions for etching the various nickel alloys for microscopic examination are described in Table 10. The acids used should be concentrated; when water is indicated, use distilled water only.

**Table 10 Etchants for microscopic examination of nickel and nickel-copper alloys for grain boundaries and general structure**

Composition of etchant	Conditions for use
Etchants for Nickel 200 and 270; Duranickel 301; and Monel 400, R-405, and K-500	
<b>1 part 10% aqueous solution of sodium cyanide, 1 part 10% aqueous solution of ammonium persulfate; mix solutions when ready to use</b>	Immerse or swab specimen for 5-90 s ( <i>Caution:</i> use fume hood; solutions release toxic fumes when mixed.)
<b>1 part nitric acid (conc), 1 part acetic acid (glacial). Use fresh solution.</b>	For revealing grain boundaries. Immerse or swab specimen for 5-20 s.
Alternative etchant for Monel K-500	
<b>Glyceregia: 10 mL nitric acid (conc), 20 mL hydrochloric acid (conc), 30-40 mL glycerol</b>	Etch by immersing or swabbing the specimen for 30 s to 5 min.

## Technique for Wrought Heat-Resisting Alloys

WROUGHT HEAT-RESISTING ALLOYS exist in three major classes: iron-nickel-chromium alloys, nickel-base alloys, and cobalt-base alloys.

Although the three classes of alloys differ significantly in composition, microstructure, and elevated-temperature properties, the technique and equipment used for preparation of metallographic specimens are essentially the same for all three classes. Further, the technique used for these wrought alloys is basically the same for their cast counterparts and similar to those used for other metals.

## Metallographic Technique for Nonferrous Metals and Special-Purpose Alloys

Edited by George F. Vander Voort, Buehler Ltd.

## Specimens for Light Microscopy

**Sectioning and Grinding.** The initial preparation stages of sectioning and mounting (if required) are virtually identical to those employed for steels. Likewise, traditional coarse and fine grinding procedures are also similar, using water-cooled SiC papers of 120, 240, 320, 400, and 600 grit. If grinding is done manually, the direction of grinding must be rotated 45 to 90° between each step.

**Polishing.** Rough polishing is generally performed with 3, 6, or 9  $\mu$ m diamond paste on a napless or low-nap cloth, such as nylon or silk, to minimize relief at the hard constituents. This step may be followed by a similar step using 0.5 or 1  $\mu$ m diamond paste on a napless or low-nap cloth. If these steps are done manually, the specimen should be rotated against the cloth in the direction opposite to wheel rotation until scratches from the previous step are removed.

Final polishing can be performed using a variety of abrasives and cloths (napless to medium nap). If two diamond polishing steps were used, final polishing may be conducted using abrasives such as 0.05  $\mu\text{m}$  alumina (water slurry) or colloidal silica. If only one diamond polishing step (e.g., 6  $\mu\text{m}$  diamond) was used, two different alumina abrasive steps, such as 0.3 and 0.05  $\mu\text{m}$ , may be desired. Polishing pressure should be light to moderate depending on the alloy being polished.

In recent years, considerable use has been made of automatic polishing devices for the grinding and polishing steps. The more fully automated devices permit precise duplication of the polishing cycle, which improves reproducibility of polishing results and generally produces better control of relief than can be achieved with manual polishing. Vibratory polishing has often been used for final polishing, with both fine diamond and fine abrasive slurries. Although polishing times are substantially longer, excellent results can be obtained. Typically, times up to about 30 min are required with each abrasive used in this manner.

**Etching.** Procedures for specific wrought heat-resisting alloys of the three major classes are listed in Tables 11, 12, and 13. Compositions of the etchants used are given in Table 14.

**Table 11 Microetching procedures for wrought iron-nickel-chromium heat-resisting alloys**

Etchant No. <sup>(a)</sup>	Etching method	Etching time, s	Cell voltage	Purpose, or characteristics revealed

Etchant No. and name	Composition <sup>(a)</sup>	Remarks on preparation and use
<b>1</b> HCl, HNO <sub>3</sub> , acetic acid	15 mL HCl, 10 mL HNO <sub>3</sub> , 10 mL acetic acid	...
<b>2</b> Chrome regia	2 g CrO <sub>3</sub> , 20 mL HCl, 80 mL water	CrO <sub>3</sub> may be increased, but staining may result.
<b>3</b> Ferric chloride-hydrochloric	5 g FeCl <sub>3</sub> , 15 mL HCl, 100 mL methanol	...
<b>4</b> Nital	5 mL HNO <sub>3</sub> , 95 mL methanol	Use colorless acid and absolute methanol.
<b>5</b> Oxalic acid	10 g oxalic acid, 100 mL water	Can be stored.
<b>6</b> Phosphoric acid	80 mL H <sub>3</sub> PO <sub>4</sub> , 20 mL water	Change to a 1:1 solution for specific results.
<b>7</b> Glyceregia	10 mL HNO <sub>3</sub> , 20 mL HCl, 40 mL glycerol	Must be freshly prepared.
<b>8</b> Hydrochloric-methanol	10 mL HCl, 90 mL methanol	Water can be substituted for methanol to show segregation.
<b>9</b> Vilella's reagent	5 mL HCl, 1 g picric acid, 100 mL methanol	A few drops of 3% H <sub>2</sub> O <sub>2</sub> will speed etching reaction.
<b>10</b> HCl-H <sub>2</sub> O	5 mL HCl, 95 mL water	...
<b>11</b> Chromic acid	2-10 g CrO <sub>3</sub> , 100 mL water	...
<b>12</b> Hydrochloric-chromic	80 mL HCl, 20 mL 50% chromic acid	Use fresh solution.
<b>13</b> Oxalic acid	10 g oxalic acid, 90 mL water	...
<b>14</b> Nitric-hydrofluoric	20 mL HNO <sub>3</sub> , 3 mL HF	Use colorless acids. Remove thoroughly by water rinse.
<b>15</b> Chromic-acetic	25 g CrO <sub>3</sub> , 7 mL water, 130 mL acetic acid	Can be stored for up to one month.
<b>16</b> Chromic acid	5 g CrO <sub>3</sub> , 100 mL water	...
<b>17</b> 47-41-12	47 mL H <sub>2</sub> SO <sub>4</sub> , 41 mL HNO <sub>3</sub> , 12 mL H <sub>3</sub> PO <sub>4</sub>	Add H <sub>2</sub> SO <sub>4</sub> last, and slowly. Produces noxious fumes and is highly corrosive. When correctly etched, the specimen surface is colored brown.
<b>18</b> Hydrochloric-acetic	10 mL acetic acid, 3 drops HCl, 90 mL water	...
<b>19</b> Inverted glyceregia	50 mL HCl, 10 mL glycerol, 10 mL HNO <sub>3</sub>	...
<b>20</b> Murakami's reagent	10 g KOH or NaOH, 10 g K <sub>3</sub> Fe(CN) <sub>6</sub> , 100 mL water	Dissolve KOH (or NaOH) and K <sub>3</sub> Fe(CN) <sub>6</sub> in boiling water; etch specimen in boiling solution. Prepare fresh for use.
<b>21</b> Nitric-hydrofluoric	50 mL HNO <sub>3</sub> , 50 drops HF	Use colorless acids.
<b>22</b> Hydrochloric-hydrofluoric-nitric	80 mL HCl, 13 mL HF, 7 mL HNO <sub>3</sub>	...
<b>23</b> Marble's reagent	4 g CuSO <sub>4</sub> ·5H <sub>2</sub> O, 20 mL HCl, 20 mL water	Dissolve CuSO <sub>4</sub> in water and add HCl.
<b>24</b> Kalling's reagent	2 g CuCl <sub>2</sub> , 40 mL HCl, 80 mL methanol	Can be stored.
<b>25</b> 92-5-3	92 mL HCl, 5 mL H <sub>2</sub> SO <sub>4</sub> , 3 mL HNO <sub>3</sub>	Must be freshly prepared.
<b>26</b> Hydrochloric-hydrogen peroxide	97 mL HCl, 3 mL 3% H <sub>2</sub> O <sub>2</sub>	Must be freshly prepared.
<b>27</b> Grosbeck's reagent (two-stage)	Stage 1: 2 to 10% CrO <sub>3</sub> in water; stage 2: equal parts 20% KMnO <sub>3</sub> , 8% NaOH	Mix second stage immediately before use.
<b>28</b> HCl-ethanol-H <sub>2</sub> O <sub>2</sub>	35 mL HCl, 65 mL ethanol (95%), 7 drops H <sub>2</sub> O <sub>2</sub> (30%)	Must be freshly prepared.

(a) Use concentrated acids, unless indicated otherwise. Use distilled water to avoid staining.

## Technique for Magnetic Alloys

METALLOGRAPHIC TECHNIQUE differs widely for the several groups of magnetic materials that include silicon steels (also called electrical steels), iron-nickel alloys, iron-cobalt alloys, ferrites and garnets, and a variety of metals used for permanent magnets.

## Silicon Steels

Techniques for cutting, mounting, grinding, and polishing are generally the same for specimens of silicon steels as for specimens of other low-carbon sheet steels.

**Etching.** For some purposes, such as revealing precipitated iron carbide in high-silicon steels, specimens are examined in the as-polished condition. Nital (2 to 10% nitric acid in ethanol) is used extensively for etching. Picral (4% picric acid in ethanol) is sometimes used instead of nital, especially for revealing grain-boundary carbides.

**Grain Orientation.** Crystallographic texture is often of particular interest in metallographic studies of silicon (electrical) steels. Pitting etchants, which selectively attack certain crystallographic planes, often are used to determine orientation with the aid of an optical goniometer. Results are not always consistent; details of preparation, including methods of rinsing and drying and other steps in the procedure, often must be determined individually for best results, and variations of the etchant are sometimes necessary. Pitting etchants that have been used successfully are listed in Table 15. Special techniques for observing magnetic domains include use of Bitter patterns, use of the magneto-optical Kerr effect, and the Lorenz technique.

**Table 15 Pitting etchants for determination of grain orientation in silicon steels by light microscopy**

Etchant	Composition (parts are by volume)	Conditions for use	Purpose
<b>1</b>	1 part HF, 1 part HNO <sub>3</sub> , 4 parts water	Immerse for 10 s	Expose {100} crystallographic faces in (110)[001] (cube-on-edge) oriented 3.25% Si steel.
<b>2</b>	2 parts HF, 1 part HNO <sub>3</sub> , 3 parts methanol, 4 parts glycerol	Swab for 1 min.	Same as for etchant 1.
<b>3</b>	A: 6 mL H <sub>2</sub> O <sub>2</sub> (30%), 0.1 mL HCl, 100 mL water B: 40 mL FeCl <sub>3</sub> ·6H <sub>2</sub> O, 40 mL ethanol, 20 mL water	Immerse in A for 10 s, rinse and dry; then immerse in B for 3 s, rinse and dry.	Develops etch pits in (110)[001] (cube-on-edge) oriented 3.25% silicon steel.
<b>4</b>	100 g ferric sulfate, 100 mL H <sub>2</sub> SO <sub>4</sub> , 1000 mL water	Immerse for 15 s in solution heated to 80 to 90 °C (175 to 195 °F)	Develops etch pits in (100)[001] (cube-on-face) oriented 3.25% silicon steel.
<b>5</b>	A: 5 mL HF, 95 mL methanol B: 100 mL H <sub>2</sub> O <sub>2</sub> (3%), 100 mL water, 2 drops HCl C: 5 mL HCl, 95 mL methanol	Polish, etch heavily in nital. Repolish, etch in nital to reveal grain boundaries. Immerse 10 s in A, rinse, dry; 2 s in B, rinse, dry; 30 s in C, rinse, dry	Exposes {100} crystallographic faces in primary recrystallized 3.25% silicon steel and nonoriented silicon steels.
<b>6</b>	600 g FeCl <sub>3</sub> , 10 g ammonium bisulfate, 600 mL HCl, 150 mL HNO <sub>3</sub> , 1650 mL water	Immerse for 1 min in solution heated to 50 to 60 °C (120 to 140 °F).	Exposes {111} crystallographic faces in secondary recrystallized 50Ni-50Fe.

## Metallographic Technique for Nonferrous Metals and Special-Purpose Alloys

Edited by George F. Vander Voort, Buehler Ltd.

### Iron-Nickel and Iron-Cobalt Alloys

Techniques used for preparing metallographic specimens of iron-nickel and iron-cobalt ferro-magnetic alloys generally are similar to those used for preparing specimens of other soft metals.

**Macroetching.** Macroexaminations of iron-nickel alloys frequently are made on specimens that have been subjected to thermal etching. In thermal etching, a polished specimen is placed in a furnace, usually with a charge of material for annealing, and is heated and cooled with the charge; annealing temperature is usually 1175 °C (2150 °F).

**Mounting.** If the grain size is to be determined on strip specimen surfaces, electropolishing and electroetching is often performed as it is simple, fast, and adequate. If the cross section is to be examined for surface conditions, inclusions, and so forth, then mounting is required. All of the usual aspects of mounting apply to these alloys.

**Mechanical grinding and polishing** of iron-nickel and iron-cobalt alloys are basically the same as for strip or sheet steel specimens. Traditional practice is to wet grind on a series of silicon carbide papers ending with 600 grit silicon

carbide. Wet grinding minimizes embedding of abrasive particles in the soft-metal specimen. Rough polishing is done with 3  $\mu\text{m}$  diamond on a napless cloth-covered wheel. Final polishing is preferably done with gamma alumina on a napped cloth.

**Electropolishing** is sometimes used for iron-nickel and iron-cobalt alloys. Common practice is to mechanically finish the specimen through 600 grit silicon carbide and then to electropolish. Two widely used electrolytes and typical electropolishing conditions are given in Table 16.

**Table 16 Electrolytes and conditions for electropolishing of iron-nickel and iron-cobalt magnetic alloys**

Alloy	Electrolyte	Conditions for use
<b>Fe-Ni only</b>	135 mL acetic acid (glacial), 25 g CrO <sub>3</sub> , 7 mL water	80 V, 0.8 to 1.6 A/cm <sup>2</sup> , 5-30 s at 7 °C (45 °F) max
<b>Fe-Ni or Fe-Co</b>	100 mL acetic acid (glacial), 10 mL perchloric acid	45 V, 0.2 A/cm <sup>2</sup> , 3-4 min at 24 °C (75 °F)

**Microetching.** Table 17 lists several etchants that may be used for iron-nickel or iron-cobalt alloys. As shown in Table 18, some of the etchants in Table 17 are suitable for both groups of alloys; selection of etchant is often arbitrary. The first etchant listed in Table 17 (HCl), CuCl<sub>2</sub>, FeCl<sub>3</sub>, HNO<sub>3</sub>, methanol, and water) is most often used. Some metallographers prefer to obtain an electrolytic etch by reducing the current following electropolishing with one of the two solutions for which compositions are given in Table 16. The pros and cons of electrolytic etching for iron-nickel and iron-cobalt alloys are much the same as for other metals. Chemical etching is preferred in most laboratories.

**Table 17 Etchants for microscopic examination of iron-nickel and iron-cobalt magnetic alloys**

See Table 18 for applicability

Etchant	Composition	Conditions for use <sup>(a)</sup>
Chemical etching		
<b>1</b>	100 mL HCl, 2 g CuCl <sub>2</sub> , 7 g FeCl <sub>3</sub> , 5 mL HNO <sub>3</sub> , 200 mL methanol, 100 mL water	Immerse or swab for 10-15 s
<b>2<sup>(b)</sup></b>	15 mL HCl, 5 g FeCl <sub>3</sub> (anhydrous), 60 mL ethanol	Immerse for 5-10 s
<b>3</b>	3 mL HCl, 1 mL HNO <sub>3</sub> saturated with CuCl <sub>3</sub>	Swab for 2-3 s
<b>4</b>	15 mL HCl, 5 mL HNO <sub>3</sub> , 10 mL glycerol	Swab for 10-15 s
<b>5</b>	Ammonium persulfate (saturated aqueous solution)	Immerse 20-30 s
<b>6</b>	2 to 10% nital (HNO <sub>3</sub> in ethanol or methanol)	Immerse for 5-10 s
<b>7</b>	50 mL HCl, 10 g CuSO <sub>4</sub> , 50 mL water (Marble's reagent)	Immerse or swab for 5 s
Electrolytic etching		
<b>8</b>	5 to 10 mL HCl, 100 mL water	2-5 s at 250-500 mA/cm <sup>2</sup>
<b>9</b>	2 g CrO <sub>3</sub> , 100 mL water	2-5 s at 100-200 mA/cm <sup>2</sup>
<b>10</b>	3% sulfuric acid	5-10 s

(a) All etchants are used at room temperature.

(b) Recommended for electron metallography.

**Table 18 Etchants in Table 17 recommended for microscopic examination of iron-nickel and iron-cobalt magnetic alloys**

Etchant	Characteristic revealed
Iron-nickel alloys	
<b>1, 2, 3, 4, 5<sup>(a)</sup>, 6</b>	Grain size, structure
<b>3<sup>(b)</sup>, 7</b>	Grain size
Iron-cobalt alloys	
<b>1, 5, 6, 8, 9, 10</b>	Grain size, structure

(a) For etching 50Fe-50Ni.

(b) For etching high-nickel alloys

## Ferrites and Garnets

Because ferrites and garnets are electrical insulators, they cannot be electropolished or etched electrolytically. In addition, these materials are chemically inert and thus are not readily attacked by most etchants.

**Preparation of specimens** up to the point of etching is essentially the same as for metals. Magnetically soft and magnetically hard ferrites, including nickel and barium ferrites, are very often examined in the as-polished condition. This technique reveals voids and second phases. Grain size can be estimated from fractographs of broken surfaces (ferrites are brittle and fracture along grain boundaries) and by etching polished surfaces with strong reagents that results in attack on grain boundaries. Most etchants for nickel ferrites contain hydrofluoric acid, combined with nitric, sulfuric, or orthophosphoric acid, and are usually heated to 60 to 90 °C (140 to 195 °F). Etching time may range from a few seconds to 30 min.

## Alnico Permanent Magnet Alloys

All Alnico alloys are hard (40 to 60 HRC) and brittle, so that specimens must be extracted by breaking or abrasive-wheel cutting, or both. When abrasive cutoff wheels are used, extreme care is needed to avoid cracking and burning of specimens; slow feeds and an adequate flow of coolant must be used. Best practice is to remove at least 1.6 mm ( $\frac{1}{16}$  in.) from the cut face or to avoid using the cut face for examination. Because of the high hardness, grinding and polishing are difficult and slow; consequently, it is advisable to use relatively small specimens (polished face no greater than 160 mm<sup>2</sup>, or  $\frac{1}{4}$  in.<sup>2</sup>).

**Mounting** prior to grinding and polishing is preferred for small specimens, although it is not essential for large specimens. Phenolic is most often used as the mounting material, but other materials may be used.

**Grinding and Polishing.** Grinding is traditionally performed using silicon carbide of progressively finer grit sizes through 600 grit. Rougher grinding may be done dry, but preferred practice is to use kerosene or light spindle oil for grinding with abrasive finer than 400 grit.

A polishing procedure satisfactory for routine examination of Alnico alloys consists of wet polishing the specimen (previously ground to the finish obtained with 600 grit abrasive) on a conventional rotating wheel with a napped cloth and 6  $\mu$ m diamond abrasive. Final polishing may employ 0.05  $\mu$ m size levigated alumina or chromic oxide of 0.5  $\mu$ m size on a medium-nap cloth.

**Etching.** Specimens of Alnico alloys sometimes are examined without etching, principally for voids, such as porosity and microshrinkage. Also, unetched specimens are sometimes used for electron microscopy. Alnico alloys resist attack by many chemicals, and thus a relatively strong etchant is required. Marble's reagent is often used. Procedures for other permanent magnet materials, such as Cunife and rare-earth-cobalt alloys, may resemble those discussed previously. In some instances, etch-polishing or electrolytic techniques are necessary.

## Technique for Tin and Tin Alloys

---

TIN AND TIN ALLOYS are extremely soft and have low recrystallization temperatures. Thus, preparation of tin and tin alloy specimens for metallographic examination presents special problems that are not often encountered in preparing specimens of other metals. However, many of the steps in preparation are similar or identical to those for other metals.

### Mounting

Mounting of tin and tin alloy specimens should be done at room temperature, because elevated temperatures can cause structural changes, such as precipitation of a second phase from the supersaturated solid solution. Compression mounting compounds are therefore unsuitable.

### Grinding and Polishing

Distortion of the surface layers of tin and tin alloys may cause recrystallization, which will mask the true structure. For tin alloys in a metastable state, distortion of the surface regions as a result of working may cause structural changes, such as precipitation from a supersaturated solid solution.

To avoid working of the surface regions, extreme care must be taken during turning, filing, sectioning, grinding, and polishing, because of the susceptibility to distortion during those operations.

**Grinding.** The specimen is wet ground on silicon carbide papers of progressively finer grit sizes (180, 240, 320, 400, and 600 grit). The papers are kept wet by a continuous stream of lubricant, usually water, that washes away the particles of metal as they are cut from the surface of the specimen. This removal prevents clogging of the papers, which would lead to surface flowing of the metal instead of cutting. For alloys containing zinc-rich and aluminum-rich phases, which may be stained by water, kerosene is used as the lubricant.

**Polishing.** A light pressure is preferred during all stages of polishing, and each stage of polishing should be continued for at least twice as long as it takes to remove the scratches from the previous stage. Polishing is usually carried out using different grades of diamond suspended in an oil-base vehicle. Every effort must be made to ensure that the polishing wheels and the pads used for diamond pastes are kept free from dust, grit, and the diamond particles from the previous polishing stage. It is essential that coarse grinding and fine polishing be done at different locations; the environment where fine polishing is conducted must be free from corrosive fumes.

Scratches from the 600 grit silicon carbide papers are removed by polishing for several minutes on a wheel covered with a short-nap or napless cloth impregnated with 6  $\mu\text{m}$  diamond paste. Next, the specimen is polished on a wheel covered with a short-nap cloth impregnated with 1  $\mu\text{m}$  diamond paste. Final polishing is conducted using alumina slurries or with colloidal silica. A vibratory polisher is very useful for tin and tin alloys.

## Etching

Although the method of polishing is the same for all types of tin and tin alloys, different enchants are used for etching the various alloys (see Table 19).

**Table 19 Etchants for use in microscopic examination of tin and tin alloys**

Etchant composition	Uses
<b>5 mL HCl, 2 g FeCl<sub>3</sub>, 30 mL water, 60 mL absolute alcohol</b>	General use for tin and tin alloys
<b>2 mL HCl, 98 mL methanol (95%) or ethanol (95%)</b>	Grain-boundary etch for pure tin
<b>10 mL HNO<sub>3</sub>, 10 mL acetic acid, 80 mL glycerol</b>	Darkens the lead in the eutectic of tin-rich tin-lead alloys
<b>5% silver nitrate in water</b>	Darkens primary and eutectic lead in lead-rich tin-lead alloys
<b>2% nital</b>	Recommended for etching tin-antimony alloys; darkens tin-rich matrix, leaving intermetallic compounds unattacked. Often used for etching specimens of babbitted bearings
<b>Picral</b>	For etching tin-coated steel and tin-coated cast iron
<b>1 drop HNO<sub>3</sub> (conc), 2 drops HF, 25 mL glycerol; then picral</b>	For etching tin-coated steel
<b>Dilute ammonium hydroxide with a few drops of 30% hydrogen peroxide</b>	For etching tin-coated copper and copper alloys

## Technique for Titanium and Titanium Alloys

PREPARATION OF METALLOGRAPHIC SPECIMENS of unalloyed titanium and of alpha, alpha-beta, and beta titanium alloys is described in this section.

## Sectioning

Sectioning of titanium and titanium alloys follows conventional procedures, but deformation and overheating must be avoided. As with the refractory metals, sectioning of titanium and its alloys is more difficult than for most metals. Deformation can result in mechanical twinning and strain-induced transformation products, as well as overheating, in changes in structure. Abrasive cutting with silicon carbide wheels is satisfactory if adequate coolant is used. A very softly bonded wheel is essential for good cuts. Use of bandsaws is common for these alloys. Sectioning using an oil-cooled precision diamond saw is recommended for small specimens to avoid overheating.

## Mounting

Titanium and its alloys are mounted in the common materials, such as phenolic, methyl methacrylate, and diallyl phthalate; when edge preservation is important, compression-mounting epoxy is recommended. Nickel plating of specimens before mounting also assists in edge preservation. In general, the temperatures encountered in compression mounting do not cause problems. However, when metallographic examination involves the hydride phase (TiH), it is best to leave the specimen unmounted or to mount it in a low-temperature setting epoxy resin because of the increased solubility of hydrogen in titanium at the higher temperatures. Sometimes, mounting in a thermosetting material can cause solution of existing hydride and, on cooling, precipitation of the hydride in an altered form, usually a fine dispersion. Adding 50 vol% of silica powder (between 200 and 325 grit) to the epoxy resin or nickel plating will aid edge preservation.

## Grinding

The traditional procedure for grinding titanium specimens is similar to that for grinding steel specimens. The specimens are ground on successive grades of silicon carbide paper, starting with 120 grit and proceeding to 240, 320, 400, and 600 grit papers, using water to keep the specimens cool and flush away loose particles of metal and abrasive. It is possible to start grinding on a paper with a grit size as coarse as 80 grit (if the cut surface is very rough), provided that pressure is light so as to minimize cold working. Embedment of SiC abrasive particles is a problem with titanium and its alloys. To reduce embedding abrasive particles in the ground surface, the papers may be dressed with solid stick wax; however, it is possible to remove these particles in the subsequent steps. Stationary abrasive sheets or rotating disk and belt grinder devices are used.

## Polishing

Manual, automatic, vibratory and electrolytic polishing may be used for specimens of titanium and titanium alloys.

**Manual polishing** is traditionally performed in three stages: rough, intermediate, and final polishing. Rough polishing is performed on a high-speed polishing wheel covered with a lintless rayon or silk cloth, using medium pressure and a slurry consisting of 35 mL of water, 15 g of 1 or 3  $\mu\text{m}$  alpha (levigated) alumina, and 5 mL of 20% chromic acid (optional). An alternative procedure for rough polishing is to use a nylon cloth and 6  $\mu\text{m}$  diamond paste. Intermediate polishing is done with the same equipment and procedure, except that 0.3  $\mu\text{m}$  alumina is used in the slurry. Final polishing is performed on a low-speed wheel covered with Microcloth (Buehler, Ltd., Lake Bluff, IL), using a slurry containing 15 g of 0.05  $\mu\text{m}$  alumina and 35 mL of water, and with light pressure on the specimen.

At the start of intermediate polishing, rather heavy pressure is applied. As polishing progresses, pressure is decreased. Several cycles of polishing and etching may be needed to remove flowed metal. Etching should be light to avoid pitting. The specimen is unetched when final polishing starts. Several cycles of polishing and etching may also be necessary during final polishing.

For rough polishing of unalloyed titanium, which is considerably softer than the alloys, use of a wheel covered with 6.4 to 12.7 mm ( $\frac{1}{4}$  to  $\frac{1}{2}$  in.) of paraffin and a slurry of 3  $\mu\text{m}$  levigated alumina has been recommended. For intermediate polishing, the same wheel may be used with a slurry of 0.3  $\mu\text{m}$  alumina. Final polishing may be performed on a wheel covered with a short-nap cloth and using a slurry of 0.05  $\mu\text{m}$  alumina.

**Automatic polishing** has an advantage in that the pressure exerted on the specimen can be controlled. Specimens are ground through 180, 240, 320, 400, and 600 grit silicon carbide paper using water or kerosene as the coolant. Final polishing is done using Microcloth and 0.05  $\mu\text{m}$  gamma alumina for about 10 min. Several specimens can be prepared simultaneously.

**Vibratory polishing**, although a slower process than electrolytic or mechanical polishing, produces excellent results. Vibratory polishing can be a two-stage operation that follows grinding on abrasive papers. Preliminary polishing is performed on a canvas cloth for 2 to 4 h or on a silk cloth for 30 to 45 min, both using a slurry of 0.3  $\mu\text{m}$  alumina. Final polishing is performed on a short-nap cloth for 15 min to 4 h, using a slurry of 0.05  $\mu\text{m}$  alumina. Several short polishing and etching cycles may be used to remove disturbed metal. Colloidal silica also produces very good results. Attack polishing agents are often added to the colloidal silica producing crisper, sharper detail.

**Electropolishing** is considerably faster than mechanical polishing. An electrolyte recommended for electropolishing contains 600 mL of methanol, 360 mL of ethylene glycol, and 60 mL of perchloric acid. Polishing time is 15 to 25 s at a current density of 1 to 1.5 A/cm<sup>2</sup>, depending on specimen size and polishing area. The electrolyte given previously, with a low concentration of perchloric acid, is nonexplosive and can be stored for several weeks. However, care should be exercised in handling concentrated perchloric acid, because it can react explosively with organic materials, such as mounting compounds.

## Etching

**Macroetching.** At least three different etchants are used for macroetching of titanium and titanium alloys. Two of these are general-purpose etchants; the choice between the two is usually arbitrary. One of the general-purpose etchants is composed of equal parts, by volume, of hydrofluoric acid, nitric acid, and water; the other is composed of 5 mL of hydrofluoric acid, 35 mL of nitric acid, and 60 mL of water. An etchant composed of 50 mL of concentrated hydrochloric acid and 50 mL of water is often preferred for macroetching of alpha-beta titanium alloys.

**Microetching** is accomplished by swabbing or immersion. Because etching by immersion can promote reprecipitation of dissolved alloying elements, such as tin, back onto the specimen surface, it is recommended that both immersion and swabbing techniques be initially evaluated to identify the presence of such etching artifacts. Swabbing usually produces a brighter, clearer etching response than immersion. Etching times are usually short, ranging from 3 to 10 s. The specimen should be examined after light etching to avoid overetching.

Nearly all etchants for titanium and titanium alloys contain hydrofluoric acid and an oxidizing agent, such as nitric acid. Table 20 gives the compositions and purposes of etchants suitable for use on unalloyed titanium and on titanium alloys. Kroll's reagent is the etchant most widely used for commercial titanium alloys.

**Table 20 Etchants for microscopic examination of titanium and titanium alloys**

Specimen metal	Composition of etchant	Purpose
<b>Unalloyed titanium</b>	1-3 mL HF, 10 mL HNO <sub>3</sub> , 30 mL lactic acid	Reveals hydrides
	1 mL HF, 30 mL HNO <sub>3</sub> , 30 mL lactic acid	Reveals hydrides
<b>Most titanium alloys</b>	Kroll's reagent: 1-3 mL HF, 2-6 mL HNO <sub>3</sub> , water to 1000 mL	General-purpose etch
	10 mL HF, 5 mL HNO <sub>3</sub> , 85 mL water	General-purpose etch
	1 mL HF, 2 mL HNO <sub>3</sub> , 50 mL H <sub>2</sub> O <sub>2</sub> , 47 mL water	Removes stain
	10 mL HF, 10 mL HNO <sub>3</sub> , 30 mL lactic acid	Chemical polish and etch
	2 mL HF, 98 mL water	Reveals alpha case
	1-2 mL HF, 4-5 mL H <sub>2</sub> O <sub>2</sub> , water to 1000 mL	Nonstaining etch
<b>Near-alpha titanium alloys</b>	2 mL HF, 98 mL water; then 1 mL HF, 2 mL HNO <sub>3</sub> , 97 mL water	General-purpose etch <sup>(a)</sup>
<b>Alpha-beta titanium alloys</b>	10 mL KOH (40%), 5 mL H <sub>2</sub> O <sub>2</sub> , 20 mL water	Stains alpha, transformed beta
<b>Ti-Al-Zr and Ti-Si alloys</b>	18.5 g benzalkonium chloride, 33 mL ethanol, 40 mL glycerol, 25 mL HF	General-purpose etch
<b>Ti-3Al-8V-6Cr-4Mo-4Zr</b>	30 mL H <sub>2</sub> O <sub>2</sub> , 3 drops HF	General-purpose etch
<b>Ti-8Mn; aged Ti-13V-11Cr-3Al</b>	2 mL HF, 4 mL HNO <sub>3</sub> , 94 mL water	General-purpose etch
<b>Ti-Si alloys</b>	2 drops HF, 1 drop HNO <sub>3</sub> , 3 mL HCl, 25 mL glycerol	General-purpose etch

(a) First etchant stains alpha phase; second etchant removes stain

## Technique for Refractory Metals and Alloys

MARKED DIFFERENCES in ductility, abrasion resistance, response to work hardening, and other pertinent properties among the refractory metals (tungsten, molybdenum, niobium, and tantalum) and their alloys necessitate the use of a variety of techniques for preparation of metallographic specimens. A particular product form, such as wire, may also require special preparation techniques.

## Tungsten

Sectioning of tungsten and tungsten alloys should be performed using a resinoid-bonded, 70 grit aluminum oxide abrasive wheel, such as A-70-T-B. Wire can be cut with wet or dry abrasive wheels, preferably after a heavy nickel plate has been applied for protection. Nickel plating also aids in edge retention and in keeping the wire sections flat. Because tungsten wire can delaminate, it should never be cut with mechanical wire cutters.

**Mounting.** Most specimens of tungsten or tungsten alloys are mounted in the same manner as specimens of other metals.

**Electrolytic Polishing.** Aqueous electrolytes containing 1 to 10% sodium hydroxide or potassium hydroxide can be used successfully for electrolytic polishing of tungsten and tungsten alloys. Usually, a 2 to 4% sodium hydroxide aqueous solution with a nickel cathode is used. Better results may be obtained if half the volume of water in the solution is replaced by glycerol and the sodium hydroxide content is increased to 5%.

**Etching.** Murakami's reagent, conventional or modified, is most often used for etching tungsten and tungsten alloys, although other etchants are sometimes used (Table 21). In addition to the etchants shown in Table 21, electrolytic etching in a 4% sodium hydroxide aqueous solution, using 1 to 5 A (ac) or 0.5 to 1 A (dc), has been successfully used in some laboratories for improving grain-boundary contrast.

**Table 21 Etchants for metallographic specimens of refractory metals**

Etchant	Composition
Etchants for tungsten and molybdenum and their alloys	
<b>1 Murakami's reagent</b>	10 g $K_3Fe(CN)_6$ , 10 g KOH or NaOH, 100 mL water
<b>2 Murakami's reagent (mod)</b>	15 g $K_3Fe(CN)_6$ , 2 g NaOH, 100 mL water
<b>3 Electrolytic</b>	5 mL $H_2SO_4$ , 1 mL HF, 100 mL methanol (95%)
<b>4<sup>(a)</sup></b>	5 mL HF, 10 mL $HNO_3$ , 30 mL lactic acid
<b>5</b>	15 mL $HNO_3$ , 3 mL HF, 80 mL water
Additional etchants for molybdenum and molybdenum alloys	
<b>6</b>	10 mL HF, 30 mL $HNO_3$ , 60 mL lactic acid
<b>7</b>	25 mL HCl, 10 mL $H_2SO_4$ , 75 mL methanol
Etchants for niobium and tantalum and their alloys	
<b>8</b>	30 mL HF, 15 mL $HNO_3$ , 30 mL HCl
<b>9</b>	10 mL HF, 10 mL $HNO_3$ , 20 mL glycerol
<b>10</b>	5 mL HF, 20 mL $HNO_3$ , 50 mL acetic acid
<b>11</b>	25 mL $HNO_3$ , 5 mL HF, 50 mL water
<b>12</b>	30 mL $H_2SO_4$ , 30 mL HF, 3 to 5 drops $H_2O_2$ (30%), 30 mL water
<b>13</b>	50 mL $HNO_3$ , 30 g ammonium bifluoride, 20 mL water
Additional etchants for niobium and niobium alloys	
<b>14</b>	20 mL HF, 15 mL $H_2SO_4$ , 5 mL $HNO_3$ , 50 mL water
<b>15</b>	30 mL lactic acid, 10 mL $HNO_3$ , 10 mL HF
<b>16</b>	20 mL $HNO_3$ , 10 mL HF, 70 mL water
<b>17</b>	15 mL HCl, 15 mL $H_2SO_4$ , 8 mL $HNO_3$ , 62 mL water
Additional etchants for tantalum and tantalum alloys	
<b>18</b>	10 g NaOH, 100 mL water
<b>19</b>	20 mL HF, 20 mL $HNO_3$ , 60 mL lactic acid
<b>20</b>	10 mL HF, 90 mL $H_2SO_4$

(a) Procedure: Swab with heavy pressure for 5-10 s, water rinse, alcohol rinse, dry, etch with Murakami's reagent (etchant 1).

## Molybdenum

Because molybdenum is relatively soft, scratches and distorted metal developed in sectioning, grinding, and polishing are difficult to eliminate, and therefore electrolytic polishing is commonly used for molybdenum.

**Electrolytic Polishing.** An excellent polish, particularly with difficult-to-polish alloys, such as TZM, can be obtained using an electrolyte consisting of 12.5% sulfuric acid with a remainder of ethanol or methanol. Nickel is used as the cathode. Voltages between 8 and 50 V dc have been used successfully.

**Etching.** A modified Murakami's reagent is recommended for etching molybdenum. It provides good grain-boundary contrast and yet minimizes etch pitting. A typical mixture contains 15 g of potassium ferricyanide, 2 g of sodium hydroxide, and 100 mL of water.

## Niobium and Tantalum

Specimens of niobium and tantalum and their alloys are prepared by techniques similar to those used for preparing stainless steel specimens.

**Polishing.** A typical method of rough polishing niobium and tantalum employs a wax wheel and 15  $\mu\text{m}$  levigated alumina. Intermediate polishing is done on a Microcloth-covered wheel using 1  $\mu\text{m}$  alumina, and final polishing is also done on a Microcloth-covered wheel using 0.3  $\mu\text{m}$  alumina.

**Etchants** used for metallographic specimens of niobium and tantalum and their alloys are listed in Table 21.

## Technique for Zinc and Zinc Alloys

METALLOGRAPHIC TECHNIQUES that are special to the preparation of specimens of zinc and zinc alloys are discussed in this section.

### Sectioning and Mounting

**Sectioning.** The initial sample may be removed from a larger mass of material by abrasive cutting, sawing, breaking, or shearing, much the same as for other metals.

**Mounting.** Specimens of rolled zinc and zinc alloys may be held by clamping; they are not mounted in plastic. Several specimens are mounted together in a screw clamp, with thin spacers of soft zinc between specimens and heavy strips of zinc between the clamp plates and the outermost specimens. The assembly is tightly clamped to prevent seepage of etchants between specimens. The zinc spacers are of known structure and serve as convenient standards of comparison for determining if the specimens have been correctly prepared.

Most specimens other than those of rolled metal are mounted in conventional plastic molding materials. See the description of mounting materials in the section "Metallographic Methods" in the article "Metallographic Practices Generally Applicable to All Metals."

### Grinding and Polishing

In grinding and polishing of cast zinc, distortion can occur to a depth 20 to 100 times as great as the deepest scratch. Therefore, in each stage of grinding and polishing, considerably more metal should be removed than the amount required for eliminating the scratches that remain from the previous stage. It is easier to prepare a distortion-free surface on specimens of fine grain zinc than on specimens of coarse grain, soft zinc.

Traditional grinding is done with silicon carbide papers using successively finer grit sizes of 180, 240, 320, 400, and 600 mesh. These papers are less susceptible to loading than emery papers. Grinding can be done by hand on papers supported on a flat surface, or by holding the specimen against the same grades of paper on a grinding wheel. Overheating of the specimen during wheel grinding should be minimized. This problem can be solved by using a low wheel speed (300 rpm max), by applying water to the silicon carbide papers during grinding, and by grinding in intervals of a few seconds and allowing the specimen to cool between intervals before grinding is resumed.

Rough polishing may be performed using 6-~~μ~~m diamond charged onto napless, low-nap or medium-nap cloths. Final polishing can be done using alumina or magnesium oxide slurries on medium-nap cloths. Colloidal silica is excellent for final polishing of zinc alloys but may cause pitting of pure zinc.

## Macroetching

Use of concentrated hydrochloric acid at room temperature, followed by rinsing and wiping off the resulting black deposit, produces good grain contrast on copper-free zinc and zinc alloys. Etchant 1 in Table 22 may be used for zinc containing 1% Cu or less. With this etchant, grain contrast is not well defined. An etchant equal to hydrochloric acid for producing grain contrast has not been found for zinc alloys containing copper.

**Table 22 Etchants for zinc and zinc alloys**

Etchant	Composition
<b>1<sup>(a)</sup></b>	200 g CrO <sub>3</sub> , 15 g Na <sub>2</sub> SO <sub>4</sub> , 1000 mL water
<b>2<sup>(b)</sup></b>	50 g CrO <sub>3</sub> , 4 g Na <sub>2</sub> SO <sub>4</sub> , 1000 mL water
<b>3</b>	200 g CrO <sub>3</sub> , 1000 mL water

- (a) For rolled zinc-copper alloys, the Na<sub>2</sub>SO<sub>4</sub> content can be reduced to 7.5 g. If desired, a smoothly etched surface can be obtained by increasing the Na<sub>2</sub>SO<sub>4</sub> to 30 g.
- (b) This etchant can be made by mixing one part (by volume) of etchant 1 and three parts of water.

## Microetching

The most useful etchants for microscopic examination of zinc and zinc alloys are aqueous solutions of chromic acid (CrO<sub>3</sub>, or chromic anhydride) to which sodium sulfate (Na<sub>2</sub>SO<sub>4</sub>) has been added. Grades of chromic acid used for chromium plating are satisfactory. Table 22 gives compositions of etchants commonly used.

Etching should follow soon after final polishing. The specimen should be cleaned in alcohol and then in running water and etched while still wet. To avoid staining, the use of etchant 1 or 2 in Table 22 should be followed immediately by a rinse in etchant 3. The specimen is then thoroughly washed in running water, dipped in alcohol, and dried with a stream of warm, clean air.

Table 23 gives recommendations for etchants and etching times for zinc and zinc die-casting alloys. The etching time may be longer or shorter for specific etching conditions (a minor difference in solution temperature may affect etching time). Also, as indicated in Table 23 for cast or rolled zinc, etching time is often decreased as the magnification to be used is increased.

**Table 23 Etchants and etching times for zinc and zinc die-casting alloys**

Specimen metal	Etchant (from Table 22)	Etching time, s, for examination at:	
		<b>250×</b>	<b>1000×</b>
<b>Cast or rolled zinc</b>	1	5	1
<b>Alloy AC41A or AG40A</b>	2	1	1

# Measurement of Microstructure

Edited by George F. Vander Voort, Buehler Ltd.

## Introduction

QUANTIFYING MICROSTRUCTURAL PARAMETERS has received considerable attention in recent years and success in developing procedures and using such data to develop structure/property relationships has been achieved. Chart methods for rating microstructures have been used for many years to evaluate microstructures, chiefly for conformance to specifications. At this time, true quantitative procedures have not replaced chart methods for such purposes, but they have gained wide usage in quality control and research studies. Examples of the applications of quantitative metallography have been reviewed by Underwood (Ref 1).

Basically, two types of measurements of microstructures are made. The first group includes measurements of depths (i.e., depth of decarburization, depth of surface hardening, or coating thicknesses). These measurements are made at a specific location (the surface) and may be subject to considerable variation. To obtain reproducible data, these surface conditions must be measured at a number of positions on a given specimen, and on several specimens if the material being sampled is rather large.

The second group of measurements belongs to the field referred to as stereology. This body of measurements describes the relationship between measurements made on the two-dimensional plane of polish and the three-dimensional microstructural features sampled. To facilitate communications, the International Society for Stereology (ISS) has proposed a standard system of notation, as shown in Table 1 (Ref 2).

**Table 1 Standard notation recommended by International Society for Stereology**

Symbol	Units	Description	Common name
$P$	...	Number of point elements or test points	...
$P_p$	...	Point fraction (number of point elements per total number of test points)	Point count
$L$	mm	Length of linear elements or test-line length	...
$P_L$	mm <sup>-1</sup>	Number of point intersections per unit length of test line	...
$L_L$	mm/mm	Sum of linear intercept lengths divided by total test-line length	Lineal fraction
$A$	mm <sup>2</sup>	Planar area of intercepted features or test area	...
$S$	mm <sup>2</sup>	Surface area or interface area, generally reserved for curved surfaces	...
$V$	mm <sup>3</sup>	Volume of three-dimensional structural elements or test volume	...
$A_A$	mm <sup>2</sup> /mm <sup>2</sup>	Sum of areas of intercepted features divided by total test area	Areal fraction
$S_V$	mm <sup>2</sup> /mm <sup>3</sup>	Surface or interface area divided by total test volume (surface-to-volume ratio)	...
$V_V$	mm <sup>3</sup> /mm <sup>3</sup>	Sum of volumes of structural features divided by total test volume	Volume fraction
$N$	...	Number of features	...
$N_L$	mm <sup>-1</sup>	Number of interceptions of features divided by total test-line length	Lineal density
$P_A$	mm <sup>-2</sup>	Number of point features divided by total test area	...
$L_A$	mm/mm <sup>2</sup>	Sum of lengths of linear features divided by total test area	Perimeter (total)
$N_A$	mm <sup>-2</sup>	Number of interceptions of features divided by total test area	Areal density
$P_V$	mm <sup>-3</sup>	Number of points per test volume	...
$L_V$	mm/mm <sup>3</sup>	Length of features per test volume	...
$N_V$	mm <sup>-3</sup>	Number of features per test volume	Volumetric density
$\bar{L}$	mm	Mean linear interception distance, $L_L/N_L$	...
$\bar{A}$	mm <sup>2</sup>	Mean area intercept, $A_A/N_A$	...
$\bar{S}$	mm <sup>2</sup>	Mean particle surface area, $S_V/N_V$	...
$\bar{V}$	mm <sup>3</sup>	Mean particle volume, $V_V/N_V$	...

Note: Fractional parameters are expressed per unit length, area or volume.

Source: Ref 2

These measurements are made manually with the aid of templates outlining a fixed field area, systems of straight or curved lines of known length, or a number of systematically spaced points. The simple counting measurements,  $P_P$ ,  $P_L$ ,  $N_L$ ,  $P_A$ , and  $N_A$ , are most important and are easily made. These measurements are useful by themselves and can be utilized to derive other important relationships. These measurements can also be made using semiautomatic or automatic image analyzers.

## Volume Fraction

One of the simplest and most useful measurements is the point count (described in ASTM E 562) used to estimate volume fractions of microstructural constituents. While other manual procedures can be employed, the point count is most efficient--it gives the best accuracy with minimum effort (Ref 3). To perform this test, a clear plastic grid with a number of systematically spaced points (usually crosses are employed, where the "point" is the intersection of the arms), typically 9, 16, 25, 49, 64, or 100, is placed on a micrograph, on a projection screen, or inserted as an eyepiece reticle. The number of points lying on the phase or constituent of interest is counted and divided by the total number of grid points. Points lying on a boundary are counted as half-points. This procedure is repeated on a number of fields selected without bias (without looking at the image).

The point fraction,  $P_P$ , is given by:

$$P_P = P_{\alpha}/P_T \quad (\text{Eq 1})$$

where  $P_{\alpha}$  is the number of grid points lying inside the feature of interest,  $\alpha$ , plus one-half the number of grid points lying on particle boundaries, and  $P_T$  is the total number of grid points. Studies have shown that the point fraction is equal to the area fraction,  $A_A$ , and volume fraction,  $V_V$ , of the second-phase particles:

$$P_P = A_A = V_V \quad (\text{Eq 2})$$

The volume fraction can also be estimated by dividing the total length of linear elements of a test pattern lying within the phase by the total length of the test pattern. The lineal fraction,  $L_L$ , is also equal to the parameters in Eq 2. Point counting is always performed on the minor phases--where  $V_V = 0.5$ . The amount of the major (matrix) phase can be determined by difference.

The fields measured should be selected at locations over the entire polished surface, not confined to a small portion of the specimen surface. The field measurements should be averaged, and the standard deviation can be used to assess the relative accuracy of the measurement, as described in ASTM E 562.

In general, the number of points on the grid should be increased as the volume fraction of the feature of interest decreases. One study (Ref 3) suggested that the optimum number of grid test points is  $3/V_V$ . Hence, for volume fractions of 0.5 (50%) and 0.01 (1%), the optimum numbers of grid points are 6 and 300, respectively. If the structure is heterogeneous, measurement accuracy is improved by using a low-point-density grid and increasing the number of fields measured.

Figure 1 demonstrates the point counting procedure and shows a synthetic microstructure consisting of 24 circular particles, each 6 mm in diameter, within a field area of 12,100 mm<sup>2</sup>. The total area of the circular particles is 678.6 mm<sup>2</sup>, which is an area fraction of 0.056 (5.6%). A square grid pattern has been drawn over this field, producing 100 intersection points. Four of these intersections are completely within the particles and four lie on the particle interface. The number of "hits" is, therefore,  $4 + \frac{1}{2}(4) = 6$ . Thus,  $P_P$  is  $\frac{6}{100}$  or 0.06 (6%), which agrees very closely with the theoretically

calculated area fraction. The area fraction,  $A_A$ , is equal to the volume fraction,  $V_V$ , as long as the sectioning plane intersects the structural features at random.

**Fig. 1** Synthetic microstructure of uniformly shaped, identical size spherical particles in a matrix phase. Test area is 12,100 mm<sup>2</sup>. Test lines, ten horizontal and ten vertical, are 110 mm long.

### Number per Unit Area

The count of the number of particles within a given measurement area,  $N_A$ , is a useful microstructural parameter and is used in other calculations. Referring again to Fig. 1, there are 24 particles in the measurement area (12,100 mm<sup>2</sup>). Hence, the number of particles per unit area,  $N_A$ , is 0.00198 mm<sup>-2</sup>. The average area of the particles can be calculated by dividing the volume fraction,  $V_V$ , by  $N_A$ :

$$A = V_V / N_A \quad (\text{Eq 3})$$

This yields an average area,  $A$ , of 28.23 mm<sup>2</sup>, which agrees well with the calculated area of a 6 mm diameter particle of 28.27 mm<sup>2</sup>. The above example illustrates the calculation of the average area of particles in a two-phase microstructure.

### $P_L$ and $N_L$

Counting of the number of intersections of a line of known length with particle or grain features,  $P_L$ , or the number of interceptions of particles or grains by a line of known length,  $N_L$ , provides two very useful microstructural parameters. For space-filling grain structures (single phase),  $P_L = N_L$ , while for two-phase structures,  $P_L = 2N_L$  (this may differ by one count in actual cases).

**Grain-Structure Measurements.** For single-phase grain structures, it is usually easier to count the grain-boundary intersections with a line of known length. This is the basis of the Heyn intercept grain-size procedure described in ASTM E 112. For most work, a circular test grid composed of three concentric circles with a total line length of 500 mm is preferred. Grain size is defined by the mean lineal intercept length,  $l$ :

$$l = 1/P_L = 1/N_L \quad (\text{Eq 4})$$

This equation must be modified, as described later, for two-phase structures. To calculate the ASTM grain size number,  $l$  can be used.

$P_L$  measurements can be utilized to define the surface area per unit volume,  $S_V$ , and the length per unit area,  $L_A$ , of grain boundaries:

$$S_V = 2P_L \quad (\text{Eq 5})$$

and

$$L_A = (\pi/2)(P_L) \quad (\text{Eq 6})$$

For single-phase structures,  $P_L$  and  $N_L$  are equal, and either measurement can be used. For two-phase structures, it is best to measure  $P_L$  to determine the phase-boundary surface area per unit volume, or phase-boundary length per unit area.

**Oriented Structures.** Measurements of  $P_L$  are utilized to assess the degree of orientation of lines or surfaces. Certain microstructures exhibit a high degree of preferred directionality on the plane of polish or within the sample volume. A structure is completely oriented if all of its elements are parallel. Partially oriented systems are those with features having both random and oriented elements. To assess the degree of orientation, the plane of polish must be longitudinal, planar, or transverse with respect to the deformation axis.

Several approaches can be utilized to assess the degree of orientation of a microstructure. For single-phase grain structures, a simple procedure is to make  $P_L$  measurements parallel and perpendicular to the deformation axis on a longitudinally oriented specimen. The degree of grain orientation is the ratio of perpendicular to parallel  $P_L$  values--i.e.,  $PL_{\perp}/PL_{\parallel}$ . Another very useful procedure is to calculate the degree of orientation,  $\Omega$ , using these  $P_L$  values:

$$\Omega = (PL_{\perp} - PL_{\parallel}) / (PL_{\perp} + 0.571PL_{\parallel}) \quad (\text{Eq 7})$$

To illustrate these measurements, a section of low-carbon steel sheet was cold rolled to reductions in thickness of 12, 30, and 70%.  $PL_{\perp}$  and  $PL_{\parallel}$  measurements were made using a grid with parallel straight test lines on a longitudinal section from each of four specimens (one specimen for each of the three reductions, plus one specimen of as-received material). Table 2 gives the results, which indicate that cold working produces an increased orientation of the grains in the longitudinal direction.

**Table 2 Degrees of grain orientation for four samples of low-carbon steel sheet**

Sample	$PL_{\perp}^{(a)}$	$PL_{\parallel}^{(a)}$	$PL_{\perp}/P_L^{(a)}$	$\Omega$ , %
<b>As-received</b>	114.06	98.86	1.15	8.9
<b>Cold rolled</b>				
<b>12% reduction</b>	126.04	75.97	1.66	29.6
<b>30% reduction</b>	167.71	60.6	2.77	52.9
<b>70% reduction</b>	349.4	34.58	10.1	85.3

(a) Number of grain-boundary intersections per millimeter

**Spacings.**  $N_L$  measurements are utilized in the study of the spacing of two-phase structures. One of the most common spacing measurements is that of lamellar pearlite or other eutectoid or eutectic structures (Ref 4). The true interlamellar spacing,  $\sigma_t$ , is difficult to measure, but the mean random spacing,  $\sigma_r$ , is readily assessable and is directly related to the mean true spacing:

$$\sigma_t = \sigma_r/2 \quad (\text{Eq 8})$$

The mean random spacing is determined by placing a test grid consisting of one or more concentric circles on the pearlite lamellae in an unbiased manner. The number of interceptions of the carbide with the test line(s) is counted and divided by the true length of the test line, to obtain  $N_L$ . The reciprocal of  $N_L$  is the mean random spacing:

$$\sigma_r = 1/N_L \quad (\text{Eq 9})$$

The mean true spacing,  $\sigma_t$ , is  $\frac{1}{2}\sigma_r$ . To make accurate measurements, the lamellae must be clearly resolved; hence, use of transmission electron microscope replicas is quite common.

Measurements of  $N_L$  are also used to measure interparticle spacings in two-phase alloys. The mean center-to-center spacing of particles,  $\sigma$ , is the reciprocal of  $N_L$ . For the second-phase particles in the idealized two-phase structure shown in Fig. 1, a count of the number of particles intercepted by the horizontal and vertical test lines yields 31 interceptions. The total line length is 2200 mm; hence,  $N_L = 0.0141 \text{ mm}^{-1}$  and  $\sigma = 70.9 \text{ mm}$ .

The mean edge-to-edge distance between such particles, known as the mean free path,  $\lambda$ , is determined in like manner but requires knowledge of the volume fraction of the particles. The mean free path is calculated:

$$\lambda = (1 - V_V)/(N_L) \quad (\text{Eq 10})$$

For the structure shown in Fig. 1, the volume fraction of the particles was estimated as 0.056. Hence,  $\lambda = 66.95 \text{ mm}$ .

The mean lineal intercept distance,  $l_\alpha$ , for these particles is determined by:

$$l_\alpha = \sigma - \lambda \quad (\text{Eq 11})$$

For this example,  $l_\alpha = 3.95 \text{ mm}$ . This value is smaller than the caliper diameter of the particles, because the test lines intercept the particles at random, not only at the maximum dimension.

## Grain Size

Perhaps the most common quantitative microstructural measurement is that of the grain size of metals and alloys. Numerous procedures have been developed to estimate grain size; these procedures are summarized in detail in ASTM E 112 and illustrated in Ref 5. Several types of grain sizes can be measured: ferrite grain size, austenite grain size, and prior-austenite grain size. Each type presents particular problems associated with revealing these boundaries so that an accurate rating can be obtained (Ref 5). To complicate matters, a variety of parameters are utilized to define grain size:

- Average grain diameter,  $d$
- Average grain area,  $A$
- Number of grains per unit area,  $N_A$
- Average intercept length,  $l$
- Number of grains intercepted by a line of fixed length
- Number of grains per unit volume,  $N_V$

- Average grain volume,  $V$

These parameters can be related to the ASTM grain size number,  $G$ .

The ASTM grain-size scale was established using the Imperial system of units, but no difficulty is introduced by metric measurements. The ASTM grain size equation is:

$$n = 2^{G-1} \quad (\text{Eq 12})$$

where  $n$  is the number of grains per square inch at 100 $\times$ . Multiplication of  $n$  by 15.5 gives the number of grains per square millimeter at 1 $\times$ ,  $N_A$ .

**Planimetric Method.** The oldest procedure for measuring the grain size of metals is the planimetric method. A circle of known size (generally 79.8 mm diameter, 5000 mm<sup>2</sup> area) is drawn on a photomicrograph or used as a template on a projection screen. The number of grains completely within the circle,  $n_1$ , and the number of grains intersecting the circle,  $n_2$ , are counted. For accurate counts, the grains must be marked off as they are counted, which makes this method slow. The number of grains per square millimeter at 1 $\times$ ,  $N_A$ , is determined:

$$N_A = f(n_1 + n_2/2) \quad (\text{Eq 13})$$

where  $f$  is the magnification squared divided by 5000 (the circle area). The average grain area,  $A$ , in square millimeters, is:

$$A = 1/N_A \quad (\text{Eq 14})$$

and the average grain diameter,  $d$ , in millimeters, is:

$$d = (A)^{1/2} = 1/(N_A)^{1/2} \quad (\text{Eq 15})$$

The ASTM grain size,  $G$ , can be found by using the tables in ASTM E 112 or by the following equation:

$$G = 3.322(\log N_A) - 2.95 \quad (\text{Eq 16})$$

Figure 2 illustrates the planimetric method. Expressing grain size in terms of  $d$  is being discouraged by ASTM Committee E-4 on Metallography, because the calculation implies that grain cross sections are square, which they are not.

**Fig. 2** Example of grain size measurement by the planimetric method. Micrograph, at 100 $\times$ , of an austenitic manganese steel that was solution annealed at 1040 °C (1900 °F) and aged at 620 °C (1150 °F) to decorate

the grain boundaries with fine pearlite. The circle has a diameter of 79.8 mm, for an area of 5000 mm<sup>2</sup>. A count is made to determine the number of grains completely within the circle (44) and the number intersecting the circle (25). The planimetric multiplier for 100× is 2. The number of grains per square millimeter at 1× is (2)(44 + 25/2) = 113. The ASTM grain size,  $G$ , is  $(3.322 \log 113) - 2.95 = 3.87$  (round to 3.9 or 4).

**The intercept method** is faster than the planimetric method because the micrograph or template does not require marking to obtain an accurate count. ASTM E 112 recommends use of a template consisting of three concentric circles with a total line length of 500 mm (template available from ASTM). The template is placed over the grain structure without bias, and the number of grain-boundary intersections,  $P$ , or the number of grains intercepted,  $N$ , is counted. Dividing  $P$  or  $N$  by the true line length,  $L$ , gives  $P_L$  or  $N_L$ , which are identical ( $N$  or  $P$  can differ slightly due to tangent hits) for a single-phase grain structure. It is usually easier to count grain-boundary intersections for single-phase structures. If a grain boundary is tangent to the line, it is counted as  $\frac{1}{2}$  of an intersection. If a triple-point line junction is intersected, it is counted as  $1\frac{1}{2}$  or 2. The latter is preferred because the small diameter of the inner circle introduces a slight bias to the measurement that is offset by weighing triple-line intersections as 2 hits.

The mean lineal intercept length,  $l$ , determined as shown in Eq 4, is a measure of ASTM grain size. It is smaller than  $d$ , because the test lines do not intersect each grain at its maximum breadth. The ASTM grain size,  $G$ , can be determined by use of the tables in ASTM E 112 or can be calculated:

$$G = -6.644 (\log l) - 3.288 \quad (\text{Eq 17})$$

where  $l$  is in millimeters. Figure 3 shows the intercept method for a single-phase alloy.

**Fig. 3** Example of grain size measurement using the intercept method. The three concentric circles have diameters of 79.5, 47.8, and 31.8 mm, for a total line length of 500 mm. The magnification of this micrograph is 500×, and hence the true line length is 1 mm. A count of the number of grain-boundary intersections (several are not well delineated by the nital etch--a common problem in such ratings, especially if automated devices are used) revealed 60 grain-boundary intersections and 7 triple line-junction intersections. Hence,  $P = 7(1.5) + 60 = 70.5$ , and  $P_L = 70.5 / 1 \text{ mm} = 70.5/\text{mm}$ . Therefore,  $l = 1/P_L = 0.0142 \text{ mm}$ . The ASTM grain-size number can be evaluated using Eq 17:  $G = -6.6457(\log 0.0142) - 3.298 = 8.98$  (round to 9).

**Nonequiaxed grain structures** require measurements on the three principle planes: the longitudinal, planar, and transverse. For such structures, the intercept method is preferred, but the test grid should consist of a number of straight, parallel test lines of known length rather than circles. Because the ends of the straight lines generally end within grains, these interceptions are counted as half-hits. Three mutually perpendicular orientations are evaluated using grain-interception counts:

- $N_{Ll}$ --parallel to the grain elongation, longitudinal plane
- $N_{Lt}$ --perpendicular to the grain elongation (through-thickness direction), transverse plane

- $N_{LP}$ --perpendicular to the grain elongation (across width), planar surface

The average  $N_L$  value is obtained from the cube root of the product of the three directional  $N_L$  values.  $G$  is determined by reference to the tables in ASTM E 112 or by use of Eq 17 ( $l$  is the reciprocal of  $N_L$ , Eq 4).

**Two-Phase Grain Structures.** The grain size of a particular phase in a two-phase structure requires determination of the volume fraction of the phase of interest, such as by point counting. The minor phase (second phase) is point-counted and the volume fraction of the major phase (matrix phase) is determined by difference.

Next, a circular test grid is applied to the microstructure without bias and the number of grains of the phase of interest intercepted by the test line,  $N_\alpha$ , is counted. The mean lineal intercept length of the alpha grains,  $l_\alpha$  is determined by:

$$l_\alpha = [(V_V)(L/M)]/N_\alpha \quad (\text{Eq 18})$$

where  $L$  is the line length and  $M$  is the magnification. The ASTM grain size number can be determined from the tables in ASTM E 112 or by use of Eq 17. The method is shown in Fig. 4.

**Fig. 4** Example of grain size measurement for a two-phase alloy using point counting and intercept counting. Micrograph, at 500 $\times$ , of a specimen of alloy Ti-6Al-2Sn-4Zr-2Mo that was forged at 955 °C (1750 °F) in the alpha-beta region and annealed at 970 °C (1775 °F) in the alpha-beta region, producing primary alpha (white) and an alpha-beta eutectoid. The specimen was etched with Kroll's reagent. Point counting was used to determine the amount of equiaxed alpha (48.5%). The three concentric circles have a total circumference of 500 mm. A count is made of the number of equiaxed alpha grains intercepted by the three circles (76). The mean lineal intercept,  $l_\alpha$ , is calculated as follows:  $l_\alpha = (0.485)(500/500)/76 = 0.006382$  mm. The ASTM grain size,  $G$ , is calculated using Eq 17:  $G = -6.646(\log 0.006382) - 3.298 = 11.29$  (round to 11.3 or 11.5).

## Inclusion Content

Assessment of inclusion types and contents is commonly performed on high-quality steels. Production evaluations utilize comparison chart methods such as those described in ASTM E 45, SAE J422a, or the German standard SEP 1570 (DIN 50602). In these chart methods, the inclusion pictures are defined by type and graded by severity (amount). Either qualitative procedures (worst rating of each type observed) or quantitative procedures (all fields in a given area rated) are employed. Only the Japanese standard JIS-G-0555 uses actual volume fraction measurements for rating of inclusion content (although the statistical significance of the data is questionable).

Manual measurement of the volume fraction of inclusions requires substantial effort to obtain acceptable measurement accuracy due to the rather low volume fractions usually encountered (Ref 6). Consequently, extensive use of image analyzers has been made to overcome this problem. Image analyzers separate the oxide and sulfide inclusions on the basis of their gray-level differences. By using automated stage movement and autofocusing, enough field measurements can be made in a relatively short time to obtain good statistical accuracy. Image analysis is also employed to measure the length of inclusions or to determine stringer lengths.

Two image analysis based standards have been developed, ASTM E 1122 and E 1245. E 1122 produces JK ratings that overcome some of the weaknesses of manual JK ratings. E 1245 is a stereological approach defining, for oxides and sulfides, the volume fraction ( $V_V$ ), number per unit area ( $N_A$ ), average length, average area, and the mean free path (spacing in the through-thickness direction). These data are easily databased and statistical in that means and standard deviations are developed so that data can be compared.

## Measurement Statistics

In performing stereological measurements, it is necessary to make these measurements on a number of fields and average the results. Measurements on a single field may not be representative of the bulk conditions, because few (if any) materials are sufficiently homogeneous. Calculation of the standard deviation of the field measurements gives a good indication of measurement variability. Calculation of the standard deviation can be done quite simply with an inexpensive pocket calculator.

A further refinement of statistical analysis is calculation of the 95% confidence limit based on the standard deviation,  $s$ , of the field measurements. The 95% confidence limit is calculated:

$$95\% \text{ CL} = ts/N^{1/2} \quad (\text{Eq 19})$$

where  $t$  is the student's  $t$  value that varies with  $N$ , the number of measurements. Many users standardize on a single value of  $t$ , 2, for calculations irrespective of  $N$ . The measurement value is expressed as the average  $X \pm$  the 95% CL value. This means that if the test were conducted 100 times, the average values would be between plus and minus the average,  $X$ , in 95 of the measurements. Next, one can calculate the relative accuracy, % RA, of the measurement:

$$\% \text{ RA} = (95\% \text{ CL})/X \quad (\text{Eq 20})$$

Usually, a 10% relative accuracy is considered to be adequate. DeHoff (Ref 7) has developed a simple formula to determine how many fields,  $N$ , must be measured to obtain a specific desired degree of relative accuracy at the 95% confidence limit:

$$N = [(200/\% \text{ RA}) - (S/X)]^2 \quad (\text{Eq 21})$$

## Image Analysis

The measurements described in this brief review and other measurements not discussed can be made by use of automatic image analyzers. These devices rely primarily on the gray level of the image on the television monitor to detect the desired features. In some instances, complex image editing can be utilized to aid separation. Some structures, however,

cannot be separated completely; and for these structures, the semiautomatic digital tracing devices can be utilized to improve measurement speed.

## **Summary**

This article reviews many of the simple stereological counting measurements and simple relationships based on these parameters. More complex measurements are discussed at length in Ref 2. The measurements described are easy to learn and use. Their application enables the metallographer to discuss microstructures in a more quantitative manner and reveals relationships between the structure and properties of the material.

## Introduction

WHY CHARACTERIZE MATERIALS? The macro, micro, and surface composition and structure of materials are determined by their processing and service histories. These conditions, in turn, control material properties and performance. Characterization of a material's composition and structure at these levels provides important information that can be used for several purposes:

- *Quality assurance*: to determine whether processing is done properly
- *Failure analysis*: to determine why properties and performance are different than expected
- *Research and product improvement*: to develop an understanding of how processing and service history influence properties and performance, and use this understanding to develop improved materials

This Section describes the principles and applications of a limited number of techniques that are most commonly used to characterize the composition and structure of metals used in engineering systems. More detailed descriptions of a wider range of characterization techniques are given in *Materials Characterization*, Volume 10, *ASM Handbook*, 1986.

## Classification of Materials Characterization Methods

Two useful ways of classifying materials characterization techniques are by the type of information they obtain and the characteristic sample dimensions from which this information is obtained.

When classified by the types of information they obtain, techniques are often classified as the following:

- *Elemental*: What elements are present (qualitative elemental analysis)? In what concentration is each element present (quantitative elemental analysis)?
- *Structural*: How are the atoms crystallographically arranged and spaced? In the case of organic materials, what is the molecular structure?
- *Morphological*: What are the sizes, shapes, arrangements, and appearances of key features, such as grains, cracks, welds, and interfaces?

When classified by the dimensions of material sampled, techniques are frequently categorized as the following:

- *Bulk*: information typically obtained and integrated over surface dimensions on the order of  $10^{-2}$  m or more and depths of at least  $50 \times 10^{-6}$  m, presumably characteristic of the bulk material
- *Micro*: able to obtain information from individual microstructural features, typically able to resolve and characterize features with dimensions of  $10^{-6}$  m or less
- *Surface*: information obtained only from the first atomic layer or so of the sample, such as sampling depths on the order of  $10^{-9}$  m

Table 1 provides an overview of the primary techniques described in this Handbook in terms of these classification schemes. While these methods have been selected primarily based on their applicability to metals, most of them are also readily applicable to other types of inorganic materials, such as ceramics and geologic materials. Polymers and other organic materials are frequently characterized using different analytical techniques.

**Table 1 Classification of characterization methods most commonly used with metals**

Type of analysis	Information obtained/method		
	<b>Elemental</b>	<b>Structural</b>	<b>Morphological</b>
<b>Bulk</b>	X-ray fluorescence spectroscopy (XRF) Optical emission spectroscopy (OES) Combustion/inert fusion analysis (LECO)	X-ray diffraction (XRD)	Macrophotography <sup>(b)</sup>
<b>Micro</b>	Scanning electron microscopy (SEM) Electron probe microanalysis (EPMA) Transmission electron microscopy (TEM)	Transmission electron microscopy (TEM) Scanning electron microscopy (SEM) <sup>(a)</sup>	Metallography (MET) <sup>(b)</sup> Scanning electron microscopy (SEM) Electron probe microanalysis (EPMA) Transmission electron microscopy (TEM)

(a) SEM has not historically been capable of this type of analysis, but recent developments are extending SEM capabilities in this area.

(b) Described in the Section "Metallography" in this Handbook.

## Selection of Materials Characterization Methods

It is very important to keep the previously described categories in mind when selecting appropriate analytical techniques. There is no universal characterization method that tells everything anyone might want to know about a sample. For each problem, a decision must be made regarding the type of information needed. Based on this, a selection must be made of one or more analytical techniques that will provide this information.

Selection and use of inappropriate methods can result in data that are analytically correct but inappropriate to the problem at hand. This misuse usually confounds the problem rather than helps solve it. For example, it would be inappropriate to use a bulk analysis technique in an effort to identify a thin layer of surface contamination on a material. The results would reflect the composition of the underlying material, not the contamination on its surface. Conversely, it would be equally inappropriate to use a surface analytical technique to determine the bulk composition of an alloy. The results would reflect whatever contaminants happened to be present on the surface, rather than the composition of the underlying alloy. In selecting analytical techniques, it is critically important to think through the current problem, determine what type of information is needed, and select one or more analytical techniques that will provide appropriate types of information. Table 1 provides a key resource in this process.

In addition, in cases where several different types of analyses may be needed to solve a problem, it is important to consider the order in which these analyses are performed, as some types of analysis are destructive or alter the sample, making subsequent types of analysis impossible.

## Introduction to Descriptions of Individual Methods

The following articles provide descriptions of the methods most commonly used for characterizing metals. This information is organized into four sections, as represented in Table 1: bulk elemental characterization, bulk structural characterization, microstructural characterization, and surface characterization.

Bulk elemental and bulk structural characterization, which are done using distinctly different techniques, are described in the articles "Bulk Elemental Analysis" and "X-Ray Diffraction for Bulk Structural Analysis," respectively. Many microstructural and surface characterization techniques, described in the articles "Microstructural Analysis" and "Surface Analysis," provide a combination of high resolution imaging of the morphologies of small features plus elemental and/or structural characterization of these features. In many cases, the elemental and structural characterizations done on a micro or surface scale are based on similar principles to those employed in bulk analysis. Hence, to obtain the most complete understanding, the reader is encouraged to read each of these articles in order.

For each method listed in Table 1, a brief overview is provided of the method's capabilities, typical uses and applications, resolution, sensitivity, precision, limitations, sample requirements, operating principles, and capabilities of related techniques. The descriptions of operating principles have been simplified to avoid the more complex physics and chemistry involved. More formal technical descriptions are available in *Materials Characterization*, Volume 10, ASM

*Handbook*, 1986, and in other texts. In cases where the same physical principles are exploited by multiple techniques, these principles are described only in the first technique described. The reader is then referred back to this description in subsequent articles. No descriptions of macrophotography or metallography (light microscopy) are given in this Section; these are covered in the Section "Metallography" in this Handbook.

# Bulk Elemental Analysis

K.H. Eckelmeyer, Microstructural Analysis Department, Sandia National Laboratories

## Introduction

THE OVERALL CHEMICAL COMPOSITION of metals and alloys is most commonly determined by x-ray fluorescence (XRF) and optical emission spectroscopy (OES). While these methods work well for most elements, they are not useful for dissolved gases and some nonmetallic elements that can be present in metals as alloying or impurity elements. High-temperature combustion and inert gas fusion methods are typically used to analyze for dissolved gases (oxygen, nitrogen, hydrogen) and, in some cases, carbon and sulfur in metals.

## X-Ray Fluorescence Spectroscopy (XRF)

### *Capabilities*

- Detection and quantification of elements with atomic number 5 or higher (older energy dispersive units with beryllium window detectors are limited to atomic number 11 or higher)

### *Typical Uses*

- Qualitative and quantitative chemical analysis for major and minor elements in metals and alloys
- Determination of composition and thickness of thin film deposits

### *Detection Threshold and Precision: Energy Dispersive Detectors*

- Threshold sensitivity:  $\sim 0.02\%$
- Precision of quantitative analyses:  $\sim 1\%$  relative or  $0.02\%$  absolute, depending on count time

### *Detection Threshold and Precision: Wavelength Dispersive Detectors*

- Threshold sensitivity:  $\sim 0.005\%$
- Precision of quantitative analyses:  $\sim 0.2\%$  relative or  $0.005\%$  absolute, whichever is greater

### *Amount of Material Sampled*

- *Powders*: Typically several grams pressed into a pellet
- *Bulk solids*: Typically  $\sim 1$  cm diameter spot on surface, sampling depth from 10 to  $100\ \mu\text{m}$  (increases with decreasing average atomic number of sample). Some instruments are designed to map compositional variations, such as segregation in cross-sectioned ingots. These instruments have variable beam diameters down to  $\sim 0.1$  mm, and  $x$ -y stages to translate the sample under the beam.

### *Limitations*

- Elements with low atomic numbers produce very few x-rays and are difficult to detect or quantify, particularly in energy dispersive systems. Wavelength dispersive instruments can go down to atomic

number 5 (boron). Modern energy dispersive systems are limited to atomic number  $\sim 7$  (nitrogen) and above. Older energy dispersive systems cannot readily analyze for elements with atomic number less than 11 (sodium).

- Some combinations of elements are difficult to analyze because of overlapping x-ray energies. Such problems sometimes can be overcome by using wavelength dispersive spectrometers, rather than energy dispersive detectors, or by using optical emission spectroscopy (see the section "Capabilities of Related Techniques" in this article).

## Sample Requirements

- Bulk metal samples typically are ground to produce a flat uncontaminated surface for analysis. Typical samples have dimensions of several centimeters; however, most instruments can accommodate samples 10 cm or more in diameter.
- Powder samples are typically attached to a non-x-ray producing substrate or are pressed into pellets.
- The technique is completely nondestructive.

## Operating Principles

**Physical Basis.** The negatively charged electrons surrounding each atom's nucleus exist in discrete energy levels or orbitals (Fig. 1). Each electron's energy depends on its quantum state (the orbital it is in) and the number of positively charged protons in the atom's nucleus. Electrons with low principal quantum numbers (those close to the nucleus) are tightly bound; they require large amounts of energy to remove them (i.e., to cause ionization). Electrons with higher principal quantum numbers (those farther from the nucleus) are less tightly bound; less energy is required to remove them. Atoms with many positive protons in the nucleus (elements of high atomic number) tend to bind their inner shell electrons more tightly. Atoms with few protons in the nucleus (elements of lower atomic number) are more easily stripped of their inner shell electrons.

**Fig. 1** Excitation of atom in sample by ejection of electrons (photoelectron production), and relaxation of excited atom by electronic transitions and accompanying characteristic x-ray emission

The net result is that each element has a unique set of known electron energy levels. Similarly, the set of energy differences between these electron energy levels is also unique for each element and constitutes a characteristic "fingerprint" by which each element can be identified. In XRF spectroscopy (as well as many other analytical methods), the combined electron energy level "fingerprints" of the elements present in the sample are experimentally obtained and are then compared to the "fingerprints" of known elements. From these comparisons, it is possible to identify the elements and their compositions present in a sample.

When sufficient energy is externally supplied to a sample (of unknown composition), some of the electrons are excited to higher quantum states (energy levels) or removed from the atom (ionization). These "excited" atoms quickly "relax" by electrons from higher energy levels filling the vacated levels. When this happens, photons are emitted whose energies are equal to the differences between the two energy levels involved; this process is called fluorescence. If the energies of these emitted photons are measured, they provide the "fingerprint" of the unknown sample. This measurement can then be compared to the known "fingerprints" of the elements, enabling determination of which elements are present in the sample and the concentration of each element present. Which elements are present can be deduced from the energies of the photons emitted by the sample. How much of each element is present can be deduced from the numbers of photons with energies characteristic of the various elements.

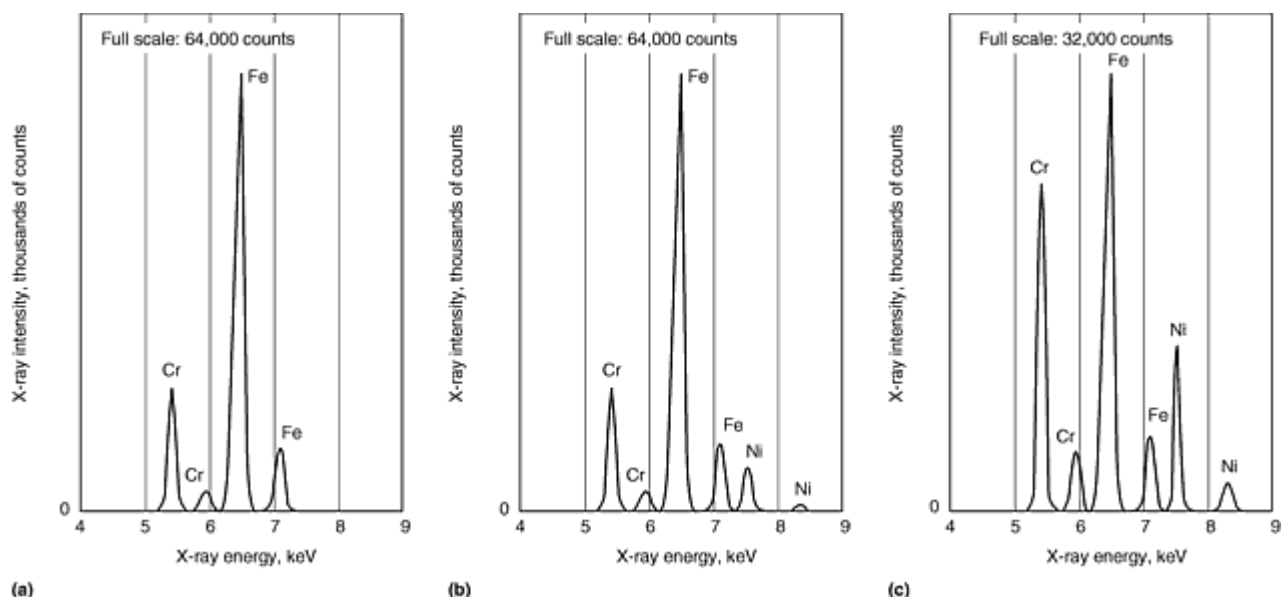

The characteristic energies emitted as excited atoms relax span a range of the electromagnetic spectrum. Electronic transitions between inner shells typically produce x-rays (photons with energies in the 200 to 20,000 eV range, characterized by wavelengths of 6 to 0.06 nm).

**Instrumentation.** A simplified schematic of an XRF spectrometer is shown in Fig. 2. A beam of x-rays is produced by electronic excitation of a metal target in the instrument's x-ray source. The beam's only function is to excite atoms in the sample. As the incident x-ray beam is directed onto the sample surface, it penetrates some small distance into the sample, typically 10 to 100  $\mu\text{m}$ , depending on the atomic numbers of the elements in the sample. Penetration depths are greater for low atomic number elements. The incident x-rays excite atoms in the sample, transitioning some of their inner shell electrons to higher energy levels. As the excited atoms relax, x-ray photons are emitted corresponding to the differences in the characteristic energy levels of the elements in the sample.

**Fig. 2** Schematic of x-ray fluorescence spectrometer. X-rays emitted from the sample are analyzed to determine the characteristic energies (or wavelengths) of x-rays emitted and the intensities of the various characteristic energies

Qualitative analysis (determination of which elements are present) is done by comparing the energies of the x-rays emitted from the sample with the known characteristic x-ray spectra of each element (Fig. 3). Quantitative determination of the concentration of each element present is computed based on the intensities of the various characteristic x-ray energies, also shown in Fig. 3. Quantitative analyses can be most accurate by comparing the x-ray intensities from the unknown sample with their counterparts from a series of standard similar and known compositions. All modern instruments are equipped with computers to facilitate this calibration and measurement process. The use of progressively more powerful computer hardware and software has substantially decreased the need for standards with compositions tailored to specific classes of alloys. Many current analyses are done based only on pure element standards, using the computer to make composition-dependent corrections by iterative means.

**Fig. 3** X-ray fluorescence spectra of (a) Fe-16.4%Cr, (b) Fe-12.3%Cr-12.5%Ni, and (c) Fe-25.7%Cr-20.7%Ni. The iron, chromium, and nickel peaks occur at the same characteristic energies, but the intensities of the peaks increase with concentration. Courtesy of Jim Brangan, Sandia National Laboratories

Due to the dual particle and wave nature of electromagnetic radiation, a simple beam of x-rays can be thought of both as a wave with a characteristic wavelength and a stream of photons each having the same characteristic energy. The photon energy is inversely related to the wavelength by the equation: photon energy =  $hc/\lambda$ , where  $h$  = Planck's constant,  $c$  = velocity of light, and  $\lambda$  = wavelength.

It is important to distinguish between x-ray energy and x-ray intensity. Energy is defined by the energies of the photons or the wavelength of the beam. Intensity is defined by the number of photons or the amplitude (height) of the wave. Of course, many x-ray beams are made up of numerous energies or wavelengths, not just one as described above.

**Wavelength Dispersive versus Energy Dispersive Detectors.** The x-rays emitted from the sample in an XRF spectrometer are detected and analyzed in one of two ways: wavelength dispersive or energy dispersive analysis. In wavelength dispersive instruments, the emitted x-ray beam is directed onto one of several crystals that separates it into its component wavelengths by diffraction (Fig. 4). The diffraction principle is described in the article "X-Ray Diffraction for Bulk Structural Analysis." For current purposes, envision it as similar to separating light into its component wavelengths by passing through a prism. An electronic counter is scanned over the angular range of the spectrometer, and a plot constructed of x-ray intensity versus wavelength (wavelength is calculated from the angle and characteristics of the diffracting crystal). Alternatively, the counter can be set to a series of predetermined wavelengths corresponding to the elements in the sample (presuming this is known or has already been determined), and the numbers of x-rays at each of these wavelengths counted for a specific length of time.

**Fig. 4** Schematic of wavelength dispersive x-ray detector. Detector can mechanically scan a range of angles to produce a plot of intensity vs. wavelength, or it can be set at specific angles corresponding to the characteristic wavelengths of elements known to be in the sample, counting the x-ray intensity at each angle.

In energy dispersive instruments, the emitted x-ray beam is analyzed electronically, photon by photon (Fig. 5). The x-ray beam is directed into a semiconductor device (a lithium-drifted silicon crystal). As each x-ray photon enters the detector crystal, it creates numerous electron-hole pairs as it expends its energy interacting with the atoms in the detector. These electrons and holes are collected and counted at positive and negatively biased sides of the detector. The energy of the photon is determined from the number of electron-hole pairs it creates (proportional to the energy of the photon). The detector electronics sense when each photon enters the detector and require that a photon's energy be analyzed before accepting input from any additional photons. Typically, several thousand photons are analyzed per second. As these energies are measured, a histogram of the numbers of photons counted corresponding to each energy is plotted on a cathode ray tube. The result is a digital plot of intensity versus energy, similar to what is obtained from wavelength dispersive spectrometers (Fig. 6).

**Fig. 5** Schematic of energy dispersive x-ray detector. Detector measures the energy of each incoming x-ray photon by counting the number of electron-hole pairs it produces. A histogram is then developed and plotted of the x-ray energies of the many (typically tens to hundreds of thousands) photons measured during the counting period.

**Fig. 6** Superimposed spectra of BaTiO<sub>3</sub> obtained from EDS and WDS systems (WDS spectrum replotted on energy scale, rather than wavelength). Note that the WDS spectrum has much sharper lines, thus enabling resolution of nearby peaks that overlap one another on EDS spectrum. Note also that the WDS spectrum has less background noise. Source: C. Brundle, C. Evans, and S. Wilson, *Encyclopedia of Materials Characterization*, Butterworth-Heinemann, 1992, p 128

Wavelength dispersive spectrometers (WDS) predate energy dispersive spectrometers (EDS), but each has inherent advantages. The primary advantage of energy dispersive systems is speed. They can collect a complete spectrum with several hundred thousand counts in approximately one minute. However, wavelength dispersive systems have superior energy resolution (this can be important for separating signals from elements whose characteristic emission energies are very close to one another), as well as improved signal-to-noise ratios. As a result, energy dispersive systems are ideally suited for performing routine qualitative analyses, as well as quantitative analyses where speed is more important than the highest possible precision. On the other hand, difficult qualitative analyses and the most precise quantitative analyses can best be performed on the slower wavelength dispersive systems.

**Fine Beam Instruments.** Some XRF instruments are specifically designed to characterize compositional uniformity and to map compositional variations within a sample. Such instruments typically are capable of collimating the incident x-ray beam to smaller diameters (as low as  $\sim 0.1$  mm), thus enabling operator-defined adjustment of lateral spatial resolution. In addition, the sample is usually mounted on an x-y stage that automatically translates it to the successive measurement points. The results of sequential analyses performed over a predefined trace on the sample are presented as a plot of composition versus position. Similarly, the results of many analyses performed over a predefined area are typically presented as a computer-generated color-coded two-dimensional map of composition versus position. This map provides a method for characterizing chemical inhomogeneities on a spatial resolution scale midway between the  $\sim 1$  cm range of "bulk XRF" and the  $\sim 1$   $\mu$ m scale of electron probe microanalysis, for example, characterizing segregation patterns in cross-sectioned ingots.

### **Capabilities of Related Techniques**

**Optical Emission Spectroscopy (OES)** operates on the same atomic principles but bases its analyses on visible light, rather than x-rays. It has somewhat better sensitivity than XRF and better detection for some light elements, such as carbon. Some combinations of elements that exhibit interferences in the x-ray regime are free of interferences in the visible light regime and can be better analyzed by OES.

**Combustion and vacuum fusion analysis** is well suited to measuring gaseous impurities in metals.

**Electron probe microanalysis (EPMA)** operates on the same atomic principle as XRF, but it uses a focused electron beam to excite and generate x-rays in very small portions of the sample. It can thus be used to perform quantitative analyses on features as small as several micrometers and to generate quantitative elemental maps with several micrometer spatial resolutions.

# Optical Emission Spectroscopy (OES)

## **Capabilities**

- Detection and quantification of most elements (poor sensitivity for halogens, hydrogen, nitrogen, oxygen, and noble gases).

## **Typical Uses**

- Qualitative and quantitative elemental analyses of major, minor, and trace elements in metals and alloys.

## **Detection Threshold and Precision**

- Threshold sensitivity on the order of tens of parts per million (ppm): 0.001 to 0.01%
- Precision of quantitative analyses: photographic instruments,  $\sim 5\%$  relative or 0.05% absolute, whichever is greater; direct reading and charge coupled device (CCD) instruments,  $\sim 1\%$  relative or 0.01% absolute, whichever is greater
- Lower threshold sensitivity and greater precision can be achieved with related techniques

## **Limitations**

- Elements such as hydrogen, oxygen, nitrogen, halogens, and noble gases cannot be analyzed quantitatively.
- Carbon and sulfur can only be measured in instruments equipped with vacuum chambers and in cases where the sample has not been powdered and mixed with these elements.
- Some combinations of elements are difficult to determine because of overlapping energies in the visible light region.

## **Amount of Material Sampled**

- *Powders*:  $\sim 1$  g (entire sample)
- *Bulk solids*: About 5 mm diameter surface spot, sampling depth  $\sim 100 \mu\text{m}$

## **Sample Requirements**

- *Metal samples* are typically ground to produce a flat uncontaminated surface for analysis. Most direct reading instruments can accommodate solid metal samples 10 cm or more in size. The technique is nondestructive except for the  $\sim 5$  mm diameter surface blemishes produced by the arc.
- *Nonconductive samples* are typically powdered and then mixed with a conductive low-atomic number material, usually graphite. Samples as small as  $\sim 10 \mu\text{g}$  of powder (conductive or non-conductive) can be analyzed in this way.

## **Operating Principles**

**Physical Basis.** Optical emission spectroscopy operates on the same atomic principles as XRF spectroscopy, except that analyses are based on visible light, rather than x-rays. Visible light is produced by transitions between electrons in outer-shells (far from the nucleus), while x-rays are produced by inner-shell transitions. Photons of visible light have much lower energies than x-rays (1.5 to 4 electron volts for visible light, compared to 200 to 20,000 electron volts for x-rays), and correspondingly much longer wavelengths ( $\sim 800$  to  $\sim 300$  nm for visible light, compared to 6 to 0.06 nm for x-rays).

The energies of the outer shell electrons on which OES is based can be substantially influenced by the surrounding atoms to which they are bonded in solid samples. As a result, these bonds need to be completely broken for OES spectra to

appropriately reflect the energies of the elements present in the sample. This break occurs by supplying sufficient energy to vaporize and decompose a portion of the sample into its component atoms, as well as to excite the atoms in this plasma.

**Instrumentation.** The external energy is frequently supplied by striking an electrical arc to the surface of the solid sample (Fig. 7). The arc vaporizes a small portion of the sample and ionizes the atoms, producing a plasma. Photons are emitted corresponding to the differences in the characteristic energy levels of the elements in the plasma. The visible light portion is analyzed by passing it through a grating to separate it into its various component wavelengths (similar to separating white light into its component wavelengths by passing it through a glass prism). The resulting spectrum is recorded and compared to the spectra of known elements to determine what elements are present. The concentrations of each element present are deduced from the intensities (numbers of photons) corresponding to each characteristic wavelength. Quantitative determination of the concentration of each element present is done by comparing the intensities from the unknown sample with their counterparts from a series of standards of known concentration.

**Fig. 7** Schematic of optical emission spectrometer. Light emitted from the vaporized and excited portion of the sample are analyzed to determine the characteristic wavelengths of light emitted and the intensities of the various characteristic wavelengths.

**Photographic Instruments.** Two methods have historically been used for recording the spectra and analyzing the data, but both of these are currently being replaced by a third method based on newer technology. In photographic emission spectroscopy, the various emitted wavelengths and intensities coming from the grating are directly recorded on a photographic plate. The elements present and their concentrations are deduced by direct visual comparison of the spectrum from the sample and spectra from standards of known composition. This process can be made more quantitative by using a densitometer to read the plates and compare the spectra. Photographic optical emission spectroscopy is readily used for both qualitative and quantitative analysis. Major and minor alloying additions can be readily detected and quantified. Trace elements can typically be detected and quantified down to the 10 to 100 ppm (parts per million) range.

**Direct Reading Instruments.** Direct reading emission spectrometers have more often been used in cases where particular combinations of elements must be routinely and frequently quantified, such as in measuring the compositions of heats being produced by an aluminum ingot production facility. In these instruments, photomultiplier tubes are set up at the wavelength positions corresponding to each element of interest. These tubes measure the intensities of light obtained from the sample at each predetermined characteristic wavelength and input the results to a computer. The computer then compares these intensities to the corresponding intensities from various standards of known composition (which are already stored in its memory) and calculates the composition of the sample in a matter of seconds. This facilitates rapid quantitative analysis of samples of unknown but similar composition. Because they are only set up to analyze for specific preselected elements and over commonly encountered composition ranges, direct reading emission spectrometers are not useful for qualitative or quantitative analysis of broader ranges of samples.

**Instruments with CCD Detectors.** Both of the previously described methods of detection are now being supplanted by CCD detectors (a high-resolution array of solid state light detectors). These detectors take the place of photographic plates and electronically record both the location (wavelength) and intensity (brightness) of the light emitted from the sample. The output of the CCD detector is input to a computer, which constructs a histogram of intensity versus wavelength. The computer also facilitates comparison of the observed wavelengths with the known characteristic wavelengths of each element, thus providing for qualitative determination of which elements are present in the sample. In addition, the computer can make quantitative determinations of the concentrations of each element present from the

intensities of the emitted light at various characteristic energies. These determinations can be made based on comparison with calibrated standards (measured by the instrument and stored in the computer memory) or based on pure element standards. Analyses based on calibrated standards are typically used in cases where greater accuracy and precision are required. In essence, then, an instrument equipped with a CCD detector is like a direct reading instrument with a semi-infinite number of detectors positioned at every wavelength of possible interest, which provides a rapid and powerful capability for both qualitative and quantitative analysis.

### ***Capabilities of Related Techniques***

**Inductively coupled plasma atomic emission spectroscopy (ICP/AES)** operates on the same atomic principle. However, solid samples are dissolved into liquid solutions that are then aspirated into an argon plasma. This process provides greater flexibility, as liquid standards can be made of essentially any combination of elements, including combinations that cannot be obtained in solid form. ICP can be used for both qualitative and quantitative elemental analysis. Its detection limits are lower than those of other OES methods; however, because the solid sample must be dissolved (and diluted) in a liquid, the effective detection limits for analyzing solid samples are similar.

**Inductively Coupled Plasma Mass Spectroscopy (ICP/MS)**. This combined technique provides better detection limits for trace elements, in some cases down to the parts per trillion range. The dissolved sample is aspirated into the plasma and ionized. Ions from the plasma are then input to a mass spectrometer that determines which elements are present in the plasma. The increased sensitivity of the mass spectrometer provides for lower detection limits, typically in the parts per billion range.

**Atomic absorption spectroscopy (AAS)** operates on the same atomic principle as OES, but it measures the intensity of light absorbed by the liquid sample aspirated into a flame or graphite furnace, rather than the light emitted. Flame AAS has similar sensitivity to OES. Graphite furnace AAS exhibits better sensitivity for trace elements, similar to ICP/MS, but is simpler and less expensive to set up and operate. Only one element can be measured at a time because single wavelength light sources are used for each element, which makes AAS inappropriate for qualitative analysis.

**X-ray fluorescence spectroscopy (XRF)** operates on similar physical principles to OES, but it excites the sample using x-rays rather than thermal energy and analyzes the x-rays emitted from the sample rather than the visible light. XRF is completely nondestructive and can be used for both qualitative and quantitative analysis. It provides a good complement to OES, because the interferences (overlapping energies) in the x-ray regime are different from those in the visible light regime. It is not as sensitive as OES for analyzing trace elements. Detection limits are typically in the 100 to 1000 ppm range.

## **Combustion and Inert Gas Fusion Analysis**

### ***Capabilities***

- Detection and quantification of carbon, sulfur, and dissolved gases

### ***Typical Uses***

- Quantitative analysis of the amounts of carbon, sulfur, and dissolved gases in metals

### ***Detection Threshold and Precision***

- Threshold sensitivity: In the vicinity of 50 ppm (0.005%) for sulfur, 10 ppm (0.001%) for carbon, 1 ppm for oxygen, nitrogen, and hydrogen
- Precision of quantitative analyses: sulfur, ~20% relative or 0.005% absolute, whichever is greater; carbon, ~5% relative or 0.001% absolute, whichever is greater; oxygen, nitrogen, and hydrogen, ~5% relative or 0.0001% absolute, whichever is greater

### ***Amount of Material Sampled***

- Entire sample (typically  $\sim 1$  g)

### **Limitations**

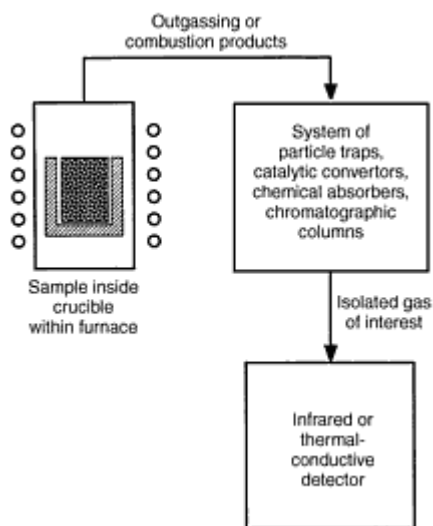

- Samples containing highly stable nitrides or oxides require special treatment.
- Metals with low boiling points require special treatment.

### **Sample Requirements**

- Solid samples in the range of 0.1 g to several grams are usually machined to fit into the sample cups of the instrument. It is desirable to use regular shapes with small ratios of surface area to volume in order to minimize the contributions of surface adsorbed gases to the results.
- Samples should be cleaned immediately prior to analysis.
- These methods destroy the sample.

### **Operating Principles**

A schematic diagram of the similar high-temperature combustion and inert gas fusion processes is shown in Fig. 8. Small samples of known weight are heated to very high temperatures. The elements of interest are driven off as either elemental gas or gaseous oxidation products. These gaseous products are then separated and detected, permitting quantification of their concentrations in the original samples.

**Fig. 8** Schematic of combustion/inert gas fusion apparatus

For many years, the LECO Corporation has been a primary manufacturer of equipment for high-temperature combustion and inert gas fusion analysis. As a result, these analyses are frequently lumped together and referred to as "LECO" analyses. The use of this common term in this article should not be taken as an endorsement of LECO Corporation instruments or as an indication that other sources of similar equipment are not available.

In the case of combustion analysis for carbon or sulfur, the sample is induction or resistance heated to  $\sim 1400$  °C (2550 °F) in oxygen, which causes the sample to be completely oxidized. The metal oxides are left as solid, but the carbon and sulfur form CO, CO<sub>2</sub>, and SO<sub>2</sub>, which are liberated as gases. These gases are then passed through a series of traps, absorbers, and converters to separate them and remove interfering elements. They are then quantified using detectors based on either thermal conductivity or absorption of infrared light.

In the case of inert gas fusion for oxygen, nitrogen, or hydrogen, the sample is heated by either induction or by passing a high current through it to  $\sim 3000$  °C (5450 °F) in an inert gas. The dissolved gases are driven off at this extremely high temperature. In some cases, these gases combine with other elements in the system; for example, oxygen reacts with carbon to form CO or CO<sub>2</sub>. The liberated gases and/or reaction products are then passed through a series of particle traps, catalytic converters, gas chemical absorbers, and chromatographic columns to separate and purify them. They are then quantified using detectors based on either thermal conductivity or absorption of infrared light, as in combustion analysis.

### ***Capabilities of Related Techniques***

**X-ray fluorescence spectroscopy (XRF)** can analyze nondestructively for carbon and sulfur but with higher detection limits and reduced precision.

**Optical emission spectroscopy (OES)** can analyze less destructively for carbon and sulfur, but with higher detection limits and reduced precision.

**Hot extraction high vacuum analysis** is similar to inert gas fusion, but gases are liberated at lower temperatures (without destroying sample). Gas evolution can be monitored as a function of time or temperature, thus permitting separation of internally dissolved and surface adsorbed gases.

# **X-Ray Diffraction for Bulk Structural Analysis**

## **Introduction**

X-RAY DIFFRACTION (XRD) is the most extensively used method for identifying and characterizing various aspects of metals related to the arrangements and spacings of their atoms. XRD techniques are equally applicable to other crystalline materials, such as ceramics, geologic materials, and most inorganic chemical compounds.

## **Overview of X-Ray Diffraction**

### ***Capabilities***

- Determination of crystal structure, lattice parameters, and interplanar spacings in crystalline materials
- Characterization of defect densities and crystallite sizes
- Characterization of preferred crystallographic orientations in polycrystalline samples
- Determination of orientations of single crystals

### ***Typical Uses***

- Identification of phases or compounds present in metals, ceramics, corrosion products, etc.
- Quantitative determination of fractions of each phase in multi-phase mixtures, such as retained austenite in steel
- Determination of lattice parameters and changes in lattice parameters due to alloying and temperature effects
- Measurement of residual stresses
- Characterization of crystallite size and perfection
- Detection of order and disorder transformations
- Characterization of preferred orientations, such as rolling textures in sheet
- Determination of single crystal orientations
- Determination of crystal structure and lattice parameters of new compounds (not described in this article)

## Operating Principles

**Physical Basis.** When an x-ray beam is directed onto a crystalline sample, a number of additional nonparallel beams emerge from the sample. The angles at which these beams emerge and their relative intensities provide information about the lattice geometry, orientations, and arrangements of atoms in the crystal(s) that make up the sample.

The incoming or incident x-ray beam consists of electromagnetic radiation, an electric field traveling at the speed of light whose strength varies sinusoidally with time at any point in the beam. When an x-ray beam is directed onto a metal sample, it penetrates some distance into the sample, typically 10 to 100  $\mu\text{m}$ , depending on the atomic numbers of the elements in the sample. Penetration depth increases with decreasing atomic number. As it penetrates, the beam interacts with the electrons associated with the atoms that make up the sample. A small fraction of these electrons are excited to higher energy states, as described in the section "X-Ray Fluorescence Spectroscopy" in the article "Bulk Elemental Analysis."

Most electrons remain unexcited but are set into oscillatory motion around their centers by the sinusoidally varying electric field of the incident beam. Each oscillating electron, in turn, emits electromagnetic radiation of the same wavelength as the incident beam. This emitted radiation goes out radially from the electron over the entire  $360^\circ$  solid angle. In effect, each electron acts as an x-ray scattering center, sending out concentric waves of x-rays with wavelengths equal to that of the incident beam (Fig. 1).

**Fig. 1** Electron scattering of x-rays. Each electron acts as a scattering center, sending out in all directions x-rays with the same wavelength as the incident beam.

By summing the contributions of the scattered beams from all of the electrons, it is possible to predict the angular distribution of the x-rays emitted from the sample. The mathematics of this summing process is not as overwhelming as it might first appear. Because the electrons are associated with atoms, each atom can be considered to be the net scattering center corresponding to all of its electrons. The additional fact that the atoms are crystallographically arranged in a three-dimensional periodic array makes the summing problem mathematically tractable. The net result is that constructive interference occurs and results in a strong diffracted beam. However, this reaction occurs only when the following equation, known as Bragg's law, is satisfied:  $n\lambda = 2d \sin\theta$ , where  $n$  = any integer,  $\lambda$  = wavelength of incident and diffracted beams,  $d$  = spacing of adjacent diffracting planes in the crystalline sample, and  $\theta$  = angle between incident beam and diffracting plane, as well as between the diffracting plane and the diffracted beam.

Bragg's law can be understood in terms of Fig. 2. Consider atom A in plane I and atom B in the adjacent plane II. Geometric construction shows that the difference in total path length is equal to  $2d \sin\theta$ . The exiting beams, A and B, will constructively interfere with one another when they are  $360^\circ$  out of phase with one another, or when  $\lambda$ , the wavelength of the incident and diffracted beams, is equal to the pathlength difference. Constructive interference will also occur if beams A and B are  $720^\circ$  or any multiple of  $360^\circ$  out of phase; hence, the general condition for constructive interference is Bragg's law, as given above.

**Fig. 2** Bragg's law, which defines the conditions for constructive interference and the angles at which diffracted beams of x-rays will be emitted from a crystalline assembly of atoms

The simple two-plane summation (Fig. 2) predicts perfectly constructive interference (maximum net diffracted intensity) at angles that result in beams A and B being  $360^\circ$  out of phase with one another. Similarly, perfectly destructive interference (zero net diffracted intensity) at angles result in beams A and B being  $180^\circ$  out of phase with one another. At other intermediate angles, beams A and B would be neither completely in phase nor out of phase with one another. So it would seem that partial constructive interference would occur, resulting in a diffracted beam intensity that varied continuously with the angle. In reality, however, this summation must be done over hundred or thousands of adjacent planes, not just two. When additional planes are included in the summing process, the outcome is virtually complete destructive interference (zero diffracted intensity) at all angles except those that satisfy Bragg's law.

Figure 2 depicts only the simplest type of atomic planes. In reality, many sets of planes can be defined, each with its own characteristic interplanar spacing, as shown for a simple two-dimensional lattice in Fig. 3. An even greater variety of planes can be defined in a three-dimensional lattice. Each of these sets of planes can give rise to diffraction. As a result, numerous diffracted beams are produced in most XRD analyses, each of these beams being associated with a particular set of planes in the crystalline sample.

**Fig. 3** Various planes of atoms defined in simple two-dimensional "crystals." Each plane is defined by its Miller indices, computed from the reciprocals of its intersections with the x- and y-axes. Each plane has a characteristic interplanar spacing. Source: Ref 1

Crystal planes are typically identified by Miller indices. The indices of a given plane are defined as the reciprocals of the fractional intercepts that the plane makes with the primary crystallographic axes. Figure 3 shows this principle for the simple case of a two-dimensional lattice. Several low-index planes in three-dimensional lattices are also shown in Fig. 4.

**Fig. 4** Planes in three-dimensional crystals defined by their Miller indices. Source: Ref 2

In simple crystal structures (e.g., cubic), planes with various combinations and permutations of the same indices have identical interplanar spacings. These spacings are referred to as types of planes. For example, in a cubic crystal (112), (121), (211), (-112), (-211), etc., all spacings are referred to as planes of the type {112}.

A number of different types of information can be determined from XRD experiments. The primary types of analyses and their uses are described in the following sections, along with information about the threshold sensitivity and precision, limitations, sample requirements, and capabilities of related techniques.

## Identification of Compounds and Phases Using X-Ray Powder Diffraction

### Typical Uses

X-ray powder diffraction is used to identify the crystalline phases present in a sample. Examples of the types of questions that can be answered using x-ray powder diffraction include:

- Is a heat treated steel sample 100% martensite, or does it contain some retained austenite?
- What compounds are present in the corrosion product that formed when an aluminum alloy was exposed to sea spray?
- What compounds are present in the scale formed on a ingot during high-temperature forging?

Solving these types of problems by x-ray powder diffraction is the most common use of XRD in metallurgy.

### Experimental Approach

In x-ray powder diffraction, an x-ray beam of a single known wavelength is used to determine the interplanar spacings of the planes in the sample. The sample is typically polycrystalline, ideally containing a semi-infinite number of randomly oriented crystals. Bragg's law dictates that each set of crystal planes will diffract at its own characteristic  $\theta$  angle. Once these  $\theta$  angles at which diffraction occurs have been experimentally determined, the interplanar spacings corresponding to each of them can then be calculated by substituting these angles and the known wavelength of radiation used into Bragg's law. The resulting set of interplanar spacings provides a "fingerprint" of the sample that can be compared to the

"interplanar spacing fingerprints" of over 100,000 known compounds, thus permitting identification of the compound(s) present in the sample.

The results of a typical x-ray powder diffraction analysis are shown in Fig. 5. The plot of diffracted intensity versus diffraction angle exhibits a number of peaks, each corresponding to a particular set of crystallographic planes and its characteristic  $d$ -spacing. The most important information is the angle at which diffraction occurs. The relative intensities of the peaks are determined by a number of factors beyond the scope of this article. Suffice it to say that, for a sample made up of randomly oriented crystals of a given metal or compound, the relative intensities of the various diffraction peaks are predictable and reproducible within a few percent. However, these intensities are of secondary importance in solving the powder diffraction pattern.

Fig. 5 X-ray powder pattern of  $\text{Al}_2\text{O}_3$ . Source: Ref 1

The pattern can also be summarized as a table of  $d$ -spacings (each corresponding to a  $\theta$  angle) and corresponding intensities, typically expressed as a percentage of the most intense peak, as shown in Tables 1(a), 1(b), and 1(c).

#### Table 1(a) Identification of powder diffraction pattern from $\text{Al}_2\text{O}_3$ using the Hanawalt search method

The diffracting angles and intensities (area under each peak) are measured from the unknown sample (in this example from the diffractometer trace in Fig. 5).  $d$ -spacings are then calculated for each diffraction peak using Bragg's law and the known wavelength of radiation used (in this case,  $\text{Cu K}\alpha$ ,  $\lambda = 1.54178 \text{ \AA}$ ).

The *d*-spacings corresponding to the most intense peaks from the sample are then compared with a database of known compounds ordered by the *d*-spacings of their most intense peaks, resulting in a tentative identification of the sample. A set of 25 compounds with similar intense peaks is shown below. Note that the 8 most intense peaks for Al<sub>2</sub>O<sub>3</sub> correspond to intense peaks from the sample pattern given in Table 1(a).

**Table 1(c) Hanawalt search method**

A card containing all of the information for the tentatively identified compound is compared with the diffraction information from the sample. The card for Al<sub>2</sub>O<sub>3</sub> is shown below. Note that all of the diffraction peaks in the sample pattern can be accounted for by Al<sub>2</sub>O<sub>3</sub>. If unidentified lines were present, it would indicate either that the tentative identification was incorrect, or that one or more additional compounds were present in the sample along with Al<sub>2</sub>O<sub>3</sub>. The information on the card enables identification of the Miller indices of the planes associated with each diffraction peak, shown in the last column of Table 1(b).

Historically, results such as those presented in Tables 1(a), 1(b), and 1(c) were compared with the  $d$ -spacing and intensity fingerprints for  $\sim 100,000$  known compounds--each tabulated on an index card and organized systematically by the  $d$ -spacings of the several most intense peaks. This search and match process is now greatly facilitated by computers that contain all of the information on known compounds in an updatable database. The search is based primarily of the  $d$ -spacing information, rather than the intensities, because the assumption that the sample consists of randomly oriented crystals is frequently violated, thus altering the intensities.

## Samples Containing Multiple Phases or Compounds

Identification of metals and compounds by x-ray powder diffraction is relatively straightforward when the sample consists of a single phase or compound. When multiple phases or compounds are present, however, the task is more complex, as multiple "fingerprints" are superimposed on one another. Fortunately, software is available to analyze and solve such complex patterns. Solution of complex overlapping patterns can be simplified by providing additional information to the computer regarding what elements are, are not, and may be in the sample. This information is typically obtained by x-ray fluorescence spectroscopy. Once this elemental information has been input, the software searches only compounds that are consistent with it.

Once the phases or compounds present in a multi-phase sample have been identified, the percentages of each phase or compound present can be deduced from the relative intensities of their diffraction peaks. A common metallurgical example is the determination of the amount of retained austenite present in heat treated steels. The most precise analyses are based on comparison of results from the unknown with those from a number of calibrated standards.

## Instrumentation

X-ray diffraction analyses have historically been conducted using two types of equipment: the Debye-Scherrer camera and the x-ray diffractometer. The Debye-Scherrer camera is used for powdered samples (Fig. 6). The camera is a light-tight hollow cylinder with a removable cover plate. The powdered sample is placed in a hollow capillary tube at the center of the camera. A strip of photographic film is then placed around its inside perimeter, and the cover plate is applied. The camera is then attached to an x-ray generating tube and the x-rays are directed onto the sample through a collimator. The diffracted x-rays are recorded on the film, which is developed following 1 to 4 h of x-ray exposure (Fig. 7). The  $\theta$  angles are measured from the film and converted to  $d$ -spacings. Intensities are either estimated by eye or quantified using a densitometer.

**Fig. 6** Schematic of Debye-Scherrer powder method. (a) Relationship of film to sample, incident beam, and diffracted beams. (b) Appearance of film when developed and laid flat. Source: Ref 3

**Fig. 7** Debye-Scherrer films identifying phases in copper-zinc alloys of various compositions. Source: Ref 2

The x-ray diffractometer avoids the use of film and is far better suited to automation. The sample is flat, typically either a polished metal surface or a powder adhered to a flat glass slide. The sample is exposed to the incident x-ray beam, and a counter is scanned over the desired range of  $\theta$  angles (Fig. 8). The result is a plot of diffracted intensity versus diffraction angle (Fig. 5).

**Fig. 8** Schematic of x-ray diffractometer. Typically, the x-ray tube remains stationary while the detector mechanically scans a range of  $\theta$  angles. The sample also rotates with the detector such that diffraction is recorded from planes parallel to the sample surface.

In recent years, position-sensitive wire detectors and solid state charge coupled device (CCD) detectors (in essence, a high resolution array of solid state light sensors) have permitted all of the diffracted signals to be collected simultaneously, thus overcoming the need to mechanically scan a detector scintillation counter over the range of diffraction angles. This method of collection greatly increases the speed with which diffraction information can be obtained, and it provides a digital electronic format that is amenable to computer-assisted data reduction and analysis.

## **Detection Threshold and Precision**

- Threshold sensitivity: A phase or compound must typically represent 1 to 2% of the sample to be detected
- Precision of interplanar spacing and lattice parameter measurements:  $\sim 0.3\%$  relative in routine measurements; within  $\sim 0.003\%$  relative in experiments optimized for this purpose
- Precision of quantitative analyses of percentage of individual phases or compounds present in samples containing multiple compounds: 5 to 10% relative or 1 to 2% absolute, whichever is greater (presumes the use of calibrated standards)

## **Amount of Material Sampled**

- Powdered samples: Entire sample
- Polished bulk materials: Typically  $\sim 1$  cm square area, sampling depth usually in the range 10 to 100  $\mu$ m (increases with decreasing average atomic number)

## **Limitations**

- Noncrystalline samples produce no diffraction peaks
- Results represent average of many grains or crystals in the sample, not an individual particle. Fine beams (down to  $\sim 100$   $\mu$ m diameter) can be used to characterize some individual particles.

## **Sample Requirements**

- *Powders*: 10 mg is typically enough
- *Flat metal samples*: Diffractometers can usually accommodate samples with lateral dimensions up to 5 cm and thicknesses up to 5 mm. Ideally, the surface should be free of deformation in order to get sharp diffraction peaks. Chemical or electropolishing can be used to remove the last vestiges of deformation in mechanically ground and/or polished samples.

## **Measurement of Lattice Parameter Changes due to Alloying or Temperature**

The addition of alloying elements, heating or cooling, and residual stresses cause slight changes in interplanar spacings, which cause slight shifts in the  $\theta$  angles at which diffraction occurs. XRD can be used to quantify these changes.

Changes resulting from solid solution alloying can be determined using a diffractometer, as described earlier. Similarly, temperature effects can be characterized using a diffractometer equipped with a furnace to heat the sample to the desired temperature.

The systematic errors inherent in XRD measurements decrease with increasing diffraction angle. As a result, lattice parameter measurements are typically based on information obtained at high diffraction angles. The most precise lattice parameter measurements make use of curve-fitting procedures to extrapolate information to the limiting  $\theta$  value of  $90^\circ$ .

## **Precision**

- $\sim 0.03\%$  relative with moderate care
- $\sim 0.003\%$  relative with the greatest care

### ***Sample Requirements***

- Identical to those indicated above for routine diffractometer examination

## **Measurement of Residual Stresses**

X-ray residual stress measurement is substantially more complex, but its key principles are not difficult to understand. Residual stresses are most often introduced during heat treating or welding and are caused by differential thermal contraction associated with temperature gradients in the material. These stresses cause elastic strains in the material, which manifest themselves as slight departures from the material's normal (unstressed) lattice parameters or interplanar spacings. XRD measurement of these changes in interplanar spacings, then, provides a direct measure of elastic strain, which can be used to calculate residual stress magnitude using the known elastic constants of the material.

Because residual stresses must be calculated from small stress-induced changes in interplanar spacing, it is critical to know precisely the interplanar spacings in an unstressed sample of the material in question. The planes that happen to be parallel to and very close to the free surface provide an internal calibration in this regard, because no stresses can be supported perpendicular to a free surface. The problem then becomes one of comparing the interplanar spacings of planes parallel to the free surface with those inclined at various angles to the surface, and using the pertinent equations of elasticity to calculate from these differences the magnitudes of the stresses in various directions parallel to the surface. From this, the principal in-plane stresses directions can be calculated.

### ***Instrumentation***

Residual stresses are typically measured using an x-ray diffractometer equipped with a special specimen holder designed to facilitate measurement of diffraction from planes inclined at various angles to the surface of the sample. (General purpose diffractometers obtain diffraction information only from planes that are parallel to the sample surface. See Fig. 8.) Portable x-ray systems are also frequently used to make field stress measurements on structural components.

Residual stresses vary with position in the component, so measurements are frequently made at numerous locations. The spatial resolution of these measurements is defined by the diameter of the x-ray beam used. The diameter is typically in the vicinity of 1 cm, but it can be as small as 30  $\mu\text{m}$ .

### ***Precision***

- $\sim 5\%$  relative or  $\sim 5$  MPa absolute, whichever is higher (in ideal laboratory conditions)
- Less precise information is obtained when portable x-ray equipment used for residual stress measurement of non-ideal structural components

### ***Limitations***

- Because XRD obtains information from the near-surface region of the sample, it only provides surface stress information and is not capable of measuring stresses in the interiors of components.

### ***Capabilities of Related Techniques***

**Neutron diffraction** residual stress measurement is based on the same principles as XRD. Because neutrons penetrate metals to far greater depths, it is possible to measure stresses in the interior of samples, rather than only surface stresses. However, a neutron source is required, so such measurements cannot be made in the field.

## Characterization of Crystal Size and Defect Density from Peak Width and Shape

When Bragg's law was discussed earlier, it was noted that the angular range over which significant diffracted intensity is obtained depends on the number of adjacent planes from which diffracted beams are summed. In the extreme case of only two adjacent planes, diffracted intensity would be maximum at the angles satisfying Bragg's law (where perfectly constructive interference occurs). However, it would vary continuously with diffraction angle, only being zero at the angles where perfectly destructive interference occurs, which would result in very broad diffraction peaks. On the other hand, when the beams scattered by a semi-infinite number of adjacent planes are summed, constructive interference and significant diffracted intensity are only obtained at angles that exactly satisfy Bragg's law. In this case, very narrow diffracted beams are obtained. Intermediate between these extremes, the width of diffraction peaks increases with decreasing crystal size. Peak broadening becomes significant as crystal size decreases below  $\sim 0.5 \mu\text{m}$ .

Most cast or wrought metals have sufficiently large grain sizes to justify the assumption that summing occurs over a semi-infinite number of adjacent planes, hence, narrow diffraction peaks are obtained. Phases formed by low-temperature deposition processes and solid state transformations, however, frequently have much finer grains whose sizes can be estimated from the widths of their diffraction peaks (Fig. 9).

**Fig. 9** Effect of crystallite size on peak width. Source: Ref 1

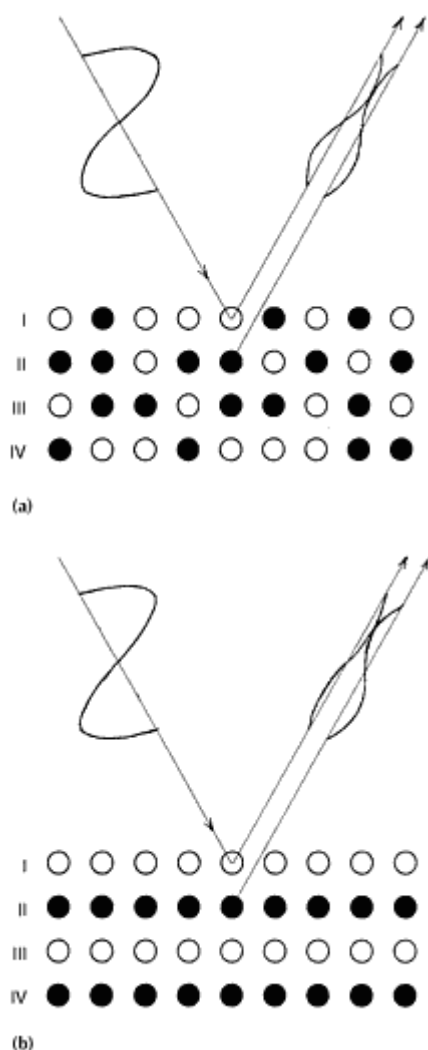

Crystal defects, such as dislocations and stacking faults, also interrupt the long-range periodicity of the crystal lattice, thus resulting in relaxation of the conditions for diffraction and broadening of diffraction peaks (Fig. 10). Analysis of peak width and shape (the details of the intensity versus diffraction angle data) can be used to obtain information on the densities of such defects in the sample.

**Fig. 10** Effect of dislocations introduced by cold working and removed by annealing on width of diffraction peaks in brass. Source: Ref 1

Peak width and shape measurements are typically made from the output of an x-ray diffractometer. The results of such analyses are useful as semiquantitative indicators of crystallite size and defect density, but typically lack quantitative precision.

Certain alloys exist as random solid solutions (atoms A and B randomly substituting for one another in identical lattice positions) at high temperature, but ordered compounds (atoms A and B arranged in specific nonrandom patterns) at lower temperature (Fig. 11). Such ordering can give rise to additional diffracted beams, thus enabling ordering to be detected and characterized by XRD.

**Fig. 11** Principles of diffraction from random and ordered solid solutions. (a) Random solid solution: All planes have equal numbers of A and B atoms, hence equal average scattering power, scattered beams from planes I and II are  $180^\circ$  out of phase and equal in amplitude, so net diffracted intensity is zero. (b) Ordered compound: Adjacent planes are made up entirely of A and B atoms, so they have unequal scattering powers. Scattered beams from planes I and II are  $180^\circ$  out of phase but unequal in amplitude, so net diffracted intensity is not zero (diffracted beam is obtained).

Because x-rays are scattered by their interactions with electrons, atoms of higher atomic number serve as more powerful scattering centers than those with lower atomic numbers. Consider Fig. 11, in which the filled circles represent A atoms of low atomic number and low scattering power, whereas the open circles represent B atoms of high atomic number and higher scattering power.

In a random solution (Fig. 11a), successive planes I, II, III, etc. will all have identical fractions of A and B atoms, so the amplitudes of the x-rays scattered from adjacent planes will be identical. If, as shown in Fig. 11(a), the beams scattered from adjacent planes are  $180^\circ$  out of phase with one another, perfect destructive interference will occur, and no diffracted beam will result.

If ordering occurs so that successive planes have different fractions of A and B atoms, as shown in Fig. 11(b), planes II and IV will have greater scattering power than planes I and III. This increased scattering will result in different amplitudes for the beams scattered from adjacent planes. Because their amplitudes are different, only partial destructive interference will occur between beams that are  $180^\circ$  out of phase with one another. As a result, a diffracted beam will be observed. The presence of extra "superlattice" lines in a diffraction pattern--diffraction at angles where no diffraction occurs for the random solid solution--is indicative of the solution becoming ordered (Fig. 12). Studies of ordering are typically conducted using Debye-Scherrer cameras or diffractometers.

**Fig. 12** Debye-Scherrer patterns for ordered and disordered Cu-25Au (at.%). (a) Ordered  $\text{Cu}_3\text{Au}$  compound obtained by slow cooling from 450 °C (840 °F); note extra "superlattice lines" not present in random disordered solid solution. (b) Random solid solution obtained by quenching from 500 °C (930 °F). Source: Ref 4

## Limitations

The intensities of these superlattice lines depends on the difference in atomic scattering power between the A and B atoms. In cases where these atoms have greatly different atomic numbers, the amplitudes of the beams scattered from adjacent planes are markedly different, so interference is far from perfectly destructive and the superlattice lines are moderately intense. In cases where the A and B atoms have nearly identical atomic numbers, however, the amplitudes of the beams scattered from adjacent planes are only slightly different. So nearly perfectly destructive interference occurs, and the superlattice lines have such low intensities that they frequently cannot be detected.

## Capabilities of Related Techniques

**Neutron diffraction** can be used to detect and characterize ordering in cases of atoms of similar atomic number. Neutron diffraction is based on the same principles as XRD, but scattering occurs based on nuclear interactions, rather than interactions with electrons. As a result, neutron scattering power does not vary regularly with atomic number, and atoms with similar atomic number frequently have greatly different neutron scattering powers. This provides for more intense neutron diffraction superlattice lines in ordered compounds involving atoms of similar atomic number.

## Characterization of Preferred Orientations (or Textures)

As noted in the section "Identification of Compounds and Phases Using X-Ray Powder Diffraction," predictable and reproducible intensities are obtained for the diffracted beams corresponding to particular sets of planes in a given material, provided the sample consists of randomly oriented grains. However, there are many causes of nonrandomness in grain orientation. In bulk metals, preferred orientations are frequently caused by metal working operations, such as rolling, forging, or drawing. Thin films deposited by methods, such as electroplating, plasma deposition, and chemical vapor deposition, also tend to grow in particular crystallographic directions. The properties of materials exhibiting preferred orientations tend to be anisotropic. For example, the forming behavior of sheet metal varies depending on the nature and degree of the preferred orientation produced by the previous rolling operations: the degree of working, the temperatures at which it was done, whether the sheet was unidirectionally rolled or cross rolled, etc. XRD provides a means of characterizing such nonrandom orientations or textures.

## Instrumentation and Characterization

The simplest way to characterize nonrandom crystallographic orientation is to merely note the degree to which the diffracted intensities from different sets of planes parallel to the surface vary from what would be expected in an ideal sample containing no preferred orientation. For example, a rolled plate in which the diffracted intensity from the {111} planes was 10 times that of a randomly oriented sample would be said to have a {111} texture, or a strong tendency to have the {111} planes aligned parallel to the surface.

A more complete description of preferred orientation can be obtained by doing an x-ray diffractometer experiment in which the incident beam and the detector are set to measure diffraction from a preselected type of plane. A specialized sample holder is used to rotate the sample through a wide range of orientations, and the diffracted intensity is measured as a function of orientation relative to the prior rolling plane and direction. The results are frequently presented in the form of a topologic map on a hemispherical projection, termed a pole figure and shown in Fig. 13. The "contour" lines denote the degree to which the plane of interest tends to be aligned in a particular orientation relative to the prior working axes. Idealized orientations are often then associated with the preferred orientation.

**Fig. 13** X-ray pole figure characterizing nonrandom distribution of  $\{111\}$  poles (plane normals) in sample from rolled sheet. Contours indicate pole densities of 1, 2, 3, 4, and 5 times those in a randomly oriented sample. Numbers indicate local maxima. Courtesy of Mike Eatough, Sandia National Laboratories

In recent years, the orientation distribution function (ODF) has been developed to more uniquely characterize the nature of preferred orientations. The ODF is geometrically equivalent to the combined information presented in pole figures corresponding to several different types of planes, but it is superior in that it provides a quantitative analytical description of the probability of particular grain orientations.

## Determination of Single Crystal Orientations

### *The Laue Technique*

The Laue technique employs an x-ray beam of continuously varying wavelength to determine the orientation of a single crystal sample of known crystal structure. Referring to Fig. 2, it can be seen that for a stationary single crystal sample in which  $d$ -spacings and diffraction angles are fixed, the right hand side of Bragg's law has a single completely defined value for each type of plane. If an incident beam with a single x-ray wavelength is used, diffraction only occurs in the fortuitous case where this wavelength (or its multiple) happens to equal one of these values, making both sides of Bragg's law equal. In general, this is not the case, so typically no diffracted beams are obtained. If the incident x-ray beam consists of a continuous range of wavelengths, however, diffraction can occur from each of the set of planes in the crystal (each set of planes "choosing" the wavelength that satisfies Bragg's law). The result is a set of diffracted beams whose arrangement is identical to what would result from a beam of light being reflected from the various types of plane in the crystal.

### *Instrumentation*

The most common experimental arrangement is the back-reflection Laue arrangements shown in Fig. 14. The x-ray beam is directed through a collimator onto the single crystal sample, and diffraction occurs from numerous crystal planes. The sample is usually mounted on a goniometer that permits it to be rotated into the desired orientation based on the results of the Laue experiment. Historically, the diffracted beams have been recorded on a flat piece of photographic film that is

developed following the experiment. In recent years, CCD cameras have been replacing film, permitting electronic data collection and computer automated reduction of the diffraction information.

Fig. 14 Schematic showing back reflection Laue geometry

The symmetry of the resulting pattern is characteristic of the orientation of the crystal, as can be seen in Fig. 15. Comparison of the angular relationships between different spots makes it possible to determine the Miller indices of the planes corresponding to each spot.

Fig. 15 Back reflection Laue photographs showing (a) low-index high symmetry orientation where the  $\langle 001 \rangle$  axis of the unit cell (in this case, cubic) is parallel to the beam (normal to the film). Note symmetry about  $180^\circ$  diffraction position at center of film. (b) Higher index orientation (note lower symmetry). Courtesy of Mike Eatough, Sandia National Laboratories

### Precision

- Routinely within 0.5 degrees
- Within 0.02 degrees under carefully controlled conditions

# Microstructural Analysis

K.H. Eckelmeyer, Microstructural Analysis Department, Sandia National Laboratories

## Introduction

MICROSTRUCTURAL ANALYSIS is the combined characterization of the morphology, elemental composition, and crystallography of microstructural features through the use of a microscope. Light microscopes have been used to characterize the microstructures of metals for over 100 years. The methods and applications of light microscopy are covered in the Section "Metallography" and will not be repeated here. While light microscopy is an important metallurgical tool, it has a number of limitations:

- *Spatial resolution:* Conventional light microscopes cannot resolve features smaller than  $\sim 1 \mu\text{m}$ .
- *Depth of field:* Light microscopes cannot image rough surfaces--samples must be flat in order to be in focus.
- *Type of information provided:* Light microscopes provide images and morphological information, but they do not provide any direct chemical or crystallographic information about the microstructural features observed.

During the past 50 years, however, several types of electron microscopy have been developed and refined to greatly extend our ability to resolve and characterize the morphologies of much smaller microstructural features, to image rough surfaces, and to obtain direct chemical and crystallographic information about microstructural features.

This article reviews the three types of electron microscopies most commonly used in metallurgical studies: scanning electron microscopy, electron probe microanalysis, and transmission electron microscopy.

## Scanning Electron Microscopy (SEM)

### *Capabilities*

The scanning electron microscope provides a valuable combination of high resolution imaging, elemental analysis, and recently, crystallographic analysis:

- Imaging of features as small as  $\sim 10 \text{ nm}$  or less, roughly 100 times smaller than can be seen with light microscopes
- Imaging of rough surfaces
- Qualitative and semi-quantitative elemental analyses on microstructural features as small as  $\sim 2 \mu\text{m}$
- Identifying crystalline compounds and determining crystallographic orientations of microstructural features as small as  $\sim 1 \mu\text{m}$  (recently developed capability--not currently widely used, but likely to become so)

### *Typical Uses*

- Characterizing fracture surface micro-appearance and determining the nature of the fracture process (dimple rupture, cleavage, fatigue, intergranular environmentally enhanced fracture, etc.)
- Quality assurance examination of microelectronic devices, interconnections, bonds, etc.
- Detecting the onset of corrosion in small components and characterizing corrosion products
- Resolving fine microstructural features on polished and etched metallographic samples
- Performing qualitative and semi-quantitative elemental analyses on microstructural features, contaminant particles, etc.
- Identifying microstructural phases and compounds by their crystal structures

- Characterizing preferred crystallographic orientations by analysis of orientations of individual grains

### ***Spatial Resolution***

- Secondary electron imaging of surface topography:  $\sim 10$  nm
- Backscattered electron imaging of atomic number contrast:  $\sim 1$   $\mu\text{m}$
- X-ray characterization of elemental chemistry:  $\sim 2$   $\mu\text{m}$  using typical beam voltages of  $\sim 20$  kV (much better resolution,  $\sim 100$  nm, can be obtained using low voltage beams)
- Electron diffraction characterization of crystal structure and orientation:  $\sim 1$   $\mu\text{m}$

### ***Elemental Analysis Detection Threshold and Precision***

- Threshold sensitivity for elemental analysis using EDS detector:  $\sim 1\%$
- Precision of quantitative elemental analysis using EDS detector:  $\sim 10\%$  relative or 2% absolute, whichever is greater

### ***Limitations***

- Energy dispersive detectors used for chemical analysis have difficulty detecting and analyzing elements with atomic numbers less than  $\sim 7$  (nitrogen); older instruments with beryllium window detector cannot detect elements with atomic numbers lower than  $\sim 11$  (sodium).

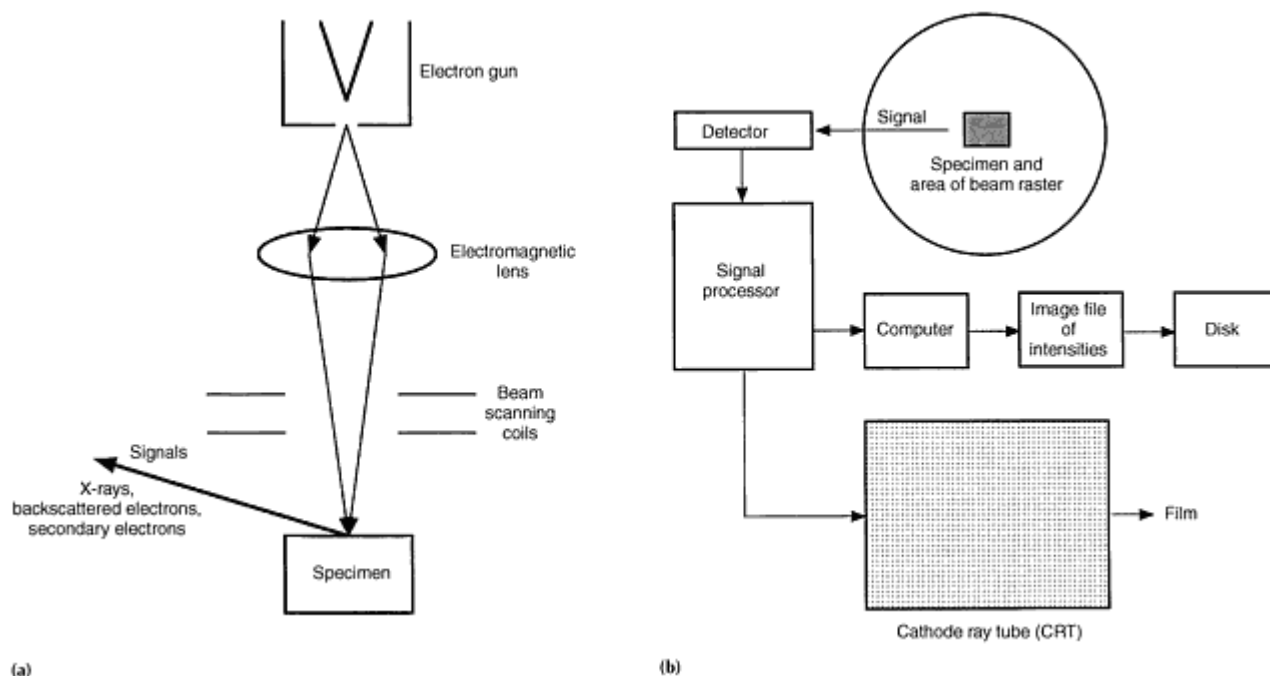

### ***Sample Requirements***

- Sample size up to  $\sim 5$  cm can be accommodated by most SEMs, and SEMs equipped with large sample chambers can readily accommodate considerably larger samples, such as 15 and 20 cm silicon wafers from microelectronics production lines.
- No preparation is typically required for clean metal samples.
- Nonconductive samples or samples with marginally conductive surface regions must be coated with a thin layer of conductive material. A thin gold-palladium layer is typically sputtered onto samples intended for imaging only, whereas a thin carbon layer is typically vacuum evaporated onto samples where x-ray microanalysis will be performed.

### ***Operating Principles***

**Instrumentation.** A simplified schematic of an SEM is shown in Fig. 1. Electrons are produced by one of several types of sources at the top microscope column. These electrons are accelerated down the column by a voltage differential in the electron gun (typically in the range of 1,000 to 50,000 V). The column must be kept under vacuum while the microscope is operating. As the beam passes down the microscope column, it is focused by variable strength electromagnetic lenses to a fine spot (in some cases as small as  $\sim 1$  nm) on the surface of the sample using the  $x$ -axis and  $y$ -axis electromagnetic beam scanning coils. The raster rate can be varied by the operator--one complete pass over the area of interest can take as little as  $\frac{1}{60}$  s (typically used for lower resolution screening of various areas on the surface), or as long as 20 s (typically used for higher resolution photographing of an area of interest). Several types of detectors are used to monitor the various signals emitted from each spot on the sample as the beam impinges on it. The outputs of these detectors are electronically processed and used to modulate the intensity of the spots on a cathode ray tube (CRT) whose scan is synchronized with that of the electron beam's raster on the sample surface. The result is a television-type image of the portion of the sample surface being scanned by the beam. Portions of the surface that produce strong response signals appear bright on the CRT, while portions that produce weak response signals appear dark.

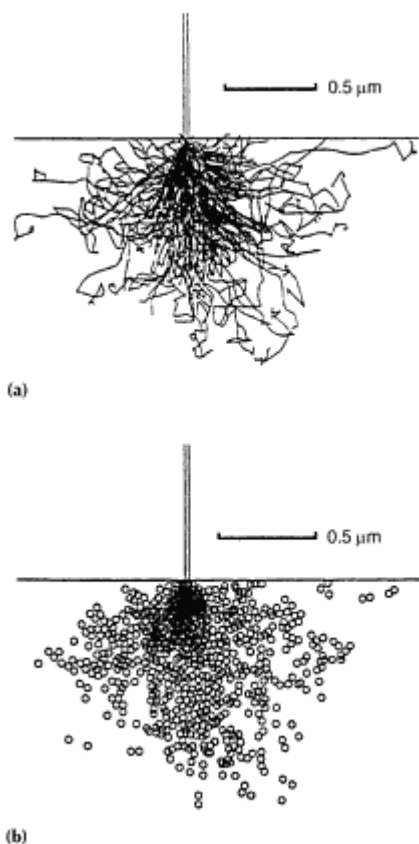

**Fig. 1** Schematic of a scanning electron microscope. (a) Electron beam produced and focused to a fine spot on sample surface. Scanning coils enable the position of the beam to be rastered across a selected portion of the sample surface. Signals produced by the sample at the point where the beam impinges include secondary electrons, backscattered electrons, and characteristic x-rays. (b) Detected signals are collected, amplified, and used to modulate the intensity of a cathode ray tube, whose raster is synchronized with that of the beam.

The images viewed on the CRT have historically been recorded photographically, but in recent years are increasingly being recorded electronically. Such electronic recording facilitates electronic image enhancement, quantification of the sizes and shapes of features appearing on the images, electronic transmission of images to other locations, and electronic incorporation of images into reports.

As can be seen from the above description, the SEM really is not a microscope in the classical sense—it has no lenses that magnify the image. The sole purpose of the magnetic lenses is to focus the beam to a very small spot on the sample surface. The magnification of the image is defined by area on the sample surface over which the electron beam is rastered and the size of the CRT screen on which the image is displayed. Magnification is increased simply by decreasing the area over which the beam is rastered, or decreased by increasing the area over which the beam is rastered.

Several types of signals can typically be detected and used to generate images on the CRT. The images corresponding to these different signals reveal different types of information. The three primary types of signals and images, secondary electrons, backscattered electrons, and x-rays, are described in the following paragraphs.

**Beam-Sample Interactions.** When the incident electron beam impinges on the surface, it penetrates a short distance into the sample, interacting with the atoms in the sample as it penetrates. Typical penetration distances range from one to several micrometers depending on the atomic numbers of the elements in the sample (greater penetration depths for low atomic number elements, lesser depths for high atomic number elements) and the incident beam accelerating voltage (greater penetration for higher accelerating voltages). The beam spreads out as it penetrates, typically resulting in a pear-shaped interaction volume (Fig. 2).

**Fig. 2** Monte Carlo simulations of the interaction volume of a 20 keV primary electron beam in an iron sample. (a) Electron trajectories. (b) Sites of K-shell ionizations and production of characteristic x-rays. Source: Ref 1

Two important types of interactions occur between the incident electrons and the sample's atoms, resulting in the three primary signals (Fig. 3). Some of the incident electrons interact with the electrons associated with the atoms of the sample, "knocking them out" of the conduction band and other orbitals, and generating secondary electrons. The atoms from which electrons have been removed are now in "excited states" and "relax" as electrons from higher energy levels fill the vacated sites. Each of these relaxation events is accompanied by the release of energy equal to the difference in energies between the two atomic energy levels involved. Transitions involving inner shell electrons often result in the generation of x-ray photons. This is identical to the atomic process described in the section on x-ray fluorescence spectroscopy in the article "Bulk Elemental Analysis." As in x-ray fluorescence spectroscopy, the energies of these x-rays can be compared to the known characteristic energies of each element, enabling the atoms in the sample to be chemically identified, as illustrated in Fig. 3 of that same article. Each incident electron typically interacts with tens to hundreds of atoms before its energy is eventually expended. Each time an incident electron interacts with an atom in this way, its path is deflected somewhat. This accounts for the spreading of the beam as it enters the sample and the pear-shaped interaction volume, as illustrated in Fig. 2 of the article "Bulk Elemental Analysis." Other incident electrons interact with the much heavier nuclei of the atoms in the sample. These electrons typically "bounce back," as would a ping pong ball striking a bowling ball. For obvious reasons, these are termed backscattered electrons.

**Fig. 3** Interaction of the primary electron beam with atoms in the sample resulting in backscattered primary electrons, secondary electrons, and characteristic x-rays

**Secondary Electron Imaging of Surface Topography.** Secondary electron images provide information on the topography of the same--a "picture" of the portion of the sample surface over which the beam is being rastered. The secondary electrons generated in the sample have relatively low energies, on the order of a few electron volts (eV). As a result, only the secondary electrons produced close to the sample surface (within  $\sim 10$  nm) are able to escape from the sample. Secondary electrons produced deeper in the interaction volume interact with other atoms, dissipate their energies, and are absorbed before reaching the surface (Fig. 4). The secondary electrons emitted from the sample are attracted to the secondary electron detector by a positive bias of several hundred volts. Because the secondary electrons have kinetic energies of only a few electron volts, their paths are easily influenced by this bias, and a high percentage of them enter the detector and are counted.

**Fig. 4** Regions in the interaction volume from which various signals escape. SE, secondary electrons; BSE backscattered electrons

The number of secondary electrons exiting the sample is controlled mostly by the local geometry of the surface at the point where the incident beam impinges on it. As can be seen in Fig. 5, when the beam impinges on a rough sample at the top of a sharp peak, a great deal of the interaction volume is within  $\sim 10$  nm of a free surface, hence a very large number of secondary electrons exit the sample and are collected by the detector. The resulting intense signal results in a bright spot on the CRT. Conversely, when the incident beam impinges at the bottom of a deep valley, very little of the interaction volume is within  $\sim 10$  nm of a free surface, hence a very few secondary electrons exit the sample, resulting in a dark spot on the CRT. For inclined surfaces, the number of escaping secondary electrons increases with increasing angle of inclination (Fig. 5).

**Fig. 5** Effect of local surface geometry on secondary electron signal strength. Cross section of rough surface illustrating that strongest secondary electron signals originate from tops of sharp peaks, strength of secondary electron signal decreases with increasing angle between the primary beam and the sample surface, and weakest secondary electron signals originate from deep holes.

The net result is that, in secondary electron images, sharp peaks appear brightest, highly inclined edges appear somewhat less bright, portions of the surface perpendicular to the beam appear darker, and the bottoms of deep recesses appear darkest. This is very similar to the pattern of contrast that results when inclined visible light impinges on a macroscopically rough surface. Our brains are accustomed to "processing" images with this type of contrast, and correctly interpret secondary electron images as topography or pictures of the sample's surface.

These principles of secondary electron contrast are apparent in the SEM photograph of a dimpled fracture surface, shown in Fig. 6. The surface consists of cup-shaped dimples, each corresponding to a microscopic failure event, and sharp ridges where adjacent failure events joined. The secondary electron image reveals the ridges as bright, the inclined dimple walls as less bright, and the perpendicular dimple bottoms are darker.

**Fig. 6** Secondary electron image of dimples on ductile fracture surface. Source: Ref 2

Because secondary electrons are collected from only the top  $\sim 10$  nm of the sample where very little beam spreading has occurred, each digital examination point on the sample surface can be quite small and still be distinct from neighboring examination points. As a result, it is possible to resolve adjacent surface features with dimensions of  $\sim 10$  nm by secondary electron imaging or less under special conditions. State of the art instruments with field emission electron guns have  $\sim 1$  nm secondary electron imaging resolution. Furthermore, the primary requirement for a sharp image is that the incident beam be focused to sharp spot on each digital examination point at which it impinges on the surface. Because the cone angle of the focused beam can be made quite small, it is possible to satisfy this requirement simultaneously for both peaks and valleys on relatively rough surfaces. This provides outstanding depth of field, which is the ability to focus simultaneously on both the highs and lows of rough surfaces.

In addition to imaging naturally rough surfaces, such as metal fractures, secondary electron imaging can also be used to examine the surfaces of polished and etched metallographic samples. The fact that secondary electron imaging can resolve features  $\sim 100$  times smaller than can be resolved by light microscopy enables SEMs to use higher magnifications to characterize fine microstructural features that cannot be resolved by light microscopy (Fig. 7).

**Fig. 7** Secondary electron image of polished and etched sample of Fe-0.8%C showing details of pearlite (A and B) growing into austenite (transformation interrupted by quenching). Source: Ref 3

**Backscattered Electron Imaging and Atomic Number Contrast.** Backscattered electron images, on the other hand, provide contrast based on differences in average atomic number of different portions of the sample. Because backscattered electrons result from direct collision of light incident electrons with the heavy nuclei of atoms in the sample, it is not surprising that the strength of the backscattered electron signal increases with increasing nuclear mass, that is, with increasing atomic number. Backscattered electrons exit the sample with kinetic energies similar to those for the incident electrons (thousands of electron volts), so their paths are essentially unaffected by the few hundred volt bias of the secondary electron detector. Backscattered electrons are typically collected by solid state annular detectors placed above the sample to maximize the number of electrons that can be collected in a line-of-sight fashion. Backscattered electron images display portions of the sample surface with relatively high average atomic number as bright; portions of the sample surface with lower average atomic number appear darker (Fig. 8).

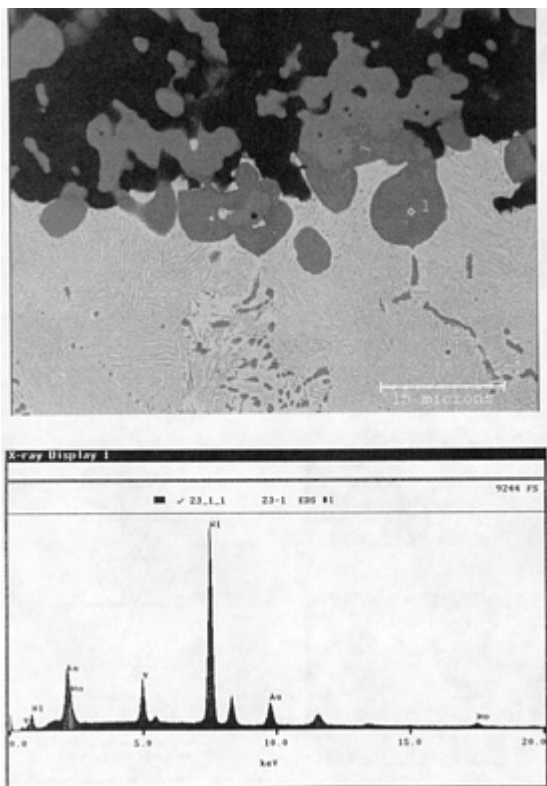

**Fig. 8** Backscattered electron image showing atomic number contrast in as-cast Cu-Al-Mg alloy. Brightest areas represent phases containing the greatest concentration of high atomic number copper. Darker areas represent phases of progressively lower average atomic number. Courtesy of Joe Michael, Sandia National Laboratories

Because backscattered electrons have higher kinetic energies than secondary electrons, they can escape from far deeper in the interaction volume. Because the beam diverges as it penetrates in the sample, backscattered electron image spatial resolution is not as good as that of secondary electron images. Backscattered electron resolution is typically  $\sim 1\ \mu\text{m}$ , similar to that of light microscopy. This resolution can be improved to  $\sim 100\ \text{nm}$  by using low voltage beams. Excellent depth of field is retained with backscattered electron imaging, for the same reason discussed for secondary electron imaging.

**X-Ray Detection and Elemental Microanalysis.** X-rays provide information on which elements are present in small portions of the sample. The atomic principles by which the characteristic x-rays are generated are identical to those discussed in the section on x-ray fluorescence spectroscopy in the article "Bulk Elemental Analysis," except that excitation is provided by the incident electron beam, rather than an incident x-ray beam. In effect, then, the scanning electron microscope provides a mini-x-ray spectrometer with a very fine incident beam that can be used to probe the chemistries of very small operator-selected portions of the sample.

Many scanning electron microscopes are equipped with an energy dispersive x-ray detector. The operation and characteristics of EDS detectors are described in the section on x-ray fluorescence spectroscopy in the article "Bulk Elemental Analysis." This detector and the associated electronics provide a histogram of the x-ray energies emitted from the sample. As with bulk x-ray spectroscopy, the characteristic x-ray energies observed tell which elements are present, and the relative intensities of the various characteristic x-ray peaks provide information on the relative concentrations of the elements present, as illustrated in Fig. 3 of that same article.

X-ray spectra can be collected either from an area on the surface defined by the beam's  $x$ - $y$  raster, or from an individual point by stopping the raster and adjusting the scan coils to move the beam to the desired location on the sample surface. In either case, x-rays are typically collected for tens to hundreds of seconds, and the x-ray histogram displayed on a second CRT, rather than the CRT used for imaging. The results of most analyses are displayed as secondary electron images with x-ray spectra corresponding to particular features of interest (Fig. 9).

**Fig. 9** Backscattered electron image of 82%Au-15.5%Ni-1.75%V-0.75%Mo active braze alloy joined to Mo-Al<sub>2</sub>O<sub>3</sub> cermet. Accompanying x-ray spectrum obtained from area 1 shows the phase forming at the interface to be rich in nickel and vanadium. Courtesy of Bonnie McKenzie, Sandia National Laboratories

If desired, a single x-ray energy can be selected corresponding to an element of interest, the instrument returned to the scanning mode, and an image generated in which the brightness is modulated by the concentration of this element at each point on the raster. The resulting x-ray maps can provide exceptionally useful information on how various elements are distributed in the sample, particularly when taken in conjunction with secondary electron or backscattered electron images. However, because energy dispersive x-ray detectors are characterized by a moderate level of background noise, the x-ray maps they generate are not as high in quality as ones generated when the x-rays are analyzed using wavelength dispersive crystal spectrometers. (See Fig. 4-6 in the section "X-Ray Fluorescence Spectroscopy" of the article "Bulk Elemental Analysis" for discussion of the strengths and weaknesses of these different types of x-ray detectors.) Scanning electron microscopes are occasionally equipped with a wavelength dispersive detector to facilitate x-ray mapping, but more often such mapping is done using an electron probe microanalyzer, as will be described in the next section.

Characteristic x-ray escape the sample from the entire interaction volume (Fig. 4). As a result, the spatial resolution for x-ray microanalysis is on the order of several micrometers. It is a common misconception that SEMs can perform chemical analyses with the same resolution as secondary electron imaging. While surface features as small as  $\sim 10$  nm can be "seen" by secondary electron imaging, chemical analyses of such features really provide elemental information on not only the feature itself, but the entire several micrometer volume surrounding it.

As with bulk x-ray fluorescence spectroscopy, only elements with atomic numbers of  $\sim 7$  or greater can be readily detected and analyzed. Elements with lower atomic numbers produce very few x-rays, and the x-rays produced have very low energies and are easily absorbed. Older instruments equipped with beryllium window detectors are limited to elements with atomic numbers of 11 or higher because the low energy x-rays produced by lower atomic number elements are mostly absorbed in the detector window. More modern ultrathin window detectors enable detection of elements down to atomic number  $\sim 5$ . Lower atomic number elements must be detected by other means, as will be described in the section on Auger electron microscopy.

**Diffacted Beams and Crystallographic Microanalysis.** Recent developments have also made it possible to collect and analyze crystallographic information from features observed in the SEM. The divergent beam of characteristic x-rays generated as the incident electron beam penetrates the sample can also be diffracted from the portion of the sample in the immediate vicinity of the beam interaction zone. The resulting diffraction pattern, termed a Kossel pattern, is particularly useful for measuring interplanar spacings with high precision. The precise interplanar spacing information can, in turn, be used to measure residual stresses in individual grains. The divergent beam of backscattered electrons also has a wave character and can similarly diffract from the planes in the surrounding grain. The resulting electron diffraction pattern, termed a Kikuchi pattern, is analogous to the x-ray Kossel pattern, but is made up of straight lines that are easier to index. These Kikuchi patterns can be used to identify crystalline phases (similar to x-ray powder diffraction but based on a different diffraction geometry), as well as to determine orientation distribution functions in a grain-by-grain fashion. These Kossel and Kikuchi patterns can be readily solved and interpreted by computer methods. An example of a Kikuchi pattern and its computer assisted solution are shown in Figure 10. Most SEMs are not yet equipped to perform these types of crystallographic analyses, but it is likely that these powerful capabilities will become more commonly available.

**Fig. 10** Kikuchi pattern identification of sigma phase in stainless steel following exposure to elevated temperature. (a) Backscattered electron image. Arrow indicates the dark sigma phase identified by the Kikuchi patterns. (b) Backscattered electron Kikuchi pattern. (c) Computer solution of Kikuchi pattern. Courtesy of Joe Michael, Sandia National Laboratories

**Voltage Contrast and Analysis of Microelectronic Devices.** Additional types of specialized imaging can also be done with scanning electron microscopes. Several types are particularly useful in examining and analyzing active microelectronic devices. For example, because secondary electrons escape from the sample with kinetic energies of only a few electron volts, the strength of the secondary electron signal will vary substantially with the voltages presenting various parts of an operating electrical device. For the simplest case of a DC device in which potential differences of a few volts exist, more secondary electrons will be emitted from negatively biased portions, and fewer from positively biased portions. In the secondary electron image, then, the negatively biased portions will appear bright and the positively biased portions will appear dark. In the more complex case of microelectronic circuit operating at high frequency, strobe-like "pictures" of the circuit's operation can be obtained by rapid "blanking" of the incident beam synchronously with the device, such that each "picture point" on the secondary electron image corresponds to the same "phase" in the circuit's operation. A series of such "strobe images" can be taken corresponding to successive phases in the circuit's operation, showing the potentials of different conduction lines and circuit elements at each phase, which provides a powerful tool for troubleshooting microelectronic circuits.

### ***Capabilities of Related Techniques:***

**Electron probe microanalysis** is very similar to SEM, but usually equipped with several crystal spectrometers for wavelength dispersive x-ray analysis. This provides greatly improved capabilities for quantitative microanalysis, x-ray mapping, and characterizing elemental profiles in the vicinities of interfaces. Flat polished samples are required in order to take full advantage of quantification capabilities.

**Transmission electron microscopy** provides markedly better spatial resolution for imaging and x-ray microanalysis, and provides for crystallographic analysis by electron diffraction. Crystallographic analysis methods are more highly developed than those for SEM. Sample preparation is tedious, and only very small portions of the sample can be viewed.

**Scanning Auger Microscopy** can perform microanalyses on low atomic number elements down to lithium (atomic number 3). Analyses originate from very near surface region (first few atomic layers), so sample surfaces must be atomically clean or results will be representative of surface contaminants rather than the underlying sample.

## Electron Probe Microanalysis (EPMA)

### *Capabilities and Typical Uses*

The electron probe microanalyzer (frequently termed the electron microprobe) is essentially a scanning electron microscope that has been optimized to perform high quality elemental microanalyses. Historically, the two instruments were developed separately and for different purposes, but as they evolved they became increasingly similar. While most SEMs are primarily imaging instruments to which rapid elemental microanalysis capabilities have been added, electron microprobes are primarily quantitative microanalyzers that are capable of imaging the areas being analyzed. Electron microprobes are used primarily for the following:

- Quantitative microanalyses of microstructural features
- Quantitative elemental profiling of compositional gradients (similar to Fig. 22b, but with  $\sim 1 \mu\text{m}$  spatial resolution)
- X-ray mapping to show how elements of interest are concentrated or depleted in different micro-areas or microstructural features (Fig. 11)

**Fig. 11** Electron microprobe elemental map showing distributions of elements in stranded wire soldered to a terminal pin. (a) Backscattered electron image. (b-h) Elemental maps showing locations and concentrations of iron, nickel, copper, silver, tin, gold, and lead, respectively. Source: Ref 3

### ***Operating Principles and Instrumentation***

The electron microprobe and scanning electron microscope operate on identical principles. The key differences are that electron microprobes are typically equipped with several crystal spectrometers to facilitate wavelength dispersive x-ray analysis. Qualitative analysis is typically performed using an energy dispersive x-ray analysis. Qualitative analysis is typically performed using an energy dispersive x-ray detector, but subsequent quantitative analyses are done using the wavelength dispersive crystal spectrometers (WDS). As described in the section on x-ray fluorescence spectroscopy in the article "Bulk Elemental Analysis" and illustrated in Fig. 4-6, wavelength dispersive x-ray analysis has several advantages over energy dispersive analysis:

- Much better signal-to-noise ratio, which facilitates qualitative analysis and the generation of much higher quality x-ray maps
- Better separation of x-rays with similar energies (or wavelengths), which enables elements that are difficult to distinguish with EDS detectors, such as molybdenum and sulfur, to be unequivocally identified and quantified
- Better detection of low atomic number elements that produce small numbers of low energy x-rays. Electron microprobes can identify and semi-quantify elements with atomic numbers in the 4 to 7 range, which are more difficult to detect and analyze with EDS systems.

Other key factors to be considered include:

- Electron microprobes have high and very stable beam currents to maximize x-ray counting statistics and minimize variations in x-ray generation rate associated with instrumental fluctuations.

- Electron microprobes have precisely controlled automated specimen stages to facilitate large numbers of composition measurements to be made in an automated computer controlled fashion.
- Electron microprobes are equipped with sophisticated computer hardware and software to facilitate data reduction and quantitative plotting and mapping of results.

### ***Spatial Resolution***

- Backscattered electron imaging of atomic number contrast:  $\sim 1 \mu\text{m}$
- X-ray characterization of elemental chemistry:  $\sim 2 \mu\text{m}$ , sampling depth  $\sim 2 \mu\text{m}$

### ***Elemental Analysis Detection Threshold and Precision***

- Threshold sensitivity for elemental analysis using WDS detector:  $\sim 0.01\%$
- Precision of quantitative elemental analysis using WDS detector:  $\sim 0.5\%$  relative or  $0.02\%$  absolute, whichever is greater

### ***Limitations***

- Precise quantitative chemical analysis is difficult for atomic numbers less than  $\sim 8$  (oxygen), and must frequently be inferred from analytical totals less than 100%.
- Elements with atomic number less than  $\sim 4$  (beryllium) cannot be detected.

### ***Sample Requirements***

- The best quantitative analyses are obtained on polished and unetched metallographic samples. Samples with rough, scratched, or etched surfaces violate some of the assumptions inherent in the data reduction software, thus degrading the precision of the quantitative analytical results.
- Nonconductive samples or samples with marginally conductive surface regions must be coated with a thin layer of conductive material, typically carbon.

### ***Capabilities of Related Techniques***

**X-Ray fluorescence spectroscopy (XRF)** provides bulk elemental analysis. X-ray fluorescence spectroscopy instruments equipped with fine beam and x-y scanning capabilities provide elemental mapping on much larger samples but with much poorer spatial resolution.

**Transmission electron microscopy (TEM)** provides markedly better spatial resolution for x-ray microanalysis but at the expense of poorer counting statistics uncertainty. TEM sample preparation is tedious, and only very small portions of the sample can be viewed.

**Scanning Auger microscopy (SAM)** can perform microanalyses on low atomic number elements down to lithium (atomic number 3), but analyses are less quantitative. Analyses originate from very near surface region (first few atomic layers), so sample surfaces must be atomically clean or results will be representative of surface contaminants rather than the underlying sample.

3. *Materials Characterization*, Vol 10, *ASM Handbook*, ASM International, 1986

## **Transmission Electron Microscopy (TEM)**

### ***Terminology***

Transmission electron microscopy (TEM) has been used since the 1950s to obtain very high resolution images of microstructures. As TEMs were enhanced to include features such as digitally scanned point beams and energy dispersive x-ray detectors for chemical microanalysis, alternative names, such as scanning transmission electron microscopy (STEM) and analytical electron microscopy (AEM), were coined and became commonly used. This section incorporates all of these under the general title transmission electron microscopy.

### ***Capabilities***

The transmission electron microscopy provides the highest resolution imaging, elemental analysis, and crystallographic analysis of all the techniques described in this article. It is capable of:

- Imaging of features as small as several tenths of nanometers, down to the scale of individual crystallographic planes and atoms
- Qualitative and semi-qualitative elemental analyses with spatial resolution approaching 10 nm, roughly 100 times better than SEMs or electron microprobes
- Identifying crystalline compounds and determining crystallographic orientations of microstructural features as small as 30 nm

### ***Typical Uses***

The combination of capabilities described above make the TEM a very powerful tool for high resolution microstructural characterization. Typical uses include:

- Characterizing dislocation arrangements resulting from deformation and annealing
- Identifying and characterizing the morphologies, elemental compositions, and crystallographic aspects of very fine microstructural features, e.g., strengthening precipitates produced during age hardening
- Determining orientation relationships between parent and product phases, matrix and twins, etc.
- Characterizing compositional gradients over very short distances, e.g., diffusion profiles associated with phase transformations
- Determining phase diagrams by characterization of microstructural phase equilibria

### ***Spatial resolution***

- Imaging:  $\sim 0.2$  nm
- X-ray characterization of elemental chemistry:  $\sim 10$  nm
- Electron diffraction characterization of crystal structure and orientation:  $\sim 30$  nm

### ***Elemental Analysis Detection Threshold and Precision***

- Threshold sensitivity:  $\sim 1\%$
- Precision of quantitative elemental analyses:  $\sim 10\%$  relative or 2% absolute, whichever is greater

### ***Limitations***

- Sample preparation is tedious, and only small portions of the sample can be analyzed.
- Elemental chemical analysis cannot be readily done for elements with atomic numbers less than  $\sim 7$ , and counting statistics are not as good as with EPMA.

### ***Sampling Requirements***

- Small samples must be carefully prepared specifically for TEM, as described below. Sample preparation is tedious.
- Care must be taken to ensure that samples are free from preparation artifacts.

- Only very small portions of the sample can be analyzed, so it is crucial to ensure that the microstructure characterized is representative of the bulk material.

## Operating Principles

**Instrumentation.** A simplified schematic of a TEM is shown in Fig. 12. The top portion of the column is similar to that of an SEM. Electrons are produced and are accelerated down the column by a voltage differential in the electron gun (typically in the range of 100,000 to 400,000 V). The column must be kept under vacuum while the microscope is operating. As the beam passes down the microscope column, it is focused by variable strength electromagnetic condenser lenses. These condenser lenses can either focus the beam to a fine spot on the sample or flood a much larger portion of the sample with a parallel beam of electrons.

**Fig. 12** Schematic of transmission electron microscope, shown operating in the conventional parallel beam mode. The beam can also be focused to a small spot and rastered over the sample. Courtesy of Tom Headley, Sandia National Laboratories

**Sample Preparation.** The sample typically consists of a 3 mm diameter disk of material that has been specially prepared so that a portion of it is thin enough to permit the electron beam to penetrate completely through it. The maximum permissible thickness varies with the elements making up the sample (high atomic number elements are less transmissive) and the beam accelerating voltage (higher accelerating voltages enhance beam penetration), but it is typically in the range of one hundred to several hundred nanometers. Samples are thinned by a variety of methods including mechanical cutting and grinding (used in the preliminary steps of sample preparation), electrolytic polishing (commonly used for final thinning of metals), and ion milling (used with both metals and insulating materials). It is crucial that any damaged layer introduced during preliminary mechanical preparation be fully removed during subsequent electropolishing or ion milling. Typically these preparation steps are done in a way that produces an hourglass cross section in the disk, as shown in Figure 13. Final thinning is continued until a hole first forms near center of the disk, then the electropolishing or ion milling processes are immediately halted. The thin tapered portions of material adjacent to the hole are frequently thin enough to be electron transparent. If electropolishing or ion milling are continued too long, the thin electron transparent sections adjacent to the hole will be removed and the remaining material will likely be too thick to be penetrated by the electron beam.

**Fig. 13** Steps in TEM specimen preparations. (a) A disk with an  $\sim 3$  mm diameter and 0.1 to 0.3 mm thick is cut from the bulk sample. (b) The disk is thinned preferentially at its center (typically by fine mechanical grinding, chemical, or electrochemical methods), producing an hourglass profile. (c) Final thinning (typically by electrochemical or ion beam methods) is continued until a hole forms. The very thin material around the hole is usually thin enough to be penetrated by the TEM electron beam.

As the preceding description implies, TEM sample preparation is a tedious and time consuming process. Even when the sample preparation process is successful, only a very small portion of the sample is electron transparent and amenable to characterization. Because the results of TEM analyses represent information obtained from very small amounts of material, it is exceedingly important to ensure that the material being characterized is representative of the bulk material. Hence, TEM should usually be done in conjunction with other types of analysis, such as metallography, x-ray diffraction, and scanning electron microscopy, which readily characterize much larger amounts of material, albeit with lower resolution. Transmission electron microscopy is an exceptionally powerful method for characterizing microstructural details, but it is important to balance this detailed look at the "leaves" with a good overview of the "forest."

**Beam-Sample Interactions.** Once a sample with adequate electron transparency has been inserted into the microscope, a wealth of crystallographic, morphological, and chemical information can be obtained from it. As the incident electron beam penetrates a crystalline sample a variety of diffraction and excitation events occur. These provide:

- Identification of phases and compounds based on interplanar spacing fingerprints obtained from electron diffraction patterns (equivalent to x-ray powder diffraction, but on very small preselected microstructural features)
- Determination of crystallographic orientations from single-crystal electron diffraction patterns (equivalent to x-ray Laue orientation determination, but on very small grains, precipitates, or other microstructural features)
- Imaging of microstructural features (similar to metallography, but with  $\sim 1000$  times better resolution, and based on a diffraction contrast, rather than reflected light contrast)
- Elemental analysis (qualitative and quantitative) based on characteristic x-ray emission (equivalent to elemental analysis in the SEM or EPMA, but with 10 to 100 times better spatial resolution)

**Electron Diffraction.** Because the electron beam has a wave character, it can be diffracted by the planes in the crystal in cases where Bragg's law is satisfied, essentially as was described in the previous article on "X-Ray Diffraction for Bulk Structural Analysis" and illustrated in Fig. 2 in that article. If such diffraction occurs from a large number of fine randomly oriented crystals in the sample, this results in a series of axisymmetric cones, each cone corresponding to a specific interplanar spacing and the associated diffraction angle that satisfies Bragg's law. These cones intersect the viewing screen as circular rings, and can be recorded either on the underlying film or CCD detector as rings. The radius of each ring can be measured and used to calculate the diffraction angle and corresponding interplanar spacing. The set of interplanar spacings can then be used to identify the crystalline phases or compound(s) making up the sample, exactly as was described in the article "X-Ray Diffraction for Bulk Structural Analysis." An example of this is shown in Figure 14.

**Fig. 14** Electron diffraction ring pattern obtained from numerous grains in a polycrystalline aluminum sample. Starting with the innermost ring, the rings correspond to {111}, {200}, {220}, {311}, and {222} planes. Source: Ref 3

Alternatively, if the electron beam impinges on a single grain or crystal, an electron diffraction pattern consisting of a series of spots is obtained. This pattern is similar to a single crystal x-ray Laue pattern. The symmetry and angular relationships between the spots enable the crystallographic orientation of the grain to be determined. Figure 15 shows an example of orientation determination from a single crystal electron diffraction pattern. In cases of related orientations, such as epitaxial nucleation of one phase on another, or the formation of oriented precipitates with a parent phase, the orientation relationships between the phases can be determined from these electron diffraction patterns.

**Fig. 15** Electron diffraction spot pattern from a single grain in a polycrystalline aluminum sample. The spots are indexed in the accompanying computer-generated drawing. Source: Ref 3

**Imaging of Microstructural Features.** Electron diffraction also provides the primary source of image contrast in metals and other crystalline materials. Consider a relatively broad incident beam that impinges uniformly across several grains in a thin sample (Fig. 16). Electron beams in the range of 100,000 to 400,000 V have much shorter wavelengths than x-rays, which makes typical diffraction angles quite small. As a result, nearly all grains diffract to some extent. Some grains are oriented in ways that particular planes satisfy Bragg's law precisely. These grains diffract strongly. Other grains are oriented in ways that none of their planes satisfy Bragg's law precisely, but some planes are within a small fraction of a degree, hence they diffract to a limited extent.

**Fig. 16** Development of TEM image contrast due to differential diffraction. Grains that are poorly oriented for diffraction transmit a higher percentage of the beam and appear bright in the image; those ideally oriented for diffraction transmit a lower percentage of the beam and appear dark in the image.

The degree to which diffraction occurs varies the extent to which the incident beam is directly transmitted through the sample from grain to grain. Grains least oriented for diffraction directly transmit much of the incident beam and diffract only a small amount of it. Other grains are ideally oriented for diffraction and directly transmit much less of the incident beam and diffract much of it. The directly transmitted beam, then, is not uniform in intensity across its diameter but carries intensity variations corresponding to the grains through which it passed and their differing level of diffraction. When the directly transmitted beam is imaged, magnified, and projected onto the viewing screen, this provides light and dark contrast in the image. Grains that transmitted a high percentage of the incident beam appear bright, and those that diffracted more of the incident beam appear dark. Figure 17 shows an example of this type of grain contrast.

**Fig. 17** Transmission electron microscopy grain orientation contrast in a sample of fine-grained polycrystalline silicon. Courtesy of Tom Headley, Sandia National Laboratories

In addition to contrast arising from grain-to-grain orientation differences, any crystalline defects that result in local variations in diffraction also produce light and dark contrast in the image. As a result, defects such as dislocations and stacking faults can be imaged by the TEM. Figure 18 shows an example of dislocations in aluminum imaged by TEM.

**Fig. 18** Transmission electron microscopy imaging of dislocations in aluminum. Source: Ref 3

In addition to the bright field images obtained from the directly transmitted beam, dark field images can also be obtained from any of the diffracted beams. These images are particularly useful in cases where two or more superimposed diffraction patterns are obtained corresponding to adjacent features in the sample. Dark field imaging makes it possible to determine which diffraction spots correspond to each feature, thus facilitating the determination of crystallographic characteristics such as orientation relationships and habit planes. An example of a dark field image obtained from multiple defraction spots is provided in Fig. 19.

**Fig. 19** Transmission electron microscopy dark field image of same area as in Fig. 17. Dark field image was obtained by imaging numerous diffraction spots, so most areas that strongly diffracted and appeared dark in Fig. 17 now appear bright. Areas that diffracted weakly and appeared bright in Fig. 17 now appear dark. Courtesy of Tom Headley, Sandia National Laboratories

Direct imaging of particular crystal planes can be accomplished using a combination of the directly transmitted beam and one or more diffracted beams. This enables high-resolution characterization of individual lattice planes and defects, as illustrated in Fig. 20.

**Fig. 20** High-resolution TEM lattice image of zinc oxide formed by combining transmitted and (002) diffracted beams. The interplanar spacing is 0.26 nm. A grain boundary, inclined to the incident beam, is visible in the upper portion of the micrograph. Source: Ref 3

Excitation and characteristic x-ray production also occurs as the incident electron beam interacts with the atoms in the sample. As in the SEM and EPMA, this provides the equivalent of a x-ray fluorescence spectrometer that can probe the chemistries of very small operator-selected portions of the sample. The energies and intensities of these characteristic x-rays are typically detected and analyzed using an EDS system, enabling qualitative identification of the elements present in the sample and quantitative determination of their relative concentrations, respectively. In the TEM, however, the thinness of the sample significantly reduces the size of the interaction volume, as shown in Fig. 21. This occurrence limits the degree to which electron beam spreading occurs in the sample, and provides the ability to perform chemical analyses with significantly better spatial resolution than in the SEM or EPMA. This resolution permits chemical characterization of features as small as 10 nm and determination of chemical gradients over submicrometer distances, as shown in Fig. 22. Because the interaction volume is much smaller than in bulk samples, however, much smaller numbers of x-ray photons are produced. This results in poorer counting statistics, so quantitative analyses obtained by TEM typically have larger degrees of uncertainty than those obtained by EPMA.

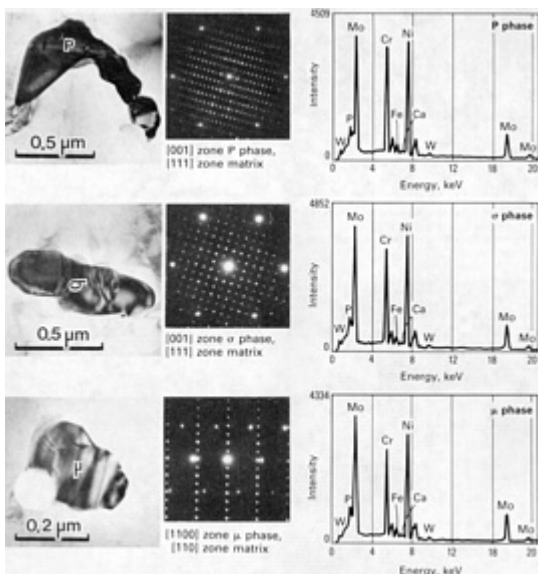

**Fig. 21** X-ray generation volume in thin TEM samples. Note that the thin sample results in reduced spreading of the incident electron beam, thus reducing the diameter of the x-ray generation region and providing better spatial resolution for elemental microanalysis than is possible with typical thick SEM or EPMA samples.

**Fig. 22** Copper concentration profile measured by TEM adjacent to the grain boundary in an aged Al-4.7%Cu alloy. (a) Transmission electron microscopy image showing large  $\text{CuAl}_2$  precipitates along boundary at left and right sides. Dark spots near the center correspond to probe positions during x-ray microanalysis. (b) Composition profile across the grain boundary. Source: Ref 3

The exceptional utility of TEM is based on its ability to obtain imaging, chemistry, and crystallographic information in combination with one another, and with very high spatial resolution (on very small microstructural features). Figure 23 provides a typical example of how these capabilities can be combined to understand microstructural phenomena in great detail. However, these strengths are seriously offset by the difficulty of specimen preparation and the fact that not only very small amounts of material are examined. Scanning electron microscopy and EPMA require much simpler sample preparation and can readily locate and characterize specific areas of interest in larger samples, including failed engineering components. Until recently, SEM and EPMA were capable only of combined imaging and chemical characterization but not crystallographic characterization. As new methods for SEM crystallographic characterization are developed, however, these instruments will become increasingly powerful. Transmission electron microscopy will remain exceptionally useful for analyses that require very high resolution, but it is likely that SEM and EPMA will be used increasingly for a broader range of application that do not require submicron spatial resolution.

**Fig. 23** Combined TEM imaging, electron diffraction identification, and elemental microanalysis of P,  $\sigma$ , and  $\mu$  intermetallic phases of alloy 22 weld metal. Source: Ref 3

### **Capabilities of Related Techniques**

**X-ray diffraction (XRD)** provides faster and more precise crystallographic information, but averaged over bulk sample rather than corresponding to individual microstructural features.

**Scanning Electron Microscopy (SEM).** Sample preparation is much simpler. Scanning electron microscopy can characterize much larger samples and selected areas of interest. Imaging resolution is not as good as TEM. Spatial resolution for chemical analysis and crystallographic analysis is not as good as TEM. Scanning electron microscopy techniques for crystallographic analysis are not as mature as those for TEM.

**Electron Probe Microanalysis (EPMA).** Sample preparation is much simpler. Electron probe microanalysis can characterize much larger samples and selected areas of interest. Spatial resolution for chemical analysis is not as good as TEM, but counting statistics are much better, providing higher quality quantitative analyses.

# Surface Analysis

K.H. Eckelmeyer, Microstructural Analysis Department, Sandia National Laboratories

## Introduction

A NUMBER OF METHODS can be used to obtain information about the chemistry of the first one to several atomic layers of samples of metals, as well as of other materials, such as semiconductors and various types of thin films. Of these methods, the scanning Auger microprobe is the most widely used. This instrument and method will be described in some detail, and the operation and capabilities of several other surface analysis methods will be more briefly described in comparison to it.

## Scanning Auger Microprobe (SAM)

### *Capabilities*

The scanning Auger microprobe is basically a scanning electron microscope (SEM) with two additional features:

- An Auger electron detector replaces an x-ray detector. The Auger detector is used to measure the energies of Auger electrons emitted from the sample. These characteristic energies enable identification of the elements present in the first few atomic layers of the surface. The concentrations of each element present can also be determined from the number of electrons detected at each characteristic energy. All elements except hydrogen and helium can be identified and analyzed in this way.
- An in situ ion milling capability provides for gradual removal of surface layers, thereby permitting depth profiling of elemental compositions within about 1  $\mu\text{m}$  of the surface.

### *Typical Uses*

These capabilities make the SAM well suited for the following types of applications:

- Identification and mapping of light elements (atomic numbers 3 to  $\sim 9$ ) that are difficult to detect using SEM or electron probe microanalysis (EPMA)
- Elemental characterization of surface contaminants
- Depth profiling of elemental compositions within  $\sim 1\text{ }\mu\text{m}$  of the surface (this is particularly widely used in microelectronics applications)

### ***Spatial Resolution***

- Secondary electron imaging of surface topography:  $\sim 10\text{ nm}$  (same as SEM)
- Auger electron characterization of elemental chemistry: 10 to 20 nm; sampling depth:  $\sim 1\text{ nm}$

### ***Elemental Analysis Detection Threshold and Precision***

- Threshold sensitivity:  $\sim 0.5\%$
- Precision of quantitative analyses:  $\sim 10\%$  relative or 0.5% absolute, whichever is greater

### ***Limitations***

- Cannot detect hydrogen or helium
- Quantitative analyses are typically lower in quality than those of EPMA

### ***Sample Requirements***

- Samples up to  $\sim 2.5\text{ cm}$  diameter and 0.5 cm thick can be accommodated by most SAMs; larger samples can be accommodated in instruments designed for this purpose.
- Provisions must be made for charge to bleed off. Ideal samples are electrically conductive and must be free of fingerprints, oils, and other high vapor pressure materials.
- Flat samples are preferred, but rough samples can also be accommodated.

### ***Operating Principles***

**Instrumentation.** As noted above, the scanning Auger microprobe is essentially an SEM to which an Auger electron detector and an ion miller have been added (Fig. 1). An electron beam is produced and focused to a small spot on the sample surface. This spot can be rastered across an operator-defined area of the surface or stopped and moved to a particular location of interest. The beam penetrates the sample and interacts with the atoms in the first  $\sim 1\text{ }\mu\text{m}$ , exciting atoms and producing secondary electrons, exactly as was shown for the scanning electron microscope in Fig. 2-4 of the article "Microstructural Analysis." A secondary electron detector provides the capability to image the surface and locate areas of particular interest, as in a scanning electron microscope. However, the primary tool for chemical analysis is the Auger electron detector.

Fig. 1 Schematic of a scanning Auger microprobe

**Physical Basis.** Auger electrons are emitted as the excited atoms relax. In a sense, they are the compliments of the characteristic x-rays that are used for chemical characterization in x-ray fluorescence (XRF), SEM, EPMA, and transmission electron microscopy (TEM). When atoms become excited by electrons being ejected from their inner shells, electrons from higher energy shells fill these vacated sites. This process always results in the release of energy equal to the energy difference between the donor and acceptor levels. For more information, see the section "X-Ray Fluorescence Spectroscopy" in the article "Bulk Elemental Analysis" in this Handbook. However, emission of characteristic x-rays is only one of the mechanisms by which this energy can be released. Another common mechanism is by the release of an Auger electron.

An Auger electron is an electron from one of the outer shells that is ejected from the atom with kinetic energy equal to the energy released by the relaxation event minus the energy required to remove the Auger electron from its orbit (Fig. 2). Because both energies associated with the relaxation events and the binding energies of the outer shell electrons provide characteristic "fingerprints" for each element, so do their differences, the energies of Auger electrons. Hence, the energies of Auger electrons can also be detected and used to identify which elements are in the portion of the sample being excited by the incident electron beam. These characteristic Auger electrons typically have energies of tens to thousands of electron volts.

Fig. 2 Comparison of production of x-rays and Auger electrons. Source: Ref 1

The tendency for excited atoms to relax by Auger electron production versus x-ray photon emission increases with decreasing atomic number. Elements with atomic numbers less than  $\sim 7$  produce few characteristic x-rays but many Auger electrons (except for hydrogen and helium). As a result, SAM is commonly used for microstructural detection and quantification of such elements. Higher atomic number elements, however, produce more x-rays, so these elements are typically detected and quantified using SEM or EPMA. Although when analysis of the first few atomic layers is desired, SAM provides elemental analyses corresponding to this very near surface region.

While Auger electrons are generated throughout the beam-sample interaction volume, most of these dissipate some or all of their characteristic energies by interacting with the electrons belonging to other atoms in the sample. The only Auger electrons that escape the sample with their original characteristic energies are those generated within a few atom layers of the sample's surface. If the energies of all emitted electrons are detected and analyzed, then a graph similar to Fig. 3 is obtained. The lowest energy range is dominated by secondary electrons, the highest energy range is dominated by backscattered electrons, and the mid-energy range is dominated by Auger electrons, nearly all of which have had their characteristic energies reduced by interactions with the sample. But if Fig. 3 is examined closely, small signals can be found at particular energies. These represent the characteristic energies of the "undisturbed" Auger electrons that were generated by atoms at the surface or within a few atomic distances below the surface.

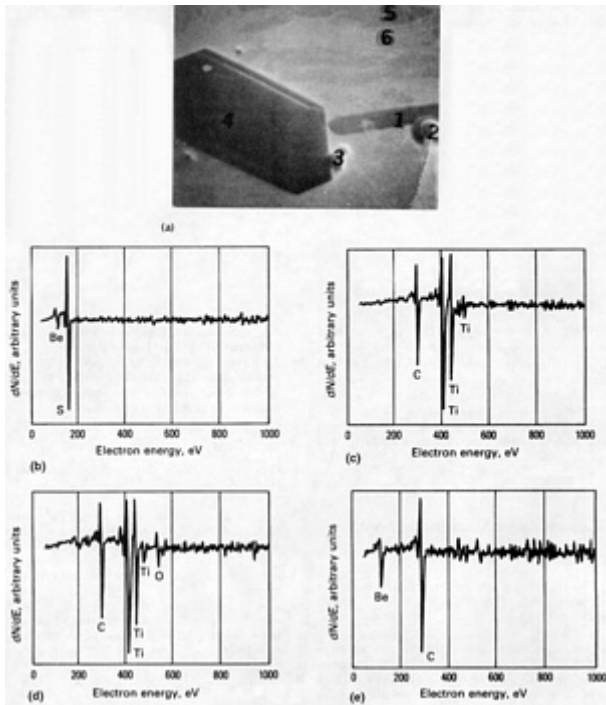

Fig. 3 Electron energy distribution from silver sample. Differentiated signal most clearly reveals the peak corresponding to Auger electrons that were produced very near the surface and exited the sample prior to interacting with other atoms. Source: Ref 2

**Electron Collection and Energy Measurement.** The energies of the emitted electrons are usually measured using a cylindrical "mirror" that has a variable negative potential applied to it, as shown in Fig. 1. As electrons enter the inlet aperture and pass through the analyzer chamber, the negative bias on the wall of the chamber repels them and causes them to travel in curved paths. The curvature of this path varies inversely with the kinetic energy of each electron; the paths of electrons with low kinetic energy are more easily deflected than those paths of electrons with high kinetic energy. This information provides a means of measuring the energy distribution of the electrons emitted from the sample. An electron detector is mounted near the exit aperture of the cylindrical mirror, and the negative bias applied to the mirror is gradually increased. The numbers of electrons entering the detector is counted as a function of mirror bias. This information enables the energy distribution of the electrons to be plotted.

The portion of the signal corresponding to the "undisturbed" Auger electrons is very small compared with the signal resulting from backscattered and Auger electrons whose energies have been reduced by interactions within the sample. This situation is typically overcome by differentiating the signal and plotting  $dN/dE$  versus  $E$ , as shown in Fig. 3. Because the Auger electrons typically originate in the outer electron shells, their energies are somewhat affected by bonding between atoms. These small energy shifts, which can frequently be discriminated by the energy analyzer, provide the ability to determine some information about the elements to which the atoms of interest are bonded.

Scanning Auger microprobe results are often presented as secondary electron images with accompanying Auger electron spectra identifying the elements present in particular features of interest. Low atomic number elements that cannot be detected by SEM and EPMA are readily detected in Auger spectra. Figure 4 provides an example of the use of Auger electrons to detect low atomic number elements with high spatial resolution.

**Fig. 4** Scanning Auger identification of elements, including some of low atomic number, present in several phases in a copper-beryllium alloy. (a) Secondary electron image showing inclusions. (b-e) Auger spectra obtained from the indicated microstructural features. (b) The long rod-shaped precipitate (point 1) is a beryllium sulfide. (c) The small round precipitate (point 2) is a titanium carbide. (d) The small irregular precipitate (point 3) is also a titanium carbide. (e) The large blocky angular precipitate (point 4) is a beryllium carbide. Source: Ref 2

Alternatively, the detector can be set to the energy associated with a particular element or compound of interest and the electron beam rastered over the surface, resulting in a map indicating the areas of high concentration of this material (Fig. 5).

Fig. 5 Scanning Auger mapping of elements, including some of low atomic number, in a foreign particle on an integrated circuit. Note also the ability to distinguish between elemental silicon and silicon oxide due to bonding effects on Auger energies. (a) Secondary electron image of particle. (b-e) Auger maps showing locations of silicon oxide, elemental silicon, oxygen, and aluminum, respectively. Source: Ref 2

An ion sputtering gun is also incorporated into the chamber of the instrument and can be used to progressively remove thin layers of material from the surface of the sample. This removal provides the opportunity to perform Auger elemental measurements at various distances from the original sample surface. The practical limit of such depth profiling is  $\sim 1 \mu\text{m}$ . An example of this depth profiling capability is shown in Fig. 6.

## Related Surface Analysis Techniques

### *Non-Surface-Specific Methods*

**Scanning Electron Microscopy, Electron Probe Microanalysis (SEM, EPMA).** These methods are better for combined imaging and elemental analysis of elements with higher atomic numbers. However, SEM and EPMA cannot readily analyze for low atomic number elements (less than  $\sim 7$  to 11), nor do they have either depth profiling capabilities or surface specific analytical capabilities.

**Transmission electron microscopy (TEM)** has better spatial resolution for imaging and chemical analysis, but an EDS system cannot readily analyze for low atomic number elements (below  $\sim 7$ ). The presence of lower atomic number elements can sometimes be inferred by electron diffraction if these elements are present in compounds that can be identified based on their interplanar spacings.

### *Surface-Specific Methods*

A number of other techniques are frequently used to characterize the chemistries of the top one to five atomic layers of materials. While detailed descriptions of all of these methods are beyond the scope of this article, the following

paragraphs provide brief summaries of two of the methods that are frequently used in metallurgical studies and comparisons of their capabilities with those of the scanning Auger microprobe.

**Secondary ion mass spectroscopy (SIMS)** directs a finely focused beam of energetic ions onto the sample surface, then it collects and analyzes the ionized atoms or clusters of atoms ejected from the sample surface by this beam. Information can be obtained with lateral spatial resolution of 100 to 500 nm. The ions removed from the surface are identified by a highly sensitive mass spectrometer. This identification provides for very sensitive detection of many elements, often in the parts per billion (ppb) range. In addition, it enables analysis for very low atomic number elements, including hydrogen. (SIMS is the only method able to detect hydrogen with microscopic spatial resolution.) The primary ion beam can be rastered over the surface, providing for high-sensitivity elemental mapping. Because it removes material from the surface, it also provides for depth profiling.

**X-ray photoelectron spectroscopy (XPS)** directs a single energy x-ray beam onto the surface. This beam penetrates 10 to 100  $\mu\text{m}$  into the sample, interacting with atoms and ejecting photoelectrons from their inner shells. The energies of these photoelectrons are equal to the energy of the x-ray photons minus the characteristic electron binding energies. Many of the photoelectrons lose some or all of their energy in interactions with other atoms, but a few that are generated very close to the surface exit the sample undisturbed. The photoelectrons are collected and their energies analyzed using a device similar to the cylindrical mirror in a SAM. Analysis of the energies of the photoelectrons permits identification of the elements in the top few atomic layers. The excellent energy resolution of the analyzer enables it to discriminate the very small shifts in energy that result from bonding of the atoms of interest to other surrounding atoms. Hence, XPS is capable of providing information on surrounding atoms and chemical bonding. X-ray photoelectron spectroscopy does not utilize a fine incident beam; therefore, it does not provide images or chemical information with high lateral spatial resolution. It is generally not as sensitive as SIMS, but it is very useful for detecting some elements for which SIMS is not very sensitive. An ion sputtering capability is generally available to facilitate depth profiling. In general, XPS is most extensively used to obtain surface analyses with chemical bonding sensitivity.

# Glossary of Metallurgical and Metalworking Terms

---

THIS GLOSSARY contains the definitions of some 3500 technical terms encountered in the metallurgical literature. The list includes terms from: general materials science, physical metallurgy, mechanical metallurgy, extractive metallurgy, melting and casting, forming and forging, powder metallurgy, heat treating, machining and grinding, welding and joining (brazing, soldering, and adhesive bonding), surface engineering (cleaning, finishing, and coating technology), corrosion and electrochemistry, tribology (wear, friction, and lubrication technology), fracture mechanics, mechanical testing, nondestructive testing and inspection, metallography, fractography, failure analysis, and materials characterization. These subject areas are representative of the topics covered in the 20-volume *ASM Handbook* series.

Many cross references to preferred terms, alternative terms, and closely related terms have been included; these cross references are printed in italics. Also, terms that are obsolete or otherwise inappropriate for use in current technical articles/reports, and so forth are so indicated. Many terms can have more than one meaning; alternative meanings are identified by parenthetical numbers preceding each alternative definition. Whenever possible, a general or generic meaning is given before a specific meaning, but there is no special significance to the order in which alternative meanings are given. In addition, many of the definitions in this glossary are compatible with (although not necessarily identical to) definitions published by ASTM, AWS, NACE, and other technical organizations.

Terms that are best defined using an accompanying figure are not included in this glossary. Examples here include weld joint configurations (e.g., tee joints, lap joints, etc.) and related nomenclature and cutting tool geometries (e.g., clearance angles, rake angles, etc.). These terms are defined and illustrated in the Sections "Joining" and "Machining," respectively, in this Handbook.

Although every effort has been made to provide as comprehensive a glossary as possible, space limitations dictate that only the most commonly used terms be defined. More specialized terms are defined in the many glossaries published throughout the *ASM Handbook* series and in the illustrated *ASM Materials Engineering Dictionary* published in 1992. The latter work also contains terms and definitions related to nonmetallic engineered materials and processing.

- **A**
- **abrasion**
  - (1) A process in which hard particles or protuberances are forced against and moved along a solid surface. (2) A roughening or scratching of a surface due to abrasive wear. (3) The process of grinding or wearing away through the use of abrasives.
- **abrasive**
  - (1) A hard substance used for grinding, honing, lapping, superfinishing, polishing, pressure blasting, or barrel finishing. Abrasives in common use are alumina, silicon carbide, boron carbide, diamond, cubic boron nitride, garnet, and quartz. (2) Hard particles, such as rocks, sand, or fragments of certain hard metals, that wear away a surface when they move across it under pressure. See also superabrasives .
- **abrasive belt**
  - A coated abrasive product, in the form of a belt, used in production grinding and polishing.
- **abrasive blasting**
  - A process for cleaning or finishing by means of an abrasive directed at high velocity against the workpiece.
- **abrasive disk**
  - (1) A grinding wheel that is mounted on a steel plate, with the exposed flat side being used for grinding. (2) A disk-shaped, coated abrasive product.
- **abrasive erosion**
  - Erosive wear caused by the relative motion of solid particles that are entrained in a fluid, moving nearly parallel to a solid surface. See also erosion .
- **abrasive flow machining**

- Removal of material by a viscous, abrasive media flowing under pressure through or across a workpiece.
- **abrasive jet machining**
  - Material removal from a workpiece by impingement of fine abrasive particles that are entrained in a focused, high-velocity gas stream.
- **abrasive machining**
  - A machining process in which the points of abrasive particles are used as machining tools. Grinding is a typical abrasive machining process.
- **abrasive waterjet machining**
  - See waterjet/abrasive waterjet machining .
- **abrasive wear**
  - The removal of material from a surface when hard particles slide or roll across the surface under pressure. The particles may be loose or may be part of another surface in contact with the surface being abraded. Compare with adhesive wear .
- **abrasive wheel**
  - A grinding wheel composed of an abrasive grit and a bonding agent.
- **absolute density**
  - See density, absolute .
- **Ac<sub>cm</sub>, Ac<sub>1</sub>, Ac<sub>3</sub>, Ac<sub>4</sub>**
  - Defined under transformation temperature .
- **accelerated corrosion test**
  - Method designed to approximate, in a short time, the deteriorating effect under normal long-term service conditions.
- **accelerated-life test**
  - A method designed to approximate, in a short time, the deteriorating effect obtained under normal long-term service conditions. See also artificial aging .
- **accelerated testing**
  - A test performed on materials or assemblies that is meant to produce failures caused by the same failure mechanism as expected in field operation but in significantly shorter time. The failure mechanism is accelerated by changing one or more of the controlling test parameters.
- **acicular ferrite**
  - A highly substructured nonequiaxed ferrite formed upon continuous cooling by a mixed diffusion and shear mode of transformation that begins at a temperature slightly higher than the transformation temperature range for upper bainite. It is distinguished from bainite in that it has a limited amount of carbon available; thus, there is only a small amount of carbide present.
- **acicular ferrite steels**
  - Ultralow-carbon (<0.08%) steels having a microstructure consisting of either acicular ferrite (low-carbon bainite) or a mixture of acicular and equiaxed ferrite.
- **acid**
  - A chemical substance that yields hydrogen ions (H<sup>+</sup>) when dissolved in water. Compare with base . (2) A term applied to slags, refractories, and minerals containing a high percentage of silica.
- **acid bottom and lining**
  - The inner bottom and lining of a melting furnace, consisting of materials like sand, siliceous rock, or silica brick that give an acid reaction at the operating temperature.
- **acid copper**
  - (1) Copper electrodeposited from an acid solution of a copper salt, usually copper sulfate. (2) The solution referred to in (1).
- **acid embrittlement**
  - A form of hydrogen embrittlement that may be induced in some metals by acid.
- **acid rain**
  - Atmospheric precipitation with a pH below 5.6 to 5.7. Burning of fossil fuels for heat and power is the major factor in the generation of oxides of nitrogen and sulfur, which are converted into nitric and sulfuric acids washed down in the rain. See also atmospheric corrosion .
- **acid refractory**
  - Siliceous ceramic materials of a high melting temperature, such as silica brick, used for metallurgical furnace linings. Compare with basic refractories .
- **acid steel**

- Steel melted in a furnace with an acid bottom and lining and under a slag containing an excess of an acid substance such as silica.
- **acoustic emission**
  - A measure of integrity of a material, as determined by sound emission when a material is stressed. Ideally, emissions can be correlated with defects and/or incipient failure.
- **actinide metals**
  - The group of radioactive elements of atomic numbers 89 through 103 of the periodic system--namely, actinium, thorium, protactinium, uranium, neptunium, plutonium, americium, curium, berkelium, californium, einsteinium, fermium, mendelevium, nobelium, and lawrencium.
- **activated rosin flux**
  - A rosin-base flux containing an additive that increases wetting by the solder.
- **activation**
  - (1) The changing of a passive surface of a metal to a chemically active state. Contrast with passivation . (2) The (usually) chemical process of making a surface more receptive to bonding with a coating or an encapsulating material.
- **activation energy**
  - The energy required for initiating a metallurgical reaction--for example, plastic flow, diffusion, chemical reaction. The activation energy may be calculated from the slope of the line obtained by plotting the natural log of the reaction rate versus the reciprocal of the absolute temperature.
- **active**
  - The negative direction of electrode potential. Also used to describe corrosion and its associated potential range when an electrode potential is more negative than an adjacent depressed corrosion rate (passive) range.
- **active metal**
  - A metal ready to corrode or being corroded.
- **activity**
  - A measure of the chemical potential of a substance, where the chemical potential is not equal to concentration, that allows mathematical relations equivalent to those for ideal systems to be used to correlate changes in an experimentally measured quantity with changes in chemical potential.
- **addition agent**
  - (1) A substance added to a solution for the purpose of altering or controlling a process. Examples: wetting agents in acid pickles; brighteners or antipitting agents in plating solutions; inhibitors. (2) Any material added to a charge of molten metal in a bath or ladle to bring the alloy to specification.
- **adhesion**
  - (1) In frictional contacts, the attractive force between adjacent surfaces. In physical chemistry, adhesion denotes the attraction between a solid surface and a second (liquid or solid) phase. This definition is based on the assumption of a reversible equilibrium. In mechanical technology, adhesion is generally irreversible. In railway engineering, adhesion often means friction. (2) Force of attraction between the molecules (or atoms) of two different phases. Contrast with cohesion . (3) The state in which two surfaces are held together by interfacial forces, which may consist of valence forces, interlocking action, or both.
- **adhesive**
  - A substance capable of holding materials together by surface attachment. Adhesive is a general term and includes, among others, cement, glue, mucilage, and paste.
- **adhesive bonding**
  - A materials joining process in which an adhesive, placed between the faying surfaces (adherends), solidifies to produce an adhesive bond.
- **adhesive wear**
  - (1) Wear by transference of material from one surface to another during relative motion due to a process of solid-phase welding. Particles that are removed from one surface are either permanently or temporarily attached to the other surface. (2) Wear due to localized bonding between contacting solid surfaces leading to material transfer between the two surfaces or loss from either surface. Compare with abrasive wear .
- **adjustable bed**
  - Bed of a press designed so that the die space height can be varied conveniently.
- **Ae<sub>cm</sub>, Ae<sub>1</sub>, Ae<sub>3</sub>, Ae<sub>4</sub>**
  - Defined under transformation temperature .

- **age hardening**
  - Hardening by aging (heat treatment) usually after rapid cooling or cold working.
- **age softening**
  - Spontaneous decrease of strength and hardness that takes place at room temperature in certain strain hardened alloys, especially those of aluminum.
- **aging**
  - (1) The effect on materials of exposure to an environment for a prolonged interval of time. (2) The process of exposing materials to an environment for a prolonged interval of time in order to predict in-service lifetime.
- **aging (heat treatment)**
  - A change in the properties of certain metals and alloys that occurs at ambient or moderately elevated temperatures after hot working or a heat treatment (quench aging in ferrous alloys, natural or artificial aging in ferrous and nonferrous alloys) or after a cold-working operation (strain aging). The change in properties is often, but not always, due to a phase change (precipitation), but never involves a change in chemical composition of the metal or alloy. See also age hardening , artificial aging , interrupted aging , natural aging , overaging , precipitation hardening , precipitation heat treatment , progressive aging , quench aging , step aging , and strain aging .
- **air acetylene welding**
  - A fuel gas welding process in which coalescence is produced by heating with a gas flame or flames obtained from the combustion of acetylene with air, without the application of pressure, and with or without the use of filler metal.
- **air bend die**
  - Angle-forming dies in which the metal is formed without striking the bottom of the die. Metal contact is made at only three points in the cross section: the nose of the male die and the two edges of a V-shape die opening.
- **air bending**
  - Bending in an air bend die .
- **air carbon arc cutting**
  - An arc cutting process in which metals to be cut are melted by the heat of a carbon arc and the molten metal is removed by a blast of air.
- **air classification**
  - The separation of metal powder into particle-size fractions by means of an air stream of controlled velocity; an application of the principle of elutriation .
- **air-hardening steel**
  - A steel containing sufficient carbon and other alloying elements to harden fully during cooling in air or other gaseous media from a temperature above its transformation range. The term should be restricted to steels that are capable of being hardened by cooling in air in fairly large sections, about 50 mm (2 in.) or more in diameter. Same as self-hardening steel.
- **air-lift hammer**
  - A type of gravity-drop hammer in which the ram is raised for each stroke by an air cylinder. Because length of stroke can be controlled, ram velocity and therefore the energy delivered to the workpiece can be varied. See also drop hammer and gravity hammer .
- **alclad**
  - Composite wrought product comprised of an aluminum alloy core having one or both surfaces a metallurgically bonded aluminum or aluminum alloy coating that is anodic to the core and thus electrochemically protects the core against corrosion.
- **alkali metal**
  - A metal in group IA of the periodic system--namely, lithium, sodium, potassium, rubidium, cesium, and francium. They form strongly alkaline hydroxides, hence the name.
- **alkaline cleaner**
  - A material blended from alkali hydroxides and such alkaline salts as borates, carbonates, phosphates, or silicates. The cleaning action may be enhanced by the addition of surface-active agents and special solvents.
- **alkaline earth metal**
  - A metal in group IIA of the periodic system--namely, beryllium, magnesium, calcium, strontium, barium, and radium--so called because the oxides or "earths" of calcium, strontium, and barium were found by the early chemists to be alkaline in reaction.

- **alligatoring**
  - (1) Pronounced wide cracking over the entire surface of a coating having the appearance of alligator hide. (2) The longitudinal splitting of flat slabs in a plane parallel to the rolled surface. Also called fish-mouthing.
- **alligator skin**
  - See orange peel .
- **allotriomorphic crystal**
  - A crystal whose lattice structure is normal but whose external surfaces are not bounded by regular crystal faces; rather, the external surfaces are impressed by contact with other crystals or another surface such as a mold wall, or are irregularly shaped because of nonuniform growth. Compare with idiomorphic crystal .
- **allotropy**
  - (1) A near synonym for polymorphism . Allotropy is generally restricted to describing polymorphic behavior in elements, terminal phases, and alloys whose behavior closely parallels that of the predominant constituent element. (2) The existence of a substance, especially an element, in two or more physical states (for example, crystals).
- **allowance**
  - (1) The specified difference in limiting sizes (minimum clearance or maximum interference) between mating parts, as computed arithmetically from the specified dimensions and tolerances of each part. (2) In a foundry, the specified clearance. The difference in limiting sizes, such as minimum clearance or maximum interference between mating parts, as computed arithmetically. See also tolerance .
- **alloy**
  - (1) A substance having metallic properties and being composed of two or more chemical elements of which at least one is a metal. (2) To make or melt an alloy.
- **alloy cast iron**
  - Highly alloyed cast irons containing more than 3% alloy content. Alloy cast irons may be of a type of white iron, gray iron, or ductile iron.
- **alloying element**
  - An element added to and remaining in a metal that changes structure and properties.
- **alloy plating**
  - The codeposition of two or more metallic elements.
- **alloy powder, alloyed powder**
  - A metal powder consisting of at least two constituents that are partially or completely alloyed with each other.
- **alloy steel**
  - Steel containing specified quantities of alloying elements (other than carbon and the commonly accepted amounts of manganese, copper, silicon, sulfur, and phosphorus) within the limits recognized for constructional alloy steels, added to effect changes in mechanical or physical properties.
- **alloy system**
  - A complete series of compositions produced by mixing in all proportions any group of two or more components, at least one of which is a metal.
- **all-weld-metal test specimen**
  - A test specimen wherein the portion being tested is composed wholly of weld metal.
- **alpha brass**
  - A solid-solution phase of one or more alloying elements in copper having the same crystal lattice as copper.
- **alpha ferrite**
  - See ferrite .
- **alpha iron**
  - The body-centered cubic form of pure iron, stable below 910 °C (1670 °F).
- **alternate immersion test**
  - A corrosion test in which the specimens are intermittently exposed to a liquid medium at definite time intervals.
- **aluminizing**
  - Forming of an aluminum or aluminum alloy coating on a metal by hot dipping, hot spraying, or diffusion.

- **amalgam**
  - A dental alloy produced by combining mercury with alloy particles of silver, tin, copper, and sometimes zinc.
- **amorphous**
  - Not having a crystal structure; noncrystalline.
- **amorphous solid**
  - A rigid material whose structure lacks crystalline periodicity; that is, the pattern of its constituent atoms or molecules does not repeat periodically in three dimensions. See also metallic glass .
- **anelastic deformation**
  - Any portion of the total deformation of a body that occurs as a function of time when load is applied and which disappears completely after a period of time when the load is removed.
- **anelasticity**
  - The property of solids by virtue of which strain is not a single-value function of stress in the low-stress range where no permanent set occurs.
- **angle of bite**
  - In the rolling of metals, the location where all of the force is transmitted through the rolls; the maximum attainable angle between the roll radius at the first contact and the line of roll centers. Operating angles less than the angle of bite are termed contact angles or rolling angles.
- **angle of nip**
  - In rolling, the angle of bite. In roll, jaw, or gyratory crushing, the entrance angle formed by the tangents at the two points of contact between the working surfaces and the (assumed) spherical particles to be crushed.
- **angstrom (unit)**
  - A unit of linear measure equal to  $10^{-10}$  m, or 0.1 nm (nanometer), sometimes used to express small distances such as interatomic distances and some wavelengths.
- **anion**
  - A negatively charged ion that migrates through the electrolyte toward the anode under the influence of a potential gradient. See also cation and ion .
- **anisotropy**
  - The characteristic of exhibiting different values of a property in different directions with respect to a fixed reference system in the material.
- **annealing**
  - A generic term denoting a treatment consisting of heating to and holding at a suitable temperature followed by cooling at a suitable rate, used primarily to soften metallic materials, but also to simultaneously produce desired changes in other properties or in microstructure. The purpose of such changes may be, but is not confined to: improvement of machinability, facilitation of cold work, improvement of mechanical or electrical properties, and/or increase in stability of dimensions. When the term is used unqualifiedly, full annealing is implied. When applied only for the relief of stress, the process is properly called stress relieving or stress-relief annealing.

In ferrous alloys, annealing usually is done above the upper critical temperature, but the time-temperature cycles vary widely both in maximum temperature attained and in cooling rate employed, depending on composition, material condition, and results desired. When applicable, the following commercial process names should be used: black annealing, blue annealing, box annealing, bright annealing, cycle annealing, flame annealing, full annealing, graphitizing, in-process annealing, isothermal annealing, malleabilizing, orientation annealing, process annealing, quench annealing, spheroidizing, subcritical annealing.

In nonferrous alloys, annealing cycles are designed to: (a) remove part or all of the effects of cold working (recrystallization may or may not be involved); (b) cause substantially complete coalescence of precipitates from solid solution in relatively coarse form; or (c) both, depending on composition and material condition. Specific process names in commercial use are final annealing, full annealing, intermediate annealing, partial annealing, recrystallization annealing, stress-relief annealing, anneal to temper.

- **annealing carbon**
  - See temper carbon .
- **annealing twin**

- A twin formed in a crystal during recrystallization.
- **anneal to temper**
  - A final partial anneal that softens a cold-worked nonferrous alloy to a specified level of hardness or tensile strength.
- **anode**
  - (1) The electrode of an electrolyte cell at which oxidation occurs. Electrons flow away from the anode in the external circuit. It is usually at the electrode that corrosion occurs and metal ions enter solution. (2) The positive (electron-deficient) electrode in an electrochemical circuit. Contrast with cathode .
- **anode copper**
  - Special-shaped copper slabs, resulting from the refinement of blister copper in a reverberatory furnace, used as anodes in electrolytic refinement.
- **anode effect**
  - The effect produced by polarization of the anode in electrolysis. It is characterized by a sudden increase in voltage and a corresponding decrease in amperage due to the anode becoming virtually separated from the electrolyte by a gas film.
- **anode efficiency**
  - Current efficiency at the anode .
- **anode film**
  - (1) The portion of solution in immediate contact with the anode, especially if the concentration gradient is steep. (2) The outer layer of the anode itself.
- **anode polarization**
  - See polarization .
- **anodic cleaning**
  - Electrolytic cleaning in which the work is the anode. Also called reverse-current cleaning.
- **anodic coating**
  - A film on a metal surface resulting from an electrolytic treatment at the anode.
- **anodic pickling**
  - Electrolytic pickling in which the work is the anode.
- **anodic polarization**
  - The change of the electrode potential in the noble (positive) direction due to current flow. See also polarization .
- **anodic protection**
  - (1) A technique to reduce the corrosion rate of a metal by polarizing it into its passive region, where dissolution rates are low. (2) Imposing an external electrical potential to protect a metal from corrosive attack. (Applicable only to metals that show active-passive behavior.) Contrast with cathodic protection .
- **anodic reaction**
  - Electrode reaction equivalent to a transfer of positive charge from the electronic to the ionic conductor. An anodic reaction is an oxidation process. An example common in corrosion is  $M(s) \rightarrow M(aq)^{2+} + 2e^-$ .
- **anodizing**
  - Forming a conversion coating on a metal surface by anodic oxidation; most frequently applied to aluminum.
- **anolyte**
  - The electrolyte adjacent to the anode in an electrolytic cell.
- **antiferromagnetic material**
  - A material wherein interatomic forces hold the elementary atomic magnets (electron spins) of a solid in alignment, a state similar to that of a ferromagnetic material but with the difference that equals numbers of elementary magnets (spins) face in opposite directions and are antiparallel, causing the solid to be weakly magnetic, that is, paramagnetic, instead of ferromagnetic.
- **antifriction material**
  - A material that exhibits low-friction or self-lubricating properties.
- **antipitting agent**
  - An addition agent for electroplating solutions to prevent the formation of pits or large pores in the electrodeposit.
- **anvil**

- A large, heavy metal block that supports the frame structure and holds the stationary die of a forging hammer. Also, the metal block on which blacksmith forgings are made.
- **anvil cap**
  - Same as sow block .
- **apparent density**
  - (1) The weight per unit volume of a powder, in contrast to the weight per unit volume of the individual particles. (2) The weight per unit volume of a porous solid, where the unit volume is determined from external dimensions of the mass. Apparent density is always less than the true density of the material itself.
- **Ar<sub>cm</sub>, Ar<sub>1</sub>, Ar<sub>3</sub>, Ar<sub>4</sub>, Ar', Ar''**
  - Defined under transformation temperature .
- **arbor**
  - (1) In machine grinding, the spindle on which the wheel is mounted. (2) In machine cutting, a shaft or bar for holding and driving the cutter. (3) In founding, a metal shape embedded in green sand or dry sand cores to support the sand or the applied load during casting.
- **arbor press**
  - A machine used for forcing arbors or mandrels into drilled or bored parts preparatory to turning or grinding. Also used for forcing bushings, shafts, or pins into or out of holes.
- **arbor-type cutter**
  - A cutter having a hole for mounting on an arbor and usually having a keyway for a driving key.
- **arc**
  - A luminous discharge of electrical current crossing the gap between two electrodes.
- **arc blow**
  - The deflection of an electric arc from its normal path because of magnetic forces.
- **arc brazing**
  - A brazing process in which the heat required is obtained from an electric arc.
- **arc cutting**
  - A group of cutting processes that melt the metals to be cut with the heat of an arc between an electrode and the base metal. See carbon arc cutting , metal arc cutting , gas metal arc cutting , gas tungsten arc cutting , plasma arc cutting , and air carbon arc cutting . Compare with oxygen arc cutting .
- **arc furnace**
  - A furnace in which metal is melted either directly by an electric arc between an electrode and the work or indirectly by an arc between two electrodes adjacent to the metal.
- **arc gouging**
  - An arc cutting process variation used to form a bevel or groove.
- **arc melting**
  - Melting metal in an electric arc furnace.
- **arc oxygen cutting**
  - See preferred term oxygen arc cutting .
- **arc plasma**
  - See plasma arc cutting .
- **arc seam weld**
  - A seam weld make by an arc welding process.
- **arc spot weld**
  - A spot weld made by an arc welding process.
- **arc spraying (ASP)**
  - A thermal spraying process using an arc between two consumable electrodes of surfacing materials as a heat source and a compressed gas to atomize and propel the surfacing material to the substrate.
- **arc strike**
  - A discontinuity consisting of any localized remelted metal, heat-affected metal, or change in the surface profile of any part of a weld or base metal resulting from an arc.
- **arc welding**
  - A group of welding processes that produce coalescence of metals by heating them with an arc, with or without the application of pressure, and with or without the use of filler metal.
- **arc welding electrode**

- See electrode (welding) .
- **argon oxygen decarburization (AOD)**
  - A secondary refining process for the controlled oxidation of carbon in a steel melt. In the AOD process, oxygen, argon, and nitrogen are injected into a molten metal bath through submerged, side-mounted tuyeres.
- **artifact**
  - A feature of artificial character, such as a scratch or a piece of dust on a metallographic specimen, that can be erroneously interpreted as a real feature.
- **artificial aging**
  - Aging above room temperature. See aging (heat treatment) . Compare with natural aging .
- **as-cast condition**
  - Castings as removed from the mold without subsequent heat treatment.
- **as-welded**
  - The condition of weld metal, welded joints, and weldments after welding, but prior to any subsequent thermal, mechanical, or chemical treatments.
- **athermal transformation**
  - A reaction that proceeds without benefit of thermal fluctuations--that is, thermal activation is not required. Such reactions are diffusionless and can take place with great speed when the driving force is sufficiently high. For example, many martensitic transformations occur athermally on cooling, even at relatively low temperatures, because of the progressively increasing drive force. In contrast, a reaction that occurs at constant temperature is an isothermal transformation; thermal activation is necessary in this case and the reaction proceeds as a function of time.
- **atmospheric corrosion**
  - The gradual degradation or alteration of a material by contact with substances present in the atmosphere, such as oxygen, carbon dioxide, water vapor, and sulfur and chlorine compounds.
- **atmospheric riser**
  - A riser that uses atmospheric pressure to aid feeding. Essentially, a blind riser into which a small core or rod protrudes; the function of the core or rod is to provide an open passage so that the molten interior of the riser will not be under a partial vacuum when metal is withdrawn to feed the casting but will always be under atmospheric pressure.
- **atomic number (Z)**
  - The number of protons in an atomic nucleus, which determines the individuality of the atom as a chemical element.
- **atomic percent**
  - The number of atoms of an element in a total of 100 representative atoms of a substance.
- **atomization**
  - The disintegration of a molten metal into particles by a rapidly moving gas or liquid stream or by other means.
- **attritious wear**
  - Wear of abrasive grains in grinding such that the sharp edges gradually become rounded. A grinding wheel that has undergone such wear usually has a glazed appearance.
- **attritor**
  - A high-intensity ball mill whose drum is stationary and whose balls are agitated by rotating baffles, paddles, or rods at right angle to the drum axis.
- **attritor grinding**
  - The intensive grinding or alloying in an attritor. Examples: milling of carbides and binder metal powders and mechanical alloying of hard dispersoid particles with softer metal or alloy powders. See also mechanical alloying .
- **Auger electron**
  - An electron emitted from an atom with a vacancy in an inner shell. Auger electrons have a characteristic energy detected as peaks in the energy spectra of the secondary electrons generated.
- **Auger electron spectroscopy (AES)**
  - A technique for chemical analysis of surface layers that identifies the atoms present in a layer by measuring the characteristic energies of their Auger electrons.
- **ausforming**
  - Thermomechanical treatment of steel in the metastable austenitic condition below the recrystallization temperature followed by quenching to obtain martensite and/or bainite.

- **austempered ductile iron**
  - A moderately alloyed ductile iron that is austempered for high strength with appreciable ductility. See also austempering .
- **austempering**
  - A heat treatment for ferrous alloys in which a part is quenched from the austenitizing temperature at a rate fast enough to avoid formation of ferrite or pearlite and then held at a temperature just above  $M_s$  until transformation to bainite is complete. Although designated as bainite in both austempered steel and austempered ductile iron (ADI), austempered steel consists of two phase mixtures containing ferrite and carbide, while austempered ductile iron consists of two phase mixtures containing ferrite and austenite.
- **austenite**
  - A solid solution of one or more elements in face-centered cubic iron (gamma iron). Unless otherwise designated (such as nickel austenite), the solute is generally assumed to be carbon.
- **austenitic grain size**
  - The size attained by the grains in steel when heated to the austenitic region. This may be revealed by appropriate etching of cross sections after cooling to room temperature.
- **austenitic manganese steel**
  - A wear-resistant material containing about 1.2% C and 12% Mn. Used primarily in the fields of earthmoving, mining, quarrying, railroading, ore processing, lumbering, and in the manufacture of cement and clay products. Also known as Hadfield steel.
- **austenitic steel**
  - An alloy steel whose structure is normally austenitic at room temperature.
- **austenitizing**
  - Forming austenite by heating a ferrous alloy into the transformation range (partial austenitizing) or above the transformation range (complete austenitizing). When used without qualification, the term implies complete austenitizing.
- **autogenous weld**
  - A fusion weld made without the addition of filler metal.
- **automatic press**
  - A press in which the work is fed mechanically through the press in synchronism with the press action. An automation press is an automatic press that, in addition, is provided with built-in electrical and pneumatic control equipment.
- **automatic welding**
  - Welding with equipment that performs the welding operation without adjustment of the controls by a welding operator. The equipment may or may not load and unload the workpieces. Contrast with machine welding .
- **auxiliary anode**
  - In electroplating, a supplementary anode positioned so as to raise the current density on a certain area of the cathode and thus obtain better distribution of plating.
- **auxiliary electrode**
  - An electrode commonly used in polarization studies to pass current to or from a test electrode. It is usually made from a noncorroding material.
- **axial rolls**
  - In ring rolling, vertically displaceable, taped rolls mounted in a horizontally displaceable frame opposite to, but on the same centerline as, the main roll and rolling mandrel. The axial rolls control ring height during rolling.
- **B**
- **Babbitt metal**
  - A nonferrous bearing alloy originated by Isaac Babbitt in 1839. Currently, the term includes several tin-base alloys consisting mainly of various amounts of copper, antimony, tin, and lead. Lead-base Babbitt metals are also used.
- **back draft**
  - A reverse taper on a casting pattern or a forging die that prevents the pattern or forged stock from being removed from the cavity.
- **backfire**
  - The momentary recession of the flame into the welding tip or cutting tip followed by immediate reappearance or complete extinction of the flame. See also flashback .
- **back gouging**

- The removal of weld metal and base metal from the other side of a partially welded joint to facilitate complete fusion and complete joint penetration upon subsequent welding from that side.
- **backing**
  - (1) In grinding, the material (paper, cloth, or fiber) that serves as the base for coated abrasives. (2) In welding, a material placed under or behind a joint to enhance the quality of the weld at the root. It may be a metal backing ring or strip; a pass of weld metal; or a nonmetal such as carbon, granular flux, or a protective gas. (3) In plain bearings, that part of the bearing to which the bearing alloy is attached, normally by a metallurgical bond.
- **backoff**
  - A rapid withdrawal of a grinding wheel or cutting tool from contact with a workpiece.
- **backward extrusion**
  - Same as indirect extrusion . See extrusion .
- **bainite**
  - A metastable aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures below the pearlite range but above  $M_s$ , the martensite start temperature. Upper bainite is an aggregate that contains parallel lath-shape units of ferrite, produces the so-called "feathery" appearance in optical microscopy, and is formed above approximately 350 °C (660 °F). Lower bainite, which has an acicular appearance similar to tempered martensite, is formed below approximately 350 °C (660 °F).
- **bainitic hardening**
  - Quench-hardening treatment resulting principally in the formation of bainite.
- **Bakelite**
  - A proprietary name for a phenolic thermosetting resin used as a plastic mounting material for metallographic samples.
- **baking**
  - (1) Heating to a low temperature in order to remove gases. (2) Curing or hardening surface coatings such as paints by exposure to heat. (3) Heating to drive off moisture, as in baking of sand cores after molding.
- **ball burnishing**
  - (1) Same as ball sizing . (2) Removing burrs and polishing small stampings and small machined parts by tumbling in the presence of metal balls.
- **ball mill**
  - A machine consisting of a rotating hollow cylinder partly filled with metal balls (usually hardened steel or white cast iron) or sometimes pebbles; used to pulverize crushed ores or other substances such as pigments or ceramics.
- **ball milling**
  - A method of grinding and mixing material, with or without liquid, in a rotating cylinder or conical mill partially filled with grinding media such as balls or pebbles.
- **ball sizing**
  - Sizing and finishing a hole by forcing a ball of suitable size, finish, and hardness through the hole or by using a burnishing bar or broach consisting of a series of spherical lands of gradually increasing size coaxially arranged. Also called ball burnishing , and sometimes ball broaching.
- **banded structure**
  - A segregated structure consisting of alternating nearly parallel bands of different composition, typically aligned in the direction of primary hot working.
- **banding**
  - Inhomogeneous distribution of alloying elements or phases aligned in filaments or plates parallel to the direction of working. See also banded structure , ferrite-pearlite banding , and segregation banding .
- **band mark**
  - An indentation in carbon steel or strip caused by external pressure on the packaging band around cut lengths or coils; it may occur in handling, transit, or storage.
- **bands**
  - Hot-rolled steel strip, usually produced for rerolling into thinner sheet or strip. Also known as hot bands or band steel.
- **bar**
  - (1) A section hot rolled from a billet to a form, such as round, hexagonal, octagonal, square, or rectangular, with sharp or rounded corners or edges and a cross-sectional area of less than 105

cm<sup>2</sup> (16 in.<sup>2</sup>). (2) A solid section that is long in relationship to its cross-sectional dimensions, having a completely symmetrical cross section and a width or greatest distance between parallel faces of 9.5 mm ( $\frac{3}{8}$  in.) or more. (3) An obsolete unit of pressure equal to 100 kPa.

- **bare electrode**
  - A filler metal electrode consisting of a single metal or alloy that has been produced into a wire, strip, or bar form and that has had no coating or covering applied to it other than that which was incidental to its manufacture or preservation.
- **bar folder**
  - A machine in which a folding bar or wing is used to bend a metal sheet whose edge is clamped between the upper folding leaf and the lower stationary jaw into a narrow, sharp, close, and accurate fold along the edge. It is also capable of making rounded folds such as those used in wiring. A universal folder is more versatile in that it is limited to width only by the dimensions of the sheet.
- **Barkhausen effect**
  - The sequence of abrupt changes in magnetic induction occurring when the magnetizing force acting on a ferromagnetic specimen is varied.
- **barrel cleaning**
  - Mechanical or electrolytic cleaning of metal in rotating equipment.
- **barrel finishing**
  - Improving the surface finish of workpieces by processing them in rotating equipment along with abrasive particles that may be suspended in a liquid. The barrel is normally loaded about 60% full with a mixture of parts, media, compound, and water.
- **barreling**
  - Convexity of the surfaces of cylindrical or conical bodies, often produced unintentionally during upsetting or as a natural consequence during compression testing.
- **barrel plating**
  - Plating articles in a rotating container, usually a perforated cylinder that operates at least partially submerged in a solution.
- **barstock**
  - Same as bar .
- **base**
  - (1) A chemical substance that yields hydroxyl ions (OH) when dissolved in water. Compare with acid . (2) The surface on which a single-point tool rests when held in a tool post. Also known as heel. (3) In forging, see anvil .
- **base metal**
  - (1) The metal present in the largest proportion in an alloy; brass, for example, is a copper-base alloy. (2) The metal to be brazed, cut, soldered, or welded. (3) After welding, that part of the metal that was not melted. (4) A metal that readily oxidizes or that dissolves to form ions. Contrast with noble metal (2) .
- **basic bottom and lining**
  - The inner bottom and lining of a melting furnace, consisting of materials such as crushed burned dolomite, magnesite, magnesite bricks, or basic slag that give a basic reaction at the operating temperature.
- **basic oxygen furnace**
  - A large tiltable vessel lined with basic refractory material that is a type of furnace for modern steelmaking. After the furnace is charged with molten pig iron (which usually comprises 65 to 75% of the charge), scrap steel, and fluxes, a lance is brought down near the surface of the molten metal and a jet of high-velocity oxygen impinges on the metal. The oxygen reacts with carbon and other impurities in the steel to form liquid compounds that dissolve in the slag and gases that escape from the top of the vessel.
- **basic refractories**
  - Refractories whose major constituent is lime, magnesia, or both, and which may react chemically with acid refractories, acid slags, or acid fluxes at high temperatures. Basic refractories are used for furnace linings. Compare with acid refractory .
- **basic steel**
  - Steel melted in a furnace with a basic bottom and lining and under a slag containing an excess of a basic substance such as magnesia or lime.

- **basis metal**
  - See preferred term substrate .
- **batch**
  - A quantity of materials formed during the same process or in one continuous process and having identical characteristics throughout. See also lot .
- **batch furnace**
  - A furnace used to heat treat a single load at a time. Batch-type furnaces are necessary for large parts such as heavy forgings and are preferred for complex alloy grades requiring long cycles.
- **Bauschinger effect**
  - The phenomenon by which plastic deformation increases yield strength in the direction of plastic flow and decreases it in other directions.
- **bauxite**
  - A whitish to reddish mineral composed largely of hydrates of alumina having a composition of  $\text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$ . It is the most important ore (source) of aluminum, alumina abrasives, and alumina-base refractories.
- **Bayer process**
  - A process for extracting alumina from bauxite ore before the electrolytic reduction. The bauxite is digested in a solution of sodium hydroxide, which converts the alumina to soluble aluminate. After the "red mud" residue has been filtered out, aluminum hydroxide is precipitated, filtered out, and calcined to alumina.
- **beach marks**
  - Macroscopic progression marks on a fatigue fracture or stress-corrosion cracking surface that indicate successive positions of the advancing crack front. The classic appearance is of irregular elliptical or semielliptical rings, radiating outward from one or more origins. Beach marks (also known as clamshell marks or arrest marks) are typically found on service fractures where the part is loaded randomly, intermittently, or with periodic variations in mean stress or alternating stress. See also striation .
- **bead**
  - (1) Half-round cavity in a mold, or half-round projection or molding on a casting. (2) A single deposit of weld metal produced by fusion.
- **beaded flange**
  - A flange reinforced by a low ridge, used mostly around a hole.
- **beading**
  - Raising a ridge or projection on sheet metal.
- **bead weld**
  - See preferred term surfacing weld .
- **bearing strength**
  - The maximum bearing stress that can be sustained. Also, the bearing stress at that point on the stress-strain curve at which the tangent is equal to the bearing stress divided by  $n\%$  of the bearing hole diameter.
- **bearing stress**
  - The shear load on a mechanical joint (such as a pinned or riveted joint) divided by the effective bearing area. The effective bearing area of a riveted joint, for example, is the sum of the diameters of all rivets times the thickness of the loaded member.
- **bearing test**
  - A method of determining the response to stress (load) of sheet products that are subjected to riveting, bolting, or a similar fastening procedure. The purpose of the test is to determine the bearing strength of the material and to measure the bearing stress versus the deformation of the hole created by a pin or rod of circular cross section that pierces the sheet perpendicular to the surface.
- **bed**
  - (1) The stationary portion of a press structure that usually rests on the floor or foundation, forming the support for the remaining parts of the press and the pressing load. The bolster and sometimes the lower die are mounted on the top surface of the bed. (2) For machine tools, the portion of the main frame that supports the tool, the work, or both. (3) Stationary part of the shear frame that supports the material being sheared and the fixed blade.
- **Beilby layer**

- A layer of metal disturbed by mechanical working, wear, or mechanical polishing presumed to be without regular crystalline structure (amorphous); originally applied to grain boundaries.
- **belt furnace**
  - A continuous-type furnace that uses a mesh-type or cast-link belt to carry parts through the furnace.
- **belt grinding**
  - Grinding with an abrasive belt.
- **bench molding**
  - Casting sand molds by hand tamping loose or production patterns at a bench without the assistance of air or hydraulic action.
- **bend allowance**
  - The length of the arc of the neutral axis between the tangent points of a bend.
- **bend angle**
  - The angle through which a bending operation is performed, that is, the supplementary angle to that formed by the two bend tangent lines or planes.
- **bending**
  - The straining of material, usually flat sheet or strip metal, by moving it around a straight axis lying in the neutral plane. Metal flow takes place within the plastic range of the metal, so that the bent part retains a permanent set after removal of the applied stress. The cross section of the bend inward from the neutral plane is in compression; the rest of the bend is in tension.
- **bending brake**
  - A form of open-frame single-action press that is comparatively wide between the housings, with a bed designed for holding long, narrow forming edges or dies. Used for bending and forming strip, plate, and sheet (into boxes, panels, roof decks, and so on). Also known as press brake .
- **bending dies**
  - Dies used in presses for bending sheet metal or wire parts into various shapes. The work is done by the punch pushing the stock into cavities or depressions of similar shape in the die or by auxiliary attachments operated by the descending punch.
- **bending moment**
  - The algebraic sum of the couples or the moments of the external forces, or both, to the left or right of any section on a member subjected to bending by couples or transverse forces, or both.
- **bending rolls**
  - Various types of machinery equipped with two or more rolls to form curved sheet and sections.
- **bend or twist (defect)**
  - Distortion similar to warpage generally caused during forging or trimming operations. When the distortion is along the length of the part, it is termed bend; when across the width, it is termed twist. When bend or twist exceeds tolerance, it is considered a defect. Corrective action consists of hand straightening, machine straightening, or cold restriking.
- **bend radius**
  - (1) The inside radius of a bend section. (2) The radius of a tool around which metal is bent during fabrication.
- **bend tangent**
  - A tangent point at which a bending arc ceases or changes.
- **bend test**
  - A test for determining relative ductility of metal that is to be formed (usually sheet, strip, plate, or wire) and for determining soundness and toughness of metal (after welding, for example). The specimen is usually bent over a specified diameter through a specified angle for a specified number of cycles.
- **beneficiation**
  - Concentration or other preparation of ore for smelting.
- **bentonite**
  - A colloidal claylike substance derived from the decomposition of volcanic ash composed chiefly of the minerals of the montmorillonite family. It is used for bonding molding sand.
- **Bessemer process**
  - A process for making steel by blowing air through molten pig iron contained in a refractory lined vessel so as to remove by oxidation most of the carbon, silicon, and manganese. This process is essentially obsolete in the United States.
- **beta ( $\beta$ ) ray**

- A ray of electrons emitted during the spontaneous disintegration of certain atomic nuclei.
- **beta ( $\beta$ ) structure**
  - A Hume-Rothery designation for structurally analogous body-centered cubic phases (similar to  $\beta$  brass) or electron compounds that have ratios of three valence electrons to two atoms. Not to be confused with a  $\beta$  phase on a phase diagram.
- **bevel**
  - An angular edge preparation in a weld member.
- **bevel flanging**
  - Same as flaring .
- **biaxiality**
  - In a biaxial stress state, the ratio of the smaller to the larger principal stress.
- **biaxial stress**
  - A state of stress in which only one of the principal stresses is zero, the other two usually being in tension.
- **billet**
  - (1) A semifinished section that is hot rolled from a metal ingot, with a rectangular cross section usually ranging from 105 to 230 cm<sup>2</sup> (16 to 36 in.<sup>2</sup>), the width being less than twice the thickness. Where the cross section exceeds 230 cm<sup>2</sup> (36 in.<sup>2</sup>), the term bloom is properly but not universally used. Sizes smaller than 105 cm<sup>2</sup> (16 in.<sup>2</sup>) are usually termed bars. (2) A solid semifinished round or square product that has been hot worked by forging, rolling, or extrusion. See also bar .
- **billet mill**
  - A primary rolling mill used for making steel billets.
- **binary alloy**
  - An alloy containing only two component elements.
- **binary system**
  - The complete series of compositions produced by mixing a pair of components in all proportions.
- **binder**
  - (1) In foundry, a material, other than water, added to foundry sand to bind the particles together, sometimes with the use of heat. (2) In powder technology, a cementing medium: either a material added to the powder to increase the green strength of the compact, which is expelled during sintering; or a material (usually of relatively low melting point) added to a powder mixture for the specific purpose of cementing together powder particles that alone would not sinter into a strong body.
- **binder metal**
  - A metal used as a binder. An example would be cobalt in cemented carbides.
- **biological corrosion**
  - Deterioration of metals as a result of the metabolic activity of microorganisms. Also known as biofouling.
- **bipolar electrode**
  - An electrode in an electrolytic cell that is not mechanically connected to the power supply, but is so placed in the electrolyte, between the anode and cathode, that the part nearer the anode becomes cathodic and the part nearer the cathode becomes anodic. Also called intermediate electrode.
- **bipolar field**
  - A longitudinal magnetic field that creates two magnetic poles within a piece of material. Compare with circular field .
- **black annealing**
  - Box annealing or pot annealing ferrous alloy sheet, strip, or wire impart a black color to the oxidized surface. See also box annealing .
- **blackheart malleable**
  - See malleable iron .
- **blackening**
  - Carbonaceous materials, such as graphite or powdered carbon, usually mixed with a binder and frequently carried in suspension in water or other liquid used as a thin facing applied to surfaces of molds or cores to improve casting finish.
- **black oxide**
  - A black finish on a metal produced by immersing it in hot oxidizing salts or salt solutions.

- **blank**
  - (1) In forming, a piece of sheet metal, produced in cutting dies, that is usually subjected to further press operations. (2) A pressed, presintered, or fully sintered powder metallurgy compact, usually in the unfinished condition and requiring cutting, machining, or some other operation to produce the final shape. (3) A piece of stock from which a forging is made, often called a slug or multiple .
- **blank carburizing**
  - Simulating the carburizing operation without introducing carbon. This is usually accomplished by using an inert material in place of the carburizing agent, or by applying a suitable protective coating to the ferrous alloy.
- **blankholder**
  - (1) The part of a drawing or forming die that holds the workpiece against the draw ring to control metal flow. (2) The part of a drawing or forming die that restrains the movement of the workpiece to avoid wrinkling or tearing of the metal.
- **blanking**
  - The operation of punching, cutting, or shearing a piece out of stock to a predetermined shape.
- **blank nitriding**
  - Simulating the nitriding operation without introducing nitrogen. This is usually accomplished by using an inert material in place of the nitriding agent or by applying a suitable protective coating to the ferrous alloy.
- **blast furnace**
  - A shaft furnace in which solid fuel is burned with an air blast to smelt ore in a continuous operation. Where the temperature must be high, as in the production of pig iron, the air is preheated. Where the temperature can be lower, as in smelting of copper, lead, and tin ores, a smaller furnace is economical, and preheating of the blast is not required.
- **blasting or blast cleaning**
  - A process for cleaning or finishing metal objects with an air blast or centrifugal wheel that throws abrasive particles against the surface of the workpiece. Small, irregular particles of metal are used as the abrasive in gritblasting; sand, in sandblasting; and steel, in shotblasting.
- **blended sand**
  - A mixture of sands of different grain size and clay content that provides suitable characteristics for foundry use.
- **blending**
  - In powder metallurgy, the thorough intermingling of powders of the same nominal composition (not to be confused with mixing ).
- **blind riser**
  - A riser that does not extend through the top of the mold.
- **blister**
  - (1) A casting defect, on or near the surface of the metal, resulting from the expansion of gas in a subsurface zone. It is characterized by a smooth bump on the surface of the casting and a hole inside the casting directly below the bump. (2) A raised area, often dome shaped, resulting from loss of adhesion between a coating or deposit and the substrate.
- **blister copper**
  - An impure intermediate product in the refining of copper, produced by blowing copper matte in a converter, the name being derived from the large blisters on the cast surface that result from the liberation of SO<sub>2</sub> and other gases.
- **block**
  - A preliminary forging operation that roughly distributes metal preparatory for finish.
- **block and finish**
  - The forging operation in which a part to be forged is blocked and finished in one heat through the use of tooling having both a block impression and a finish impression in the same die block.
- **blocker**
  - The impression in the dies (often one of a series of impressions in a single die set) that imparts to the forging an intermediate shape, preparatory to forging of the final shape. Also called blocking impression.
- **blocker dies**
  - Forging dies having generous contours, large radii, draft angles of 7° or more, and liberal finish allowances. See also finish allowance .

- **blocker-type forging**
  - A forging that approximates the general shape of the final part with relatively generous finish allowance and radii. Such forgings are sometimes specified to reduce die costs where only a small number of forgings are described and the cost of machining each part to its final shape is not excessive.
- **blocking**
  - In forging, a preliminary operation performed in closed dies, usually hot, to position metal properly so that in the finish operation the dies will be filled correctly. Blocking can ensure proper working of the material and can increase die life.
- **blocking impression**
  - Same as blocker .
- **bloom**
  - (1) A semifinished hot-rolled product, rectangular in cross section, produced on a blooming mill. See also billet . For steel, the width of a bloom is not more than twice the thickness, and the cross-sectional area is usually not less than about 230 cm<sup>2</sup> (36 in.<sup>2</sup>). Steel blooms are sometimes made by forging. (2) A visible exudation or efflorescence on the surface of an electroplating bath. (3) A bluish fluorescent cast to a painted surface caused by deposition of a thin film of smoke, dust, or oil. (4) A loose, flowerlike corrosion product that forms when certain metals are exposed to a moist environment.
- **blooming mill**
  - A primary rolling mill used to make blooms.
- **blowhole**
  - A hole in a casting or a weld caused by gas entrapped during solidification. See also porosity .
- **blue annealing**
  - Heating hot-rolled ferrous sheet in an open furnace to a temperature within the transformation range, then cooling in air to soften the metal. A bluish oxide surface layer forms.
- **blue brittleness**
  - Brittleness exhibited by some steels after being heated to some temperature within the range of about 205 to 370 °C (400 to 700 °F), particularly if the steel is worked at the elevated temperature. Killed steels are virtually free of this kind of brittleness.
- **bluing**
  - Subjecting the scale-free surface of a ferrous alloy to the action of air, steam, or other agents at a suitable temperature, thus forming a thin blue film of oxide and improving the appearance and resistance to corrosion. This term is ordinarily applied to sheet, strip, or finished parts. It is used also to denote the heating of springs after fabrication to improve their properties.
- **board hammer**
  - A type of forging hammer in which the upper die and ram are attached to "boards" that are raised to the striking position by power-driven rollers and let fall by gravity. See also gravity hammer .
- **bolster**
  - A plate to which dies may be fastened, the assembly being secured to the top surface of a press bed. In mechanical forging, such a plate is also attached to the ram .
- **bond**
  - (1) In grinding wheels and other relatively rigid abrasive products, the material that holds the abrasive grains together. (2) In welding, brazing, or soldering, the junction of joined parts. Where filler metal is used, it is the junction of the fused metal and the heat-affected base metal. (3) In an adhesive-bonded or diffusion-bonded joint, the line along which the faying surfaces are joined together. (4) In thermal spraying, the junction between the material deposited and the substrate, or its strength.
- **book mold**
  - A split permanent mold hinged like a book.
- **bore**
  - A hole or cylindrical cavity produced by a single-point or multipoint tool other than a drill.
- **boriding**
  - Thermochemical treatment involving the enrichment of the surface layer of an object with borides. This surface-hardening process is performed below the Ac<sub>1</sub> temperature. Also referred to as boronizing.
- **boring**

- Enlarging a hole by removing metal with a single- or occasionally a multiple-point cutting tool moving parallel to the axis of rotation of the work or tool.
- **bort**
  - (1) Natural diamond of a quality not suitable for gem use. (2) Industrial diamond.
- **bosh**
  - (1) The section of a blast furnace extending upward from the tuyeres to the plane of maximum diameter. (2) A lining of quartz that builds up during the smelting of copper ores and that decreases the diameter of the furnace at the tuyeres. (3) A tank, often with sloping sides, used for washing metal parts or for holding cleaned parts.
- **boss**
  - A relatively short protrusion or projection from the surface of a forging or casting, often cylindrical in shape. Usually intended for drilling and tapping for attaching parts.
- **bottom board**
  - In casting, a flat base for holding the flask in making sand molds.
- **bottom drill**
  - A flat-ended twist drill used to convert a cone at the bottom of a drilled hole into a cylinder.
- **bottoming tap**
  - A tap with a chamfer of 1 to  $1\frac{1}{2}$  threads in length.
- **bottom pipe**
  - An oxide-lined fold or cavity at the butt end of a slab, bloom, or billet; formed by folding the end of an ingot over on itself during primary rolling. Bottom pipe is not pipe, in that it is not a shrinkage cavity, and in that sense, the term is a misnomer. Bottom pipe is similar to extrusion pipe. It is normally discarded when the slab, bloom, or billet is cropped following primary reduction.
- **bowing**
  - Deviation from flatness.
- **box annealing**
  - Annealing a metal or alloy in a sealed container under conditions that minimize oxidation. In box annealing a ferrous alloy, the charge is usually heated slowly to a temperature below the transformation range, but sometimes above or within it, and is then cooled slowly; this process is also called close annealing or pot annealing. See also black annealing.
- **boxing**
  - The continuation of a fillet weld around a corner of a member as an extension of the principal weld.
- **brake**
  - A device for bending sheet metal to a desired angle.
- **brale indenter**
  - A conical 120° diamond indenter with a conical tip (a 0.2 mm tip radius is typical) used in certain types of Rockwell and scratch hardness tests.
- **brass**
  - A copper-zinc alloy containing up to 40% Zn, to which smaller amounts of other elements may be added.
- **braze**
  - A weld produced by heating an assembly to suitable temperatures and by using a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base metal. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.
- **brazeability**
  - The capacity of a metal to be brazed under the fabrication conditions imposed into a specific suitably designed structure and to perform satisfactorily in the intended service.
- **braze welding**
  - A method of welding by using a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base metals. Unlike brazing, in braze welding, the filler metal is not distributed in the joint by capillary attraction.
- **brazing**
  - A group of welding processes that join solid materials together by heating them to a suitable temperature and using a filler metal having a liquidus above 450 °C (840 °F) and below the

solidus of the base materials. The filler metal is distributed between the closely fitted surfaces of the joint by capillary attraction.

- **brazing alloy**
  - See preferred term brazing filler metal .
- **brazing filler metal**
  - (1) The metal that fills the capillary gap and has a liquidus above 450 °C (840 °F) but below the solidus of the base materials. (2) A nonferrous filler metal used in brazing and braze welding.
- **brazing sheet**
  - Brazing filler metal in sheet form.
- **breakdown**
  - (1) An initial rolling or drawing operation, or a series of such operations, for the purpose of reducing a casting or extruded shape prior to the finish reduction to desired size. (2) A preliminary press-forging operation.
- **breaking stress**
  - Same as fracture stress (1) .
- **breaks**
  - Creases or ridges usually in "untempered" or in aged material where the yield point has been exceeded. Depending on the origin of the breaks, they may be termed cross breaks , coil breaks , edge breaks, or sticker breaks .
- **bridge die**
  - A two-section extrusion die capable of producing tubing or intricate hollow shapes without the use of a separate mandrel. Metal separates into two streams as it is extruded past a bridge section, which is attached to the main die section and holds a stub mandrel in the die opening; the metal then is rewelded by extrusion pressure before it enters the die opening.
- **bridging**
  - (1) Premature solidification of metal across a mold section before the metal below or beyond solidifies. (2) Solidification of slag within a cupola at or just above the tuyeres. (3) Welding or mechanical locking of the charge in a downfeed melting or smelting furnace. (4) In powder metallurgy, the formation of arched cavities in a powder mass. (5) In soldering, an unintended solder connection between two or more conductors, either securely or by mere contact. Also called a crossed joint or solder short.
- **bright annealing**
  - Annealing in a protective medium to prevent discoloration of the bright surface.
- **bright dip**
  - A solution that produces, through chemical action, a bright surface on an immersed metal.
- **brightener**
  - An agent or combination of agents added to an electroplating bath to produce a lustrous deposit.
- **bright finish**
  - A high-quality finish produced on ground and polished rolls. Suitable for electroplating.
- **bright nitriding**
  - Nitriding in a protective medium to prevent discoloration of the bright surface. Compare with blank nitriding .
- **bright plate**
  - An electrodeposit that is lustrous in the as-plated condition.
- **Brinell hardness number (HB)**
  - A number related to the applied load and to the surface area of the permanent impression made by a ball indenter computed from:

$$HB = 0.012 \times \frac{2F}{D(D - \sqrt{D^2 - d^2})}$$

- where  $F$  is the test force, N;  $D$  is diameter of ball, mm; and  $d$  is mean diameter of the impression, mm.
- **Brinell hardness test**

- A test for determining the hardness of a material by forcing a hard steel or carbide ball of specified diameter (typically, 10 mm) into it under a specified load. The result is expressed as the Brinell hardness number.
- **brinelling**
  - (1) Indentation of the surface of a solid body by repeated local impact or impacts, or static overload. Brinelling may occur especially in a rolling-element bearing. (2) Damage to a solid bearing surface characterized by one or more plastically formed indentations brought about by overload. See also false brinelling .
- **brine quenching**
  - A quench in which brine (salt water-chlorides, carbonates, and cyanides) is the quenching medium. The salt addition improves the efficiency of water at the vapor phase or hot stage of the quenching process.
- **brittle crack propagation**
  - A very sudden propagation of a crack with the absorption of no energy except that stored elastically in the body. Microscopic examination may reveal some deformation even though it is not noticeable to the unaided eye. Contrast with ductile crack propagation .
- **brittle fracture**
  - Separation of a solid accompanied by little or no macroscopic plastic deformation. Typically, brittle fracture occurs by rapid crack propagation with less expenditure of energy than for ductile fracture. Brittle tensile fractures have a bright, granular appearance and exhibit little or no necking. A chevron pattern may be present on the fracture surface, pointing toward the origin of the crack, especially in brittle fractures in flat platelike components. Examples of brittle fracture include transgranular cracking (cleavage and quasi-cleavage fracture) and intergranular cracking (decohesive rupture).
- **brittleness**
  - The tendency of a material to fracture without first undergoing significant plastic deformation. Contrast with ductility .
- **broaching**
  - Cutting with a tool that consists of a bar having a single edge or a series of cutting edges (i.e., teeth) on its surface. The cutting edges of multiple-tooth, or successive single-tooth, broaches increase in size and/or change in shape. The broach cuts in a straight line or axial direction when relative motion is produced in relation to the workpiece, which may also be rotating. The entire cut is made in single or multiple passes over the workpiece to shape the required surface contour.
- **bronze**
  - A copper-rich copper-tin alloy with or without small proportions of other elements such as zinc and phosphorus. By extension, certain copper-base alloys containing considerably less tin than other alloying elements, such as manganese bronze (copper-zinc plus manganese, tin, and iron) and leaded tin bronze (copper-lead plus tin and sometimes zinc). Also, certain other essentially binary copper-base alloys containing no tin, such as aluminum bronze (copper-aluminum), silicon bronze (copper-silicon), and beryllium bronze (copper-beryllium). Also, trade designations for certain specific copper-base alloys that are actually brasses, such as architectural bronzes (57 Cu, 40 Zn, 3 Pb) and commercial bronze (90 Cu, 10 Zn).
- **bronzing**
  - (1) Applying a chemical finish to copper or copper-alloy surfaces to alter the color. (2) Plating a copper-tin alloy on various materials.
- **brush anodizing**
  - An anodizing process similar to brush plating .
- **brush plating**
  - Plating with a concentrated solution or gel held in or fed to an absorbing medium, pad, or brush carrying the anode (usually insoluble). The brush is moved back and forth over the area of the cathode to be plated.
- **buckle**
  - (1) Bulging of a large, flat face of a casting; in investment casting, caused by dip coat peeling from the pattern. (2) An indentation in a casting, resulting from expansion of the sand, can be termed the start of an expansion defect. (3) A local waviness in metal bar or sheet, usually transverse to the direction of rolling.
- **buckling**

- (1) A mode of failure generally characterized by an unstable lateral material deflection due to compressive action on the structural element involved. (2) In metal forming, a bulge, bend, kink, or other wavy condition of the workpiece caused by compressive stresses. See also compressive stress .
- **buffer**
  - (1) A substance that by its addition or presence tends to minimize the physical and chemical effects of one or more of the substances in a mixture. Properties often buffered include pH, oxidation potential, and flame or plasma temperatures. (2) A substance whose purpose is to maintain a constant hydrogen-ion concentration in water solutions, even where acids or alkalis are added. Each buffer has a characteristic limited range of pH over which it is effective.
- **buffing**
  - Developing a lustrous surface by contacting the work with a rotating buffing wheel.
- **buffing wheel**
  - Buff sections assembled to the required face width for use on a rotating shaft between flanges. Sometimes called a buff.
- **buildup**
  - (1) A weld surfacing variation in which surfacing metal is deposited to achieve the required dimensions. See also buttering . (2) Excessive electrodeposition that occurs on high-current-density areas, such as corners or edges.
- **built-up edge**
  - (1) Chip material adhering to the tool face adjacent to the cutting edge during cutting. (2) Material from the workpiece, especially in machining, which is stationary with respect to the tool.
- **bulging**
  - (1) Expanding the walls of a cup, shell, or tube with an internally expanded segmented punch or a punch composed of air, liquids, or semiliquids such as waxes, rubber, and other elastomers. (2) The process of increasing the diameter of a cylindrical shell (usually to a spherical shape) or of expanding the outer walls of any shell or box shape whose walls were previously straight.
- **bulk forming**
  - Forming processes, such as extrusion, forging, rolling, and drawing, in which the input material is in billet, rod, or slab form and a considerable increase in surface-to-volume ratio in the formed part occurs under the action of largely compressive loading. Compare with sheet forming .
- **bulk modulus of elasticity ( $K$ )**
  - The measure of resistance to change in volume; the ratio of hydrostatic stress to the corresponding unit change in volume. This elastic constant can be expressed by:

$$K = \frac{\sigma_m}{\Delta V} = \frac{-p}{\Delta V} = \frac{1}{\beta}$$

- where  $K$  is the bulk modulus of elasticity,  $\sigma_m$  is hydrostatic or mean stress tensor,  $p$  is hydrostatic pressure, and  $\beta$  is compressibility. Also known as bulk modulus, compression modulus, hydrostatic modulus, and volumetric modulus of elasticity.
- **bull block**
  - A machine with a power-driven revolving drum for cold drawing wire through a drawing die as the wire winds around the drum.
- **bulldozer**
  - Slow-acting horizontal mechanical press with a large bed used for bending and straightening. The work is done between dies and can be performed hot or cold. The machine is closely allied to a forging machine.
- **bullion**
  - (1) A semirefined alloy containing sufficient precious metal to make recovery profitable. (2) Refined gold or silver, uncoined.
- **bull's-eye structure**
  - The microstructure of malleable or ductile cast iron when graphite nodules are surrounded by a ferrite layer in a pearlitic matrix.
- **bumper**

- A machine used for packing molding sand in a flask by repeated jarring or jolting. See also jolt ramming .
- **bumping**
  - (1) Forming a dish in metal by means of many repeated blows. (2) Forming a head. (3) Setting the seams on sheet metal parts. (4) Ramming sand in a flask by repeated jarring and jolting.
- **burned deposit**
  - A dull, nodular electrodeposit resulting from excessive plating current density.
- **burned-in sand**
  - A defect consisting of a mixture of sand and metal cohering to the surface of a casting.
- **burned-on sand**
  - A mixture of sand and cast metal adhering to the surface of a casting. In some instances, may resemble metal penetration .
- **burned plating**
  - See burned deposit .
- **burning**
  - (1) Permanently damaging a metal or alloy by heating to cause either incipient melting or intergranular oxidation. See also overheating . (2) During subcritical annealing, particularly in continuous annealing, production of a severely decarburized and grain-coarsened surface layer that results from excessively prolonged heating to an excessively high temperature. (3) In grinding, getting the work hot enough to cause discoloration or to change the microstructure by tempering or hardening. (4) In sliding contacts, the oxidation of a surface due to local heating in an oxidizing environment.
- **burnishing**
  - Finish sizing and smooth finishing of surfaces (previously machined or ground) by displacement, rather than removal, of minute surface irregularities with smooth-point or line-contact fixed or rotating tools.
- **burnoff**
  - (1) Unintentional removal of an autocatalytic deposit from a nonconducting substrate, during subsequent electroplating operations, owing to the application of excessive current or a poor contact area. (2) Removal of volatile lubricants such as metallic stearates from metal powder compacts by heating immediately prior to sintering.
- **burr**
  - (1) A thin ridge or roughness left on a workpiece (e.g., forgings or sheet metal blanks) resulting from cutting, punching, or grinding. (2) A rotary tool having teeth similar to those on hand files.
- **burring**
  - Same as deburring .
- **bushing**
  - A bearing or guide.
- **buster**
  - A pair of shaped dies used to combine preliminary forging operations, such as edging and blocking, or to loosen scale.
- **butler finish**
  - A semilustrous metal finish composed of fine, uniformly distributed parallel lines, usually produced with a soft abrasive buffing wheel; similar in appearance to the traditional hand-rubbed finish on silver.
- **buttering**
  - A form of surfacing in which one or more layers of weld metal are deposited on the groove face of one member (for example, a high-alloy weld deposit on steel base metal that is to be welded to a dissimilar base metal). The buttering provides a suitable transition weld deposit for subsequent completion of the butt weld (joint).
- **button**
  - (1) A globule of metal remaining in an assaying crucible or cupel after fusion has been completed. (2) That part of a weld that tears out in destructive testing of a spot, seam, or projection welded specimen.
- **C**
- **cake**
  - (1) A copper or copper alloy casting, rectangular in cross section, used for rolling into sheet or strip. (2) A coalesced mass of unpressed metal powder.

- **calcination**
  - Heating ores, concentrates, precipitates, or residues to decompose carbonates, hydrates, or other compounds.
- **calomel electrode**
  - (1) An electrode widely used as a reference electrode of known potential in electrometric measurement of acidity and alkalinity, corrosion studies, voltammetry, and measurement of the potentials of other electrodes. (2) A secondary reference electrode of the composition: Pt/Hg-Hg<sub>2</sub>Cl<sub>2</sub>/KCl solution. For 1.0 N KCl solution, its potential versus a hydrogen electrode at 25 °C (77 °F) and one atmosphere is +0.281 V.
- **calorizing**
  - Imparting resistance to oxidation to an iron or steel surface by heating in aluminum powder at 800 to 1000 °C (1470 to 1830 °F).
- **camber**
  - (1) Deviation from edge straightness, usually referring to the greatest deviation of side edge from a straight line. (2) The tendency of material being sheared from sheet to bend away from the sheet in the same plane. (3) Sometimes used to denote crown in rolls where the center diameter has been increased to compensate for deflection caused by the rolling pressure. (4) The planar deflection of a flat cable or flexible laminate from a straight line of specified length. A flat cable or flexible laminate with camber is similar to the curve of an unbanked race track.
- **cam press**
  - A mechanical forming press in which one or more of the slides are operated by cams; usually a double-action press in which the blankholder slide is operated by cams through which the dwell is obtained.
- **can**
  - A sheathing of soft metal that encloses a sintered metal billet for the purpose of hot working (hot isostatic pressing, hot extrusion) without undue oxidation.
- **canning**
  - (1) A dished distortion in a flat or nearly flat sheet metal surface, sometimes referred to as oil canning. (2) Enclosing a highly reactive metal within a relatively inert material for the purpose of hot working without undue oxidation of the active metal.
- **capillary action**
  - (1) The phenomenon of intrusion of a liquid into interconnected small voids, pores, and channels in a solid, resulting from surface tension. (2) The force by which liquid, in contact with a solid, is distributed between closely fitted faying surfaces of the joint to be brazed or soldered.
- **capillary attraction**
  - (1) The combined force of adhesion and cohesion that causes liquids, including molten metals, to flow between very closely spaced and solid surfaces, even against gravity. (2) In powder metallurgy, the driving force for the infiltration of the pores of a sintered compact by a liquid.
- **capped steel**
  - A type of steel similar to rimmed steel, usually cast in a bottle-top ingot mold, in which the application of a mechanical or a chemical cap renders the rimming action incomplete by causing the top metal to solidify. The surface condition of capped steel is much like that of rimmed steel, but certain other characteristics are intermediate between those of rimmed steel and those of semikilled steel .
- **capping**
  - Partial or complete separation of a powder metallurgy compact into two or more portions by cracks that originate near the edges of the punch faces and that proceed diagonally into the compact.
- **carbide**
  - A compound of carbon with one or more metallic elements.
- **carbide tools**
  - Cutting or forming tools, usually made from tungsten, titanium, tantalum, or niobium carbides, or a combination of them, in a matrix of cobalt, nickel, or other metals. Carbide tools are characterized by high hardnesses and compressive strengths and may be coated to improve wear resistance. See also cemented carbide .
- **carbon arc cutting**
  - An arc cutting process in which metals are severed by melting them with the heat of an arc between a carbon electrode and the base metal.

- **carbon arc welding**
  - An arc welding process that produces coalescence of metals by heating them with an arc between a carbon electrode and the work. No shielding is used. Pressure and filler metal may or may not be used.
- **carbon edges**
  - Carbonaceous deposits in a wavy pattern along the edges of a steel sheet or strip; also known as snaky edges.
- **carbon electrode**
  - A nonfiller material electrode used in arc welding or cutting, consisting of a carbon or graphite rod, which may be coated with copper or other coatings.
- **carbon equivalent**
  - (1) For cast iron, an empirical relationship of the total carbon, silicon, and phosphorus contents expressed by the formula:

$$CE = \%C + 0.3(\%Si) + 0.33(\%P) - 0.027(\%Mn) + 0.4(\%S)$$

- (2) For rating of weldability:

$$CE = C + \frac{Mn}{6} + \frac{Ni}{15} + \frac{Cu}{15} + \frac{Cr}{5} + \frac{Mo}{5} + \frac{V}{5}$$

- **carbonitriding**
  - A case-hardening process in which a suitable ferrous material is heated above the lower transformation temperature in a gaseous atmosphere of such composition as to cause simultaneous absorption of carbon and nitrogen by the surface and, by diffusion, create a concentration gradient. The heat-treating process is completed by cooling at a rate that produces the desired properties in the workpiece.
- **carbonization**
  - The high-temperature conversion of an organic substance into elemental carbon. Should not be confused with *carburization*.
- **carbonizing flame**
  - See preferred term reducing flame .
- **carbon potential**
  - A measure of the ability of an environment containing active carbon to alter or maintain, under prescribed conditions, the carbon level of a steel. In any particular environment, the carbon level attained will depend on such factors as temperature, time, and steel composition.
- **carbon steel**
  - Steel having no specified minimum quantity for any alloying element--other than the commonly accepted amounts of manganese (1.65%), silicon (0.60%), and copper (0.60%)--and containing only an incidental amount of any element other than carbon, silicon, manganese, copper, sulfur, and phosphorus. Low-carbon steels contain up to 0.30% C, medium-carbon steels contain from 0.30 to 0.60% C, and high-carbon steels contain from 0.60 to 1.00% C.
- **carbonyl powder**
  - Metal powders prepared by the thermal decomposition of a metal carbonyl compound such as nickel tetracarbonyl  $Ni(CO)_4$  or iron pentacarbonyl  $Fe(CO)_5$ . See also thermal decomposition .
- **carburizing**
  - Absorption and diffusion of carbon into solid ferrous alloys by heating, to a temperature usually above  $A_{c3}$ , in contact with a suitable carbonaceous material. A form of case hardening that produces a carbon gradient extending inward from the surface, enabling the surface layer to be hardened either by quenching directly from the carburizing temperature or by cooling to room temperature, then re-austenitizing and quenching.
- **carburizing flame**
  - A gas flame that will introduce carbon into some heated metals, as during a gas welding operation. A carburizing flame is a reducing flame, but a reducing flame is not necessarily a carburizing flame.
- **case**

- In heat treating, that portion of a ferrous alloy, extending inward from the surface, whose composition has been altered during case hardening. Typically considered to be the portion of an alloy (a) whose composition has been measurably altered from the original composition, (b) that appears light when etched, or (c) that has a higher hardness value than the core. Contrast with core .
- **case crushing**
  - A term used to denote longitudinal gouges arising from fracture in case-hardened gears.
- **case hardening**
  - A generic term covering several processes applicable to steel that change the chemical composition of the surface layer by absorption of carbon, nitrogen, or a mixture of the two and, by diffusion, create a concentration gradient. The processes commonly used are carburizing and quench hardening; cyaniding; nitriding; and carbonitriding. The use of the applicable specific process name is preferred.
- **CASS test**
  - Abbreviation for copper-accelerated salt-spray test .
- **castable**
  - In casting, a combination of refractory grain and suitable bonding agent that, after the addition of a proper liquid, is generally poured into place to form a refractory shape or structure that becomes rigid because of chemical action.
- **castability**
  - (1) A complex combination of liquid-metal properties and solidification characteristics that promotes accurate and sound final castings. (2) The relative ease with which a molten metal flows through a mold or casting die.
- **casting**
  - (1) Metal object cast to the required shape by pouring or injecting liquid metal into a mold, as distinct from one shaped by a mechanical process. (2) Pouring molten metal into a mold to produce an object of desired shape.
- **casting defect**
  - Any imperfection in a casting that does not satisfy one or more of the required design or quality specifications. This term is often used in a limited sense for those flaws formed by improper casting solidification.
- **casting shrinkage**
  - The amount of dimensional change per unit length of the casting as it solidifies in the mold or die and cools to room temperature after removal from the mold or die. There are three distinct types of casting shrinkage. Liquid shrinkage refers to the reduction in volume of liquid metal as it cools to the liquidus. Solidification shrinkage is the reduction in volume of metal from the beginning to the end of solidification. Solid shrinkage involves the reduction in volume of metal from the solidus to room temperature.
- **casting strains**
  - Strains in a casting caused by casting stresses that develop as the casting cools.
- **casting stresses**
  - Residual stresses set up when the shape of a casting impedes contraction of the solidified casting during cooling.
- **cast iron**
  - A generic term for a large family of cast ferrous alloys in which the carbon content exceeds the solubility of carbon in austenite at the eutectic temperature. Most cast irons contain at least 2% carbon, plus silicon and sulfur, and may or may not contain other alloying elements. See also compacted graphite iron , ductile iron , gray iron , malleable iron , and white iron .
- **cast steel**
  - Steel in the form of a casting.
- **cast structure**
  - The metallographic structure of a casting evidenced by shape and orientation of grains and by segregation of impurities.
- **catalyst**
  - A substance capable of changing the rate of a reaction without itself undergoing any net change.
- **catastrophic failure**
  - Sudden failure of a component or assembly that frequently results in extensive secondary damage to adjacent components or assemblies.

- **cathode**
  - The negative electrode of an electrolytic cell at which reduction is the principal reaction. (Electrons flow toward the cathode in the external circuit.) Typical cathodic processes are cations taking up electrons and being discharged, oxygen being reduced, and the reduction of an element or group of elements from a higher to a lower valence state. Contrast with anode .
- **cathode copper**
  - Copper deposited at the cathode in electrolytic refining.
- **cathode efficiency**
  - Current efficiency at the cathode.
- **cathode film**
  - The portion of solution in immediate contact with the cathode during electrolysis.
- **cathodic cleaning**
  - Electrolytic cleaning in which the work is the cathode.
- **cathodic corrosion**
  - Corrosion resulting from a cathodic condition of a structure usually caused by the reaction of an amphoteric metal with the alkaline products of electrolysis.
- **cathodic pickling**
  - Electrolytic pickling in which the work is the cathode.
- **cathodic polarization**
  - The change of the electrode potential in the active (negative) direction due to current flow. See also polarization .
- **cathodic protection**
  - (1) Reduction of corrosion rate by shifting the corrosion potential of the electrode toward a less oxidizing potential by applying an external electromotive force. (2) Partial or complete protection of a metal from corrosion by making it a cathode, using either a galvanic or an impressed current. Contrast with anodic protection .
- **cathodic reaction**
  - Electrode reaction equivalent to a transfer of negative charge from the electronic to the ionic conductor. A cathodic reaction is a reduction process. An example common in corrosion is  $M(aq)^{2+} + 2e^- \rightarrow M(s)$ .
- **catholyte**
  - The electrolyte adjacent to the cathode of an electrolytic cell.
- **cation**
  - A positively charged ion that migrates through the electrolyte toward the cathode under the influence of a potential gradient. See also anion and ion .
- **caustic**
  - (1) Burning or corrosive. (2) A hydroxide of a light metal, such as sodium hydroxide or potassium hydroxide.
- **caustic cracking**
  - A form of stress-corrosion cracking most frequently encountered in carbon steels or iron-chromium-nickel alloys that are exposed to concentrated hydroxide solutions at temperatures of 200 to 250 °C (400 to 480 °F). Also known as caustic embrittlement.
- **caustic dip**
  - A strongly alkaline solution into which metal is immersed for etching, for neutralizing acid, or for removing organic materials such as greases or paints.
- **caustic embrittlement**
  - An obsolete historical term denoting a form of stress-corrosion cracking most frequently encountered in carbon steels or iron-chromium-nickel alloys that are exposed to concentrated hydroxide solutions at temperatures of 200 to 250 °C (400 to 480 °F).
- **caustic quenching**
  - Quenching with aqueous solutions of 5 to 10% sodium hydroxide (NaOH).
- **cavitation**
  - The formation and collapse, within a liquid, of cavities or bubbles that contain vapor or gas or both. In general, cavitation originates from a decrease in the static pressure in the liquid. It is distinguished in this way from boiling, which originates from an increase in the liquid temperature. There are certain situations where it may be difficult to make a clear distinction between cavitation and boiling, and the more general definition that is given here is therefore to

be preferred. In order to erode a solid surface by cavitation, it is necessary for the cavitation bubbles to collapse on or close to that surface.

- **cavitation corrosion**
  - A process involving conjoint corrosion and cavitation.
- **cavitation damage**
  - The degradation of a solid body resulting from its exposure to cavitation. This may include loss of material, surface deformation, or changes in properties or appearance.
- **cavitation erosion**
  - Progressive loss of original material from a solid surface due to continuing exposure to cavitation.
- **cavity**
  - The mold or die impression that gives a casting its external shape.
- **CCT diagram**
  - See continuous cooling transformation diagram .
- **cell (electrochemistry)**
  - Electrochemical system consisting of an anode and a cathode immersed in an electrolyte. The anode and cathode may be separate metals or dissimilar areas on the same metal. The cell includes the external circuit, which permits the flow of electrons from the anode toward the cathode. See also electrochemical cell .
- **cementation**
  - The introduction of one or more elements into the outer portion of a metal object by means of diffusion at high temperature.
- **cement copper**
  - Impure copper recovered by chemical deposition when iron (most often shredded steel scrap) is brought into prolonged contact with a dilute copper sulfate solution.
- **cemented carbide**
  - A solid and coherent mass made by pressing and sintering a mixture of powders of one or more metallic carbides, such as tungsten carbide, and a much smaller amount of a metal, such as cobalt, to serve as a binder.
- **cementite**
  - A hard (800 HV), brittle compound of iron and carbon, known chemically as iron carbide and having the approximate chemical formula  $\text{Fe}_3\text{C}$ . It is characterized by an orthorhombic crystal structure. When it occurs as a phase in steel, the chemical composition will be altered by the presence of manganese and other carbide-forming elements. The highest cementite contents are observed in white cast irons, which are used in applications where high wear resistance is required.
- **center drilling**
  - Drilling a short, conical hole in the end of a workpiece--a hole to be used to center the workpiece for turning on a lathe.
- **centerless grinding**
  - Grinding the outside or inside diameter of a cylindrical piece that is supported on a work support blade instead of being held between centers and that is rotated by a so-called regulating or feed wheel.
- **centrifugal casting**
  - The process of filling molds by (1) pouring metal into a sand or permanent mold that is revolving about either its horizontal or its vertical axis or (2) pouring metal into a mold that is subsequently revolved before solidification of the metal is complete. See also centrifuge casting .
- **centrifuge casting**
  - A casting technique in which mold cavities are spaced symmetrically about a vertical axial common downgate. The entire assembly is rotated about that axis during pouring and solidification.
- **ceramic tools**
  - Cutting tools made from sintered, hot-pressed, or hot isostatically pressed alumina-base or silicon nitride-base ceramic materials.
- **cermet**
  - A powder metallurgy product consisting of ceramic particles bonded with a metal.
- **C-frame press**
  - Same as gap-frame press .
- **CG iron**

- Same as compacted graphite cast iron .
- **chamfer**
  - (1) A beveled surface to eliminate an otherwise sharp corner. (2) A relieved angular cutting edge at a tooth corner.
- **chamfer angle**
  - (1) The angle between a reference surface and the bevel. (2) On a milling contour, the angle between a beveled surface and the axis of the cutter.
- **chamfering**
  - Making a sloping surface on the edge of a member. Also called beveling.
- **chaplet**
  - Metal support that holds a core in place within a casting mold; molten metal solidifies around a chaplet and fuses it into the finished casting.
- **charge**
  - (1) The materials fed into a furnace. (2) Weights of various liquid and solid materials put into a furnace during one feeding cycle.
- **charging**
  - (1) For a lap, impregnating the surface with fine abrasive. (2) Placing materials into a furnace.
- **Charpy test**
  - An impact test in which a V-notched, keyhole-notched, or U-notched specimen, supported at both ends, is struck behind the notch by a striker mounted at the lower end of a bar that can swing as a pendulum. The energy that is absorbed in fracture is calculated from the height to which the striker would have risen had there been no specimen and the height to which it actually rises after fracture of the specimen. Contrast with Izod test .
- **chase (machining)**
  - To make a series of cuts each, except for the first, following in the path of the cut preceding it, as in chasing a thread.
- **chatter**
  - In machining or grinding, (1) a vibration of the tool, wheel, or workpiece producing a wavy surface on the work and (2) the finish produced by such vibration. (3) In tribology, elastic vibrations resulting from frictional or other instability.
- **chatter marks**
  - Surface imperfections on the work being ground, usually caused by vibrations transferred from the wheel-work interface during grinding.
- **check**
  - The intermediate section of a flask that is used between the cope and the drag when molding a shape that requires more than one parting plane.
- **checked edges**
  - Sawtooth edges seen after hot rolling and/or cold rolling.
- **checkers**
  - In a chamber associated with a metallurgical furnace, bricks stacked openly so that heat may be absorbed from the combustion products and later transferred to incoming air when the direction of flow is reversed.
- **checks**
  - (1) Numerous, very fine cracks in a coating or at the surface of a metal part. Checks may appear during processing or during service and are most often associated with thermal treatment or thermal cycling. Also called check marks, or heat checks . (2) Minute cracks in the surface of a casting caused by unequal expansion or contraction during cooling. (3) Cracks in a die impression corner, generally due to forging strains or pressure, localized at some relatively sharp corner. Die blocks too hard for the depth of the die impression have a tendency to check or develop cracks in impression corners. (4) A series of small cracks resulting from thermal fatigue of hot forging dies.
- **chelating agent**
  - (1) An organic compound in which atoms form more than one coordinate bond with metals in solution. (2) A substance used in metal finishing to control or eliminate certain metallic ions present in undesirable quantities.
- **chemical conversion coating**

- A protective or decorative nonmetallic coating produced in situ by chemical reaction of a metal with a chosen environment. It is often used to prepare the surface prior to the application of an organic coating.
- **chemical deposition**
  - The precipitation or plating-out of a metal from solutions of its salts through the introduction of another metal or reagent to the solution.
- **chemical flux cutting**
  - An oxygen-cutting process in which metals are severed using a chemical flux to facilitate cutting.
- **chemically precipitated powder**
  - A metal powder that is produced as a fine precipitate by chemical displacement.
- **chemical machining**
  - Removing metal stock by controlled selective chemical dissolution.
- **chemical metallurgy**
  - See process metallurgy .
- **chemical milling**
  - The machining process in which metal is formed into intricate shapes by masking certain portions and then etching away the unwanted material.
- **chemical polishing**
  - A process that produces a polished surface by the action of a chemical etching solution. The etching solution is compounded so that peaks in the topography of the surface are dissolved preferentially.
- **chemical vapor deposition (CVD)**
  - A coating process, similar to gas carburizing and carbonitriding, whereby a reactant atmosphere gas is fed into a processing chamber where it decomposes at the surface of the workpiece, liberating one material for either absorption by, or accumulation on, the workpiece. A second material is liberated in gas form and is removed from the processing chamber, along with excess atmosphere gas.
- **chemical wear**
  - See corrosive wear .
- **chevron pattern**
  - A fractographic pattern of radial marks (shear ledges) that look like nested letters "V"; sometimes called a herringbone pattern. Chevron patterns are typically found on brittle fracture surfaces in parts whose widths are considerably greater than their thicknesses. The points of the chevrons can be traced back to the fracture origin.
- **chill**
  - (1) A metal or graphite insert embedded in the surface of a casting sand mold or core or placed in a mold cavity to increase the cooling rate at that point. (2) White iron occurring on a gray or ductile iron casting, such as the chill in the wedge test. See also chilled iron . Compare with inverse chill .
- **chilled iron**
  - Cast iron that is poured into a metal mold or against a mold insert so as to cause the rapid solidification that often tends to produce a white iron structure in the casting.
- **Chinese-script eutectic**
  - A configuration of eutectic constituents, found particularly in some cast alloys of aluminum containing iron and silicon and in magnesium alloys containing silicon, that resembles the characters in Chinese script.
- **chip breaker**
  - (1) Notch or groove in the face of a tool parallel to the cutting edge, designed to break the continuity of the chip. (2) A step formed by an adjustable component clamped to the face of the cutting tool.
- **chipping**
  - (1) Removing seams and other surface imperfections in metals manually with a chisel or gouge, or by a continuous machine, before further processing. (2) Similarly, removing excessive metal.
- **chips**
  - Pieces of material removed from a workpiece by cutting tools or by an abrasive medium.
- **chlorination**

- (1) Roasting ore in contact with chlorine or a chloride salt to produce chlorides. (2) Removing dissolved gases and entrapped oxides by passing chlorine gas through molten metal such as aluminum and magnesium.
- **chromadizing**
  - Improving paint adhesion on aluminum or aluminum alloys, mainly aircraft skins, by treatment with a solution of chromic acid. Also called chromidizing or chromatizing. Not to be confused with chromating or chromizing .
- **chromate treatment**
  - A treatment of metal in a solution of a hexavalent chromium compound to produce a conversion coating consisting of trivalent and hexavalent chromium compounds.
- **chromating**
  - Performing a chromate treatment.
- **chromizing**
  - A surface treatment at elevated temperature, generally carried out in pack, vapor, or salt baths, in which an alloy is formed by the inward diffusion of chromium into the base metal.
- **chuck**
  - A device for holding work or tools on a machine so that the part can be held or rotated during machining or grinding.
- **CIP**
  - The acronym for cold isostatic pressing .
- **circle grid**
  - A regular pattern of circles, often 2.5 mm (0.1 in.) in diameter, marked on a sheet metal blank.
- **circle-grid analysis**
  - The analysis of deformed circles to determine the severity with which a sheet metal blank has been deformed.
- **circle grinding**
  - Either cylindrical grinding or internal grinding ; the preferred terms.
- **circle shear**
  - A shearing machine with two rotary disk cutters mounted on parallel shafts driven in unison and equipped with an attachment for cutting circles where the desired piece of material is inside the circle. It cannot be employed to cut circles where the desired material is outside the circle.
- **circular field**
  - The magnetic field that (a) surrounds a nonmagnetic conductor of electricity, (b) is completely contained within a magnetic conductor of electricity, or (c) both exists within and surrounds a magnetic conductor. Generally applied to the magnetic field within any magnetic conductor resulting from a current being passed through the part or through a section of the part. Compare with bipolar field .
- **clad brazing sheet**
  - A metal sheet on which one or both sides are clad with brazing filler metal .
- **cladding**
  - (1) A layer of material, usually metallic, that is mechanically or metallurgically bonded to a substrate. Cladding may be bonded to the substrate by any of several processes, such as roll-cladding and explosive forming. (2) A relatively thick layer (1 mm, or 0.04 in.) of material applied by surfacing for the purpose of improved corrosion resistance or other properties. See also coating , surfacing , and hardfacing .
- **clad metal**
  - A composite metal containing two or more layers that have been bonded together. The bonding may have been accomplished by co-rolling, co-extrusion, welding, diffusion bonding, casting, heavy chemical deposition, or heavy electroplating.
- **clamshell marks**
  - Same as beach marks .
- **classification**
  - (1) The separation of ores into fractions according to size and specific gravity, generally in accordance with Stokes' law of sedimentation. (2) Separation of a metal powder into fractions according to particle size.
- **clearance**
  - (1) The gap or space between two mating parts. (2) Space provided between the relief of a cutting tool and the surface that has been cut.

- **cleavage**
  - (1) Fracture of a crystal by crack propagation across a crystallographic plane of low index. (2) The tendency to cleave or split along definite crystallographic planes.
- **cleavage fracture**
  - A fracture, usually of a polycrystalline metal, in which most of the grains have failed by cleavage, resulting in bright reflecting facets. It is one type of crystalline fracture and is associated with low-energy brittle fracture. Contrast with shear fracture .
- **cleavage plane**
  - A characteristic crystallographic plane or set of planes in a crystal on which cleavage fracture occurs easily.
- **climb cutting**
  - Analogous to climb milling .
- **climb milling**
  - Milling in which the cutter moves in the direction of feed at the point of contact.
- **close annealing**
  - Same as box annealing .
- **closed-die forging**
  - The shaping of hot metal completely within the walls or cavities of two dies that come together to enclose the workpiece on all sides. The impression for the forging can be entirely either die or divided between the top and bottom dies. Impression-die forging, often used interchangeably with the term closed-die forging, refers to a closed-die operation in which the dies contain a provision for controlling the flow of excess material, or flash , that is generated. By contrast, in flashless forging, the material is deformed in a cavity that allows little or no escape of excess material.
- **closed dies**
  - Forging or forming impression dies designed to restrict the flow of metal to the cavity within the die set, as opposed to open dies, in which there is little or no restriction to lateral flow.
- **closed pass**
  - A pass of metal through rolls where the bottom roll has a groove deeper than the bar being rolled and the top roll has a collar fitting into the groove, thus producing the desired shape free from flash or fin.
- **close-tolerance forging**
  - A forging held to unusually close dimensional tolerances so that little or no machining is required after forging. See also precision forging .
- **cluster mill**
  - A rolling mill in which each of the two working rolls of small diameter is supported by two or more larger diameter backup rolls.
- **coalescence**
  - (1) The union of particles of a dispersed phase into larger units, usually effected at temperatures below the fusion point. (2) The growing together or growth into one body of the materials being welded. (3) Growth of grains at the expense of the remainder by absorption or the growth of a phase or particle at the expense of the remainder by absorption or reprecipitation.
- **coarsening**
  - An increase in grain size, usually, but not necessarily, by grain growth.
- **coated abrasive**
  - An abrasive product (sandpaper, for example) in which a layer of abrasive particles is firmly attached to a paper, cloth, or fiber backing by means of glue or synthetic-resin adhesive.
- **coated electrode**
  - See preferred terms covered electrode and lightly coated electrode .
- **coating**
  - A relatively thin layer (<1 mm, or 0.04 in.) of material applied by surfacing for the purpose of corrosion prevention, resistance to high-temperature scaling, wear resistance, lubrication, or other purposes.
- **coaxing**
  - Improvement of the fatigue strength of a specimen by the application of a gradually increasing stress amplitude, usually starting below the fatigue limit.
- **coefficient of friction**

- The dimensionless ratio of the friction force ( $F$ ) between two bodies to the normal force ( $N$ ) pressing these bodies together: ( $\mu$  or  $f$ ) = ( $F/N$ ).
- **coercive force**
  - The magnetizing force that must be applied in the direction opposite to that of the previous magnetizing force in order to reduce magnetic flux density to zero; thus, a measure of the magnetic retentivity of magnetic materials.
- **cogging**
  - The reducing operation in working an ingot into a billet with a forging hammer or a forging press.
- **cogging mill**
  - A blooming mill .
- **coherent precipitate**
  - A crystalline precipitate that forms from solid solution with an orientation that maintains continuity between the crystal lattice of the precipitate and the lattice of the matrix, usually accompanied by some strain in both lattices. Because the lattices fit at the interface between precipitate and matrix, there is no discernible phase boundary.
- **cohesion**
  - (1) The state in which the particles of a single substance are held together by primary or secondary valence forces. As used in the adhesive field, the state in which the particles of the adhesive (or adherend) are held together. (2) Force of attraction between the molecules (or atoms) within a single phase. Contrast with adhesion .
- **cohesive strength**
  - (1) The hypothetical stress causing tensile fracture without plastic deformation. (2) The stress corresponding to the forces between atoms.
- **coil**
  - (1) An assembly consisting of one or more magnet wire windings. (2) Rolled metal sheet or strip.
- **coil breaks**
  - Creases or ridges in sheet or strip that appear as parallel lines across the direction of rolling and that generally extend the full width of the sheet or strip.
- **coining**
  - (1) A closed-die squeezing operation, usually performed cold, in which all surfaces of the work are confined or restrained, resulting in a well-defined imprint of the die upon the work. (2) A restriking operation used to sharpen or change an existing radius or profile. (3) The final pressing of a sintered powder metallurgy compact to obtain a definite surface configuration (not to be confused with sizing ).
- **coin silver**
  - An alloy containing 90% silver, with copper being the usual alloying element.
- **coke**
  - A porous, gray, infusible product resulting from the dry distillation of bituminous coal, petroleum, or coal tar pitch that drives off most of the volatile matter. Used as a fuel in cupola melting.
- **cold box process**
  - In foundry practice, a two-part organic resin binder system mixed in conventional mixers and blown into shell or solid core shapes at room temperature. A vapor mixed with air is blown into the core, permitting instant setting and immediate pouring of metal around it.
- **cold chamber machine**
  - A die casting machine with an injection system that is charged with liquid metal from a separate furnace. Compare with hot chamber machine .
- **cold compacting**
  - See preferred term cold pressing .
- **cold cracking**
  - (1) Cracks in cold or nearly cold cast metal due to excessive internal stress caused by contraction. Often brought about when the mold is too hard or the casting is of unsuitable design. (2) A type of weld cracking that usually occurs below 205 °C (400 °F). Cracking may occur during or after cooling to room temperature, sometimes with a considerable time delay. Three factors combine to produce cold cracks; stress (for example, from thermal expansion and contraction), hydrogen (from hydrogen-containing welding consumables), and a susceptible microstructure (plate martensite is most susceptible to cracking, ferritic and bainitic structures are least susceptible). See also hot cracking , lamellar tearing , and stress-relief cracking .

- **cold die quenching**
  - A quench utilizing cold, flat, or shaped dies to extract heat from a part. Cold die quenching is slow, expensive, and is limited to smaller parts with large surface areas.
- **cold heading**
  - Working metal at room temperature such that the cross-sectional area of a portion or all of the stock is increased. See also heading and upsetting .
- **cold inspection**
  - A visual (usually final) inspection of forgings for visible imperfections, dimensions, weight, and surface condition at room temperature. The term may also be used to describe certain nondestructive tests such as magnetic-particle, dye-penetrant, and sonic inspection.
- **cold isostatic pressing (CIP)**
  - Forming technique in which high fluid pressure is applied to a powder (metal or ceramic) part at ambient temperature. Water or oil is used as the pressure medium.
- **cold lap**
  - (1) Wrinkled markings on the surface of an ingot or casting from incipient freezing of the surface and too low a casting temperature. (2) A flaw that results when a workpiece fails to fill the die cavity during the first forging. A seam is formed as subsequent dies force metal over this gap to leave a seam on the workpiece surface. See also cold shut .
- **cold mill**
  - A mill for cold rolling of sheet or strip.
- **cold pressing**
  - Forming a powder metallurgy compact at a temperature low enough to avoid sintering, usually room temperature. Contrast with hot pressing .
- **cold-rolled sheets**
  - A metal mill product produced from a hot-rolled pickled coil that has been given substantial cold reduction at room temperature. The resulting product usually requires further processing to make it suitable for most common applications. The usual end product is characterized by improved surface, greater uniformity in thickness, and improved mechanical properties compared with hot-rolled sheet.
- **cold-setting process**
  - In foundry practice, any of several systems for bonding mold or core aggregates by means of organic binders, relying on the use of catalysts rather than heat for polymerization (setting).
- **cold shortness**
  - Brittleness that exists in some metals at temperatures below the recrystallization temperature.
- **cold shot**
  - (1) A portion of the surface of an ingot or casting showing premature solidification; caused by splashing of molten metal onto a cold mold wall during pouring. (2) Small globule of metal embedded in, but not entirely fused with, the casting.
- **cold shut**
  - (1) A discontinuity that appears on the surface of cast metal as a result of two streams of liquid meeting and failing to unite. (2) A lap on the surface of a forging or billet that was closed without fusion during deformation. (3) Freezing of the top surface of an ingot before the mold is full.
- **Coldstream process**
  - In powder metallurgy, a method of producing cleavage fractures in hard particles through particle impingements in a high-velocity cold gas stream. Also referred to as impact crushing.
- **cold treatment**
  - Exposing steel to suitable subzero temperatures (-85 °C, or -120 °F) for the purpose of obtaining desired conditions or properties such as dimensional or microstructural stability. When the treatment involves the transformation of retained austenite, it is usually followed by tempering.
- **cold trimming**
  - The removal of flash or excess metal from a forging at room temperature in a trimming press.
- **cold welding**
  - A solid-state welding process in which pressure is used at room temperature to produce coalescence of metals with substantial deformation at the weld. Compare with hot pressure welding , diffusion welding , and forge welding .
- **cold work**
  - Permanent strain in a metal accompanied by strain hardening.
- **cold-worked structure**

- A microstructure resulting from plastic deformation of a metal or alloy below its recrystallization temperature.
- **cold working**
  - Deforming metal plastically under conditions of temperature and strain rate that induce strain hardening. Usually, but not necessarily, conducted at room temperature. Contrast with hot working .
- **collapsibility**
  - The tendency of a sand mixture to break down under the pressures and temperatures developed during casting.
- **collet**
  - A split sleeve used to hold work or tools during machining or grinding.
- **color buffing**
  - Producing a final high luster by buffing. Sometimes called coloring .
- **coloring**
  - Producing desired colors on metal by a chemical or electrochemical reaction. See also color buffing .
- **columnar structure**
  - A coarse structure of parallel elongated grains formed by unidirectional growth, most often observed in castings, but sometimes seen in structures resulting from diffusional growth accompanied by a solid-state transformation.
- **combination die**
  - (1) A die-casting die having two or more different cavities for different castings. (2) For forming, see compound die .
- **combination mill**
  - An arrangement of a continuous mill for roughing and a guide mill or looping mill for shaping.
- **combined carbon**
  - Carbon in iron or steel that is combined chemically with other elements; not in the free state as graphite or temper carbon. The difference between the total carbon and the graphite carbon analyses. Contrast with free carbon .
- **combined cyanide**
  - The cyanide of a metal-cyanide complex ion.
- **combined stresses**
  - Any state of stress that cannot be represented by a single component of stress; that is, one that is more complicated than simple tension, compression, or shear.
- **combustion analysis**
  - An analytical technique for determining the concentration of carbon and sulfur in samples. The sample is burned in a graphite crucible in the presence of oxygen, which causes carbon and sulfur to leave the sample as carbon dioxide and sulfur dioxide. These gases are then detected by infrared or thermal conductive means.
- **comet tails**
  - A group of comparatively deep unidirectional scratches that form adjacent to a microstructural discontinuity during mechanical polishing. They have the general shape of a comet tail. Comet tails form only when a unidirectional motion is maintained between the surface being polished and the polishing cloth.
- **comminution**
  - (1) Breaking up or grinding an ore into small fragments. (2) Reducing metal to powder by mechanical means. (3) The act or process of reduction of powder particle size, usually but not necessarily by grinding or milling. See also pulverization .
- **compact**
  - (1) The object produced by the compression of metal powder, generally while confined in a die. (2) The operation or process of producing a compact; sometimes called pressing.
- **compacted graphite iron**
  - Cast iron having a graphite shape intermediate between the flake form typical of gray cast iron and the spherical form of fully spherulitic ductile cast iron. An acceptable compacted graphite iron structure is one that contains no flake graphite, <20% spheroidal graphite, and 80% compacted graphite (ASTM A 247, type IV). Also known as CG iron or vermicular iron, compacted graphite cast iron is produced in a manner similar to that for ductile cast iron, but using a technique that inhibits the formation of fully spherulitic graphite nodules.

- **compacting pressure**
  - In powder metallurgy, the specific compacting force related to the area of contact with the press punch expressed in megapascals, meganewtons per square meter, or tons per square inch.
- **compaction**
  - (1) The act of forcing particulate or granular material together (consolidation) under pressure or impact to yield a relatively dense mass or formed object. (2) In powder metallurgy, the preparation of a compact or object produced by the compression of a powder, generally while confined in a die, with or without the inclusion of lubricants, binders, and so forth. With or without the concurrent applications of heat.
- **compatibility**
  - A measure of the extent to which materials are mutually soluble in the solid state.
- **complete fusion**
  - Fusion that has occurred over the entire base material surfaces intended for welding and between all layers and weld beads.
- **complexing agent**
  - A substance that is an electron donor and that will combine with a metal ion to form a soluble complex ion.
- **complexion**
  - An ion that may be formed by the addition reaction of two or more other ions.
- **component**
  - (1) One of the elements or compounds used to define a chemical (or alloy) system, including all phases, in terms of the fewest substances possible. (2) One of the individual parts of a vector as referred to a system of coordinates. (3) An individual functional element in a physically independent body that cannot be further reduced or divided without destroying its stated function, for example, a resistor, capacitor, diode, or transistor.
- **composite coating**
  - A coating on a metal or nonmetal that consists of two or more components, one of which is often particulate in form. Example: a cermet composite coating on a cemented carbide cutting tool. Also known as multilayer coating.
- **composite electrode**
  - A welding electrode made from two or more distinct components, at least one of which is filler metal. A composite electrode may exist in any of various physical forms, such as stranded wires, filled tubes, or covered wire.
- **composite joint**
  - A joint in which welding is used in conjunction with mechanical joining.
- **composite material**
  - A combination of two or more materials (reinforcing elements, fillers, and composite matrix binder), differing in form or composition on a macroscale. The constituents retain their identities, that is, they do not dissolve or merge completely into one another although they act in concert. Normally, the components can be physically identified and exhibit an interface between one another. Examples are cermets and metal-matrix composites.
- **composite plate**
  - An electrodeposit consisting of layers of at least two different compositions.
- **composite powder**
  - A powder in which each particle consists of two or more different materials.
- **composite structure**
  - A structural member (such as a panel, plate, pipe, or other shape) that is built up by bonding together two or more distinct components, each of which may be made of a metal, alloy, nonmetal, or composite material. Examples of composite structures include: honeycomb panels, clad plate, electrical contacts, sleeve bearings, carbide-tipped drills or lathe tools, and weldments constructed of two or more different alloys.
- **compound compact**
  - A powder metallurgy compact consisting of mixed metals, the particles of which are joined by pressing or sintering, or both, with each metal particle retaining substantially its original composition.
- **compound die**

- Any die designed to perform more than one operation on a part with one stroke of the press, such as blanking and piercing, in which all functions are performed simultaneously within the confines of the blank size being worked.
- **compressibility**
  - (1) The ability of a powder to be formed into a compact having well-defined contours and structural stability at a given temperature and pressure; a measure of the plasticity of powder particles. (2) A density ratio determined under definite testing conditions. Also referred to as compactibility.
- **compression ratio (powder metallurgy)**
  - The ratio of the volume of the loose powder to the volume of the compact made from it.
- **compressive strength**
  - The maximum compressive stress that a material is capable of developing, based on original area of cross section. If a material fails in compression by a shattering fracture, the compressive strength has a very definite value. If a material does not fail in compression by a shattering fracture, the value obtained for compressive strength is an arbitrary value depending on the degree of distortion that is regarded as indicating complete failure of the material.
- **compressive stress**
  - A stress that causes an elastic body to deform (shorten) in the direction of the applied load. Contrast with tensile stress .
- **concentration**
  - (1) The mass of a substance contained in a unit volume of sample, for example, grams per liter. (2) A process for enrichment of an ore in valuable mineral content by separation and removal of waste material, or gangue.
- **concentration cell**
  - An electrolytic cell, the electromotive force of which is caused by a difference in concentration of some component in the electrolyte. This difference leads to the formation of discrete cathode and anode regions.
- **concentration polarization**
  - That portion of the polarization of a cell produced by concentration changes resulting from passage of current through the electrolyte.
- **concurrent heating**
  - The application of supplemental heat to a structure during a welding or cutting operation.
- **conditioning heat treatment**
  - A preliminary heat treatment used to prepare a material for a desired reaction to a subsequent heat treatment. For the term to be meaningful, the exact heat treatment must be specified.
- **cone**
  - The conical part of an oxyfuel gas flame next to the orifice of the tip.
- **cone angle**
  - The angle that the cutter axis makes with the direction along which the blades are moved for adjustment, as in adjustable-blade reamers where the base of the blade slides on a conical surface.
- **conformal coating**
  - A coating that covers and exactly fits the shape of the coated object.
- **congruent melting**
  - An isothermal or isobaric melting in which both the solid and liquid phases have the same composition throughout the transformation.
- **congruent transformation**
  - An isothermal or isobaric phase change in metals in which both of the phases concerned have the same composition throughout the process.
- **conjugate phases**
  - In microstructural analysis, those states of matter of unique composition that coexist at equilibrium at a single point in temperature and pressure. For example, the two coexisting phases of a two-phase equilibrium.
- **constant life fatigue diagram**
  - In failure analysis, a plot (usually on rectangular coordinates) of a family of curves, each of which is for a single fatigue life (number of cycles), relating alternating stress, maximum stress, minimum stress, and mean stress. The constant life fatigue diagram is generally derived from a family of *S-N* curves, each of which represents a different stress ratio for a 50% probability of

survival. See also nominal stress , maximum stress , minimum stress , *S-N* curve , fatigue life , and stress ratio .

- **constituent**
  - (1) One of the ingredients that make up a chemical system. (2) A phase or a combination of phases that occurs in a characteristic configuration in an alloy microstructure.
- **constitution diagram**
  - See phase diagram .
- **constraint**
  - Any restriction that limits the transverse contraction normally associated with a longitudinal tension and that hence causes a secondary tension in the transverse direction; usually used in connection with welding. Contrast with restraint .
- **consumable electrode**
  - A general term for any arc welding electrode made chiefly of filler metal. Use of specific names such as covered electrode , bare electrode , flux cored electrode , and lightly coated electrode is preferred.
- **consumable-electrode remelting**
  - A process for refining metals in which an electric current passes between an electrode made of the metal to be refined and an ingot of the refined metal, which is contained in a water-cooled mold. As a result of the passage of electric current, droplets of molten metal form on the electrode and fall to the ingot. The refining action occurs from contact with the atmosphere, vacuum, or slag through which the drop falls. See also electroslag remelting and vacuum arc remelting .
- **contact corrosion**
  - A term primarily used in Europe to describe galvanic corrosion between dissimilar metals.
- **contact fatigue**
  - Cracking and subsequent pitting of a surface subjected to alternating Hertzian stresses such as those produced under rolling contact or combined rolling and sliding. The phenomenon of contact fatigue is encountered most often in rolling-element bearings or in gears, where the surface stresses are high due to the concentrated loads and are repeated many times during normal operation.
- **contact plating**
  - A metal plating process wherein the plating current is provided by galvanic action between the work metal and a second metal, without the use of an external source of current.
- **contact potential**
  - In corrosion technology, the potential difference at the junction of two dissimilar substances.
- **container**
  - The chamber into which an ingot or billet is inserted prior to extrusion. The container for backward extrusion of cups or cans is sometimes called a die.
- **contaminant**
  - An impurity or foreign substance present in a material or environment that affects one or more properties of the material.
- **continuous casting**
  - A casting technique in which a cast shape is continuously withdrawn through the bottom of the mold as it solidifies, so that its length is not determined by mold dimensions. Used chiefly to produce semifinished mill products such as billets, blooms, ingots, slabs, strip, and tubes. See also strand casting .
- **continuous cooling transformation (CCT) diagram**
  - Set of curves drawn using logarithmic time and linear temperature as coordinates, which define, for each cooling curve of an alloy, the beginning and end of the transformation of the initial phase.
- **continuous mill**
  - A rolling mill consisting of a number of strands of synchronized rolls (in tandem) in which metal undergoes successive reductions as it passes through the various strands.
- **continuous phase**
  - In an alloy or portion of an alloy containing more than one phase, the phase that forms the matrix in which the other phase or phases are dispersed.
- **continuous precipitation**

- Precipitation from a supersaturated solid solution in which the precipitate particles grow by long-range diffusion without recrystallization of the matrix. Continuous precipitates grow from nuclei distributed more or less uniformly throughout the matrix. They usually are randomly oriented, but may form a Widmanstätten structure. Also called general precipitation. Compare with discontinuous precipitation and localized precipitation .
- **continuous-type furnace**
  - A furnace used for heat treating materials that progress continuously through the furnace, entering one door and being discharged from another.
- **continuous weld**
  - A weld extending continuously from one end of a joint to the other or, where the joint is essentially circular, completely around the joint. Contrast with intermittent weld .
- **contour forming**
  - See roll forming , stretch forming , tangent bending , and wiper forming .
- **contour machining**
  - Machining of irregular surfaces, such as those generated in tracer turning, tracer boring, and tracer milling.
- **contour milling**
  - Milling of irregular surfaces. See also tracer milling .
- **contraction**
  - The volume change that occurs in metals and alloys upon solidification and cooling to room temperature.
- **controlled atmosphere**
  - (1) A specified inert gas or mixture of gases at a predetermined temperature in which selected processes take place. (2) As applied to sintering, to prevent oxidation and destruction of the powder compacts.
- **controlled cooling**
  - Cooling a metal or alloy from an elevated temperature in a predetermined manner to avoid hardening, cracking, or internal damage, or to produce desired microstructure or mechanical properties.
- **controlled-pressure cycle**
  - A forming cycle during which the hydraulic pressure in the forming cavity is controlled by an adjustable cam that is coordinated with the punch travel.
- **controlled rolling**
  - A hot-rolling process in which the temperature of the steel is closely controlled, particularly during the final rolling passes, to produce a fine-grain microstructure.
- **conventional forging**
  - A forging characteristic by design complexity and tolerances that falls within the broad range of general forging practice.
- **conventional milling**
  - Milling in which the cutter moves in the direction opposite to the feed at the point of contact. Contrast with climb milling .
- **conventional strain**
  - See engineering strain and strain .
- **conventional stress**
  - See engineering stress and stress .
- **conversion coating**
  - A coating consisting of a compound of the surface metal, produced by chemical or electrochemical treatments of the metal. Examples include chromate coatings on zinc, cadmium, magnesium, and aluminum, and oxide and phosphate coatings on steel. See also chromate treatment and phosphating .
- **converter**
  - A furnace in which air is blown through a bath of molten metal or matte, oxidizing the impurities and maintaining the temperature through the heat produced by the oxidation reaction. A typical converter is the argon oxygen decarburization vessel.
- **coolant**
  - The liquid used to cool the work during grinding and to prevent it from rusting. It also lubricates, washes away chips and grits, and aids in obtaining a finer finish. In metal cutting, the preferred term is cutting fluid.

- **cooling curve**
  - A graph showing the relationship between time and temperature during the cooling of a material. It is used to find the temperatures at which phase changes occur. A property or function other than time may occasionally be used--for example, thermal expansion.
- **cooling rate**
  - The average slope of the time-temperature curve taken over a specified time and temperature interval.
- **cooling stresses**
  - Residual stresses in castings resulting from nonuniform distribution of temperature during cooling.
- **cope**
  - In casting, the upper or topmost section of a flask, mold, or pattern.
- **copper-accelerated salt-spray (CASS) test**
  - An accelerated corrosion test for some electrodeposits and for anodic coatings on aluminum.
- **copper brazing**
  - A term improperly used to denote brazing with a copper filler metal.
- **core**
  - (1) A specially formed material inserted in a mold to shape the interior or other part of a casting that cannot be shaped as easily by the pattern. (2) In a ferrous alloy prepared for case hardening, that portion of the alloy that is not part of the case. Typically considered to be the portion that (a) appears dark (with certain etchants) on an etched cross section, (b) has an essentially unaltered chemical composition, or (c) has a hardness, after hardening, less than a specified value.
- **core assembly**
  - In casting, a complex core consisting of a number of sections.
- **core binder**
  - In casting, any material used to hold the grains of core sand together.
- **core blow**
  - A gas pocket in a casting adjacent to a cored cavity and caused by entrapped gases from the core.
- **core blower**
  - A machine for making foundry cores using compressed air to blow and pack the sand into the core box.
- **core box**
  - In casting, a wood, metal, or plastic structure containing a shaped cavity into which sand is packed to make a core.
- **cored bars**
  - In powder metallurgy, a compact of bar shape heated by its own electrical resistance to a temperature high enough to melt its interior.
- **core forging**
  - (1) Displacing metal with a punch to fill a die cavity. (2) The product of such an operation.
- **core knockout machine**
  - In casting, a mechanical device for removing cores from castings.
- **core rod**
  - In powder metallurgy, a member of a die assembly used in molding a hole in a compact.
- **core sand**
  - In casting, sand for making cores to which a binding material has been added to obtain good cohesion and permeability after drying; usually low in clays.
- **coring**
  - (1) A condition of variable composition between the center and surface of a unit of microstructure (such as a dendrite, grain, carbide particle); results from nonequilibrium solidification, which occurs over a range of temperature. (2) A central cavity at the butt end of a rod extrusion, sometimes called extrusion pipe .
- **corona (resistance welding)**
  - The area sometimes surrounding the nugget of a spot weld at the faying surfaces which provides a degree of solid-state welding.
- **corrodkote test**
  - An accelerated corrosion test for electrodeposits.
- **corrosion**

- The chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties.
- **corrosion effect**
  - A change in any part of the corrosion system caused by corrosion.
- **corrosion embrittlement**
  - The severe loss of ductility of a metal resulting from corrosive attack, usually intergranular and often not visually apparent.
- **corrosion-erosion**
  - See erosion-corrosion .
- **corrosion fatigue**
  - The process in which a metal fractures prematurely under conditions of simultaneous corrosion and repeated cyclic loading at lower stress levels or fewer cycles than would be required in the absence of the corrosive environment.
- **corrosion inhibitor**
  - See inhibitor .
- **corrosion potential ( $E_{\text{corr}}$ )**
  - The potential of a corroding surface in an electrolyte, relative to a reference electrode. Also called rest potential, open-circuit potential, or freely corroding potential.
- **corrosion product**
  - Substance formed as a result of corrosion.
- **corrosion protection**
  - Modification of a corrosion system so that corrosion damage is mitigated.
- **corrosion rate**
  - Corrosion effect on a metal per unit of time. The type of corrosion rate used depends on the technical system and on the type of corrosion effect. Thus, corrosion rate may be expressed as an increase in corrosion depth per unit of time (penetration rate, for example, mils/yr) or the mass of metal turned into corrosion products per unit area of surface per unit of time (weight loss, for example, g/m<sup>2</sup>/yr). The corrosion effect may vary with time and may not be the same at all points of the corroding surface. Therefore, reports of corrosion rates should be accompanied by information on the type, time dependency, and location of the corrosion effect.
- **corrosion resistance**
  - The ability of a material to withstand contact with ambient natural factors or those of a particular, artificially created atmosphere, without degradation or change in properties. For metals, this could be pitting or rusting; for organic materials, it could be crazing.
- **corrosion system**
  - System consisting of one or more metals and all parts of the environment that influence corrosion.
- **corrosive wear**
  - Wear in which chemical or electrochemical reaction with the environment is significant. See also oxidative wear .
- **corrugating**
  - The forming of sheet metal into a series of straight, parallel alternate ridges and grooves with a rolling mill equipped with matched roller dies or a press brake equipped with a specially shaped punch and die.
- **corrugations**
  - In metalforming, transverse ripples caused by a variation in strip shape during hot or cold reduction.
- **Cottrell process**
  - Removal of solid particulates from gases with electrostatic precipitation.
- **coulometer**
  - An electrolytic cell arranged to measure the quantity of electricity by the chemical action produced in accordance with Faraday's law.
- **counterblow hammer**
  - A forging hammer in which both the ram and the anvil are driven simultaneously toward each other by air or steam pistons.
- **counterboring**
  - Removal of material to enlarge a hole for part of its depth with a rotary, pilot guided, end cutting tool having two or more cutting lips and usually having straight or helical flutes for the passage of chips and the admission of a cutting fluid.

- **countersinking**
  - Beveling or tapering the work material around the periphery of a hole creating a concentric surface at an angle less than  $90^\circ$  with the centerline of the hole for the purpose of chamfering holes or recessing screw and rivet heads.
- **covered electrode**
  - A composite filler metal electrode consisting of a core of a bare electrode or metal cored electrode to which a covering sufficient to provide a slag layer on the weld metal has been applied. The covering may contain materials providing such functions as shielding from the atmosphere, deoxidation, and arc stabilization and can serve as a source of metallic additions to the weld. Compare with lightly coated electrode .
- **covering power**
  - (1) The ability of a solution to give satisfactory plating at very low current densities, a condition that exists in recesses and pits. This term suggests an ability to cover, but not necessarily to build up, a uniform coating, whereas throwing power suggests the ability to obtain a coating of uniform thickness on an irregularly shaped object. (2) The degree to which a porcelain enamel coating obscures the underlying surface.
- **crack**
  - (1) A fracture type discontinuity characterized by a sharp tip and high ratio of length and width to opening displacement. (2) A line of fracture without complete separation.
- **crack growth**
  - Rate of propagation of a crack through a material due to a static or dynamic applied load.
- **crack length (depth) ( $a$ )**
  - In fatigue and stress-corrosion cracking, the physical crack size used to determine the crack growth rate and the stress-intensity factor. For a compact-type specimen, crack length is measured from the line connecting the bearing points of load application. For a center-crack tension specimen, crack length is measured from the perpendicular bisector of the central crack. See also crack size .
- **crack mouth opening displacement (CMOD)**
  - See crack opening displacement .
- **crack opening displacement**
  - On a  $K_{Ic}$  specimen, the opening displacement of the notch surfaces at the notch and in the direction perpendicular to the plane of the notch and the crack. The displacement at the tip is called the crack tip opening displacement (CTOD); at the mouth, it is called the crack mouth opening displacement (CMOD). See also stress-intensity factor for definition of  $K_{Ic}$ .
- **crack size ( $a$ )**
  - A lineal measure of a principal planar dimension of a crack. This measure is commonly used in the calculation of quantities descriptive of the stress and displacement fields. In practice, the value of crack size is obtained from procedures for measurement of physical crack size, original crack size, or effective crack size, as appropriate to the situation under consideration. See also crack length (depth) .
- **crack tip opening displacement (CTOD)**
  - See crack opening displacement .
- **crank press**
  - A mechanical press whose slides are actuated by a crankshaft.
- **crater**
  - In arc welding, a depression at the termination of a weld bead or in the molten weld pool.
- **crater crack**
  - A crack in the crater of a weld bead.
- **crater wear**
  - The wear that occurs on the rake face of a cutting tool due to contact with the material in the chip that is sliding along that face.
- **craze cracking**
  - Irregular surface cracking of a metal associated with thermal cycling. This term is used more in the United Kingdom than in the United States, where the term checking is used instead. See also checks .
- **creep**

- Time-dependent strain occurring under stress. The creep strain occurring at a diminishing rate is called primary creep; that occurring at a minimum and almost constant rate, secondary creep; and that occurring at an accelerating rate, tertiary creep.
- **creep-feed grinding**
  - A grinding process that produces deeper cuts at slow traverse rates.
- **creep limit**
  - (1) The maximum stress that will cause less than a specified quantity of creep in a given time. (2) The maximum nominal stress under which the creep strain rate decreases continuously with time under constant load and at constant temperature. Sometimes used synonymously with creep strength.
- **creep rate**
  - The slope of the creep-time curve at a given time. Deflection with time under a given static load.
- **creep recovery**
  - The time-dependent decrease in strain in a solid, following the removal of force.
- **creep-rupture embrittlement**
  - Embrittlement under creep conditions. Failure occurs by intergranular cracking of the embrittled material.
- **creep-rupture strength**
  - The stress that causes fracture in a creep test at a given time, in a specified constant environment. This is sometimes referred to as the stress-rupture strength.
- **creep-rupture test**
  - A test in which progressive specimen deformation and the time for rupture are both measured. In general, deformation is much greater than that developed during a creep test. Also known as stress-rupture test.
- **creep strain**
  - The time-dependent total strain (extension plus initial gage length) produced by applied stress during a creep test.
- **creep strength**
  - The stress that will cause a given creep strain in a creep test at a given time in a specified constant environment.
- **creep stress**
  - The constant load divided by the original cross-sectional area of the specimen.
- **creep test**
  - A method of determining the extension of metals under a given load at a given temperature. The determination usually involves the plotting of time-elongation curves under constant load; a single test may extend over many months. The results are often expressed as the elongation (in millimeters or inches) per hour on a given gage length (e.g., 25 mm, or 1 in.).
- **crevice corrosion**
  - Localized corrosion of a metal surface at, or immediately adjacent to, an area that is shielded from full exposure to the environment because of close proximity between the metal and the surface of another material.
- **crimping**
  - The forming of relatively small corrugations in order to set down and lock a seam, to create an arc in a strip of metal, or to reduce an existing arc or diameter. See also corrugating .
- **critical cooling rate**
  - The minimum rate of continuous cooling for preventing undesirable transformations. For steel, unless otherwise specified, it is the slowest rate at which austenite can be cooled from above critical temperature to prevent its transformation above the martensite start temperature.
- **critical current density**
  - In an electrolytic process, a current density at which an abrupt change occurs in an operating variable or in the nature of an electrodeposit or electrode film.
- **critical flaw size**
  - The size of a flaw (defect) in a structure that will cause failure at a particular stress level.
- **critical point**
  - (1) The temperature or pressure at which a change in crystal structure, phase, or physical properties occurs. Also termed transformation temperature . (2) In an equilibrium diagram, that combination of composition, temperature, and pressure at which the phases of an inhomogeneous system are in equilibrium.

- **critical shear stress**
  - The shear stress required to cause slip in a designated slip direction on a given slip plane. It is called the critical resolved shear stress if the shear stress is induced by tensile or compressive forces acting on the crystal.
- **critical strain**
  - (1) In mechanical testing, the strain at the yield point. (2) The strain just sufficient to cause recrystallization; because the strain is small, usually only a few percent, recrystallization takes place from only a few nuclei, which produces a recrystallized structure consisting of very large grains.
- **critical stress-intensity factor**
  - See stress-intensity factor .
- **critical temperature**
  - That temperature above which the vapor phase cannot be condensed to liquid by an increase in pressure. Synonymous with critical point if pressure is constant.
- **critical temperature range**
  - Synonymous with transformation ranges , which is the preferred term.
- **Croning process**
  - In casting, a shell molding process that uses a phenolic resin binder. Sometimes referred to as C process or Chronizing.
- **crop**
  - (1) An end portion of an ingot that is cut off as scrap. (2) To shear a bar or billet.
- **cross breaks**
  - Same as coil breaks .
- **cross-country mill**
  - A rolling mill in which the mill stands are so arranged that their tables are parallel with a transfer (or crossover) table connecting them. Such a mill is used for rolling structural shapes, rails, and any special form of bar stock not rolled in the ordinary bar mill.
- **cross direction**
  - See transverse direction .
- **cross forging**
  - Preliminary working of forging stock in flat dies to develop mechanical properties, particularly in the center portions of heavy sections.
- **cross rolling**
  - Rolling of metal or sheet or plate so that the direction of rolling is about 90° from the direction of a previous rolling.
- **cross-wire weld**
  - A weld made at the junction between crossed wires or bars.
- **crown**
  - (1) The upper part (head) of a forming press frame. On hydraulic presses, the crown usually contains the cylinder; on mechanical presses, the crown contains the drive mechanism. See also hydraulic press and mechanical press . (2) A shape (crown) ground into a flat roll to ensure flatness of cold- (and hot-) rolled sheet and strip. (3) A contour on a sheet or roll where the thickness or diameter increases from edge to center.
- **crucible furnace**
  - A melting or holding furnace in which the molten metal is contained in a pot-shaped (hemispherical) shell. Electric heaters or fuel-fired burners outside the shell generate the heat that passes through the shell (crucible) to the molten metal.
- **crush**
  - (1) Buckling or breaking of a section of a casting mold due to incorrect register when the mold is closed. (2) An indentation in the surface of a casting due to displacement of sand when the mold was closed.
- **crush forming**
  - Shaping a grinding wheel by forcing a rotating metal roll into its face so as to reproduce the desired contour.
- **crushings test**
  - (1) A radial compressive test applied to tubing, sintered-metal bearings, or other similar products for determining radial crushing strength (maximum load in compression). (2) An axial compressive test for determining quality of tubing, such as soundness of weld in welded tubing.

- **cryogenic treatment**
  - See cold treatment .
- **crystal**
  - (1) A solid composed of atoms, ions, or molecules arranged in a pattern that is repetitive in three dimensions. (2) That form, or particle, or piece of a substance in which its atoms are distributed in one specific orderly geometrical array, called a "lattice," essentially throughout. Crystals exhibit characteristic optical and other properties and growth or cleavage surfaces, in characteristic directions.
- **crystalline**
  - That form of a substance that comprises predominantly (one or more) crystals, as opposed to glassy or amorphous.
- **crystalline fracture**
  - A pattern of brightly reflecting crystal facets on the fracture surface of a polycrystalline metal, resulting from cleavage fracture of many individual crystals. Contrast with fibrous fracture , and silky fracture ; see also granular fracture .
- **crystallization**
  - (1) The separation, usually from a liquid phase on cooling, of a solid crystalline phase. (2) The progressive process in which crystals are first nucleated (started) and then grown in size within a host medium that supplies their atoms. The host may be gas, liquid, or of another crystalline form.
- **crystal orientation**
  - See orientation .
- **crystal system**
  - One of seven groups into which all crystals may be divided; triclinic, monoclinic, orthorhombic, hexagonal, rhombohedral, tetragonal, and cubic.
- **cubic plane**
  - A plane perpendicular to any one of the three crystallographic axes of the cubic (isometric) system; the Miller indices are {100}.
- **cup**
  - (1) A sheet metal part; the product of the first drawing operation. (2) Any cylindrical part or shell closed at one end.
- **cup-and-cone-fracture**
  - A mixed-mode fracture, often seen in tensile-test specimens of a ductile material, where the central portion undergoes plane-strain fracture and the surrounding region undergoes plane-stress fracture. It is called a cup fracture (or cup-and-cone fracture) because one of the mating fracture surfaces looks like a miniature cup--that is, it has a central depressed flat-face region surrounded by a shear lip; the other fracture surface looks like a miniature truncated cone.
- **cupellation**
  - Oxidation of molten lead containing gold and silver to produce lead oxide, thereby separating the precious metals from the base metal.
- **cupola**
  - A cylindrical vertical furnace for melting metal, especially cast iron, by having the charge come in contact with the hot fuel, usually metallurgical coke.
- **cupping**
  - (1) The first step in deep drawing. (2) Fracture of severely worked rods or wire where one end has the appearance of a cup and the other that of a cone.
- **cupping test**
  - A mechanical test used to determine the ductility and stretching properties of sheet metal. It consists of measuring the maximum part depth that can be formed before fracture. The test is typically carried out by stretching the test piece clamped at its edges into a circular die using a punch with a hemispherical end. See also Erichsen test , Olsen ductility test , and Swift cup test .
- **Curie temperature**
  - The temperature marking the transition between ferromagnetism and paramagnetism, or between the ferroelectric phase and the paraelectric phase. Also known as Curie point. See also ferromagnetism and paramagnetism .
- **curling**
  - Rounding the edge of sheet metal into a closed or partly closed loop.
- **current**

- The net transfer of electric charge per unit time. Also called electric current. See also current density .
- **current decay**
  - In spot, seam, or projection welding, the controlled reduction of the welding current from its peak amplitude to a lower value to prevent excessively rapid cooling of the weld nugget.
- **current density**
  - The current flowing to or from a unit area of an electrode surface.
- **current efficiency**
  - (1) The ratio of the electrochemical equivalent current density for a specific reaction to the total applied current density. (2) The proportion of current used in a given process to accomplish a desired result; in electroplating, the proportion used in depositing or dissolving metal.
- **cut (foundry practice)**
  - (1) To recondition molding sand by mixing on the floor with a shovel or blade-type machine. (2) To form the sprue cavity in a mold. (3) Defect in a casting resulting from erosion of the sand by metal flowing over the mold or cored surface.
- **cut edge**
  - A mechanically sheared edge obtained by slitting, shearing, or blanking.
- **cut-off (casting)**
  - Removing a casting from the sprue by refractory wheel or saw, arc-air torch, or gas torch.
- **cut-off (metalfforming)**
  - A pair of blades positioned in dies or equipment (or a section of the die milled to produce the same effect as inserted blades) used to separate the forging from the bar after forging operations are completed. Used only when forgings are produced from relatively long bars instead of from individual, precut multiples or blanks. See also blank and multiple .
- **cutoff wheel**
  - A thin abrasive wheel for severing or slotting any material or part.
- **cutting down**
  - Removing roughness or irregularities of a metal surface by abrasive action.
- **cutting edge**
  - The leading edge of a cutting tool (such as a lathe tool, drill, or milling cutter) where a line of contact is made with the work during machining.
- **cutting fluid**
  - A fluid used in metal cutting to improve finish, tool life, or dimensional accuracy. On being flowed over the tool and work, the fluid reduces friction, the heat generated, and tool wear, and prevents galling. It conducts the heat away from the point of generation and also serves to wash the chips away.
- **cutting speed**
  - The linear or peripheral speed of relative motion between the tool and workpiece in the principal direction of cutting.
- **cutting tip**
  - That part of an oxygen cutting torch from which the gases issue.
- **cutting torch (arc)**
  - A device used in air carbon arc cutting, gas tungsten arc cutting, and plasma arc cutting to control the position of the electrode, to transfer current, and to control the flow of gases.
- **cutting torch (oxyfuel gas)**
  - A device used for directing the preheating flame produced by the controlled combustion of fuel gases and to direct and control the cutting oxygen.
- **cyanic copper**
  - Copper electrodeposited from an alkali-cyanide solution containing a complex ion made up of univalent copper and the cyanide radical; also the solution itself.
- **cyanide slimes**
  - Finely divided metallic precipitates that are formed when precious metals are extracted from their ores using cyanide solutions.
- **cyaniding**
  - A case-hardening process in which a ferrous material is heated above the lower transformation temperature range in a molten salt containing cyanide to cause simultaneous absorption of carbon and nitrogen at the surface and, by diffusion, create a concentration gradient. Quench hardening completes the process.

- **cycle (*N*)**
  - In fatigue, one complete sequence of values of applied load that is repeated periodically. See also *S-N* curve .
- **cycle annealing**
  - An annealing process employing a predetermined and closely controlled time-temperature cycle to produce specific properties or microstructures.
- **cyclic load**
  - (1) Repetitive loading, as with regularly recurring stresses on a part, that sometimes leads to fatigue fracture. (2) Loads that change value by following a regular repeating sequence of change.
- **cylindrical grinding**
  - Grinding the outer cylindrical surface of a rotating part.
- **cylindrical land**
  - Land having zero relief.
- **D**
- **damage tolerance**
  - (1) A design measure of crack growth rate. Cracks in damage-tolerant designed structures are not permitted to grow to critical size during expected service life. (2) The ability of a part component, such as an aerospace engine, to resist failure due to the presence of flaws, cracks, or other damage for a specified period of usage. The damage tolerance approach is used extensively in the aerospace industry.
- **damping**
  - The loss in energy, as dissipated heat, that results when a material or material system is subjected to an oscillatory load or displacement.
- **damping capacity**
  - The ability of a material to absorb vibration (cyclical stresses) by internal friction, converting the mechanical energy into heat.
- **daylight**
  - The distance, in the open position, between the moving and the fixed tables or the platens of a hydraulic press. In the case of a multiplaten press, daylight is the distance between adjacent platens. Daylight provides space for removal of the molded/formed part from the mold/die.
- **dc casting**
  - Same as direct chill casting .
- **dead soft**
  - A temper of nonferrous alloys and some ferrous alloys corresponding to the condition of minimum hardness and tensile strength produced by full annealing.
- **dealloying**
  - The selective corrosion of one or more components of a solid solution alloy. Also called parting or selective leaching . See also decarburization , decobaltification , denickelification , dezincification , and graphitic corrosion .
- **deburring**
  - Removing burrs, sharp edges, or fins from metal parts by filing, grinding, or rolling the work in a barrel containing abrasives suspended in a suitable liquid medium. Sometimes called burring.
- **decalescence**
  - A phenomenon, associated with the transformation of  $\alpha$ iron to  $\gamma$ iron on the heating (superheating) of iron or steel, revealed by the darkening of the metal surface owing to the sudden decrease in temperature caused by the fast absorption of the latent heat of transformation. Contrast with recalescence .
- **decarburization**
  - Loss of carbon from the surface layer of a carbon-containing alloy due to reaction with one or more chemical substances in a medium that contacts the surface.
- **decobaltification**
  - Corrosion in which cobalt is selectively leached from cobalt-base alloys or from cemented carbides with cobalt binders. See also dealloying and selective leaching .
- **decohesive rupture**
  - A brittle fracture that exhibits little or no bulk plastic deformation and does not occur by dimple rupture, cleavage, or fatigue. This type of fracture is generally the result of a reactive

environment or a unique microstructure and is associated almost exclusively with rupture along grain boundaries.

- **decomposition**
  - Separation of a compound into its chemical elements or components.
- **decomposition potential (or voltage)**
  - The potential of a metal surface necessary to decompose the electrolyte of a cell or a component thereof.
- **deep drawing**
  - Forming deeply recessed parts by forcing sheet metal to undergo plastic flow between dies, usually without substantial thinning of the sheet.
- **deep etching**
  - In metallography, macroetching, especially for steels, to determine the overall character of the material, that is, the presence of imperfections, such as seams, forging bursts, shrinkage-void remnants, cracks, and coring.
- **defect**
  - (1) A discontinuity whose size, shape, orientation, or location makes it detrimental to the useful service of the part in which it occurs. (2) A discontinuity or discontinuities which by nature or accumulated effect (for example, total crack length) render a part or product unable to meet minimum applicable acceptance standards or specifications. This term designates rejectability. See also discontinuity and flaw .
- **defective**
  - A quality control term, describing a unit of product or service containing at least one defect , or having several lesser imperfections that, in combination, cause the unit not to fulfill its anticipated function.
- **deflection**
  - In metalforming and forging, the amount of deviation from a straight line or plane when a force is applied to a press member. Generally used to specify the allowable bending of the bed, slide, or frame at rated capacity with a load of predetermined distribution.
- **deformation**
  - A change in the form of a body due to stress, thermal change, change in moisture, or other causes. Measured in units of length.
- **deformation bands**
  - Parts of a crystal that have rotated differently during deformation to produce bands of varied orientation without individual grains.
- **deformation limit**
  - In drawing, the limit of deformation is reached when the load required to deform the flange becomes greater than the load-carrying capacity of the cup wall. The deformation limit (limiting drawing ratio, LDR) is defined as the ratio of the maximum blank diameter that can be drawn into a cup without failure, to the diameter of the punch.
- **degasifier**
  - A substance that can be added to molten metal to remove soluble gases that might otherwise be occluded or entrapped in the metal during solidification.
- **degassing**
  - (1) A chemical reaction resulting from a compound added to molten metal to remove gases from the metal. Inert gases are often used in this operation. (2) A fluxing procedure used for aluminum alloys in which nitrogen, chlorine, chlorine and nitrogen, and chlorine and argon are bubbled up through the metal to remove dissolved hydrogen gases and oxides from the alloy. See also flux .
- **degradation**
  - A deleterious change in the chemical structure, physical properties, or appearance of a material.
- **degreasing**
  - The removal of grease and oils from a surface. Can be accomplished by immersion in liquid organic solvent, by solvent vapors condensing on the parts being cleaned (vapor degreasing), or by spraying the parts with solvent.
- **delayed yield**
  - A phenomenon involving a delay in time between the application of a stress and the occurrence of the corresponding yield-point strain.
- **delta ferrite**
  - See ferrite .

- **Demarest process**
  - A fluid forming process in which cylindrical and conical sheet metal parts are formed by a modified rubber bulging punch. The punch, equipped with a hydraulic cell, is placed inside the workpiece, which in turn is placed inside the die. Hydraulic pressure expands the punch.
- **dendrite**
  - A crystal that has a treelike branching pattern, being most evident in cast metals slowly cooled through the solidification range.
- **dendritic powder**
  - Particles usually of electrolytic origin typically having the appearance of a pine tree.
- **denickelification**
  - Corrosion in which nickel is selectively leached from nickel-containing alloys. Most commonly observed in copper-nickel alloys after extended service in fresh water. See also dealloying and selective leaching .
- **density, absolute**
  - The mass per unit volume of a solid material, expressed in  $\text{g/cm}^3$ ,  $\text{kg/m}^3$ , or  $\text{lb/ft}^3$ .
- **density ratio**
  - The ratio of the determined density of a powder compact to the absolute density of metal of the same composition, usually expressed as a percentage. Also referred to as percent theoretical density.
- **deoxidation**
  - Removal of excess oxygen from the molten metal; usually accomplished by adding materials with a high affinity for oxygen.
- **deoxidation products**
  - Those nonmetallic inclusions that form as a result of adding deoxidizing agents to molten metal.
- **deoxidized copper**
  - Copper from which cuprous oxide has been removed by adding a deoxidizer , such as phosphorus, to the molten bath.
- **deoxidizer**
  - A substance that can be added to molten metal to remove either free or combined oxygen.
- **deoxidizing**
  - (1) The removal of oxygen from molten metals through the use of a suitable deoxidizer. (2) Sometimes refers to the removal of undesirable elements other than oxygen through the introduction of elements or compounds that readily react with them. (3) In metal finishing, the removal of oxide films from metal surfaces by chemical or electrochemical reaction.
- **dephosphorization**
  - The elimination of phosphorus from molten steel.
- **depolarization**
  - A decrease in the polarization of an electrode.
- **deposit corrosion**
  - Corrosion occurring under or around a discontinuous deposit on a metallic surface. Also called poultice corrosion.
- **deposition efficiency (arc welding)**
  - The ratio of the weight of deposited metal to the net weight of filler metal consumed, exclusive of stubs.
- **deposition sequence**
  - The order in which the increments of weld metal are deposited.
- **depth of cut**
  - The thickness of material removed from a workpiece in a single machining part.
- **depth of fusion**
  - The distance that fusion extends into the base metal or previous pass from the surface melted during welding.
- **descaling**
  - (1) Removing the thick layer of oxides formed on some metals at elevated temperatures. (2) A chemical or mechanical process for removing scale or investment material from castings.
- **desulfurizing**
  - The removal of sulfur from molten metal by reaction with a suitable slag or by the addition of suitable compounds.

- **detonation flame spraying**
  - A thermal spraying process variation in which the controlled explosion of a mixture of fuel gas, oxygen, and powdered coating material is utilized to melt and propel the material to the workpiece.
- **detritus**
  - See wear debris .
- **developed blank**
  - A sheet metal blank that yields a finished part without trimming or with the least amount of trimming.
- **dewaxing**
  - In casting, the process of removing the expendable wax pattern from an investment mold or shell mold; usually accomplished by melting out the application of heat or dissolving the wax with an appropriate solvent.
- **dezincification**
  - Corrosion in which zinc is selectively leached from zinc-containing alloys leaving a relatively weak layer of copper and copper oxide. Most commonly found in copper-zinc alloys containing less than 85% Cu after extended service in water containing dissolved oxygen. See also dealloying and selective leaching .
- **diamagnetic material**
  - A material whose specific permeability is less than unity and is therefore repelled weakly by a magnet. Compare with ferromagnetic material and paramagnetic material .
- **diamond pyramid hardness test**
  - See Vickers hardness test .
- **diamond tool**
  - (1) A diamond, shaped or formed to the contour of a single-point cutting tool, for use in precision machining of nonferrous or nonmetallic materials. (2) An insert made from polycrystalline diamond compacts.
- **diamond wheels**
  - A grinding wheel in which crushed and sized industrial diamonds are held in a resinoid, metal, or vitrified bond.
- **diaphragm**
  - (1) A porous or permeable membrane separating anode and cathode compartments of an electrolytic cell from each other or from an intermediate compartment. (2) Universal die member made of rubber or similar material used to contain hydraulic fluid within the forming cavity and to transmit pressure to the part being formed.
- **dichromate treatment**
  - A chromate conversion coating produced on magnesium alloys in a boiling solution of sodium dichromate.
- **didymium**
  - A natural mixture of the rare-earth elements praseodymium and neodymium, often given the quasi-chemical symbol Di.
- **die**
  - A tool, usually containing a cavity, that imparts shape to solid, molten, or powdered metal primarily because of the shape of the tool itself. Used in many press operations (including blanking, drawing, forging, and forming), in die casting, and in forming green powder metallurgy compacts. Die-casting and powder metallurgy dies are sometimes referred to as molds . See also forging dies .
- **die block**
  - A block, often made of heat-treated steel, into which desired impressions are machined or sunk and from which closed-die forgings or sheet metal stampings are produced using hammers or presses. In forging, die blocks are usually used in pairs, with part of the impression in one of the blocks and the rest of the impression in the other. In sheet metal forming, the female die is used in conjunction with a male punch. See also closed-die forging .
- **die body**
  - The stationary or fixed part of a powder pressing die.
- **die casting**

- (1) A casting made in a die. (2) A casting process in which molten metal is forced under high pressure into the cavity of a metal mold. See also cold chamber machine and hot chamber machine .
- **die cavity**
  - The machined recess that gives a forging or stamping its shape.
- **die clearance**
  - Clearance between a mated punch and die; commonly expressed as clearance per side. Also called clearance or punch-to-die clearance.
- **die cushion**
  - A press accessory placed beneath or within a bolster plate or die block to provide an additional motion or pressure for stamping or forging operations; actuated by air, oil, rubber, springs, or a combination of these.
- **die forging**
  - A forging that is formed to the required shape and size through working in machined impressions in specially prepared dies.
- **die forming**
  - The shaping of solid or powdered metal by forcing it into or through the die cavity.
- **die holder**
  - A plate or block, on which the die block is mounted, having holes or slots for fastening to the bolster plate or the bed of the press.
- **die impression**
  - The portion of the die surface that shapes a forging or sheet metal part.
- **die insert**
  - A relatively small die that contains part or all of the impression of a forging or sheet metal part and is fastened to the master die block.
- **die life**
  - The productive life of a die impression, usually expressed as the number of units produced before the impression has worn beyond permitted tolerances.
- **die lubricant**
  - (1) A lubricant applied to the working surfaces of dies and punches to facilitate drawing, pressing, stamping, and/or ejection. In powder metallurgy, the die lubricant is sometimes mixed into the powder before pressing into a compact. (2) A compound that is sprayed, swabbed, or otherwise applied on die surfaces or the workpiece during the forging or forming process to reduce friction. Lubricants also facilitate release of the part from the dies and provide thermal insulation. See also lubricant .
- **die match**
  - The condition where dies, after having been set up in a press or other equipment, are in proper alignment relative to each other.
- **die opening**
  - (1) In flash or upset welding, the distance between the electrodes, usually measured with the parts in contact before welding has commenced or immediately upon completion of the cycle but before upsetting. (2) In powder metallurgy, the entrance to the die cavity.
- **die proof**
  - A casting of a die impression made to confirm the accuracy of the impression.
- **die radius**
  - The radius on the exposed edge of a deep-drawing die, over which the sheet flows in forming drawn shells.
- **die set**
  - A tool or tool holder consisting of a die base and punch plate for the attachment of a die and punch, respectively.
- **die shift**
  - The condition that occurs after the dies have been set up in a forging unit in which a portion of the impression of one die is not in perfect alignment with the corresponding portion of the other die. This results in a mismatch in the forging, a condition that must be held within the specified tolerance.
- **die sinking**
  - The machining of the die impressions to produce forgings of required shapes and dimensions.
- **die stamping**

- The general term for a sheet metal part that is formed, shaped, or cut by a die in a press in one or more operations.
- **die welding**
  - See preferred terms forge welding and cold welding .
- **differential aeration cell**
  - An electrolytic cell, the electromagnetic force of which is due to a difference in air (oxygen) concentration at one electrode as compared with that at another electrode of the same material. See also concentration cell .
- **differential coating**
  - A coated product having a specified coating on one surface and a significantly lighter coating on the other surface (such as a hot dip galvanized product or electrolytic tin plate).
- **differential floatation**
  - Separating a complex ore into two or more valuable minerals and gangue by flotation. Also called selective flotation.
- **differential heating**
  - Heating that intentionally produces a temperature gradient within an object such that, after cooling, a desired stress distribution or variation in properties is present within the object.
- **diffusion**
  - (1) Spreading of a constituent in a gas, liquid, or solid, tending to make the composition of all parts uniform. (2) The spontaneous movement of atoms or molecules to new sites within a material.
- **diffusion aid**
  - A solid filler metal sometimes used in diffusion welding .
- **diffusion bonding**
  - See preferred terms diffusion welding and diffusion brazing .
- **diffusion brazing**
  - A brazing process that produces coalescence of metals by heating them to suitable temperatures and by using a filler metal or an in situ liquid phase. The filler metal may be distributed by capillary action or may be placed or formed at the faying surfaces. The filler metal is diffused with the base metal to the extent that the joint properties have been changed to approach those of the base metal. Pressure may or may not be applied.
- **diffusion coating**
  - Any process whereby a base metal or alloy is either (1) coated with another metal or alloy and heated to a sufficient temperature in a suitable environment or (2) exposed to a gaseous or liquid medium containing the other metal or alloy, thus causing diffusion of the coating or of the other metal or alloy into the base metal with resultant changes in the composition and properties of its surface.
- **diffusion coefficient**
  - A factor of proportionality representing the amount of substance diffusing across a unit area through a unit concentration gradient in unit time.
- **diffusion welding**
  - A solid-state welding process that produces coalescence of the faying surfaces by the application of pressure at elevated temperature. The process does not involve macroscopic deformation, melting, or relative motion of parts. A solid filler metal (diffusion aid) may or may not be inserted between the faying surfaces. See also forge welding , hot pressure welding , and cold welding .
- **dilatometer**
  - An instrument for measuring the linear expansion or contraction in a metal resulting from changes in such factors as temperature and allotropy.
- **dimple rupture**
  - A fractographic term describing ductile fracture that occurs through the formation and coalescence of microvoids along the fracture path. The fracture surface of such a ductile fracture appears dimpled when observed at high magnification and usually is most clearly resolved when viewed in a scanning electron microscope.
- **dimpling**
  - (1) The stretching of a relatively small, shallow indentation into sheet metal. (2) In aircraft, the stretching of metal into a conical flange for a countersunk head rivet.
- **dip brazing**

- A brazing process in which the heat required is furnished by a molten chemical or metal bath. When a molten chemical bath is used, the bath may act as a flux . When a molten metal bath is used, the bath provides the filler metal.
- **dip coat**
  - (1) In the solid mold technique of investment casting, an extremely fine ceramic precoat applied as a slurry directly to the surface of the pattern to reproduce maximum surface smoothness. This coating is surrounded by coarser, less expensive, and more permeable investment to form the mold. (2) In the shell mold technique of investment casting, an extremely fine ceramic coating called the first coat, applied as a slurry directly to the surface of the pattern to reproduce maximum surface smoothness. The first coat is followed by other dip coats of different viscosity and usually containing different grading of ceramic particles. After each dip, coarser stucco material is applied to the still-wet coating. A buildup of several coats forms an investment shell mold. See also investment casting .
- **diphase cleaning**
  - Removing soil by an emulsion that produces two phases in the cleaning tank: a solvent phase and an aqueous phase. Cleaning is effected by both solvent action and emulsification.
- **dip plating**
  - Same as immersion plating .
- **dip soldering**
  - A soldering process in which the heat required is furnished by a molten metal bath that provides the solder filler metal.
- **direct chill casting**
  - A continuous method of making ingots for rolling or extrusion by pouring the metal into a short mold. The base of the mold is a platform that is gradually lowered while the metal solidifies, the frozen shell of metal acting as a retainer for the liquid metal below the wall of the mold. The ingot is usually cooled by the impingement of water directly on the mold or on the walls of the solid metal as it is lowered. The length of the ingot is limited by the depth to which the platform can be lowered; therefore, it is often called semicontinuous casting.
- **direct current arc furnace**
  - An electric arc furnace in which a single electrode positioned at the center of the furnace roof is the cathode of the system. Current passes from the electrode through the charge or bath to a cathode located at the bottom of the furnace. Current from the bottom of the furnace then passes through the furnace refractories to a copper base plate to outside cables. Used in the production of ferroalloys, carbon and alloy steels, and stainless steels. See also arc furnace .
- **direct current electrode negative (DCEN)**
  - The arrangement of direct current arc welding leads in which the work is the positive pole and the electrode is the negative pole of the welding arc. Also referred to as straight polarity.
- **direct current electrode positive (DCEP)**
  - The arrangement of direct current arc welding leads in which the work is the negative pole and the electrode is the positive pole of the welding arc. Also referred to as reverse polarity.
- **direct current reverse polarity (DCRP)**
  - See direct current electrode positive .
- **direct current straight polarity (DCSP)**
  - See direct current electrode negative .
- **direct (forward) extrusion**
  - See extrusion .
- **directional property**
  - Property whose magnitude varies depending on the relation of the test axis to a specific direction within the metal. The variation results from preferred orientation or from fibering of constituents or inclusions.
- **directional solidification**
  - Controlled solidification of molten metal in a casting so as to provide feed metal to the solidifying front of the casting.
- **direct quenching**
  - (1) Quenching carburized parts directly from the carburizing operation. (2) Also used for quenching pearlitic malleable parts directly from the malleabilizing operation.
- **discontinuity**

- (1) Any interruption in the normal physical structure or configuration of a part, such as cracks, laps, seams, inclusions, or porosity. A discontinuity may or may not affect the utility of the part.
- (2) An interruption of the typical structure of a weldment, such as a lack of homogeneity in the mechanical, metallurgical, or physical characteristics of the material or weldment. A discontinuity is not necessarily a defect. See also defect and flaw .
- **discontinuous precipitation**
  - Precipitation from a supersaturated solid solution in which the precipitate particles grow by short-range diffusion, accompanied by recrystallization of the matrix in the region of precipitation. Discontinuous precipitates grow into the matrix from nuclei near grain boundaries, forming cells of alternate lamellae of precipitate and depleted (and recrystallized) matrix. Often referred to as cellular or nodular precipitation. Compare with continuous precipitation and localized precipitation .
- **discontinuous yielding**
  - The nonuniform plastic flow of a metal exhibiting a yield point in which plastic deformation is inhomogeneously distributed along the gage length. Under some circumstances, it may occur in metals not exhibiting a distinct yield point, either at the onset of or during plastic flow.
- **dishing**
  - Forming a shallow concave surface, the area being large compared to the depth.
- **disk grinding**
  - Grinding with the flat side of an abrasive disk or segmented wheel. Also called vertical-spindle surface grinding.
- **dislocation**
  - A linear imperfection in a crystalline array of atoms. Two basic types are recognized: (1) an edge dislocation corresponds to the row of mismatched atoms along the edge formed by an extra, partial plane of atoms within the body of a crystal; (2) a screw dislocation corresponds to the axis of a spiral structure in a crystal, characterized by a distortion that joins normally parallel planes together to form a continuous helical ramp (with a pitch of one interplanar distance) winding about the dislocation. Most prevalent is the so-called mixed dislocation, which is any combination of an edge dislocation and a screw dislocation.
- **disordered structure**
  - The crystal structure of a solid solution in which the atoms of different elements are randomly distributed relative to the available lattice sites. Contrast with ordered structure .
- **disordering**
  - Forming a lattice arrangement in which the solute and solvent atoms of a solid solution occupy lattice sites at random. See also superlattice .
- **dispersing agent**
  - A substance that increases the stability of a suspension of particles in a liquid medium by deflocculation of the primary particles.
- **dispersion hardening**
  - See dispersion strengthening .
- **dispersion-strengthened material**
  - A metallic material that contains a fine dispersion of nonmetallic phase(s), such as  $\text{Al}_2\text{O}_3$ ,  $\text{MgO}$ ,  $\text{SiO}_2$ ,  $\text{CdO}$ ,  $\text{ThO}_2$ ,  $\text{Y}_2\text{O}_3$ , or  $\text{ZrO}_2$  singly or in combination, to increase the hot strength of the metallic matrix. Examples include dispersion-strengthened copper ( $\text{Al}_2\text{O}_3$ ) used for welding electrodes, silver ( $\text{CdO}$ ) used for electrical contacts, and nickel-chromium ( $\text{Y}_2\text{O}_3$ ) superalloys used for gas turbine components. See also mechanical alloying .
- **dispersion strengthening**
  - The strengthening of a metal or alloy by incorporating chemically stable submicron size particles of a nonmetallic phase that impede dislocation movement at elevated temperature.
- **dispersoid**
  - Finely divided particles of relatively insoluble constituents visible in the microstructure of certain metallic alloys.
- **distortion**
  - Any deviation from an original size, shape, or contour that occurs because of the application of stress or the release of residual stress.
- **disturbed metal**
  - The cold-worked metal layer formed at a polished surface during the process of mechanical grinding and polishing.

- **divided cell**
  - A cell containing a diaphragm or other means for physically separating the anolyte from the catholyte .
- **divorced eutectic**
  - A metallographic appearance in which the two constituents of a eutectic structure appear as massive phases rather than the finely divided mixture characteristic of normal eutectics. Often, one of the constituents of the eutectics is continuous and indistinguishable from an accompanying proeutectic constituent.
- **domain, magnetic**
  - A substructure in a ferromagnetic material within which all the elementary magnets (electron spins) are held aligned in one direction by interatomic forces; if isolated, a domain would be a saturated permanent magnet.
- **double-acting hammer**
  - A forging hammer in which the ram is raised by admitting steam or air into a cylinder below the piston, and the blow intensified by admitting steam or air above the piston on the downward stroke.
- **double-action die**
  - A die designed to perform more than one operation in a single stroke of the press.
- **double-action forming**
  - Forming or drawing in which more than one action is achieved in a single stroke of the press.
- **double-action mechanical press**
  - A press having two independent parallel movements by means of two slides, one moving within the other. The inner slide or plunger is usually operated by a crankshaft; the outer or blankholder slide, which dwells during the drawing operation, is usually operated by a toggle mechanism or by cams. See also slide .
- **double aging**
  - Employment of two different aging treatments to control the type of precipitate formed from a supersaturated matrix in order to obtain the desired properties. The first aging treatment, sometimes referred to as intermediate or stabilizing, is usually carried out at higher temperature than the second.
- **double tempering**
  - A treatment in which a quench-hardened ferrous metal is subjected to two complete tempering cycles, usually at substantially the same temperature, for the purpose of ensuring completion of the tempering reaction and promoting stability of the resulting microstructure.
- **double-welded joint**
  - In arc and oxyfuel gas welding, any joint welded from both sides.
- **downgate**
  - Same as sprue .
- **downhand welding**
  - See flat-position welding .
- **down milling**
  - See preferred term climb milling .
- **downsprue**
  - Same as sprue .
- **Dow process**
  - A process for the production of magnesium by electrolysis of molten magnesium chloride.
- **draft**
  - (1) An angle or taper on the surface of a pattern, core box, punch, or die (or of the parts made with them) that facilitates removal of the parts from a mold or die cavity, or a core from a casting. (2) The change in cross section that occurs during rolling or cold drawing.
- **drag**
  - The bottom section of a flask , mold , or pattern .
- **drag**
  - (thermal cutting). The offset distance between the actual and the theoretical exit points of the cutting oxygen stream measured on the exit surface of the material.
- **drawability**
  - A measure of the formability of a sheet metal subject to a drawing process. The term is usually used to indicate the ability of a metal to be deep drawn. See also drawing and deep drawing .

- **draw bead**
  - An insert or riblike projection on the draw ring or hold-down surfaces that aids in controlling the rate of metal flow during deep draw operations. Draw beads are especially useful in controlling the rate of metal flow in irregularly shaped stampings.
- **drawbench**
  - The stand that holds the die and draw head used in drawing of wire, rod, and tubing.
- **draw forging**
  - See radial forging .
- **draw forming**
  - A method of curving bars, tubes, or rolled or extruded sections in which the stock is bent around a rotating form block. Stock is bent by clamping it to the form block, then rotating the form block while the stock is pressed between the form block and a pressure die held against the periphery of the form block.
- **draw head**
  - Set of rolls or dies mounted on a drawbench for forming a section from strip, tubing, or solid stock. See also Turk's-head rolls .
- **drawing**
  - A term used for a variety of forming operations, such as deep drawing a sheet metal blank; redrawing a tubular part; and drawing rod, wire, and tube. The usual drawing process with regard to sheet metal working in a press is a method for producing a cuplike form from a sheet metal disk by holding it firmly between blankholding surfaces to prevent the formation of wrinkles while the punch travel produces the required shape.
- **drawing compound**
  - (1) A substance applied to prevent pickup and scoring during drawing or pressing operations by preventing metal-to-metal contact of the work and die. Also known as die lubricant . (2) In metalworking, a lubricant having extreme-pressure properties. See also extreme-pressure lubricant .
- **drawing out**
  - A stretching operation resulting from forging a series of upsets along the length of the workpiece.
- **draw marks**
  - See scoring , galling , and pickup .
- **drawn shell**
  - An article formed by drawing sheet metal into a hollow structure having a predetermined geometrical configuration.
- **draw plate**
  - (1) In metalforming, a circular plate with a hole in the center contoured to fit a forming punch; used to support the blank during the forming cycle. (2) In casting, a plate attached to a pattern to facilitate drawing of a pattern from the mold.
- **draw radius**
  - The radius at the edge of a die or punch over which sheet metal is drawn.
- **draw ring**
  - A ring-shaped die part (either the die ring itself or a separate ring) over which the inner edge of sheet metal is drawn by the punch.
- **draw stock**
  - The forging operation in which the length of a metal mass (stock) is increased at the expense of its cross section; no upset is involved. The operation includes converting ingot to pressed bar using "V," round, or flat dies.
- **dress**
  - (1) Cutting, breaking down, or crushing the surface of a grinding wheel to improve its cutting ability and accuracy. (2) Removing dulled grains from the cutting face of a grinding wheel to restore cutting quality.
- **drift**
  - (1) A flat piece of steel of tapering width used to remove taper shank drills and other tools from their holders. (2) A tapered rod used to force mismatched holes into line for riveting or bolting. Sometimes called a drift pin.
- **drilling**
  - Hole making with a rotary end-cutting tool having one or more cutting lips and one or more helical or straight flutes or tubes for the ejection of chips and the passage of a cutting fluid.

- **drop forging**
  - (1) The forging obtained by hammering metal in a pair of closed dies to produce the form in the finishing impression under a drop hammer. (2) Forging method requiring special dies for each shape.
- **drop hammer**
  - A term generally applied to forging hammers in which energy for forging is provided by gravity, steam, or compressed air. See also air-lift hammer , board hammer , and steam hammer .
- **drop hammer forming**
  - A process for producing shapes by the progressive deformation of sheet metal in matched dies under the repetitive blows of a gravity-drop or power-drop hammer. The process is restricted to relatively shallow parts and thin sheet from approximately 0.6 to 1.6 mm (0.024 to 0.064 in.).
- **droplet erosion**
  - Erosive wear caused by the impingement of liquid droplets on a solid surface. See also erosion .
- **drop-through**
  - An undesirable sagging or surface irregularity, usually encountered when brazing or welding near the solidus of the base metal, caused by overheating with rapid diffusion or alloying between the filler metal and the base metal.
- **dross**
  - (1) The scum that forms on the surface of molten metal largely because of oxidation but sometimes because of the rising of impurities to the surface. (2) Oxide and other contaminants that form on the surface of molten solder.
- **dry corrosion**
  - See gaseous corrosion .
- **dry cyaniding (obsolete)**
  - Same as carbonitriding .
- **dry sand mold**
  - A casting mold made of sand and then dried at 100 °C (212 °F) or above before being used. Contrast with green sand mold .
- **dry strength (casting)**
  - The maximum strength of a molded sand specimen that has been thoroughly dried at 100 to 110 °C (220 to 230 °F) and cooled to room temperature. Also known as dry bond strength.
- **dual-phase steels**
  - A class of high-strength low-alloy steels characterized by a tensile strength value of approximately 550 MPa (80 ksi) and by a microstructure consisting of about 20% hard martensite particles dispersed in a soft ductile ferrite matrix. The term dual phase refers to the predominance in the microstructure of two phases, ferrite and martensite. However, small amounts of other phases, such as bainite, pearlite, or retained austenite, may also be present.
- **ductile crack propagation**
  - Slow crack propagation that is accompanied by noticeable plastic deformation and requires energy to be supplied from outside the body. Contrast with brittle crack propagation .
- **ductile fracture**
  - Fracture characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. Contrast with brittle fracture .
- **ductile iron**
  - A cast iron that has been treated while molten with an element such as magnesium or cerium to induce the formation of free graphite as nodules or spherulites, which imparts a measurable degree of ductility to the cast metal. Also known as nodular cast iron, spherulitic graphite cast iron, and spheroidal graphite (SG) iron.
- **ductility**
  - The ability of a material to deform plastically without fracturing.
- **dummy block**
  - In extrusion, a thick unattached disk placed between the ram and the billet to prevent overheating of the ram.
- **dummy cathode**
  - (1) A cathode, usually corrugated to give variable current densities, that is plated at low current densities to preferentially remove impurities from a plating solution. (2) A substitute cathode that is used during adjustment of operating conditions.
- **duplex grain size**

- The simultaneous presence of two grain sizes in substantial amounts, with one grain size appreciably larger than the others. Also termed mixed grain size.
- **duplexing**
  - Any two-furnace melting or refining process. Also called duplex melting or duplex processing.
- **duplex microstructure**
  - A two-phase structure.
- **duplex stainless steels**
  - Stainless steels having a fine-grained mixed microstructure of ferrite and austenite with a composition centered around 26Cr-6.5Ni.
- **duralumin (obsolete)**
  - A term frequently applied to the class of age-hardenable aluminum-copper alloys containing manganese, magnesium, or silicon.
- **dusting**
  - (1) A phenomenon, usually affecting carbon-base electrical motor brushes or other current-carrying contacts, wherein at low relative humidity or high applied current density, a powdery "dust" is produced during operation. (2) Applying a powder, such as sulfur to molten magnesium or graphite to a mold surface.
- **dynamic**
  - Moving, or having high velocity. Frequently used with high strain rate ( $>0.1 \text{ s}^{-1}$ ) testing of metal specimens.
- **dynamic creep**
  - Creep that occurs under conditions of fluctuating load or fluctuating temperature.
- **E**
- **earing**
  - The formation of ears or scalloped edges around the top of a drawn shell, resulting from directional differences in the plastic-working properties of rolled metal, with, across, or at angles to the direction of rolling.
- **eccentric press**
  - A mechanical press in which an eccentric, instead of a crankshaft, is used to move the slide.
- **ECM**
  - An abbreviation for electrochemical machining .
- **eddy-current testing**
  - An electromagnetic nondestructive testing method in which eddy-current flow is induced in the test object. Changes in flow caused by variations in the object are reflected into a nearby coil or coils where they are detected and measured by suitable instrumentation.
- **edge dislocation**
  - See dislocation .
- **edger (edging impression)**
  - The portion of a die impression that distributes metal during forging into areas where it is most needed in order to facilitate filling the cavities of subsequent impressions to be used in the forging sequence. See also fuller (fullering impression) .
- **edge strain**
  - Transverse strain lines or Lüders lines ranging from 25 to 300 mm (1 to 12 in.) in from the edges of cold rolled steel sheet or strip. See also Lüders lines .
- **edging**
  - (1) In sheet metal forming, reducing the flange radius by retracting the forming punch a small amount after the stroke but before release of the pressure. (2) In rolling, the working of metal in which the axis of the roll is parallel to the thickness dimension. Also called edge rolling. (3) The forging operation of working a bar between contoured dies while turning it  $90^\circ$  between blows to produce a varying rectangular cross section. (4) In a forging, removing flash that is directed upward between dies, usually accomplished using a lathe.
- **EDM**
  - Abbreviation for electrical discharge machining .
- **effective crack size**
  - The physical crack size augmented for the effects of crack tip plastic deformation. Sometimes the effective crack size is calculated from a measured value of a physical crack size plus a calculated value of a plastic zone adjustment. A preferred method for calculation of effective crack size

compares compliance from the secant of a load-deflection trace with the elastic compliance from a calibration for the type of specimen.

- **effective draw**
  - The maximum limits of forming depth that can be achieved with a multiple-action press; sometimes called maximum draw or maximum depth of draw.
- **885 °F (475 °C) embrittlement**
  - Embrittlement of stainless steels upon extended exposure to temperatures between 400 and 510 °C (750 and 950 °F). This type of embrittlement is caused by fine, chromium-rich precipitates that segregate at grain boundaries; time at temperature directly influences the amount of segregation. Grain-boundary segregation of the chromium-rich precipitates increases strength and hardness, decreases ductility and toughness, and changes corrosion resistance. This type of embrittlement can be reversed by heating above the precipitation range.
- **ejector**
  - A device mounted in such a way that it removes or assists in removing a formed part from a die.
- **ejector half**
  - The movable half of a die-casting die containing the ejector pins.
- **ejector rod**
  - A rod used to push out a formed piece.
- **elastic constants**
  - The factors of proportionality that relate elastic displacement of a material to applied forces. See also bulk modulus of elasticity , modulus of elasticity , Poisson's ratio , and shear modulus .
- **elastic deformation**
  - A change in dimensions directly proportional to and in phase with an increase or decrease in applied force.
- **elastic hysteresis**
  - A misnomer for an anelastic strain that lags a change in applied stress, thereby creating energy loss during cyclic loading. More properly termed mechanical hysteresis .
- **elasticity**
  - The property of a material by virtue of which deformation caused by stress disappears upon removal of the stress. A perfectly elastic body completely recovers its original shape and dimensions after release of stress.
- **elastic limit**
  - The maximum stress that a material is capable of sustaining without any permanent strain (deformation) remaining upon complete release of the stress. A material is said to have passed its elastic limit when the load is sufficient to initiate plastic, or nonrecoverable, deformation. See also proportional limit .
- **elastic modulus**
  - Same as modulus of elasticity .
- **elastic ratio**
  - Yield point divided by tensile strength.
- **elastic strain**
  - See elastic deformation .
- **elastic strain energy**
  - The energy expended by the action of external forces in deforming a body elastically. Essentially all the work performed during elastic deformation is stored as elastic energy, and this energy is recovered upon release of the applied force.
- **electrical discharge grinding**
  - Grinding by spark discharges between a negative electrode grinding wheel and a positive workpiece separated by a small gap containing a dielectric fluid such as petroleum oil.
- **electrical discharge machining (EDM)**
  - Metal removed by a rapid spark discharge between different polarity electrodes, one on the workpiece and the other the tool separated by a gap distance of 0.013 to 0.9 mm (0.0005 to 0.035 in.). The gap is filled with dielectric fluid and metal particles that are melted, in part vaporized, and expelled from the gap.
- **electrical discharge wire cutting**
  - A special form of electrical discharge machining wherein the electrode is a continuous moving conductive wire. Also referred to as traveling wire electrical discharge machining.
- **electrical disintegration**

- Metal removal by an electrical spark acting in air. It is not subject to precise control, the most common application being the removal of broken tools such as taps and drills.
- **electrical pitting**
  - The formation of surface cavities by removal of metal as a result of an electrical discharge across an interface.
- **electric arc furnace**
  - See arc furnace .
- **electric arc spraying**
  - See preferred term arc spraying .
- **electric furnace**
  - A metal melting or holding furnace that produces heat from electricity. It may operate on the resistance or induction principle. See also induction furnace .
- **electrochemical cell**
  - An electrochemical system consisting of an anode and a cathode in metallic contact and immersed in an electrolyte. The anode and cathode may be different metals or dissimilar areas on the same metal surface. See also cathodic protection .
- **electrochemical corrosion**
  - Corrosion that is accompanied by a flow of electrons between cathodic and anodic areas on metallic surfaces.
- **electrochemical discharge machining**
  - Metal removal by a combination of the processes of electrochemical machining and electrical discharge machining. Most of the metal removal occurs via anodic dissolution (i.e., ECM action). Oxide films which form as a result of electrolytic action through an electrolytic fluid are removed by intermittent spark discharges (i.e., EDM action). Hence, the combination of the two actions.
- **electrochemical equivalent**
  - The weight of an element or group of elements oxidized or reduced at 100% efficiency by the passage of a unit quantity of electricity. Usually expressed as grams per coulomb.
- **electrochemical grinding**
  - A process whereby metal is removed by deplating. The workpiece is the anode; the cathode is a conductive aluminum oxide-copper or metal-bonded diamond grinding wheel with abrasive particles. Most of the metal is removed by deplating; 0.05 to 10% is removed by abrasive cutting.
- **electrochemical machining (ECM)**
  - Controlled metal removal by anodic dissolution. Direct current passes through flowing film of conductive solution which separates the workpiece from the electrode tool. The workpiece is the anode, and the tool is the cathode.
- **electrochemical potential**
  - The partial derivative of the total electrochemical free energy of a constituent with respect to the number of moles of this constituent where all factors are kept constant. It is analogous to the chemical potential of a constituent except that it includes the electric as well as chemical contributions to the free energy. The potential of an electrode in an electrolyte relative to a reference electrode measured under open circuit conditions.
- **electrochemical reaction**
  - A reaction caused by passage of an electric current through a medium that contains mobile ions (as in electrolysis); or, a spontaneous reaction made to cause current to flow in a conductor external to this medium (as in a galvanic cell). In either event, electrical connection is made to the external portion of the circuit via a pair of electrodes. See also electrolyte .
- **electrochemical series**
  - Same as electromotive force series .
- **electrode**
  - Compressed graphite or carbon cylinder or rod used to conduct electric current in electric arc furnaces, arc lamps, and so forth.
- **electrode (electrochemistry)**
  - One of a pair of conductors introduced into an electrochemical cell, between which the ions in the intervening medium flow in opposite directions and on whose surfaces reactions occur (when appropriate external connection is made). In direct current operation, one electrode or "pole" is positively charged, the other negatively. See also anode , cathode , electrochemical reaction , and electrolyte .
- **electrode (welding)**

- (1) In arc welding, a current-carrying rod that supports the arc between the rod and work, or between two rods as in twin carbon-arc welding. It may or may not furnish filler metal. See also bare electrode , covered electrode , flux cored electrode , lightly coated electrode , metal cored electrode , metal electrode , and stranded electrode . (2) In resistance welding, a part of a resistance welding machine through which current and, in most instances, pressure are applied directly to the work. The electrode may be in the form of a rotating wheel, rotating roll, bar, cylinder, plate, clamp, chuck, or modification thereof. (3) In arc and plasma spraying, the current-carrying components that support the arc.
- **electrode cable**
  - Same as electrode lead .
- **electrode deposition**
  - The weight of weld-metal deposit obtained from a unit length of electrode.
- **electrode extension**
  - For gas metal arc welding, flux cored arc welding, and submerged arc welding, the length of unmelted electrode extending beyond the end of the contact tube.
- **electrode force**
  - The force between electrodes in a spot, seam, and projection weld.
- **electrode holder**
  - A device used for mechanically holding the electrode while conducting current to it.
- **electrode indentation (resistance welding)**
  - The depression formed on the surface of workpieces by electrodes.
- **electrode lead**
  - The electrical conductor between the source of arc welding current and the electrode holder.
- **electrode polarization**
  - Change of electrode potential with respect to a reference value. The change may be caused, for example, by the application of an external electrical current or by the addition of an oxidant or reductant.
- **electrodeposition**
  - (1) The deposition of a conductive material from a plating solution by the application of electrical current. (2) The deposition of a substance on an electrode by passing electric current through an electrolyte. Electroplating, electroforming, electrorefining, and electrowinning result from electrodeposition.
- **electrode potential**
  - The potential of an electrode in electrolysis as measured against a reference electrode. The electrode potential does not include any resistance losses in potential in either the solution or external circuit. It represents the reversible work to move a unit charge from the electrode surface through the solution to the reference electrode.
- **electrode reaction**
  - Interfacial reaction equivalent to a transfer of charge between electronic and ionic conductors. See also anodic reaction and cathodic reaction .
- **electroforming**
  - Making parts by electrodeposition on a removable form.
- **electrogalvanizing**
  - The electroplating of zinc upon iron or steel.
- **electrogas welding (EGW)**
  - An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the work. Molding shoes are used to confine the molten weld metal for vertical position welding. The electrodes may either be flux cored or solid. Shielding may or may not be obtained from an externally supplied gas or mixture.
- **electroless plating**
  - (1) A process in which metal ions in a dilute aqueous solution are plated out on a substrate by means of autocatalytic chemical reduction. (2) The deposition of conductive material from an autocatalytic plating solution without the application of electrical current.
- **electrolysis**
  - (1) Chemical change resulting from the passage of an electric current through an electrolyte. (2) The separation of chemical components by the passage of current through an electrolyte.
- **electrolyte**

- (1) A chemical substance or mixture, usually liquid, containing ions that migrate in an electric field. (2) A chemical compound or mixture of compounds which when molten or in solution will conduct an electric current.
- **electrolytic brightening**
  - Same as electropolishing .
- **electrolytic cell**
  - An assembly, consisting of a vessel, electrodes, and an electrolyte, in which electrolysis can be carried out.
- **electrolytic cleaning**
  - A process of removing soil, scale, or corrosion products from a metal surface by subjecting it as an electrode to an electric current in an electrolytic bath.
- **electrolytic copper**
  - Copper that has been refined by electrodeposition, including cathodes that are the direct product of the refining operation, refinery shapes cast from melted cathodes, and, by extension, fabricators' products made therefrom. Usually when this term is used alone, it refers to electrolytic tough pitch copper without elements other than oxygen being present in significant amounts. See also tough pitch copper .
- **electrolytic deposition**
  - Same as electrodeposition .
- **electrolytic grinding**
  - A combination of grinding and machining wherein a metal-bonded abrasive wheel, usually diamond, is the cathode in physical contact with the anodic workpiece, the contact being made beneath the surface of a suitable electrolyte. The abrasive particles that produce grinding act as nonconducting spacers permitting simultaneous machining through electrolysis.
- **electrolytic machining**
  - Controlled removal of metal using an applied potential and a suitable electrolyte to produce the shapes and dimensions desired.
- **electrolytic picking**
  - Pickling in which electric current is used, the work being one of the electrodes.
- **electrolytic polishing**
  - An electrochemical polishing process in which the metal to be polished is made the anode in an electrolytic cell where preferential dissolution at high points in the surface topography produces a specularly reflective surface. Also referred to as electropolishing .
- **electrolytic powder**
  - Powder produced by electrodeposition or by pulverizing of an electrodeposit.
- **electrolytic protection**
  - See preferred term cathodic protection .
- **electrolytic tough pitch**
  - A term describing the method of raw copper preparation to ensure a good physical- and electrical-grade copper-finished product.
- **electromagnetic forming**
  - A process for forming metal by the direct application of an intense, transient magnetic field. The workpiece is formed without mechanical contact by the passage of a pulse of electric current through a forming coil. Also known as magnetic pulse forming.
- **electromagnetic radiation**
  - Energy propagated at the speed of light by an electromagnetic field. The electromagnetic spectrum includes the following approximate wavelength regions:

Region	Wavelength, Å (nm)
Gamma-ray	0.005 to 1.40 (0.0005 to 0.14)
X-ray	0.1 to 100 (0.01 to 10)
Far-ultraviolet	100 to 2000 (10 to 200)
Near-ultraviolet	2000 to 3800 (200 to 380)

Visible	3800 to 7800 (380 to 780)
Near-infrared	7800 to 30,000 (0.78 to 3 $\mu\text{m}$ )
Middle-infrared	$3 \times 10^4$ to $3 \times 10^5$ (3 to 30 $\mu\text{m}$ )
Far-infrared	$3 \times 10^5$ to $3 \times 10^6$ (30 to 300 $\mu\text{m}$ )
Microwave	$3 \times 10^6$ to $1 \times 10^{10}$ (0.3 mm to 1 m)

- **electromechanical polishing**
  - An attack-polishing method in which the chemical action of the polishing fluid is enhanced or controlled by the application of an electric current between the specimen and the polishing wheel.
- **electrometallurgy**
  - Industrial recovery or processing of metals and alloys by electric or electrolytic methods.
- **electromotive force**
  - (1) The force that determines the flow of electricity; a difference of electric potential. (2) Electrical potential; voltage.
- **electromotive force series (emf series)**
  - A series of elements arranged according to their standard electrode potentials, with "noble" metals such as gold being positive and "active" metals such as zinc being negative. In corrosion studies, the analogous but more practical galvanic series of metals is generally used. The relative positions of a given metal are not necessarily the same in the two series.
- **electron bands**
  - Energy states for the free electrons in a metal, as described by the use of the band theory (zone theory) of electron structure. Also called Brillouin zones.
- **electron beam cutting**
  - A cutting process that uses the heat obtained from a concentrated beam composed primarily of high-velocity electrons, which impinge on the workpieces to be cut; it may or may not use an externally supplied gas.
- **electron beam heat treating**
  - A selective surface hardening process that rapidly heats a surface by direct bombardment with an accelerated stream of electrons.
- **electron beam machining**
  - Removing material by melting and vaporizing the workpiece at the point of impingement of a focused high-velocity beam of electrons. The machining is done in high vacuum to eliminate scattering of the electrons due to interaction with gas molecules. The most important use of electron beam machining is for hole drilling.
- **electron beam welding (EBW)**
  - A welding process that produces coalescence of metals with the heat obtained from a concentrated beam composed primarily of high-velocity electrons impinging on the surfaces to be joined.
- **electrophoresis**
  - Transport of charged colloidal or macromolecular materials in an electric field.
- **electroplate**
  - The application of a metallic coating on a surface by means of electrolytic action.
- **electroplating**
  - The electrodeposition of an adherent metallic coating on an object serving as a cathode for the purpose of securing a surface with properties or dimensions different from those of the substrate.
- **electropolishing**
  - A technique commonly used to prepare metallographic specimens, in which a high polish is produced making the specimen the anode in an electrolytic cell, where preferential dissolution at high points smooths the surface. Also referred to as electrolytic polishing .
- **electrorefining**
  - Using electric or electrolytic methods to convert impure metal to purer metal, or to produce an alloy from impure or partly purified raw materials.
- **electroslag remelting (ESR)**
  - A consumable-electrode remelting process in which heat is generated by the passage of electric current through a conductive slag. The droplets of metal are refined by contact with the slag.
- **electroslag welding (ESW)**

- A welding process that produces coalescence of metals with molten slag that melts the filler metal and the surfaces of the workpieces. The weld pool is shielded by this slag, which moves along the full cross section of the joint as welding progresses. The process is initiated by an arc that heats the slag. The arc is then extinguished by the conductive slag, which is kept molten by its resistance to electric current passing through the electrode and the workpieces.
- **electrostrictive effect**
  - The reversible interaction, exhibited by some crystalline materials, between an elastic strain and an electric field. The direction of the strain is independent of the polarity of the field. Compare with piezoelectric effect .
- **electroplating**
  - Electroplating tin on an object.
- **electrotyping**
  - The production of printing plates by electroforming .
- **electrowinning**
  - Recovery of a metal from an ore by means of electrochemical processes.
- **elongation**
  - (1) A term used in mechanical testing to describe the amount of extension of a test piece when stressed. (2) In tensile testing, the increase in the gage length, measured after fracture of the specimen within the gage length, usually expressed as a percentage of the original gage length. See also elongation, percent .
- **elongation, percent**
  - The extension of a uniform section of a specimen expressed as a percentage of the original gage length:

$$\text{Elongation, \%} = \frac{(L_x - L_o)}{L_o} \times 100$$

- where  $L_o$  is the original gage length and  $L_x$  is the final gage length.
- **elutriation**
  - A test for particle size in which the speed of a liquid or gas is used to suspend particles of a desired size, with larger sizes settling for removal and weighing, while smaller sizes are removed, collected, and weighed at certain time intervals.
- **embossing**
  - (1) Technique used to create depressions of a specific pattern in plastic film and sheeting. Such embossing in the form of surface patterns can be achieved on molded parts by the treatment of the mold surface with photoengraving or another process. (2) Raising a design in relief against a surface.
- **embossing die**
  - A die used for producing embossed designs.
- **embrittlement**
  - The severe loss of ductility or toughness or both, of a material, usually a metal or alloy. Many forms of embrittlement can lead to brittle fracture. Many forms can occur during thermal treatment or elevated-temperature service (thermally induced embrittlement). Some of these forms of embrittlement, which affect steels, include blue brittleness, 885 °F (475 °C) embrittlement, quench-age embrittlement, sigma-phase embrittlement, strain-age embrittlement, temper embrittlement, tempered martensite embrittlement, and thermal embrittlement. In addition, steels and other metals and alloys can be embrittled by environmental conditions (environmentally assisted embrittlement). The forms of environmental embrittlement include acid embrittlement, caustic embrittlement, corrosion embrittlement, creep-rupture embrittlement, hydrogen embrittlement, liquid metal embrittlement, neutron embrittlement, solder embrittlement, solid metal embrittlement, and stress-corrosion cracking.
- **emf**
  - An abbreviation for electromotive force .
- **emission spectroscopy**
  - The branch of spectroscopy treating the theory, interpretation, and application of spectra originating in the emission of electromagnetic radiation by atoms, ions, radicals, and molecules.

- **emissivity**
  - Ratio of the amount of energy or of energetic particles radiated from a unit area of a surface to the amount radiated from a unit area of an ideal emitter under the same conditions.
- **emulsion**
  - A stable dispersion of one liquid in another, generally by means of an emulsifying agent that has affinity for both the continuous and discontinuous phases. The emulsifying agent, discontinuous phase, and continuous phase can together produce another phase that serves as an enveloping (encapsulating) protective phase around the discontinuous phase.
- **emulsion cleaner**
  - A cleaner consisting of organic solvents dispersed in an aqueous medium with the aid of an emulsifying agent.
- **enameling iron**
  - A low-carbon, cold-rolled sheet steel, produced specifically for use as a base metal for porcelain enamel.
- **enantiotropy**
  - The relation of crystal forms of the same substance in which one form is stable above a certain temperature and the other form is stable below that temperature. For example, ferrite and austenite are enantiotropic in ferrous alloys.
- **end mark**
  - A roll mark caused by the end of a sheet marking the roll during hot or cold rolling.
- **end milling**
  - A method of machining with a rotating cutting tool with cutting edges on both the face end and the periphery. See also face milling and milling .
- **endothermic atmosphere**
  - A gas mixture produced by the partial combustion of a hydrocarbon gas with air in an endothermic reaction. Also known as endogas.
- **endothermic reaction**
  - Designating or pertaining to a reaction that involves the absorption of heat. See also exothermic reaction .
- **end-quench hardenability test**
  - A laboratory procedure for determining the hardenability of a steel or other ferrous alloy; widely referred to as the Jominy test. Hardenability is determined by heating a standard specimen above the upper critical temperature, placing the hot specimen in a fixture so that a stream of cold water impinges on one end, and, after cooling to room temperature is completed, measuring the hardness near the surface of the specimen at regularly spaced intervals along its length. The data are normally plotted as hardness versus distance from the quenched end.
- **endurance limit**
  - The maximum stress that a material can withstand for an infinitely large number of fatigue cycles. See also fatigue limit and fatigue strength .
- **endurance ratio**
  - The ratio of the endurance limit for completely reversed flexural stress to the tensile strength of a given material.
- **engineering strain ( $e$ )**
  - A term sometimes used for average linear strain or conventional strain in order to differentiate it from true strain. In tension testing it is calculated by dividing the change in the gage length by the original gage length.
- **engineering stress ( $s$ )**
  - A term sometimes used for conventional stress in order to differentiate it from true stress. In tension testing, it is calculated by dividing the breaking load applied to the specimen by the original cross-sectional area of the specimen.
- **environmental cracking**
  - Brittle fracture of a normally ductile material in which the corrosive effect of the environment is a causative factor. Environmental cracking is a general term that includes corrosion fatigue, high-temperature hydrogen attack, hydrogen blistering, hydrogen embrittlement, liquid metal embrittlement, solid metal embrittlement, stress-corrosion cracking, and sulfide stress cracking. The following terms have been used in the past in connection with environmental cracking, but are becoming obsolete: caustic embrittlement, delayed fracture, season cracking, static fatigue,

stepwise cracking, sulfide corrosion cracking, and sulfide stress-corrosion cracking. See also embrittlement .

- **epitaxy**
  - Growth of an electrodeposit or vapor deposit in which the orientation of the crystals in the deposit are directly related to crystal orientations in the underlying crystalline substrate.
- **epsilon ( $\epsilon$ )**
  - Designation generally assigned to intermetallic, metal-metalloid, and metal-nonmetallic compounds found in ferrous alloy systems, for example,  $\text{Fe}_3\text{Mo}_2$ ,  $\text{FeSi}$ , and  $\text{Fe}_3\text{P}$ .
- **epsilon carbide**
  - Carbide with hexagonal close-packed lattice that precipitates during the first stage of tempering of primary martensite. Its composition corresponds to the empirical formula  $\text{Fe}_{2.4}\text{C}$ .
- **epsilon structure**
  - Structurally analogous close-packed phases or electron compounds that have ratios of seven valence electrons to four atoms.
- **equiaxed grain structure**
  - A structure in which the grains have approximately the same dimensions in all directions.
- **equilibrium**
  - The dynamic condition of physical, chemical, mechanical, or atomic balance that appears to be a condition of rest rather than one of change.
- **equilibrium diagram**
  - A graph of the temperature, pressure, and composition limits of phase fields in an alloy system as they exist under conditions of thermodynamical equilibrium. In metal systems, pressure is usually considered constant. Compare with phase diagram .
- **Erichsen test**
  - A cupping test used to assess the ductility of sheet metal. The method consists of forcing a conical or hemispherical-ended plunger into the specimen and measuring the depth of the impression at fracture.
- **erosion**
  - (1) Loss of material from a solid surface due to relative motion in contact with a fluid that contains solid particles. Erosion in which the relative motion of particles is nearly parallel to the solid surface is called abrasive erosion. Erosion in which the relative motion of the solid particles is nearly normal to the solid surface is called impingement erosion or impact erosion. (2) Progressive loss of original material from a solid surface due to mechanical interaction between that surface and a fluid, a multicomponent fluid, and impinging liquid, or solid particles. (3) Loss of material from the surface of an electrical contact due to an electrical discharge (arcing). See also cavitation erosion , electrical pitting , and erosion-corrosion .
- **erosion-corrosion**
  - A conjoint action involving corrosion and erosion in the presence of a moving corrosive fluid, leading to the accelerated loss of material.
- **erosivity**
  - The characteristic of a collection of particles, liquid stream, or a slurry that expresses its tendency to cause erosive wear when forced against a solid surface under relative motion.
- **etchant**
  - A chemical solution used to etch a metal to reveal structural details. See also etching .
- **etch cleaning**
  - Removing soil by dissolving away some of the underlying metal.
- **etch cracks**
  - Shallow cracks in hardened steel containing high residual surface stresses, produced by etching in an embrittling acid.
- **etch figures**
  - Characteristic markings produced on crystal surfaces by chemical attack, usually having facets parallel to low-index crystallographic planes.
- **etching**
  - (1) Subjecting the surface of a metal to preferential chemical or electrolytic attack in order to reveal structural details for metallographic examination. (2) Chemically or electrochemically removing tenacious films from a metal surface to condition the surface for a subsequent treatment, such as painting or electroplating.
- **eutectic**

- (1) An isothermal reversible reaction in which a liquid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectic point on a phase diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectic reaction often in the form of regular arrays of lamellas or rods.
- **eutectic carbide**
  - Carbide formed during freezing as one of the mutually insoluble phases participating in the eutectic reaction of ferrous alloys.
- **eutectic melting**
  - Melting of localized microscopic areas whose composition corresponds to that of the eutectic in the system.
- **eutectic point**
  - The composition of a liquid phase in univariant equilibrium with two or more solid phases; the lowest melting alloy of a composition series.
- **eutectoid**
  - (1) An isothermal reversible reaction in which a solid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectoid point on a phase diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectoid reaction.
- **eutectoid point**
  - The composition of a solid phase that undergoes univariant transformation into two or more other solid phases upon cooling.
- **exfoliation**
  - Corrosion that proceeds laterally from the sites of initiation along planes parallel to the surface, generally at grain boundaries, forming corrosion products that force metal away from the body of the material, giving rise to a layered appearance. Most commonly associated with wrought aluminum alloys.
- **exogenous inclusion**
  - An inclusion that is derived from external causes. Slag, dross, entrapped mold materials, and refractories are examples of inclusions that would be classified as exogenous. In most cases, these inclusions are macroscopic or visible to the naked eye. Compare with indigenous inclusion .
- **exothermic**
  - Characterized by the liberation of heat.
- **exothermic atmosphere**
  - A gas mixture produced by the partial combustion of a hydrocarbon gas with air in an exothermic reaction. Also known as exogas.
- **exothermic reaction**
  - A reaction that liberates heat, such as the burning of fuel or when certain plastic resins are cured chemically.
- **expanding**
  - A process used to increase the diameter of a cup, shell, or tube. See also bulging .
- **expendable pattern**
  - A pattern that is destroyed in making a casting. It is usually made of wax (investment casting) or expanded polystyrene (lost foam casting).
- **explosion welding**
  - A solid-state welding process that produces coalescence by a controlled detonation, which causes the parts to move together at high velocity. The resulting bond zone has a characteristic wavy appearance.
- **explosive forming**
  - The shaping of metal parts in which the forming pressure is generated by an explosive charge that takes the place of the punch in conventional forming. See also high-energy-rate forming .
- **extensometer**
  - An instrument for measuring changes in length over a given gage length caused by application or removal of a force. Commonly used in tension testing.
- **extractive metallurgy**

- The branch of process metallurgy dealing with the winning of metals from their ores. Compare with refining .
- **extra hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by values of tensile strength and hardness about one-third of the way from those of full hard to those of extra spring temper.
- **extra spring**
  - A temper of nonferrous alloys and some ferrous alloys corresponding approximately to a cold-worked state above full hard beyond which further cold work will not measurably increase strength or hardness.
- **extreme-pressure lubricant**
  - A lubricant that imparts increased load-carrying capacity to rubbing surfaces under severe operating conditions. Extreme-pressure lubricants usually contain sulfur, halogens, or phosphorus.
- **extruded hole**
  - A hole formed by a punch that first cleanly cuts a hole and then is pushed farther through to form a flange with an enlargement of the original hole.
- **extrusion**
  - The conversion of an ingot or billet into lengths of uniform cross section by forcing metal to flow plastically through a die orifice. In forward (direct) extrusion, the die and ram are at opposite ends of the extrusion stock, and the product and ram travel in the same direction. Also, there is relative motion between the extrusion stock and the die. In backward (indirect) extrusion, the die is at the ram end of the stock and the product travels in the direction opposite that of the ram, either around the ram (as in the impact extrusion of cylinders such as cases for dry cell batteries) or up through the center of a hollow ram. See also hydrostatic extrusion and impact extrusion .
- **extrusion billet**
  - A metal slug used as extrusion stock .
- **extrusion defect**
  - See preferred term extrusion pipe .
- **extrusion forging**
  - (1) Forcing metal into or through a die opening by restricting flow in other directions. (2) A part made by the operation.
- **extrusion ingot**
  - A cast metal slug used as extrusion stock .
- **extrusion pipe**
  - A central oxide-lined discontinuity that occasionally occurs in the last 10 to 20% of an extruded metal bar. It is caused by the oxidized outer surface of the billet flowing around the end of the billet and into the center of the bar during the final stages of extrusion. Also called coring .
- **extrusion stock**
  - A rod, bar, or other section used to make extrusions.
- **eyeletting**
  - The displacing of material about an opening in sheet or plate so that a lip protruding above the surface is formed.
- **F**
- **face**
  - In a lathe tool, the surface against which the chips bear as they are formed.
- **face milling**
  - Milling a surface that is perpendicular to the cutter axis.
- **face-type cutters**
  - Cutters that can be mounted directly on and driven from the machine spindle nose.
- **facing**
  - (1) In machining, generating a surface on a rotating workpiece by the traverse of a tool perpendicular to the axis of rotation. (2) In foundry practice, any material applied in a wet or dry condition to the face of a mold or core to improve the surface of the casting. See also mold wash . (3) For abrasion resistance, see preferred term hardfacing .
- **failure**
  - A general term used to imply that a part in service (a) has become completely inoperable, (b) is still operable but incapable of satisfactorily performing its intended function, or (c) has deteriorated seriously, to the point that it has become unreliable or unsafe for continued use.

- **failure mechanism**
  - A structural or chemical process, such as corrosion or fatigue, that causes failure.
- **false bottom**
  - An insert put in either member of a die set to increase the strength and improve the life of the die.
- **false brinelling**
  - (1) Damage to a solid bearing surface characterized by indentations not caused by plastic deformation resulting from overload, but thought to be due to other causes such as fretting corrosion. (2) Local spots appearing when the protective film on a metal is broken continually by repeated impacts, usually in the presence of corrosive agents. The appearance is generally similar to that produced by brinelling but corrosion products are usually visible. It may result from fretting corrosion. This term should be avoided when a more precise description is possible. False brinelling (race fretting) can be distinguished from true brinelling because in false brinelling, surface material is removed so that original finishing marks are removed. The borders of a false brinell mark are sharply defined, whereas a dent caused by a rolling element does not have sharp edges and the finishing marks are visible in the bottom of the dent.
- **fatigue**
  - The phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the ultimate tensile strength of the material. Fatigue failure generally occurs at loads that applied statically would produce little perceptible effect. Fatigue fractures are progressive, beginning as minute cracks that grow under the action of the fluctuating stress.
- **fatigue crack growth rate ( $da/dN$ )**
  - The rate of crack extension caused by constant-amplitude fatigue loading, expressed in terms of crack extension per cycle of load application, and plotted logarithmically against the stress-intensity factor range,  $\Delta K$ .
- **fatigue failure**
  - Failure that occurs when a specimen undergoing fatigue completely fractures into two parts or has softened or been otherwise significantly reduced in stiffness by thermal heating or cracking.
- **fatigue life ( $N$ )**
  - (1) The number of cycles of stress or strain of a specified character that a given specimen sustains before failure of a specified nature occurs. (2) The number of cycles of deformation required to bring about failure of a test specimen under a given set of oscillating conditions (stresses or strains). See also  $S$ - $N$  curve .
- **fatigue limit**
  - The maximum stress that presumably leads to fatigue fracture in a specified number of stress cycles. The value of the maximum stress and the stress ratio also should be stated. See also endurance limit .
- **fatigue notch factor ( $K_f$ )**
  - The ratio of the fatigue strength of an unnotched specimen to the fatigue strength of a notched specimen of the same material and condition; both strengths are determined at the same number of stress cycles.
- **fatigue notch sensitivity ( $q$ )**
  - An estimate of the effect of a notch or hole of a given size and shape on the fatigue properties of a material, measured by  $q = (K_f - 1)/(K_t - 1)$  where  $K_f$  is the fatigue notch factor and  $K_t$  is the stress-concentration factor. A material is said to be fully notch sensitive if  $q$  approaches a value of 1.0; it is not notch sensitive if the ratio approaches 0.
- **fatigue ratio**
  - The ratio of fatigue strength to tensile strength. Mean stress and alternating stress must be stated.
- **fatigue strength**
  - The maximum cyclical stress a material can withstand for a given number of cycles before failure occurs.
- **fatigue strength at  $N$  cycles ( $S_N$ )**
  - A hypothetical value of stress for failure at exactly  $N$  cycles as determined from an  $S$ - $N$  curve. The value of  $S_N$  thus determined is subject to the same conditions as those that apply to the  $S$ - $N$  curve. The value of  $S_N$  that is commonly found in the literature is the hypothetical value of maximum stress,  $S_{\max}$ , minimum stress  $S_{\min}$ , or stress amplitude,  $S_a$ , at which 50% of the specimens of a given sample could survive  $N$  stress cycles in which the mean stress  $S_m = 0$ . This is also known as the median fatigue strength at  $N$  cycles . See also  $S$ - $N$  curve .
- **fatigue-strength reduction factor**

- The ratio of the fatigue strength of a member or specimen with no stress concentration to the fatigue strength with stress concentration. This factor has no meaning unless the stress range and the shape, size, and material of the member or specimen are stated.
- **fatigue striation**
  - Parallel lines frequently observed in electron microscope fractographs or fatigue fracture surfaces. The lines are transverse to the direction of local crack propagation; the distance between successive lines represents the advance of the crack front during the one cycle of stress variation.
- **fatigue test**
  - A method for determining the range of alternating (fluctuating) stresses a material can withstand without failing.
- **fatigue wear**
  - (1) Removal of particles detached by fatigue arising from cyclic stress variations. (2) Wear of a solid surface caused by fracture arising from material fatigue. See also spalling .
- **faying surface**
  - The mating surface of a member that is in contact with or in close proximity to another member to which it is to be joined.
- **feed**
  - The rate at which a cutting tool or grinding wheel advances along or into the surface of a workpiece, the direction of advance depending on the type of operation involved.
- **feeder (feeder head, feedhead)**
  - In foundry practice, a riser .
- **feeding**
  - (1) In casting, providing molten metal to a region undergoing solidification, usually at a rate sufficient to fill the mold cavity ahead of the solidification front and to compensate for any shrinkage accompanying solidification. (2) Conveying metal stock or workpieces to a location for use or processing, such as wire to a consumable electrode, strip to a die, or workpieces to an assembler.
- **feed lines**
  - Linear marks on a machined or ground surface that are spaced at intervals equal to the feed per revolution or per stroke.
- **ferrimagnetic material**
  - (1) A material that macroscopically has properties similar to those of a ferromagnetic material but that microscopically also resembles an antiferromagnetic material in that some of the elementary magnetic moments are aligned antiparallel. If the moments are of different magnitudes, the material may still have a large resultant magnetization. (2) A material in which unequal magnetic moments are lined up antiparallel to each other. Permeabilities are of the same order of magnitude as those of ferromagnetic materials, but are lower than they would be if all atomic moments were parallel and in the same direction. Under ordinary conditions the magnetic characteristics of ferrimagnetic materials are quite similar to those of ferromagnetic material.
- **ferrite**
  - (1) A solid solution of one or more elements in body-centered cubic iron. Unless otherwise designated (for instance, as chromium ferrite), the solute is generally assumed to be carbon. On some equilibrium diagrams, there are two ferrite regions separated by an austenite area. The lower area is  $\alpha$  ferrite; the upper,  $\delta$  ferrite. If there is no designation,  $\alpha$  ferrite is assumed. (2) An essentially carbon-free solid solution in which  $\alpha$  iron is the solvent and which is characterized by a body-centered cubic crystal structure. Fully ferritic steels are only obtained when the carbon content is quite low. The most obvious microstructural features in such metals are the ferrite grain boundaries.
- **ferrite banding**
  - Parallel bands of free ferrite aligned in the direction of working. Sometimes referred to as ferrite streaks.
- **ferrite number**
  - An arbitrary, standardized value designating the ferrite content of an austenitic stainless steel weld metal. This value directly replaces percent ferrite or volume percent ferrite and is determined by the magnetic test described in AWS A4.2
- **ferrite-pearlite banding**
  - Inhomogeneous distribution of ferrite and pearlite aligned in filaments or plates parallel to the direction of working.

- **ferrite streaks**
  - Same as ferrite banding .
- **ferritic grain size**
  - The grain size of the ferritic matrix of a steel.
- **ferritic malleable**
  - See malleable iron .
- **ferritizing anneal**
  - A treatment given as-cast gray or ductile (nodular) iron to produce an essentially ferritic matrix. For the term to be meaningful, the final microstructure desired or the time-temperature cycle used must be specified.
- **ferroalloy**
  - An alloy of iron that contains a sufficient amount of one or more other chemical elements to be useful as an agent for introducing these elements into molten metal, especially into steel or cast iron.
- **ferroelectric**
  - A crystalline material that exhibits spontaneous electrical polarization, hysteresis, and piezoelectric properties.
- **ferroelectric effect**
  - The phenomenon whereby certain crystals may exhibit a spontaneous dipole moment (which is called ferroelectric by analogy with ferromagnetism exhibiting a permanent magnetic moment). Ferroelectric crystals often show several Curie points, domain structures, and hysteresis, much as do ferromagnetic crystals.
- **ferrograph**
  - An instrument used to determine the size distribution of wear particles in lubricating oils of mechanical systems. The technique relies on the debris being capable of being attracted to a magnet.
- **ferromagnetic material**
  - A material that in general exhibits the phenomena of hysteresis and saturation, and whose permeability is dependent on the magnetizing force. Microscopically, the elementary magnets are aligned parallel in volumes called domains (see domain, magnetic ). The unmagnetized condition of a ferromagnetic material results from the overall neutralization of the magnetization of the domains to produce zero external magnetization.
- **ferromagnetism**
  - A property exhibited by certain metals, alloys, and compounds of the transition (iron group), rare-earth, and actinide elements in which, below a certain temperature termed the Curie temperature, the atomic magnetic moments tend to line up in a common direction. Ferromagnetism is characterized by the strong attraction of one magnetized body for another. See also Curie temperature . Compare with paramagnetism .
- **ferrous**
  - Metallic materials in which the principal component is iron.
- **fiber**
  - (1) The characteristic of wrought metal that indicates directional properties and is revealed by etching of a longitudinal section or is manifested by the fibrous or woody appearance of a fracture. It is caused chiefly by extension of the constituents of the metal, both metallic and nonmetallic, in the direction of working. (2) The pattern of preferred orientation of metal crystals after a given deformation process, usually wiredrawing. See also fibering and preferred orientation .
- **fibering**
  - Elongation and alignment of internal boundaries, second phases, and inclusions in particular directions corresponding to the direction of metal flow during deformation processing.
- **fiber metallurgy**
  - The technology of producing solid bodies from fibers or chopped filaments, with or without a metal matrix. The fibers may consist of such nonmetals as graphite or aluminum oxide, or of such metals as tungsten or boron. See also metal-matrix composites .
- **fiber stress**
  - Local stress through a small area (a point or line) on a section where the stress is not uniform, as in a beam under a bending load.
- **fibrous fracture**

- A gray and amorphous fracture that results when a metal is sufficiently ductile for the crystals to elongate before fracture occurs. When a fibrous fracture is obtained in an impact test, it may be regarded as definite evidence of toughness of the metal. See also crystalline fracture and silky fracture .
- **fibrous structure**
  - (1) In forgings, a structure revealed as laminations, not necessarily detrimental, on an etched section or as a ropy appearance on a fracture. It is not to be confused with silky or ductile fracture of a clean metal. (2) In wrought iron, a structure consisting of slag fibers embedded in ferrite. (3) In rolled steel plate stock, a uniform, fine-grained structure on a fractured surface, free of laminations or shale-type discontinuities.
- **filamentary shrinkage**
  - A fine network of shrinkage cavities, occasionally found in steel castings, that produces a radiographic image resembling lace.
- **file hardness**
  - Hardness as determined by the use of a steel file of standardized hardness on the assumption that a material that cannot be cut with the file is as hard as, or harder than, the file. Files covering a range of hardnesses may be employed; the most common are files heat treated to approximately 67 to 70 HRC.
- **filiform corrosion**
  - Corrosion that occurs under some coatings in the form of randomly distributed thread-like filaments.
- **filler metal**
  - Metal added in making a brazed, soldered, or welded joint. See also brazing filler metal , electrode (welding) , solder , welding rod , and welding wire .
- **fillet**
  - (1) Concave corner piece usually used at the intersection of casting sections. Also the radius of metal at such junctions as opposed to an abrupt angular junction. (2) A radius (curvature) imparted to inside meeting surfaces.
- **final annealing**
  - An imprecise term used to denote the last anneal given to a nonferrous alloy prior to shipment.
- **final polishing**
  - A polishing process in which the primary objective is to produce a final surface suitable for microscopic examination.
- **fineness**
  - A measure of the purity of gold or silver expressed in parts per thousand.
- **fines**
  - (1) The product that passes through the finest screen in sorting crushed or ground material. (2) Sand grains that are substantially smaller than the predominating size in a batch or lot of foundry sand. (3) The portion of a powder composed of particles smaller than a specified size, usually 44  $\mu\text{m}$  (325 mesh).
- **fine silver**
  - Silver with a fineness of three nines (999); equivalent to a minimum content of 99.9% Ag with the remaining content unrestricted.
- **finish**
  - (1) Surface condition, quality, or appearance of a metal. (2) Stock on a forging or casting to be removed in finish machining. (3) The forging operation in which the part is forged into its final shape in the finish die. If only one finish operation is scheduled to be performed in the finish die, this operation will be identified simply as finish; first, second, or third finish designations are so termed when one or more finish operations are to be performed in the same finish die.
- **finish allowance**
  - (1) The amount of excess metal surrounding the intended final configuration of a formed part; sometimes called forging envelope, machining allowance, or cleanup allowance. (2) Amount of stock left on the surface of a casting for machining.
- **finish annealing**
  - A subcritical annealing treatment applied to cold-worked low- or medium-carbon steel. Finish annealing, which is a compromise treatment, lowers residual stresses, thereby minimizing the risk of distortion in machining while retaining most of the benefits to machinability contributed by cold working. Compare with final annealing .

- **finished steel**
  - Steel that is ready for the market and has been processed beyond the stages of billets, blooms, sheet bars, slabs, and wire rods.
- **finisher (finishing impression)**
  - The die impression that imparts the final shape to a forged part.
- **finish grinding**
  - The final grinding action on a workpiece, of which the objectives are surface finish and dimensional accuracy.
- **finishing die**
  - The die set used in the last forging step.
- **finishing temperature**
  - The temperature at which hot working is completed.
- **finish machining**
  - A machining process analogous to finish grinding .
- **firecracker welding**
  - A variation of the shielded metal arc welding process in which a length of covered electrode is placed along the joint in contact with the workpieces. During the welding operation, the stationary electrode is consumed as the arc travels the length of the electrode.
- **fire-refined copper**
  - Copper that has been refined by the use of a furnace process only, including refinery shapes and, by extension, fabricators' products made therefrom. Usually, when this term is used alone it refers to fire-refined tough pitch copper without elements other than oxygen being present in significant amounts.
- **fir-tree crystal**
  - A type of dendrite .
- **fisheye**
  - An area on a steel fracture surface having a characteristic white crystalline appearance.
- **fisheye (weld defect)**
  - A discontinuity found on the fracture surface of a weld in steel that consists of a small pore or inclusion surrounded by an approximately round, bright area.
- **fishmouthing**
  - See alligatoring .
- **fishscale**
  - A scaly appearance in a porcelain enamel coating in which the evolution of hydrogen from the base metal (iron or steel) causes loss of adhesion between the enamel and the base metal. The scales are somewhat like blisters that have cracked partway around the perimeter but still remain attached to the coating around the rest of the perimeter.
- **fishtail**
  - (1) In roll forging, the excess trailing end of a forging. It is often used, before being trimmed off, as a tong hold for a subsequent forging operation. (2) In hot rolling or extrusion, the imperfectly shaped trailing end of a bar or special section that must be cut off and discarded as mill scrap.
- **fissure**
  - A small cracklike weld discontinuity with only slight separation (opening displacement) of the fracture surfaces. The prefixes macro or micro indicate relative size.
- **fixed-feed grinding**
  - Grinding in which the wheel is fed into the work, or vice versa, by given increments or at a given rate.
- **fixed position welding**
  - Welding in which the work is held in a stationary position.
- **fixture**
  - A device designed to hold parts to be joined in proper relation to each other.
- **flake**
  - A short, discontinuous internal crack in ferrous metals attributed to stresses produced by localized transformation and hydrogen-solubility effects during cooling after hot working. In fracture surfaces, flakes appear as bright, silvery areas with a coarse texture. In deep acid-etched transverse sections, they appear as discontinuities that are usually in the midway to center location of the section. Also termed hairline cracks and shatter cracks.
- **flake graphite**

- Graphitic carbon, in the form of platelets, occurring in the microstructure of gray iron.
- **flaking**
  - (1) The removal of material from a surface in the form of flakes or scalelike particles. (2) A form of pitting resulting from fatigue. See also spalling .
- **flame annealing**
  - Annealing in which the heat is applied directly by a flame.
- **flame cleaning**
  - Cleaning metal surfaces of scale, rust, dirt, and moisture by use of a gas flame.
- **flame cutting**
  - See preferred term oxygen cutting .
- **flame hardening**
  - A process for hardening the surfaces of hardenable ferrous alloys in which an intense flame is used to heat the surface layers above the upper transformation temperature, whereupon the workpiece is immediately quenched.
- **flame spraying**
  - A thermal spraying process in which an oxyfuel gas flame is the source of heat for melting the surfacing material. Compressed gas may or may not be used for atomizing and propelling the surfacing material to the substrate.
- **flame straightening**
  - Correcting distortion in metal structures by localized heating with a gas flame.
- **flank**
  - The end surface of a tool that is adjacent to the cutting edge and below it when the tool is in a horizontal position, as for turning.
- **flank wear**
  - The loss of relief on the flank of the tool behind the cutting edge due to rubbing contact between the work and the tool during cutting; measured in terms of linear dimension behind the original cutting edge.
- **flare test**
  - A test applied to tubing, involving tapered expansion over a cone. Similar to pin expansion test .
- **flaring**
  - (1) Forming an outward acute-angle flange on a tubular part. (2) Forming a flange by using the head of a hydraulic press.
- **flash**
  - (1) In forging, metal in excess of that required to fill the blocking or finishing forging impression of a set of dies completely. Flash extends out from the body of the forging as a thin plate at the line where the dies meet and is subsequently removed by trimming. Because it cools faster than the body of the component during forging, flash can serve to restrict metal flow at the line where dies meet, thus ensuring complete filling of the impression. See also closed-die forging . (2) In casting, a fin of metal that results from leakage between mating mold surfaces. (3) In welding, the material that is expelled or squeezed out of a weld joint and that forms around the weld.
- **flashback**
  - A recession of the welding or cutting torch flame into or back of the mixing chamber of the torch.
- **flash extension**
  - That portion of flash remaining on a forged part after trimming; usually included in the normal forging tolerances.
- **flashing**
  - In flash welding, the heating portion of the cycle, consisting of a series of rapidly recurring localized short circuits followed by molten metal expulsions, during which time the surfaces to be welded are moved one toward the other at a predetermined speed.
- **flash land**
  - Configuration in the blocking or finishing impression of forging dies designed to restrict or to encourage the growth of flash at the parting line, whichever may be required in a particular case to ensure complete filling of the impression.
- **flash line**
  - The line left on a forging after the flash has been trimmed off.
- **flash plate**
  - A very thin final electrodeposited film of metal.
- **flash welding**

- A resistance welding process that produces coalescence at the faying surfaces of abutting members by a flashing action and by the application of pressure after heating is substantially completed. The flashing action, caused by the very high current densities at small contacts between the parts, forcibly expels the material from the joint as the parts are slowly moved together. The weld is completed by a rapid upsetting of the workpieces.
- **flask**
  - A metal or wood frame used for making and holding a sand mold. The upper part is called the cope; the lower, the drag. See also blind riser .
- **flat-die forging**
  - Forging metal between flat or simple-contour dies by repeated strokes and manipulation of the workpiece. Also known as open-die forging , hand forging, or smith forging.
- **flat drill**
  - A rotary end-cutting tool constructed from a flat piece of material, provided with suitable cutting lips at the cutting end.
- **flat edge trimmer**
  - A machine for trimming notched edges on shells. The slide is cam driven so as to obtain a brief dwell at the bottom of the stroke, at which time the die, sometimes called a shimmy die, oscillates to trim the part.
- **flat-position welding**
  - Welding from the upper side, the face of the weld being horizontal. Also called downhand welding.
- **flattening**
  - (1) A preliminary operation performed on forging stock to position the metal for a subsequent forging operation. (2) The removal of irregularities or distortion in sheets or plates by a method such as roller leveling or stretcher leveling.
- **flattening dies**
  - Dies used to flatten sheet metal hems, that is, dies that can flatten a bend by closing it. These dies consist of a top and bottom die with a flat surface that can close one section (flange) to another (hem, seam).
- **flattening test**
  - A quality test for tubing in which a specimen is flattened to a specified height between parallel plates.
- **flat wire**
  - A roughly rectangular or square mill product, narrower than strip, in which all surfaces are rolled or drawn without any previous slitting, shearing, or sawing.
- **flaw**
  - A nonspecific term often used to imply a crack-like discontinuity. See preferred terms discontinuity and defect .
- **flexible cam**
  - An adjustable pressure-control cam of spring steel strips used to obtain varying pressure during a forming cycle.
- **flex roll**
  - A movable jump roll designed to push up against a metal sheet as it passes through a roller leveler. The flex roll can be adjusted to deflect the sheet any amount up to the roll diameter.
- **flex rolling**
  - Passing metal sheets through a flex roll unit to minimize yield-point elongation in order to reduce the tendency for stretcher strains to appear during forming.
- **flexural strength**
  - A property of solid material that indicates its ability to withstand a flexural or transverse load.
- **floating die**
  - (1) In metalforming, a die mounted in a die holder or punch mounted in its holder such that a slight amount of motion compensates for tolerance in the die parts, the work, or the press. (2) A die mounted on heavy springs to allow vertical motion in some trimming, shearing, and forming operations.
- **floating plug**
  - In tube drawing, an unsupported mandrel that locates itself at the die inside the tube, causing a reduction in wall thickness while the die is reducing the outside diameter of the tube.
- **flop forging**

- A forging in which the top and bottom die impressions are identical, permitting the forging to be turned upside down during the forging operation.
- **flospinning**
  - Forming cylindrical, conical and curvilinear shaped parts by power spinning over a rotating mandrel. See also spinning .
- **flotation**
  - The concentration of valuable minerals from ores by agitation of the ground material with water, oil, and flotation chemicals. The valuable minerals are generally wetted by the oil, lifted to the surface by clinging air bubbles, and then floated off.
- **flow**
  - Movement (slipping or sliding) of essentially parallel planes within an element of a material in parallel directions; occurs under the action of shear stress. Continuous action in this manner, at constant volume and without disintegration of the material, is termed yield, creep, or plastic deformation.
- **flowability**
  - (1) In casting, a characteristic of a foundry sand mixture that enables it to move under pressure or vibration so that it makes intimate contact with all surfaces of the pattern or core box. (2) In welding, brazing, or soldering, the ability of molten filler metal to flow or spread over a metal surface.
- **flow brightening**
  - (1) Melting of an electrodeposit, followed by solidification, especially of tin plate. (2) Fusion (melting) of a chemically or mechanically deposited metallic coating on a substrate, particularly as it pertains to soldering.
- **flow lines**
  - (1) Texture showing the direction of metal flow during hot or cold working. Flow lines can often be revealed by etching the surface or a section of a metal part. See accompanying macrograph. (2) In mechanical metallurgy, paths followed by minute volumes of metal during deformation.
- **flow stress**
  - The stress required to produce plastic deformation in a solid metal.
- **flow through**
  - A forging defect caused by metal flow past the base of a rib with resulting rupture of the grain structure.
- **fluid-cell process**
  - A modification of the Guerin process for forming sheet metal, the fluid-cell process uses higher pressure and is primarily designed for forming slightly deeper parts, using a rubber pad as either the die or punch. A flexible hydraulic fluid cell forces an auxiliary rubber pad to follow the contour of the form block and exert a nearly uniform pressure at all points on the workpiece. See also fluid forming and rubber-pad forming .
- **fluid forming**
  - A modification of the Guerin process , fluid forming differs from the fluid-cell process in that the die cavity, called a pressure dome, is not completely filled with rubber, but with hydraulic fluid retained by cup-shaped rubber diaphragm. See also rubber-pad forming .
- **fluidity**
  - The ability of liquid metal to run into and fill a mold cavity.
- **fluidized bed**
  - A contained mass of a finely divided solid that behaves like a fluid when brought into suspension in a moving gas or liquid.
- **fluorescent magnetic-particle inspection**
  - Inspection with either dry magnetic particles or those in a liquid suspension, the particles being coated with a fluorescent substance to increase the visibility of the indications.
- **fluorescent penetrant inspection**
  - Inspection using a fluorescent liquid that will penetrate any surface opening; after the surface has been wiped clean, the location of any surface flaws may be detected by the fluorescence, under ultraviolet light, of back-seepage of the fluid.
- **fluoroscopy**
  - An inspection procedure in which the radiographic image of the subject is viewed on a fluorescent screen, normally limited to low-density materials or thin sections of metals because of the low light output of the fluorescent screen at safe levels of radiation.

- **flute**
  - (1) As applied to drills, reamers, and taps, the channels or grooves formed in the body of the tool to provide cutting edges and to permit passage of cutting fluid and chips. (2) As applied to milling cutters and hobs, the chip space between the back of one tooth and the face of the following tooth.
- **flutes**
  - Elongated grooves or voids that connect widely spaced cleavage planes.
- **fluting**
  - (1) Forming longitudinal recesses in a cylindrical part, or radial recesses in a conical part. (2) A series of sharp parallel kinks or creases occurring in the arc when sheet metal is roll formed into a cylindrical shape. (3) Grinding the grooves of a twist drill or tap.
- **flux**
  - (1) In metal refining, a material added to a melt to remove undesirable substances, like sand, ash, or dirt. Fluxing of the melt facilitates the agglomeration and separation of such undesirable constituents from the melt. It is also used as a protective covering for certain molten metal baths. Lime or limestone is generally used to remove sand, as in iron smelting; sand, to remove iron oxide in copper refining. (2) In brazing, cutting, soldering, or welding, material used to prevent the formation of, or to dissolve and facilitate removal of, oxides and other undesirable substances.
- **flux cored arc welding (FCAW)**
  - An arc welding process that joins metal by heating them with an arc between a continuous tubular filler-metal electrode and the work. Shielding is provided by a flux contained within the consumable tubular electrode. Additional shielding may or may not be obtained from an externally supplied gas or gas mixture. See also flux cored electrode .
- **flux cored electrode**
  - A composite filler metal electrode consisting of a metal tube or other hollow configuration containing ingredients to provide such functions as shielding atmosphere, deoxidation, arc stabilization, and slag formation. Minor amounts of alloying materials may be included in the core. External shielding may or may not be used.
- **flux density**
  - In magnetism, the number of flux lines per unit area passing through a cross section at right angles. It is given by  $B = \mu H$ , where  $\mu$  and  $H$  are permeability and magnetic-field intensity, respectively.
- **flux lines**
  - Imaginary lines used as a means of explaining the behavior of magnetic and other fields. Their concept is based on the pattern of lines produced when magnetic particles are sprinkled over a permanent magnet. Sometimes called magnetic lines of force.
- **fly cutting**
  - Cutting with a single-tooth milling cutter.
- **flying shear**
  - A machine for cutting continuous rolled products to length that does not require a halt in rolling, but rather moves along the runout table at the same speed as the product while performing the cutting, and then returns to the starting point in time to cut the next piece.
- **fog quenching**
  - Quenching in a fine vapor or mist.
- **foil**
  - Metal in sheet form less than 0.15 mm (0.006 in.) thick.
- **fold**
  - (1) A defect in metal, usually on or near the surface, caused by continued fabrication of overlapping surfaces. (2) A forging defect caused by folding metal back onto its own surface during its flow in the die cavity. See also lap .
- **follow board**
  - In foundry practice, a board contoured to a pattern to facilitate the making of a sand mold.
- **follow die**
  - A progressive die consisting of two or more parts in a single holder; used with a separate lower die to perform more than one operation (such as piercing and blanking) on a part in two or more stations.
- **forced-air quench**

- A quench utilizing blasts of compressed air against relatively small parts such as a gear.
- **forgeability**
  - Term used to describe the relative ability of material to deform without fracture. Also describes the resistance to flow from deformation. See also formability .
- **forged roll Scleroscope hardness number (HFRSc or HFRSd)**
  - A number related to the height of rebound of a diamond-tipped hammer dropped on a forged steel roll. It is measured on a scale determined by dividing into 100 units the average rebound of a hammer from a forged steel roll of accepted maximum hardness. See also Scleroscope hardness number and Scleroscope hardness test .
- **forged structure**
  - The macrostructure through a suitable section of a forging that reveals direction of working.
- **forge welding**
  - Solid-state welding in which metals are heated in a forge (in air) and then welded together by applying pressure or blows sufficient to cause permanent deformation at the interface.
- **forging**
  - The process of working metal to a desired shape by impact or pressure in hammers, forging machines (upsetters), presses, rolls, and related forming equipment. Forging hammers, counterblow equipment, and high-energy-rate forging machines apply impact to the workpiece, while most other types of forging equipment apply squeeze pressure in shaping the stock. Some metals can be forged at room temperature, but most are made more plastic for forging by heating. Specific forging processes defined in this glossary include closed-die forging , high-energy-rate forging , hot upset forging , isothermal forging , open-die forging , powder forging , precision forging , radial forging , ring rolling , roll forging , rotary forging , and rotary swaging .
- **forging billet**
  - A wrought metal slug used as forging stock .
- **forging dies**
  - Forms for making forgings; they generally consist of a top and bottom die. The simplest will form a completed forging in a single impression; the most complex, consisting of several die inserts, may have a number of impressions for the progressive working of complicated shapes. Forging dies are usually in pairs, with part of the impression in one of the blocks and the rest of the impression in the other block.
- **forging envelope**
  - See finish allowance .
- **forging ingot**
  - A cast metal slug used as forging stock .
- **forging machine (upsetter or header).**
  - A type of forging equipment, related to the mechanical press , in which the principal forming energy is applied horizontally to the workpiece, which is gripped and held by prior action of the dies. See also heading , hot upset forging , and upsetting .
- **forging plane**
  - In forging, the plane that includes the principal die face and that is perpendicular to the direction of ram travel. When parting surfaces of the dies are flat, the forging plane coincides with the parting line.
- **forging range**
  - Temperature range in which a metal can be forged successfully.
- **forging rolls**
  - Power-driven rolls used in preforming bar or billet stock that have shaped contours and notches for introduction of the work. See also roll forging .
- **forging stock**
  - A wrought rod, bar, or other section suitable for subsequent change in cross section by forging.
- **formability**
  - The ease with which a metal can be shaped through plastic deformation. Evaluation of the formability of a metal involves measurement of strength, ductility, and the amount of deformation required to cause fracture. The term workability is used interchangeably with formability; however, formability refers to the shaping of sheet metal, while workability refers to shaping materials by bulk forming. See also forgeability .
- **form block**

- Tooling, usually the male part, used for forming sheet metal contours; generally used in rubber-pad forming.
- **form cutter**
  - Any cutter, profile sharpened or cam relieved, shaped to produce a specified form on the work.
- **form die**
  - A die used to change the shape of a sheet metal blank with minimal plastic flow.
- **form grinding**
  - Grinding with a wheel having a contour on its cutting face that is a mating fit to the desired form.
- **forming**
  - (1) Making a change, with the exception of shearing or blanking, in the shape or contour of a metal part without intentionally altering its thickness. (2) The plastic deformation of a billet or a blanked sheet between tools (dies) to obtain the final configuration. Metalforming processes are typically classified as bulk forming and sheet forming. Also referred to as metalworking.
- **forming limit diagram (FLD)**
  - A diagram in which the major strains at the onset of necking in sheet metal are plotted vertically and the corresponding minor strains are plotted horizontally. The onset-of-failure line divides all possible strain combinations into two zones: the safe zone (in which failure during forming is not expected) and the failure zone (in which failure during forming is expected).
- **form-relieved cutter**
  - A cutter so relieved that by grinding only the tooth face of the original form is maintained throughout its life.
- **form rolling**
  - Hot rolling to produce bars having contoured cross sections; not to be confused with roll forming of sheet metal or with roll forging.
- **form tool**
  - A single-edge, nonrotating cutting tool, circular or flat, that produces its inverse or reverse form counterpart upon a workpiece.
- **forward extrusion**
  - Same as direct extrusion. See extrusion .
- **fouling**
  - An accumulation of deposits. This term includes accumulation and growth of marine organisms on a submerged metal surface and also includes the accumulation of deposits (usually inorganic) on heat exchanger tubing. See also biological corrosion .
- **foundry**
  - A commercial establishment or building where metal castings are produced.
- **foundry returns**
  - Metal in the form of gates, sprues, runners, risers, and scrapped castings of known composition returned to the furnace for remelting.
- **four-high mill**
  - A type of rolling mill, commonly used for flat-rolled mill products, in which two large-diameter backup rolls are employed to reinforce two smaller work rolls, which are in contact with the product. Either the work rolls or the backup rolls may be driven. Compare with two-high mill and cluster mill .
- **four-point press**
  - A press whose slide is actuated by four connections and four cranks, eccentrics, or cylinders, the chief merit being to equalize the pressure at the corners of the slides.
- **fractography**
  - Descriptive treatment of fracture of materials, with specific reference to photographs of the fracture surface. Macrofractography involves photographs at low magnification (<25×); microfractography, photographs at high magnification (>25×).
- **fracture**
  - The irregular surface produced when a piece of metal is broken. See also brittle fracture , cleavage fracture , crystalline fracture , decohesive rupture , dimple rupture , ductile fracture , fibrous fracture , granular fracture , intergranular fracture , silky fracture , and transgranular fracture .
- **fracture grain size**

- Grain size determined by comparing a fracture of a specimen with a set of standard fractures. For steel, a fully martensitic specimen is generally used, and the depth of hardening and the prior austenitic grain size are determined.
- **fracture mechanics**
  - A quantitative analysis for evaluating structural behavior in terms of applied stress, crack length, and specimen or machine component geometry. See also linear elastic fracture mechanics .
- **fracture strength**
  - The normal stress at the beginning of fracture. Calculated from the load at the beginning of fracture during a tension test and the original cross-sectional area of the specimen.
- **fracture stress**
  - The true, normal stress on the minimum cross-sectional area at the beginning of fracture. The term usually applies to tension tests of unnotched specimens.
- **fracture surface markings**
  - Fracture surface features that may be used to determine the fracture origin location and the nature of the stress that produced the fracture.
- **fracture test**
  - Test in which a specimen is broken and its fracture surface is examined with the unaided eye or with a low-power microscope to determine such factors as composition, grain size, case depth, or discontinuities.
- **fracture toughness**
  - A generic term for measures of resistance to extension of a crack. The term is sometimes restricted to results of fracture mechanics tests, which are directly applicable in fracture control. However, the term commonly includes results from simple tests of notched or precracked specimens not based on fracture mechanics analysis. Results from tests of the latter type are often useful for fracture control, based on either service experience or empirical correlations with fracture mechanics tests. See also stress-intensity factor .
- **fragmentation**
  - The subdivision of a grain into small, discrete crystallite outlined by a heavily deformed network of intersecting slip bands as a result of cold working. These small crystals or fragments differ in orientation and tend to rotate to a stable orientation determined by the slip systems.
- **freckling**
  - A type of segregation revealed as dark spots on a macroetched specimen of a consumable-electrode vacuum-arc-remelted alloy.
- **free bend**
  - The bend obtained by applying forces to the ends of a specimen without the application of force at the point of maximum bending.
- **free carbon**
  - The part of the total carbon in steel or cast iron that is present in elemental form as graphite or temper carbon. Contrast with combined carbon .
- **free ferrite**
  - (1) Ferrite that is formed directly from the decomposition of hypoeutectoid austenite during cooling, without the simultaneous formation of cementite. (2) Ferrite formed into separate grains and not intimately associated with carbides as in pearlite. Also called *proeutectoid ferrite*.
- **free machining**
  - Pertains to the machining characteristics of an alloy to which one or more ingredients have been introduced to produce small broken chips, lower power consumption, better surface finish, and longer tool life; among such additions are sulfur or lead to steel, lead to brass, lead and bismuth to aluminum, and sulfur or selenium to stainless steel.
- **freezing point**
  - See preferred term liquidus and solidus . See also melting point .
- **freezing range**
  - That temperature range between liquidus and solidus temperatures in which molten and solid constituents coexist.
- **fretting**
  - A type of wear that occurs between tight-fitting surfaces subjected to cyclic relative motion of extremely small amplitude. Usually, fretting is accompanied by corrosion, especially of the very fine wear debris. Also referred to as fretting corrosion and false brinelling (in rolling-element bearings).

- **fretting corrosion**
  - (1) The accelerated deterioration at the interface between contacting surfaces as the result of corrosion and slight oscillatory movement between the two surfaces. (2) A form of fretting in which chemical reaction predominates. Fretting corrosion is often characterized by the removal of particles and subsequent formation of oxides, which are often abrasive and so increase the wear. Fretting corrosion can involve other chemical reaction products, which may not be abrasive.
- **fretting fatigue**
  - (1) Fatigue fracture that initiates at a surface area where fretting has occurred. The progressive damage to a solid surface that arises from fretting. *Note:* If particles of wear debris are produced, then the term fretting wear may be applied.
- **fretting wear**
  - Wear arising as a result of fretting .
- **friction**
  - The resisting force tangential to the common boundary between two bodies when, under the action of an external force, one body moves or tends to move relative to the surface of the other.
- **friction coefficient**
  - See coefficient of friction .
- **friction welding (FRW)**
  - A solid-state welding process that produces coalescence of materials under compressive force contact of workpieces rotating or moving relative to one another to produce heat and plastically displace material from the faying surfaces.
- **fuel gases**
  - Gases usually used with oxygen for heating such as acetylene, natural gas, hydrogen, propane, stabilized methylacetylene propadiene, and other synthetic fuels and hydrocarbons.
- **full annealing**
  - An imprecise term that denotes an annealing cycle to produce minimum strength and hardness. For the term to be meaningful, the composition and starting condition of the material and the time-temperature cycle used must be stated.
- **full center**
  - Mild waviness down the center of a metal sheet or strip.
- **fuller (fullering impression)**
  - Portion of the die used in hammer forging primarily to reduce the cross section and to lengthen a portion of the forging stock. The fullering impression is often used in conjunction with an edger (edging impression) .
- **full hard**
  - A temper of nonferrous alloys and some ferrous alloys corresponding approximately to a cold-worked state beyond which the material can no longer be formed by bending. In specifications, a full hard temper is commonly defined in terms of minimum hardness or minimum tensile strength (or, alternatively, a range of hardness or strength) corresponding to a specific percentage of cold reduction following a full anneal. For aluminum, a full hard temper is equivalent to a reduction of 75% from dead soft ; for austenitic stainless steels, a reduction of about 50 to 55%.
- **full mold**
  - A trade name for an expendable pattern casting process in which the polystyrene pattern is vaporized by the molten metal as the mold is poured. See also lost foam casting .
- **furnace brazing**
  - A mass-production brazing process in which the filler metal is preplaced on the joint, then the entire assembly is heated to brazing temperature in a furnace.
- **fused spray deposit**
  - A self-fluxing spray deposit which is deposited by conventional thermal spraying and subsequently fused using either a heating torch or a furnace.
- **fused zone**
  - See preferred terms fusion zone , nugget , and weld interface .
- **fusible alloys**
  - A group of binary, ternary, quaternary, and quinary alloys containing bismuth, lead, tin, cadmium, and indium. The term "fusible alloy" refers to any of more than 100 alloys that melt at relatively low temperatures, that is, below the melting point of tin-lead solder (183 °C, or 360 °F). The melting points of these alloys range as low as 47 °C (116 °F).

- **fusion**
  - The melting together of filler metal and base metal (substrate), or of base metal only, which results in coalescence. See also depth of fusion .
- **fusion welding**
  - Any welding process that uses fusion of the base metal to make the weld.
- **fusion zone**
  - The area of base metal melted as determined on the cross section of a weld.
- **G**
- **gage**
  - (1) The thickness of sheet or the diameter of wire. The various standards are arbitrary and differ with regard to ferrous and nonferrous products as well as sheet and wire. (2) An aid for visual inspection that enables an inspector to determine more reliably whether the size or contour of a formed part meets dimensional requirements. (3) An instrument used to measure thickness or length.
- **gage length**
  - The original length of that portion of the specimen over which strain, change of length and other characteristics are measured.
- **gall**
  - To damage the surface of a powder metallurgy compact or die part, caused by adhesion of powder to the die cavity wall or a punch surface.
- **galling**
  - (1) A condition whereby excessive friction between high spots results in localized welding with subsequent spalling and a further roughening of the rubbing surfaces of one or both of two mating parts. (2) A severe form of scuffing associated with gross damage to the surfaces or failure. Galling has been used in many ways in tribology; therefore, each time it is encountered its meaning must be ascertained from the specific context of the usage. See also scoring and scuffing .
- **galvanic cell**
  - (1) A cell in which chemical change is the source of electrical energy. It usually consists of two dissimilar conductors in contact with each other and with an electrolyte, or of two similar conductors in contact with each other and with dissimilar electrolytes. (2) A cell or system in which a spontaneous oxidation-reduction reaction occurs, the resulting flow of electrons being conducted in an external part of the circuit.
- **galvanic corrosion**
  - Corrosion associated with the current of a galvanic cell consisting of two dissimilar conductors in an electrolyte or two similar conductors in dissimilar electrolytes. Where the two dissimilar metals are in contact, the resulting reaction is referred to as couple action.
- **galvanic couple**
  - A pair of dissimilar conductors, commonly metals, in electrical contact. See also galvanic corrosion .
- **galvanic current**
  - The electric current that flows between metals or conductive nonmetals in a galvanic couple.
- **galvanic series**
  - A list of metals and alloys arranged according to their relative corrosion potentials in a given environment. Compare with electromotive force series .
- **galvanize**
  - To coat a metal surface with zinc using any of various processes.
- **galvanneal**
  - To produce a zinc-iron alloy coating on iron or steel by keeping the coating molten after hot dip galvanizing until the zinc alloys completely with the basis metal.
- **gamma iron**
  - The face-centered cubic form of pure iron, stable from 910 to 1400 °C (1670 to 2550 °F).
- **gamma ray**
  - Short-wavelength electromagnetic radiation, similar to x-rays but of nuclear origin, with a range of wavelength from about  $10^{-14}$  to  $10^{-10}$  m. See also electromagnetic radiation .
- **gamma structure**
  - Structurally analogous phases or electron compounds having ratios of 21 valence electrons to 13 atoms. This is generally a large, complex cubic structure.

- **gang milling**
  - Milling with several cutters mounted on the same arbor or with workpieces similarly positioned for cutting either simultaneously or consecutively during a single setup.
- **gang slitter**
  - A machine with a number of pairs of rotary cutters spaced on two parallel shafts, used for slitting metal into strips or for trimming the edges of sheets.
- **gangue**
  - The worthless portion of an ore that is separated from the desired part before smelting is commenced.
- **gap-frame press**
  - A general classification of press in which the uprights or housings are made in the form of a letter C, thus making three sides of the die space accessible.
- **gas atomization**
  - An atomization process whereby molten metal is broken up into particles by a rapidly moving inert gas stream.
- **gas classification**
  - The separation of a powder into its particle size fractions by means of a gas stream of controlled velocity flowing counterstream to the gravity-induced fall of the particles. The method is used to classify submesh-size particles.
- **gaseous corrosion**
  - Corrosion with gas as the only corrosive agent and without any aqueous phase on the surface of the metal. Also called dry corrosion. See also hot corrosion , oxidation , and sulfidation .
- **gas holes**
  - Holes in castings or welds that are formed by gas escaping from molten metal as it solidifies. Gas holes may occur individually, in clusters, or throughout the solidified metal.
- **gas metal arc cutting**
  - An arc cutting process used to sever metals by melting them with the heat of an arc between a continuous metal (consumable) electrode and the work. Shielding is obtained entirely from an externally supplied gas or gas mixture.
- **gas metal arc welding (GMAW)**
  - An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the workpieces. Shielding is obtained entirely from an externally supplied gas.
- **gas pocket**
  - A cavity caused by entrapped gas.
- **gas porosity**
  - Fine holes or pores within a metal that are caused by entrapped gas or by the evolution of dissolved gas during solidification.
- **gas shielded arc welding**
  - A general term used to describe gas metal arc welding, gas tungsten arc welding, and flux cored arc welding (when gas shielding is employed).
- **gassing**
  - (1) Absorption of gas by a metal. (2) Evolution of gas from a metal during melting operations or upon solidification. (3) Evolution of gas from an electrode during electrolysis.
- **gas torch**
  - See preferred terms cutting torch (arc) , cutting torch (oxyfuel gas) , welding torch (arc) , and welding torch (oxyfuel gas) .
- **gas tungsten arc cutting**
  - An arc-cutting process in which metals are severed by melting them with an arc between a single tungsten (nonconsumable) electrode and the workpiece. Shielding is obtained from a gas or gas mixture.
- **gas tungsten arc welding (GTAW)**
  - An arc welding process that produces coalescence of metals by heating them with an arc between a tungsten (nonconsumable) electrode and the work. Shielding is obtained from a gas or gas mixture. Pressure may or may not be used and filler metal may or may not be used.
- **gas welding**
  - See preferred term oxyfuel gas welding .
- **gate**

- The portion of the runner in a mold through which molten metal enters the mold cavity. The generic term is sometimes applied to the entire network of connecting channels that conduct metal into the mold cavity. See also gating system .
- **gated pattern**
  - In foundry practice, a pattern that includes not only the contours of the part to be cast but also the gates.
- **gathering**
  - A forging operation that increases the cross section of part of the stock; usually a preliminary operation.
- **gathering stock**
  - Any operation whereby the cross section of a portion of the forging stock is increased beyond its original size.
- **gating system**
  - The complete assembly of sprues, runners, and gates in a mold through which metal flows to enter casting cavity. The term is also applied to equivalent portions of the pattern.
- **gear cutting**
  - Producing tooth profiles of equal spacing on the periphery, internal surface, or face of a workpiece by means of an alternate shear gear-form cutter or a gear generator.
- **geared press**
  - A press whose main crank or eccentric shaft is connected by gears to the driving source.
- **gear hobbing**
  - Gear cutting by use of a tool resembling a worm gear in appearance, having helically spaced cutting teeth. In a single-thread hob, the rows of teeth advance exactly one pitch as the hob makes one revolution. With only one hob, it is possible to cut interchangeable gears of a given pitch of any number of teeth within the range of the hobbing machine.
- **gear milling**
  - Gear cutting with a milling cutter that has been formed to the shape of the tooth space to be cut. The tooth spaces are machined one at a time.
- **gear shaping**
  - Gear cutting with a reciprocating gear-shaped cutter rotating in mesh with the work blank.
- **general corrosion**
  - (1) A form of deterioration that is distributed more or less uniformly over a surface. (2) Corrosion dominated by uniform thinning that proceeds without appreciable localized attack. See also uniform corrosion .
- **gibs**
  - Guides or shoes that ensure the proper parallelism, squareness, and sliding fit between metalforming press components such as the slide and the frame. They are usually adjustable to compensate for wear and to establish operating clearance.
- **glazing**
  - Dulling the abrasive grains in the cutting face of a wheel during grinding.
- **glide**
  - (1) Same as slip . (2) A noncrystallographic shearing movement, such as of one grain over another.
- **globular transfer**
  - In consumable-electrode arc welding, a type of metal transfer in which molten filler metal passes across the arc as large droplets. Compare with short-circuiting transfer and spray transfer .
- **gold filled**
  - Covered on one or more surfaces with a layer of gold alloy to form a clad or composite material. Gold-filled dental restorations are an example of such materials.
- **gooseneck**
  - In die casting, a spout connecting a molten metal holding pot, or chamber, with a nozzle or sprue hole in the die and containing a passage through which molten metal is forced on its way to the die. It is the metal injection mechanism in a hot chamber machine .
- **gouging**
  - In welding practice, the forming of a bevel or groove by material removal. See also arc gouging and oxygen gouging .
- **gouging abrasion**

- A form of high-stress abrasion in which easily observable grooves or gouges are created on the surface. See also abrasion .
- **G-P zone**
  - A Guinier-Preston zone .
- **graded abrasive**
  - An abrasive powder in which the sizes of the individual particles are confined to certain specified limits. See also grit size .
- **grain**
  - An individual crystal in a polycrystalline material; it may or may not contain twinned regions and subgrains.
- **grain boundary**
  - A narrow zone in a metal or ceramic corresponding to the transition from one crystallographic orientation to another, thus separating one grain from another; the atoms in each grain are arranged in an orderly pattern.
- **grain-boundary corrosion**
  - Same as intergranular corrosion . See also interdendritic corrosion .
- **grain-boundary sulfide precipitation**
  - An intermediate state of overheating of metals in which sulfide inclusions are redistributed to the austenitic grain boundaries by partial solution at the overheating temperature and reprecipitation during subsequent cooling.
- **grain coarsening**
  - A heat treatment that produces excessively large austenitic grains in metals.
- **grain flow**
  - Fiberlike lines on polished and etched sections of forgings caused by orientation of the constituents of the metal in the direction of working during forging. Grain flow produced by proper die design can improve required mechanical properties of forgings. See also flow lines and forged structure .
- **grain growth**
  - (1) An increase in the average size of the grains in polycrystalline material, usually as a result of heating at elevated temperature. (2) In polycrystalline materials, a phenomenon occurring fairly close below the melting point in which the larger grains grow still larger while the smallest ones gradually diminish and disappear. See also recrystallization .
- **grain refinement**
  - The manipulation of the solidification process to cause more (and therefore smaller) grains to be formed and/or to cause the grains to form in specific shapes. The term refinement is usually used to denote a chemical addition to the metal but can refer to control of the cooling rate.
- **grain refiner**
  - A material added to a molten metal to induce a finer-than-normal grain size in the final structure.
- **grain size**
  - (1) For metals, a measure of the areas or volumes of grains in a polycrystalline material, usually expressed as an average when the individual sizes are fairly uniform. In metals containing two or more phases, grain size refers to that of the matrix unless otherwise specified. Grain size is reported in terms of number of grains per unit area or volume, in terms of average diameter, or as a grain-size number derived from area measurements. (2) For grinding wheels, see preferred term grit size .
- **grain size distribution**
  - Measures of the characteristic grain or crystallite dimensions (usually, diameters) in a polycrystalline solid; or of their populations by size increments from minimum to maximum. Usually determined by microscopy.
- **granular fracture**
  - A type of irregular surface produced when metal is broken that is characterized by a rough, grainlike appearance, rather than a smooth or fibrous one. It can be subclassified as transgranular fracture or intergranular fracture. This type of fracture is frequently called crystalline fracture; however, the inference that the metal broke because it "crystallized" is not justified, because all metals are crystalline in the solid state. See also fibrous fracture and silky fracture .
- **granulated metal**
  - Small pellets produced by pouring liquid metal through a screen or by dropping it onto a revolving disk, and, in both instances, chilling with water.

- **graphitic carbon**
  - Free carbon in steel or cast iron.
- **graphitic corrosion**
  - Corrosion of gray iron in which the iron matrix is selectively leached away, leaving a porous mass of graphite behind; it occurs in relatively mild aqueous solutions and on buried pipe and fittings.
- **graphitic steel**
  - Alloy steel made so that part of the carbon is present as graphite.
- **graphitization**
  - The formation of graphite in iron or steel. Where graphite is formed during solidification, the phenomenon is termed primary graphitization; where formed later by heat treatment, secondary graphitization.
- **graphitizing**
  - Annealing a ferrous alloy such that some or all the carbon precipitates as graphite.
- **gravity hammer**
  - A class of forging hammer in which energy for forging is obtained by the mass and velocity of a freely falling ram and the attached upper die. Examples are the board hammer and air-lift hammer.
- **gravity segregation**
  - Variable composition of a casting or ingot caused by settling out of heavy constituents, or rising of light constituents, before or during solidification.
- **gray cast iron**
  - See gray iron .
- **gray iron**
  - A cast iron characterized by a gray fracture surface due to the presence of flake graphite.
- **green compact**
  - An unsintered powder metallurgy or ceramic compact.
- **green density**
  - The density of a green compact .
- **green rot**
  - A form of high-temperature attack on stainless steels, nickel-chromium alloys, and nickel-chromium-iron alloys subjected to simultaneous oxidation and carburization. Basically, attack occurs first by precipitation of chromium as chromium carbide, then by oxidation of the carbide particles.
- **green sand**
  - A naturally bonded sand, or a compounded molding sand mixture, that has been "tempered" with water and that is used while still moist.
- **green sand core**
  - (1) A core made of green sand and used as-rammed. (2) A sand core that is used in the unbaked condition.
- **green sand mold**
  - A casting mold composed of moist prepared molding sand. Contrast with dry sand mold .
- **green strength**
  - (1) The strength of a tempered foundry sand mixture at room temperature. (2) The ability of a green compact to maintain its size and shape during handling and storage prior to sintering. (3) The tensile or compressive strength of a green compact.
- **grindability**
  - Relative ease of grinding, analogous to machinability .
- **grindability index**
  - A measure of the grindability of a material under specified grinding conditions, expressed in terms of volume of material removed per unit volume of wheel wear.
- **grinding**
  - Removing material from a workpiece with a grinding wheel or abrasive belt.
- **grinding burn**
  - See burning .
- **grinding cracks**

- Shallow cracks formed in the surfaces of relatively hard materials because of excessive grinding heat or the high sensitivity of the material. See also grinding sensitivity .
- **grinding fluid**
  - An oil- or water-based fluid introduced into grinding operations to (1) reduce and transfer heat during grinding, (2) lubricate during chip formation, (3) wash loose chips or swarf from the grinding belt or wheel, and (4) chemically aid the grinding action or machine maintenance.
- **grinding oil**
  - An oil-type grinding fluid; it may contain additives, but not water.
- **grinding relief**
  - A groove or recess located at the boundary of a surface to permit the corner of the wheel to overhang during grinding.
- **grinding sensitivity**
  - Susceptibility of a material to surface damage such as grinding cracks; it can be affected by such factors as hardness, microstructure, hydrogen content, and residual stress.
- **grinding stress**
  - Residual stress, generated by grinding, in the surface layer of work. It may be tensile or compressive, or both.
- **grinding wheel**
  - A cutting tool of circular shape made of abrasive grains bonded together. See also diamond wheels .
- **grit**
  - Crushed ferrous or synthetic abrasive material in various mesh sizes that is used in abrasive blasting equipment to clean castings. For materials used for grinding belts or grinding wheels, see the preferred term abrasive .
- **grit blasting**
  - Abrasive blasting with small irregular pieces of steel, malleable cast iron, or hard nonmetallic materials.
- **grit size**
  - Nominal size of abrasive particles in a grinding wheel, corresponding to the number of openings per linear inch in a screen through which the particles can pass.
- **Grossmann number ( $H$ )**
  - A ratio describing the ability of a quenching medium to extract heat from a hot steel workpiece in comparison to still water defined by the following equation:

$$H = \frac{h}{2k}$$

- where  $h$  is the heat transfer coefficient and  $k$  is the conductivity of the metal.
- **gross porosity**
  - In weld metal or in a casting, pores, gas holes, or globular voids that are larger and in much greater numbers than those obtained in good practice.
- **groundbed**
  - A buried item, such as junk steel or graphite rods, that serves as the anode for the cathodic protection of pipelines or other buried structures.
- **ground connection**
  - In arc welding, a device used for attaching the work lead (ground cable) to the work.
- **growth (cast iron)**
  - A permanent increase in the dimensions of cast iron resulting from repeated or prolonged heating at temperatures above 480 °C (900 °F) due either to graphitizing of carbides or oxidation.
- **Guerin process**
  - A rubber-pad forming process for forming sheet metal. The principal tools are the rubber pad and form block, or punch.
- **guided bend**
  - The bend obtained by use of a plunger to force the specimen into a die in order to produce the desired contour of the outside and inside surfaces of the specimen.
- **guided bend test**

- A test in which the specimen is bent to a definite shape by means of a punch (mandrel) and a bottom block.
- **guide mill**
  - A small hand mill with several stands in a train and with guides for the work at the entrance to the rolls.
- **Guinier-Preston (G-P) zone**
  - A small precipitation domain in a supersaturated metallic solid solution. A G-P zone has no well-defined crystalline structure of its own and contains an abnormally high concentration of solute atoms. The formation of G-P zones constitutes the first stage of precipitation and is usually accompanied by a change in properties of the solid solution in which they occur.
- **gun drill**
  - A drill, usually with one or more flutes and with coolant passages through the drill body, used for deep hole drilling.
- **gutter**
  - A depression around the periphery of a forging die impression outside the flash pan that allows space for the excess metal; surrounds the finishing impression and provides room for the excess metal used to ensure a sound forging. A shallow impression outside the parting line.
- **H**
- **habit plane**
  - The plane or system of planes of a crystalline phase along which some phenomenon, such as twinning or transformation, occurs.
- **Hadfield steel**
  - See austenitic manganese steel .
- **half cell**
  - An electrode immersed in a suitable electrolyte, designed for measurements of electrode potential.
- **half hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength about midway between those of dead soft and full hard tempers.
- **Hall process**
  - A commercial process for winning aluminum from alumina by electrolytic reduction of a fused bath of alumina dissolved in cryolite.
- **hammer**
  - A machine that applies a sharp blow to the work area through the fall of a ram onto an anvil. The ram can be driven by gravity or power. See also gravity hammer .
- **hammer forging**
  - Forging in which the work is deformed by repeated blows.
- **hammering**
  - The working of metal sheet into a desired shape over a form or on a high-speed hammer and a similar anvil to produce the required dishing or thinning.
- **hammer welding**
  - Forge welding by hammering.
- **hand brake**
  - A small manual folding machine designed to bend sheet metal, similar in design and purpose to a press brake .
- **hand forge (smith forge)**
  - A forging operation in which forming is accomplished on dies that are generally flat. The piece is shaped roughly to the required contour with little or no lateral confinement; operations involving mandrels are included. The term hand forge refers to the operation performed, while hand forging applies to the part produced.
- **handling breaks**
  - Irregular breaks caused by improper handling of metal sheets during processing. These breaks result from bending or sagging of the sheets during handling.
- **hard chromium**
  - Chromium electrodeposited for engineering purposes (such as to increase the wear resistance of sliding metal surfaces) rather than as a decorative coating. It is usually applied directly to substrate and is customarily thicker ( $>1.2\text{ }\mu\text{m}$ , or 0.05 mil) than a decorative deposit, but not necessarily harder.

- **hard drawn**
  - An imprecise term applied to drawn products, such as wire and tubing, that indicates substantial cold reduction without subsequent annealing. Compare with light drawn .
- **hardenability**
  - The relative ability of a ferrous alloy to form martensite when quenched from a temperature above the upper critical temperature. Hardenability is commonly measured as the distance below a quenched surface at which the metal exhibits a specific hardness (50 HRC, for example) or a specific percentage of martensite in the microstructure.
- **hardener**
  - An alloy rich in one or more alloying elements that is added to a melt to permit closer control of composition than is possible by the addition of pure metals, or to introduce refractory elements not readily alloyed with the base metal. Sometimes called master alloy or rich alloy.
- **hardening**
  - Increasing hardness of metals by suitable treatment, usually involving heating and cooling. When applicable, the following, more specific terms should be used: age hardening , case hardening , flame hardening , induction hardening , precipitation hardening , and quench hardening .
- **hardfacing**
  - The application of a hard, wear-resistant material to the surface of a component by welding, spraying, or allied welding processes to reduce wear or loss of material by abrasion, impact, erosion, galling, and cavitation. See also surfacing .
- **hardfacing alloys**
  - Wear-resistant materials available as bare welding rod, flux-coated rod, long-length solid wires, long-length tubular wires, or powders that are deposited by hardfacing.
- **hard metal**
  - A collective term that designates a sintered material with high hardness, strength, and wear resistance and is characterized by a tough metallic binder phase and particles of carbides, borides, or nitrides of the refractory metals. The term is in general use abroad, while for the carbides the term cemented carbide is preferred in the U.S., and the boride and nitride materials are usually categorized as cermets .
- **hardness**
  - A measure of the resistance of a material to surface indentation or abrasion; may be thought of as a function of the stress required to produce some specified type of surface deformation. There is no absolute scale for hardness; therefore, to express hardness quantitatively, each type of test has its own scale of arbitrarily defined hardness. Indentation hardness can be measured by Brinell, Rockwell, Vickers, Knoop, and Scleroscope hardness tests.
- **hard solder**
  - A term erroneously used to denote silver-base brazing filler metals.
- **hard surfacing**
  - See preferred terms surfacing or hardfacing .
- **hard temper**
  - Same as full hard temper.
- **Haring cell**
  - A four-electrode cell for measurement of electrolyte resistance and electrode polarization during electrolysis.
- **H-band steel**
  - Carbon, carbon-boron, or alloy steel produced to specified limits of hardenability; the chemical composition range may be slightly different from that of the corresponding grade of ordinary carbon or alloy steel.
- **heading**
  - The upsetting of wire, rod, or bar stock in dies to form parts that usually contain portions that are greater in cross-sectional area than the original wire, rod, or bar.
- **hearth**
  - The bottom portions of certain furnaces, such as blast furnaces, air furnaces, and other reverberatory furnaces, that support the charge and sometimes collect and hold molten metal.
- **heat**
  - A stated tonnage of metal obtained from a period of continuous melting in a cupola or furnace, or the melting period required to handle this tonnage.
- **heat-affected zone (HAZ)**

- That portion of the base metal that was not melted during brazing, cutting, or welding, but whose microstructure and mechanical properties were altered by the heat.
- **heat check**
  - A pattern of parallel surface cracks that are formed by alternate rapid heating and cooling of the extreme surface metal, sometimes found on forging dies and piercing punches. There may be two sets of parallel cracks, one set perpendicular to the other.
- **heat-resistant alloy**
  - An alloy developed for very-high-temperature service where relatively high stresses (tensile, thermal, vibratory, or shock) are encountered and where oxidation resistance is frequently required.
- **heat sink**
  - A material that absorbs or transfers heat away from a critical element or part.
- **heat tinting**
  - Coloration of a metal surface through oxidation by heating to reveal details of the microstructure.
- **heat treatable alloy**
  - An alloy that can be hardened by heat treatment.
- **heat treating film**
  - A thin coating or film, usually an oxide, formed on the surface of a metal during heat treatment.
- **heat treatment**
  - Heating and cooling a solid metal or alloy in such a way as to obtain desired conditions or properties. Heating for the sole purpose of hot working is excluded from the meaning of this definition.
- **heavy metal**
  - A sintered tungsten alloy with nickel, copper, and/or iron, the tungsten content being at least 90 wt% and the density being at least 16.8 g/cm<sup>3</sup>.
- **heel**
  - Synonymous with base .
- **heel block**
  - A block or plate usually mounted on or attached to a lower die in a forming or forging press that serves to prevent or minimize the deflection of punches or cams.
- **hemming**
  - A bend of 180° made in two steps. First, a sharp-angle bend is made; next the bend is closed using a flat punch and a die.
- **HERF**
  - A common abbreviation for high-energy-rate forging or high-energy-rate forming .
- **herringbone pattern**
  - Same as chevron pattern .
- **high-conductivity copper**
  - Copper that, in the annealed condition, has a minimum electrical conductivity of 100% IACS as determined by ASTM test methods.
- **high-cycle fatigue**
  - Fatigue that occurs at relatively large numbers of cycles. The arbitrary, but commonly accepted, dividing line between high-cycle fatigue and low-cycle fatigue is considered to be about 10<sup>4</sup> to 10<sup>5</sup> cycles. In practice, this distinction is made by determining whether the dominant component of the strain imposed during cyclic loading is elastic (high cycle) or plastic (low cycle), which in turn depends on the properties of the metal and on the magnitude of the nominal stress.
- **high-energy-rate forging (HERF)**
  - A closed-die hot- or cold-forging process in which the stored energy of high-pressure gas is used to accelerate a ram to unusually high velocities in order to effect deformation of the workpiece. Ideally, the final configuration of the forging is developed in one blow or, at most, a few blows. In high-energy-rate forging, the velocity of the ram, rather than its mass, generates the major forging force. Also known as HERF processing, high-velocity forging, and high-speed forging.
- **high-energy-rate forming**
  - A group of forming processes that applies a high rate of strain to the material being formed through the application of high rates of energy transfer. See also explosive forming , high-energy-rate forging , and electromagnetic forming .
- **high frequency resistance welding**

- A group of resistance welding process variations that uses high frequency welding current to concentrate the welding heat at the desired location.
- **highlighting**
  - Buffing or polishing selected areas of a complex shape to increase the luster or change the color of those areas.
- **high residual phosphorus copper**
  - Deoxidized copper with residual phosphorus present in amounts (usually 0.013 to 0.04%) generally sufficient to decrease appreciably the conductivity of the copper.
- **high-speed machining**
  - High-productivity machining processes that achieve cutting speeds in excess of 600 m/min (2000 sfm) and up to 18,000 m/min (60,000 sfm).
- **high-strength low-alloy (HSLA) steels**
  - Steels designed to provide better mechanical properties and/or greater resistance to atmospheric corrosion than conventional carbon steels. They are not considered to be alloy steels in the normal sense because they are designed to meet specific mechanical properties rather than a chemical composition (HSLA steels have yield strengths greater than 275 MPa, or 40 ksi). The chemical composition of a specific HSLA steel may vary for different product thicknesses to meet mechanical property requirements. The HSLA steels have low carbon contents (0.05 to 0.25% C) in order to produce adequate formability and weldability, and they have manganese contents up to 2.0%. Small quantities of chromium, nickel, molybdenum, copper, nitrogen, vanadium, niobium, titanium, and zirconium are used in various combinations.
- **high-temperature hydrogen attack**
  - A loss of strength and ductility of steel by high-temperature reaction of absorbed hydrogen with carbides in the steel resulting in decarburization and internal fissuring.
- **hindered contraction**
  - Contraction where the shape will not permit a metal casting to contract in certain regions in keeping with the coefficient of expansion.
- **HIP**
  - See hot isostatic pressing .
- **hob**
  - A rotary cutting tool with its teeth arranged along a helical thread, used for generating gear teeth or other evenly spaced forms on the periphery of a cylindrical workpiece. The hob and the workpiece are rotated in timed relationship to each other while the hob is fed axially or tangentially across or radially into the workpiece. Hobs should not be confused with multiple-thread milling cutters, rack cutters, and similar tools, where the teeth are not arranged along a helical thread.
- **hogging**
  - Machining a part from bar stock, plate, or a simple forging in which much of the original stock is removed.
- **holddown plate (pressure pad)**
  - A pressurized plate designed to hold the workpiece down during a press operation. In practice, this plate often serves as a stripper and is also called a stripper plate.
- **holding**
  - In heat treating of metals, that portion of the thermal cycle during which the temperature of the object is maintained constant.
- **holding furnace**
  - A furnace into which molten metal can be transferred to be held at the proper temperature until it can be used to make castings.
- **holding temperature**
  - In heat treating of metals, the constant temperature at which the object is maintained.
- **holding time**
  - Time for which the temperature of the heat treated metal object is maintained constant.
- **hole expansion test**
  - A simulative test in which a flat metal sheet specimen with a circular hole in its center is clamped between annular die plates and deformed by a punch, which expands and ultimately cracks the edge of the hole.
- **hole flanging**

- The forming of an integral collar around the periphery of a previously formed hole in a sheet metal part.
- **holidays**
  - Discontinuities in a coating (such as porosity, cracks, gaps, and similar flaws) that allow areas of substrate to be exposed to any corrosive environment that contacts the coated surface.
- **homogeneous carburizing**
  - Use of a carburizing process to convert a low-carbon ferrous alloy to one of uniform and higher carbon content throughout the section.
- **homogenizing**
  - A heat treating practice whereby a metal object is held at high temperature to eliminate or decrease chemical segregation by diffusion.
- **honoring**
  - A low-speed finishing process used chiefly to produce uniform high dimensional accuracy and fine finish, most often on inside cylindrical surfaces. In honing, very thin layers of stock are removed by simultaneously rotating and reciprocating a bonded abrasive stone or stick that is pressed against the surface being honed with lighter force than is typical of grinding.
- **Hooke's law**
  - A generalization applicable to all solid material, which states that stress is directly proportional to strain and is expressed as:

$$\frac{\text{Stress}}{\text{Strain}} = \frac{\sigma}{\epsilon} = \text{constant} = E$$

- where  $E$  is the modulus of elasticity or Young's modulus. The constant relationship between stress and strain applies only below the proportional limit. See also modulus of elasticity .
- **Hoopes process**
  - An electrolytic refining process for aluminum, using three liquid layers in the reduction cell.
- **horn**
  - (1) In a resistance welding machine, a cylindrical arm or beam that transmits the electrode pressure and usually conducts the welding current. (2) A cone-shaped member that transmits ultrasonic energy from a transducer to a welding or machining tool. See also ultrasonic impact grinding and ultrasonic welding .
- **horn press**
  - A mechanical metal forming press equipped with or arranged for a cantilever block or horn that acts as the die or support for the die, used in forming, piercing, setting down, or riveting hollow cylinders and odd-shaped work.
- **horn spacing**
  - The distance between adjacent surfaces of the horns of a resistance welding machine.
- **hot box process**
  - In foundry practice, resin-base (furan or phenolic) binder process for molding sands similar to shell coremaking; cores produced with it are solid unless mandrelled out.
- **hot chamber machine**
  - A die casting machine in which the metal chamber under pressure is immersed in the molten metal in a furnace. The chamber is sometimes called a gooseneck, and the machine is sometimes called a gooseneck machine.
- **hot-cold working**
  - (1) A high-temperature thermomechanical treatment consisting of deforming a metal above its transformation temperature and cooling fast enough to preserve some or all of the deformed structure. (2) A general term synonymous with warm working .
- **hot corrosion**
  - An accelerated corrosion of metal surfaces that results from the combined effect of oxidation and reactions with sulfur compounds and other contaminants, such as chlorides, to form a molten salt on a metal surface that fluxes, destroys, or disrupts the normal protective oxide. See also gaseous corrosion .
- **hot crack**
  - A crack that develops in a weldment or casting during solidification.
- **hot-die forging**

- A hot forging process in which both the dies and the forging stock are heated; typical die temperatures are 110 to 225 °C (200 to 400 °F) lower than the temperature of the stock. Compare with isothermal forging .
- **hot dip**
  - Covering a surface by dipping the surface to be coated into a molten bath of the coating material. See also hot dip coating .
- **hot dip coating**
  - A metallic coating obtained by dipping the substrate into a molten metal.
- **hot extrusion**
  - A process whereby a heated billet is forced to flow through a shaped die opening. The temperature at which extrusion is performed depends on the material being extruded. Hot extrusion is used to produce long, straight metal products of constant cross section, such as bars, solid and hollow sections, tubes, wires, and strips, from materials that cannot be formed by cold extrusion.
- **hot forging**
  - (1) A forging process in which the die and/or forging stock are heated. See also hot-die forging and isothermal forging . (2) The plastic deformation of a pressed and/or sintered powder compact in at least two directions at temperatures above the recrystallization temperature.
- **hot forming**
  - See hot working .
- **hot isostatic pressing**
  - (1) A process for simultaneously heating and forming a compact in which the powder is contained in a sealed flexible sheet metal or glass enclosure and the so-contained powder is subjected to equal pressure from all directions at a temperature high enough to permit plastic deformation and sintering to take place. (2) A process that subjects a component (casting, powder forgings, etc.) to both elevated temperature and isostatic gas pressure in an autoclave. The most widely used pressurizing gas is argon. When castings are hot isostatically pressed, the simultaneous application of heat and pressure virtually eliminates internal voids and microporosity through a combination of plastic deformation, creep, and diffusion.
- **hot mill**
  - A production line or facility for hot rolling of metals.
- **hot press forging**
  - Plastically deforming metals between dies in presses at temperatures high enough to avoid strain hardening.
- **hot pressing**
  - Simultaneous heating and forming of a powder compact. See also pressure sintering .
- **hot pressure welding**
  - A solid-state welding process that produces coalescence of materials with heat and application of pressure sufficient to produce macrodeformation of the base material. Vacuum or other shielding media may be used. See also diffusion welding and forge welding . Compare with cold welding .
- **hot quenching**
  - An imprecise term for various quenching procedures in which a quenching medium is maintained at a prescribed temperature above 70 °C (160 °F).
- **hot shortness**
  - A tendency for some alloys to separate along grain boundaries when stressed or deformed at temperatures near the melting point. Hot shortness is caused by a low-melting constituent, often present only in minute amounts, that is segregated at grain boundaries.
- **hot tear**
  - A fracture formed in a metal during solidification because of hindered contraction .
- **hot top**
  - (1) A reservoir, thermally insulated or heated, that holds molten metal on top of a mold for feeding of the ingot or casting as it contracts on solidifying, thus preventing formation of pipe or voids. (2) A refractory-lined steel or iron casting that is inserted into the tip of the mold and is supported at various heights to feed the ingot as it solidifies.
- **hot trimming**
  - The removal of flash or excess metal from a hot part (such as a forging) in a trimming press.
- **hot upset forging**

- A bulk forming process for enlarging and reshaping some of the cross-sectional area of a bar, tube, or other product form of uniform (usually round) section. It is accomplished by holding the heated forging stock between grooved dies and applying pressure to the end of the stock, in the direction of its axis, by the use of a heading tool, which spreads (upsets) the end by metal displacement. Also called hot heading or hot upsetting. See also heading and upsetting .
- **hot-worked structure**
  - The structure of a material worked at a temperature higher than the recrystallization temperature.
- **hot working**
  - (1) The plastic deformation of metal at such a temperature and strain rate that recrystallization takes place simultaneously with the deformation, thus avoiding any strain hardening. Also referred to as hot forging and hot forming. (2) Controlled mechanical operations for shaping a product at temperatures above the recrystallization temperature. Contrast with cold working .
- **hubbing**
  - The production of forging die cavities by pressing a male master plug, known as a hub, into a block of metal.
- **Hull cell**
  - A special electrodeposition cell giving a range of known current densities for test work.
- **hydraulic hammer**
  - A gravity-drop forging hammer that uses hydraulic pressure to lift the hammer between strokes.
- **hydraulic-mechanical press brake**
  - A mechanical press brake that uses hydraulic cylinders attached to mechanical linkages to power the ram through its working stroke.
- **hydraulic press**
  - A press in which fluid pressure is used to actuate and control the ram. Hydraulic presses are used for both open- and closed-die forging.
- **hydrodynamic machining**
  - Removal of material by the impingement of a high-velocity fluid against a workpiece. See also waterjet/abrasive waterjet machining .
- **hydrogen-assisted cracking (HAC)**
  - See hydrogen embrittlement .
- **hydrogen-assisted stress-corrosion cracking (HSCC)**
  - See hydrogen embrittlement .
- **hydrogen blistering**
  - The formation of blisters on or below a metal surface from excessive internal hydrogen pressure. Hydrogen may be formed during cleaning, plating, or corrosion.
- **hydrogen brazing**
  - A term sometimes used to denote brazing in a hydrogen-containing atmosphere, usually in a furnace; use of the appropriate process name is preferred.
- **hydrogen damage**
  - A general term for the embrittlement, cracking, blistering, and hydride formation that can occur when hydrogen is present in some metals.
- **hydrogen embrittlement**
  - A process resulting in a decrease of the toughness or ductility of a metal due to the presence of atomic hydrogen. Hydrogen embrittlement has been recognized classically as being of two types. The first, known as internal hydrogen embrittlement, occurs when the hydrogen enters molten metal which becomes supersaturated with hydrogen immediately after solidification. The second type, environmental hydrogen embrittlement, results from hydrogen being absorbed by solid metals. This can occur during elevated-temperature thermal treatments and in service during electroplating, contact with maintenance chemicals, corrosion reactions, cathodic protection, and operating in high-pressure hydrogen. In the absence of residual stress or external loading, environmental hydrogen embrittlement is manifested in various forms, such as blistering, internal cracking, hydride formation, and reduced ductility. With a tensile stress or stress-intensity factor exceeding a specific threshold, the atomic hydrogen interacts with the metal to induce subcritical crack growth leading to fracture. In the absence of a corrosion reaction (polarized cathodically), the usual term used is hydrogen-assisted cracking (HAC) or hydrogen stress cracking (HSC). In the presence of active corrosion, usually as pits or crevices (polarized anodically), the cracking is generally called stress-corrosion cracking (SCC), but should more properly be called hydrogen-assisted stress-corrosion cracking (HSCC). Thus, HSC and electrochemically anodic SCC can

operate separately or in combination (HSCC). In some metals, such as high-strength steels, the mechanism is believed to be all, or nearly all, HSC. The participating mechanism of HSC is not always recognized and may be evaluated under the generic heading of SCC.

- **hydrogen-induced cracking (HIC)**
  - Same as hydrogen embrittlement .
- **hydrogen-induced delayed cracking**
  - A term sometimes used to identify a form of hydrogen embrittlement in which a metal appears to fracture spontaneously under a steady stress less than the yield stress. There is usually a delay between the application of stress (or exposure of the stressed metal to hydrogen) and the onset of cracking. Also referred to as static fatigue.
- **hydrogen loss**
  - The loss in weight of metal powder or a compact caused by heating a representative sample according to a specified procedure in a purified hydrogen atmosphere. Broadly, a measure of the oxygen content of the sample when applied to materials containing only such oxides as are reducible with hydrogen and no hydride-forming element.
- **hydrogen overvoltage**
  - In electroplating, overvoltage associated with the liberation of hydrogen gas.
- **hydrogen stress cracking (HSC)**
  - See hydrogen embrittlement .
- **hydrometallurgy**
  - Industrial winning or refining of metals using water or an aqueous solution.
- **hydrostatic extrusion**
  - A method of extruding a billet through a die by pressurized fluid instead of the ram used in conventional extrusion.
- **hydrostatic pressing**
  - A special case of isostatic pressing that uses a liquid such as water or oil as a pressure transducing medium and is therefore limited to near room-temperature operation.
- **hydrostatic tension**
  - Three equal and mutually perpendicular tensile stresses.
- **hypereutectic alloy**
  - In an alloy system exhibiting a eutectic, any alloy whose composition has an excess of alloying element compared with the eutectic composition and whose equilibrium microstructure contains some eutectic structure.
- **hypereutectoid alloy**
  - In an alloy system exhibiting a eutectoid, any alloy whose composition has an excess of alloying element compared with the eutectoid composition, and whose equilibrium microstructure contains some eutectoid structure.
- **hypo-eutectic alloy**
  - In an alloy system exhibiting a eutectic, any alloy whose composition has an excess of base metal compared with the eutectic composition and whose equilibrium microstructure contains some eutectic structure.
- **hypo-eutectoid alloy**
  - In an alloy system exhibiting a eutectoid, any alloy whose composition has an excess of base metal compared with the eutectoid composition and whose equilibrium microstructure contains some eutectoid structure.
- **hysteresis (magnetic)**
  - The lag of the magnetization of a substance behind any cyclic variation of the applied magnetizing field.
- **hysteresis (mechanical)**
  - The phenomenon of permanently absorbed or lost energy that occurs during any cycle of loading or unloading when a material is subjected to repeated loading.
- **I**
- **IACS**
  - International annealed copper standard; a standard reference used in reporting electrical conductivity. The conductivity of a material, in %IACS, is equal to 1724.1 divided by the electrical resistivity of the material in  $n\Omega \cdot m$ .
- **ideal critical diameter ( $D_I$ )**

- Under an ideal quench condition, the bar diameter that has 50% martensite at the center of the bar when the surface is cooled at an infinitely rapid rate (that is, when  $H = \infty$ , where  $H$  is the quench severity factor or Grossmann number ).
- **idiomorphic crystal**
  - An individual crystal that has grown without restraint so that the habit planes are clearly developed. Compare with allotriomorphic crystal .
- **immersed-electrode furnace**
  - A furnace used for liquid carburizing of parts by heating molten salt baths with the use of electrodes immersed in the liquid. See also submerged-electrode furnace .
- **immersion cleaning**
  - Cleaning in which the work is immersed in a liquid solution.
- **immersion coating**
  - A coating produced in a solution by chemical or electrochemical action without the use of external current.
- **immersion plating**
  - Depositing a metallic coating on a metal immersed in a liquid solution, without the aid of an external electric current. Also called dip plating.
- **impact energy**
  - The amount of energy, usually given in joules or foot-pound force, required to fracture a material, usually measured by means of an Izod test or Charpy test. The type of specimen and test conditions affect the values and therefore should be specified.
- **impact extrusion**
  - The process (or resultant product) in which a punch strikes a slug (usually unheated) in a confining die. The metal flow may be either between punch and die or through another opening. The impact extrusion of unheated slugs is often called cold extrusion.
- **impact line**
  - A blemish on a drawn sheet metal part caused by a slight change in metal thickness. The mark is called an impact line when it results from the impact of the punch on the blank; it is called a recoil line when it results from transfer of the blank from the die to the punch during forming, or from a reaction to the blank being pulled sharply through the draw ring.
- **impact load**
  - An especially severe shock load such as that caused by instantaneous arrest of a falling mass, by shock meeting of two parts (in a mechanical hammer, for example), or by explosive impact, in which there can be an exceptionally rapid buildup of stress.
- **impact strength**
  - A measure of the resiliency or toughness of a solid. The maximum force or energy of a blow (given by a fixed procedure) that can be withstood without fracture, as opposed to fracture strength under a steady applied force.
- **impact test**
  - A test for determining the energy absorbed in fracturing a test piece at high velocity, as distinct from static test. The test may be carried out in tension, bending, or torsion, and the test bar may be notched or unnotched. See also Charpy test , impact energy , and Izod test .
- **impact wear**
  - Wear of a solid surface resulting from repeated collisions between that surface and another solid body. The term erosion is preferred in the case of multiple impacts and when the impacting body or bodies are very small relative to the surface being impacted.
- **impingement**
  - A process resulting in a continuing succession of impacts between liquid or solid particles and a solid surface.
- **impingement attack**
  - Corrosion associated with turbulent flow of liquid. May be accelerated by entrained gas bubbles. See also erosion-corrosion and impingement corrosion .
- **impingement corrosion**
  - A form of erosion-corrosion generally associated with the local impingement of a high-velocity, flowing fluid against a solid surface.
- **impingement erosion**
  - Loss of material from a solid surface due to liquid impingement. See also erosion .
- **impregnation**

- (1) Treatment of porous castings with a sealing medium to stop pressure leaks. (2) The process of filling the pores of a sintered compact, usually with a liquid such as a lubricant. (3) The process of mixing particles of a nonmetallic substance in a cemented carbide matrix, as in diamond-impregnated tools.
- **impression-die forging**
  - A forging that is formed to the required shape and size by machined impressions in specially prepared dies that exert three-dimensional control on the workpiece.
- **impurities**
  - (1) Elements or compounds whose presence in a material is undesirable. (2) In a chemical or material, minor constituent(s) or component(s) not included deliberately; usually to some degree or above some level, undesirable.
- **inclinable press**
  - A press that can be inclined to facilitate handling of the formed parts. See also open-back inclinable press .
- **inclusion**
  - (1) A physical and mechanical discontinuity occurring within a material or part, usually consisting of solid, encapsulated foreign material. Inclusions are often capable of transmitting some structural stresses and energy fields, but to a noticeably different degree than from the parent material. (2) Particles of foreign material in a metallic matrix. The particles are usually compounds, such as oxides, sulfides, or silicates, but may be of any substance that is foreign to (and essentially insoluble in) the matrix. See also exogenous inclusion , indigenous inclusion , and stringer .
- **inclusion count**
  - Determination of the number, kind, size, and distribution of nonmetallic inclusions in metals.
- **incomplete fusion**
  - In welding, fusion that is less than complete.
- **indentation hardness**
  - (1) The resistance of a material to indentation. This is the usual type of hardness test, in which a pointed or rounded indenter is pressed into a surface under a substantially static load. (2) Resistance of a solid surface to the penetration of a second, usually harder, body under prescribed conditions. Numerical values used to express indentation hardness are not absolute physical quantities, but depend on the hardness scale used to express hardness. See also Brinell hardness test , Knoop hardness test , nanohardness test , Rockwell hardness test , and Vickers hardness test .
- **indenter**
  - In hardness testing, a solid body of prescribed geometry, usually chosen for its high hardness, that is used to determine the resistance of a solid surface to penetration.
- **indigenous inclusion**
  - An inclusion that is native, innate, or inherent in the molten metal treatment. Indigenous inclusions include sulfides, nitrides, and oxides derived from the chemical reaction of the molten metal with the local environment. Such inclusions are small and require microscopic magnification for identification. Compare with exogenous inclusion .
- **indirect-arc furnace**
  - An electric arc furnace in which the metallic charge is not one of the poles of the arc.
- **indirect (backward) extrusion**
  - See extrusion .
- **induction brazing**
  - A brazing process in which the heat required is obtained from the resistance of the workpieces to induced electric current.
- **induction furnace**
  - An alternating current electric furnace in which the primary conductor is coiled and generates, by electromagnetic induction, a secondary current that develops heat within the metal charge.
- **induction hardening**
  - A surface-hardening process in which only the surface layer of a suitable ferrous workpiece is heated by electromagnetic induction to above the upper critical temperature and immediately quenched.
- **induction heating**

- Heating by combined electrical resistance and hysteresis losses induced by subjecting a metal to the varying magnetic field surrounding a coil carrying alternating current.
- **induction melting**
  - Melting in an induction furnace.
- **induction soldering**
  - A soldering process in which the heat required is obtained from the resistance of the workpieces to induced electric current.
- **induction tempering**
  - Tempering of steel using low-frequency electrical induction heating.
- **induction welding**
  - A welding process that produces coalescence of metals by the heat obtained from the resistance of the workpieces to the flow of induced high-frequency welding current with or without the application of pressure. The effect of the high-frequency welding current is to concentrate the welding heat at the desired location.
- **induction work coil**
  - The inductor used when induction heating and melting as well as induction welding, brazing, and soldering.
- **inductor**
  - A device consisting of one or more associated windings, with or without a magnetic core, for introducing inductance into an electric circuit.
- **industrial atmosphere**
  - An atmosphere in an area of heavy industry with soot, fly ash, and sulfur compounds as the principal constituents.
- **inert anode**
  - An anode that is insoluble in the electrolyte under the conditions prevailing in the electrolysis.
- **inert gas**
  - (1) A gas, such as helium, argon, or nitrogen, that is stable, does not support combustion, and does not form reaction products with other materials. (2) In welding, a gas that does not normally combine chemically with the base metal or filler metal. See also protective atmosphere .
- **infiltration**
  - The process of filling the pores of a sintered or unsintered compact with a metal or alloy of lower melting temperature.
- **infrared brazing**
  - A brazing process in which the heat required is furnished by infrared radiation.
- **infrared soldering**
  - A soldering process in which the heat required is furnished by infrared radiation.
- **infrared spectroscopy**
  - The study of the interaction of material systems with electromagnetic radiation in the infrared region of the spectrum. The technique is useful for determining the molecular structure of organic and inorganic compounds by identifying the rotational and vibrational energy levels associated with the various molecules. See also electromagnetic radiation .
- **ingate**
  - Same as gate .
- **ingot**
  - A casting of simple shape, suitable for hot working or remelting.
- **ingot iron**
  - Commercially pure iron.
- **inhibitor**
  - A substance that retards some specific chemical reaction, e.g., corrosion. Pickling inhibitors retard the dissolution of metal without hindering the removal of scale from steel.
- **inoculant**
  - Material that, when added to molten metal, modifies the structure and thus changes the physical and mechanical properties to a degree not explained on the basis of the change in composition resulting from their use. Ferrosilicon-base alloys are commonly used to inoculate gray irons and ductile irons.
- **inoculation**
  - The addition of a material to molten metal to form nuclei for crystallization. See also inoculant .
- **insert**

- (1) A part formed from a second material, usually a metal, which is placed in the molds and appears as an integral structural part of the final casting. (2) A removable portion of a die or mold.
- **insert die**
  - A relatively small die that contains part or all of the impression of a forging and that is fastened to a master die block.
- **inserted-blade cutters**
  - Cutters having replaceable blades that are either solid or tipped and are usually adjustable.
- **instrumented impact test**
  - An impact test in which the load on the specimen is continually recorded as a function of time and/or specimen deflection prior to fracture.
- **intense quenching**
  - Quenching in which the quenching medium is cooling the part at a rate at least two and a half times faster than still water. See also Grossmann number .
- **intercept method**
  - A quantitative metallographic technique in which the desired quantity, such as grain size or inclusion content, is expressed as the number of times per unit length a straight line on a metallographic image crosses particles of the feature being measured.
- **interconnected porosity**
  - A network of connecting pores in a sintered object that permits a fluid or gas to pass through the object. Also referred to as interlocking or open porosity.
- **intercritical annealing**
  - Any annealing treatment that involves heating to, and holding at, a temperature between the upper and lower critical temperatures to obtain partial austenitization, followed by either slow cooling or holding at a temperature below the lower critical temperature.
- **intercrystalline**
  - Between the crystals, or grains, of a polycrystalline material.
- **intercrystalline corrosion**
  - See intergranular corrosion .
- **intercrystalline cracking**
  - See intergranular cracking .
- **interdendritic corrosion**
  - Corrosive attack that progresses preferentially along interdendritic paths. This type of attack results from local differences in composition, such as coring commonly encountered in alloy castings.
- **interdendritic porosity**
  - Voids occurring between the dendrites in cast metal.
- **interface**
  - The boundary between any two phases. Among the three phases (gas, liquid, and solid), there are five types of interfaces: gas-liquid, gas-solid, liquid-liquid, liquid-solid, and solid-solid.
- **interfacial tension**
  - The contractile force of an interface between two phases.
- **intergranular**
  - Between crystals or grains. Also called intercrystalline. Contrast with transgranular .
- **intergranular corrosion**
  - Corrosion occurring preferentially at grain boundaries, usually with slight or negligible attack on the adjacent grains. See also interdendritic corrosion .
- **intergranular cracking**
  - Cracking or fracturing that occurs between the grains or crystals in a polycrystalline aggregate. Also called intercrystalline cracking. Contrast with transgranular cracking .
- **intergranular fracture**
  - Brittle fracture of a polycrystalline material in which the fracture is between the grains, or crystals, that form the material. Also called intercrystalline fracture. Contrast with transgranular fracture .
- **intergranular penetration**
  - In welding, the penetration of a filler metal along the grain boundaries of a base metal.
- **intergranular stress-corrosion cracking (IGSCC)**
  - Stress-corrosion cracking in which the cracking occurs along grain boundaries.

- **intermediate annealing**
  - Annealing wrought metals at one or more stages during manufacture and before final treatment.
- **intermediate electrode**
  - Same as bipolar electrode .
- **intermediate phase**
  - In an alloy or a chemical system, a distinguishable homogeneous phase whose composition range does not extend to any of the pure components of the system.
- **intermetallic compound**
  - An intermediate phase in an alloy system, having a narrow range of homogeneity and relatively simple stoichiometric proportions; the nature of the atomic binding can be of various types, ranging from metallic to ionic.
- **intermetallic phases**
  - Compounds, or intermediate solid solutions, containing two or more metals, which usually have compositions, characteristic properties, and crystal structures different from those of the pure components of the system.
- **intermittent weld**
  - A weld in which the continuity is broken by recurring unwelded spaces.
- **internal friction**
  - The conversion of energy into heat by a material subjected to fluctuating stress.
- **internal grinding**
  - Grinding an internal surface such as that inside a cylinder or hole.
- **internal oxidation**
  - The formation of isolated particles of corrosion products beneath the metal surface. This occurs as the result of preferential oxidation of certain alloy constituents by inward diffusion of oxygen, nitrogen, sulfur, and so forth. Also called subscale formation.
- **internal shrinkage**
  - A void or network of voids within a casting caused by inadequate feeding of that section during solidification.
- **internal stress**
  - See preferred term residual stress .
- **interpass temperature**
  - In a multiple-pass weld, the temperature (minimum or maximum as specified) of the deposited weld metal before the next pass is started.
- **interrupted aging**
  - Aging at two or more temperatures, by steps, and cooling to room temperature after each step. See also aging , and compare with progressive aging and step aging .
- **interrupted-current plating**
  - Plating in which the flow of current is discontinued for periodic short intervals to decrease anode polarization and elevate the critical current density. It is most commonly used in cyanide copper plating.
- **interrupted quenching**
  - A quenching procedure in which the workpiece is removed from the first quench at a temperature substantially higher than that of the quenchant and is then subjected to a second quenching system having a different cooling rate than the first.
- **interstitial solid solution**
  - A type of solid solution that sometimes forms in alloy systems having two elements of widely different atomic sizes. Elements of small atomic size, such as carbon, hydrogen, and nitrogen, often dissolve in solid metals to form this solid solution. The space lattice is similar to that of the pure metal, and the atoms of carbon, hydrogen, and nitrogen occupy the spaces or interstices between the metal atoms. See also substitutional solid solution .
- **intracrystalline**
  - Within or across the crystals or grains of a metal; same as transcrystalline and transgranular.
- **intracrystalline cracking**
  - See transgranular cracking .
- **inverse chill**
  - The condition in a casting section in which the interior is mottled or white, while the other sections are gray iron. Also known as reverse chill, internal chill, and inverted chill.
- **inverse segregation**

- A concentration of low-melting constituents in those regions of an alloy in which solidification first occurs.
- **investing**
  - In investment casting, the process of pouring the investment slurry into a flask surrounding the pattern to form the mold.
- **investment**
  - A flowable mixture, or slurry, of a graded refractory filler, a binder, and a liquid vehicle that, when poured around the patterns, conforms to their shape and subsequently sets hard to form the investment mold.
- **investment casting**
  - (1) Casting metal into a mold produced by surrounding, or investing, an expendable pattern with a refractory slurry coating that sets at room temperature, after which the wax or plastic pattern is removed through the use of heat prior to filling the mold with liquid metal. Also called precision casting or lost wax process . (2) A part made by the investment casting process.
- **investment compound**
  - A mixture of a graded refractory filler, a binder, and a liquid vehicle, used to make molds for investment casting.
- **investment precoat**
  - An extremely fine investment coating applied as a thin slurry directly to the surface of the pattern to reproduce maximum surface smoothness. The coating is surrounded by a coarser, cheaper, and more permeable investment to form the mold. See also dip coat and investment casting .
- **investment shell**
  - Ceramic mold obtained by alternately dipping a pattern set up in dip coat slurry and stuccoing with coarse ceramic particles until the shell of desired thickness is obtained. See also investment casting .
- **ion**
  - An atom, or group of atoms, which by loss or gain of one or more electrons has acquired an electric charge. If the ion is formed from an atom of hydrogen or an atom of a metal, it is usually positively charged; if the ion is formed from an atom of a nonmetal or from a group of atoms, it is usually negatively charged. The number of electronic charges carried by an ion is termed its electrovalence. The charges are denoted by superscripts that give their sign and number; for example, a sodium ion, which carries one positive charge, is denoted by  $\text{Na}^+$ ; a sulfate ion, which carries two negative charges, by  $\text{SO}_4^{2-}$  .
- **ion carburizing**
  - A method of surface hardening in which carbon ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma carburizing or glow-discharge carburizing.
- **ion exchange**
  - The reversible interchange of ions between a liquid and solid, with no substantial structural changes in the solid.
- **ion implantation**
  - The process of modifying the physical or chemical properties of the near surface of a solid (target) by embedding appropriate atoms into it from a beam of ionized particles.
- **ion nitriding**
  - A method of surface hardening in which nitrogen ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma nitriding or glow-discharge nitriding.
- **ion plating**
  - A generic term applied to atomistic film deposition processes in which the substrate surface and/or the depositing film is subjected to a flux of high-energy particles (usually gas ions) sufficient to cause changes in the interfacial region or film properties.
- **iron casting**
  - A part made of cast iron.
- **ironing**
  - An operation used to increase the length of a tube or cup through reduction of wall thickness and outside diameter, the inner diameter remaining unchanged.
- **iron rot**

- Deterioration of wood in contact with iron-base alloys.
- **iron soldering**
  - A soldering process in which the heat required is obtained from a soldering iron .
- **irradiation**
  - The exposure of a material or object to x-rays, gamma rays, ultraviolet rays, or other ionizing radiation.
- **isocorrosion diagram**
  - A graph or chart that shows constant corrosion behavior with changing solution (environment) composition and temperature.
- **isomorphous**
  - Having the same crystal structure. This usually refers to intermediate phases that form a continuous series of solid solutions.
- **isostatic pressing**
  - A process for forming a powder metallurgy compact by applying pressure equally from all directions to metal powder contained in a sealed flexible mold. See also cold isostatic pressing and hot isostatic pressing .
- **isothermal annealing**
  - Austenitizing a ferrous alloy, then cooling to and holding at a temperature at which austenite transforms to a relatively soft ferrite-carbide aggregate. See also austenitizing .
- **isothermal forging**
  - A hot-forging process in which a constant and uniform temperature is maintained in the workpiece during forging by heating the dies to the same temperature as the workpiece. Compare with hot-die forging .
- **isothermal transformation**
  - A change in phase that takes place at a constant temperature. The time required for transformation to be completed, and in some instances the time delay before transformation begins, depends on the amount of supercooling below (or superheating above) the equilibrium temperature for the same transformation.
- **isothermal transformation (IT) diagram**
  - A diagram that shows the isothermal time required for transformation of austenite to begin and to finish as a function of temperature. Same as time-temperature-transformation (TTT) diagram or S-curve.
- **isotropic**
  - Having uniform properties in all directions. The measured properties of an isotropic material are independent of the axis of testing.
- **isotropy**
  - The condition of having the same values of properties in all directions.
- **Izod test**
  - A type of impact test in which a V-notched specimen, mounted vertically, is subjected to a sudden blow delivered by the weight at the end of a pendulum arm. The energy required to break off the free end is a measure of the impact strength or toughness of the material. Contrast with Charpy test .
- **J**
- **jaw crusher**
  - A machine for the primary disintegration of metal pieces, ores, or agglomerates into coarse powder.
- **jig**
  - A mechanism for holding a part and guiding the tool during machining or assembly operation.
- **jig boring**
  - Boring with a single-point tool where the work is positioned upon a table that can be located so as to bring any desired part of the work under the tool. Thus, holes can be accurately spaced. This type of boring can be done on milling machines or jig borers.
- **J-integral**
  - A mathematical expression; a line or surface integral that encloses the crack front from one crack surface to the other, used to characterize the fracture toughness of a material having appreciable plasticity before fracture. The  $J$ -integral eliminates the need to describe the behavior of the material near the crack tip by considering the local stress-strain field around the crack front;  $J_{Ic}$  is the critical value of the  $J$ -integral required to initiate growth of a preexisting crack.

- **joint**
  - The location where two or more members are to be or have been fastened together mechanically or by welding, brazing, soldering, or adhesive bonding.
- **joint clearance**
  - The distance between the faying surfaces of a joint. In brazing, this distance is referred to as that which is present before brazing, at the brazing temperature, or after brazing is completed.
- **joint efficiency**
  - The ratio of the strength of a welded joint to the strength of the base metal, expressed in percent.
- **jolt ramming**
  - Packing sand in a mold by raising and dropping the sand, pattern, and flask on a table. Jolt-type, jolt squeezers, jarring machines, and jolt rammers are machines using this principle. Also called jar ramming.
- **Jominy test**
  - See end-quench hardenability test.
- **K**
- **karat**
  - A unit for designating the fineness of gold in an alloy. In this system, 24 karat (24 k) is 1000 fine or pure gold. The most popular jewelry golds are:

Karat designation	Gold content
24k	100% Au (99.5% min)
18k	18/24ths, or 75% Au
14k	14/24ths or 58.33% Au
10k	10/24ths, or 41.67% Au

- **keel block**
  - A standard test casting, for steel and other high-shrinkage alloys, consisting of a rectangular bar that resembles the keel of a boat, attached to the bottom of a large riser, or shrinkhead. Keel blocks that have only one bar are often called Y-blocks; keel blocks having two bars, double keel blocks. Test specimens are machined from the rectangular bar, and the shrinkhead is discarded.
- **kerf**
  - The width of the cut produced during a cutting process.
- **keyhole**
  - A technique of welding in which a concentrated heat source, such as a plasma arc, penetrates completely through a workpiece forming a hole at the leading edge of the molten weld metal. As the heat source progresses, the molten metal fills in behind the hold to form the weld bead.
- **keyhole specimen**
  - A type of specimen containing a hole-and-slot notch, shaped like a keyhole, usually used in impact bend tests. See also Charpy test and Izod test .
- **killed steel**
  - Steel treated with a strong deoxidizing agent such as silicon or aluminum in order to reduce the oxygen content to such a level that no reaction occurs between carbon and oxygen during solidification.
- **kiln**
  - A large furnace used for baking, drying, or burning firebrick or refractories, or for calcining ores or other substances.
- **$K_{Isc}$** 
  - Abbreviation for the critical value of the plane strain stress-intensity factor that will produce crack propagation by stress-corrosion cracking of a given material in a given environment.
- **kish**
  - Free graphite that forms in molten hypereutectic cast iron as it cools. In castings, the kish may segregate toward the cope surface, where it lodges at or immediately beneath the casting surface.
- **knife-line attack**

- Intergranular corrosion of an alloy, usually stabilized stainless steel, along a line adjoining or in contact with a weld after heating into the sensitization temperature range.
- **knockout**
  - (1) Removal of sand cores from a casting. (2) Jarring of an investment casting mold to remove the casting and investment from the flask. (3) A mechanism for freeing formed parts from a die used for stamping, blanking, drawing, forging, or heading operations. (4) A partially pierced hole in a sheet metal part, where the slug remains in the hole and can be forced out by hand if a hole is needed.
- **Knoop hardness number (HK)**
  - A number related to the applied load and to the projected area of the permanent impression made by a rhombic-based pyramidal diamond indenter having included edge angles of 172° 30' and 130° 0' computed from the equation:

$$HK = \frac{P}{0.07028 d^2}$$

- where  $P$  is applied load, kgf; and  $d$  is the length of the long diagonal of the impression, mm. In reporting Knoop hardness numbers, the test load is stated.
- **Knoop hardness test**
  - An indentation hardness test using calibrated machines to force a rhombic-based pyramidal diamond indenter having specified edge angles, under specified conditions, into the surface of the material under test and to measure the long diagonal after removal of the load.
- **knuckle-lever press**
  - A heavy short-stroke press in which the slide is directly actuated by a single toggle joint that is opened and closed by a connection and crank. It is used for embossing, coining, sizing, heading, swaging, and extruding.
- **knurling**
  - Impressing a design into a metallic surface, usually by means of small, hard rollers that carry the corresponding design on their surfaces.
- **Kroll process**
  - A process for the production of metallic titanium sponge by the reduction of titanium tetrachloride with a more active metal, such as magnesium or sodium. The sponge is further processed to granules or powder.
- **L**
- **lack of fusion (LOF)**
  - A condition in a welded joint in which fusion is less than complete.
- **lack of penetration (LOP)**
  - A condition in a welded joint in which joint penetration is less than that specified.
- **ladle**
  - Metal receptacle frequently lined with refractories used for transporting and pouring molten metal.
- **ladle metallurgy**
  - Degassing processes for steel carried out in a ladle.
- **lamellar tearing**
  - Occurs in the base metal adjacent to weldments due to high through-thickness strains introduced by weld metal shrinkage in highly restrained joints. Tearing occurs by decohesion and linking along the working direction of the base metal; cracks usually run roughly parallel to the fusion line and are steplike in appearance.
- **laminate**
  - (1) A composite metal, usually in the form of flat sheets, composed of two or more metal layers so bonded that the composite metal forms a structural member. (2) To form a metallic product of two or more bonded layers.
- **lamination**
  - (1) A type of discontinuity with separation or weakness generally aligned parallel to the worked surface of a metal. May be the result of pipe, blisters, seams, inclusions, or segregation elongated and made directional by working. Laminations may also occur in powder metallurgy compacts.

(2) In electrical products such as motors, a blanked piece of electrical sheet that is stacked up with several other identical pieces to make a stator or rotor.

- **lancing**
  - (1) A press operation in which a single-line cut is made in strip stock without producing a detached slug. Chiefly used to free metal for forming, or to cut partial contours for blanked parts, particularly in progressive dies. (2) A piercing (cutting) process carried out by metal powder cutting or oxyfuel gas cutting.
- **land**
  - (1) For profile-sharpened milling cutters, the relieved portion immediately behind the cutting edge. (2) For reamers, drills, and taps, the solid section between the flutes. (3) On punches, the portion adjacent to the nose that is parallel to the axis and of maximum diameter.
- **lap**
  - A surface imperfection, with the appearance of a seam, caused by hot metal, fins, or sharp corners being folded over and then being rolled or forged into the surface but without being welded.
- **lapping**
  - A finishing operation using fine abrasive grits loaded into a lapping material such as cast iron. Lapping provides major refinements in the workpiece including extreme accuracy of dimension, correction of minor imperfections of shape, refinement of surface finish, and close fit between mating surfaces.
- **laser**
  - A device that produces a concentrated coherent light beam by stimulating electronic or molecular transitions to lower energy levels. Laser is an acronym for light amplification by stimulated emission of radiation.
- **laser alloying**
  - See laser surface processing .
- **laser beam cutting**
  - A thermal cutting process that severs materials by melting or vaporizing them with the heat obtained from a laser beam, with or without the application of gas jets to augment the removal of material.
- **laser beam machining**
  - Use of a highly focused monofrequency collimated beam of light to melt or sublime material at the point of impingement on a workpiece.
- **laser beam welding (LBW)**
  - A welding process that produces coalescence of materials with the heat obtained from the application of a concentrated coherent light beam impinging upon the joint.
- **laser hardening**
  - A surface-hardening process that uses a laser to quickly heat a surface. Heat conduction into the interior of the part will quickly cool the surface, leaving a shallow martensitic layer.
- **laser surface processing**
  - The use of lasers with continuous outputs of 0.5 to 10 kW to modify the metallurgical structure of a surface and to tailor the surface properties without adversely affecting the bulk properties. The surface modification can take the following three forms. The first is transformation hardening in which a surface is heated so that thermal diffusion and solid-state transformations can take place. The second is surface melting, which results in a refinement of the structure due to the rapid quenching from the melt. The third is surface (laser) alloying, in which alloying elements are added to the melt pool to change the composition of the surface. The novel structures produced by laser surface melting and alloying can exhibit improved electrochemical and tribological behavior.
- **latent heat**
  - Thermal energy absorbed or released when a substance undergoes a phase change.
- **lateral extrusion**
  - An operation in which the product is extruded sideways through an orifice in the container wall.
- **lath martensite**
  - Martensite formed partly in steels containing less than approximately 1.0% C and solely in steels containing less than approximately 0.5% C as parallel arrays of packets of lath-shape units 0.1 to 0.3  $\mu\text{m}$  thick.
- **lattice constants**
  - See lattice parameter .

- **lattice parameter**
  - The length of any side of a unit cell of a given crystal structure. The term is also used for the fractional coordinates  $x$ ,  $y$ , and  $z$  of lattice points when these are variable.
- **launder**
  - (1) A channel for transporting molten metal. (2) A box conduit conveying particles suspended in water.
- **lay**
  - Direction of predominant surface pattern remaining after cutting, grinding, lapping, or other processing.
- **lead**
  - (1) The axial advance of a helix in one complete turn. (2) The slight bevel at the outer end of a face cutting edge of a face mill.
- **lead angle**
  - In cutting tools, the helix angle of the flutes.
- **lead burning**
  - A misnomer for welding of lead.
- **leak testing**
  - A nondestructive test for determining the escape or entry of liquids or gases from pressurized or into evacuated components or systems intended to hold these liquids. Leak testing systems, which employ a variety of gas detectors, are used for locating (detecting and pinpointing) leaks, determining the rate of leakage from one leak or from a system, or monitoring for leakage.
- **ledeburite**
  - The eutectic of the iron-carbon system, the constituents of which are austenite and cementite. The austenite decomposes into ferrite and cementite on cooling below  $A_{r1}$ , the temperature at which transformation of austenite to ferrite or ferrite plus cementite is completed during cooling.
- **left-hand cutting tool**
  - A cutter all of whose flutes twist away in a counterclockwise direction when viewed from either end.
- **Leidenfrost phenomenon**
  - Slow cooling rates associated with a hot vapor blanket that surrounds a part being quenched in a liquid medium such as water. The gaseous vapor envelope acts as an insulator, thus slowing the cooling rate.
- **leveler lines**
  - Lines on sheet or strip running transverse to the direction of roller leveling. These lines may be seen upon stoning or light sanding after leveling (but before drawing) and can usually be removed by moderate stretching.
- **leveling**
  - Flattening of rolled sheet, strip, or plate by reducing or eliminating distortions. See also stretcher leveling and roller leveling.
- **levigation**
  - (1) Separation of fine powder from coarser material by forming a suspension of the fine material in a liquid. (2) A means of classifying a material as to particle size by the rate of settling from a suspension.
- **levitation melting**
  - An induction melting process in which the metal being melted is suspended by the electromagnetic field and is not in contact with a container.
- **light drawn**
  - An imprecise term, applied to drawn products such as wire and tubing, that indicates a lesser amount of cold reduction than for hard drawn products.
- **lightly coated electrode**
  - A filler-metal electrode used in arc welding, consisting of a metal wire with a light coating, usually of metal oxides and silicates, applied subsequent to the drawing operation primarily for stabilizing the arc. Contrast with covered electrode .
- **light metal**
  - One of the low-density metals, such as aluminum, magnesium, titanium, beryllium, or their alloys.
- **limiting current density**

- The maximum current density that can be used to obtain a desired electrode reaction without undue interference such as from polarization.
- **limiting dome height (LDH) test**
  - A mechanical test, usually performed unlubricated on sheet metal, that simulates the fracture conditions in a practical press-forming operation.
- **lineage structure**
  - (1) Deviations from perfect alignment of parallel arms of a columnar dendrite as a result of interdendritic shrinkage during solidification from a liquid. This type of deviation may vary in orientation from a few minutes to as much as two degrees of arc. (2) A type of substructure consisting of elongated subgrains.
- **linear elastic fracture mechanics**
  - A method of fracture analysis that can determine the stress (or load) required to induce fracture instability in a structure containing a cracklike flaw of known size and shape. See also fracture mechanics and stress-intensity factor.
- **linear (tensile or compressive) strain**
  - The change per unit length due to force in an original linear dimension. An increase in length is considered positive.
- **liner**
  - (1) The slab of coating metal that is placed on the core alloy and is subsequently rolled down to clad sheet as a composite. (2) In extrusion, a removable alloy steel cylindrical chamber, having an outside longitudinal taper firmly positioned in the container or main body of the press, into which the billet is placed for extrusion.
- **line reaming**
  - Simultaneous reaming of coaxial holes in various sections of a workpiece with a reamer having cutting faces or piloted surfaces with the desired alignment.
- **lip-pour ladle**
  - Ladle in which the molten metal is poured over a lip, much as water is poured out of a bucket.
- **liquation**
  - (1) The separation of a low-melting constituent of an alloy from the remaining constituents, usually apparent in alloys having a wide melting range. (2) Partial melting of an alloy, usually as a result of coring or other compositional heterogeneities.
- **liquation temperature**
  - The lowest temperature at which partial melting can occur in an alloy that exhibits the greatest possible degree of segregation.
- **liquid carburizing**
  - Surface hardening of steel by immersion into a molten bath consisting of cyanides and other salts.
- **liquid honing**
  - Producing a finely polished finish by directing an air-ejected chemical emulsion containing fine abrasives against the surface to be finished.
- **liquid metal embrittlement (LME)**
  - Catastrophic brittle failure of a normally ductile metal when in contact with a liquid metal and subsequently stressed in tension. See also solid metal embrittlement .
- **liquid nitriding**
  - A method of surface hardening in which molten nitrogen-bearing, fused-salt baths containing both cyanides and cyanates are exposed to parts at subcritical temperatures.
- **liquid nitrocarburizing**
  - A nitrocarburizing process (where both carbon and nitrogen are absorbed into the surface) utilizing molten liquid salt baths below the lower critical temperature.
- **liquid penetrant inspection**
  - A type of nondestructive inspection that locates discontinuities that are open to the surface of a metal by first allowing a penetrating dye or fluorescent liquid to infiltrate the discontinuity, removing the excess penetrant, and then applying a developing agent that causes the penetrant to seep back out of the discontinuity and register as an indication. Liquid penetrant inspection is suitable for both ferrous and nonferrous materials, but is limited to the detection of open surface discontinuities in nonporous solids.
- **liquid phase sintering**
  - Sintering of a compact or loose powder aggregate under conditions where a liquid phase is present during part of the sintering cycle.

- **liquid shrinkage**
  - The reduction in volume of liquid metal as it cools to the liquidus.
- **liquidus**
  - (1) The lowest temperature at which a metal or an alloy is completely liquid.(2) In a phase diagram, the locus of points representing the temperatures at which the various compositions in the system begin to freeze on cooling or finish melting on heating. See also solidus .
- **loading**
  - (1) In cutting, building up of a cutting tool back of the cutting edge by undesired adherence of material removed from the work. (2) In grinding, filling the pores of a grinding wheel with material from the work, usually resulting in a decrease in production and quality of finish. (3) In powder metallurgy, filling of the die cavity with powder.
- **loam**
  - A molding material consisting of sand, silt, and clay, used over brickwork or other structural backup material for making massive castings, usually of iron or steel.
- **local action**
  - Corrosion due to the action of "local cells," that is, galvanic cells resulting from inhomogeneities between adjacent areas on a metal surface exposed to an electrolyte.
- **local cell**
  - A galvanic cell resulting from inhomogeneities between areas on a metal surface in an electrolyte. The inhomogeneities may be of physical or chemical nature in either the metal or its environment.
- **local current density**
  - Current density at a point or on a small area.
- **localized corrosion**
  - Corrosion at discrete sites, for example, crevice corrosion, pitting, and stress-corrosion cracking.
- **localized precipitation**
  - Precipitation from a supersaturated solid solution similar to continuous precipitation , except that the precipitate particles form at preferred locations, such as along slip planes, grain boundaries, or incoherent twin boundaries.
- **lock**
  - In forging, a condition in which the flash line is not entirely in one plane. Where two or more plane changes occur, it is called compound lock. Where a lock is placed in the die to compensate for die shift caused by a steep lock, it is called a counterlock.
- **longitudinal direction**
  - That direction parallel to the direction of maximum elongation in a worked material. See also normal direction and transverse direction .
- **longitudinal field**
  - A magnetic field that extends within a magnetized part from one or more poles to one or more other poles and that is completed through a path external to the part.
- **longitudinal resistance seam welding**
  - The making of a resistance seam weld in a direction essentially parallel to the throat depth of a resistance welding machine.
- **long transverse**
  - See transverse direction .
- **looping mill**
  - An arrangement of hot rolling stands such that a hot bar, while being discharged from one stand, is fed into a second stand in the opposite direction.
- **loose metal**
  - Refers to an area in a formed panel that is not stiff enough to hold its shape, may be confused with oil canning.
- **lost foam casting**
  - An expendable pattern process in which an expandable polystyrene pattern surrounded by the unbonded sand, is vaporized during pouring of the molten metal.
- **lost wax process**
  - An investment casting process in which a wax pattern is used.
- **lot**
  - (1) A specific amount of material produced at one time using one process and constant conditions of manufacture, and offered for sale as a unit quantity. (2) A quantity of material that is thought

to be uniform in one or more stated properties such as isotopic, chemical, or physical characteristics. (3) A quantity of bulk material of similar composition whose properties are under study. Compare with batch .

- **low-alloy steels**
  - A category of ferrous materials that exhibit mechanical properties superior to plain carbon steels as the result of additions of such alloying elements as nickel, chromium, and molybdenum. Total alloy content can range from 2.07% up to levels just below that of stainless steels, which contain a minimum of 10% Cr.
- **low-cycle fatigue**
  - Fatigue that occurs at relatively small numbers of cycles ( $<10^4$  cycles). Low-cycle fatigue may be accompanied by some plastic, or permanent, deformation. Compare with high-cycle fatigue .
- **lower ram**
  - The part of a pneumatic or hydraulic press that is moving in a lower cylinder and transmits pressure to the lower punch.
- **low-hydrogen electrode**
  - A covered arc welding electrode that provides an atmosphere around the arc and molten weld metal that is low in hydrogen.
- **low-residual-phosphorus copper**
  - Deoxidized copper with residual phosphorus present in amounts (usually 0.004 to 0.012%) generally too small to decrease appreciably the electrical conductivity of the copper.
- **lubricant**
  - (1) Any substance interposed between two surfaces in relative motion for the purpose of reducing the friction or wear between them. (2) A material applied to dies, molds, plungers, or workpieces that promotes the flow of metal, reduces friction and wear, and aids in the release of the finished part.
- **lubrication**
  - (1) The reduction of frictional resistance and wear, or other forms of surface deterioration, between two load-bearing surfaces by the application of a lubricant. (2) Mixing or incorporating a lubricant with a powder to facilitate compacting and ejecting of the compact from the die cavity; also, applying a lubricant to die walls and/or punch surfaces.
- **Lüders lines**
  - Elongated surface markings or depressions in sheet metal, often visible with the unaided eye, caused by discontinuous (inhomogeneous) yielding. Also known as Lüders bands, Hartmann lines, Piobert lines, or stretcher strains.
- **luster finish**
  - A bright, as-rolled finish, produced on ground metal rolls; it is suitable for decorative painting or plating, but usually must undergo additional surface preparation after forming.
- **M**
- **machinability**
  - The relative ease of machining a metal.
- **machinability index**
  - A relative measure of the machinability of an engineering material under specified standard conditions. Also known as machinability rating.
- **machine forging**
  - Forging performed in upsetters or horizontal forging machines.
- **machine welding**
  - Welding with equipment that performs the welding operation under the constant observation and control of a welding operator. The equipment may or may not load and unload the workpiece. See also automatic welding .
- **machining**
  - Removing material from a metal part, usually using a cutting tool, and usually using a power-driven machine.
- **machining allowance**
  - See finish allowance .
- **machining damage**
  - Irregularities or changes on the surface of a material due to machining or grinding operations that may deleteriously affect the performance of the material/part.
- **machining stress**

- Residual stress caused by machining.
- **macrograph**
  - A graphic representation of the surface of a prepared specimen at a magnification not exceeding 25×. When photographed, the reproduction is known as a photomacrograph.
- **macrohardness test**
  - A term applied to such hardness testing procedures as the Rockwell or Brinell hardness tests to distinguish them from microindentation hardness tests such as the Knoop or Vickers tests.
- **macroscopic stress**
  - Residual stress in a material in a distance comparable to the gage length of strain measurement devices (as opposed to stresses within very small, specific regions, such as individual grains). Compare with microscopic stress .
- **macroshrinkage**
  - Isolated, clustered, or interconnected voids in a casting that are detectable macroscopically. Such voids are usually associated with abrupt changes in section size and are caused by feeding that is insufficient to compensate for solidification shrinkage.
- **macrostructure**
  - The structure of metals as revealed by macroscopic examination of the etched surface of a polished specimen.
- **magnetically hard alloy**
  - See permanent magnet material .
- **magnetically soft alloy**
  - See soft magnetic material .
- **magnetic-analysis inspection**
  - A nondestructive method of inspection to determine the existence of variations in magnetic flux in ferromagnetic materials of constant cross section, such as might be caused by discontinuities and variations in hardness. The variations are usually indicated by a change in pattern on an oscilloscope screen.
- **magnetic-particle inspection**
  - A nondestructive method of inspection for determining the existence and extent of surface cracks and similar imperfections in ferromagnetic materials. Finely divided magnetic particles, applied to the magnetized part, are attracted to and outline the pattern of any magnetic leakage fields created by discontinuities.
- **magnetic pole**
  - The area on a magnetized part at which the magnetic field leaves or enters the part. It is a point of maximum attraction in a magnet.
- **magnetic separator**
  - A device used to separate magnetic from less magnetic or nonmagnetic materials. The crushed material is conveyed on a belt past a magnet.
- **magnetizing force**
  - A force field, resulting from the flow of electric currents or from magnetized bodies, that produces magnetic induction.
- **magnetostriction**
  - Changes in dimensions of a body resulting from application of a magnetic field.
- **malleability**
  - The characteristic of metals that permits plastic deformation in compression without fracture. See also ductility .
- **malleabilizing**
  - Annealing white iron in such a way that some or all of the combined carbon is transformed into graphite or, in some cases, so that part of the carbon is removed completely.
- **malleable iron**
  - A cast iron made by prolonged annealing of white iron in which decarburization, graphitization, or both take place to eliminate some or all of the cementite. The graphite is in the form of temper carbon. If decarburization is the predominant reaction, the product will exhibit a light fracture surface; hence whiteheart malleable. Otherwise, the fracture surface will be dark; hence blackheart malleable. Only the blackheart malleable is produced in the United States. Ferritic malleable has a predominantly ferritic matrix; pearlitic malleable may contain pearlite, spheroidite, or tempered martensite, depending on heat treatment and desired hardness.
- **mandrel**

- (1) A blunt-ended tool or rod used to retain the cavity in a hollow metal product during working.
  - (2) A metal bar around which other metal may be cast, bent, formed, or shaped. (3) A shaft or bar for holding work to be machined. (4) A form, such as a mold or matrix, used as a cathode in electroforming.
- **mandrel forging**
  - The process of rolling or forging a hollow blank over a mandrel to produce a weldless, seamless ring or tube. See also radial forging .
- **Mannesmann process**
  - A process for piercing tube billets in making seamless tubing. The billet is rotated between two heavy rolls mounted at an angle and is forced over a fixed mandrel.
- **manual welding**
  - A welding operation performed and controlled completely by hand. See also automatic welding , machine welding , and semiautomatic welding .
- **maraging**
  - A precipitation-hardening treatment applied to a special group of high-nickel iron-base alloys (maraging steels) to precipitate one or more intermetallic compounds in a matrix of essentially carbon-free martensite.
- **Marforming process**
  - A rubber-pad forming process developed to form wrinkle-free shrink flanges and deep-drawn shells. It differs from the Guerin process in that the sheet metal blank is clamped between the rubber pad and the blankholder before forming begins.
- **marquenching**
  - See martempering .
- **martempering**
  - (1) A hardening procedure in which an austenitized ferrous material is quenched into an appropriate medium at a temperature just above the martensite start temperature of the material, held in the medium until the temperature is uniform throughout, although not long enough for bainite to form, then cooled in air. The treatment is frequently followed by tempering. (2) When the process is applied to carburized material, the controlling martensite start temperature is that of the case. This variation of the process is frequently called marquenching.
- **martensite**
  - A generic term for microstructures formed by diffusionless phase transformation in which the parent and product phases have a specific crystallographic relationship. Martensite is characterized by an acicular pattern in the microstructure in both ferrous and nonferrous alloys. In alloys where the solute atoms occupy interstitial positions in the martensitic lattice (such as carbon in iron), the structure is hard and highly strained; but where the solute atoms occupy substitutional positions (such as nickel in iron), the martensite is soft and ductile. The amount of high-temperature phase that transforms to martensite on cooling depends to a large extent on the lowest temperature attained, there being a rather distinct beginning temperature ( $M_s$ ) and a temperature at which the transformation is essentially complete ( $M_f$ ). See also lath martensite , plate martensite , and tempered martensite .
- **marsensite range**
  - The interval between the martensite start ( $M_s$ ) and the martensite finish ( $M_f$ ) temperatures.
- **martensitic**
  - A platelike constituent having an appearance and a mechanism of formation similar to that of martensite. See also lath martensite and plate martensite .
- **martensitic transformation**
  - A reaction that takes place in some metals on cooling, with the formation of an acicular structure called martensite .
- **master alloy**
  - An alloy, rich in one or more desired addition elements, that is added to a metal melt to raise the percentage of a desired constituent.
- **master alloy powder**
  - A prealloyed metal powder of high concentration of alloy content, designed to be diluted when mixed with a base powder to produce the desired composition. See also prealloyed powder .
- **master pattern**
  - In foundry practice, a pattern embodying a double contraction allowance in its construction, used for making castings to be employed as patterns in production work.

- **match**
  - A condition in which a point in one metalforming or forging die half is aligned properly with the corresponding point in the opposite die half within specified tolerance.
- **matched edges**
  - Two edges of the die face that are machined exactly at 90° to each other, and from which all dimensions are taken in laying out the die impression and aligning the dies in the forging equipment. Also referred to as match lines.
- **match plate**
  - A plate of metal or other material on which patterns for metal casting are mounted (or formed as an integral part) to facilitate molding. The pattern is divided along its parting plane by the plate.
- **materials characterization**
  - The use of various analytical methods (spectroscopy, microscopy, chromatography, etc.) to describe those features of composition (both bulk and surface) and structure (including defects) of a material that are significant for a particular preparation, study of properties, or use. Test methods that yield information primarily related to materials properties, such as thermal, electrical, and mechanical properties, are excluded from this definition.
- **matrix**
  - The continuous or principal phase in which another constituent is dispersed.
- **matte**
  - An intermediate product of smelting ; an impure metallic sulfide mixture made by melting a roasted sulfide ore, such as an ore of copper, lead, or nickel.
- **matte finish**
  - (1) A dull texture produced by rolling sheet or strip between rolls that have been roughened by blasting. (2) A dull finish characteristic of some electrodeposits, such as cadmium or tin.
- **maximum stress ( $S_{\max}$ )**
  - The stress having the highest algebraic value in the stress cycle, tensile stress being considered positive and compressive stress negative. The nominal stress is used most commonly.
- **maximum stress intensity factor ( $K_{\max}$ )**
  - The maximum value of the stress-intensity factor in a fatigue cycle.
- **McQuaid-Ehn grain size**
  - The austenitic grain size developed in steels by carburizing at 927 °C (1700 °F) followed by slow cooling. Eight standard McQuaid-Ehn grain sizes rate the structure, from No. 8, the finest, to No. 1, the coarsest. The use of standardized ASTM methods for determining grain size is recommended.
- **mean stress ( $S_m$ )**
  - The algebraic average of the maximum and minimum stresses in one cycle, that is,  $S_m = (S_{\max} + S_{\min})/2$ . Also referred to as steady component of stress.
- **mechanical alloying (MA)**
  - An alternate cold welding and shearing of particles of two or more species of greatly differing hardness. The operation is carried out in high-intensity ball mills, such as attritors, and is the preferred method of producing oxide-dispersion-strengthened (ODS) materials. See also attritor grinding and dispersion-strengthened material .
- **mechanical hysteresis**
  - Energy absorbed in a complete cycle of loading and unloading within the elastic limit and represented by the closed loop of the stress-strain curves for loading and unloading. Sometimes referred to as elastic, but more properly, mechanical.
- **mechanical metallurgy**
  - The science and technology dealing with the behavior of metals when subjected to applied forces; often considered to be restricted to plastic working or shaping of metals.
- **mechanical plating**
  - Plating wherein fine metal powders are peened onto the work by tumbling or other means. The process is used primarily to provide ferrous parts with coatings of zinc, cadmium, tin, and alloys of these metals in various combinations.
- **mechanical polishing**
  - A process that yields a specularly reflecting surface entirely by the action of machining tools, which are usually the points of abrasive particles suspended in a liquid among the fibers of a polishing cloth.
- **mechanical press**

- A press whose slide is operated by a crank, eccentric, cam, toggle links, or other mechanical device.
- **mechanical properties**
  - The properties of a material that reveal its elastic and inelastic behavior when force is applied, thereby indicating its suitability for mechanical applications; for example, modulus of elasticity, tensile strength, elongation, hardness, and fatigue limit. Compare with physical properties .
- **mechanical testing**
  - The methods by which the mechanical properties of a metal are determined.
- **mechanical twin**
  - A twin formed in a crystal by simple shear under external heating.
- **mechanical working**
  - The subjecting of metals to pressure exerted by rolls, hammers, or presses in order to change the shape or physical properties of the metal.
- **median fatigue life**
  - The middle value when all of the observed fatigue life values of the individual specimens in a group tested under identical conditions are arranged in order of magnitude. When an even number of specimens are tested, the average of the two middlemost values is used. Use of the sample median rather than the arithmetic mean (that is, the average) is usually preferred.
- **median fatigue strength at  $N$  cycles**
  - An estimate of the stress level at which 50% of the population would survive  $N$  cycles. The estimate is derived from a particular point of the fatigue life distribution, since there is no test procedure by which a frequency distribution of fatigue strengths at  $N$  cycles can be directly observed. Also known as fatigue strength at  $N$  cycles .
- **melting point**
  - The temperature at which a pure metal, compound, or eutectic changes from solid to liquid; the temperature at which the liquid and the solid are at equilibrium.
- **melting range**
  - The range of temperatures over which an alloy other than a compound or eutectic changes from solid to liquid; the range of temperatures from solidus to liquidus at any given composition on a phase diagram.
- **melting temperature**
  - See melting point .
- **melt-through**
  - Complete joint penetration for a joint welded from one side.
- **merchant mill (obsolete)**
  - A mill, consisting of a group of stands of three rolls each arranged in a straight line and driven by one power unit, used to roll rounds, squares or flats of smaller dimensions than would be rolled on a bar mill.
- **mesh**
  - (1) The number of screen openings per linear inch of screen; also called *mesh size*. (2) The screen number on the finest screen of a specified standard screen scale through which almost all of the particles of a powder sample will pass. See also sieve analysis and sieve classification .
- **mesh-belt conveyor furnace**
  - A continuously operating furnace that uses a conveyor belt for the transport of the charge.
- **metal**
  - (1) An opaque lustrous elemental chemical substance that is a good conductor of heat and electricity and, when polished, a good reflector of light. Most elemental metals are malleable and ductile and are, in general, denser than the other elemental substances. (2) As to structure, metals may be distinguished from nonmetals by their atomic binding and electron availability. Metallic atoms tend to lose electrons from the outer shells, the positive ions thus formed being held together by the electron gas produced by the separation. The ability of these "free electrons" to carry an electric current, and the fact that this ability decreases as temperature increases, establish the prime distinctions of a metallic solid. (3) From a chemical viewpoint, an elemental substance whose hydroxide is alkaline. (4) An alloy.
- **metal arc cutting**
  - Any of a group of arc cutting processes that severs metals by melting them with the heat of an arc between a metal electrode and the base metal. See also gas metal arc cutting and shielded metal arc cutting .

- **metal arc welding**
  - Any of a group of arc welding processes in which metals are fused together using the heat of an arc between a metal electrode and the work. Use of the specific process name is preferred.
- **metal cored electrode**
  - A composite filler metal welding electrode consisting of a metal tube or other hollow configuration containing alloying ingredients. Minor amounts of ingredients facilitate arc stabilization and fluxing of oxides. External shielding gas may or may not be used.
- **metal dusting**
  - Accelerated deterioration of metals in carbonaceous gases at elevated temperatures to form a dustlike corrosion product.
- **metal electrode**
  - An electrode used in arc welding or cutting that consists of a metal wire or rod that is either bare or covered with a suitable covering or coating.
- **metallic glass**
  - A noncrystalline metal or alloy, commonly produced by drastic supercooling of a molten alloy, by molecular deposition, which involves growth from the vapor phase (e.g., thermal evaporation and sputtering) or from a liquid phase (e.g., electroless deposition and electrodeposition), or by external action techniques (e.g., ion implantation and ion beam mixing).
- **metallizing**
  - Forming a metallic coating by atomized spraying with molten metal or by vacuum deposition. Also called spray metallizing.
- **metallograph**
  - An optical instrument designed for visual observation and photomicrography of prepared surfaces of opaque materials at magnifications of 25 to approximately 2000×. The instrument consists of a high-intensity illuminating source, a microscope, and a camera bellows. On some instruments, provisions are made for examination of specimen surfaces using polarized light, phase contrast, oblique illumination, dark-field illumination, and bright-field illumination.
- **metallography**
  - The study of the structure of metals and alloys by various methods, especially by optical and electron microscopy.
- **metallurgical bond**
  - The principal bond that holds metal together and is formed between base metals and filler metals in all welding processes. This is a primary bond arising from the increased spatial extension of the valence electron wave functions when an aggregate of metal atoms is brought close together. Also referred to as metallic bond.
- **metallurgical coke**
  - A coke, usually low in sulfur, having a very high compressive strength at elevated temperatures; used in metallurgical furnaces not only as fuel, but also to support the weight of the charge.
- **metallurgy**
  - The science and technology of metals and alloys. Process metallurgy is concerned with the extraction of metals from their ores and with refining of metals; physical metallurgy, with the physical and mechanical properties of metals as affected by composition, processing, and environmental conditions; and mechanical metallurgy, with the response of metals to applied forces.
- **metal-matrix composite**
  - A material that consists of a nonmetallic reinforcement, such as ceramic fibers or filaments, incorporated into a metallic matrix.
- **metal penetration**
  - A surface condition in metal castings in which metal or metal oxides have filled voids between sand grains without displacing them.
- **metal powder**
  - Elemental metals or alloy particles, usually in the size range of 0.1 to 1000  $\mu\text{m}$ .
- **metal powder cutting**
  - A technique that supplements an oxyfuel torch with a stream of iron or blended iron-aluminum powder to facilitate flame cutting of difficult-to-cut materials. The powdered material propagates and accelerates the oxidation reaction, as well as the melting and spalling action of the materials to be cut.
- **metal spraying**

- Coating metal objects by spraying molten metal against their surfaces. See also thermal spraying .
- **metastable**
  - (1) Of a material not truly stable with respect to some transition, conversion, or reaction but stabilized kinetically either by rapid cooling or by some molecular characteristics as, for example, by the extremely high viscosity of polymers. (2) Possessing a state of pseudoequilibrium that has a free energy higher than that of the true equilibrium state.
- **M<sub>f</sub> temperature**
  - For any alloy system, the temperature at which martensite formation on cooling is essentially finished. See also transformation temperature for the definition applicable to ferrous alloys.
- **microcrack**
  - A crack of microscopic proportions. Also termed microfissure .
- **microfissure**
  - A crack of microscopic proportions.
- **micrograph**
  - A graphic reproduction of the surface of a specimen at a magnification greater than 25×. If produced by photographic means it is called a photomicrograph (not a microphotograph).
- **microhardness**
  - The hardness of a material as determined by forcing an indenter such as a Vickers or Knoop indenter into the surface of a material under very light load; usually, the indentations are so small that they must be measured with a microscope. Capable of determining hardnesses of different microconstituents within a structure, or of measuring steep hardness gradients such as those encountered in case hardening. See also microhardness test .
- **microhardness number**
  - A commonly used term for the more technically correct term microindentation hardness number .
- **microhardness test**
  - A microindentation hardness test using a calibrated machine to force a diamond indenter of specific geometry, under a test load of 1 to 1000 gram-force, into the surface of the test material and to measure the diagonal or diagonals optically. See also Knoop hardness test and Vickers hardness test .
- **microindentation**
  - (1) In hardness testing, the small residual impression left in a solid surface when an indenter, typically a pyramidal diamond stylus, is withdrawn after penetrating the surface. Typically, the dimensions of the microindentations are measured to determine microindentation hardness number. (2) The process of indenting a solid surface, using a hard stylus of prescribed geometry and under a slowly applied normal force, usually for the purpose of determining its microindentation hardness number. See also Knoop hardness number , microindentation hardness number , and Vickers hardness number .
- **microindentation hardness number**
  - A numerical quantity, usually stated in units of pressure (kg/mm<sup>2</sup>), that expresses the resistance to penetration of a solid surface by a hard indenter of prescribed geometry and under a specified, slowly applied normal force. The prefix "micro" indicates that the indentations produced are typically between 10.0 and 200.0 μm across. See also Knoop hardness number , nanohardness test , and Vickers hardness number .
- **microscopic**
  - Visible at magnifications above 25×.
- **microscopic stress**
  - Residual stress in a material within a distance comparable to the grain size. See also macroscopic stress .
- **microsegregation**
  - Segregation within a grain, crystal, or small particle. See also coring .
- **microshrinkage**
  - A casting imperfection, not detectable microscopically, consisting of interdendritic voids. Microshrinkage results from contraction during solidification where the opportunity to supply filler material is inadequate to compensate for shrinkage. Alloys with wide ranges in solidification temperature are particularly susceptible.
- **microstrain**

- The strain over a gage length comparable to interatomic distances. These are the strains being averaged by the macrostrain measurement. Microstrain is not measurable by existing techniques. Variance of the microstrain distribution can, however, be measured by x-ray diffraction.
- **microstress**
  - Same as microscopic stress .
- **microstructure**
  - The structure of an object, organism, of material as revealed by a microscope at magnifications greater than 25×.
- **middling**
  - A product intermediate between concentrate and tailing and containing enough of a valuable mineral to make retreatment profitable.
- **MIG welding**
  - Metal inert-gas welding; see preferred term gas metal arc welding .
- **mild steel**
  - Carbon steel with a maximum of about 0.25% C and containing 0.4 to 0.7% Mn, 0.1 to 0.5% Si, and some residuals of sulfur, phosphorus, and/or other elements.
- **mill**
  - (1) A factory in which metals are hot worked, cold worked, or melted and cast into standard shapes suitable for secondary fabrication into commercial products. (2) A production line, usually of four or more stands, for hot or cold rolling metal standard shapes such as bar, rod, plate, sheet, or strip. (3) A single machine or hot rolling, cold rolling, or extruding metal; examples include blooming mill, cluster mill, four-high mill, and Sendzimir mill. (4) A shop term for a milling cutter. (5) A machine or group of machines for grinding or crushing ores and other minerals. (6) A machine for grinding or mixing material, for example, a ball mill and a paint mill. (7) Grinding or mixing a material, for example, milling a powder metallurgy material.
- **mill edge**
  - The normal edge produced in hot rolling of sheet metal. This edge is customarily removed when hot rolled sheets are further processed into cold rolled sheets.
- **Miller indices**
  - A system for identifying planes and directions in any crystal system by means of sets of integers. The indices of a plane are related to the intercepts of that plane with the axes of a unit cell; the indices of a direction, to the multiples of lattice parameter that represent the coordinates of a point on a line parallel to the direction and passing through the arbitrarily chosen origin of a unit cell.
- **mill finish**
  - A nonstandard (and typically nonuniform) surface finish on mill products that are delivered without being subjected to a special surface treatment (other than a corrosion-preventive treatment) after the final working or heat-treating step.
- **milling (machining)**
  - Removing metal with a milling cutter.
- **milling (powder technology)**
  - The mechanical comminution of a material, usually in a ball mill, to alter the size or shape of the individual particles, to coat one component of a mixture with another, or to create uniform distributions of components.
- **milling cutter**
  - A rotary cutting tool provided with one or more cutting elements, called teeth, that intermittently engage the workpiece and remove material by relative movement of the workpiece and cutter.
- **mill product**
  - Any commercial product of a mill.
- **mill scale**
  - The heavy oxide layer that forms during the hot fabrication or heat treatment of metals.
- **mineral dressing**
  - Physical and chemical concentration of raw ore into a product from which a metal can be recovered at a profit.
- **minimized spangle**
  - A hot dip galvanized coating of very small grain size, which makes the spangle less visible when the part is subsequently painted.
- **minimum bend radius**

- The minimum radius over which a metal product can be bent to a given angle without fracture.
- **minimum stress ( $S_{\min}$ )**
  - In fatigue, the stress having the lowest algebraic value in the cycle, tensile stress being considered positive and compressive stress negative.
- **minimum stress-intensity factor ( $K_{\min}$ )**
  - In fatigue, the minimum value of the stress-intensity factor in a cycle. This value corresponds to the minimum load when the load ratio is  $>0$  and is taken to be zero when the load ratio is  $\leq 0$ .
- **minus sieve**
  - The portion of a powder sample that passes through a standard sieve of a specified number. See also plus sieve and sieve analysis .
- **mischmetal**
  - An natural mixture of rare-earth elements (atomic numbers 57 through 71) in metallic form. It contains about 50% Ce, the remainder being principally lanthanum and neodymium.
- **mismatch**
  - The misalignment or error in register of a pair of forging dies; also applied to the condition of the resulting forging.
- **misrun**
  - Denotes an irregularity on a cast metal surface caused by incomplete filling of the mold due to low pouring temperatures, gas back pressure from inadequate venting of the mold, and inadequate gating.
- **mixed potential**
  - The potential of a specimen (or specimens in a galvanic couple) when two or more electrochemical reactions are occurring. Also called galvanic couple potential.
- **mixing**
  - In powder metallurgy, the thorough intermingling of powders of two or more different materials (not to be confused with blending ).
- **modification**
  - Treatment of molten hypoeutectic (8 to 13% Si) or hypereutectic (13 to 19% Si) aluminum-silicon alloys to improve mechanical properties of the solid alloy by refinement of the size and distribution of the silicon phase. Involves additions of small percentages of sodium, strontium, or calcium (hypoeutectic alloys) or of phosphorus (hypereutectic alloys).
- **modulus of elasticity ( $E$ )**
  - (1) The measure of rigidity or stiffness of a material; the ratio of stress, below the proportional limit, to the corresponding strain. If a tensile stress of 13.8 MPa (2.0 ksi) results in an elongation of 1.0%, the modulus of elasticity is 13.8 MPa (2.0 ksi) divided by 0.01, or 1380 MPa (200 ksi).
  - (2) In terms of the stress-strain curve, the modulus of elasticity is the slope of the stress-strain curve in the range of linear proportionality of stress to strain. Also known as Young's modulus . For materials that do not conform to Hooke's law throughout the elastic range, the slope of either the tangent to the stress-strain curve at the origin or at low stress, the secant drawn from the origin to any specified point on the stress-strain curve, or the chord connecting any two specific points on the stress-strain curve is usually taken to be the modulus of elasticity. In these cases, the modulus is referred to as the tangent modulus, secant modulus, or chord modulus, respectively.
- **modulus of resilience**
  - The amount of energy stored in a material when loaded to its elastic limit. It is determined by measuring the area under the stress-strain curve up to the elastic limit. See also resilience and strain energy .
- **modulus of rigidity**
  - See shear modulus .
- **modulus of rupture**
  - Nominal stress at fracture in a bend test or torsion test. In bending, modulus of rupture is the bending moment at fracture divided by the section modulus. In torsion, modulus of rupture is the torque at fracture divided by the polar section modulus.
- **Mohs hardness**
  - The hardness of a body according to a scale proposed by Mohs, based on ten minerals, each of which would scratch the one below it. These minerals, in decreasing order of hardness, are:

Diamond	10
Corundum	9
Topaz	8
Quartz	7
Othoclase (feldspar)	6
Apatite	5
Fluorite	4
Calcite	3
Gypsum	2
Talc	1

- **mold**
  - (1) The form, made of sand, metal, or refractory material, that contains the cavity into which molten metal is poured to produce a casting of desired shape. (2) A die.
- **mold cavity**
  - The space in a mold that is filled with liquid metal to form the casting upon solidification. The channel through which liquid metal enters the mold cavity (sprue, runner, gates) and reservoirs for liquid metal (risers) are not considered part of the mold cavity proper.
- **molding machine**
  - A machine for making sand molds by mechanically compacting sand around a pattern.
- **molding press**
  - A press used to form powder metallurgy compacts.
- **molding sands**
  - Foundry sands containing more than 5% natural clay, usually between 8 and 20%.
- **mold jacket**
  - Wood or metal form that is slipped over a sand mold for support during pouring of a casting.
- **mold wash**
  - An aqueous or alcoholic emulsion or suspension of various materials used to coat the surface of a casting mold cavity.
- **molten weld pool**
  - The liquid state of a weld prior to solidification as weld metal.
- **Mond process**
  - A process for extracting and purifying nickel. The main features consist of forming nickel carbonyl by reaction of finely divided reduced metal with carbon monoxide, then decomposing the nickel carbonyl to deposit purified nickel on small nickel pellets.
- **monotectic**
  - An isothermal reversible reaction in a binary system, in which a liquid on cooling decomposes into a second liquid of a different composition and a solid. It differs from a eutectic in that only one of the two products of the reaction is below its freezing range.
- **monotropism**
  - The ability of a solid to exist in two or more forms (crystal structures), but in which one form is the stable modification at all temperatures and pressures. Ferrite and martensite are a monotropic pair below the temperature at which austenite begins to form, for example, in steels. Alternate spelling is monotrophism.
- **morphology**
  - The characteristic shape, form, or surface texture or contours of the crystals, grains, or particles of (or in) a material, generally on a microscopic scale.
- **mosaic structure**
  - In crystals, a substructure in which adjoining regions have only slightly different orientations.
- **mottled cast iron**
  - Iron that consists of a mixture of variable proportions of gray cast iron and white cast iron; such a material has a mottled fracture appearance.
- **mounting**

- A means by which a specimen for metallographic examination may be held during preparation of a section surface. The specimen can be embedded in plastic or secured mechanically in clamps.
- **mounting resin**
  - Thermosetting or thermoplastic resins used to mount metallographic specimens.
- **M<sub>s</sub> temperature**
  - For any alloy system, the temperature at which martensite starts to form on cooling. See transformation temperature for the definition applicable to ferrous alloys.
- **mulling**
  - The mixing and kneading of foundry molding sand with moisture and clay to develop suitable properties for molding.
- **multiaxial stresses**
  - Any stress state in which two or three principal stresses are not zero.
- **multiple**
  - A piece of stock for forging that is cut from bar or billet lengths to provide the exact amount of material for a single workpiece.
- **multiple-pass weld**
  - A weld made by depositing filler metal with two or more successive passes.
- **multiple-slide press**
  - A press with individual slides, built into the main slide or connected to individual eccentrics on the main shaft, that can be adjusted to vary the length of stroke and the timing. See also slide .
- **multiple spot welding**
  - Spot welding in which several spots are made during one complete cycle of the welding machine.
- **m-value**
  - See strain-rate sensitivity .
- **N**
- **nanohardness test**
  - An indentation hardness testing procedure, usually relying on indentation force versus tip displacement data, to make assessments of the resistance of surfaces to penetrations of the order of 10 to 1000 nm deep.
- **native metal**
  - (1) Any deposit in the earth's crust consisting of uncombined metal. (2) The metal in such a deposit.
- **natural aging**
  - Spontaneous aging of a supersaturated solid solution at room temperature. See also aging . Compare with artificial aging .
- **natural strain**
  - See true strain .
- **NDE**
  - See nondestructive evaluation .
- **NDI**
  - See nondestructive inspection .
- **NDT**
  - See nondestructive testing .
- **near-net shape**
  - See net shape .
- **necking**
  - (1) The reduction of the cross-sectional area of a material in a localized area by uniaxial tension or by stretching. (2) The reduction of the diameter of a portion of the length of a cylindrical shell or tube.
- **necking down**
  - Localized reduction in area of a specimen during tensile deformation.
- **net shape**
  - The shape of a powder metallurgy part, casting, or forging that conforms closely to specified dimensions. Such a part requires no secondary machining or finishing. A near-net shape part can be either one in which some but not all of the surfaces are net or one in which the surfaces require only minimal machining or finishing.
- **Neumann band**

- Mechanical twin in ferrite.
- **neutral flame**
  - (1) A gas flame in which there is no excess of either fuel or oxygen in the inner flame. Oxygen from ambient air is used to complete the combustion of  $\text{CO}_2$  and  $\text{H}_2$  produced in the inner flame.
  - (2) An oxyfuel gas flame in which the portion used is neither oxidizing nor reducing. See also carburizing flame , oxidizing flame , and reducing flame .
- **neutron embrittlement**
  - Embrittlement resulting from bombardment with neutrons, usually encountered in metals that have been exposed to a neutron flux in the core of the reactor. In steels, neutron embrittlement is evidenced by a rise in the ductile-to-brittle transition temperature.
- **nibbling**
  - Contour cutting of sheet metal by use of a rapidly reciprocating punch that makes numerous small cuts.
- **nip angle**
  - See angle of bite .
- **nitriding**
  - Introducing nitrogen into the surface layer of a solid ferrous alloy by holding at a suitable temperature (below  $A_{c1}$  for ferritic steels) in contact with a nitrogenous material, usually ammonia or molten cyanide of appropriate composition. Quenching is not required to produce a hard case. See also bright nitriding and liquid nitriding .
- **nitrocarburizing**
  - Any of several processes in which both nitrogen and carbon are absorbed into the surface layers of a ferrous material at temperatures below the lower critical temperature and, by diffusion, create a concentration gradient. Nitrocarburizing is performed primarily to provide an anticuffing surface layer and to improve fatigue resistance. Compare with carbonitriding .
- **noble**
  - The positive direction of electrode potential, thus resembling noble metals such as gold and platinum.
- **noble metal**
  - (1) A metal whose potential is highly positive relative to the hydrogen electrode. (2) A metal with marked resistance to chemical reaction, particularly to oxidation and to solution by inorganic acids. The term as often used is synonymous with precious metal .
- **noble potential**
  - A potential more cathodic (positive) than the standard hydrogen potential.
- **no-draft (draftless) forging**
  - A forging with extremely close tolerances and little or no draft that requires minimal machining to produce the final part. Mechanical properties can be enhanced by closer control of grain flow and by retention of surface material in the final component.
- **nodular graphite**
  - Graphite in nodular (rounded) form as opposed to flake form (see flake graphite ). See also ductile iron and spheroidal graphite .
- **nodular iron**
  - See preferred term ductile iron.
- **nominal stress**
  - The stress at a point calculated on the net cross section without taking into consideration the effect on stress of geometric discontinuities, such as holes, grooves, fillets, and so forth. The calculation is made using simple elastic theory.
- **nondestructive evaluation (NDE)**
  - Broadly considered synonymous with nondestructive inspection (NDI) . More specifically, the quantitative analysis of NDI findings to determine whether the material will be acceptable for its function, despite the presence of discontinuities. With NDE, a discontinuity can be classified by its size, shape, type, and location, allowing the investigator to determine whether or not the flaw(s) is acceptable. Damage tolerant design approaches are based on the philosophy of ensuring safe operation in the presence of flaws.
- **nondestructive inspection (NDI)**
  - A process or procedure, such as ultrasonic or radiographic inspection, for determining the quality or characteristics of a material, part, or assembly, without permanently altering the subject or its

properties. Used to find internal anomalies in a structure without degrading its properties or impairing its serviceability.

- **nondestructive testing (NDT)**
  - Broadly considered synonymous with nondestructive inspection (NDI).
- **nonmetallic inclusions**
  - See inclusions .
- **normal direction**
  - That direction perpendicular to the plane of working in a worked material. See also longitudinal direction and transverse direction .
- **normalizing**
  - Heating a ferrous alloy to a suitable temperature above the transformation range and then cooling in air to a temperature substantially below the transformation range.
- **normal segregation**
  - Concentration of alloying constituents that have low melting points in those portions of a casting that solidify last. Compare with inverse segregation .
- **normal solution**
  - An aqueous solution containing one gram equivalent of the active reagent in 1 L of the solution.
- **normal stress**
  - The stress component that is perpendicular to the plane on which the forces act. Normal stress may be either tensile or compressive.
- **nose radius**
  - The radius of the rounded portion of the cutting edge of a tool.
- **notch acuity**
  - Relates to the severity of the stress concentration produced by a given notch in a particular structure. If the depth of the notch is very small compared with the width (or diameter) of the narrowest cross section, acuity may be expressed as the ratio of the notch depth to the notch root radius. Otherwise, acuity is defined as the ratio of one-half the width (or diameter) of the narrowest cross section to the notch root radius.
- **notch brittleness**
  - Susceptibility of a material to brittle fracture at points of stress concentration. For example, in a notch tensile test, the material is said to be notch brittle if the notch strength is less than the tensile strength of an unnotched specimen. Otherwise, it is said to be notch ductile.
- **notch depth**
  - The distance from the surface of a test specimen to the bottom of the notch. In a cylindrical test specimen, the percentage of the original cross-sectional area removed by machining an annular groove.
- **notch ductility**
  - The percentage reduction in area after complete separation of the metal in a tensile test of a notched specimen.
- **notched specimen**
  - A test specimen that has been deliberately cut or notched, usually in a V-shape, to induce and locate point of failure.
- **notch factor**
  - Ratio of the resilience determined on a plain specimen to the resilience determined on a notched specimen.
- **notching**
  - Cutting out various shapes from the edge of a strip, blank, or part.
- **notching press**
  - A mechanical press used for notching internal and external circumferences and also for notching along a straight line. These presses are equipped with automatic feeds because only one notch is made per stroke.
- **notch rupture strength**
  - The ratio of applied load to original area of the minimum cross section in a stress-rupture test of a notched specimen.
- **notch sensitivity**
  - The extent to which the sensitivity of a material to fracture is increased by the presence of a stress concentration, such as a notch, a sudden change in cross section, a crack, or a scratch. Low notch

sensitivity is usually associated with ductile materials, and high notch sensitivity is usually associated with brittle materials.

- **notch strength**
  - The maximum load on a notched tension-test specimen divided by the minimum cross-sectional area (the area at the root of the notch). Also called notch tensile strength.
- **nuclear grade**
  - Material of a quality adequate for use in nuclear application.
- **nucleation**
  - The initiation of a phase transformation at discrete sites, with the new phase growing on the nuclei. See also nucleus (2) .
- **nucleus**
  - (1) The heavy central core of an atom, in which most of the mass and the total positive electric charge are concentrated. (2) The first structurally stable particle capable of initiating recrystallization of a phase or the growth of a new phase and possessing an interface with the parent metallic matrix. The term is also applied to a foreign particle that initiates such action.
- **nugget**
  - (1) A small mass of metal, such as gold or silver, found free in nature. (2) The weld metal in a spot, seam, or projection weld.
- **n-value**
  - See strain-hardening exponent .
- **O**
- **offhand grinding**
  - Grinding where the operator manually forces the wheel against the work, or vice versa. It often implies casual manipulation of either grinder or work to achieve the desired result. Dimensions and tolerances frequently are not specified, or are only loosely specified; the operator relies mainly on visual inspection to determine how much grinding should be done. Contrast with precision grinding .
- **offset**
  - The distance along the strain coordinate between the initial portion of a stress-strain curve and a parallel line that intersects the stress-strain curve at a value of stress (commonly 0.2%) that is used as a measure of the yield strength. Used for materials that have no obvious yield point.
- **offset yield strength**
  - The stress at which the strain exceeds by a specific amount (the offset) an extension of the initial, approximately linear, proportional portion of the stress-strain curve. It is expressed in force per unit area.
- **oil canning**
  - See canning .
- **oil quenching**
  - Hardening of carbon steel in an oil bath.
- **Olsen ductility test**
  - A cupping test in which a piece of sheet metal, restrained except at the center, is deformed by a standard steel ball until fracture occurs. The height of the cup at the time of fracture is a measure of the ductility.
- **open-back inclinable press**
  - A vertical crank press that can be inclined so that the bed will have an inclination generally varying from 0 to 30°. The formed parts slide off through an opening in the back. It is often called an OBI press.
- **open-die forging**
  - The hot mechanical forming of metals between flat or shaped dies in which metal flow is not completely restricted. Also known as hand or smith forging. See also hand forge (smith forge) .
- **open dies**
  - Dies with flat surfaces that are used for preforming stock or producing hand forgings.
- **open hearth furnace**
  - A reverberatory melting furnace with a shallow hearth and a low roof. The flame passes over the charge on the hearth, causing the charge to be heated both by direct flame and by radiation from the roof and sidewalls of the furnace. See also reverberatory furnace .
- **open rod press**

- A hydraulic press in which the slide is guided by vertical, cylindrical rods (usually four) that also serve to hold the crown and bed in position.
- **optical emission spectroscopy**
  - Pertaining to emission spectroscopy in the near-ultraviolet, visible, or near-infrared wavelength regions of the electromagnetic spectrum. See also electromagnetic radiation .
- **orange peel**
  - A surface roughening in the form of a pebble-grained pattern that occurs when a metal of unusually coarse grain size is stressed beyond its elastic limit. Also called pebbles and alligator skin.
- **orbital forging**
  - See rotary forging .
- **ordered structure**
  - The crystal structure of a solid solution in which the atoms of different elements seek preferred lattice positions. Contrast with disordered structure .
- **ore**
  - A natural mineral that may be mined and treated for the extraction of any of its components, metallic or otherwise, at a profit.
- **ore dressing**
  - Same as mineral dressing .
- **orientation**
  - Arrangements in space of the axes of the lattice of a crystal with respect to a chosen reference or coordinate system. See also preferred orientation .
- **original crack size ( $a_0$ )**
  - The physical crack size at the start of testing.
- **oscillating die press**
  - A small high-speed metal forming press in which the die and punch move horizontally with the strip during the working stroke. Through a reciprocating motion, the die and punch return to their original positions to begin the next stroke.
- **overaging**
  - Aging under conditions of time and temperature greater than those required to obtain maximum change in a certain property, so that the property is altered in the direction of the initial value.
- **overbending**
  - Bending metal through a greater arc than that required in the finished part to compensate for springback.
- **overdraft**
  - A condition wherein a metal curves upward on leaving the rolls because of the higher speed of the lower roll.
- **overhead-drive press**
  - A mechanical press with the driving mechanism mounted in or on the crown or upper parts of the uprights.
- **overheating**
  - Heating a metal or alloy to such a high temperature that its properties are impaired. When the original properties cannot be restored by further heat treating, by mechanical working, or by a combination of working and heat treating, the overheating is known as burning.
- **overlap**
  - In resistance seam welding, the area in a given weld remelted by the succeeding weld.
- **oversize powder**
  - Powder particles larger than the maximum permitted by a particle size specification.
- **overstressing**
  - In fatigue testing, cycling at a stress level higher than that used at the end of the test.
- **oxidation**
  - (1) A reaction in which there is an increase in valence resulting from a loss of electrons. Contrast with reduction . (2) A corrosion reaction in which the corroded metal forms an oxide; usually applied to reaction with a gas containing elemental oxygen, such as air. Elevated temperatures increase the rate of oxidation. (3) A chemical reaction in which one substance is changed to another by oxygen combining with the substance. Much of the dross from holding and melting furnaces is the result of oxidation of the alloy held in the furnace.
- **oxidation losses**

- Reduction in the amount of metal or alloy through oxidation.
- **oxidative wear**
  - (1) A corrosive wear process in which chemical reaction with oxygen or oxidizing environment predominates. (2) A type of wear resulting from the sliding action between two metallic components that generates oxide films on the metal surfaces. These oxide films prevent the formation of a metallic bond between the sliding surfaces, resulting in fine wear debris and low wear rates.
- **oxidized steel surface**
  - Surface having a thin, tightly adhering oxidized skin (from straw to blue in color), extending in from the edge of a coil or sheet.
- **oxidizing agent**
  - A compound that causes oxidation, thereby itself being reduced.
- **oxidizing atmosphere**
  - A furnace atmosphere with an oversupply of oxygen that tends to oxidize materials placed in it.
- **oxidizing flame**
  - A gas flame produced with excess oxygen in the inner flame that has an oxidizing effect. See also neutral flame and reducing flame .
- **oxyacetylene cutting**
  - An oxyfuel gas cutting process in which the fuel gas is acetylene.
- **oxyacetylene welding**
  - An oxyfuel gas welding process in which the fuel gas is acetylene.
- **oxyfuel gas cutting**
  - Any of a group of processes used to sever metals by means of chemical reaction between hot base metal and a fine stream of oxygen. The necessary metal temperature is maintained by gas flames resulting from combustion of a specific fuel gas such as acetylene, hydrogen, natural gas, propane, propylene, or Mapp gas (stabilized methylacetylene-propadiene).
- **oxyfuel gas welding (OFW)**
  - Any of a group of processes used to fuse metals together by heating them with gas flames resulting from combustion of a specific fuel gas such as acetylene, hydrogen, natural gas, or propane. The process may be used with or without the application of pressure to the joint, and with or without adding any filler metal.
- **oxygas cutting**
  - See preferred term oxygen cutting .
- **oxygen arc cutting**
  - An oxygen cutting process used to sever metals by means of the chemical reaction of oxygen with the base metal at elevated temperatures. The necessary temperature is maintained by an arc between a consumable tubular electrode and the base metal.
- **oxygen cutting**
  - A group of cutting processes used to sever or remove metals by means of the chemical reaction between oxygen and the base metal at elevated temperatures. In the case of oxidation-resistant metals, the reaction is facilitated by the use of a chemical flux or metal powder. See also chemical flux cutting , metal powder cutting , oxyfuel gas cutting , oxygen arc cutting , and oxygen lance cutting .
- **oxygen-free copper**
  - Electrolytic copper free from cuprous oxide, produced without the use of residual metallic or metalloidal deoxidizers.
- **Oxygen gouging**
  - Oxygen cutting in which a bevel or groove is formed.
- **oxygen lance**
  - A length of pipe used to convey oxygen either beneath or on top of the melt in a steelmaking furnace, or to the point of cutting in oxygen lance cutting.
- **oxygen lance cutting**
  - An oxygen cutting process used to sever metals with oxygen supplied through a consumable lance; the preheat to start the cutting is obtained by other means.
- **oxygen probe**
  - An atmosphere-monitoring device that electronically measures the difference between the partial pressure of oxygen in a furnace or furnace supply atmosphere and the external air.
- **P**

- **pack carburizing**
  - A method of surface hardening of steel in which parts are packed in a steel box with a carburizing compound and heated to elevated temperatures. This process has been largely supplanted by gas and liquid carburizing processes.
- **pack nitriding**
  - A method of surface hardening of steel in which parts are packed in a steel box with a nitriding compound and heated to elevated temperatures.
- **pack rolling**
  - Hot rolling a pack of two or more sheets of metal; scale prevents their being welded together.
- **pancake forging**
  - A rough forged shape, usually flat, that can be obtained quickly with minimal tooling. Considerable machining is usually required to attain the finish size.
- **pancake grain structure**
  - A metallic structure in which the lengths and widths of individual grains are large compared to their thicknesses.
- **paramagnetic material**
  - (1) A material whose specific permeability is greater than unity and is practically independent of the magnetizing force. (2) Material with a small positive susceptibility due to the interaction and independent alignment of permanent atomic and electronic magnetic moments with the applied field. Compare with ferromagnetic material .
- **paramagnetism**
  - A property exhibited by substances that, when placed in a magnetic field, are magnetized parallel to the field to an extent proportional to the field (except at very low temperatures or in extremely large magnetic fields). Compare with ferromagnetism .
- **Parkes process**
  - A process used to recover precious metals from lead and based on the principle that if 1 to 2% Zn is stirred into the molten lead, a compound of zinc with gold and silver separates out and can be skimmed off.
- **partial annealing**
  - An imprecise term used to denote a treatment given cold-worked metallic material to reduce its strength to a controlled level or to effect stress relief. To be meaningful, the type of material, the degree of cold work, and the time-temperature schedule must be stated.
- **particle shape**
  - The appearance of a metal particle, such as spherical, rounded, angular, acicular, dendritic, irregular, porous, fragmented, blocky, rod, flake, nodular, or plate.
- **particle size**
  - The controlling lineal dimension of an individual particle as determined by analysis with screens or other suitable instruments. See also sieve analysis and sieve classification .
- **particle size distribution**
  - The percentage, by weight or by number, of each fraction into which a powder or sand sample has been classified with respect to sieve number or particle size.
- **particle sizing**
  - Segregation of granular material into specified particle size ranges.
- **parting**
  - (1) In the recovery of precious metals, the separation of silver from gold. (2) The zone of separation between cope and drag portions of the mold or flask in sand casting. (3) A composition sometimes used in sand molding to facilitate the removal of the pattern. (4) Cutting simultaneously along two parallel lines or along two lines that balance each other in side thrust. (5) A shearing operation used to produce two or more parts from a stamping.
- **parting compound**
  - A material dusted or sprayed on foundry (casting) patterns to prevent adherence of sand and to promote easy separation of cope and drag parting surfaces when the cope is lifted from the drag.
- **parting line**
  - (1) The intersection of the parting plane of a casting or plastic mold or the parting plane between forging dies with the mold or die cavity. (2) A raised line or projection on the surface of a casting, plastic part, or forging that corresponds to said intersection.
- **parting plane**

- (1) In forging, the dividing line between dies. (2) In casting, the dividing line between mold halves.
- **parting sand**
  - In foundry practice, a fine sand for dusting on sand mold surfaces that are to be separated.
- **pass**
  - (1) A single transfer of metal through a stand of rolls. (2) The open space between two grooved rolls through which metal is processed. (3) The weld metal deposited in one trip along the axis of a weld. See also weld pass .
- **passivation**
  - (1) A reduction of the anodic reaction rate of an electrode involved in corrosion. (2) The process in metal corrosion by which metals become passive. (3) The changing of a chemically active surface of a metal to a much less reactive state. Contrast with activation .
- **passive**
  - (1) A metal corroding under the control of a surface reaction product. (2) The state of the metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal.
- **passive-active cell**
  - A corrosion cell in which the anode is a metal in the active state and the cathode is the same metal in the passive state.
- **passivity**
  - A condition in which a piece of metal, because of an impervious covering of oxide or other compound, has a potential much more positive than that of the metal in the active state.
- **patenting**
  - In wiremaking, a heat treatment applied to medium- or high-carbon steel before drawing of wire or between drafts. This process consists of heating to a temperature above the transformation range and then cooling to a temperature below  $A_{e1}$  in air or in a bath of molten lead or salt.
- **patent leveling**
  - Same as stretcher leveling .
- **patina**
  - The coating, usually green, that forms on the surface of metals such as copper and copper alloys exposed to the atmosphere. Also used to describe the appearance of a weathered surface of any metal.
- **pattern**
  - (1) A form of wood, metal, or other material around which molding material is placed to make a mold for casting metals. (2) A form of wax- or plastic-base material around which refractory material is placed to make a mold for casting metals. (3) A full-scale reproduction of a part used as a guide in cutting.
- **pearlite**
  - A metastable lamellar aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures above the bainite range.
- **pearlitic malleable**
  - See malleable iron .
- **pearlitic structure**
  - A microstructure resembling that of the pearlite constituent in steel. Therefore, it is a lamellar structure of varying degrees of coarseness.
- **peeling**
  - The detaching of one layer of a coating from another, or from the substrate, because of poor adherence.
- **peel test**
  - A destructive method of inspection that mechanically separates a lap joint by peeling.
- **peening**
  - Mechanical working of metal by hammer blows or shot impingement.
- **penetrant**
  - A liquid with low surface tension used in liquid penetrant inspection to flow into surface openings of parts being inspected.
- **penetrant inspection**
  - See preferred term liquid penetrant inspection .
- **penetration**

- (1) In founding, an imperfection on a casting surface caused by metal running into voids between sand grains; usually referred to as metal penetration . (2) In welding, the distance from the original surface of the base metal to that point at which fusion ceased.
- **penetration hardness**
  - Same as indentation hardness .
- **percussion welding**
  - A resistance welding process that produces coalescence of abutting surfaces using heat from an arc produced by a rapid discharge of electrical energy. Pressure is applied percussively during or immediately following the electrical discharge.
- **perforating**
  - The punching of many holes, usually identical and arranged in a regular pattern, in a sheet, workpiece blank, or previously formed part. The holes are usually round, but may be any shape. The operation is also called multiple punching. See also piercing .
- **peripheral milling**
  - Milling a surface parallel to the axis of the cutter.
- **peritectic**
  - An isothermal reversible reaction in metals in which a liquid phase reacts with a solid phase to produce a single (and different) solid phase on cooling.
- **peritectoid**
  - An isothermal reversible reaction in which a solid phase reacts with a second solid phase to produce a single (and different) solid phase on cooling.
- **permanent magnet material**
  - A ferromagnetic alloy capable of being magnetized permanently because of its ability to retain induced magnetization and magnetic poles after removal of externally applied fields; an alloy with high coercive force. The name is based on the fact that the quality of the early permanent magnets was related to their hardness.
- **permanent mold**
  - A metal, graphite, or ceramic mold (other than an ingot mold) of two or more parts that is used repeatedly for the production of many castings of the same form. Liquid metal is usually poured in by gravity.
- **permanent set**
  - The deformation remaining after a specimen has been stressed a prescribed amount in tension, compression, or shear for a specified time period and released for a specified time period. For creep tests, the residual unrecoverable deformation after the load causing the creep has been removed for a substantial and specified period of time. Also, the increase in length, expressed as a percentage of the original length, by which an elastic material fails to return to its original length after being stressed for a standard period of time.
- **permeability**
  - (1) The passage or diffusion (or rate of passage) of a gas, vapor, liquid, or solid through a material (often porous) without physically or chemically affecting it; the measure of fluid flow (gas or liquid) through a material. (2) A general term used to express various relationships between magnetic induction and magnetizing force. These relationships are either "absolute permeability," which is a change in magnetic induction divided by the corresponding change in magnetizing force, or "specific (relative) permeability," the ratio of the absolute permeability to the permeability of free space. (3) In metal casting, the characteristics of molding materials that permit gases to pass through them. "Permeability number" is determined by a standard test.
- **pewter**
  - A tin-base white metal containing antimony and copper. Originally, pewter was defined as an alloy of tin and lead, but to avoid toxicity and dullness of finish, lead is excluded from modern pewter. These modern compositions contain 1 to 8% Sb and 0.25 to 3% Cu.
- **pH**
  - The negative logarithm of the hydrogen-ion activity; it denotes the degree of acidity or basicity of a solution. At 25 °C (77 °F), 7.0 is the neutral value. Decreasing values below 7.0 indicates increasing acidity; increasing values above 7.0, increasing basicity. The pH values range from 0 to 14.
- **phase**
  - A physically homogeneous and distinct portion of a material system.
- **phase change**

- The transition from one physical state to another, such as gas to liquid, liquid to solid, gas to solid, or vice versa.
- **phase diagram**
  - A graphical representation of the temperature and composition limits of phase fields in an alloy or ceramic system as they actually exist under the specific conditions of heating or cooling. A phase diagram may be an equilibrium diagram, an approximation to an equilibrium diagram, or a representation of metastable conditions or phases. Synonymous with constitution diagram. Compare with equilibrium diagram .
- **phase rule**
  - The maximum number of phases ( $P$ ) that may coexist at equilibrium is two, plus the number of components ( $C$ ) in the mixture, minus the number of degrees of freedom ( $F$ ):  $P + F = C + 2$ .
- **phosphating**
  - Forming an adherent phosphate coating on a metal by immersion in a suitable aqueous phosphate solution. Also called phosphatizing. See also conversion coating .
- **phosphorized copper**
  - General term applied to copper deoxidized with phosphorus. The most commonly used deoxidized copper.
- **photoelasticity**
  - An optical method for evaluating the magnitude and distribution of stresses, using a transparent model of a part, or a thick film of photoelastic material bonded to a real part.
- **photomacrograph**
  - A macrograph produced by photographic means.
- **photomicrograph**
  - A micrograph produced by photographic means.
- **physical crack size ( $a_p$ )**
  - In fracture mechanics, the distance from a reference plane to the observed crack front. This distance may represent an average of several measurements along the crack front. The reference plane depends on the specimen form, and it is normally taken to be either the boundary or a plane containing either the load line or the centerline of a specimen or plate.
- **physical metallurgy**
  - The science and technology dealing with the properties of metals and alloys, and of the effects of composition, processing, and environment on those properties.
- **physical properties**
  - Properties of a material that are relatively insensitive to structure and can be measured without the application of force; for example, density, electrical conductivity, coefficient of thermal expansion, magnetic permeability, and lattice parameter. Does not include chemical reactivity. Compare with mechanical properties .
- **physical testing**
  - Methods used to determine the entire range of the material's physical properties of a material. In addition to density and thermal, electrical, and magnetic properties, physical testing methods may be used to assess simple fundamental physical properties such as color, crystalline form, and melting point.
- **physical vapor deposition (PVD)**
  - A coating process whereby the deposition species are transferred and deposited in the form of individual atoms or molecules. The most common PVD methods are sputtering and evaporation. Sputtering, which is the principal PVD process, involves the transport of a material from a source (target) to a substrate by means of the bombardment of the target by gas ions that have been accelerated by a high voltage. Evaporation, which was the first PVD process used, involves the transfer of material to form a coating by physical means alone, essentially vaporization. Physical vapor deposition coatings are used to improve the wear, friction, and hardness properties of cutting tools and as corrosion-resistant coatings.
- **pickle liquor**
  - A spent acid-pickling bath.
- **pickle stain**
  - Discoloration of metal due to chemical cleaning without adequate washing and drying.
- **pickling**

- The chemical removal of surface oxides (scale) and other contaminants such as dirt from iron and steel by immersion in an aqueous acid solution. The most common pickling solutions are sulfuric and hydrochloric acids.
- **pickoff**
  - An automatic device for removing a finished part from the press die after it has been stripped.
- **pickup**
  - (1) Transfer of metal from tools to part or from part to tools during a forming operation. (2) Small particles of oxidized metal adhering to the surface of a mill product.
- **Pidgeon process**
  - A process for production of magnesium by reduction of magnesium oxide with ferrosilicon.
- **piercing**
  - The general term for cutting (shearing or punching) openings, such as holes and slots, in sheet material, plate, or parts. This operation is similar to blanking; the difference is that the slug or pierce produced by piercing is scrap, while the blank produced by blanking is the useful part.
- **piezoelectric effect**
  - The reversible interaction, exhibited by some crystalline materials, between an elastic strain and an electric field. The direction of the strain depends on the polarity of the field or vice versa. Compare with electrostrictive effect .
- **pig**
  - A metal casting used in remelting.
- **pig iron**
  - (1) High-carbon iron made by reduction of iron ore in the blast furnace. (2) Cast iron in the form of pigs.
- **Pilger tube-reducing process**
  - See tube reducing .
- **pin (for bend testing)**
  - The plunger or tool used in making semiguided, guided, or wraparound bend tests to apply the bending force to the inside surface of the bend. In free bends or semiguided bends to an angle of 180°, a shim or block of the proper thickness may be placed between the legs of the specimen as bending is completed. This shim or block is also referred to as a pin or mandrel. See also mandrel .
- **pinchers**
  - Surface disturbances on metal sheet or strip that result from rolling processes and that ordinarily appear as fernlike ripples running diagonally to the direction of rolling.
- **pinch pass**
  - A pass of sheet metal through rolls to effect a very small reduction in thickness.
- **pinch trimming**
  - The trimming of the edge of a tubular metal part or shell by pushing or pinching the flange or lip over the cutting edge of a stationary punch or over the cutting edge of a draw punch.
- **pin expansion test**
  - A test for determining the ability of a tube to be expanded or for revealing the presence of cracks or other longitudinal weaknesses, made by forcing a tapered pin into the open end of the tube.
- **pinhole porosity**
  - Porosity consisting of numerous small gas holes (pinholes) distributed throughout the metal; found in weld metal, castings, and electrodeposited metal.
- **Piobert lines**
  - See Lüders lines .
- **pipe**
  - (1) The central cavity formed by contraction in metal, especially ingots, during solidification. (2) An imperfection in wrought or cast products resulting from such a cavity. (3) A tubular metal product, cast or wrought. See also extrusion pipe .
- **pipe tap**
  - A tap for making internal pipe threads within pipe fittings or holes.
- **pipe threads**
  - Internal or external machine threads, usually tapered, of a design intended for making pressure-tight mechanical joints in piping systems.
- **pit**

- A small, regular or irregular crater in the surface of a material created by exposure to the environment, for example, corrosion, wear, or thermal cycling. See also pitting .
- **pitting**
  - (1) Forming small sharp cavities in a surface by corrosion, wear, or other mechanically assisted degradation. (2) Localized corrosion of a metal surface, confined to a point or small area, that takes the form of cavities.
- **plane strain**
  - The stress condition in linear elastic fracture mechanics in which there is zero strain in a direction normal to both the axis of applied tensile stress and the direction of crack growth (that is, parallel to the crack front); most nearly achieved in loading thick plates along a direction parallel to the plate surface. Under plane-strain conditions, the plane of fracture instability is normal to the axis of the principal tensile stress.
- **plane-strain fracture toughness ( $K_{Ic}$ )**
  - The crack extension resistance under conditions of crack-tip plane strain. See also stress-intensity factor .
- **plane stress**
  - The stress condition in linear elastic fracture mechanics in which the stress in the thickness direction is zero; most nearly achieved in loading very thin sheet along a direction parallel to the surface of the sheet. Under plane-stress conditions, the plane of fracture instability is inclined  $45^\circ$  to the axis of the principal tensile stress.
- **plane-stress fracture toughness ( $K_{Ic}$ )**
  - In linear elastic fracture mechanics, the value of the crack-extension resistance at the instability condition determined from the tangency between the R-curve and the critical crack-extension force curve of the specimen. See also stress-intensity factor .
- **planimetric method**
  - A method of measuring grain size in which the grains within a definite area are counted.
- **planing**
  - Producing flat surfaces by linear reciprocal motion of work and the table to which it is attached, relative to a stationary single-point cutting tool.
- **planishing**
  - Producing a smooth finish on metal by a rapid succession of blows delivered by highly polished dies or by a hammer designed for the purpose, or by rolling in a planishing mill.
- **plasma arc cutting**
  - An arc cutting process that severs metals by melting a localized area with heat from a constricted arc and removing the molten metal with a high-velocity jet of hot, ionized gas issuing from the plasma torch.
- **plasma arc welding (PAW)**
  - An arc welding process that produces coalescence of metals by heating them with a constricted arc between an electrode and the workpiece (transferred arc) or the electrode and the constricting nozzle (nontransferred arc). Shielding is obtained from hot, ionized gas issuing from an orifice surrounding the electrode and may be supplemented by an auxiliary source of shielding gas, which may be an inert gas or a mixture of gases. Pressure may or may not be used, and filler metal may or may not be supplied.
- **plasma-assisted chemical vapor deposition**
  - A chemical vapor deposition process that uses low-pressure glow-discharge plasmas to promote the chemical deposition reactions. Also called plasma-enhanced chemical vapor deposition.
- **plasma carburizing**
  - Same as ion carburizing .
- **plasma nitriding**
  - Same as ion nitriding .
- **plasma spraying**
  - A thermal spraying process in which a nontransferred arc of a plasma torch is utilized to create a gas plasma that acts as the source of heat for melting and propelling the surfacing material to the substrate.
- **plaster molding**
  - Molding in which a gypsum-bonded aggregate flour in the form of a water slurry is poured over a pattern, permitted to harden, and, after removal of the pattern, thoroughly dried. This technique is used to make smooth nonferrous castings of accurate size.

- **plastic deformation**
  - The permanent (inelastic) distortion of materials under applied stresses that strain the material beyond its elastic limit.
- **plastic flow**
  - The phenomenon that takes place when metals are stretched or compressed permanently without rupture.
- **plasticity**
  - The property of a material that allows it to be repeatedly deformed without rupture when acted upon by a force sufficient to cause deformation and that allows it to retain its shape after the applied force has been removed.
- **plastic-strain ratio (*r*-value)**
  - In formability testing of metals, the ratio of the true width strain to the true thickness strain in a sheet tensile test,  $r = \epsilon_w / \epsilon_t$ . A formability parameter that relates to drawing, it is also known as the anisotropy factor. A high *r*-value indicates a material with good drawing properties.
- **plate**
  - A flat-rolled metal product of some minimum thickness and width arbitrarily dependent on the type of metal. Plate thicknesses commonly range from 6 to 300 mm (0.25 to 12 in.); widths from 200 to 2000 mm (8 to 80 in.).
- **plate martensite**
  - Martensite formed partly in steel containing more than approximately 0.5% C and solely in steel containing more than approximately 1.0% C that appears as lenticular-shape plates (crystals).
- **platen**
  - (1) The sliding member, slide, or ram of a metal forming press. (2) A part of a resistance welding, mechanical testing, or other machine with a flat surface to which dies, fixtures, backups, or electrode holders are attached and that transmits pressure or force.
- **plating**
  - Forming an adherent layer of metal on an object; often used as a shop term for electroplating. See also electrodeposition and electroless plating .
- **plating rack**
  - A fixture used to hold work and conduct current to it during electroplating.
- **plug**
  - (1) A rod or mandrel over which a pierced tube is forced. (2) A rod or mandrel that fills a tube as it is drawn through a die. (3) A punch or mandrel over which a cup is drawn. (4) A protruding portion of a die impression for forming a corresponding recess in the forging. (5) A false bottom in a die.
- **plug tap**
  - A tap with chamfer extending from three to five threads.
- **plug weld**
  - A weld made in a circular hole in one member of a joint, fusing that member to another member.
- **plumbage**
  - A special quality of powdered graphite used to coat molds and, in a mixture of clay, to make crucibles.
- **plunge grinding**
  - Grinding wherein the only relative motion of the wheel is radially toward the work.
- **plus mesh**
  - The powder sample retained on a screen of stated size, identified by the retaining mesh number. See also sieve analysis and sieve classification .
- **plus sieve**
  - The portion of a sample of a granular substance (such as metal powder) retained on a standard sieve of specified number. Contrast with minus sieve . See also sieve analysis and sieve classification .
- **plymetal**
  - Sheet consisting of bonded layers of dissimilar metals.
- **P/M**
  - The acronym for powder metallurgy .
- **pneumatic press**
  - A press that uses air or a gas to deliver the pressure to the upper and lower rams.
- **point angle**

- In general, the angle at the point of a cutting tool. Most commonly, the included angle at the point of a twist drill, the general-purpose angle being 118°.
- **Poisson's ratio ( $\nu$ )**
  - The absolute value of the ratio of transverse (lateral) strain to the corresponding axial strain resulting from uniformly distributed axial stress below the proportional limit of the material.
- **polarity (welding)**
  - See direct current electrode negative and direct current electrode positive .
- **polarization**
  - (1) The change from the open-circuit electrode potential as the result of the passage of current. (2) A change in the potential of an electrode during electrolysis, such that the potential of an anode becomes more noble, and that of a cathode more active, than their respective reversible potentials. Often accomplished by formation of a film on the electrode surface.
- **polarization curve**
  - A plot of current density versus electrode potential for a specific electrode-electrolyte combination.
- **pole**
  - (1) A means of designating the orientation of a crystal plane by stereographically plotting its normal. For example, the north pole defines the equatorial plane. (2) Either of the two regions of a permanent magnet or electromagnet where most of the lines of induction enter or leave.
- **pole figure**
  - A stereoscopic projection of a polycrystalline aggregate showing the distribution of poles, or plane normals, of a specific crystalline plane, using specimen axes as reference axes. Pole figures are used to characterize preferred orientation in polycrystalline materials.
- **polishing**
  - (1) Smoothing metal surfaces, often to a high luster, by rubbing the surface with a fine abrasive, usually contained in a cloth or other soft lap. Results in microscopic flow of some surface metal together with actual removal of a small amount of surface metal. (2) Removal of material by the action of abrasive grains carried to the work by a flexible support, generally either a wheel or a coated abrasive belt. (3) A mechanical, chemical, or electrolytic process or combination thereof used to prepare a smooth, reflective surface suitable for microstructural examination that is free of artifacts or damage introduced during prior sectioning or grinding. See also electrolytic polishing and electropolishing .
- **polycrystalline**
  - Pertaining to a solid comprised of many crystals or crystallites, intimately bonded together. May be homogeneous (one substance) or heterogeneous (two or more crystal types or compositions).
- **polymorphism**
  - A general term for the ability of a solid to exist in more than one form. In metals, alloys, and similar substances, this usually means the ability to exist in two or more crystal structures, or in an amorphous state and at least one crystal structure. See also allotropy , enantiotropy , and monotropism .
- **pop-off**
  - Loss of small portions of a porcelain enamel coating. The usual cause is outgassing of hydrogen or other gases from the substrate during firing, but pop-off may also occur because of oxide particles or other debris on the surface of the substrate. Usually, the pits are minute and cone shaped, but when pop-off is the result of severe fishscale the pits may be much larger and irregular.
- **porcelain enamel**
  - A substantially vitreous or glassy, inorganic coating (borosilicate glass) bonded to metal by fusion at a temperature above 425 °C (800 °F). Porcelain enamels are applied primarily to components made of sheet iron or steel, cast iron, aluminum, or aluminum-coated steels.
- **pore**
  - (1) A small opening, void, interstice, or channel within a consolidated solid mass or agglomerate, usually larger than atomic or molecular dimensions. (2) A minute cavity in a powder metallurgy compact, sometimes added intentionally. (3) A minute perforation in an electroplated coating.
- **porosity**
  - (1) Fine holes or pores within a solid; the amount of these pores is expressed as a percentage of the total volume of the solid. (2) Cavity-type discontinuities in weldments formed by gas

entrapment during solidification. (3) A characteristic of being porous, with voids or pores resulting from trapped air or shrinkage in a casting. See also gas porosity and pinhole porosity .

- **postheating**
  - Heating weldments immediately after welding, for tempering, for stress relieving, or for providing a controlled rate of cooling to prevent formation of a hard or brittle structure. See also postweld heat treatment .
- **postweld heat treatment**
  - Any heat treatment that follows the welding operation.
- **pot**
  - (1) A vessel for holding molten metal. (2) The electrolytic reduction cell used to make such metals as aluminum from a fused electrolyte.
- **pot annealing**
  - Same as box annealing .
- **potential**
  - (1) Any of various functions from which intensity or velocity at any point in a field may be calculated. (2) The driving influence of an electrochemical reaction .
- **poultice corrosion**
  - A term used in the automotive industry to describe the corrosion of vehicle body parts due to the collection of road salts and debris on ledges and in pockets that are kept moist by weather and washing. Also called deposit corrosion or attack.
- **pouring**
  - The transfer of molten metal from furnace to ladle, ladle to ladle, or ladle into molds.
- **pouring basin**
  - In metal casting, a basin on top of a mold that receives the molten metal before it enters the sprue or downgate.
- **powder**
  - An aggregate of discrete particles that are usually in the size range of 1 to 1000  $\mu\text{m}$ .
- **powder cutting**
  - See preferred terms chemical flux cutting and metal powder cutting .
- **powder flame spraying**
  - A thermal spraying process variation in which the material to be sprayed is in powder form.
- **powder forging**
  - The plastic deformation of a powder metallurgy compact or preform into a fully dense finished shape by using compressive force; usually done hot and within closed dies.
- **powder lubricant**
  - In powder metallurgy, an agent or component incorporated into a mixture to facilitate compacting and ejecting of the compact from its mold.
- **powder metallurgy (P/M)**
  - The technology and art of producing metal powders and utilizing metal powders for production of massive materials and shaped objects.
- **powder metallurgy forging**
  - See powder forging .
- **powder metallurgy part**
  - A shaped object that has been formed from metal powders and sintered by heating below the melting point of the major constituent. A structural or mechanical component made by the powder metallurgy process.
- **prealloyed powder**
  - A metallic powder composed of two or more elements that are alloyed in the powder manufacturing process and in which the particles are of the same nominal composition throughout.
- **precious metals**
  - Relatively scarce, highly corrosion resistant, valuable metals found in periods 5 and 6 (groups VIII and Ib) of the periodic table. They include ruthenium, rhodium, palladium, silver, osmium, iridium, platinum, and gold. See also noble metal .
- **precipitation**
  - In metals, the separation of a new phase from solid or liquid solution, usually with changing conditions of temperature, pressure, or both.

- **precipitation hardening**
  - Hardening in metals caused by the precipitation of a constituent from a supersaturated solid solution. See also age hardening and aging .
- **precipitation heat treatment**
  - Artificial aging of metals in which a constituent precipitates from a supersaturated solid solution.
- **precision casting**
  - A metal casting of reproducible, accurate dimensions, regardless of how it is made. Often used interchangeably with investment casting .
- **precision forging**
  - A forging produced to closer tolerances than normally considered standard by the industry. With precision forging, a net shape, or at least a near-net shape, can be produced in the as-forged condition. See also net shape .
- **precision grinding**
  - Machine grinding to specified dimensions and low tolerances.
- **precoat**
  - (1) In investment casting, a special refractory slurry applied to a wax or plastic expendable pattern to form a thin coating that serves as a desirable base for application of the main slurry. See also investment casting . (2) To make the thin coating. (3) The thin coating itself.
- **precoated metal products**
  - Mill products that have a metallic, organic, or conversion coating applied to their surfaces before they are fabricated into parts.
- **precracked specimen**
  - A mechanical test specimen that is notched and subjected to alternating stresses until a crack has developed at the root of the notch.
- **preferred orientation**
  - A condition of a polycrystalline aggregate in which the crystal orientations are not random, but rather exhibit a tendency for alignment with a specific direction in the bulk material, commonly related to the direction of working. See also texture .
- **preforming**
  - (1) The initial pressing of a metal powder to form a compact that is to be subjected to a subsequent pressing operation other than coining or sizing. (2) Preliminary forming operations, especially for impression-die forging.
- **preheating**
  - (1) Heating before some further thermal or mechanical treatment. For tool steel, heating to an intermediate temperature immediately before final austenitizing. For some nonferrous alloys, heating to a high temperature for a long time, in order to homogenize the structure before working. (2) In welding and related processes, heating to an intermediate temperature for a short time immediately before welding, brazing, soldering, cutting, or thermal spraying. (3) In powder metallurgy, an early stage in the sintering procedure when, in a continuous furnace, lubricant or binder burnoff occurs without atmosphere protection prior to actual sintering in the protective atmosphere of the high heat chamber.
- **presintering**
  - Heating a powder metallurgy compact to a temperature below the final sintering temperature, usually to increase the ease of handling or shaping of a compact or to remove a lubricant or binder (burnoff) prior to sintering.
- **press**
  - A machine tool having a stationary bed and a slide or ram that has reciprocating motion at right angles to the bed surface, the slide being guided in the frame of the machine. See also hydraulic press , mechanical press , and slide .
- **press brake**
  - An open-frame single-action press used to bend, blank, corrugate, curl, notch, perforate, pierce, or punch sheet metal or plate.
- **press-brake forming**
  - A metalforming process in which the workpiece is placed over an open die and pressed down into the die by a punch that is actuated by the ram portion of a press brake. The process is most widely used for the forming of relatively long, narrow parts that are not adaptable to press forming and for applications in which production quantities are too small to warrant the tooling cost for contour roll forming.

- **pressed density**
  - The weight per unit volume of an unsintered compact. Same as green density .
- **press forming**
  - Any sheet metalforming operation performed with tooling by means of a mechanical or hydraulic press.
- **pressing area**
  - The clear distance (left to right) between housings, stops, gibs, gibways, or shoulders of strain rods, multiplied by the total distance from front to back on the bed of a metalforming press. Sometimes called working area.
- **pressing crack**
  - A rupture in a green powder metallurgy compact that develops during ejection of the compact from the die. Sometimes referred to as a slip crack.
- **press quenching**
  - A quench in which hot dies are pressed and aligned with a part before the quenching process begins. Then the part is placed in contact with a quenching medium in a controlled manner. This process avoids part distortion.
- **pressure casting**
  - (1) Making castings with pressure on the molten or plastic metal, as in die casting, centrifugal casting, cold chamber pressure casting, and squeeze casting. (2) A casting made with pressure applied to the molten or plastic metal.
- **pressure-controlled welding**
  - A resistance welding process variation in which a number of spot or projection welds are made with several electrodes functioning progressively under the control of a pressure-sequencing device.
- **pressure gas welding**
  - An oxyfuel gas welding process that produces coalescence simultaneously over the entire area of abutting surfaces by heating them with gas flames obtained from combustion of a fuel gas with oxygen and by application of pressure, without the use of filler metal.
- **pressure sintering**
  - A hot-pressing technique that usually employs low loads, high sintering temperatures, continuous or discontinuous sintering, and simple molds to contain the powder. Although the terms pressure sintering and hot pressing are used interchangeably, distinct differences exist between the two processes. In pressure sintering, the emphasis is on thermal processing; in hot pressing, applied pressure is the main process variable.
- **pressure welding**
  - See preferred terms cold welding , diffusion welding , forge welding , hot pressure welding , pressure-controlled welding , pressure gas welding , and solid-state welding .
- **primary creep**
  - The first, or initial, stage of creep, or time-dependent deformation.
- **primary crystals**
  - The first type of crystals that separate from a melt during solidification.
- **primary metal**
  - Metal extracted from minerals and free of reclaimed metal scrap. Compare with native metal .
- **primary mill**
  - A mill for rolling ingots or the rolled products of ingots to blooms, billets, or slabs. This type of mill is often called a blooming mill and sometimes called a cogging mill.
- **principal stress (normal)**
  - The maximum or minimum value of the normal stress at a point in a plane considered with respect to all possible orientations of the considered plane. On such principal planes the shear stress is zero. There are three principal stresses on three mutually perpendicular planes. The state of stress at a point may be (1) uniaxial, a state of stress in which two of the three principal stresses are zero, (2) biaxial, a state of stress in which only one of the three principal stresses is zero, and (3) triaxial, a state of stress in which none of the principal stresses is zero. Multiaxial stress refers to either biaxial or triaxial stress.
- **process annealing**
  - A heat treatment used to soften metal for further cold working. In ferrous sheet and wire industries, heating to a temperature close to but below the lower limit of the transformation range and subsequently cooling for working. In the nonferrous industries, heating above the

recrystallization temperatures at a time and temperature sufficient to permit the desired subsequent cold working.

- **process metallurgy**
  - The science and technology of winning metals from their ores and purifying metals; sometimes referred to as chemical metallurgy. Its two chief branches are extractive metallurgy and refining.
- **proeutectoid phase**
  - Particles of a phase in ferrous alloys that precipitate during cooling after austenitizing but before the eutectoid transformation takes place. See also eutectoid .
- **profiling**
  - Any operation that produces an irregular contour on a workpiece, for which a tracer or template-controlled duplicating equipment usually is employed.
- **progressive aging**
  - Aging by increasing the temperature in steps or continuously during the aging cycle. See also aging and compare with interrupted aging and step aging .
- **progressive die**
  - A die with two or more stations arranged in line for performing two or more operations on a part; one operation is usually performed at each station.
- **progressive forming**
  - Sequential forming at consecutive stations with a single die or separate dies.
- **projection welding**
  - A resistance welding process that produces coalescence of metals with the heat obtained from resistance to electric current through the work parts held together under pressure by electrodes. The resulting welds are localized at predetermined points by projections, embossments, or intersections.
- **proof**
  - (1) To test a component or system at its peak operating load or pressure. (2) Any reproduction of a die impression in any material; often a lead or plaster cast. See also die proof .
- **proof load**
  - A predetermined load, generally some multiple of the service load, to which a specimen or structure is submitted before acceptance for use.
- **proof stress**
  - (1) A specified stress to be applied to a member or structure to indicate its ability to withstand service loads. (2) The stress that will cause a specified small permanent set in a material.
- **proportional limit**
  - The greatest stress a material is capable of developing without a deviation from straight-line proportionality between stress and strain. See also elastic limit and Hooke's law .
- **protective atmosphere**
  - (1) A gas or vacuum envelope surrounding the part to be brazed, welded, or thermal sprayed, with the gas composition controlled with respect to chemical composition, dew point, pressure, flow rate, and so forth. Examples are inert gases, combusted fuel gases, hydrogen, and vacuum. (2) The atmosphere in a heat treating or sintering furnace designed to protect the parts or compacts from oxidation, nitridation, or other contamination from the environment.
- **pseudobinary system**
  - (1) A three-component or ternary alloy system in which an intermediate phase acts as a component. (2) A vertical section through a ternary diagram.
- **puckering**
  - Wrinkling or buckling in a drawn shell in an area originally inside the draw ring.
- **pull cracks**
  - In a casting, cracks that are caused by residual stresses produced during cooling and that result from the shape of the object.
- **pulverization**
  - The process of reducing metal powder particle sizes by mechanical means; also called comminution or mechanical disintegration.
- **punch**
  - (1) The male part of a die--as distinguished from the female part, which is called the die. The punch is usually the upper member of the complete die assembly and is mounted on the slide or in a die set for alignment (except in the inverted die). (2) In double-action draw dies, the punch is the inner portion of the upper die, which is mounted on the plunger (inner slide) and does the

drawing. (3) The act of piercing or punching a hole. Also referred to as punching . (4) The movable tool that forces material into the die in powder molding and most metalforming operations. (5) The movable die in a trimming press or a forging machine. (6) The tool that forces the stock through the die in rod and tube extrusion and forms the internal surface in can or cup extrusion.

- **punching**
  - (1) The die shearing of a closed contour in which the sheared out sheet metal part is scrap. (2) Producing a hole by die shearing, in which the shape of the hole is controlled by the shape of the punch and its mating die. Multiple punching of small holes is called perforating . See also piercing .
- **punch press**
  - (1) In general, any mechanical press. (2) In particular, an endwheel gap-frame press with a fixed bed, used in piercing.
- **punch radius**
  - The radius on the end of the punch that first contacts the work, sometimes called nose radius .
- **push bench**
  - Equipment used for drawing moderately heavy-gage tubes by cupping sheet metal and forcing it through a die by pressure exerted against the inside bottom of the cup.
- **pusher furnace**
  - A type of continuous furnace in which parts to be heated are periodically charged into the furnace in containers, which are pushed along the hearth against a line of previously charged containers thus advancing the containers toward the discharge end of the furnace, where they are removed.
- **push welding**
  - Spot or projection welding in which the force is applied manually to one electrode, and the work or backing plate takes the place of the other electrode.
- **pyramidal plane**
  - In noncubic crystals, any plane that intersects all three axes.
- **pyrometallurgy**
  - High-temperature winning or refining of metals.
- **pyrometer**
  - A device for measuring temperatures above the range of liquid thermometers.
- **pyrophoric powder**
  - A powder whose particles self-ignite and burn when exposed to oxygen or air.
- **Q**
- **quality**
  - (1) The totality of features and characteristics of a product or service that bear on its ability to satisfy a given need (fitness-for-use concept of quality). (2) Degree of excellence of a product or service (comparative concept). Often determined subjectively by comparison against an ideal standard or against similar products or services available from other sources. (3) A quantitative evaluation of the features and characteristics of a product or service (quantitative concept).
- **quantitative metallography**
  - Determination of specific characteristics of a microstructure by quantitative measurements on micrographs or metallographic images. Quantities so measured include volume concentration of phases, grain size, particle size, mean free path between like particles or secondary phases, and surface-area-to-volume ratio of microconstituents, particles, or grains.
- **quarter hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength about midway between that of dead soft and half hard tempers.
- **quasi-binary system**
  - In a ternary or higher-order system, a linear composition series between two substances each of which exhibits congruent melting, wherein all equilibria, at all temperatures or pressures, involve only phases having compositions occurring in the linear series, so that the series may be represented as a binary on a phase diagram.
- **quasi-cleavage fracture**
  - A fracture mode that combines the characteristics of cleavage fracture and dimple fracture. An intermediate type of fracture found in certain high-strength metals.
- **quench-age embrittlement**

- Embrittlement of low-carbon steels resulting from precipitation of solute carbon at existing dislocations and from precipitation hardening of the steel caused by differences in the solid solubility of carbon in ferrite at different temperatures. Quench-age embrittlement usually is caused by rapid cooling of the steel from temperatures slightly below  $A_{c1}$  (the temperature at which austenite begins to form), and can be minimized by quenching from lower temperatures.
- **quench aging**
  - Aging induced by rapid cooling after solution heat treatment.
- **quench annealing**
  - Annealing an austenitic ferrous alloy by solution heat treatment followed by rapid quenching.
- **quench cracking**
  - Fracture of a metal during quenching from elevated temperature. Most frequently observed in hardened carbon steel, alloy steel, or tool steel parts of high hardness and low toughness. Cracks often emanate from fillets, holes, corners, or other stress raisers and result from high stresses due to the volume changes accompanying transformation to martensite.
- **quench hardening**
  - (1) Hardening suitable  $\alpha$ - $\beta$  alloys (most often certain copper to titanium alloys) by solution treating and quenching to develop a martensitic-like structure. (2) In ferrous alloys, hardening by austenitizing and then cooling at a rate such that a substantial amount of austenite transforms to martensite.
- **quenching**
  - Rapid cooling of metals (often steels) from a suitable elevated temperature. This generally is accomplished by immersion in water, oil, polymer solution, or salt, although forced air is sometimes used. See also brine quenching , caustic quenching , direct quenching , fog quenching , forced-air quenching , hot quenching , intense quenching , interrupted quenching , oil quenching , press quenching , selective quenching , spray quenching , time quenching , and water quenching .
- **quenching crack**
  - A crack formed in a metal as a result of thermal stresses produced by rapid cooling from a high temperature.
- **quenching oil**
  - Oil used for quenching metals during a heat treating operation.
- **R**
- **rabbit ear**
  - Recess in the corner of a metalforming die to allow for wrinkling or folding of the blank.
- **racking**
  - A term used to describe the placing of metal parts to be heat treated on a rack or tray. This is done to keep parts in a proper position to avoid heat-related distortions and to keep the parts separated.
- **radial draw forming**
  - The forming of sheet metals by the simultaneous application of tangential stretch and radial compression forces. The operation is done gradually by tangential contact with the die member. This type of forming is characterized by very close dimensional control.
- **radial forging**
  - A process using two or more moving anvils or dies for producing shafts with constant or varying diameters along their length or tubes with internal or external variations. Often incorrectly referred to as rotary forging .
- **radial marks**
  - Lines on a fracture surface that radiate from the fracture origin and are visible to the unaided eye or at low magnification. Radial marks result from the intersection and connection of brittle fractures propagating at different levels. Also known as shear ledges. See also chevron pattern .
- **radiation damage**
  - A general term for the alteration of properties of a material arising from exposure to ionizing radiation (penetrating radiation), such as x-rays, gamma rays, neutrons, heavy-particle radiation, or fission fragments in nuclear fuel material. See also neutron embrittlement .
- **radioactive element**
  - An element that has at least one isotope that undergoes spontaneous nuclear disintegration to emit positive  $\alpha$  particles, negative  $\beta$  particles, or  $\gamma$  rays.
- **radioactivity**

- (1) The property of the nuclei of some isotopes to spontaneously decay (lose energy). Usual mechanisms are emission of  $\alpha$ ,  $\beta$ , or other particles and splitting (fissioning). Gamma rays are frequently, but not always, given off in the process. (2) A particular component from a radioactive source, such as  $\beta$  radioactivity.
- **radiograph**
  - A photographic shadow image resulting from uneven absorption of penetrating radiation in a test object. See also radiography .
- **radiography**
  - A method of nondestructive inspection in which a test object is exposed to a beam of x-rays or  $\gamma$  rays and the resulting shadow image of the object is recorded on photographic film placed behind the object, or displayed on a viewing screen or television monitor (real-time radiography). Internal discontinuities are detected by observing and interpreting variations in the image caused by differences in thickness, density, or absorption within the test object. See also real-time radiography .
- **radius of bend**
  - The radius of the cylindrical surface of the pin or mandrel that comes in contact with the inside surface of the bend during bending. In the case of free or semiguided bends to 180° in which a shim or block is used, the radius of bend is one-half the thickness of the shim or block.
- **rake**
  - The angular relationship between the tooth face, or a tangent to the tooth face at a given point, and a given reference plane or line.
- **ram**
  - The moving or falling part of a drop hammer or press to which one of the dies is attached; sometimes applied to the upper flat die of a steam hammer. Also referred to as the slide .
- **ramming**
  - (1) Packing foundry sand, refractory, or other material into a compact mass. (2) The compacting of molding (foundry) sand in forming a mold.
- **random sequence**
  - A longitudinal welding sequence wherein the weld-bead increments are deposited at random to minimize distortion.
- **range of stress ( $S_r$ )**
  - The algebraic difference between the maximum and minimum stress in one cycle--that is,  $S_r = S_{\max} - S_{\min}$ .
- **rapid solidification**
  - The cooling or quenching of liquid (molten) metals at rates that range from  $10^4$  to  $10^8$  °C/s.
- **rare earth metal**
  - A group of 17 chemically similar metals that includes the elements scandium and yttrium (atomic numbers 21 and 39, respectively) and the lanthanide elements (atomic numbers 57 through 71).
- **ratcheting**
  - Progressive cyclic inelastic deformation (growth, for example) that occurs when a component or structure is subjected to a cyclic secondary stress superimposed on a sustained primary stress. The process is called thermal ratcheting when cyclic strain is induced by cyclic changes in temperature, and isothermal ratcheting when cyclic strain is mechanical in origin (even though accompanied by cyclic changes in temperature).
- **ratchet marks**
  - Lines or markings on a fatigue fracture surface that results from the intersection and connection of fatigue fractures propagating from multiple origins. Ratchet marks are parallel to the overall direction of crack propagation and are visible to the unaided eye or at low magnification.
- **rate of strain hardening**
  - Rate of change of true stress with respect to true strain in the plastic range.
- **rattail**
  - A surface imperfection on a casting, occurring as one or more irregular lines, caused by expansion of sand in the mold. Compare with buckle (2).
- **reaction sintering**
  - The sintering of a metal powder mixture consisting of at least two components that chemically react during the treatment.
- **reactive metal**

- A metal that readily combines with oxygen at elevated temperatures to form very stable oxides, for example, titanium, zirconium, and beryllium. Reactive metals may also become embrittled by the interstitial absorption of oxygen, hydrogen, and nitrogen.
- **real-time radiography**
  - A method of nondestructive inspection in which a two-dimensional radiographic image can be immediately displayed on a viewing screen or television monitor. This technique does not involve the creation of a latent image; instead, the unabsorbed radiation is converted into an optical or electronic signal, which can be viewed immediately or can be processed in near real time with electronic and video equipment. See also radiography .
- **reaming**
  - An operation in which a previously formed hole is sized and contoured accurately by using a rotary cutting tool (reamer) with one or more cutting elements (teeth). The principal support for the reamer during the cutting action is obtained from the workpiece.
- **recalcrescence**
  - (1) The increase in temperature that occurs after undercooling, because the rate of liberation of heat during transformation of a material exceeds the rate of dissipation of heat. (2) A phenomenon, associated with the transformation of  $\gamma$  iron to  $\alpha$  iron on cooling (supercooling) of iron or steel, that is revealed by the brightening (reglowing) of the metal surface owing to the sudden increase in temperature caused by the fast liberation of the latent heat of transformation. Contrast with decalcrescence .
- **recarburize**
  - (1) To increase the carbon content of molten cast iron or steel by adding carbonaceous material, high-carbon pig iron, or a high-carbon alloy. (2) To carburize a metal part to return surface carbon lost in processing; also known as carbon restoration.
- **recess**
  - A groove or depression in a surface.
- **recovery**
  - (1) The time-dependent portion of the decrease in strain following unloading of a specimen at the same constant temperature as the initial test. Recovery is equal to the total decrease in strain minus the instantaneous recovery. (2) Reduction or removal of work-hardening effects in metals without motion of large-angle grain boundaries. (3) The proportion of the desired component obtained by processing an ore, usually expressed as a percentage.
- **recrystallization**
  - (1) The formation of a new, strain-free grain structure from that existing in cold-worked metal, usually accomplished by heating. (2) The change from one crystal structure to another, as occurs on heating or cooling through a critical temperature. (3) A process, usually physical, by which one crystal species is grown at the expense of another or at the expense of others of the same substance but smaller in size. See also crystallization .
- **recrystallization annealing**
  - Annealing cold-worked metal to produce a new grain structure without phase change.
- **recrystallization temperature**
  - The approximate minimum temperature at which complete recrystallization of a cold-worked metal occurs within a specified time.
- **recrystallized grain size**
  - (1) The grain size developed by heating cold-worked metal. The time and temperature are selected so that, although recrystallization is complete, essentially no grain growth occurs. (2) In aluminum and magnesium alloys, the grain size after recrystallization, without regard to grain growth or the recrystallized conditions. See also recrystallization .
- **recuperator**
  - Equipment for transferring heat from gaseous products of combustion to incoming air or fuel. The incoming material passes through pipes surrounded by a chamber through which the outgoing gases pass.
- **red mud**
  - A residue, containing a high percentage of iron oxide, obtained in purifying bauxite in the production of alumina in the Bayer process.
- **redox potential**
  - This potential of a reversible oxidation-reduction electrode measured with respect to a reference electrode, corrected to the hydrogen electrode, in a given electrode.

- **redrawing**
  - The second and successive deep-drawing operations in which cup-like shells are deepened and reduced in cross-sectional dimensions. See also deep drawing .
- **reducing agent**
  - (1) A compound that causes reduction, thereby itself becoming oxidized. (2) A chemical that, at high temperatures, lowers the state of oxidation of other batch chemicals.
- **reducing atmosphere**
  - (1) A furnace atmosphere that tends to remove oxygen from substances or materials placed in the furnace. (2) A chemically active protective atmosphere that at elevated temperature will reduce metal oxides to their metallic state. Reducing atmosphere is a relative term and such an atmosphere may be reducing to one oxide but not to another oxide.
- **reducing flame**
  - (1) A gas flame produced with excess fuel in the inner flame. (2) A gas flame resulting from combustion of a mixture containing too much fuel or too little air. See also neutral flame and oxidizing flame .
- **reduction**
  - (1) In cupping and deep drawing, a measure of the percentage decrease from blank diameter to cup diameter, or of diameter reduction in redrawing. (2) In forging, rolling, and drawing, either the ratio of the original to final cross-sectional area or the percentage decrease in cross-sectional area. (3) A reaction in which there is a decrease in valence resulting from a gain in electrons. Contrast with oxidation .
- **reduction cell**
  - A pot or tank in which either a water solution of a salt or a fused salt is reduced electrolytically to form free metals or other substances.
- **reduction in area (RA)**
  - The difference between the original cross-sectional area of a tensile specimen and the smallest area at or after fracture as specified for the material undergoing testing. Also known as reduction of area.
- **reel**
  - (1) A spool or hub for coiling or feeding wire or strip. (2) To straighten and planish a round bar by passing it between contoured rolls.
- **reel breaks**
  - Transverse breaks or ridges on successive inner laps of a coil that results from crimping of the lead end of the coil into a gripping segmented mandrel. Also called reel kinks.
- **reference electrodes**
  - A nonpolarizable electrode with a known and highly reproducible potential used for potentiometric and voltammetric analyses. See also calomel electrode .
- **reference material**
  - In materials characterization, a material of definite composition that closely resembles in chemical and physical nature the material with which an analyst expects to deal; used for calibration or standardization. See also standard reference material .
- **refining**
  - The branch of process metallurgy dealing with the purification of crude or impure metals. Compare with extractive metallurgy .
- **reflowing**
  - Melting of an electrodeposit followed by solidification. The surface has the appearance and physical characteristics of a hot dipped surface (especially tin or tin alloy plates). Also called flow brightening .
- **refractory**
  - (1) A material (usually an inorganic, nonmetallic, ceramic material) of very high melting point with properties that make it suitable for such uses as furnace linings and kiln construction. (2) The quality of resisting heat.
- **refractory alloy**
  - (1) A heat-resistant alloy. (2) An alloy having an extremely high melting point. See also refractory metal . (3) An alloy difficult to work at elevated temperatures.
- **refractory metal**
  - A metal having an extremely high melting point and low vapor pressure; for example, niobium, tantalum, molybdenum, tungsten, and rhenium.

- **regenerator**
  - Same as recuperator except that the gaseous products or combustion heat brick checkerwork in a chamber connected to the exhaust side of the furnace while the incoming air and fuel are being heated by the brick checkerwork in a second chamber, connected to the entrance side. At intervals, the gas flow is reversed so that incoming air and fuel contact hot checkerwork while that in the second chamber is being reheated by exhaust gases.
- **regulator**
  - A device for controlling the delivery of welding or cutting gas at some substantially constant pressure.
- **reliability**
  - A quantitative measure of the ability of a product or service to fulfill its intended function for a specified period of time.
- **relieving**
  - Buffing or other abrasive treatment of the high points of an embossed metal surface to produce highlights that contrast with the finish in the recesses.
- **remanence**
  - The magnetic induction remaining in a magnetic circuit after removal of the applied magnetizing force. Sometimes called remanent induction.
- **repressing**
  - The application of pressure to a previously pressed and sintered powder metallurgy compact, usually for the purpose of improving some physical or mechanical property or for dimensional accuracy.
- **residual elements**
  - Small quantities of elements unintentionally present in an alloy.
- **residual stress**
  - (1) The stress existing in a body at rest, in equilibrium, at uniform temperature, and not subjected to external forces. Often caused by the forming or thermal processing curing process. (2) An internal stress not depending on external forces resulting from such factors as cold working, phase changes, or temperature gradients. (3) Stress present in a body that is free of external forces or thermal gradients. (4) Stress remaining in a structure or member as a result of thermal or mechanical treatment or both. Stress arises in fusion welding primarily because the weld metal contracts on cooling from the solidus to room temperature.
- **resilience**
  - (1) The amount of energy per unit volume released on unloading. (2) The capacity of a material, by virtue of high yield strength and low elastic modulus, to exhibit considerable elastic recovery on release of load.
- **resinoid wheel**
  - A grinding wheel bonded with a synthetic resin.
- **resist**
  - (1) Coating material used to mask or protect selected areas of a substrate from the action of an etchant, solder, or plating. (2) A material applied to prevent flow of brazing filler metal into unwanted areas.
- **resistance brazing**
  - A brazing process in which the heat required is obtained from the resistance to electric current flow in a circuit of which the workpiece is a part.
- **resistance seam welding**
  - A resistance welding process that produces coalescence at the faying surfaces of overlapped parts progressively along a length of a joint. The weld may be made with overlapping weld nuggets, a continuous weld nugget, or by forging the joint as it is heated to the welding temperature by resistance to the flow of the welding current.
- **resistance soldering**
  - A soldering process in which the heat required is obtained from the resistance to electric current flow in a circuit of which the workpiece is a part.
- **resistance spot welding**
  - A resistance welding process that produces coalescence at the faying surfaces of a joint by the heat obtained from resistance to the flow of welding current through the workpieces from electrodes that serve to concentrate the welding current and pressure at the weld areas.
- **resistance welding**

- A group of welding processes that produce coalescence of metals with resistance heating and pressure. See also flash welding , projection welding , resistance seam welding , and resistance spot welding .
- **resistance welding electrode**
  - The part(s) of a resistance welding machine through which the welding current and, in most cases, force are applied directly to the work. The electrode may be in the form of a rotating wheel, rotating bar, cylinder, plate, clamp, chuck, or modification thereof.
- **restraint**
  - Any external mechanical force that prevents a part from moving to accommodate changes in dimension due to thermal expansion or contraction. Often applied to weldments made while clamped in a fixture. Compare with constraint .
- **restriking**
  - (1) The striking of a trimmed but slightly misaligned or otherwise faulty forging with one or more blows to improve alignment, improve surface condition, maintain close tolerances, increase hardness, or effect other improvements. (2) A sizing operation in which coining or stretching is used to correct or alter profiles and to counteract distortion. (3) A salvage operation following a primary forging operation in which the parts involved are rehit in the same forging die in which the pieces were last forged.
- **retort**
  - A vessel used for distillation of volatile materials, as in separation of some metals and in destructive distillation of coal.
- **reverberatory furnace**
  - A furnace in which the flame used for melting the metal does not impinge on the metal surface itself, but is reflected off the walls of the roof of the furnace. The metal is actually melted by the generation of heat from the walls and the roof of the furnace.
- **reverse-current cleaning**
  - Electrolytic cleaning in which a current is passed between electrodes through a solution, and the part is set up as the anode. Also called anodic cleaning .
- **reverse drawing**
  - Redrawing of a sheet metal part in a direction opposite to that of the original drawing.
- **reverse polarity**
  - See preferred term direct current electrode positive (DCEP) .
- **reverse redrawing**
  - A second drawing operation in a direction opposite to that of the original drawing.
- **rheocasting**
  - Casting of a continuously stirred semisolid metal slurry. The process involves vigorous agitation of the melt during the early stages of solidification to break up solid dendrites into small spherulites. See also semisolid metal forming .
- **rib**
  - A long V-shaped or radiused indentation used to strengthen large sheet metal panels. (2) A long, usually thin protuberance used to provide flexural strength to a forging (as in a rib-web forging).
- **rigging**
  - The engineering design, layout, and fabrication of pattern equipment for producing castings; including a study of the casting solidification program, feeding and gating, risering, skimmers, and fitting flasks.
- **rimmed steel**
  - A low-carbon steel containing sufficient iron oxide to give a continuous evolution of carbon monoxide while the ingot is solidifying, resulting in a case or rim of metal virtually free of voids. Sheet and strip products made from rimmed steel ingots have very good surface quality.
- **ring and circle shear**
  - A cutting or shearing machine with two rotary-disk cutters driven in unison and equipped with a circle attachment for cutting inside circles or rings from sheet metal, where it is impossible to start the cut at the edge of the sheet. One cutter shaft is inclined to the other to provide cutting clearance so that the outside section remains flat and usable. See also circle shear and rotary shear .
- **ring rolling**
  - The process of shaping weldless rings from pierced disks or shaping thick-wall ring-shaped blanks between rolls that control wall thickness, ring diameter, height, and contour.

- **riser**
  - A reservoir of molten metal connected to a casting to provide additional metal to the casting, required as the result of shrinkage before and during solidification.
- **riser blocks**
  - (1) Plates or pieces inserted between the top of a metalforming press bed or bolster and the die to decrease the height of the die space. (2) Spacers placed between bed and housings to increase shut height on a four-piece tie-rod straight-side press.
- **river pattern**
  - A term used in fractography to describe a characteristic pattern of cleavage steps running parallel to the local direction of crack propagation on the fracture surfaces of grains that have separated by cleavage.
- **riveting**
  - Joining of two or more members of a structure by means of metal rivets, the unheaded end being upset after the rivet is in place.
- **roasting**
  - Heating an ore to effect some chemical change that will facilitate smelting.
- **robber**
  - An extra cathode or cathode extension that reduces the current density on what would otherwise be a high-current-density area on work being electroplated.
- **Rochelle copper**
  - (1) A copper electrodeposit obtained from copper cyanide plating solution to which Rochelle salt (sodium potassium tartrate) has been added for grain refinement, better anode corrosion, and cathode efficiency. (2) The solution from which a Rochelle copper electrodeposit is obtained.
- **rock candy fracture**
  - A fracture that exhibits separated-grain facets; most often used to describe an intergranular fracture in a large-grained metal.
- **rocking shear**
  - A type of guillotine shear that utilizes a curved blade to shear sheet metal progressively from side to side by a rocker motion.
- **Rockwell hardness number**
  - A number derived from the net increase in the depth of impression as the load on an indenter is increased from a fixed minor load to a major load and then returned to the minor load. Various scales of Rockwell hardness numbers have been developed based on the hardness of the materials to be evaluated. The scales are designated by alphabetic suffixes to the hardness designation. For example, 64 HRC represents the Rockwell hardness number of 64 on the Rockwell C scale. See also Rockwell superficial hardness number .
- **Rockwell hardness test**
  - An indentation hardness test using a calibrated machine that utilizes the depth of indentation, under constant load, as a measure of hardness. Either a 120° diamond cone with a slightly rounded point or a 1.6 or 3.2 mm ( $\frac{1}{16}$  or  $\frac{1}{8}$  in.) diam steel ball is used as the indenter.
- **Rockwell superficial hardness number**
  - Like the Rockwell hardness number, the superficial Rockwell number is expressed by the symbol HR followed by a scale designation. For example, 81 HR30N represents the Rockwell superficial hardness number of 81 on the Rockwell 30N scale.
- **Rockwell superficial hardness test**
  - The same test as used to determine the Rockwell hardness number except that smaller minor and major loads are used. In Rockwell testing, the minor load is 10 kgf, and the major load is 60, 100, or 150 kgf. In superficial Rockwell testing, the minor load is 3 kgf, and major loads are 15, 30, or 45 kgf. In both tests, the indenter may be either a diamond cone or a steel ball, depending principally on the characteristics of the material being tested.
- **rod**
  - A solid round metal section 9.5 mm ( $\frac{3}{8}$  in.) or greater in diameter, whose length is great in relation to its diameter.
- **rod mill**
  - (1) A hot mill for rolling rod. (2) A mill for fine grinding, somewhat similar to a ball mill, but employing long steel rods instead of balls to effect grinding.
- **roll bending**

- Curving sheets, bars, and sections by means of rolls. See also bending rolls .
- **roll compacting**
  - Progressive compacting of metal powders by use of a rolling mill.
- **roller hearth furnace**
  - A modification of the pusher-type continuous furnace that provides for rollers in the hearth or muffle of the furnace whereby friction is greatly reduced and lightweight trays can be used repeatedly without risk of unacceptable distortion and damage to the work. See also pusher furnace .
- **roller leveler breaks**
  - Obvious transverse breaks usually about 3 to 6 mm ( $\frac{1}{8}$  to  $\frac{1}{4}$  in.) apart caused by the sheet metal fluting during roller leveling. These will not be removed by stretching.
- **roller leveler lines**
  - Same as leveler lines .
- **roller leveling**
  - Leveling by passing flat sheet metal stock through a machine having a series of small-diameter staggered rolls that are adjusted to produce repeated reverse bending.
- **roller stamping die**
  - An engraved roller used for impressing designs and markings on sheet metal.
- **roll flattening**
  - The flattening of metal sheets that have been rolled in packs by passing them separately through a two-high cold mill with virtually no deformation. Not to be confused with roller leveling .
- **roll forging**
  - A process of shaping stock between two driven rolls that rotate in opposite directions and have one or more matching sets of grooves in the rolls; used to produce finished parts or preforms for subsequent forging operations.
- **roll forming**
  - Metalforming through the use of power-driven rolls whose contour determines the shape of the product; sometimes used to denote power spinning.
- **rolling**
  - The reduction of the cross-sectional area of metal stock, or the general shaping of metal products, through the use of rotating rolls. See also rolling mills .
- **rolling-contact fatigue**
  - Repeated stressing of a solid surface due to rolling contact between it and another solid surface or surfaces. Continued rolling-contact fatigue of bearing or gear surfaces may result in rolling-contact damage in the form of subsurface fatigue cracks and/or material pitting and spallation.
- **rolling mills**
  - Machines used to decrease the cross-sectional area of metal stock and to produce certain desired shapes as the metal passes between rotating rolls mounted in a framework comprising a basic unit called a stand. Cylindrical rolls produce flat shapes; grooved rolls produce rounds, squares, and structural shapes. See also four-high mill , Sendzimir mill , and two-high mill .
- **roll straightening**
  - The straightening of metal stock of various shapes by passing it through a series of staggered rolls, the rolls usually being in horizontal and vertical planes, or by reeling in two-roll straightening machines.
- **roll threading**
  - See preferred term thread rolling .
- **roll welding**
  - Solid-state welding in which metals are heated, then welded together by applying pressure, with rolls, sufficient to cause deformation at the faying surfaces. See also forge welding .
- **root crack**
  - A crack in either the weld or heat-affected zone at the root of a weld.
- **rosette**
  - (1) Rounded configuration of microconstituents in metals arranged in whorls or radiating from a center. (2) Strain gages arranged to indicate at a single position strains in three different directions.
- **rotary forging**

- A process in which the workpiece is pressed between a flat anvil and a swiveling (rocking) die with a conical working face; the platens move toward each other during forging. Also called orbital forging. Compare with radial forging .
- **rotary furnace**
  - A circular furnace constructed so that the hearth and workpieces rotate around the axis of the furnace during heating. Also called rotary hearth furnace.
- **rotary press**
  - A machine for forming powder metallurgy parts that is fitted with a rotating table carrying multiple die assemblies in which powder is compacted.
- **rotary retort furnace**
  - A continuous-type furnace in which the work advances by means of an internal spiral, which gives good control of the retention time within the heated chamber.
- **rotary shear**
  - A sheet metal cutting machine with two rotating-disk cutters mounted on parallel shafts driven in unison.
- **rotary swager**
  - A swaging machine consisting of a power-driven ring that revolves at high speed, causing rollers to engage cam surfaces and force the dies to deliver hammerlike blows on the work at high frequency. Both straight and tapered sections can be produced.
- **rotary swaging**
  - A bulk forming process for reducing the cross-sectional area or otherwise changing the shape of bars, tubes, or wires by repeated radial blows with one or more pairs of opposed dies.
- **rouge finish**
  - A highly reflective finish produced with rouge (finely divided, hydrated iron oxide) or other very fine abrasive, similar in appearance to the bright polish or mirror finish on sterling silver utensils.
- **rough blank**
  - A blank for a metalforming or drawing operation, usually of irregular outline, with necessary stock allowance for process metal, which is trimmed after forming or drawing to the desired size.
- **rough grinding**
  - Grinding without regard to finish, usually to be followed by a subsequent operation.
- **roughing stand**
  - The first stand (or several stands) of rolls through which a reheated billet passes in front of the finishing stands. See also rolling mills and stand .
- **rough machining**
  - Machining without regard to finish, usually to be followed by a subsequent operation.
- **roughness**
  - (1) Relatively finely spaced surface irregularities, the heights, widths, and directions of which establish the predominant surface pattern. (2) The microscopic peak-to-valley distances of surface protuberances and depressions. See also surface roughness .
- **rubber forming**
  - Forming a sheet metal wherein rubber or another resilient material is used as a functional die part. Processes in which rubber is employed only to contain the hydraulic fluid are not classified as rubber forming.
- **rubber-pad forming**
  - A sheet metal forming operation for shallow parts in which a confined, pliable rubber pad attached to the press slide (ram) is forced by hydraulic pressure to become a mating die for a punch or group of punches placed on the press bed or baseplate. Also known as the Guerin process . Variations of the Guerin process include the fluid-cell process , fluid forming , and Marforming process .
- **rubber wheel**
  - A grinding wheel made with a rubber bond.
- **runner**
  - (1) A channel through which molten metal flows from one receptacle to another. (2) The portion of the gate assembly of a casting that connects the sprue with the gate(s). (3) Parts of patterns and finished castings corresponding to the portion of the gate assembly described in (2).
- **runner box**
  - A distribution box that divides molten metal into several streams before it enters the casting mold cavity.

- **runout**
  - (1) The unintentional escape of molten metal from a mold, crucible, or furnace. (2) An imperfection in a casting caused by the escape of metal from the mold.
- **rupture stress**
  - The stress at failure. Also known as breaking stress or fracture stress .
- **rust**
  - A visible corrosion product consisting of hydrated oxides of iron. Applied only to ferrous alloys. See also white rust .
- **S**
- **sacrificial protection**
  - Reduction of corrosion of a metal in an electrolyte by galvanically coupling it to a more anodic metal; a form of cathodic protection.
- **saddling**
  - Forming a seamless metal ring by forging a pierced disk over a mandrel (or saddle).
- **sag**
  - An increase or decrease in the section thickness of a casting caused by insufficient strength of the mold sand of the cope or of the core.
- **salt bath heat treatment**
  - Heat treatment for metals carried out in a bath of molten salt.
- **salt fog test**
  - An accelerated corrosion test in which specimens are exposed to a fine mist of a solution usually containing sodium chloride, but sometimes modified with other chemicals. Also known as salt spray test.
- **salt spray test**
  - See salt fog test .
- **sample**
  - (1) One or more units of a product (or a relatively small quantity of a bulk material) withdrawn from a lot or process stream and then tested or inspected to provide information about the properties, dimensions, or other quality characteristics of the lot or process stream. (2) A portion of a material intended to be representative of the whole.
- **sand**
  - A granular material naturally or artificially produced by the disintegration or crushing of rocks or mineral deposits. In casting, the term denotes an aggregate, with an individual particle (grain) size of 0.06 to 2 mm (0.002 to 0.08 in.) in diameter, that is largely free of finer constituents, such as silt and clay, which are often present in natural sand deposits. The most commonly used foundry sand is silica; however, zircon, olivine, aluminum silicates, and other crushed ceramics are used for special applications.
- **sandblasting**
  - Abrasive blasting with sand. See also blasting or blast cleaning and compare with shotblasting .
- **sand casting**
  - Metal castings produced in sand molds.
- **sand hole**
  - A pit in the surface of a sand casting resulting from a deposit of loose sand on the surface of the mold.
- **sandwich rolling**
  - Rolling two or more strips of metal in a pack, sometimes to form a roll-welded composite.
- **satin finish**
  - A diffusely reflecting surface finish on metals, lustrous but not mirrorlike. One type is a butler finish.
- **saw gumming**
  - In saw manufacture, grinding away of punch marks or milling marks in the gullets (spaces between the teeth) and, in some cases, simultaneous sharpening of the teeth; in reconditioning of worn saws, restoration of the original gullet size and shape.
- **sawing**
  - Using a toothed blade or disk to sever parts or cut contours.
- **scab**
  - A defect on the surface of a casting that appears as a rough, slightly raised surface blemish, crusted over by a thin porous layer of metal, under which is a honeycomb or cavity that usually

contains a layer of sand; defect common to thin-wall portions of the casting or around hot areas of the mold.

- **scale**
  - Surface oxidation, consisting of partially adherent layers of corrosion products, left on metals by heating or casting in air or in other oxidizing atmospheres.
- **scale pit**
  - (1) A surface depression formed on a forging due to scale remaining in the dies during the forging operation. (2) A pit in the ground in which scale (such as that carried off by cooling water from rolling mills) is allowed to settle out as one step in the treatment of effluent waste water.
- **scaling**
  - (1) Forming a thick layer of oxidation products on metals at high temperature. Scaling should be distinguished from rusting, which involves the formation of hydrated oxides. See also rust . (2) Depositing water-insoluble constituents on a metal surface, as in cooling tubes and water boilers.
- **scalping**
  - Removing surface layers from an ingot, billet, or slab.
- **scanning Auger microscopy (SAM)**
  - An analytical technique that measures the lateral distribution of elements on the surface of a material by recording the intensity of their Auger electrons versus the position of the electron beam.
- **scarfing**
  - Cutting surface areas of metal objects, ordinarily by using an oxyfuel gas torch. The operation permits surface imperfections to be cut from ingots, billets, or the edges of plate that are to be beveled for butt welding. See also chipping .
- **Scleroscope hardness number (HSc or HSd)**
  - A number related to the height of rebound of a diamond-tipped hammer dropped on the material being tested. It is measured on a scale determined by dividing into 100 units the average rebound of the hammer from a quenched (to maximum hardness) and untempered AISI W-5 tool steel test block.
- **Scleroscope hardness test**
  - A dynamic indentation hardness test using a calibrated instrument that drops a diamond-tipped hammer from a fixed height onto the surface of the material being tested. The height of rebound of the hammer is a measure of the hardness of the material.
- **scorification**
  - Oxidation, in the presence of fluxes, of molten lead containing precious metals, to partly remove the lead in order to concentrate the precious metals.
- **scoring**
  - (1) The formation of severe scratches in the direction of sliding. (2) The act of producing a scratch or narrow groove in a surface by causing a sharp instrument to move along that surface. (3) The marring or scratching of any formed metal part by metal pickup on the punch or die. (4) The reduction in thickness of a material along a line to weaken it intentionally along that line.
- **scouring**
  - (1) A wet or dry cleaning process involving mechanical scrubbing. (2) A wet or dry mechanical finishing operation, using fine abrasive and low pressure, carried out by hand or with a cloth or wire wheel to produce satin or butler-type finishes.
- **scrap**
  - (1) Products that are discarded because they are defective or otherwise unsuitable for sale. (2) Discarded metallic material, from whatever source, that may be reclaimed through melting and refining.
- **scratch hardness**
  - The hardness of a metal determined by the width of a scratch made by drawing a cutting point across the surface under a given pressure.
- **screen**
  - (1) The woven wire or fabric cloth, having square openings, used in a sieve for retaining particles greater than the particular mesh size. U.S. standard, ISO, or Tyler screen sizes are commonly used. (2) One of a set of sieves, designated by the size of the openings, used to classify granular aggregates such as sand, ore, or coke by particle size. (3) A perforated sheet placed in the gating system of a mold to separate impurities from the molten metal.
- **screw dislocation**

- See dislocation .
- **screw press**
  - A high-speed press in which the ram is activated by a large screw assembly powered by a drive mechanism.
- **scuffing**
  - (1) Localized damage caused by the occurrence of solid-phase welding between sliding surfaces, without local surface melting. (2) A mild degree of galling that results from the welding of asperities due to frictional heat. The welded asperities break, causing surface degradation.
- **seal coat**
  - Material applied to infiltrate the pores of a thermal spray deposit.
- **sealing**
  - (1) Closing pores in anodic coatings to render them less absorbent. (2) Plugging leaks in a casting by introducing thermosetting plastics into porous areas and subsequently setting the plastic with heat.
- **seal weld**
  - Any weld designed primarily to provide a specific degree of tightness against leakage.
- **seam**
  - (1) On a metal surface, an unwelded fold or lap that appears as a crack, usually resulting from a discontinuity. (2) A surface defect on a casting related to but of lesser degree than a cold shut . (3) A ridge on the surface of a casting caused by a crack in the mold face.
- **seam weld**
  - A continuous weld made between or upon overlapping members, in which coalescence may start and occur on the faying surfaces, or may have proceeded from the outer surface of one member. The continuous weld may consist of a single weld bead or a series of overlapping spot welds.
- **seam welding**
  - See arc seam weld and resistance seam welding .
- **season cracking**
  - An obsolete historical term usually applied to stress-corrosion cracking of brass.
- **secondary alloy**
  - Any alloy whose major constituent is obtained from recycled scrap metal.
- **secondary creep**
  - See creep.
- **secondary ion mass spectroscopy (SIMS)**
  - An analytical technique that measures the masses of ions emitted from the surface of a material when exposed to a beam of incident ions. The incident ions are usually monoenergetic and are all of the same species, for example, 5 keV Ne<sup>+</sup> ions.
- **secondary metal**
  - Metal recovered from scrap by remelting and refining.
- **sectioning**
  - The removal of a conveniently sized, representative specimen from a larger sample for metallographic inspection. Sectioning methods include shearing, sawing (using hacksaws, band saws, and diamond wire saws), abrasive cutting, and electrical discharge machining.
- **segment die**
  - A die made of parts that can be separated for ready removal of the workpiece. Synonymous with split die .
- **segregation**
  - (1) Nonuniform distribution of alloying elements, impurities, or microphases in metals and alloys. (2) A casting defect involving a concentration of alloying elements at specific regions, usually as a result of the primary crystallization of one phase with the subsequent concentration of other elements in the remaining liquid. Microsegregation refers to normal segregation on a microscopic scale in which material richer in an alloying element freezes in successive layers on the dendrites (coring) and in constituent network. Macrosegregation refers to gross differences in concentration (for example, from one area of a casting to another). See also inverse segregation and normal segregation .
- **segregation banding**
  - Inhomogeneous distribution of alloying elements aligned in filaments or plates parallel to the direction of working.
- **seizing**

- The stopping of a moving part by a mating surface as a result of excessive friction.
- **seizure**
  - The stopping of relative motion as the result of interfacial friction. Seizure may be accompanied by gross surface welding. The term is sometimes used to denote scuffing .
- **Sejournet process**
  - See Ugine-Sejournet process .
- **selective heating**
  - Intentionally heating only certain portions of a workpiece.
- **selective leaching**
  - Corrosion in which one element is preferentially removed from an alloy, leaving a residue (often porous) of the elements that are more resistant to the particular environment. Also called dealloying or parting. See also decarburization , decobaltification , denickelification , dezincification , and graphitic corrosion .
- **selective quenching**
  - Quenching only certain portions of an object.
- **self-diffusion**
  - Thermally activated movement of an atom to a new site in a crystal of its own species, as, for example, a copper atom within a crystal of copper.
- **self-hardening steel**
  - See preferred term air-hardening steel .
- **self-lubricating material**
  - Any solid material that shows low friction without application of a lubricant.
- **semiautomatic arc welding**
  - Arc welding with equipment that controls only the filler metal feed. The advance of the welding is manually controlled.
- **semiautomatic plating**
  - Plating in which prepared cathodes are mechanically conveyed through the plating baths, with intervening manual transfers.
- **semiconductor**
  - A solid crystalline material whose electrical resistivity is intermediate between that of a metal conductor and an insulator, ranging from about  $10^{-3}$  to  $10^8 \Omega \cdot \text{cm}$ , and is usually strongly temperature dependent.
- **semifinisher**
  - An impression in a series of forging dies that only approximates the finish dimensions of the forging. Semifinishers are often used to extend die life or the finishing impression, to ensure proper control of grain flow during forging, and to assist in obtaining desired tolerances.
- **semifinishing**
  - Preliminary operations performed prior to finishing.
- **semiguided bend**
  - The bend obtained by applying a force directly to the specimen in the portion that is to be bent. The specimen is either held at one end and forced around a pin or rounded edge or is supported near the ends and bent by a force applied on the side of the specimen opposite the supports and midway between them. In some instances, the bend is started in this manner and finished in the manner of a free bend.
- **semikilled steel**
  - Steel that is incompletely deoxidized and contains sufficient dissolved oxygen to react with the carbon to form carbon monoxide and thus offset solidification shrinkage.
- **semipermanent mold**
  - A permanent mold in which sand cores or plaster are used.
- **semisolid metal forming**
  - A two-step casting/forging process in which a billet is cast in a mold equipped with a mixer that continuously stirs the thixotropic melt, thereby breaking up the dendritic structure of the casting into a fine-grained spherical structure. After cooling, the billet is stored for subsequent use. Later, a slug from the billet is cut, heated to the semisolid state, and forged in a die. Normally the cast billet is forged when 30 to 40% is in the liquid state. See also rheocasting .
- **sensitization**
  - In austenitic stainless steels, the precipitation of chromium carbides, usually at grain boundaries, on exposure to temperatures of about 540 to 845 °C (about 1000 to 1550 °F), leaving the grain

boundaries depleted of chromium and therefore susceptible to preferential attack by a corroding medium. Welding is the most common cause of sensitization. Weld decay (sensitization) caused by carbide precipitation in the weld heat-affected zone leads to intergranular corrosion.

- **sensitizing heat treatment**
  - A heat treatment, whether accidental, intentional, or incidental (as during welding), that causes precipitation of constituents at grain boundaries, often causing the alloy to become susceptible to intergranular corrosion or intergranular stress-corrosion cracking. See also sensitization .
- **Sendzimir mill**
  - A type of cluster mill with small-diameter work rolls and larger-diameter backup rolls, backed up by bearings on a shaft mounted eccentrically so that it can be rotated to increase the pressure between the bearing and the backup rolls. Used to roll precision and very thin sheet and strip.
- **series welding**
  - Resistance welding in which two or more spot, seam, or projection welds are made simultaneously by a single welding transformer with three or more electrodes forming a series circuit.
- **settling**
  - (1) Separation of solids from suspension in a fluid of lower density, solely by gravitational effects. (2) A process for removing iron from liquid magnesium alloys by holding the melt at a low temperature after manganese has been added to it.
- **severity of quench**
  - Ability of quenching medium to extract heat from a hot steel workpiece; expressed in terms of the Grossmann number (H).
- **shadowing**
  - Directional deposition of carbon or a metallic film on a plastic replica so as to highlight features to be analyzed by transmission electron microscopy. Most often used to provide maximum detail and resolution of the features of fracture surfaces.
- **shakeout**
  - Removal of castings from a sand mold. See also knockout .
- **shaker-hearth furnace**
  - A continuous type furnace that uses a reciprocating shaker motion to move the parts along the hearth.
- **shank**
  - (1) The portion of a die or tool by which it is held in position in a forging unit or press. (2) The handle for carrying a small ladle or crucible. (3) The main body of a lathe tool. If the tool is an inserted type, the shank is the portion that supports the insert.
- **shank-type cutter**
  - A cutter having a straight or tapered shank to fit into a machine-tool spindle or adapter.
- **shape memory alloys**
  - A group of metallic materials that demonstrate the ability to return to some previously defined shape or size when subjected to the appropriate thermal procedure.
- **shaping**
  - Producing flat surfaces using single-point tools. The work is held in a vise or fixture or is clamped directly to the table. The ram supporting the tool is reciprocated in a linear motion past the work.
- **shatter crack**
  - See flake .
- **shaving**
  - (1) As a finishing operation, the accurate removal of a thin layer of a work surface by straightline motion between a cutter and the surface. (2) Trimming parts such as stampings, forgings, and tubes to remove uneven sheared edges or to improve accuracy.
- **shear**
  - (1) The type of force that causes or tends to cause two contiguous parts of the same body to slide relative to each other in a direction parallel to their plane of contact. (2) A machine or tool for cutting metal and other material by the closing motion of two sharp, closely adjoining edges; for example, squaring shear and circular shear. (3) An inclination between two cutting edges, such as between two straight knife blades or between the punch cutting edge and the die cutting edge, so that a reduced area will be cut each time. This lessens the necessary force, but increases the

required length of the working stroke. This method is referred to as angular shear. (4) The act of cutting by shearing dies or blades, as in shearing lines.

- **shear angle**
  - The angle that the shear plane, in metal cutting, makes with the work surface.
- **shear bands**
  - (1) Bands of very high shear strain that are observed during rolling of sheet metal. During rolling, these form at approximately  $35^\circ$  to the rolling plane, parallel to the transverse direction. They are independent of grain orientation and at high strain rates traverse the entire thickness of the rolled sheet. (2) Highly localized deformation zones in metals that are observed at very high strain rates, such as those produced by high velocity (100 to 3600 m/s, or 330 to 11,800 ft/s) projectile impacts or explosive rupture.
- **shear fracture**
  - A mode of fracture in crystalline materials resulting from translation along slip planes that are preferentially oriented in the direction of the shearing stress.
- **shear ledges**
  - See radial marks .
- **shear lip**
  - A narrow, slanting ridge along the edge of a fracture surface. The term sometimes also denotes a narrow, often crescent-shaped, fibrous region at the edge of a fracture that is otherwise of the cleavage type, even though this fibrous region is in the same plane as the rest of the fracture surface.
- **shear modulus ( $G$ )**
  - The ratio of shear stress to the corresponding shear strain for shear stresses below the proportional limit of the material. Values of shear modulus are usually determined by torsion testing. Also known as modulus of rigidity.
- **shear plane**
  - A confined zone along which shear takes place in metal cutting. It extends from the cutting edge to the work surface.
- **shear strain**
  - The tangent of the angular change, caused by a force between two lines originally perpendicular to each other through a point in a body. Also called angular strain.
- **shear stress**
  - (1) The stress component tangential to the plane on which the forces act. (2) A stress that exists when parallel planes in metal crystals slide across each other.
- **sheet**
  - A flat-rolled metal product of some maximum thickness and minimum width arbitrarily dependent on the type of metal. It has a width-to-thickness ratio greater than about 50. Generally, such flat products under 6.5 mm ( $\frac{1}{4}$  in.) thick are called sheets, and those 6.5 mm ( $\frac{1}{4}$  in.) thick and over are called plates.
- **sheet forming**
  - The plastic deformation of a piece of sheet metal by tensile loads into a three-dimensional shape, often without significant changes in sheet thickness or surface characteristics. Compare with bulk forming .
- **shelf roughness**
  - Roughness on upward-facing surfaces where undissolved solids have settled on parts during a plating operation.
- **shell**
  - (1) A hollow structure or vessel. (2) An article formed by deep drawing. (3) The metal sleeve remaining when a billet is extruded with a dummy block of somewhat smaller diameter. (4) In shell molding, a hard layer of sand and thermosetting plastic or resin formed over a pattern and used as the mold wall. (5) A tubular casting used in making seamless drawn tube. (6) A pierced forging.
- **shell core**
  - A shell-molded sand core.
- **shell hardening**
  - A surface-hardening process in which a suitable steel workpiece, when heated through and quench hardened, develops a martensite layer or shell that closely follows the contour of the

piece and surrounds a core of essentially pearlitic transformation product. This result is accomplished by a proper balance among section size, steel hardenability, and severity of quench.

- **shelling**
  - (1) A term used in railway engineering to describe an advanced phase of spalling. (2) A mechanism of deterioration of coated abrasive products in which entire abrasive grains are removed from the coating that holds the abrasive to the backing layer of the product.
- **shell molding**
  - A foundry process in which a mold is formed from thermosetting resin-bonded sand mixtures brought in contact with preheated (150 to 260 °C, or 300 to 500 °F) metal patterns, resulting in a firm shell with a cavity corresponding to the outline of the pattern. Also called Croning process .
- **shielded metal arc cutting**
  - A metal arc cutting process in which metals are severed by melting them with the heat of an arc between a covered metal electrode and the base metal.
- **shielded metal arc welding (SMAW)**
  - An arc welding process that produces coalescence of metals by heating them with an arc between a covered metal electrode and the workpieces. Shielding is obtained from decomposition of the electrode covering. Pressure is not used, and filler metal is obtained from the electrode. Also commonly referred to as stick welding.
- **shielding gas**
  - (1) Protective gas used to prevent atmospheric contamination during welding. (2) A stream of inert gas directed at the substrate during thermal spraying so as to envelop the plasma flame and substrate; intended to provide a barrier to the atmosphere in order to minimize oxidation.
- **shift**
  - A casting imperfection caused by mismatch of cope and drag or of cores and molds.
- **shim**
  - A thin piece of material used between two surfaces to obtain a proper fit, adjustment, or alignment.
- **shimmy die**
  - See flat edge trimmer .
- **shock load**
  - The sudden application of an external force that results in a very rapid buildup of stress--for example, piston loading in internal combustion engines.
- **shoe**
  - (1) A metal block used in a variety of bending operations to form or support the part being processed. (2) An anvil cap or sow block.
- **Shore hardness test**
  - Same as Scleroscope hardness test .
- **short-circuiting transfer**
  - In consumable electrode arc welding, a type of metal transfer similar to globular transfer, but in which the drops are so large that the arc is short circuited momentarily during the transfer of each drop to the weld pool. Compare with globular transfer and spray transfer .
- **shortness**
  - A form of brittleness in metal. It is designated as cold shortness or hot shortness to indicate the temperature range in which the brittleness occurs.
- **short transverse**
  - See transverse direction .
- **shot**
  - (1) Small, spherical particles of metal. (2) The injection of molten metal into a die casting die. The metal is injected so quickly that it can be compared to the shooting of a gun.
- **shotblasting**
  - Blasting with metal shot; usually used to remove deposits or mill scale more rapidly or more effectively than can be done by sandblasting.
- **shot peening**
  - A method of cold working metals in which compressive stresses are induced in the exposed surface layers of parts by the impingement of a stream of shot, directed at the metal surface at high velocity under controlled conditions.
- **shotting**

- The production of shot by pouring molten metal in finely divided streams. Solidified spherical particles are formed during descent in a tank of water.
- **shrinkage**
  - (1) The contraction of metal during cooling after hot forging. Die impressions are made oversize according to precise shrinkage scales to allow the forgings to shrink to design dimensions and tolerances. (2) See casting shrinkage .
- **shrinkage cavity**
  - A void left in cast metal as a result of solidification shrinkage. Shrinkage cavities can appear as either isolated or interconnected irregularly shaped voids. See also casting shrinkage .
- **shrinkage cracks**
  - Cracks that form in metal as a result of the pulling apart of grains by contraction before complete solidification. See also hot tear .
- **shrinkage rule**
  - A measuring ruler with graduations expanded to compensate for the change in the dimensions of the solidified casting as it cools in the mold.
- **shroud**
  - A protective, refractory-lined metal-delivery system to prevent reoxidation of molten steel when it is poured from ladle to tundish to mold during continuous casting.
- **shut height**
  - For a metalforming press, the distance from the top of the bed to the bottom of the slide with the stroke down and adjustment up. In general, it is the maximum die height that can be accommodated for normal operation, taking the bolster plate into consideration. See also bolster .
- **side milling**
  - Milling with cutters having peripheral and side teeth. They are usually profile sharpened but may be form relieved.
- **sieve**
  - A standard wire mesh or screen used in graded sets to determine the mesh size or particle size distribution of particulate and granular solids. See also sieve analysis .
- **sieve analysis**
  - A method of determining particle size distribution, usually expressed as the weight percentage retained upon each of a series of standard screens of decreasing mesh size.
- **sieve classification**
  - The separation of powder into particle size ranges by the use of a series of graded sieves. Also called screen analysis.
- **sieve fraction**
  - That portion of a powder sample that passes through a sieve of specified number and is retained by some finer mesh sieve of specified number. See also sieve analysis .
- **sigma phase**
  - A hard, brittle, nonmagnetic intermediate phase with a tetragonal crystal structure, containing 30 atoms per unit cell, space group,  $P4/mnm$ , occurring in many binary and ternary alloys of the transition elements. The composition of this phase in the various systems is not the same, and the phase usually exhibits a wide range in homogeneity. Alloying with a third transition element usually enlarges the field homogeneity and extends it deep into the ternary section.
- **sigma-phase embrittlement**
  - Embrittlement of iron-chromium alloys (most notably austenitic stainless steels) caused by precipitation at grain boundaries of the hard, brittle intermetallic  $\sigma$  phase during long periods of exposure to temperatures between approximately 560 and 980 °C (1050 and 1800 °F). Sigma-phase embrittlement results in severe loss in toughness and ductility and can make the embrittled material susceptible to intergranular corrosion. See also sensitization .
- **siliconizing**
  - Diffusing silicon into solid metal, usually low-carbon steels, at an elevated temperature in order to improve corrosion or wear resistance.
- **silky fracture**
  - A metal fracture in which the broken metal surface has a fine texture, usually dull in appearance. Characteristic of tough and strong metals. Contrast with crystalline fracture and granular fracture .
- **silver soldering**

- Nonpreferred term used to denote brazing with a silver-base filler metal. See preferred terms furnace brazing , induction brazing , and torch brazing .
- **single-action press**
  - A metalforming press that provides pressure from one side.
- **single impulse welding**
  - A resistance welding process variation in which spot, projection, or upset welds are made with a single impulse.
- **single-point tool**
  - A cutting tool having one face and one continuous cutting edge.
- **single-stand mill**
  - A rolling mill designed such that the product contacts only two rolls at a given moment. Contrast with tandem mill .
- **single welded joint**
  - In arc and gas welding, any joint welded from one side only.
- **sinkhead**
  - Same as riser .
- **sinking**
  - (1) The operation of machining the impression of a desired forging into die blocks. (2) See tube sinking .
- **sintered density**
  - The quotient of the mass (weight) over the volume of the sintered body expressed in grams per cubic centimeter.
- **sintering**
  - The bonding of adjacent surfaces of particles in a mass of powder or a compact by heating. Sintering strengthens a powder mass and normally produces densification and, in powdered metals, recrystallization. See also liquid phase sintering and solid-state sintering .
- **size effect**
  - Effect of the dimensions of a piece of metal on its mechanical and other properties and on manufacturing variables such as forging reduction and heat treatment. In general, the mechanical properties are lower for a larger size.
- **sizing**
  - (1) Secondary forming or squeezing operations needed to square up, set down, flatten, or otherwise correct surfaces to produce specified dimensions and tolerances. See also restriking . (2) Some burnishing, broaching, drawing, and shaving operations are also called sizing. (3) A finishing operation for correcting ovality in tubing. (4) Final pressing of a sintered powder metallurgy part to obtain a desired dimension.
- **skelp**
  - The starting stock for making welded pipe or tubing; most often it is strip stock of suitable width, thickness, and edge configuration.
- **skim gate**
  - In foundry practice, a gating arrangement designed to prevent the passage of slag and other undesirable materials into a casting.
- **skimming**
  - Removing or holding back dirt or slag from the surface of the molten metal before or during pouring.
- **skin**
  - A thin outside metal layer, not formed by bonding as in cladding or electroplating, that differs in composition, structure, or other characteristics from the main mass of metal.
- **skin lamination**
  - In flat-rolled metals, a surface rupture resulting from the exposure of a subsurface lamination by rolling.
- **skin pass**
  - See temper rolling .
- **skiving**
  - (1) Removal of a material in thin layers or chips with a high degree of shear or slippage, or both, of the cutting tool. (2) A machining operation in which the cut is made with a form tool with its face so angled that the cutting edge progresses from one end of the work to the other as the tool feeds tangentially past the rotating workpiece.

- **skull**
  - (1) A layer of solidified metal or dross on the walls of a pouring vessel after the metal has been poured. (2) The unmelted residue from a liquated weld filler metal.
- **slab**
  - A flat-shaped semifinished rolled metal ingot with a width not less than 250 mm (10 in.) and a cross-sectional area not less than 105 cm<sup>2</sup> (16 in.<sup>2</sup>).
- **slabbing mill**
  - A primary mill that produces slabs.
- **slab milling**
  - See preferred term peripheral milling .
- **slack quenching**
  - The incomplete hardening of steel due to quenching from the austenitizing temperature at a rate slower than the critical cooling rate for the particular steel, resulting in the formation of one or more transformation products in addition to martensite.
- **slag**
  - A nonmetallic product resulting from the mutual dissolution of flux and nonmetallic impurities in smelting, refining, and certain welding operations (see, for example, electrosag welding ). In steelmaking operations, the slag serves to protect the molten metal from the air and to extract certain impurities.
- **slag inclusion**
  - (1) Slag or dross entrapped in a metal. (2) Nonmetallic solid material entrapped in weld metal or between weld metal and base metal.
- **slant fracture**
  - A type of fracture in metals, typical of plane-stress fractures, in which the plane of separation is inclined at an angle (usually about 45°) to the axis of applied stress.
- **slide**
  - The main reciprocating member of a metalforming press, guided in the press frame, to which the punch or upper die is fastened; sometimes called the ram . The inner slide of a double-action press is called the plunger or punch-holder slide; the outer slide is called the blankholder slide. The third slide of a triple-action press is called the lower slide, and the slide of a hydraulic press is often called the platen.
- **slime**
  - (1) A material of extremely fine particle size encountered in ore treatment. (2) A mixture of metals and some insoluble compounds that forms on the anode in electrolysis.
- **slip**
  - Plastic deformation by the irreversible shear displacement (translation) of one part of a crystal relative to another in a definite crystallographic direction and usually on specific crystallographic plane. Sometimes called glide.
- **slip band**
  - A group of parallel slip lines so closely spaced as to appear as a single line when observed under an optical microscope. See also slip line .
- **slip direction**
  - The crystallographic direction in which the translation of slip takes place.
- **slip flask**
  - A tapered flask that depends on a movable strip of metal to hold foundry sand in position. After closing the mold, the strip is refracted and the flask can be removed and reused. Molds thus made are usually supported by a mold jacket during pouring.
- **slip line**
  - Visible traces of slip planes on metal surfaces; the traces are (usually) observable only if the surface has been polished before deformation. The usual observation on metal crystals (under a light microscope) is of a cluster of slip lines known as a slip band .
- **slip plane**
  - The crystallographic plane in which slip occurs in a crystal.
- **slitting**
  - Cutting or shearing along single lines to cut strips from a metal sheet or to cut along lines of a given length or contour in a sheet or workpiece.
- **sliver**

- An imperfection consisting of a very thin elongated piece of metal attached by only one end to the parent metal into whose surface it has been worked.
- **slot furnace**
  - A common batch furnace for heat treating metals where stock is charged and removed through a slot or opening.
- **slotting**
  - Cutting a narrow aperture or groove with a reciprocating tool in a vertical shaper or with a cutter, broach, or grinding wheel.
- **slow strain rate technique**
  - An experimental technique for evaluating susceptibility to stress-corrosion cracking. It involves pulling the specimen to failure in uniaxial tension at a controlled slow strain rate while the specimen is in the test environment and examining the specimen for evidence of stress-corrosion cracking.
- **slug**
  - (1) A short piece of metal to be placed in a die for forging or extrusion. (2) A small piece of material produced by piercing a hole in sheet material. See also blank .
- **slugging**
  - The act of adding a separate piece or pieces of material in a joint before or during welding that results in a welded joint not complying with design, drawing, or specification requirements.
- **slush casting**
  - A hollow casting usually made of an alloy with a low but wide melting temperature range. After the desired thickness of metal has solidified in the mold, the remaining liquid is poured out. Considered an obsolete practice.
- **smelting**
  - Thermal processing wherein chemical reactions take place to produce liquid metal from a beneficiated ore.
- **smith forging**
  - See hand forge (smith forge) .
- **smut**
  - A reaction product sometimes left on the surface of a metal after pickling, electroplating, or etching.
- **snagging**
  - (1) Heavy stock removal of superfluous material from a workpiece by using a portable or swing grinder mounted with a coarse grain abrasive wheel. (2) Offhand grinding on castings and forgings to remove surplus metal such as gate and riser pads, fins, and parting lines.
- **snake**
  - (1) The product formed by twisting and bending of hot metal rod prior to its next rolling process. (2) Any crooked surface imperfection in a plate, resembling a snake. (3) A flexible mandrel used in the inside of a shape to prevent flattening or collapse during a bending operation.
- **snap flask**
  - A foundry flask hinged on one corner so that it can be opened and removed from the mold for reuse before the metal is poured.
- **snap temper**
  - A precautionary interim stress-relieving treatment applied to high-hardenability steels immediately after quenching to prevent cracking because of delay in tempering them at the prescribed higher temperature.
- **S-N curve**
  - A plot of stress ( $S$ ) against the number of cycles to failure ( $N$ ). The stress can be the maximum stress ( $S_{\max}$ ) or the alternating stress amplitude ( $S_a$ ). The stress values are usually nominal stress; i.e., there is no adjustment for stress concentration. The diagram indicates the  $S$ - $N$  relationship for a specified value of the mean stress ( $S_m$ ) or the stress ratio ( $A$  or  $R$ ) and a specified probability of survival. For  $N$  a log scale is almost always used. For  $S$  a linear scale is used most often, but a log scale is sometimes used. Also known as  $S$ - $N$  diagram.
- **soak cleaning**
  - Immersion cleaning without electrolysis.
- **soaking**
  - In heat treating of metals, prolonged holding at a selected temperature to effect homogenization of structure or composition. See also homogenizing .

- **soft magnetic material**
  - A ferromagnetic alloy that becomes magnetized readily upon application of a field and that returns to practically a nonmagnetic condition when the field is removed; an alloy with the properties of high magnetic permeability, low coercive force, and low magnetic hysteresis loss.
- **soft soldering**
  - See preferred term soldering .
- **soft temper**
  - Same as dead soft temper.
- **solder**
  - A filler metal used in soldering that has a liquidus not exceeding 450 °C (840 °F).
- **solderability**
  - The relative ease and speed with which a surface is wetted by molten solder.
- **solder embrittlement**
  - Reduction in mechanical properties of a metal as a result of local penetration of solder along grain boundaries.
- **soldering**
  - A group of processes that join metals by heating them to a suitable temperature below the solidus of the base metals and applying a filler metal having a liquidus not exceeding 450 °C (840 °F). Molten filler metal is distributed between the closely fitted surfaces of the joint by capillary action. See also solder .
- **soldering flux**
  - See flux .
- **soldering iron**
  - A soldering tool having an internally or externally heated metal bit usually made of copper.
- **solid cutters**
  - Cutters made of a single piece of material rather than a composite of two or more materials.
- **solidification**
  - The change in state from liquid to solid upon cooling through the melting temperature or melting range.
- **solidification range**
  - The temperature between the liquidus and the solidus.
- **solidification shrinkage**
  - The reduction in volume of metal from beginning to end of solidification. See also casting shrinkage .
- **solidification shrinkage crack**
  - A crack that forms, usually at elevated temperature, because of the internal (shrinkage) stresses that develop during solidification of a metal casting. Also termed hot crack.
- **solid lubricant**
  - Any solid used as a powder or thin film on a surface to provide protection from damage during relative movement and to reduce friction and wear.
- **solid metal embrittlement**
  - The occurrence of embrittlement in a material below the melting point of the embrittling species. See also liquid metal embrittlement .
- **solid solution**
  - A single, solid, homogeneous crystalline phase containing two or more chemical species.
- **solid-state sintering**
  - A sintering procedure for compacts or loose powder aggregates during which no component melts. Contrast with liquid phase sintering.
- **solid-state welding**
  - A group of welding processes that join metals at temperatures essentially below the melting points of the base materials, without the addition of a brazing filler metal. Pressure may or may not be applied to the joint. Examples include cold welding , diffusion welding , forge welding , hot pressure welding , and roll welding .
- **solidus**
  - (1) The highest temperature at which a metal or alloy is completely solid. (2) In a phase diagram, the locus of points representing the temperatures at which various compositions stop freezing upon cooling or begin to melt upon heating. See also liquidus .

- **solute**
  - The component of either a liquid or solid solution that is present to a lesser or minor extent; the component that is dissolved in the solvent.
- **solution heat treatment**
  - Heating an alloy to a suitable temperature, holding at that temperature long enough to cause one or more constituents to enter into solid solution, and then cooling rapidly enough to hold these constituents in solution.
- **solution potential**
  - Electrode potential where half-cell reaction involves only the metal electrode and its ion.
- **solvent**
  - The component of either a liquid or solid solution that is present to a greater or major extent; the component that dissolves the solute.
- **solvus**
  - In a phase or equilibrium diagram, the locus of points representing the temperature at which solid phases with various compositions coexist with other solid phases, that is, the limits of solid solubility.
- **sorbite (obsolete)**
  - A fine mixture of ferrite and cementite produced either by regulating the rate of cooling of steel or by tempering steel after hardening. The first type is very fine pearlite that is difficult to resolve under the microscope; the second type is tempered martensite.
- **sour gas**
  - A gaseous environment containing hydrogen sulfide and carbon dioxide in hydrocarbon reservoirs. Prolonged exposure to sour gas can lead to hydrogen damage, sulfide-stress cracking, and/or stress-corrosion cracking in ferrous alloys.
- **sow block**
  - A block of heat-treated steel placed between the anvil of the hammer and the forging die to prevent undue wear to the anvil. Sow blocks are occasionally used to hold insert dies. Also called anvil cap.
- **space lattice**
  - A regular, periodic array of points (lattice points) in space that represents the locations of atoms of the same kind in a perfect crystal. The concept may be extended, where appropriate, to crystalline compounds and other substances, in which case the lattice points often represent locations of groups of atoms of identical composition, arrangement, and orientation.
- **spade drill**
  - See preferred term flat drill .
- **spalling**
  - (1) Separation of particles from a surface in the form of flakes. The term spalling is commonly associated with rolling-element bearings and with gear teeth. Spalling is usually a result of subsurface fatigue and is more extensive than pitting. (2) The spontaneous chipping, fragmentation, or separation of a surface or surface coating. (3) A chipping or flaking of a surface due to any kind of improper heat treatment or material dissociation.
- **spangle**
  - The characteristic crystalline form in which a hot dipped zinc coating solidifies on steel strip.
- **spark testing**
  - A method used for the classification of ferrous alloys according to their chemical compositions, by visual examination of the spark pattern or stream that is thrown off when the alloys are held against a grinding wheel rotating at high speed.
- **spatter**
  - The metal particles expelled during arc or gas welding. They do not form part of the weld.
- **spatter loss**
  - The metal lost due to spatter.
- **specific energy**
  - In cutting or grinding, the energy expended or work done in removing a unit volume of material.
- **specimen**
  - A test object, often of standard dimensions and/or configuration, that is used for destructive or nondestructive testing. One or more specimens may be cut from each unit of a sample.
- **speed of travel**

- In welding, the speed with which a weld is made along its longitudinal axis, usually measured in meters per second or inches per minute.
- **speiss**
  - Metallic arsenides and antimonides that result from smelting metal ores such as those of cobalt or lead.
- **spheroidal graphite**
  - Graphite of spheroidal shape with a polycrystalline radial structure. This structure can be obtained, for example, by adding cerium or magnesium to the melt. See also ductile iron and nodular graphite .
- **spheroidite**
  - An aggregate of iron or alloy carbides of essentially spherical shape dispersed throughout a matrix of ferrite.
- **spheroidized structure**
  - A microstructure consisting of a matrix containing spheroidal particles of another constituent.
- **spheroidizing**
  - Heating and cooling to produce a spheroidal or globular form of carbide in steel. Spheroidizing methods frequently used are: (1) Prolonged holding at a temperature just below  $A_{e1}$ . (2) Heating and cooling alternatively between temperatures that are just above and just below  $A_{e1}$ . (3) Heating to a temperature above  $A_{e1}$  or  $A_{e3}$  and then cooling very slowly in the furnace or holding at a temperature just below  $A_{e1}$ . (4) Cooling at a suitable rate from the minimum temperature at which all carbide is dissolved to prevent the reformation of a carbide network, and then reheating in accordance with method 1 or 2 above. (Applicable to hypereutectoid steel containing a carbide network.)
- **spiegeleisen (spiegel)**
  - A pig iron containing 15 to 30% Mn and 4.5 to 6.5% C.
- **spindle**
  - (1) Shaft of a machine tool on which a cutter or grinding wheel may be mounted. (2) Metal shaft to which a mounted wheel is cemented.
- **spinning**
  - The forming of a seamless hollow metal part by forcing a rotating blank to conform to a shaped mandrel that rotates concentrically with the blank. In the typical application, a flat-rolled metal blank is forced against the mandrel by a blunt, rounded tool; however, other stock (notably, welded or seamless tubing) can be formed. A roller is sometimes used as the working end of the tool.
- **spinodal structure**
  - A fine, homogeneous mixture of two phases that form by the growth of composition waves in a solid solution during suitable heat treatment. The phases of a spinodal structure differ in composition from each other and from the parent phase, but have the same crystal structure as the parent phase.
- **spline**
  - Any of a series of longitudinal, straight projections on a shaft that fit into slots on a mating part to transfer rotation to or from the shaft.
- **split die**
  - A die made of parts that can be separated for ready removal of the workpiece. Also known as segment die.
- **split punch**
  - A segmented punch or a set of punches in a powder metallurgy forming press that allow(s) a separate positioning for different powder fill heights and compact levels in dual-step and multistep parts. See also stepped compact .
- **sponge**
  - A form of metal characterized by a porous condition that is the result of the decomposition or reduction of a compound without fusion. The term is applied to forms of iron, titanium, zirconium, uranium, plutonium, and the platinum-group metals.
- **sponge iron**
  - A coherent, porous mass of substantially pure iron produced by solid-state reduction of iron oxide (mill scale or iron ore).
- **spot drilling**

- Making an initial indentation in a work surface, with a drill, to serve as a centering guide in a subsequent machining process.
- **spotfacing**
  - Using a rotary, hole-piloted end-facing tool to produce a flat surface normal to the axis of rotation of the tool on or slightly below the workpiece surface.
- **spot weld**
  - A weld made between or upon overlapping members in which coalescence may start and occur on the faying surfaces or may proceed from the surface of one member. The weld cross section is approximately circular.
- **spot welding**
  - See arc spot weld and resistance spot welding .
- **spray quenching**
  - A quenching process using spray nozzles to spray water or other liquids on a part. The quench rate is controlled by the velocity and volume of liquid per unit area per unit of time of impingement.
- **spray transfer**
  - In consumable-electrode arc welding, a type of metal transfer in which the molten filler metal is propelled across the arc as fine droplets. Compare with globular transfer and short-circuiting transfer .
- **springback**
  - (1) The elastic recovery of metal after stressing. (2) The extent to which metal tends to return to its original shape or contour after undergoing a forming operation. This is compensated for by overbending or by a secondary operation of restriking. (3) In flash, upset, or pressure welding, the deflection in the welding machine caused by the upset pressure.
- **spring temper**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength and hardness about two-thirds of the way from full hard to extra spring temper.
- **sprue**
  - (1) The mold channel that connects the pouring basin with the runner or, in the absence of a pouring basin, directly into which molten metal is poured. Sometimes referred to as downsprue or downgate. (2) Sometimes used to mean all gates, risers, runners, and similar scrap that are removed from castings after shakeout.
- **sputtering**
  - The bombardment of a solid surface with a flux of energetic particles (ions) that results in the ejection of atomic species. The ejected material may be used as a source for deposition. See also physical vapor deposition .
- **square drilling**
  - Making square holes by means of a specially constructed drill made to rotate and also to oscillate so as to follow accurately the periphery of a square guide bushing or template.
- **squaring shear**
  - A machining tool, used for cutting sheet metal or plate, consisting essentially of a fixed cutting knife (usually mounted on the rear of the bed) and another cutting knife mounted on the front of a reciprocally moving crosshead, which is guided vertically in side housings. Corner angles are usually 90°.
- **squeeze casting**
  - A hybrid liquid metal forging process in which liquid metal is forced into a permanent mold by a hydraulic press.
- **stabilizing treatment**
  - (1) Before finishing to final dimensions, repeatedly heating a ferrous or nonferrous part to or slightly above its normal operating temperature and then cooling to room temperature to ensure dimensional stability in service. (2) Transforming retained austenite in quenched hardenable steels, usually by cold treatment. (3) Heating a solution-treated stabilized grade of austenitic stainless steel to 870 to 900 °C (1600 to 1650 °F) to precipitate all carbon as TiC, NbC, or TaC so that sensitization is avoided on subsequent exposure to elevated temperature.
- **stack cutting**
  - Thermal cutting of stacked metal plates arranged so that all the plates are severed by a single cut.
- **stack molding**

- A foundry practice that makes use of both faces of a mold section, one face acting as the drag and the other as the cope. Sections, when assembled to other similar sections, form several tiers of mold cavities, all castings being poured together through a common sprue.
- **staggered-tooth cutters**
  - Milling cutters with alternate flutes of oppositely directed helixes.
- **stainless steel**
  - Any of several steels containing at least 10.5% Cr as the principal alloying element; they usually exhibit passivity in aqueous environments.
- **staking**
  - Fastening two parts together permanently by recessing one part within the other and then causing plastic flow at the joint.
- **stamping**
  - The general term used to denote all sheet metal pressworking. It includes blanking, shearing, hot or cold forming, drawing, bending, or coining.
- **stand**
  - A piece of rolling mill equipment containing one set of work rolls. In the usual sense, any pass of a cold- or hot-rolling mill. See also rolling mills .
- **standard electrode potential**
  - The reversible potential for an electrode process when all products and reactions are at unit activity on a scale in which the potential for the standard hydrogen half-cell is zero.
- **standard gold**
  - A gold alloy containing 10% Cu; at one time used for legal coinage in the United States.
- **standard reference material**
  - A reference material, the composition or properties of which are certified by a recognized standardizing agency or group.
- **starting sheet**
  - A thin sheet of metal used as the cathode in electrolyte refining.
- **state of strain**
  - A complete description of the deformation within a homogeneously deformed volume or at a point. The description requires, in general, the knowledge of the independent components of strain.
- **state of stress**
  - A complete description of the stresses within a homogeneously stressed volume or at a point. The description requires, in general, the knowledge of the independent components of stress.
- **static fatigue**
  - A term sometimes used to identify a form of hydrogen embrittlement in which a metal appears to fracture spontaneously under a steady stress less than the yield stress. There almost always is a delay between the application of stress (or exposure of the stressed metal to hydrogen) and the onset of cracking. More properly referred to as hydrogen-induced delayed cracking .
- **steadite**
  - A hard structural constituent of cast iron that consists of a binary eutectic of ferrite, containing some phosphorus in solution, and iron phosphide ( $\text{Fe}_3\text{P}$ ). The eutectic consists of 10.2% P and 89.8% Fe. The melting temperature is 1050 °C (1920 °F).
- **Stead's brittleness**
  - A condition of brittleness that causes transcrystalline fracture in the coarse grain structure that results from prolonged annealing of thin sheets of low-carbon steel previously rolled at a temperature below about 705 °C (1300 °F). The fracture usually occurs at about 45° to the direction of rolling.
- **steam hammer**
  - A type of drop hammer in which the ram is raised for each stroke by a double-action steam cylinder and the energy delivered to the workpiece is supplied by the velocity and weight of the ram and attached upper die driven downward by steam pressure. The energy delivered during each stroke can be varied.
- **steam treatment**
  - The treatment of a sintered ferrous part in steam at temperatures between 510 and 595 °C (950 to 1100 °F) in order to produce a layer of black iron oxide (magnetite, or ferrous-ferric oxide,  $\text{FeO}\cdot\text{Fe}_2\text{O}_3$ ) on the exposed surface for the purpose of increasing hardness and wear resistance.
- **Steckel mill**

- A cold reducing mill having two working rolls and two backup rolls, none of which is driven. The strip is drawn through the mill by a power reel in one direction as far as the strip will allow and then reversed by a second power reel, and so on until the desired thickness is attained.
- **steel**
  - An iron-base alloy, malleable in some temperature ranges as initially cast, containing manganese, usually carbon, and often other alloying elements. In carbon steel and low-alloy steel, the maximum carbon is about 2.0%; in high-alloy steel, about 2.5%. The dividing line between low-alloy and high-alloy steels is generally regarded as being at about 5% metallic alloying elements.

Steel is said to be differentiated from two general classes of "irons": the cast irons, on the high-carbon side and the relatively pure irons such as ingot iron, carbonyl iron, and electrolytic iron, on the low-carbon side. In some steels containing extremely low carbon, the manganese content is the principal differentiating factor, steel usually containing at least 0.25% and ingot iron considerably less.
- **step aging**
  - Aging of metals at two or more temperatures, by steps, without cooling to room temperature after each step. See also aging , and compare with interrupted aging and progressive aging .
- **stepped compact**
  - A powder metallurgy compact with one (dual step) or more (multistep) abrupt cross-sectional changes, usually obtained by pressing with split punches, each section of which uses a different pressure and a different rate of compaction. See also split punch .
- **stepped extrusion**
  - See extrusion .
- **step fracture**
  - Cleavage fractures that initiate on many parallel cleavage planes.
- **stereoscopic micrographs**
  - A pair of micrographs (or fractographs) of the same area, but taken from different angles so that the two micrographs when properly mounted and viewed reveal the structures of the objects in their three-dimensional relationships.
- **sterling silver**
  - A silver alloy containing at least 92.5% Ag, the remainder being unspecified but usually copper. Sterling silver is used for flat and hollow tableware and for various items of jewelry.
- **stick electrode**
  - A shop term for covered electrode .
- **stick welding**
  - See preferred term shielded metal arc welding .
- **sticker breaks**
  - Arc-shaped coil breaks, usually located near the center of sheet or strip.
- **stiffness**
  - (1) The rate of stress with respect to strain; the greater the stress required to produce a given strain, the stiffer the material is said to be. (2) The ability of a material or shape to resist elastic deflection. For identical shapes, the stiffness is proportional to the modulus of elasticity. For a given material, the stiffness increases with increasing moment of inertia, which is computed from cross-sectional dimensions.
- **stock**
  - A general term used to refer to a supply of metal in any form or shape and also to an individual piece of metal that is formed, forged, or machined to make parts.
- **stopoff**
  - A material used on the surfaces adjacent to the joint to limit the spread of soldering or brazing filler metal. See also resist .
- **stopper rod**
  - A device in a bottom-pour ladle for controlling the flow of metal through the nozzle into a mold. The stopper rod consists of a steel rod, protective refractory sleeves, and a graphite stopper head.
- **stopping off**
  - (1) Applying a resist. (2) Depositing a metal (copper, for example) in localized areas to prevent carburization, decarburization, or nitriding in those areas. (3) Filling in a portion of a mold cavity to keep out molten metal.

- **straddle milling**
  - Face milling a workpiece on both sides at once using two cutters spaced as required.
- **straightening**
  - (1) Any bending, twisting, or stretching operation to correct any deviation from straightness in bars, tubes, or similar long parts or shapes. This deviation can be expressed as either camber (deviation from a straight line) or as total indicator reading (TIR) per unit of length. (2) A finishing operation for correcting misalignment in a forging or between various sections of a forging. See also roll straightening .
- **straight polarity**
  - See preferred term direct current electrode negative (DCEN) .
- **strain**
  - The unit of change in the size or shape of a body due to force. Also known as nominal strain. The term is also used in a broader sense to denote a dimensionless number that characterizes the change in dimensions of an object during a deformation or flow process. See also engineering strain and true strain .
- **strain-age embrittlement**
  - A loss in ductility accompanied by an increase in hardness and strength that occurs when low-carbon steel (especially rimmed or capped steel) is aged following plastic deformation. The degree of embrittlement is a function of aging time and temperature, occurring in a matter of minutes at about 200 °C (400 °F), but requiring a few hours to a year at room temperature.
- **strain aging**
  - (1) Aging following plastic deformation. (2) The changes in ductility, hardness, yield point, and tensile strength that occur when a metal or alloy that has been cold worked is stored for some time. In steel, strain aging is characterized by a loss of ductility and a corresponding increase in hardness, yield point, and tensile strength.
- **strain energy**
  - The potential energy stored in a body by virtue of elastic deformation, equal to the work that must be done to produce this deformation.
- **strain hardening**
  - An increase in hardness and strength of metals caused by plastic deformation at temperatures below the recrystallization range. Also known as work hardening.
- **strain-hardening coefficient**
  - See strain-hardening exponent .
- **strain-hardening exponent**
  - The value of  $n$  in the relationship:

$$\sigma = K \epsilon^n$$

- where  $\sigma$  is the true stress,  $\epsilon$  is the true strain, and  $K$ , which is called the strength coefficient, is equal to the true stress at a true strain of 1.0. The strain-hardening exponent, also called " $n$ -value," is equal to the slope of the true stress/true strain curve up to maximum load, when plotted on log-log coordinates. The  $n$ -value relates to the ability of a sheet metal to be stretched in metalworking operations. The higher the  $n$ -value, the better the formability (stretchability).
- **strain rate**
  - The time rate of straining for the usual tensile test. Strain as measured directly on the specimen gage length is used for determining strain rate. Because strain is dimensionless, the units of strain rate are reciprocal time.
- **strain-rate sensitivity ( $m$ -value)**
  - The increase in stress ( $\sigma$ ) needed to cause a certain increase in plastic strain rate ( $\dot{\epsilon}$ ) at a given level of plastic strain ( $\epsilon$ ) and a given temperature ( $T$ ):

$$\text{Strain-rate sensitivity} = m = \left( \frac{\Delta \log \sigma}{\Delta \log \dot{\epsilon}} \right)_{\epsilon, T}$$

- **strain rods**

- (1) Rods sometimes used on gapframe metalforming presses to lessen the frame deflection. (2) Rods used to measure elastic strain and thus stresses, in frames of metalforming presses.
- **strain state**
  - See state of strain .
- **strand casting**
  - A generic term describing continuous casting of one or more elongated shapes such as billets, blooms, or slabs; if two or more shapes are cast simultaneously, they are often of identical cross section.
- **stranded electrode**
  - A composite filler metal electrode consisting of stranded wires that may mechanically enclose materials to improve properties, stabilize the arc, or provide shielding.
- **stray current**
  - (1) Current flowing through paths other than the intended circuit. (2) Current flowing in electrodeposition by way of an unplanned and undesired bipolar electrode that may be the tank itself or a poorly connected electrode.
- **stray-current corrosion**
  - Corrosion resulting from direct current flow through paths other than the intended circuit. For example, by an extraneous current in the earth.
- **stress**
  - The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area. Stress can be normal (tension or compression) or shear. See also compressive stress , engineering stress , mean stress , nominal stress , normal stress , residual stress , shear stress , tensile stress , and true stress .
- **stress amplitude**
  - One-half the algebraic difference between the maximum and minimum stresses in one cycle of a repetitively varying stress.
- **stress concentration**
  - On a macromechanical level, the magnification of the level of an applied stress in the region of a notch, void, hole, or inclusion.
- **stress concentration factor ( $K_t$ )**
  - A multiplying factor for applied stress that allows for the presence of a structural discontinuity such as a notch or hole;  $K_t$  equals the ratio of the greatest stress in the region of the discontinuity to the nominal stress for the entire section. Also called theoretical stress concentration factor.
- **stress corrosion**
  - Preferential attack of areas under stress in a corrosive environment, where such an environment alone would not have caused corrosion.
- **stress-corrosion cracking (SCC)**
  - A cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. This excludes corrosion-reduced sections that fail by fast fracture. It also excludes intercrystalline or transcrystalline corrosion, which can disintegrate an alloy without applied or residual stress. Stress-corrosion cracking may occur in combination with hydrogen embrittlement.
- **stress-intensity factor**
  - A scaling factor, usually denoted by the symbol  $K$ , used in linear-elastic fracture mechanics to describe the intensification of applied stress at the tip of a crack of known size and shape. At the onset of rapid crack propagation in any structure containing a crack, the factor is called the critical stress-intensity factor, or the fracture toughness. Various subscripts are used to denote different loading conditions or fracture toughnesses:

$K_c$	Plane-stress fracture toughness. The value of stress intensity at which crack propagation becomes rapid in sections thinner than those in which plane-strain conditions prevail.
$K_I$	Stress-intensity factor for a loading condition that displaces the crack faces in a direction normal to the crack plane (also known as the opening mode of deformation).

$K_{Ic}$	Plane-strain fracture toughness. The minimum value of $K_{Ic}$ for any given material and condition
$K_{Id}$	Dynamic fracture toughness. The fracture toughness determined under dynamic loading conditions; it is used as an approximation of $K_{Ic}$ for very tough materials.
$K_{Isc}$	Threshold stress-intensity factor for stress-corrosion cracking. The critical plane-strain stress intensity at the onset of stress-corrosion cracking under specified conditions.
$K_Q$	Provisional value for plane-strain fracture toughness.
$K_{th}$	Threshold stress intensity for stress-corrosion cracking. The critical stress intensity at the onset of stress-corrosion cracking under specified conditions.
$\frac{\Delta K}{K}$	The range of the stress-intensity factor during a fatigue cycle. See also fatigue crack growth rate .

- **stress-intensity factor range ( $\Delta K$ )**
  - In fatigue, the variation in the stress-intensity factor in a cycle, that is,  $K_{max} - K_{min}$ . See also fatigue crack growth rate .
- **stress raisers**
  - Design features (such as sharp corners) or mechanical defects (such as notches) that act to intensify the stress at these locations.
- **stress range**
  - See range of stress .
- **stress ratio ( $A$  or  $R$ )**
  - The algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are: (1) the ratio of the alternating stress amplitude to the mean stress,  $A = S_a/S_m$ ; and (2) the ratio of the minimum stress to the maximum stress,  $R = S_{min}/S_{max}$ .
- **stress relaxation**
  - The time-dependent decrease in stress in a solid under constant constraint at constant temperature.
- **stress-relaxation curve**
  - A plot of the remaining or relaxed stress as a function of time. The relaxed stress equals the initial stress minus the remaining stress. Also known as stress-time curve.
- **stress-relief cracking**
  - Cracking in the heat-affected zone or weld metal that occurs during the exposure of weldments to elevated temperatures during postweld heat treatment, in order to reduce residual stresses and improve toughness, or high-temperature service.
- **stress-relief heat treatment**
  - Uniform heating of a structure or a portion thereof to a sufficient temperature to relieve the major portion of the residual stresses, followed by uniform cooling.
- **stress relieving**
  - Heating to a suitable temperature, holding long enough to reduce residual stresses, and then cooling slowly enough to minimize the development of new residual stresses.
- **stress-rupture strength**
  - See creep-rupture strength .
- **stress-rupture test**
  - See creep-rupture test .
- **stress state**
  - See state of stress .
- **stress-strain curve**
  - A graph in which corresponding values of stress and strain from a tension, compression, or torsion test are plotted against each other. Values of stress are usually plotted vertically (ordinates or y-axis) and values of strain horizontally (abscissas or x-axis). Also known as deformation curve and stress-strain diagram.
- **stretcher leveling**
  - The leveling of a piece of sheet metal (that is, removing warp and distortion) by gripping it at both ends and subjecting it to a stress higher than its yield strength.
- **stretcher straightening**
  - A process for straightening rod, tubing, and shapes by the application of tension at the ends of the stock. The products are elongated a definite amount to remove warpage.
- **stretcher strains**

- Elongated markings that appear on the surface of some sheet materials when deformed just past the yield point. These markings lie approximately parallel to the direction of maximum shear stress and are the result of localized yielding. See also Lüders lines .
- **stretch former**
  - (1) A machine used to perform stretch forming operations. (2) A device adaptable to a conventional press for accomplishing stretch forming.
- **stretch forming**
  - The shaping of a metal sheet or part, usually of uniform cross section, by first applying suitable tension or stretch and then wrapping it around a die of the desired shape.
- **stretching**
  - The extension of the surface of a metal sheet in all directions. In stretching, the flange of the flat blank is securely clamped. Deformation is restricted to the area initially within the die. The stretching limit is the onset of metal failure.
- **striation**
  - A fatigue fracture feature, often observed in electron micrographs, that indicates the position of the crack front after each succeeding cycle of stress. The distance between striations indicates the advance of the crack front across that crystal during one stress cycle, and a line normal to the striations indicates the direction of local crack propagation. See also beach marks .
- **strike**
  - (1) A thin electrodeposited film of metal to be overlaid with other plated coatings. (2) A plating solution of high covering power and low efficiency designed to electroplate a thin, adherent film of metal.
- **striking**
  - Electrodepositing, under special conditions, a very thin film of metal that will facilitate further plating with another metal or with the same metal under different conditions.
- **striking surface**
  - Those areas on the faces of a set of metalforming dies that are designed to meet when the upper die and lower die are brought together. The striking surface helps protect impressions from impact shock and aids in maintaining longer die life.
- **stringer**
  - In wrought materials, an elongated configuration of microconstituents or foreign material aligned in the direction of working. The term is commonly associated with elongated oxide or sulfide inclusions in steel.
- **stringer bead**
  - A continuous weld bead made without appreciable transverse oscillation (weaving motion). Contrast with weave bead .
- **strip**
  - (1) A flat-rolled metal product of some maximum thickness and width arbitrarily dependent on the type of metal; narrower than sheet. (2) A roll-compacted metal powder product. See also roll compacting . (3) Removal of a powder metallurgy compact from the die. An alternative to ejecting or knockout.
- **stripper**
  - A plate designed to remove, or strip, sheet metal stock from the punching members during the withdrawal cycle. Strippers are also used to guide small precision punches in close-tolerance dies to guide scrap away from dies and to assist in the cutting action. Strippers are made in two types: fixed and movable.
- **stripper punch**
  - A punch that serves as the top or bottom of a metalforming die cavity and later moves farther into the die to eject the part or compact. See also ejector rod and knockout(3) .
- **stripping**
  - (1) Removing a coating from a metal surface. (2) Removing a foundry pattern from the mold or the core box from the core.
- **structural shape**
  - A piece of metal of any of several designs accepted as standard by the structural branch of the iron and steel industries.
- **structure**

- As applied to a crystal, the shape and size of the unit cell and the location of all atoms within the unit cell. As applied to microstructure, the size, shape, and arrangement of phases. See also unit cell .
- **stud arc welding**
  - An arc welding process that produces coalescence of metals by heating them with an arc between a metal stud, or similar part, and the other workpiece. When the surfaces to be joined are properly heated, they are brought together under pressure. Partial shielding may be obtained by the use of a ceramic ferrule surrounding the stud. Shielding gas or flux may or may not be used.
- **stud welding**
  - A general term for joining a metal stud or similar part to a workpiece. Welding may be accommodated by arc, resistance, friction, or other processes with or without external gas shielding.
- **styrofoam pattern**
  - An expendable pattern of foamed plastic, especially expanded polystyrene, used in manufacturing castings by the lost foam process. See also lost foam casting .
- **subboundary structure (subgrain structure)**
  - A network of low-angle boundaries, usually with misorientations less than  $1^\circ$  within the main grains of a microstructure.
- **subcritical annealing**
  - An annealing treatment in which a steel is heated to a temperature below the  $A_1$  temperature, then cooled slowly to room temperature. See also transformation temperature .
- **subgrain**
  - A portion of a crystal or grain, with an orientation slightly different from the orientation of neighboring portions of the same crystal.
- **submerged arc welding (SAW)**
  - An arc welding process that produces coalescence of metals by heating them with an arc or arcs between a bare metal electrode or electrodes and the workpieces. The arc and molten metal are shielded by a blanket of granular, fusible material on the workpieces. Pressure is not used, and filler metal is obtained from the electrode and sometimes from a supplemental source (welding rod, flux, or metal granules).
- **submerged-electrode furnace**
  - A furnace used for liquid carburizing of parts by heating molten salt baths with the use of electrodes submerged in the ceramic lining. See also immersed-electrode furnace .
- **subsieve fraction**
  - Particles that will pass through a 44  $\mu\text{m}$  (325 mesh) screen.
- **subsieve size**
  - See preferred term subsieve fraction .
- **substitutional element**
  - An alloying element with an atomic size and other features similar to the solvent that can replace or substitute for the solvent atoms in the lattice and form a significant region of solid solution in the phase diagram.
- **substitutional solid solution**
  - A solid solution in which the solvent and solute atoms are located randomly at the atom sites in the crystal structure of the solution. See also interstitial solid solution .
- **substrate**
  - The material, workpiece, or substance on which the coating is deposited.
- **substructure**
  - Same as subboundary structure .
- **subsurface corrosion**
  - Formation of isolated particles of corrosion products beneath a metal surface. This results from the preferential reactions of certain alloy constituents to inward diffusion of oxygen, nitrogen, or sulfur.
- **sulfidation**
  - The reaction of a metal or alloy with a sulfur-containing species to produce a sulfur compound that forms on or beneath the surface on the metal or alloy.
- **sulfide stress cracking (SSC)**
  - Brittle fracture by cracking under the combined action of tensile stress and corrosion in the presence of water and hydrogen sulfide. See also environmental cracking .

- **sulfur dome**
  - An inverted container, holding a high concentration of sulfur dioxide gas, used in die casting to cover a pot of molten magnesium to prevent burning.
- **sulfur print**
  - A macrographic method of examining for distribution of sulfide inclusions by placing a sheet of wet acidified photographic paper in contact with the polished sheet surface to be examined.
- **superabrasives**
  - Synthetically produced diamond and cubic boron nitride (CBN) used in a wide variety of cutting and grinding applications.
- **superalloys**
  - Heat-resistant alloys based on nickel, iron-nickel, or cobalt that exhibit high strength and resistance to surface degradation at elevated temperatures.
- **superconductivity**
  - A property of many metals, alloys, compounds, oxides, and organic materials at temperatures near absolute zero by virtue of which their electrical resistivity vanishes and they become strongly diamagnetic.
- **supercooling**
  - Cooling of a substance below the temperature at which a change of state would ordinarily take place without such a change of state occurring, for example, the cooling of a liquid below its freezing point without freezing taking place; this results in a metastable state.
- **superficial hardness test**
  - See Rockwell superficial hardness test .
- **superfines**
  - The portion of a metal powder that is composed of particles smaller than a specified size, usually 10  $\mu\text{m}$ .
- **superfinishing**
  - A low-velocity abrading process very similar to honing; however, unlike honing, superfinishing processes focus primarily on the improvement of surface finish and much less on correction of geometric errors (dimensional accuracy). Also known as microhoning.
- **superheating**
  - (1) Heating of a substance above the temperature at which a change of state would ordinarily take place without a change of state occurring, for example, the heating of a liquid above its boiling point without boiling taking place; this results in a metastable state. (2) Any increment of temperature above the melting point of a metal; sometimes construed to be any increment of temperature above normal casting temperatures introduced for the purpose of refining, alloying, or improving fluidity.
- **superlattice**
  - See ordered structure .
- **superplastic forming (SPF)**
  - A strain rate sensitive sheet metal forming process that uses characteristics of materials exhibiting high tensile elongation. During superplastic forming, gas pressure is imposed on a superplastic sheet, causing the material to form into the die configuration. See also superplasticity .
- **superplasticity**
  - The ability of certain metals (most notably aluminum- and titanium-base alloys) to develop extremely high tensile elongations at elevated temperatures and under controlled rates of deformation.
- **supersaturated**
  - A metastable solution in which the dissolved material exceeds the amount the solvent can hold in normal equilibrium at the temperature and other conditions that prevail.
- **support pins**
  - Rods or pins of precise length used to support the overhang of irregularly shaped punches in metal forming presses.
- **support plate**
  - A plate that supports a draw ring or draw plate in a sheet metal forming press. It also serves as a spacer. See also draw plate and draw ring .
- **surface alterations**
  - Irregularities or changes on the surface of a material due to machining or grinding operations. The types of surface alterations associated with metal removal practices include mechanical (for

example, plastic deformation, hardness variations, cracks, etc.), metallurgical (for example, phase transformations, twinning, recrystallization, and untempered or overtempered martensite), chemical (for example, intergranular attack, embrittlement, and pitting), thermal (heat-affected zone, recast, or redeposited metal, and resolidified material), and electrical surface alterations (conductivity change or resistive heating).

- **surface checking**
  - Same as checks .
- **surface damage**
  - In tribology, damage to a solid surface resulting from mechanical contact with another substance, surface, or surfaces moving relatively to it and involving the displacement or removal of material. In certain contexts, wear is a form of surface damage in which material is progressively removed. In another context, surface damage involves a deterioration of function of a solid surface even though there is no material loss from that surface. Surface damage may therefore precede wear.
- **surface finish**
  - (1) The geometric irregularities in the surface of a solid material. Measurement of surface finish shall not include inherent structural irregularities unless these are the characteristics being measured. (2) Condition of a surface as a result of a final treatment. See also roughness .
- **surface grinding**
  - Producing a plane surface by grinding.
- **surface hardening**
  - A generic term covering several processes applicable to a suitable ferrous alloy that produces, by quench hardening only, a surface layer that is harder or more wear resistant than the core. There is no significant alteration of the chemical composition of the surface layer. The processes commonly used are carbonitriding, carburizing, induction hardening, flame hardening, nitriding, and nitrocarburizing. Use of the applicable specific process name is preferred.
- **surface modification**
  - The alteration of surface composition or structure by the use of energy or particle beams. Two types of surface modification methods commonly employed are ion implantation and laser surface processing.
- **surface roughness**
  - Fine irregularities in the surface texture of a material, usually including those resulting from the inherent action of the production process. Surface roughness is usually reported as the arithmetic roughness average,  $R_a$ , and is given in micrometers or microinches.
- **surface texture**
  - The roughness, waviness, lay, and flaws associated with a surface. See also lay .
- **surfacing**
  - The deposition of filler metal (material) on a base metal (substrate) to obtain desired properties or dimensions, as opposed to making a joint. See also buildup , buttering , cladding , coating , and hardfacing .
- **surfacing weld**
  - A type of weld composed of one or more stringer or weave beads deposited on an unbroken surface to obtain desired properties or dimensions.
- **swage**
  - (1) The operation of reducing or changing the cross-sectional area of stock by the fast impact of revolving dies. (2) The tapering of bar, rod, wire, or tubing by forging, hammering, or squeezing; reducing a section by progressively tapering lengthwise until the entire section attains the smaller dimension of the taper.
- **swaging**
  - Tapering bar, rod, wire, or tubing by forging, hammering, or squeezing; reducing a section by progressively tapering lengthwise until the entire section attains the smaller dimension of the taper. See also rotary swaging .
- **swarf**
  - Intimate mixture of grinding chips and fine particles of abrasive and bond resulting from a grinding operation.
- **sweat soldering**
  - A soldering process variation in which two or more parts that have been precoated with solder are reheated and assembled into a joint without the use of additional solder.

- **sweep**
  - A type of foundry pattern that is a template cut to the profile of the desired mold shape that, when revolved around a stake or spindle, produces that shape in the mold.
- **Swift cup test**
  - A simulative test for determining formability of sheet metal in which circular blanks of various diameters are clamped in a die ring and deep drawn into a cup by a flat-bottomed cylindrical punch. The ratio of the largest blank diameter that can be drawn successfully to the cup diameter is known as the limiting drawing ratio (LDR) or deformation limit.
- **swing forging machine**
  - Equipment for continuously hot reducing ingots, blooms, or billets to square flats, rounds, or rectangles by the crank-driven oscillating action of paired dies.
- **swing frame grinder**
  - A grinding machine suspended by a chain at the center point so that it may be turned and swung in any direction for grinding of billets, large castings, or other heavy work. Principal use is removing surface imperfections and roughness.
- **synthetic cold-rolled sheet**
  - A hot-rolled pickled sheet given a sufficient final temper pass to impart a surface approximating that of cold-rolled steel.
- **T**
- **tacking**
  - Making tack welds.
- **tack weld**
  - A weld made to hold parts of a weldment in proper alignment until the final welds are made.
- **tailings**
  - The discarded portion of a crushed ore, separated during concentration.
- **tandem mill**
  - A rolling mill consisting of two or more stands arranged so that the metal being processed travels in a straight line from stand to stand. In continuous rolling, the various stands are synchronized so that the strip can be rolled in all stands simultaneously. Contrast with single-stand mill . See also rolling mills .
- **tandem welding**
  - Arc welding in which two or more electrodes are in a plane parallel to the line of travel.
- **tangent bending**
  - The forming of one or more identical bends having parallel axes by wiping sheet metal around one or more radius dies in a single operation. The sheet, which may have side flanges, is clamped against the radius die and then made to conform to the radius die by pressure from a rocker-plate die that moves along the periphery of the radius die. See also wiper forming (wiping) .
- **tap**
  - A cylindrical or conical thread-cutting tool with one or more cutting elements having threads of a desired form on the periphery. By a combination of rotary and axial motions, the leading end cuts an internal thread, the tool deriving its principal support from the thread being produced.
- **tap density**
  - The apparent density of a powder, obtained when the volume receptacle is tapped or vibrated during loading under specified conditions.
- **tapping**
  - (1) Producing internal threads with a cylindrical cutting tool having two or more peripheral cutting elements shaped to cut threads of the desired size and form. By a combination of rotary and axial motion, the leading end of the tap cuts the thread while the tap is supported mainly by the thread it produces. See also tap . (2) Opening the outlet of a melting furnace to remove molten metal. (3) Removing molten metal from a furnace.
- **tarnish**
  - Surface discoloration of a metal caused by formation of a thin film of corrosion product.
- **teapot ladle**
  - A ladle in which, by means of an external spout, metal is removed from the bottom rather than the top of the ladle.
- **teeming**
  - Pouring molten metal from a ladle into ingot molds. The term applies particularly to the specific operation of pouring either iron or steel into ingot molds.

- **temper**
  - (1) In heat treatment, reheating hardened steel or hardened cast iron to some temperature below the eutectoid temperature for the purpose of decreasing hardness and increasing toughness. The process also is sometimes applied to normalized steel. (2) In tool steels, temper is sometimes used, but inadvisedly, to denote the carbon content. (3) In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties, or reduction in area during cold working. (4) To moisten green sand for casting molds with water.
- **temper brittleness**
  - See temper embrittlement .
- **temper carbon**
  - Clusters of finely divided graphite, such as that found in malleable iron, that are formed as a result of decomposition of cementite, for example, by heating white cast iron above the ferrite-austenite transformation temperature and holding at these temperatures for a considerable period of time. Also known as annealing carbon.
- **temper color**
  - A thin, tightly adhering oxide skin (only a few molecules thick) that forms when steel is tempered at a low temperature, or for a short time, in air or a mildly oxidizing atmosphere. The color, which ranges from straw to blue depending on the thickness of the oxide skin, varies with both tempering time and temperature.
- **tempered layer**
  - A surface or subsurface layer in a steel specimen that has been tempered by heating during some stage of the metallographic preparation sequence (usually grinding). When observed in a section after etching, the layer appears darker than the base material.
- **tempered martensite**
  - The decomposition products that result from heating martensite below the ferrite-austenite transformation temperature.
- **tempered martensite embrittlement**
  - Embrittlement of high-strength alloy steels caused by tempering in the temperature range of 205 to 370 °C (400 to 700 °F); also called 350 °C or 500 °F embrittlement. Tempered martensite embrittlement is thought to result from the combined effects of cementite precipitation on prior-austenite grain boundaries or interlath boundaries and the segregation of impurities at prior-austenite grain boundaries. It differs from temper embrittlement in the strength of the material and the temperature exposure range. In temper embrittlement, the steel is usually tempered at a relatively high temperature, producing lower strength and hardness, and embrittlement occurs upon slow cooling after tempering and during service at temperatures within the embrittlement range. In tempered martensite embrittlement, the steel is tempered within the embrittlement range, and service exposure is usually at room temperature.
- **temper embrittlement**
  - Embrittlement of low-alloy steels caused by holding within or cooling slowly through a temperature range (generally 300 to 600 °C, or 570 to 1110 °F) just below the transformation range. Embrittlement is the result of the segregation at grain boundaries of impurities such as arsenic, antimony, phosphorus, and tin; it is usually manifested as an upward shift in ductile-to-brittle transition temperature. Temper embrittlement can be reversed by retempering above the critical temperature range, then cooling rapidly. Compare with tempered martensite embrittlement .
- **tempering**
  - In heat treatment, reheating hardened steel to some temperature below the eutectoid temperature to decrease hardness and/or increase toughness.
- **temper rolling**
  - Light cold rolling of sheet steel to improve flatness, to minimize the formation of stretcher strains, and to obtain a specified hardness or temper.
- **tensile strength**
  - In tensile testing, the ratio of maximum load to original cross-sectional area. Also called ultimate strength . Compare with yield strength .
- **tensile stress**

- A stress that causes two parts of an elastic body, on either side of a typical stress plane, to pull apart. Contrast with compressive stress .
- **tensile testing**
  - See tension testing .
- **tension**
  - The force or load that produces elongation.
- **tension testing**
  - A method of determining the behavior of materials subjected to uniaxial loading, which tends to stretch the material. A longitudinal specimen of known length and diameter is gripped at both ends and stretched at a slow, controlled rate until rupture occurs. Also known as tensile testing.
- **terminal phase**
  - A solid solution having a restricted range of compositions, one end of the range being a pure component of an alloy system.
- **terminal solid solution**
  - In a multicomponent system, any solid phase of limited composition range that includes the composition of one of the components of the system. See also solid solution .
- **ternary alloy**
  - An alloy that contains three principal elements.
- **ternary system**
  - The complete series of compositions produced by mixing three components in all proportions.
- **terne**
  - An alloy of lead containing 3 to 15% Sn, used as a hot dip coating for steel sheet or plate. The term long terne is used to describe terne-coated sheet, whereas short terne is used for terne-coated plate. Terne coatings, which are smooth and dull in appearance (terne means dull or tarnished in French), give the steel better corrosion resistance and enhance its ability to be formed, soldered, or painted.
- **tertiary creep**
  - See creep .
- **texture**
  - In a polycrystalline aggregate, the state of distribution of crystal orientations. In the usual sense, it is synonymous with preferred orientation , in which the distribution is not random. Not to be confused with surface texture . See also fiber .
- **thermal aging**
  - Exposure of a material or component to a given thermal condition or a programmed series of conditions for prescribed periods of time.
- **thermal analysis**
  - A method for determining transformations in a metal by noting the temperatures at which thermal arrests occur. These arrests are manifested by changes in slope of the plotted or mechanically traced heating and cooling curves. When such data are secured under nearly equilibrium conditions of heating and cooling, the method is commonly used for determining certain critical temperatures required for the construction of phase diagrams.
- **thermal cutting**
  - A group of cutting processes that melts the metal (material) to be cut. See also air carbon arc cutting , arc cutting , carbon arc cutting , electron beam cutting , laser beam cutting , metal powder cutting , oxyfuel gas cutting , oxygen arc cutting , oxygen cutting , and plasma arc cutting .
- **thermal decomposition**
  - (1) The decomposition of a compound into its elemental species at elevated temperatures. (2) A process whereby fine solid particles can be produced from a gaseous compound. See also carbonyl powder .
- **thermal electromotive force**
  - The electromotive force generated in a circuit containing two dissimilar metals when one junction is at a temperature different from that of the other. See also thermocouple .
- **thermal embrittlement**
  - Intergranular fracture of maraging steels with decreased toughness resulting from improper processing after hot working. Thermal embrittlement occurs upon heating above 1095 °C (2000 °F) and then slow cooling through the temperature range of 980 to 815 °C (1800 to 1500 °F), and

has been attributed to precipitation of titanium carbides and titanium carbonitrides at austenite grain boundaries during cooling through the critical temperature range.

- **thermal fatigue**
  - Fracture resulting from the presence of temperature gradients that vary with time in such a manner as to produce cyclic stresses in a structure.
- **thermal inspection**
  - A nondestructive test method in which heat-sensing devices are used to measure temperature variations in components, structures, systems, or physical processes. Thermal methods can be useful in the detection of subsurface flaws or voids, provided the depth of the flaw is not large compared to its diameter. Thermal inspection becomes less effective in the detection of subsurface flaws as the thickness of an object increases, because the possible depth of the defects increases.
- **thermally induced embrittlement**
  - See embrittlement .
- **thermal-mechanical treatment**
  - See thermomechanical working .
- **thermal shock**
  - The development of a steep temperature gradient and accompanying high stresses within a material or structure.
- **thermal spraying**
  - A group of coating or welding processes in which finely divided metallic or nonmetallic materials are deposited in a molten or semimolten condition to form a coating. The surfacing material may be in the form of powder, rod, or wire. See also electric arc spraying , flame spraying , plasma spraying , and powder flame spraying .
- **thermal stresses**
  - Stresses in a material resulting from nonuniform temperature distribution.
- **thermal wear**
  - Removal of material due to softening, melting, or evaporation during sliding or rolling. Thermal shock and high-temperature erosion may be included in the general description of thermal wear. Wear by diffusion of separate atoms from one body to the other, at high temperatures, is also sometimes denoted as thermal wear.
- **thermit reactions**
  - Strongly exothermic self-propagating reactions such as that where finely divided aluminum reacts with a metal oxide. A mixture of aluminum and iron oxide produces sufficient heat to weld steel, the filler metal being produced in the reaction. See also thermit welding .
- **thermit welding**
  - A welding process that produces coalescence of metals by heating them with superheated liquid metal from a chemical reaction between a metal oxide and aluminum, with or without the application of pressure. Filler metal is obtained from the liquid metal.
- **thermochemical machining**
  - Removal of workpiece material--usually only burrs and fins--by exposure to hot fuel gases that are formed by igniting an explosive, combustible mixture of natural gas and oxygen. Also known as the thermal energy method.
- **thermochemical treatment**
  - Heat treatment for steels carried out in a medium suitably chosen to produce a change in the chemical composition of the object by exchange with the medium.
- **thermocouple**
  - A device for measuring temperatures, consisting of lengths of two dissimilar metals or alloys that are electrically joined at one end and connected to a voltage-measuring instrument at the other end. When one junction is hotter than the other, a thermal electromotive force is produced that is roughly proportional to the difference in temperature between the hot and cold junctions.
- **thermomechanical working**
  - A general term covering a variety of metalforming processes combining controlled thermal and deformation treatments to obtain synergistic effects, such as improvement in strength without loss of toughness. Same as thermal-mechanical treatment.
- **thief**
  - A racking device or nonfunctional pattern area used in the electroplating process to provide a more uniform current density on plated parts. Thieves absorb the unevenly distributed current on

irregularly shaped parts, thereby ensuring that the parts will receive an electroplated coating of uniform thickness. See also robber .

- **thin-wall casting**
  - A term used to define a casting that has the minimum wall thickness to satisfy its service function.
- **threading**
  - Producing external threads on a cylindrical surface.
- **thread rolling**
  - The production of threads by rolling the piece between two grooved die plates, one of which is in motion, or between rotating grooved circular rolls. Also known as roll threading.
- **three-quarters hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength and hardness about midway between those of half hard and full hard tempers.
- **three-point bending**
  - The bending of a piece of metal or a structural member in which the object is placed across two supports and force is applied between and in opposition to them. See also V-bend die .
- **threshold stress**
  - Threshold stress for stress-corrosion cracking. The critical gross section stress at the onset of stress-corrosion cracking under specified conditions.
- **throwing power**
  - (1) The relationship between the current density at a point on a surface and its distance from the counterelectrode. The greater the ratio of the surface resistivity shown by the electrode reaction to the volume resistivity of the electrolyte, the better is the throwing power of the process. (2) The ability of a plating solution to produce a uniform metal distribution on an irregularly shaped cathode. Compare with covering power .
- **tiger stripes**
  - Continuous bright lines on sheet or strip in the rolling direction.
- **TIG welding**
  - Tungsten inert-gas welding; see preferred term gas tungsten arc welding .
- **tilt boundary**
  - A subgrain boundary consisting of an array of edge dislocations.
- **tilt mold**
  - A casting mold, usually a book (permanent) mold, that rotates from a horizontal to a vertical position during pouring, which reduces agitation and thus the formation and entrapment of oxides.
- **tilt mold ingot**
  - An ingot made in a tilt mold .
- **time quenching**
  - A quench in which the cooling rate of the part being quenched must be changed abruptly at some time during the cooling cycle.
- **time-temperature curve**
  - A curve produced by plotting time against temperature.
- **time-temperature-transformation (TTT) diagram**
  - See isothermal transformation (IT) diagram .
- **tinning**
  - Coating metal with a very thin layer of molten solder or brazing filler metal.
- **tin pest**
  - A polymorphic modification of tin that causes it to crumble into a powder known as gray tin. It is generally accepted that the maximum rate of transformation occurs at about -40 °C (-40 °F), but transformation can occur at as high as about 13 °C (55 °F).
- **tint etching**
  - Immersing metallographic specimens in specially formulated chemical etchants in order to produce a stable film on the specimen surface. When viewed under an optical microscope, these surface films produce colors that correspond to the various phases in the alloy. Also known as color etching.
- **tin tossing**
  - Oxidizing impurities in molten tin by pouring it from one vessel to another in air, forming a dross that is mechanically separable.

- **toggle press**
  - A mechanical press in which the slide is actuated by one or more toggle links or mechanisms.
- **tolerance**
  - The specified permissible deviation from a specified nominal dimension, or the permissible variation in size or other quality characteristic of a part.
- **tolerance limits**
  - The extreme values (upper and lower) that define the range of permissible variation in size or other quality characteristic of a part.
- **tonghold**
  - The portion of a forging billet, usually on one end, that is gripped by the operator's tongs. It is removed from the part at the end of the forging operation. Common to drop hammer and press-type forging.
- **tooling**
  - A generic term applying to die assemblies and related items used for forming and forging metals.
- **tool steel**
  - Any of a class of carbon and alloy steels commonly used to make tools. Tool steels are characterized by high hardness and resistance to abrasion, often accompanied by high toughness and resistance to softening at elevated temperature. These attributes are generally attained with high carbon and alloy contents.
- **tooth**
  - (1) A projection on a multipoint tool (such as on a saw, milling cutter, or file) designed to produce cutting. (2) A projection on the periphery of a wheel or segment thereof--as on a gear, spline, or sprocket, for example--designed to engage another mechanism and thereby transmit force or motion, or both. A similar projection on a flat member such as a rack.
- **tooth point**
  - The chamfered cutting edge of a face milling blade, to which a flat is sometimes added to produce a shaving effect and to improve finish.
- **top-and-bottom process**
  - A process for separating copper and nickel, in which their molten sulfides are separated into two liquid layers by the addition of sodium sulfide. The lower layer holds most of the nickel.
- **torch**
  - See preferred terms cutting torch (arc) , cutting torch (oxyfuel gas) , welding torch (arc) , and welding torch (oxyfuel gas) .
- **torch brazing**
  - A brazing process in which the heat required is furnished by a fuel gas flame.
- **torch soldering**
  - A soldering process in which the heat required is furnished by a fuel gas flame.
- **torsion**
  - (1) A twisting deformation of a solid or tubular body about an axis in which lines that were initially parallel to the axis become helices. (2) A twisting action resulting in shear stresses and strains.
- **torsional moment**
  - In a body being twisted, the algebraic sum of the couples or the moments of the external forces about the axis of twist, or both.
- **total carbon**
  - The sum of the free carbon and combined carbon (including carbon in solution) in a ferrous alloy.
- **total elongation**
  - The total amount of permanent extension of a test piece broken in a tensile test usually expressed as a percentage over a fixed gage length. See also elongation, percent .
- **toughness**
  - Ability of a material to absorb energy and deform plastically before fracturing. Toughness is proportional to the area under the stress-strain curve from the origin to the breaking point. In metals, toughness is usually measured by the energy absorbed in a notch impact test. See also impact test .
- **tough pitch copper**
  - Copper containing from 0.02 to 0.04% O, obtained by refining copper in a reverberatory furnace.
- **tracer milling**

- Duplication of a three-dimensional form by means of a cutter controlled by a tracer that is directed by a master form.
- **tramp alloys**
  - Residual alloying elements that are introduced into steel when unidentified alloy steel is present in the scrap charge to a steelmaking furnace.
- **tramp element**
  - Contaminant in the components of a furnace charge, or in the molten metal or castings, whose presence is thought to be either unimportant or undesirable to the quality of the casting. Also called trace element.
- **transcrystalline**
  - See transgranular .
- **transcrystalline cracking**
  - Cracking or fracturing that occurs through or across a crystal. Also termed intracrystalline cracking.
- **transformation hardening**
  - Heat treatment of steels comprising austenitization followed by cooling under conditions such that the austenite transforms more or less completely into martensite and possibly into bainite.
- **transformation-induced plasticity**
  - A phenomenon, occurring chiefly in certain highly alloyed steels that have been heat treated to produce metastable austenite or metastable austenite plus martensite, whereby, on subsequent deformation, part of the austenite undergoes strain-induced transformation to martensite. Steels capable of transforming in this manner, commonly referred to as TRIP steels, are highly plastic after heat treatment, but exhibit a very high rate of strain hardening and thus have high tensile and yield strengths after plastic deformation at temperatures between about 20 and 500 °C (70 and 930 °F). Cooling to 195 °C (320 °F) may or may not be required to complete the transformation to martensite. Tempering usually is done following transformation.
- **transformation ranges**
  - Those ranges of temperature within which austenite forms during heating and transforms during cooling. The two ranges are distinct, sometimes overlapping but never coinciding. The limiting temperatures of the ranges depend on the composition of the alloy and on the rate of change of temperature, particularly during cooling. See also transformation temperature .
- **transformation temperature**
  - The temperature at which a change in phase occurs. This term is sometimes used to denote the limiting temperature of a transformation range. The following symbols are used for irons and steels:

<b>A<sub>cm</sub></b>	In hypereutectoid steel
<b>A<sub>c1</sub></b>	The temperature at which austenite begins to form during heating.
<b>A<sub>c3</sub></b>	The temperature at which transformation of ferrite to austenite is completed during heating.
<b>A<sub>c4</sub></b>	The temperature at which austenite transforms to $\delta$ ferrite during heating.
<b>A<sub>e<sub>cm</sub></sub>, A<sub>e1</sub>, A<sub>e3</sub>, A<sub>e4</sub></b>	The temperatures of phase changes at equilibrium
<b>A<sub>r<sub>cm</sub></sub></b>	In hypereutectoid steel
<b>A<sub>r1</sub></b>	The temperature at which transformation of austenite to ferrite or to ferrite plus cementite is completed during cooling.
<b>A<sub>r3</sub></b>	The temperature at which austenite begins to transform to ferrite during cooling.
<b>A<sub>r4</sub></b>	The temperature at which $\delta$ ferrite transforms to austenite during cooling.
<b>A<sub>r'</sub></b>	The temperature at which transformation of austenite to pearlite starts during cooling.
<b>M<sub>f</sub></b>	The temperature at which transformation of austenite to martensite is completed during cooling.
<b>M<sub>s</sub>(or A<sub>r''</sub>)</b>	The temperature at which transformation of austenite to martensite starts during cooling.

- NOTE: All these changes, except formation of martensite, occur at lower temperatures during cooling than during heating, and depend on the rate of change of temperature.
- **transgranular**
  - Through or across crystals or grains. Also called intracrystalline or transcrystalline.
- **transgranular cracking**
  - Cracking or fracturing that occurs through or across a crystal or grain. Also called transcrystalline cracking. Contrast with intergranular cracking .
- **transgranular fracture**
  - Fracture through or across the crystals or grains of a material. Also called transcrystalline fracture or intracrystalline fracture. Contrast with intergranular fracture .
- **transition lattice**
  - An unstable crystallographic configuration that forms as an intermediate step in a solid-state reaction such as precipitation from solid solution or eutectoid decomposition.
- **transition metal**
  - A metal in which the available electron energy levels are occupied in such a way that the *d*-band contains less than its maximum number of ten electrons per atom, for example, iron, cobalt, nickel, and tungsten. The distinctive properties of the transition metals result from the incompletely filled *d*-levels.
- **transition phase**
  - A nonequilibrium state that appears in a chemical system in the course of transformation between two equilibrium states.
- **transition point**
  - At a stated pressure, the temperature (or at a stated temperature, the pressure) at which two solid phases exist in equilibrium--that is, an allotropic transformation temperature (or pressure).
- **transition structure**
  - In precipitation from solid solution, a metastable precipitate that is coherent with the matrix.
- **transition temperature**
  - (1) An arbitrarily defined temperature that lies within the temperature range in which metal fracture characteristics (as usually determined by tests of notched specimens) change rapidly, such as the ductile-to-brittle transition temperature (DBTT). The DBTT can be assessed in several ways, the most common being the temperature for 50% ductile and 50% brittle fracture (50% fracture appearance transition temperature, or FATT), or the lowest temperature at which the fracture is 100% ductile (100% fibrous criterion). (2) Sometimes used to denote an arbitrarily defined temperature within a range in which the ductility changes rapidly with temperature.
- **transverse direction**
  - Literally, "across," usually signifying a direction or plane perpendicular to the direction of working. In rolled plate or sheet, the direction across the width is often called long transverse; the direction through the thickness, short transverse.
- **transverse rolling machine**
  - Equipment for producing complex preforms or finished forgings from round billets inserted transversely between two or three rolls that rotate in the same direction and drive the billet. The rolls, carrying replaceable die segments with appropriate impressions, make several revolutions for each rotation of the workpiece.
- **transverse rupture strength (TRS)**
  - The stress, calculated from the bending stress formula, required to break a powder metallurgy specimen of a given dimension. The specimen is supported near its ends with a load applied midway between the fixed centerline of the supports. From the value of the break load, the TRS can be calculated using:

$$TRS = \frac{3FL}{WH^2}$$

- where *F* is the load at fracture, *L* is the span between supports, and *W* and *H* are the width and height of the test bar, respectively.
- **trees**
  - Visible projections of electrodeposited metal formed at sites of high current density.
- **trepanning**

- A machining process for producing a circular hole or groove in solid stock, or for producing a disk, cylinder, or tube from solid stock, by the action of a tool containing one or more cutters (usually single-point) revolving around a center.
- **triaxiality**
  - In a triaxial stress state, the ratio of the smallest to the largest principal stress, all stresses being tensile.
- **triaxial stress**
  - A state of stress in which none of the three principal stresses is zero. See also principal stress (normal) .
- **tribology**
  - (1) The science and technology of interacting surfaces in relative motion and of the practices related thereto. (2) The science concerned with the design, friction, lubrication, and wear of contacting surfaces that move relative to each other (as in bearings, cams, or gears, for example).
- **trimmer blade**
  - The portion of the trimmers through which a forging is pushed to shear off the flash.
- **trimmer die**
  - The punch press die used for trimming flash from a forging.
- **trimmer punch**
  - The upper portion of the trimmer that contacts the forging and pushes it through the trimmer blades; the lower end of the trimmer punch is generally shaped to fit the surface of the forging against which it pushes.
- **trimmers**
  - The combination of trimmer punch, trimmer blades, and perhaps trimming shoe used to remove the flash from the forging.
- **trimming**
  - (1) In forging, removing any parting-line flash or excess material from the part with a trimmer in a trim press; can be done hot or cold. (2) In drawing, shearing the irregular edge of the drawn part. (3) In casting, the removal of gates, risers, and fins.
- **trimming press**
  - A power press suitable for trimming flash from forgings.
- **trimming shoe**
  - The holder used to support trimmers. Sometimes called trimming chair.
- **triple-action press**
  - A mechanical or hydraulic press having three slides with three motions properly synchronized for triple-action drawing, redrawing, and forming. Usually, two slides--the blankholder slide and the plunger--are located above and a lower slide is located within the bed of the press. See also hydraulic press , mechanical press , and slide .
- **triple point**
  - (1) A point on a phase diagram where three phases of a substance coexist in equilibrium. (2) The intersection of the boundaries of three adjoining grains, as observed in a metallographic section.
- **TRIP steel**
  - A commercial steel product exhibiting transformation-induced plasticity .
- **troostite (obsolete)**
  - A previously unresolvable, rapidly etching, fine aggregate of carbide and ferrite produced either by tempering martensite at low temperature or by quenching a steel at a rate slower than the critical cooling rate. Preferred terminology for the first product is tempered martensite; for the latter, fine pearlite.
- **Troy ounce**
  - A unit of weight for precious metals that is equal to 31.1034768 g (1.0971699 oz avoirdupois).
- **true current density**
  - See preferred term local current density .
- **true strain**
  - (1) The ratio of the change in dimension, resulting from a given load increment, to the magnitude of the dimension immediately prior to applying the load increment. (2) In a body subjected to axial force, the natural logarithm of the ratio of the gage length at the moment of observation to the original gage length. Also known as natural strain.
- **true stress**

- The value obtained by dividing the load applied to a member at a given instant by the cross-sectional area over which it acts.
- **truing**
  - The removal of the outside layer of abrasive grains on a grinding wheel for the purpose of restoring its face.
- **tuberculation**
  - The formation of localized corrosion products scattered over the surface in the form of knoblike mounds called tubercles. The formation of tubercles is usually associated with biological corrosion.
- **tube reducing**
  - Reducing both the diameter and wall thickness of tubing with a mandrel and a pair of rolls. See also spinning .
- **tube sinking**
  - Drawing tubing through a die or passing it through rolls without the use of an interior tool (such as a mandrel or plug) to control inside diameter; sinking generally produces a tube of increased wall thickness and length.
- **tube stock**
  - A semifinished tube suitable for subsequent reduction and finishing.
- **tumbling**
  - Rotating workpieces, usually castings or forgings, in a barrel partly filled with metal slugs or abrasives, to remove sand, scale, or fins. It may be done dry, or with an aqueous solution added to the contents of the barrel. See also barrel finishing .
- **Turk's-head rolls**
  - Four undriven working rolls, arranged in a square or rectangular pattern, through which metal strip, wire, or tubing is drawn to form square or rectangular sections.
- **turning**
  - Removing material by forcing a single-point cutting tool against the surface of a rotating workpiece. The tool may or may not be moved toward or along the axis of rotation while it cuts away material.
- **tuyere**
  - An opening in a cupola, blast furnace, or converter for the introduction of air or inert gas.
- **twin**
  - Two portions of a crystal with a definite orientation relationship; one may be regarded as the parent, the other as the twin. The orientation of the twin is a mirror image of the orientation of the parent across a twinning plane or an orientation that can be derived by rotating the twin portion about a twinning axis. See also annealing twin and mechanical twin .
- **twin bands**
  - Bands across a crystal grain, observed on a polished and etched section, where crystallographic orientations have a mirror-image relationship to the orientation of the matrix grain across a composition plane that is usually parallel to the sides of the band.
- **twist boundary**
  - A subgrain boundary consisting of an array of screw dislocations.
- **two-high mill**
  - A type of rolling mill in which only two rolls, the working rolls, are contained in a single housing. Compare with four-high mill and cluster mill.
- **type metal**
  - Any of a series of alloys containing lead (58.5 to 95%), antimony (2.5 to 25%), and tin (2.5 to 20%) used to make printing type. Small amounts of copper (1.5 to 2.0%) are added to increase hardness in some applications.
- **U**
- **U-bend die**
  - A die, commonly used in press-brake forming, that is machined horizontally with a square or rectangular cross-sectional opening that provides two edges over which metal is drawn into a channel shape.
- **Ugine-Sejournet process**
  - A direct extrusion process for metals that uses molten glass to insulate the hot billet and to act as a lubricant.
- **ultimate elongation**

- The elongation at rupture.
- **ultimate strength**
  - The maximum stress (tensile, compressive, or shear) a material can sustain without fracture; determined by dividing maximum load by the original cross-sectional area of the specimen. Also known as nominal strength or maximum strength.
- **ultimate tensile strength**
  - The ultimate or final (highest) stress sustained by a specimen in a tension test.
- **ultrahard tool materials**
  - Very hard, wear-resistant materials--specifically, polycrystalline diamond and polycrystalline cubic boron nitride--that are fabricated into solid or layered cutting tool blanks for machining applications.
- **ultrahigh-strength steels**
  - Structural steels with minimum yield strengths of 1380 MPa (200 ksi).
- **ultraprecision finishing**
  - Machining processes used to alter surface characteristics such as finish, waviness, roundness, etc., with substantial removal of the work material. Examples include lapping and polishing of optical lenses, computer chips, or magnetic heads, and honing of cylinder liners.
- **ultrasonic beam**
  - A beam of acoustical radiation with a frequency higher than the frequency range for audible sound--i.e., above about 20 kHz.
- **ultrasonic cleaning**
  - Immersion cleaning aided by ultrasonic waves that cause microagitation.
- **ultrasonic frequency**
  - A frequency, associated with elastic waves, that is greater than the highest audible frequency, generally regarded as being higher than 20 kHz.
- **ultrasonic impact grinding**
  - A form of abrasive grinding in which a nonrotating tool vibrating at ultrasonic frequency causes a grit-loaded slurry to impinge on the surface of a workpiece, and thereby remove material. Compare with ultrasonic machining .
- **ultrasonic inspection**
  - A nondestructive method in which beams of high-frequency sound waves are introduced into materials for the detection of surface and subsurface flaws in the material. The sound waves travel through the material with some attendant loss of energy (attenuation) and are reflected at interfaces. The reflected beam is displayed and then analyzed to define the presence and location of flaws or discontinuities. Most ultrasonic inspection is done at frequencies between 0.1 and 25 MHz--well above the range of human hearing, which is about 20 Hz to 20 kHz.
- **ultrasonic machining**
  - Material removal by means of the ultrasonic vibration of a rotating diamond core drill or milling tool. The process does not involve an abrasive slurry; instead, the diamond tool contacts and cuts the workpiece. Compare with ultrasonic impact grinding .
- **ultrasonic soldering**
  - A soldering process variation in which high-frequency vibratory energy is transmitted through molten solder to remove undesirable surface films and thereby promote wetting of the base metal. This operation is usually accomplished without a flux.
- **ultrasonic testing**
  - See ultrasonic inspection .
- **ultrasonic welding**
  - A solid-state welding process in which materials are welded by locally applying high-frequency vibratory energy to a joint held together under pressure.
- **underbead crack**
  - A crack in the heat-affected zone of a weld generally not extending to the surface of the base metal.
- **undercooling**
  - Same as supercooling .
- **underdraft**
  - A condition wherein a metal curves downward on leaving a set of rolls because of higher speed in the upper roll.
- **underfill**

- (1) In weldments, a depression on the face of the weld or root surface extending below the surface of the adjacent base metal. (2) A portion of a forging that has insufficient metal to give it the true shape of the impression.
- **underfilm corrosion**
  - Corrosion that occurs under organic films in the form of randomly distributed threadlike filaments or spots. In many cases this is identical to filiform corrosion .
- **understressing**
  - Applying a cyclic stress lower than the endurance limit. This may improve fatigue life if the member is later cyclically stressed at levels above the endurance limit.
- **uniaxial stress**
  - A state of stress in which two of the three principal stresses are zero. See also principal stress (normal) .
- **uniform corrosion**
  - (1) A type of corrosion attack (deterioration) uniformly distributed over a metal surface. (2) Corrosion that proceeds at approximately the same rate over a metal surface. Also called general corrosion.
- **uniform elongation**
  - The elongation at maximum load and immediately preceding the onset of necking in a tensile test.
- **uniform strain**
  - The strain occurring prior to the beginning of localization of strain (necking); the strain to maximum load in the tension test.
- **unit cell**
  - A parallelepiped element of crystal structure, containing a certain number of atoms, the repetition of which through space will build up the complete crystal.
- **unit power**
  - The net amount of power required during machining or grinding to remove a unit volume of material in unit time.
- **universal forging mill**
  - A combination of four hydraulic presses arranged in one plane equipped with billet manipulators and automatic controls, used for radial or draw forging.
- **universal mill**
  - A rolling mill in which rolls with a vertical axis roll the edges of the metal stock between some of the passes through the horizontal rolls.
- **upset**
  - (1) The localized increase in cross-sectional area of a workpiece or weldment resulting from the application of pressure during mechanical fabrication or welding. (2) That portion of a welding cycle during which the cross-sectional area is increased by the application of pressure. (3) Bulk deformation resulting from the application of pressure in welding. The upset may be measured as a percent increase in interfacial area, a reduction in length, or a percent reduction in thickness (for lap joints).
- **upset forging**
  - A forging obtained by upset of a suitable length of bar, billet, or bloom.
- **upsetting**
  - The working of metal so that the cross-sectional area of a portion or all of the stock is increased. See also heading .
- **upset welding**
  - A resistance welding process in which the weld is produced, simultaneously over the entire area of abutting surfaces or progressively along a joint, by applying mechanical force (pressure) to the joint, then causing electrical current to flow across the joint to heat the abutting surfaces. Pressure is maintained throughout the heating period.
- **V**
- **vacancy**
  - A structural imperfection in which an individual atom site is temporarily unoccupied.
- **vacuum arc remelting (VAR)**
  - A consumable-electrode remelting process in which heat is generated by an electric arc between the electrode and the ingot. The process is performed inside a vacuum chamber. Exposure of the droplets of molten metal to the reduced pressure reduces the amount of dissolved gas in the metal. See also consumable-electrode remelting .

- **vacuum carburizing**
  - A high-temperature gas carburizing process using furnace pressures between 13 and 67 kPa (0.1 to 0.5 torr) during the carburizing portion of the cycle. Steels undergoing this treatment are austenitized in a rough vacuum, carburized in a partial pressure of hydrocarbon gas, diffused in a rough vacuum, and then quenched in either oil or gas.
- **vacuum casting**
  - A casting process in which metal is melted and poured under very low atmospheric pressure; a form of permanent mold casting in which the mold is inserted into liquid metal, vacuum is applied, and metal is drawn up into the cavity.
- **vacuum degassing**
  - The use of vacuum techniques to remove dissolved gases from molten alloys.
- **vacuum deposition**
  - Deposition of a metal film onto a substrate in a vacuum by metal evaporation techniques.
- **vacuum furnace**
  - A furnace using low atmospheric pressures instead of a protective gas atmosphere like most heat-treating furnaces.
- **vacuum hot pressing**
  - A method of processing materials (especially metal and ceramic powders) at elevated temperatures, consolidation pressures, and low atmospheric pressures.
- **vacuum induction melting (VIM)**
  - A process for remelting and refining metals in which the metal is melted inside a vacuum chamber by induction heating. The metal can be melted in a crucible and then poured into a mold.
- **vacuum melting**
  - Melting in a vacuum to prevent contamination from air and to remove gases already dissolved in the metal; the solidification can also be carried out in a vacuum or at low pressure.
- **vacuum nitrocarburizing**
  - A subatmospheric nitrocarburizing process using a basic atmosphere of 50% ammonia/50% methane, containing controlled oxygen additions of up to 2%.
- **vacuum refining**
  - Melting in a vacuum to remove gaseous contaminants from the metal.
- **vacuum sintering**
  - Sintering of ceramics or metals at subatmospheric pressure.
- **vapor degreasing**
  - Degreasing of work in the vapor over a boiling liquid solvent, the vapor being considerably heavier than air. At least one constituent of the soil must be soluble in the solvent. Modifications of this cleaning process include vapor-spray-vapor, warm liquid-vapor, boiling liquid-warm liquid-vapor, and ultrasonic degreasing.
- **vapor deposition**
  - See chemical vapor deposition , physical vapor deposition , and sputtering .
- **vapor plating**
  - Deposition of a metal or compound on a heated surface by reduction or decomposition of a volatile compound at a temperature below the melting points of the deposit and the base material. The reduction is usually accomplished by a gaseous reducing agent such as hydrogen. The decomposition process may involve thermal dissociation or reaction with the base material. See also vacuum deposition .
- **V-bend die**
  - A die commonly used in press-brake forming, usually machined with a triangular cross-sectional opening to provide two edges as fulcrums for accomplishing three-point bending.
- **vent**
  - A small opening in a foundry mold for the escape of gases.
- **vermicular graphite iron**
  - Same as compacted graphite iron .
- **vibratory finishing**
  - A process for deburring and surface finishing in which the product and an abrasive mixture are placed in a container and vibrated.
- **Vickers hardness number (HV)**

- A number related to the applied load and the surface area of the permanent impression made by a square-based pyramidal diamond indenter having included face angles of  $136^\circ$ , computed from:

$$HV = 2P \sin \frac{\alpha/2}{d^2} = \frac{1.8544P}{d^2}$$

- where  $P$  is applied load (kgf),  $d$  is mean diagonal of the impression (mm), and  $\alpha$  is the face angle of the indenter ( $136^\circ$ ).
- **Vickers hardness test**
  - A microindentation hardness test employing a  $136^\circ$  diamond pyramid indenter (Vickers) and variable loads, enabling the use of one hardness scale for all ranges of hardness--from very soft lead to tungsten carbide. Also known as diamond pyramid hardness test. See also microindentation and microindentation hardness number .
- **virgin metal**
  - Same as primary metal .
- **void**
  - (1) A shrinkage cavity produced in castings or weldments during solidification. (2) A term generally applied to paints to describe holidays, holes, and skips in a film.
- **V process**
  - A molding (casting) process in which the sand is held in place in the mold by vacuum. The mold halves are covered with a thin sheet of plastic to retain the vacuum.
- **W**
- **walking-beam furnace**
  - A continuous-type heat treating or sintering furnace consisting of two sets of rails, one stationary and the other movable, that lift and advance parts inside the hearth. With this system, the moving rails lift the work from the stationary rails, move it forward, and then lower it back onto the stationary rails. The moving rails then return to the starting position and repeat the process to advance the parts again.
- **Wallner lines**
  - A distinct pattern of intersecting sets of parallel lines, sometimes producing a set of V-shaped lines, sometimes observed when viewing brittle fracture surfaces at high magnification in an electron microscope. Wallner lines are attributed to interaction between a shock wave and a brittle crack front propagating at high velocity. Sometimes Wallner lines are misinterpreted as fatigue striations.
- **warm working**
  - Deformation of metals at elevated temperatures below the recrystallization temperature. The flow stress and rate of strain hardening are reduced with increasing temperature; therefore, lower forces are required than in cold working. See also cold working and hot working .
- **warpage**
  - (1) Deformation other than contraction that develops in a casting between solidification and room temperature. (2) The distortion that occurs during annealing, stress relieving, and high-temperature service.
- **wash**
  - (1) A coating applied to the face of a mold prior to casting. (2) An imperfection at a cast surface similar to a cut (3) .
- **wash metal**
  - Molten metal used to wash out a furnace, ladle, or other container.
- **waterjet/abrasive waterjet machining**
  - A hydrodynamic machining process that uses a high-velocity stream of water as a cutting tool. This process is limited to the cutting of nonmetallic materials when the jet stream consists solely of water. However, when fine abrasive particles are injected into the water stream, the process can be used to cut harder and denser materials. Abrasive waterjet machining has expanded the range of fluid jet machining to include the cutting of metals, glass, ceramics, and composite materials.
- **water quenching**
  - A quench in which water is the quenching medium. The major disadvantage of water quenching is its poor efficiency at the beginning or hot stage of the quenching process. See also quenching .

- **waviness**
  - A wavelike variation from a perfect surface, generally much larger and wider than the roughness caused by tool or grinding marks.
- **wax pattern**
  - A precise duplicate, allowing for shrinkage, of the casting and required gates, usually formed by pouring or injecting molten wax into a die or mold. See also investment casting .
- **wear**
  - Damage to a solid surface, generally involving progressive loss of material, due to a relative motion between that surface and a contacting surface or substance. Compare with surface damage .
- **wear debris**
  - Particles that become detached in a wear process.
- **wear pad**
  - In forming, an expendable pad of rubber or rubberlike material of nominal thickness that is placed against the diaphragm to lessen the wear on it. See also diaphragm (2) .
- **weathering**
  - Exposure of materials to the outdoor environment.
- **weathering steels**
  - Copper-bearing high-strength low-alloy steels that exhibit high resistance to atmospheric corrosion in the unpainted condition.
- **weave bead**
  - A type of weld bead made with transverse oscillation.
- **web**
  - (1) A relatively flat, thin portion of a forging that effects an interconnection between ribs and bosses; a panel or wall that is generally parallel to the forging plane. See also rib . (2) For twist drills and reamers, the central portion of the tool body that joins the lands. (3) A plate or thin portion between stiffening ribs or flanges, as in an I-beam, H-beam, or other similar section.
- **weight percent**
  - Percentage composition by weight. Contrast with atomic percent .
- **weld**
  - A localized coalescence of metals or nonmetals produced either by heating the materials to suitable temperatures, with or without the application of pressure, or by the application of pressure alone with or without the use of filler metal.
- **weldability**
  - The capacity of a material to be welded under the imposed fabrication conditions into a specific, suitably designed structure and to perform satisfactorily in the intended service.
- **weld bead**
  - A deposit of filler metal from a single welding pass.
- **weld crack**
  - A crack in weld metal.
- **weld decay**
  - Intergranular corrosion, usually of stainless steels or certain nickel-base alloys, that occurs as the result of sensitization in the heat-affected zone during the welding operation. See also sensitization .
- **welding**
  - (1) Joining two or more pieces of material by applying heat or pressure, or both, with or without filler material, to produce a localized union through fusion or recrystallization across the interface. The thickness of the filler material is much greater than the capillary dimensions encountered in brazing. (2) May also be extended to include brazing and soldering. (3) In tribology, adhesion between solid surfaces in direct contact at any temperature.
- **welding current**
  - The current in the welding circuit during the making of a weld.
- **welding cycle**
  - The complete series of events involved in the making of a weld.
- **welding electrode**
  - See electrode (welding) .
- **welding ground**
  - Same as work lead .

- **welding leads**
  - The electrical cables that serve as either work lead or electrode lead of an arc welding circuit.
- **welding machine**
  - Equipment used to perform the welding operation. For example, spot welding machine, arc welding machine, seam welding machine, etc.
- **welding rod**
  - A form of filler metal used for welding or brazing that does not conduct the electrical current, and which may be either fed into the weld pool or preplaced in the joint.
- **welding sequence**
  - The order in which the various component parts of a weldment or structure are welded.
- **welding stress**
  - Residual stress caused by localized heating and cooling during welding.
- **welding tip**
  - A welding torch tip designed for welding.
- **welding torch (arc)**
  - A device used in the gas tungsten and plasma arc welding processes to control the position of the electrode, to transfer current to the arc, and to direct the flow of shielding and plasma gas. See also gas tungsten arc welding and plasma arc welding .
- **welding torch (oxyfuel gas)**
  - A device used in oxyfuel gas welding, torch brazing, and torch soldering for directing the heating flame produced by the controlled combustion of fuel gases. See also oxyfuel gas welding .
- **welding wire**
  - A form of welding filler metal, normally packaged as coils or spools, that may or may not conduct electrical current depending on the welding process with which it is used. See also electrode (welding) and welding rod .
- **weld interface**
  - The interface between weld metal and base metal in a fusion weld, between base metals in a solid-state weld without filler metal, or between filler metal and base metal in a solid-state weld with a filler metal and in a braze.
- **weld line**
  - See preferred term weld interface .
- **weldment**
  - An assembly whose component parts are joined by welding.
- **weld metal**
  - That portion of a weld that has been melted during welding.
- **weld nugget**
  - The weld metal in spot, seam or projection welding. See also nugget and resistance spot welding .
- **weld pass**
  - A single progression of a welding or surfacing operation along a joint, weld deposit, or substrate. The result of a pass is a weld bead, layer, or spray deposit.
- **weld pool**
  - The localized volume of molten metal in a weld prior to its solidification as weld metal.
- **weld puddle**
  - See preferred term weld pool .
- **weld reinforcement**
  - Weld metal in excess of the quantity required to fill a joint.
- **Wenstrom mill**
  - A rolling mill similar to a universal mill but where the edges and sides of a rolled section are acted on simultaneously.
- **wet blasting**
  - A process for cleaning or finishing by means of a slurry of abrasive in water directed at high velocity against the workpieces.
- **wetting**
  - (1) The spreading, and sometimes absorption, of a fluid on or into a surface. (2) A condition in which the interface tension between a liquid and a solid is such that the contact angle is 0° to 90°. (3) The phenomenon whereby a liquid filler metal or flux spreads and adheres in a thin continuous layer on a solid base metal.

- **wetting agent**
  - (1) A substance that reduces the surface tension of a liquid, thereby causing it to spread more readily on a solid surface. (2) A surface-active agent that produces wetting by decreasing the cohesion within the liquid.
- **whisker**
  - (1) A short single crystal fiber or filament used as a reinforcement in a matrix. Whisker diameters range from 1 to 25  $\mu\text{m}$ , with aspect ratios (length to diameter ratio) generally between 50 and 150. (2) Metallic filamentary growths, often microscopic, sometimes formed during electrodeposition and sometimes spontaneously during storage or service, after finishing.
- **white-etching layer**
  - A surface layer in a steel that, as viewed in a section after etching, appears whiter than the base metal. The presence of the layer may be due to a number of causes, including plastic deformation induced by machining or surface rubbing, heating during a metallographic preparation stage to such an extent that the layer is austenitized and then hardened during cooling, and diffusion of extraneous elements into the surface.
- **whiteheart malleable**
  - See malleable iron .
- **white iron**
  - A cast iron that is essentially free of graphite, and most of the carbon content is present as separate grains of hard  $\text{Fe}_3\text{C}$ . White iron exhibits a white, crystalline fracture surface because fracture occurs along the iron carbide platelets.
- **white layer**
  - (1) Compound layer that forms in steels as a result of the nitriding process. (2) In tribology, a white-etching *layer*, typically associated with ferrous alloys, that is visible in metallographic cross sections of bearing surfaces. See also Beilby layer .
- **white metal**
  - (1) A general term covering a group of white-colored metals of relatively low melting points based on tin or lead. (2) A copper matte of about 77% Cu obtained from smelting of sulfide copper ores.
- **white rust**
  - Zinc oxide; the powder product of corrosion of zinc or zinc-coated surfaces.
- **Widmanstätten structure**
  - A structure characterized by a geometrical pattern resulting from the formation of a new phase along certain crystallographic planes of the parent solid solution. The orientation of the lattice in the new phase is related crystallographically to the orientation of the lattice in the parent phase. The structure was originally observed in meteorites, but is readily produced in many alloys, such as titanium, by appropriate heat treatment.
- **wildness**
  - A condition that exists when molten metal, during cooling, evolves so much gas that it becomes violently agitated, forcibly ejecting metal from the mold or other container.
- **winning**
  - Recovering a metal from an ore or chemical compound using any suitable hydrometallurgical, pyrometallurgical, or electrometallurgical method.
- **wiped coat**
  - A hot dipped galvanized coating from which virtually all free zinc is removed by wiping prior to solidification, leaving only a thin zinc-iron alloy layer.
- **wiped joint**
  - A joint made with solder having a wide melting range and with the heat supplied by the molten solder poured onto the joint. The solder is manipulated with a hand-held cloth or paddle so as to obtain the required size and contour.
- **wiper forming, wiping**
  - Method of curving sheet metal sections or tubing over a form block or die in which this form block is moved relative to a wiper block or slide block.
- **wiping effect**
  - Activation of a metal surface by mechanical rubbing or wiping to enhance the formation of conversion coatings, such as phosphate coatings.
- **wire**

- (1) A thin, flexible, continuous length of metal, usually of circular cross section, and usually produced by drawing through a die. The size limits for round wire sections range from approximately 0.13 mm (0.005 in.) to 25 mm (1 in.). Larger rounds are commonly referred to as bars. See also flat wire . (2) A length of single metallic electrical conductor, it may be of solid, stranded or tinsel construction, and may be either bare or insulated.
- **wire bar**
  - A cast shape, particularly of tough pitch copper, that has a cross section approximately square with tapered ends, designed for hot rolling to rod for subsequent drawing into wire.
- **wire drawing**
  - Reducing the cross section of wire by pulling it through a die.
- **wire flame spraying**
  - A thermal spraying process variation in which the material to be sprayed is in wire or rod form. See also flame spraying .
- **wire rod**
  - Hot-rolled coiled stock that is to be cold drawn into wire.
- **wiring**
  - Formation of a curl along the edge of a shell, tube, or sheet and insertion of a rod or wire within the curl for stiffening the edge. See also curling .
- **woody structure**
  - A macrostructure, found particularly in wrought iron and in extruded rods of aluminum alloys, that shows elongated surfaces of separation when fractured.
- **work hardening**
  - Same as strain hardening .
- **working electrode**
  - The test or specimen electrode in an electrochemical cell.
- **work lead**
  - The electrical conductor connecting the source of arc welding current to the work. Also called work connection, welding ground, or ground lead.
- **worm**
  - An exudation (sweat) of molten metal forced through the top crust of solidifying metal by gas evolution. See also zinc worms .
- **wrap forming**
  - See stretch forming .
- **wrinkling**
  - A wavy condition obtained in deep drawing of sheet metal, in the area of the metal between the edge of the flange and the draw radius. Wrinkling may also occur in other forming operations when unbalanced compressive forces are set up.
- **wrought iron**
  - A commercial iron consisting of slag (iron silicate) fibers entrained in a ferrite matrix.
- **X**
- **x-ray**
  - A penetrating electromagnetic radiation, usually generated by accelerating electrons to high velocity and suddenly stopping them by collision with a solid body. Wavelengths of x-rays range from about  $10^{-1}$  to  $10^{-2}$  Å, the average wavelength used in research being about 1 Å. Also known as roentgen ray or x-radiation. See also electromagnetic radiation .
- **x-ray diffraction (XRD)**
  - An analytical technique in which measurements are made of the angles at which x-rays are preferentially scattered from a sample (as well as of the intensities scattered at various angles) in order to deduce information on the crystalline nature of the sample--its crystal structure, orientations, and so on.
- **x-ray fluorescence**
  - Emission by a substance of its characteristic x-ray line spectrum on exposure to x-rays.
- **x-ray map**
  - An intensity map (usually corresponding to an image) in which the intensity in any area is proportional to the concentration of a specific element in that area.
- **x-ray photoelectron spectroscopy (XPS)**

- An analytical technique that measures the energy spectra of electrons emitted from the surface of a material when exposed to monochromatic x-rays.
- **x-ray spectrometry**
  - Measurement of wavelengths of x-rays by observing their diffraction by crystals of known lattice spacing.
- **x-ray spectrum**
  - The plot of the intensity or number of x-ray photons versus energy (or wavelength).
- **x-ray topography**
  - A technique that comprises topography and x-ray diffraction. The term topography refers to a detailed description and mapping of physical (surface) features in a region. In the context of the x-ray diffraction, topographic methods are used to survey the lattice structure and imperfections in crystalline materials.
- **Y**
- **Y-block**
  - A single keel block .
- **yellow brass**
  - A name sometimes used in reference to the 65Cu-35Zn type of brass.
- **yield**
  - (1) Evidence of plastic deformation in structural materials. Also known as plastic flow or creep. See also flow . (2) The ratio of the number of acceptable items produced in a production run to the total number that were attempted to be produced. (3) Comparison of casting weight to the total weight of metal poured into the mold.
- **yield point**
  - The first stress in a material, usually less than the maximum attainable stress, at which an increase in strain occurs without an increase in stress. Only certain materials--those that exhibit a localized, heterogeneous type of transition from elastic to plastic deformation--produce a yield point. If there is a decrease in stress after yielding, a distinction may be made between upper and lower yield points. The load at which a sudden drop in the flow curve occurs is called the upper yield point. The constant load shown on the flow curve is the lower yield point.
- **yield point elongation**
  - In materials that exhibit a yield point, the difference between the elongation at the completion and at the start of discontinuous yield.
- **yield strength**
  - The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many materials, particularly metals. Compare with tensile strength .
- **yield stress**
  - The stress level of highly ductile materials at which large strains take place without further increase in stress.
- **Young's modulus**
  - A term used synonymously with modulus of elasticity. The ratio of tensile or compressive stresses to the resulting strain. See also modulus of elasticity .
- **Z**
- **zinc worms**
  - Surface imperfections, characteristic of high-zinc brass castings, that occur when zinc vapor condenses at the mold/metal interface, where it is oxidized and then becomes entrapped in the solidifying metals.
- **zincrometal**
  - A steel coil-coated product consisting of a mixed-oxide underlayer containing zinc particles and a zinc-rich organic (epoxy) topcoat. It is weldable, formable, paintable, and compatible with commonly used adhesives. Zincrometal is used to protect outer body door panels in automobiles from corrosion.
- **zone melting**
  - Highly localized melting, usually by induction heating, of a small volume of an otherwise solid metal piece, usually a metal rod. By moving the induction coil along the rod, the melted zone can be transferred from one end to the other. In a binary mixture where there is a large difference in composition on the liquidus and solidus lines, high purity can be attained by concentrating one of the constituents in the liquid as it moves along the rod.
